REINFORCED NOTCHED CROSS-LAMINATED TIMBER PLATES: LOAD-BEARING CAPACITY AND METHODOLOGY FOR PREDICTING THE FORCE IN REINFORCEMENT

Alen Malagic[1], Erik Serrano[3], Manfred Augustin[1], Gerhard Schickhofer[1, 2]

ABSTRACT: This paper deals with the estimation of the design force in self-tapping screws used as a reinforcement of notched cross laminated timber plates (CLT). With the reinforcement, apart from an increased load-carrying capacity, a more ductile behaviour of this detail can be achieved. An analytical model based on the Timoshenko Beam Theory was developed, enabling the estimation of the axial force in the reinforcement. A parametric numerical analysis was conducted to verify the model and to provide possible ways for the calibration. The results show a good matching of the model with the numerical results. The load-bearing capacity is analysed using a simple fracture mechanics model taking into consideration the effect of the reinforcement to correctly depict the increase in performance. Theoretical and numerical results are compared with experimental findings and show acceptable correlations encouraging a further development and a subsequent implementation in EN 1995-1-1.

KEYWORDS: reinforcement, self-tapping screw, notches, fracture mechanics, screw stiffness, CLT

1 INTRODUCTION

Unreinforced "notches" in cross laminated timber (CLT) plates (Figure 1), severely reduce the load-bearing capacity of this member and fail in general by delamination in a brittle manner. Hence, they should be generally avoided, and if unavoidable, notches should be reinforced. Since the efforts required for their application are small compared to the increase in the load-bearing capacity, ductility and robustness, an effective way for the reinforcement is the application of fully threaded, self-tapping screws. With this method, beside increased load-bearing capacity even up to the level of the unnotched configuration, also a stabilisation of crack growth and prevention of complete delamination of the plate along the crack plane can be achieved, if the screws are designed accordingly.

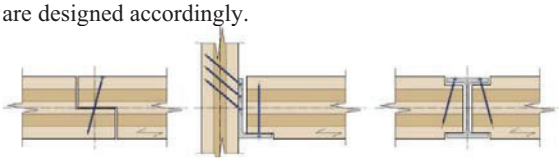

Figure 1: *Various types of notches in CLT plates*

In addition to mechanical loading the crack initiation and growth can also be caused by climate changes [1]. The geometry of the notch makes the timber in the area of the notch significantly more susceptible to moisture content (MC) variations and hence induced residual stresses. These constant MC variations lead to a crack initiation and with each subsequent MC variation to an increase in crack length. The crack lengths are relatively small but they tend to increase over time potentially, reaching critical crack lengths and leading to the failure. The reinforcement increases the critical crack length by a factor 2 and improves the overall behaviour [1], thus mitigating the influence of the moisture variations.

At present, as known to the authors, no explicit rules and expressions are given in standards, guidelines, approvals or in the literature for the calculation of the load-bearing capacity of unreinforced as well as reinforced notches in layered timber products like CLT. Nevertheless, it is evident that the layered structure has an influence on the mechanical behaviour of such members. Thus, known approaches developed and valid for unlayered products and beams out of structural timber and glulam are not mechanically consistent as they disregard the influence of the timber fracture properties and the layup. For these reasons a mechanically consistent approach is desired and should be developed.

The development of such approach for the calculation of the load-bearing capacity suitable for the hand calculation is complex. The main difficulty is the constantly changing mode mixity at the crack tip G_{II} / G_I (τ_{zx} / σ_z) as a function of the crack length, therefore complicating the decomposition of the mixed energy release rate (ERR). An attempt to develop such mechanically consistent approach, still applicable for the implementation in standards or guidelines is presented in this paper.

2 STATE OF THE ART

2.1 RULES FOR REINFORCED NOTCHED BEAMS IN STANDARDS

Due to the lack of specific rules for CLT, the following review is related to the comparable situation for unlayered timber products (beams) only. Although no related rules are mentioned in EN 1995-1-1:2004/A2:2014 [2], specific sections are given in the German and Austrian National Annex DIN EN 1995-1-1:2010 [3] and ÖNORM B 1995-1-1:2019 [4].

The design force $F_{t,90,d}$, to be carried by the reinforcement, is defined there as a function of the shear force V_d and the notch parameter α. This design approach was developed by Henrici [5] simplifying his findings into the condensed form of Eq. (1).

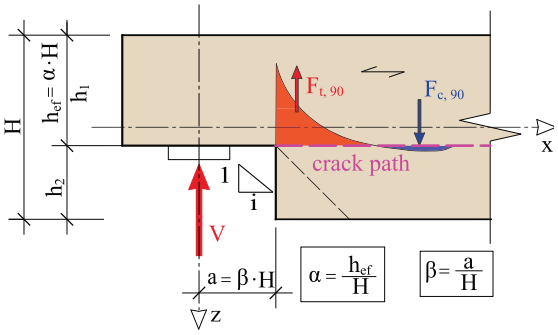

Figure 2: *Geometrical parameters of a notched beam [4]*

$$F_{t,90,d} = 1.3 \cdot V_d \cdot \left[3 \cdot (1-\alpha)^2 - 2 \cdot (1-\alpha)^3\right] \qquad (1)$$

with V_d … design value of the shear force, α …ratio of heights h_{ef} / H

Remark:
To avoid misunderstandings, in the following the denotation for the height ratio α (valid for unlayered timber products) is substituted by ω (valid for layered products like CLT).

In Eq. (1) the force in the reinforcement is calculated by integrating the parabolic shear stresses up to the crack line. The pre-factor 1.3, being a product of the elastic analysis in [5], considers the orthotropy of the timber and the geometry of the notch, leading to conservative values for $\alpha < 0.65$ and $\beta < 0.3$.

Recently, a modified format of Eq. (1) with additional parameters k_α and k_β was proposed in the draft code prEN 1995-1-1:20XX [6] as

$$F_{t,90,d} = k_\alpha \cdot k_\beta \cdot V_d \cdot \left[3 \cdot (1-\alpha)^2 - 2 \cdot (1-\alpha)^3\right] \qquad (2)$$

where

$$k_\alpha = 0.9 + 0.5 \cdot (2\alpha - 1)^2, \; k_\beta = 1 + 2 \cdot \beta$$

for $\alpha \leq 0.6$ and $\beta \leq 0.2$ the product $k_\alpha \cdot k_\beta$ may be taken as $k_\alpha \cdot k_\beta = 1.3$

As an intermediate summary it can be stated that current methodologies for predicting the force in reinforced notches (of unlayered timber members) disregard several important aspects such as: properties and position of the reinforcement as well as length of the crack. Thus, a mechanically more accurate and robust approach considering the mentioned parameters is desired and should be developed.

2.2 LOAD-BEARING CAPACITY

Relatively big notches with $\alpha < 0.7$, drastically decrease the load-bearing capacity of notched timber members. By reinforcing them, an increase of the load-bearing capacity by a factor of 1.5 up to 2.5 can be achieved. The failure of the reinforced notch is governed by the axial and the shear capacity of the reinforcement and the splitting strength of the timber respectively. Since the strength of the timber is disregarded in the current design procedures, the load-bearing capacity is proportional to the axial load-bearing capacity of the reinforcement and the number of reinforcing elements. By substituting the axial capacity of the reinforcement in Eq. (1) the failure load at the notch $V_{f,d}$ can be calculated (for unlayered products) as follows:

$$V_{f,d} = \frac{n_{ef} \cdot R_{ax,d}}{1.3 \cdot \left[3 \cdot (1-\alpha)^2 - 2 \cdot (1-\alpha)^3\right]} \qquad (3)$$

with $n_{ef} = n$ and $R_{ax,d}$ … design value of the axial load-carrying capacity per screw

The strength of the timber is indirectly considered in a proposal authored by Dietsch [7] and also mentioned in prEN 1995-1-1:20XX [6]. The load-bearing capacity there is limited to twice the value of the unreinforced notch. This simple and practical proposal for standards is based on insights made in [1] on a basis of extensive experimental test results and the theoretical insights regarding the fracture energy in pure mode II failure. However, an implementation in this form is questionable for highly orthotropic products such as CLT due to the increased influence of the rolling shear behaviour. Significant discrepancies between the load-bearing capacity calculated by Eq. (3) and experimental results were observed in [1] and [10]. The Eq. (3) provided unsafe results in some configurations. Placing a large amount of reinforcements at the notch can cause this disagreement due to the shift of the failure mode from the reinforcement to the failure at the notch by excessive cracking and subsequent delamination. In CLT notches this fact transforms to: failure in the screw (underreinforced), failure due to the splitting of the timber at the crack tip (overreinforced) and failure due to the splitting and simultaneous failure of the screw (balanced). Naturally, the balanced case is hardly achievable.

The predictions by Eq. (3) have been also compared with the experimental results conducted on reinforced notched CLT plates, see chapter 5.

The load-bearing capacity of reinforced notches in beams was investigated by Jockwer ([1], [8]), proposing an analytical model based on energy balance method of *Linear Elastic Fracture Mechanics* (LEFM). The total energy release rate (ERR) in the mixed fracture mode was evaluated and then a mode partitioning according to the approach from Riipola [9] was applied. A pronounced influence of the crack shearing (mode II) with increasing

https://doi.org/10.52202/069179-0322

crack length and α-value was noted, leading to the reported increase of the load-bearing capacity. The increase of the load-bearing capacity by a factor of about 2 reported in [1] corresponds well with around 4 times larger fracture energy in pure mode II leading to increase in the load-bearing capacity $\sqrt{G_{II} / G_I} \approx 2$ according to LEFM.

A more detailed approach is given by Sorin et. al. [10]. The load-bearing capacity of the notch is calculated according to the *Equivalent Linear Elastic Fracture Mechanics* (Equiv. LEFM) taking into account the quasi-brittleness of the timber and employing crack growth curves (R curves). The linear elastic calculations are made iteratively on different crack lengths. Each crack length has a unique crack growth resistance in separate fracture modes. This model can accurately predict the force evolution and failure load as a function of the crack length, however on the cost of simplicity when compared to [8].

The increase of the load-bearing capacity of reinforced notches can be vividly illustrated by an analogy regarding the timber anatomy: It is a well-known occurrence during the testing of fracture properties on timber specimens that the presence of knots along the fracture plane cause an increase in fracture energy and failure load of the tested specimen. Such specimens are not desired in the analysis and will be commonly disregarded but show a positive influence of knots on the fracture parameters. The knots in such cases are carrying forces between the cross sections divided by the crack and therefore lead to an increase in system stiffness and fracture energy. A similar effect can be achieved by placing self-tapped screws at the notch.

2.3 FORCE IN THE REINFORCEMENT

Literature references regarding the calculation of the design forces in the reinforcement at the notch – in particular for layered timber products – are rather scarce, if not missing. An analytical model for unlayered notched beams based on the Timoshenko Beam Theory was presented in Jockwer [1]. As known to the authors, no other paper of such matter is present, consequently there is a need for further investigations on this topic.

3 METHODOLOGY FOR PREDICTING THE FORCE IN REINFORCEMENT

In the chapters 3 and 4 diagrams regarding the force in reinforcement and the load-bearing capacity of notched CLT plates will be shown. All presented diagrams are related to a reference case in order to clearly present results and parameter relations. The reference case is a 5-layered CLT-plate with the layup: 30-30-30-30-30 mm (underlined numbers indicate the thickness of cross-layers). For a consistent comparison a constant parameter $\beta = 0.5$ was chosen. In all presented diagrams dashed lines refer to the analytical beam model (section 3.1 and 4.1), while solid lines refer to the numerical model (section 3.2).

3.1 ANALYTICAL MODEL

The analytical model is based on the Timoshenko Beam Theory. The used system is graphically depicted in Figure 3. For the application of the model a crack-length L_{crack} has to be pre-assumed. The screw (group) is substituted by spring element of equivalent stiffness. However, to enable a closed form solution, the lateral screw stiffness is ignored. The impact of this simplification is further investigated in the scope of the numerical parametric analysis.

The axial stiffness for part of the single screw under/above the crack is calculated according to Eq. (4) from Ringhofer [11]. The axial stiffness of the whole screw K_{ser} is calculated taking into account the series effect acting on the screw because of the crack.

$$K_{ser,i} = k_{ax} \cdot 160 \cdot \left(\frac{\rho_{12}}{420} \right)^{0.85} \cdot d^{0.9} \cdot l_{ef,i}^{0.6} \qquad (4)$$

with k_{ax} = 1.0 for α = 90°, ρ_{12} … density at moisture content u = 12% [kg/m³], d … diameter of the screw [mm], $l_{ef,i}$ …penetration length of the screw in timber under the crack and above the crack [mm], $K_{ser,i}$ … axial stiffness for part of the screw under/above the crack interface resp. [N/mm]

Remark: The stiffness of the screw group is given as: $K_{ser} \cdot n_{screw}$, where n_{screw} … number of screws, $K_{ser\ ...}$ stiffness of the whole screw

The forces in the reinforcement are calculated by applying the principle of virtual forces on the first order statically indeterminate system shown in Figure 3.

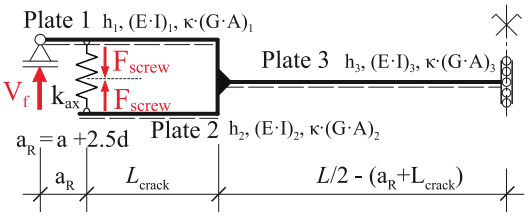

Figure 3: *Analytical beam model*

After simplification the axial force in the reinforcement $F_{t,90,d}$ in the notched CLT plate of width w is as follows:

$$F_{t,90,d} = \frac{\frac{L_{crack}^{\ 2}}{6 \cdot EI_1} \cdot \left(3 \cdot a_R + 2 \cdot L_{crack}\right) + \frac{L_{crack}}{GA_1}}{\frac{L_{crack}^{\ 3}}{3} \cdot \left(\frac{1}{EI_1} + \frac{1}{EI_2}\right) + \frac{1}{k_{ax}} + \left(\frac{1}{GA_1} + \frac{1}{GA_2}\right) \cdot L_{crack}} \qquad (5)$$

3.2 (PARAMETRIC) NUMERICAL MODEL

In order to verify the analytical model from section 3.1 a parametric numerical analysis was conducted. In its frame 3-, 5- and 7-layered CLT plates were investigated. The calculation was elaborated using the finite element software package ANSYS APDL 2021 R1. For ease of work, sets with a range of parameters were submitted as batch file to the solver. Detailed information regarding the considered layups are given in Table 1. The geometry, loading and boundary conditions of the analysed model are illustrated in Figure 4.

https://doi.org/10.52202/069179-0322

A plane stress model was applied on the plate width w = 600 mm to match the width of CLT plates from experimental tests. The plate is loaded by a point load in the symmetric mid span 3-point bending configuration. The support is modelled by means of a steel plate to avoid singularity and unrealistic deformations. It is restrained in the Z-direction and free in X-direction, with free rotation about the Y-axis (Figure 4). A global mesh size of 5 mm was used, while the local mesh refinement at the crack tip and along the crack interface was applied in sizes of 1.5 to 2.0 mm. The material model is linear elastic orthotropic represented by the properties given in Table 2.

Table 1: *Parameters used in the numerical analysis*

Input and analysis parameters for the analytical and numerical models			
Num. of layers	3	5	7
Layup[a)] [mm]	40-<u>40</u>-40	30-<u>30</u>-30-<u>30</u>-30 40-<u>20</u>-40-<u>20</u>-40 40-<u>20</u>-20-<u>20</u>-40 40-<u>40</u>-40-<u>40</u>-40	30-<u>30</u>-30-<u>30</u>-30-<u>30</u>-30 30-30-<u>30</u>-30-<u>30</u>-30
ω [-]	$0.5 \leq \omega < 1.0$		
β [-]	0.25, 0.5, 1.0		
L_{crack} [mm]	$2.5 \cdot d_{screw} \leq L_{crack} \leq 2 \cdot H_{plate}$		

[a)] Underlined numbers indicate the thickness of cross layers

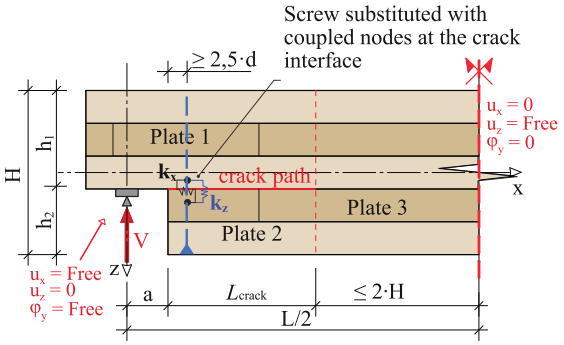

Figure 4: *Illustration of the (parametric) numerical model*

Due to the application of a plane stress model the screw could not be considered as a beam element. Instead, a coupling of the nodes with spring elements at the crack interface was applied. The number of parameters to be considered for the definition of the numerical model in a notched layered member is significantly higher compared to the notched beams made of structural timber or glulam. For example, the parameters defining the number of layers and the layup of the CLT plate need to be defined in addition. Subsequently, the complexity of the parametric analysis, as well as the needed computational time increase exponentially.

Table 2: *Material properties used in the numerical analysis*

Parameter	Value	Description
E_0 E_{90}	11000; 390	MOE longitudinal; transversal [MPa]
$G_{0,\,90}$ $G_{90,\,90}$	690; 69.0	Shear modulus, longitudinal; transversal [MPa]
$G_{c,\,I}$ $G_{c,\,II}$	0.30; 0.90	Critical energy release rate, Mode I; Mode II [mJ/mm²]
$\nu_{,\,LR}$ $\nu_{,\,RT}$	0.56; 0.03	Poisson ratios [-]

In the present analysis the number of considered parameters was reduced by introducing several assumptions in line with the features of CLT-plates and construction practice: The most relevant adoption was made involving the type of reinforcement used in notched CLT-plates as well as the configuration of the reinforcement. Due to the relatively small thickness of the CLT-plate and a width of up to 3 m, the only feasible way of reinforcing such elements in practice is the application of self-tapping screws. In line with the proposals in [7] the reinforcement should be placed in one row and at a distance of about $2.5 \cdot d_{screw}$ from the notch face to the screw. Moreover, the width of the CLT-plates requires a maximum screw distance in a row to be defined. Otherwise, a crack propagation between the screws may occur, severely reducing the load-bearing capacity. In this work a maximum screw distance of 150 mm is proposed and considered. This distance is in line with the situation in practice, however, a maximal distance should be determined on the basis of experimental tests. Screws of the nominal diameter d = 8 mm and a length equal to the plate thickness with an inclination angle of $\alpha = 90°$ were assumed for the reinforcement in this work. With the mentioned assumptions the stiffness of a group of screws can be defined. The axial screw stiffness was considered as given by Eq. (4).

In the numerical model the fracture parameters at the crack tip were obtained as a function of the crack length. The total (mixed) energy release rates and respective modal contributions in the modes I and II were evaluated with the built-in software module "Virtual-crack-closing-technique" (VCCT). To verify the mixed ERR from VCCT the J-integral was applied in the numerical analysis. The modal contributions were verified with the ratio of shear and normal stresses (τ_{zx} / σ_z) giving the mode mixity ratio G_{II} / G_I. The verification calculations for the total ERR showed no difference to the VCCT method and mode partitioning showed minor differences but the same tendency in results.

3.3 FORCES IN THE REINFORCMENT

Predictions for the forces in the reinforcement were computed at specific positions for different notch heights as illustrated in Figure 5.

https://doi.org/10.52202/069179-0322

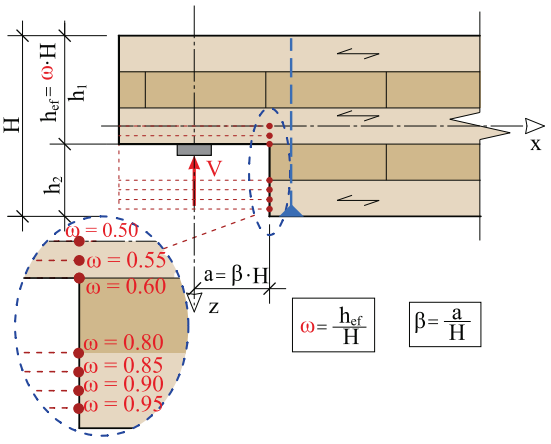

Figure 5: *Positions of notches used in comparison*

The notches in the CLT have a special failure mode when the notch is situated in a transversal layer: The crack there propagates under an angle of approximately 45° up to the layer interface and then continues along the interface [12]. As a consequence, the transversal layer should be excluded from the calculations of the load-bearing capacity in the notched CLT-plates and also excluded from the predictions of the force in the screw, Eq. (5).

The reinforcement leads to an exchange of forces between the upper and lower part of the plate. This exchange depends on the geometry parameters of the notch (ω, β), but also on the crack length L_{crack} and the stiffness of the screw.

In Figure 6 the results from the numerical and analytical analysis regarding the influence of the crack length on the force in the screw are depicted.

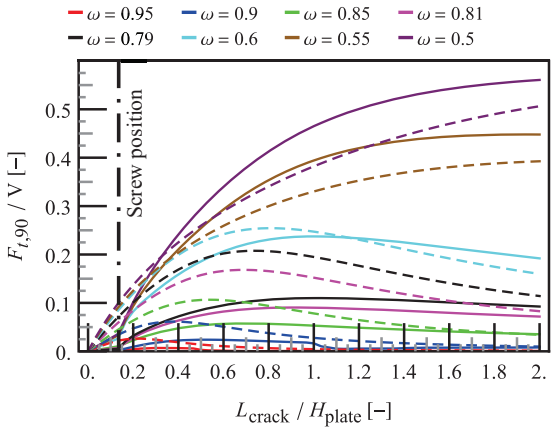

Figure 6: *Axial force in the screw depending on the crack length (dashed lines … analytical model, solid lines … numerical model)*

The analytical and the numerical model show a comparable tendency of an increasing force in the reinforcement with an increasing crack length. This was verified for all investigated ω-values. Additionally, it can be recognised that for bigger crack lengths a decreasing trend in the force of the screw may occur. This can be explained by the fact that the stiffness of the system decreases with an increasing L_{crack}. In the analytical model the point of the local maximum could be obtained by applying the condition $dF / dL_{crack} = 0$. However, this point is not of practical relevance for the design of the reinforcement.

The crack propagation is initiated at the notch tip "behind" the position of the screw. However, until the crack passed the screw position no force, or even compression forces, in the screw were observed. Thus, forces at $L_{crack} = 0$ are assumed to be zero in the numerical analysis.

Jockwer [1] mentions the possibility of an interaction between the member parts under and above the crack in reinforced notches during the crack growth. This occurrence renders the analytical model inappropriate due to the assumption, that the crack interface is not in contact. This assumption was investigated in the numerical model by defining contact elements along the opening crack interface. Within the inspected layups from Table 1 a consistent behaviour could be recognised. The interaction at the crack interface occurs for larger crack lengths and small notches of up to $h_2 = 15$ mm. The analytical model in this range of ω shows conservative results in comparison to the numerical one. This is noted on all inspected CLT layups, therefore the applicability of the taken assumption in the analytical model is acceptable.

As mentioned, the failure of reinforced notches can occur due to the pull-out of the reinforcement. In order to determine the occurring failure mode in the analysed notches the predicted force in the reinforcement for the screw group was compared with their load-bearing capacity determined as

$$\left(\frac{F_{ax,Ed}}{F_{ax,Rd}}\right)^2 + \left(\frac{F_{v,Ed}}{F_{v,Rd}}\right)^2 = 1\,. \qquad (6)$$

with $F_{ax,Rd}$,, $F_{v,Rd}$ … axial and lateral load-bearing capacity of the screw group

The load-bearing capacity was determined according to the expressions given in EN 1995-1-1 [2], sections 8.3 and 8.5. The detailed calculation is excluded here for simplicity. The acting shear force is taken from the numerical analysis and was included in Eq. (6). In order to simplify the results, the maximal shear force obtained for each ω was used.

The resulting load-bearing capacity for the screw group is illustrated in Figure 7. Their failure load capacities are significantly higher than the maximal forces in the reinforcement for the relevant crack lengths, i.e. pointing out a low risk of screw pull-out during the crack propagation. This leads to the "over-reinforced" case of the notch; hence the failure in the timber occurs due to crack propagation. This hypothesis is questioned on the basis of the experimental results in chapter 5.

https://doi.org/10.52202/069179-0322

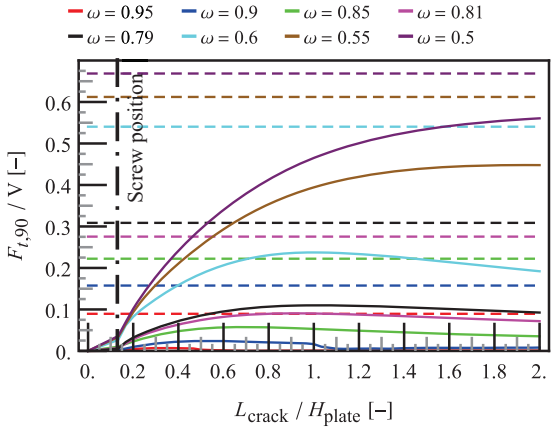

Figure 7: *Comparison of the axial force in the screw to the load-bearing capacity of the applied screws group depending on the crack length (solid lines ... numerical model, dashed lines ... load-bearing capacity of the screw group, Eq. (6.))*

In contrast to the axial force $F_{t,90}$, the shear force F_v shows a constant increase of the force in the screw with increasing crack length (Figure 8). Thus, the load-bearing capacity of the reinforcement in shear is relevant for the determination of the load-bearing capacity of the notched CLT plate for larger notch parameter β and larger crack lengths. The main goal of a reinforcement is to reduce and limit the crack opening at small crack lengths. However, that increases the shear loading at the crack and induces a mode II failure at the crack tip. In order to further increase the load-bearing capacity, the shear loading at the crack should be reduced by increasing the lateral stiffness of the screw. This is accomplished, e.g. by inclining the screws at an angle to grain below 60° ([1],[8]).

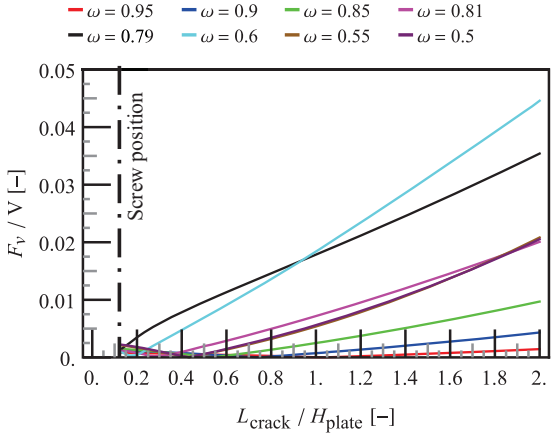

Figure 8: *Shear force in the screws depending on the crack length (numerical model)*

An interesting occurrence can be recognised in the distribution of the shear force: The maximum shear force in the reference case is obtained for ω = 0.6 and ω = 0.79 instead of ω = 0.5 as expected from the distribution of the axial forces. This occurs at the interface of the transversal and longitudinal layer due to the increased compliance caused by rolling shear in the transversal layer. This implies a bigger influence of the mode II failure at the interface of the layers, cf. section 4.2.

The influence of the parameter β on the axial force in the screw is illustrated in Figure 9. The crack length in the analysis was assumed as L_{crack} = 150 mm. This assumption is based on observations from experimental tests conducted by the author ([12]) and found in literature [1] respectively, as the approximate, where a failure of the reinforced notch occurred. The chosen length refers to failures in cases, where inclined screws were used. The lengths for non-inclined screws are smaller and can be expected in the region of 80 to 100 mm. However, a bigger crack length was chosen for the analysis in order to obtain more conservative results.

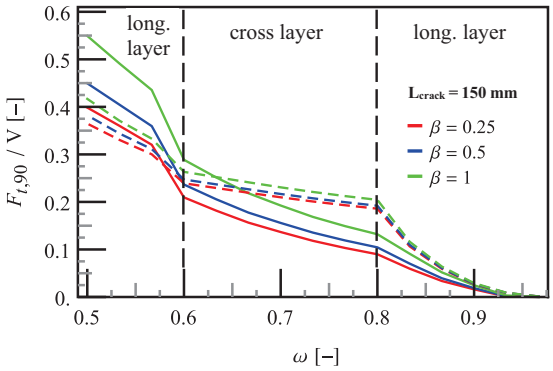

Figure 9: *Axial force in the screw for L_{crack} = 150 mm depending on the parameter ω and β (dashed line ... analytical model, solid line ... numerical model)*

It can be seen that the analytical model is conservative in the area of the first longitudinal and transversal layer ($\omega \geq$ 0.6), but with an increasing notch height the results diverge to the unsafe region compared to the numerical results. This was observed for all considered layups. The differences in the reference case are equal to 15% of the force at the support; for other lay-ups the differences grow up to 25%. As a consequence this implies that the analytical approach should be applied only in the region $\beta \leq$ 0.5. Alternatively, a correction factor increasing the effective notch length as a function of β could be applied.

3.4 COMPARISON OF DIFFERENT METHODS AND VERIFICATION

In this section a comparison of methods for the prediction of the force in the reinforcement related to the reference configuration is given. Beside the analytical and numerical method explained in the sections 3.1 and 3.2, also present methods for unlayered notched beams (see section 2.1; Eq. (1) and (2)) were included, although they are not mechanically consistent with the layered timber product CLT.

A comparison of the results for the axial force in the screw between the analytical and numerical approach is shown in Figure 10. With an increasing crack length, the analytical model converges to the numerical one. This behaviour can be explained due to the assumptions made

https://doi.org/10.52202/069179-0322

in the Timoshenko Beam Theory characterised by a dominant shear deformation of the cracked plate parts under and above the crack interface for small crack lengths and small notch heights. Improved results can be obtained by increasing the effective crack length to overcome the restrictions of the beam theory. In general, the predictions of the analytical model significantly overestimate the forces in the reinforcement predicted by numerical model. On the other side for $\omega < 0.6$ the analytical model underestimates forces in numerical model in range of 20%. These differences are significant and can't be neglected, therefore further investigation and refinement of the model is needed!

In Figure 10 for $\omega = 0.95$ and 0.9 the roughness of the curves is noted. The roughness is caused by the predictions in the numerical model. In mentioned range, the crack interface is in contact and it is causing constant change in force in the screw in contrary to assumption of analytical model.

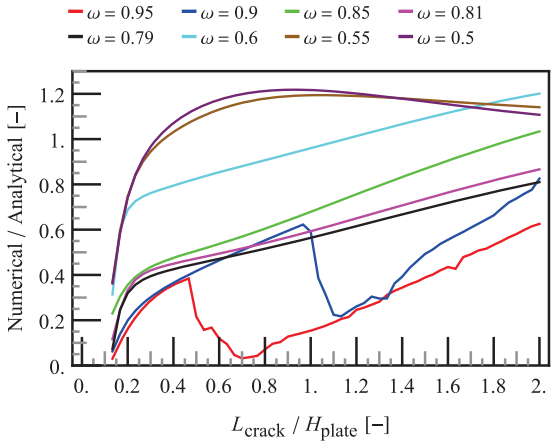

Figure 10: *Comparison of the axial force in the screw between the numerical and analytical model for the reference configuration*

A comparison of different methods for the prediction of the force in the screw of the reference CLT plate is shown in Figure 11. The analytical and numerical solutions were computed for the crack lengths L_{crack} = 100 mm and 150 mm, i.e. in the domain relevant for failure of the notch (cf. section 3.3). In order to check their applicability, although the methods are not consistent with the layered timber products like CLT, in addition results for the regulations valid for unlayered notched timber products specified in the National Annexes [3] and [4] to EN 1995-1-1 and the current draft prEN 1995-1-1:20XX [6] are included.

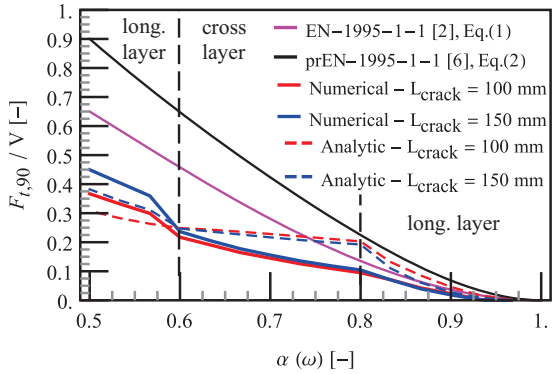

Figure 11: *Force in the screw according to different methods for different parameter ω and $\beta = 0.5$*

In the draft prEN1995-1-1:20XX [6] (Eq. 2) a new approach for the calculation of the force in the reinforcement is specified as described in section 2.1. This method is compared with the regulations in the National Annexes in [3] and [4] (Eq. 1) (Figure 12). It can be recognised that the new approach in the draft standard leads to substantially higher forces in the reinforcement for the full range of the investigated parameter α and β.

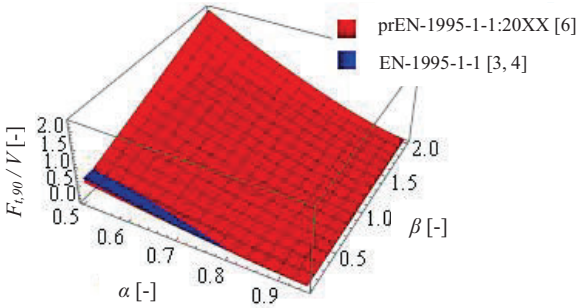

Figure 12: *Illustration of the force in the reinforcement (screw) depending on the parameter α and β for the methods in [3], [4] and [6] resp.*

In Table 3 a comparison of results for different layups applying the mentioned methods is listed. The analytical model and the numerical model for CLT show a good match. The approaches in [3], [4] and [6] resp. are leading to very conservative results, which was expected as these methods are not considering the layered structure of CLT and the influences of cracks, as well as the reinforcements are not taken into account.

If the stiffness of the screw is ignored, the results of the analytical method for the prediction of the force in the reinforcement of CLT plates, Eq. (5), is approaching the results in the National Annexes to the standard EN-1995-1-1, [3] and [4]. This can be achieved by assuming an infinite stiffness for the screw. Further the crack length is assumed again as L_{crack} = 150 mm. The results over the complete range of the important parameters ω and β are presented in Figure 13. If an infinite stiffness of the screw is assumed, the results of the analytical model lead to increased forces in the screw in an expected range of 20% to 30% for all analysed configurations.

https://doi.org/10.52202/069179-0322

Table 3: *Comparison of results for the prediction of the force in the screw according to the different methods and different layups; parameter β = 0.5 and crack length L_{crack} = 150 mm (results are normalised to $F_{t,90}$ / V; the comparison is given in % and normalised to the numerical solution)*

Method	Layup			
	40-20-20-20-40 mm		30-30-30-30-30-30 mm	
	α (ω) = 0.57	α (ω) = 0.50	α (ω) = 0.57	α (ω)= 0.43*
	$F_{t,90}$ / V [-]		$F_{t,90}$ / V [-]	
Analytical model - CLT	0.29 (+26%)	0.37 (-16%)	0.36 (-5%)	0.38 (-15%)
Numerical model - CLT	0.23	0.44	0.38	0.45
prEN 1995-1-1:20XX	0.72 (+213%)	0.90 (+104%)	0.72 (+90%)	1.09 (+142%)
EN 1995-1-1	0.51 (+121%)	0.65 (+47%)	0.51 (+34%)	0.78 (+73%)

* α (ω) = 0.43 is used as α (ω) = 0.5 is situated in a transversal layer

With the increased forces considering an infinite stiffness of the screw the results match better with the approach in the National Annexes (Eq. 1). However, these results underestimate the level of the force in the first layer of the CLT and overestimate the force at the top of the transversal layer. The matching of the methods depends heavily on the layups, but in general the differences are small for $\beta < 1.0$. It can be concluded that the mentioned procedure can be used for standardisation, but in addition the influence of the CLT layup should be taken into account by a fitting factor.

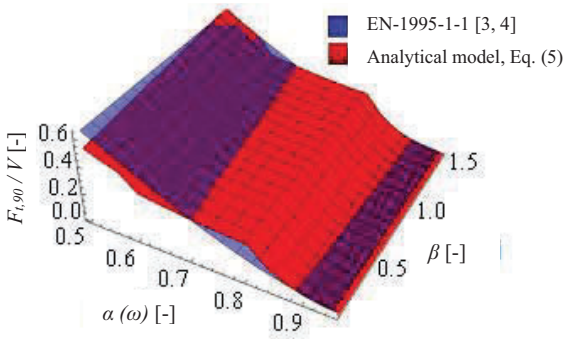

Figure 13: *Comparison of the force in the screw according to [3], [4] and the analytical model (assuming a crack length L_{crack} = 150 mm) for different parameter β, α and ω respectively*

4 LOAD-BEARING CAPACITY

In comparison to the unreinforced notches in CLT the development of mechanically consistent model but also appropriate for hand calculation for reinforced case is more difficult. Due to the pronounced mixed mode failure in reinforced notches a failure criterion needs to be considered.

In this chapter the basics for the computation of the load-bearing capacity of the reinforced notched CLT-plate will be briefly described. The proposed model is based on the energy balance method of LEFM considering all important parameters influencing the load-bearing capacity. Furthermore, assumptions of the critical crack length need to be made for hand calculations with the analytical model.

4.1 ANALYTICAL MODEL FOR THE PREDICTION OF THE MODE MIXITY AND LOAD-BEARING CAPACITY IN REINFORCED CLT-PLATES

The total energy release rate (ERR) of the system in Figure 3 in the frame of the LEFM (expecting a brittle failure in the interface) is given as:

$$G_m = \left[\left(\frac{M_1^2}{EI_1}\right)+\left(\frac{M_2^2}{EI_2}\right)-\left(\frac{M_3^2}{EI_3}\right)\right]+\left[\left(\frac{V_1^2}{\kappa GA_1}\right)+\left(\frac{V_2^2}{\kappa GA_2}\right)-\left(\frac{V_3^2}{\kappa GA_3}\right)\right] \quad (7)$$

where

κGA_i, shear stiffnesses for the plate parts 1, 2, 3

EI_i, bending stiffnesses for the plate parts 1, 2, 3

M_i, V_i moment and shear forces at the crack tip of the plate parts 1, 2, 3

The main challenge regarding Eq. (7) is to decompose it in modal ERR constituents, i.e. mode I and mode II respectively. In the literature the mode decomposition of unlayered cross sections as well as for laminates is well researched. In the pioneering work of Williams [15] a so called "global method" of decomposition was developed. Williams proposed a partitioning method based on the assumptions that: (i) a pure mode I exist when opposite moments act on the plates above and below the crack; and (ii) a pure mode II is obtained when the curvature in the two plates separated by the crack is the same. Such assumptions, however, lead to incorrect results when they are applied to laminates with unsymmetric layups and layers not of the same thickness. For that reason, the accuracy of Williams theory is often questioned when applying it to laminate cross sections such as CLT. The applicability of Williams method was briefly investigated in the scope of this paper. A mode decomposition showed a good matching for the symmetric case with ω = 0.5, but greater deviations for ω ≠ 0.5 compared to the numerical model were observed.

The mode mixity is evaluated as a function of the crack length with the numerical method based on VCCT. The numerical approach is considered as a reliable method for the analysis of fracture properties and mode mixity. Nonetheless, an analytical approach was also developed for easier handling of the parameters and to verify the possibility of using an analytical model for the mode decomposition.

"An Elastic Interface Model for Coupled Laminates" developed by Bennati [16] was used to derive the mode mixity in notched CLT plates. The model is based on the Timoshenko Laminate Theory. The solution is derived based on the crack tip element (CTE) illustrated in Figure 14. The CTE includes the crack tip and a part of the beam behind the crack tip. The CLT laminate is divided by a crack interface into two sublaminates, which are coupled with continuously distributed linear elastic springs

https://doi.org/10.52202/069179-0322

enabling a better description of the deformation at the crack tip. This step requires a fitting with experimental or numerical results. The sensitivity of the spring stiffness on mode mixity was analysed and it has been shown that for $k_z > 1000$ N/mm the mode mixity is constant, therefore $k_z = 1000$ N/mm was taken. To include the influence of transversal layers, the stiffness k_x was defined as $k_z / k_x = 10$. The strain, displacement and stress distributions in the CTE are derived by simultaneously solving a set of two differential equations which define the interface stresses. Then, the mixed energy release rate and its mode I and mode II contributions are evaluated based on Rice's J -integral. The solution of this integral for the total ERR in mode I and II is given in Eq. (8)

$$G_I = \frac{\sigma_z^2}{2 \cdot k_z} \qquad G_{II} = \frac{\tau_{zx}^2}{2 \cdot k_x} \tag{8}$$

with

G_I, G_{II}	ERR in mode I and II [mJ/ m^2]
k_x, k_z	spring stiffness in the horizontal (x) and the vertical (z) direction
σ_z	maximum normal stress at x = 0 (crack tip) in direction perpendicular to grain
τ_{zx}	maximum shear stress at x = 0 (crack tip)

The mode mixity is represented as the phase angle $\psi = \arctan\left(\sqrt{G_{II} / G_I}\right)$ where $\psi = 90°$ refers to the pure mode II and $\psi = 0°$ to the pure mode I fracture.

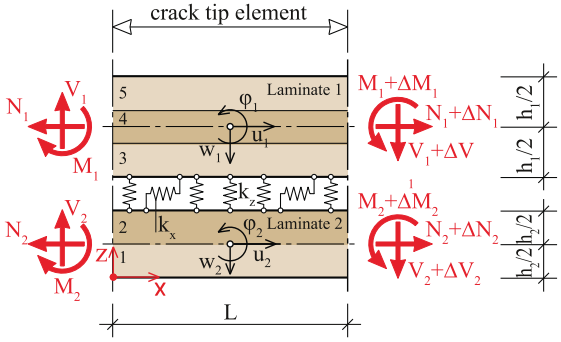

Figure 14: *Crack tip element (CTE) - Elastic Interface model*

4.2 FRACTURE BEHAVIOUR OF REINFORCED CLT NOTCHES

The distribution of the mode I ERR (G_I) as a function of the crack length normalized to the height of the plate is shown for the reference case in Figure 15. The diagram clearly shows the decreasing tendency of the G_I with an increasing crack length. For comparison the G_I in unreinforced notches is causing the failure of the notch as G_I increases with a crack length leading to the failure at relatively small crack lengths of around 50 mm.

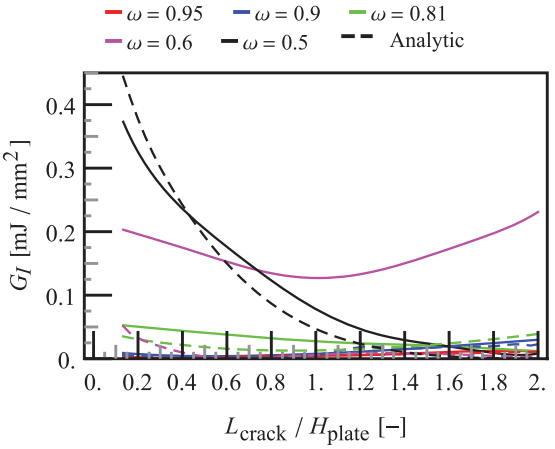

Figure 15: *ERR in mode I for the reference layup*

The effect of the reinforcement is clearly recognisable as the reinforcement reduces the cracking tendency of the plate, as it reduces the crack opening and hence the mode I influence. This effect is increasing with stiffer reinforcements. The agreement of the analytical and numerical model for G_I is relatively poor, especially at the interface between the longitudinal and transversal layer mainly due to the influence of significantly different shear and elastic modulus between them. However, G_I shows the same tendency for all notch heights in the numerical model, excluding the solution at the interface.

The distribution of the mode II ERR (G_{II}) is shown in Figure 16. In this case the G_{II} increases with the crack length. Again, for the same reason the agreement with the numerical model is poor at the interface. Otherwise, a good agreement between the models was observed.

The increasing mode II is also present in the unreinforced notches [1], but the ratio G_{II} / G_I is significantly lower compared to the reinforced case. Moreover, the value of G_{II} doesn't influence the load-bearing capacity of the unreinforced notches significantly as the fracture energy in mode I is up to three times lower compared to that of mode II.

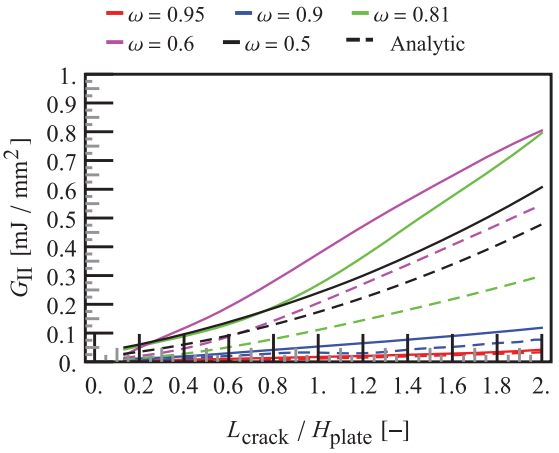

Figure 16: *ERR in mode II for the reference layup*

https://doi.org/10.52202/069179-0322

The load-bearing capacity of reinforced CLT notches is heavily dependent upon the dominant mode of fracture. Therefore, the plots of the mixed mode ratio and mode mixity were investigated. The mixed mode ratio for mode I is shown in Figure 17. It can be seen that the share of the mode I in total mixed mode ERR (G_{mixed}) shows a descending tendency when a reinforcement is applied. This decreasing tendency is especially pronounced in the range $\omega = 0.5$ to 0.6, where for smaller crack lengths the mode I failure is dominant. The decrease of G_I is mainly responsible for the significant increase of the load-bearing capacity in reinforced notches (see Table 4).

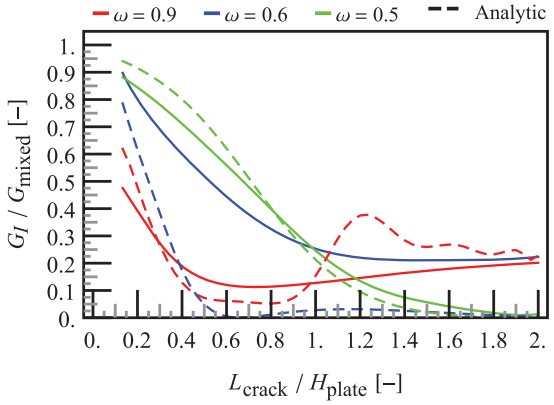

Figure 17: *Mixed mode ratio of mode I for reference layup*

For big ω-values the mode II is dominant, already at small crack lengths. For larger crack lengths they converge to constant value (Figure 18). It is noted that for $\omega = 0.9$ and large crack lengths the delaminated parts of the plate are in contact, therefore producing a significant portion of mode II.

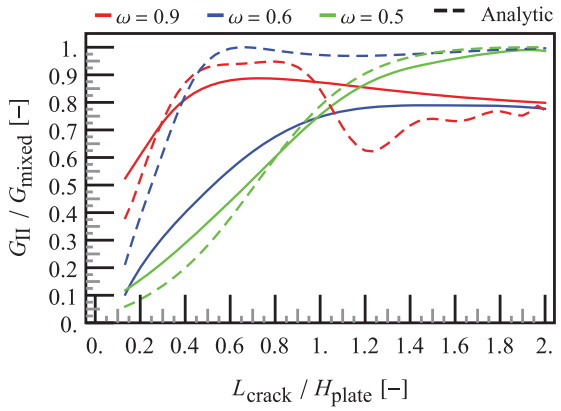

Figure 18: *Mixed mode ratio of mode II for reference layup*

Two plots of the mode mixity are shown with the intention to investigate the influence of the force in the screw on the mode mixity and subsequently on the load-bearing capacity. The Figure 19 and Figure 20 refer to the solution with forces from the numerical and analytical analysis respectively.

It can be seen that the force in the screw plays a big role on the accuracy of the mode mixity. To increase accuracy, a correction factor for Eq. (5) can be developed.

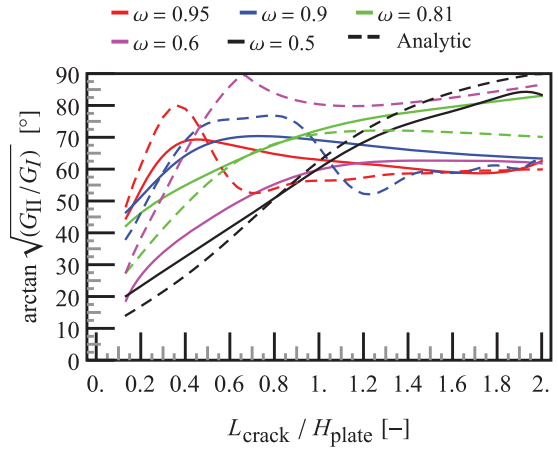

Figure 19: *Mode mixity of the reference layup with forces in the reinforcement from the numerical analysis*

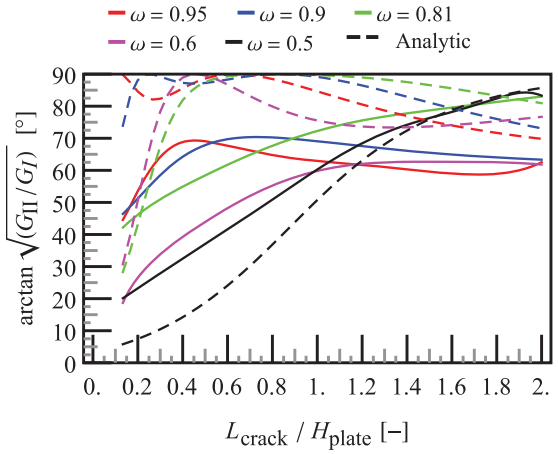

Figure 20: *Mode mixity of the reference layup with forces in the reinforcement from the analytical solution*

4.3 LOAD-BEARING CAPACITY

The load-bearing capacity of a reinforced CLT notch can be explicitly calculated applying Eq. (7) if the mode mixity is known. For that reason, an effort is made in the following to determine the mode mixity. The closed form solution of the mode mixity can't be defined with an expression which would be suitable for the application in standards. Therefore, a regression curve can be developed based on important geometric parameters (ω, β) and the CLT layup. The significant mode mixity of the reinforced beam in failure endorses the implementation of a failure criterion. In Eq. (9) a semi-quadratic criterion was used. However, other failure criteria could also be appropriate.

$$\left(\frac{G_I}{G_{I,C}}\right)+\left(\frac{G_{II}}{G_{II,C}}\right)^2 = 1 \qquad (9)$$

with

$G_{I,C}$ and $G_{II,C}$ critical ERR in mode I and II, respectively

https://doi.org/10.52202/069179-0322

The solution of Eq. (9) is illustrated in Figure 21.

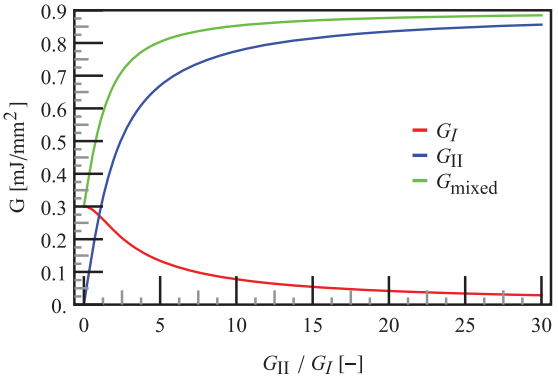

Figure 21: *Progression of the critical ERR in mode I, II and mixed mode G_{mixed} as a function of G_{II} / G_I*

Next, a brief methodology for the determination of the load-bearing capacity for the proposed analytical model is given.

(i) Determine the force in the screw applying Eq. (5), assuming L_{crack} = 150 mm – a conservative approximation compared to L_{crack} = 100 mm.

(ii) Obtain the phase angle of the mode mixity from a regression curve obtained from the analytical or numerical model. In the regression curve a critical crack length should be assumed – proposal from experimental results in this work and from literature for not inclined screws is L_{crack} = 100 mm

(iii) Determine from Eq. (9) or with a regression curve the critical mixed mode ERR G_{mixed} and calculate the load-bearing capacity with Eq. (10)

$$V_{f,d} = \sqrt{\frac{2 \cdot w \cdot G_{mixed}}{\left(\frac{(1-\eta)^2}{(\kappa GA)_1} + \frac{\eta^2}{(\kappa GA)_2} - \frac{1}{(\kappa GA)_3}\right) + H \cdot \left(\frac{(1+\beta-\eta)^2}{(EI)_1} + \frac{\eta^2}{(EI)_2} - \frac{(1+\beta)^2}{(EI)_3}\right)}} \quad (10)$$

where
$\eta = F_{t,90} / V_d$

5 EXPERIMENTAL RESULTS AND VERIFICATION

For the analytical method described in the previous section a comparison of the predicted load-bearing capacity with experimental results presented in [12] was prepared. The summary of the conducted experimental tests on reinforced notched CLT plates is illustrated in Table 4. For determining the mode mixity the results from Figure 19 were taken, as a better matching was obtained. The comparison showed conservative predictions of the model in a range of 10% to 17% (Figure 22). The results show that this method can be used to explicitly predict the failure load of reinforced notched CLT plates. It should be noted that the analytical method for the prediction of the force in the screw and also Elastic Interface model can be utilised for solid timber or glulam beams.

Table 4: *Detailed overview of experimental tests on reinforced notched CLT elements*

Layup [mm]	Series	n_{screws}	Screw angle [°]	α / β	$V_{f,mean,unreinforced}$ [kN]	$V_{f,mean,reinforced}$ [kN]	$V_{f,reinf}/V_{f,unreinf}$

6 CONCLUSIONS

In this paper a contribution for prediction of the force in the reinforcement and the load-bearing capacity in reinforced notched CLT plates is given. In general, notches should be avoided due to the severe impact on the load-bearing capacity, robustness and ductility of load-bearing timber members, but if used they should be reinforced in any case.

The proposed way of reinforcing notched CLT plates is with self-tapping screws placed in one row at a maximum distance a_1 = 150 mm and distance $a_{3c} = 2.5 \cdot d_{screw}$ from the notch tip. A force in the screw can be calculated with Eq. (5), assuming a conservative crack length L_{crack} = H, for simplification. The current method for unlayered reinforced notches in the National Annexes [3] and [4] to EC-1995-1-1 also potentially show a possibility to predict the force in the reinforcement of notched CLT plates. However, more investigations should be conducted. Nonetheless, it is questionable, if such mechanical inconsistent approaches should be utilized in standards and guidelines for CLT after all.

An explicit and mechanically consistent analytical model for the prediction of the load-bearing capacity in reinforced notches of CLT plates was presented. The analytical model showed a good accuracy with the numerical model in scope of mode mixity, being important for the determination of the load-bearing capacity. The analytical model also showed a good correspondence with conducted experimental results. Nonetheless the analytical approach should be further refined and simplified as much as possible in order to be applicable in standards and guidelines.

For a further refinement of the analytical model, it would be of interest to apply fracture mechanics based methods of higher order, e.g. Zig-Zag theory, as the shear in the transversal layers has a big influence on the deformations at the crack tip and therefore on the load-bearing capacity. For the future work it is essential to conduct additional experimental tests on reinforced notched CLT plates including a wide range of different layups and parameters ω and β in order to further verify the given proposals.

ACKNOWLEDGEMENT

This research work was prepared within the frame of the project "Notches in CLT and CLT ribbed panels" which was funded in the program line FFG Collective Research by the Austrian Research Promotion Agency FFG.
The work of Erik Serrano was part of the project InnoCrossLam, supported under the umbrella of ERA-NET Cofund ForestValue.

ANALYSIS OF DIFFERENT NUMERICAL MODELLING STRATEGIES OF MULTI-STOREY CLT SHEAR WALLS

Elisabetta Maria Ruggeri[1], Giuseppe D'Arenzo[2], Marinella Fossetti[3], Werner Seim[4]

ABSTRACT: CLT platform-type buildings are characterized by a high level of redundancy due to the high number of connections used in the perimeter of the CLT panels. In this regard, in addition to the connections placed at the base of the walls, other structural components including the floor diaphragms and the lintels above the openings, along with their connections, influence the lateral performances of CLT shear walls. In this paper, an extensive analysis on the lateral behaviour of multi-storey CLT shear walls with openings realized with two different construction techniques is conducted. The study compares the results obtained from a simplified modelling strategy commonly used in practical design with more advanced modelling strategies that consider in detail the effects of structural interactions between floors and wall segments and between lintels and wall segments. The results of the elastic analyses conducted in this study showed significant differences in the lateral behaviour of systems analysed with the two modelling strategies, emphasizing that the simplified modelling strategies cannot always be reliable methodologies to describe the lateral behaviour of multi-storey CLT shear walls due to the significant effect of structural interactions provided by floors and lintels.

KEYWORDS: CLT structures, Multi-storey shear walls, Structural interactions, Numerical modelling, Elastic analyses

1 INTRODUCTION

CLT "box-type" buildings, and in particular those erected using the platform construction method, present a high level of structural redundancy due to the numerous connections between external walls, internal partitions and floor diaphragms, see Figure 1. Connections of this type, which are typically neglected in practical design, generate structural interactions that have a significant impact on the lateral performance of CLT shear walls and, as a result, the entire structure subjected to lateral loads.
Typically, in the practical design, the lateral stiffness of a CLT building is calculated based on the shear walls and their individual stiffness in the direction of the horizontal load. However, the high number of connections used in the perimeter of the CLT panels, provide an additional stiffening contribution due to the interaction between floor diaphragms and wall segments and between lintels and wall segments, which modifies the deformation mechanisms of a generic shear wall, see for instance [1–5].
The effects of the interactions between lintels and wall segments also depend on the method used for the construction of the openings, which include opening cut

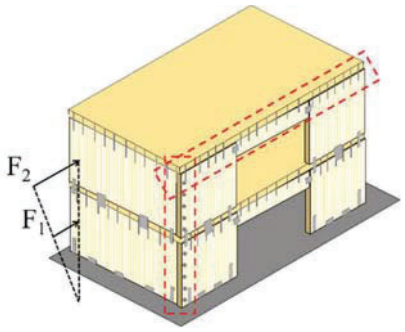

Figure 1: *CLT "box-type" building erected using the platform construction method under lateral loads.*

out of the panel or opening realized by assembling different CLT panel elements. In case where the openings are directly cut out of the CLT panel, the structural continuity between lintels and wall segments is ensured and the shear wall behaves as a unique structural element, see Figure 2 (a). On the other hand, in case where the openings are realized by assembling wall segments and lintels through mechanical connections, such as screws or

metal brackets, a full structural continuity is difficult to achieve and, in this case, the wall segments can be assumed as independent cantilever elements [6], see Figure 2 (b). The lateral performance of CLT buildings realized with these two construction techniques has been the focus of different experimental studies, see for instance [7–9], which showed a different lateral behaviour for multi-storey CLT systems realized with the two construction techniques.

The results of various studies conducted in the literature, [7,10,11], reveal that the lateral behaviour of multi-storey CLT shear walls is influenced by the structural interactions between the wall segments and the surrounding structural elements and the different construction techniques used to realize the openings. Despite these structural interactions have an impact on the lateral behaviour of multi-storey CLT systems, they are often not considered in practical design and in simplified models.

This study investigates in detail the effects of the structural interactions provided by floors and lintels on the lateral behaviour of multi-storey CLT shear walls. The approach used in this study consisted of comparing the results obtained from the elastic analyses of simplified modelling strategies, in which the effects of the structural interactions are not taken into account, with those obtained from more advanced modelling strategies, which consider the structural interactions due to floors and lintels. Results of this numerical study show how the different modelling strategies lead to different lateral performance of the systems, highlighting the need to more carefully consider the different structural elements of CLT systems in the analysis of their lateral behaviour.

2 NUMERICAL STUDY

2.1 MODELLING STRATEGIES

Typically, multi-storey CLT shear walls are modelled by means of a simplified modelling strategy, identified as SM in this study, see Figure 3. In this case, stability for horizontal loads of multi-storey CLT shear walls is provided by wall segments, schematized as cantilever elements. Whereas, lintels are modelled as pinned elements, which connect the wall segments and have the only function of transferring horizontal and vertical loads to the wall segments, and have no ability to transfer moment at their extremities. The lateral stability of the system is ensured by the wall base connections, namely, hold-downs, which are placed at the two extremities of each wall segment, and angle brackets, which are placed along the length of the wall panels.

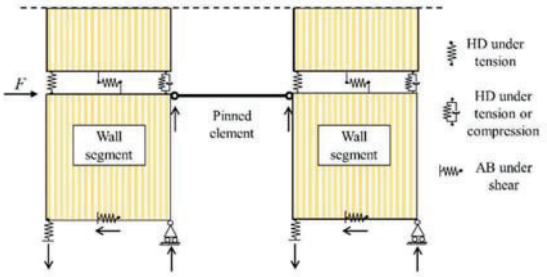

Figure 3: *Simplified modelling strategy of multi-storey CLT shear walls (SM).*

With this modelling strategy, the bending contribution of the floor diaphragms and lintels is neglected, and as a result, no bending moment is transmitted between the wall segments and the lintels, and the system failure occurs in the mechanical anchors placed at the base of the wall segments.

In order to realistically simulate the lateral behaviour of multi-storey CLT shear walls, a more advanced modelling strategy that takes into account the interactions between floor diaphragms and wall segments and between lintels and wall segments is required. In this regard, an advanced modelling strategy that considers these structural interactions (IM) is proposed and applied to the two construction techniques shown in Figure 2, for the case of monolithic (IM-MSW) and assembled (IM-ASW) multi-storey shear walls, see Figure 4 and Figure 5, respectively.

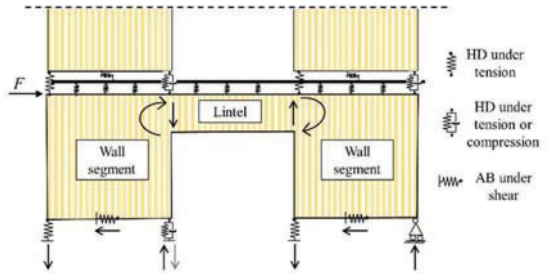

Figure 4: *Advanced modelling strategy with interactions in case of monolithic multi-storey CLT shear walls (IM-MSW).*

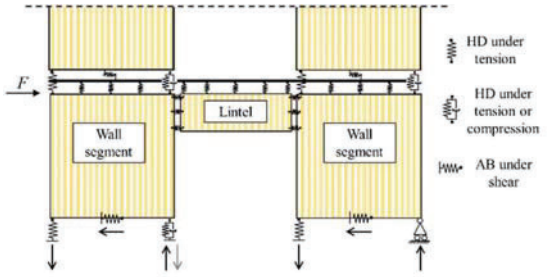

Figure 5: *Advanced modelling strategy with interactions in case of assembled multi-storey CLT shear walls (IM-ASW).*

https://doi.org/10.52202/069179-0323

When structural interactions are taken into account, higher lateral performance and different lateral deformation mechanisms are expected than the SM strategy, due to the bending contribution of the floor diaphragms and, in case of monolithic walls, also due to the capability of the lintel to transfer bending actions. In case of monolithic shear walls (IM-MSW) the system failure can occur either in the connections at the base of the wall segments or in the corner of the openings in correspondence of the lintel element, depending on the stresses level in this critical zone [7,8,12]. On the other hand, in case of assembled shear walls (IM-ASW), the system failure may occur in the floor panel or in the base connections. In the following, the configurations and the mechanical parameters used for the numerical analysis are presented.

2.2 STRUCTURAL CONFIGURATIONS CONSIDERED IN THE STUDY

In order to investigate the effects of the structural interactions, a numerical analysis was performed considering different multi-storey CLT shear wall systems. An investigation was conducted to analyse the impact of different modelling strategies on two construction techniques involving shear walls. These construction techniques include the creation of shear walls as monolithic elements with openings or as assemblies of different CLT elements with openings. The numerical analysis was developed considering nine different multi-storey CLT shear walls structures consisting of one-, three- and five-storey systems and three different geometries, see Figure 6.

The first geometry, Geometry 1, has one opening of 3 m in length; the second geometry, Geometry 2, has two openings of 1 m in length; while the third geometry, Geometry 3, has three openings of 1 m in length. The height of the wall segments is equal to 3 m for all configurations analysed, while the lintels and the floors are 400 and 200 mm high, respectively. Geometrical dimensions of the three geometries are shown in Figure 7.

The numerical study was conducted considering three different thicknesses of CLT wall panels along the height of the structures. The distribution of the different wall panels along the height of the structures is reported in Table 1. Wall panel 1 (WP1) consists of a three-layered

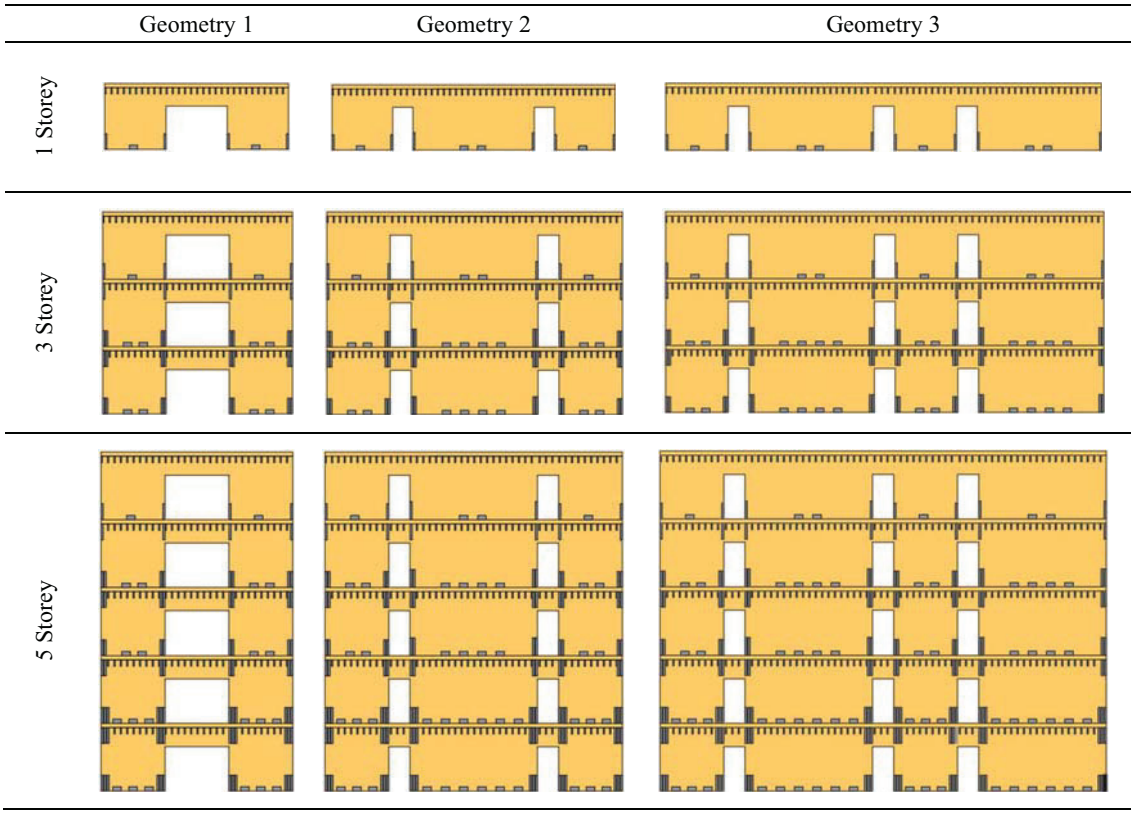

Figure 6: *Multi-storey CLT shear walls configurations and mechanical anchors distribution.*

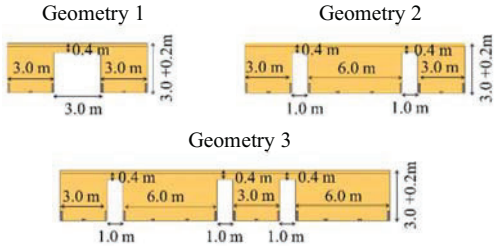

Figure 7: *CLT shear walls geometries and dimensions.*

panel with a thickness of 80 mm and layer thicknesses of **30**-20-**30** mm (in bold the layers of wooden laminated arranged in the vertical direction). Wall panel 2 (WP2) consists of a five-layered panel with a thickness of 120 mm and layer thicknesses of **30**-20-**20**-20-**30** mm. Wall panel 3 (WP3) consists of a five-layered panel with a thickness of 160 mm and layer thicknesses of **40**-20-**40**-20-**40** mm.

Table 1: *Distribution of the CLT panels thicknesses.*

	1 storey	3 storey	5 storey
Fifth storey			WP1
Fourth storey			WP2
Third storey		WP1	WP2
Second storey		WP2	WP3
First storey	WP1	WP2	WP3

A different direction of the external wooden laminates was adopted for the wall segments and the lintels: in case of monolithic shear walls, the orientation of the external wooden laminates of the CLT panels was assumed in the vertical direction for both wall segments and lintels, while in case of assembled shear wall, a vertical orientation was assumed for wall segments and a horizontal orientation for lintels (Figure 2). For all configurations, a floor panel (FP) with a total thickness of 200 mm and five layers with thicknesses of **40**-40-**40**-40-**40** mm, was adopted.

Regarding the elastic properties of CLT panels, the modulus of elasticity parallel to the grain (E_0), the modulus of elasticity perpendicular to the grain (E_{90}), and the shear modulus in the plane (G_0) of the wooden laminates were assumed equal to 11700 MPa, 390 MPa and 730 MPa, respectively.

The values of the elastic stiffness of the base connections, hold-downs and angle brackets, were defined according to the experimental results of Casagrande et al [13]. On the basis of this study, hold-downs (HDs) type WHT440 with thirty 4×60 mm annular ring nails were used and the value of vertical elastic stiffness was set equal to 6.61 kN/mm. Whereas, angle brackets (ABs) type TTF200 with thirty 4×60 mm annular ring nails were used and the value of horizontal elastic stiffness was set equal to 8.94 kN/mm. The distribution of the base connections, hold-downs and angle brackets, of the multi-storey CLT shear walls was determined based on the increase of the shear force from the upper storeys to the foundation, see Figure 6. Mechanical properties of the floor-to-wall connections (f-w) were assigned according to the experimental results of Gavric et al. [14]. Based on this study, the vertical stiffness (withdrawal, w-w_v) and the horizontal stiffness (shear, w-w_h) of one screw was set equal to 4.00 and 1.45 kN/mm, respectively. A spacing of 300 mm was chosen for these connections in all the analyses.

Table 2 summarizes the elastic stiffnesses used in the numerical analyses for one hold-down in the vertical direction, one angle bracket in the horizontal direction, and one floor-to-wall connection in both vertical (v) and horizontal (h) directions.

Table 2: *Stiffness of the connections used for the numerical analyses.*

	K_{el} [kN/mm]
HD	6.61
AB	8.94
w-w_v	4.00
w-w_h	1.45

The values of the elastic stiffness of the base connections, hold-downs and angle brackets, reported in Table 2, were modified to account for the significative influence of the connection properties on the lateral deformation of a CLT shear wall. In this context, the stiffness of each hold-down and angle bracket was multiplied by three different coefficients α equal to 0.5, 1.0, and 1.5, which lead to 3 different arrangements of connection stiffnesses in multi-storey shear walls. Table 3 provides a summary of these arrangements.

Table 3: *Stiffness of connections as function of α.*

	α=0.5	α=1.0	α=1.5
K_{HD} [kN/mm]	3.30	6.61	9.91
K_{AB} [kN/mm]	4.47	8.94	13.41

A vertical load *q* equal to 10 kN/m was applied on each storey of the system, while a triangular distribution of horizontal loads *F* was adopted. The values of the horizontal loads used in each geometry are reported in Table 4.

https://doi.org/10.52202/069179-0323

1			First storey	21.43	33.33	50.00

2.3 NUMERICAL MODELS

The elastic behaviour of multi-storey CLT shear walls with openings was investigated using finite element models (FEM) developed in the software package SAP2000 [15].

To accurately capture the elastic behaviour of wall segments and lintels with varying thicknesses, orthotropic shell elements were adopted in the numerical models. Specifically, the CLT panels were simulated using four-node quadrilateral shell elements with a mesh size of 100×100 mm. The mechanical properties of CLT panels were assigned considering the layered structure of the three different sections, WP1, WP2 and WP3, according to the composite theory of Blaß and Fellmoser [17]. The effective moduli of elasticity in the vertical direction, $E_{eff,v}$, and horizontal direction, $E_{eff,h}$, of the panel were defined according to Equation (1) and Equation (2), where t_v and t_h represent the total thickness of the vertical and horizontal wooden laminates, while t_{CLT} denotes the total thickness of the CLT panel.

$$E_{eff,v} = \frac{E_0 t_v + E_{90} t_h}{t_{CLT}} \quad (1)$$

$$E_{eff,h} = \frac{E_0 t_h + E_{90} t_v}{t_{CLT}} \quad (2)$$

The effective in-plane shear modulus of the wooden laminates, G_{eff}, was defined according to Bogensperger et al. [18], see Equation (3), in which w denotes the width of the wooden boards, t_{mean} represents the mean thickness of the wooden laminates and can be calculated with Equation (4), while α_T can be calculated by using Equation (5).

$$G_{eff} = \frac{G_0}{1 + 6\alpha_T \left(\frac{t_{mean}}{w}\right)^2} \quad (3)$$

$$t_{mean} = \frac{t_{CLT}}{N} \quad (4)$$

$$\alpha_T = p \left(\frac{t_{mean}}{w}\right)^{-0.79} \quad (5)$$

In Equation (4) and Equation (5), N is the number of the section's layers, while p is a parameter equal to 0.535 and 0.425 for three- and five-layered CLT panels, respectively. The elastic properties of the CLT panels adopted for wall segments and lintels are summarized in Table 5.

Table 5: *Elastic properties of CLT wall panels.*

	$E_{eff,z}$ [MPa]	$E_{eff,x}$ [MPa]	G_{eff} [MPa]
WP1	8872	3217	573
WP2	7930	4160	598
WP3	8872	3217	570

In the following, Figure 8, Figure 9 and Figure 10 illustrate the different modelling strategies employed in this study for the case of Geometry 1 and three-storey. A representation of the simplified modelling strategy of multi-storey CLT shear walls (SM) is shown in Figure 8. The lintels were modelled as pinned beam elements with infinite axial stiffness. In case of the SM strategy, analyses were conducted by applying the horizontal forces F at the top of the wall segments to each storey, while a vertical load q was applied to the first row of shell elements as equivalent load per unit area and as uniformly distributed load on the pinned elements.

A representation of the advanced modelling strategies of multi-storey CLT shear walls in case of monolithic (IM-MSW) and assembled (IM-ASW) systems is shown in Figure 9 (a) and (b), respectively. According to Figure 9 (a), in case of monolithic shear walls analysed with the advanced modelling strategy (IM-MSW), the wall segments and the lintels were modelled as unique shell element with the same orientation of the external wooden laminates (z-direction). Whereas, in case of assembled shear walls (IM-ASW), the wall segments and lintels were modelled as separate shell elements with different orientation of the external wooden laminates (z- and x-direction, respectively). According to Figure 9 (b), wall

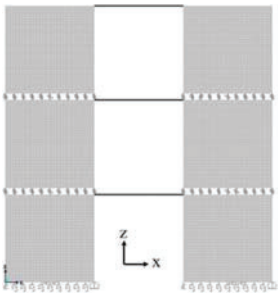

Figure 8: *Simplified modelling strategy of multi-storey CLT shear walls (SM).*

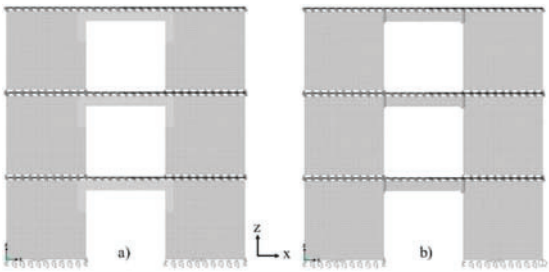

Figure 9: *Advanced modelling strategy with interactions of multi-storey CLT shear walls: a) IM-MSW, b) IM-ASW.*

segments and lintels were connected through the wall-to-lintel connections (w-l). In the modelling strategies with interactions, the floor panels were modelled as beam elements. The assigned bending stiffness, E_0I_{eff}, was determined based on the FP's layered structure outlined in section 2.2, considering only the layers arranged parallelly to the bending stresses. The effective moment of inertia, I_{eff}, was calculated by using Equation (6), where t_i is the thickness of each layer considered in the calculation, a_i is the distance of each layer from the centroid of the section, while b_f represents the floor width. The floor width b_f depends on the effective collaborative section that works in case of internal bending actions, which was calculated using the methodology proposed by Masoudnia et al [19].

$$I_{eff} = \frac{\sum_{i=1}^{n} t_i^3 \, b_f}{12} + \sum_{i=1}^{n} t_i b_f a_i^2 \qquad (6)$$

In these modelling strategies, the horizontal loads F were applied on the top of the wall segments at each storey and a vertical load q was applied to the first row of shell elements as equivalent load per unit area.

Modelling strategies that consider structural interactions (IM-MSW and IM-ASW) were compared with the SM strategy and another additional numerical model that represents a comparison system, called CS, see Figure 10. The CS strategy takes into account the structural interactions due to floors and walls and considers the same configurations of the multi-storey CLT shear walls without openings. As the SM and CS strategies represent the cases of maximum and minimum lateral flexibility,

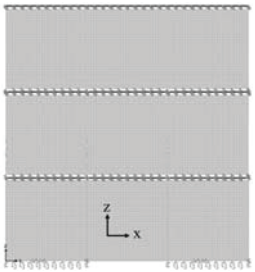

Figure 10: *Advanced modelling strategy with interactions in case of multi-storey CLT shear walls without openings (CS).*

respectively, the CS can offer valuable information on the lateral behaviour of multi-storey CLT shear walls.

For both modelling strategies SM and IM, multi-linear elastic links were employed to model the connections. In particular, mechanical anchors were modelled by means of one- and two-joint multi-linear elastic links from SAP2000 library. Figure 11 provides the force–displacement curves of the connections adopted in the numerical models for the elastic analyses. According to Polastri et al. [20], the hold-downs (HDs) were modelled with different behaviour for tensile and compressive forces (z-direction): for tensile forces the tensile stiffness of the hold-downs was considered, while for compressive forces the link simulated the contact between panel and foundation through high stiffness, see Figure 11 (a). Angle brackets (ABs) were modelled with symmetric elastic behaviour in the horizontal direction (x-direction), according to Yasumura et al. [8], in order to reproduce the behaviour of the angle brackets for shear loads, see Figure 11 (b). In order to reproduce the contact between the wall segments and the foundation, both the SM and IM modelling strategies utilized gap elements with rigid compression-only behaviour, see Figure 11 (c). Additionally, these gap elements were employed between the wall segments of two consecutive storeys in the SM strategy.

In case of IM strategies, the floor-to-wall connections (f-w) were modelled as a series of two-joint multilinear elastic links from SAP2000 [15] library. These connections were characterized by a symmetric elastic behaviour in the horizontal shear direction (x-direction), Figure 11 (b), while they were modelled with elastic behaviour, for tensile loads, in order to simulate the withdrawal behaviour of the connection, and with a stiff behaviour, for compressive loads, to simulate the contact between floor and wall, see Figure 11 (a). In case of assembled shear wall (IM-ASW) the wall-to-lintel connections (w-l) were modelled as a series of two-joint multi-linear elastic links with rigid compression-only behaviour in the horizontal direction (x-direction), in order to reproduce the contact between wall segments and lintels, neglecting the relative low stiffness contribution of these connections, see Figure 11 (c).

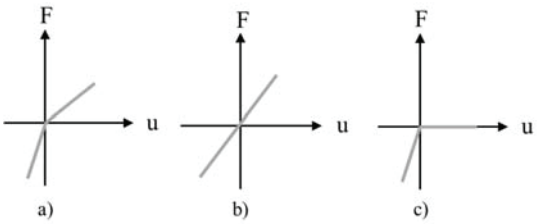

Figure 11: *Force-displacement curves of the connections used in the numerical models: a) HD and f-w in z-direction, b) AB and f-w in x direction, c) GAP in z-direction and w-l in x-direction.*

3 RESULTS AND DISCUSSION

The results of the elastic analyses in terms of lateral storey displacements, lateral stiffness and deformation mechanisms are presented in this section. Results obtained from the advanced modelling strategy (IM) were compared with those obtained from the simplified modelling strategy (SM) and the comparison system (CS). Figure 12 shows the results in terms of lateral storey displacements of multi-storey CLT shear walls. Each graph reports four curves representing the lateral storey displacement of each structure obtained from the four modelling strategies SM, IM-ASW, IM-MSW and CS. In particular, the lateral storey displacement values are normalized with respect to the lateral storey displacement of the upper storey obtained through the SM strategy.

From Figure 12 it can be observed that the deformed shape of the monolithic (IM-MSW) and assembled shear walls (IM-ASW) modelled with interactions is very close, meaning that the floor alone strongly influences the lateral behaviour of the systems. The largest difference between the deformed shape of the IM-MSW and IM-ASW strategies is reached in case of Geometry 1 and five-storey systems, which is the case of the minimum bending stiffness of lintels and floors and the maximum lateral flexibility of the multi-storey system. In general, it can be observed that the lateral storey displacements decrease when moving from Geometry 1 to Geometry 3. This trend can be attributed to the increase in stiffness of the systems.

The graphs illustrated in Figure 12 indicate that when employing the IM-MSW and IM-ASW modelling strategies, which incorporate structural interactions, the lateral storey displacements are lower compared to those obtained using the SM strategy. In particular, the lateral storey displacements are much closer to those obtained from the CS strategy. According to Figure 12, in case of three-storey systems, the lateral storey displacements obtained from the modelling strategies with interactions of monolithic and assembled shear wall (IM-MSW and IM-ASW, respectively) reach both a maximum of 42% of those obtained from the SM strategy. Whereas, in case of five-storey systems, the lateral storey displacements obtained from the IM-MSW and IM-ASW strategies reach a maximum of 36% and 42% of those obtained from the SM strategy, respectively.

Figure 13 shows the results in terms of normalized lateral stiffness of multi-storey CLT shear walls against the coefficient α used to modify the stiffness of the wall base connections, see Table 3. Each graph shows four curves, representing the lateral stiffness of a multi-storey CLT shear wall modelled with the four modelling strategies (SM, IM-ASW, IM-MSW and CS) and normalized respect to the lateral stiffness obtained from the CS strategy. The lateral stiffness of each system was calculated as the ratio between the base shear and the lateral displacement at the top of the shear wall obtained from the numerical analyses.

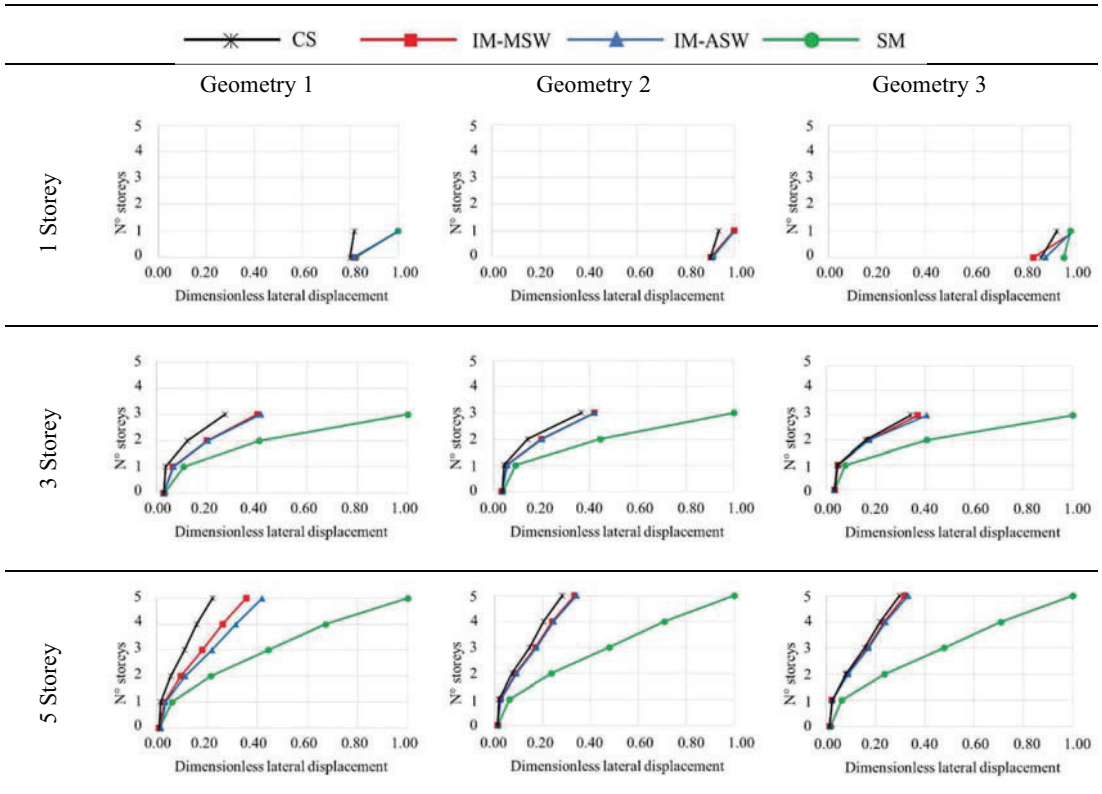

Figure 12: *Results in terms of lateral storey displacement.*

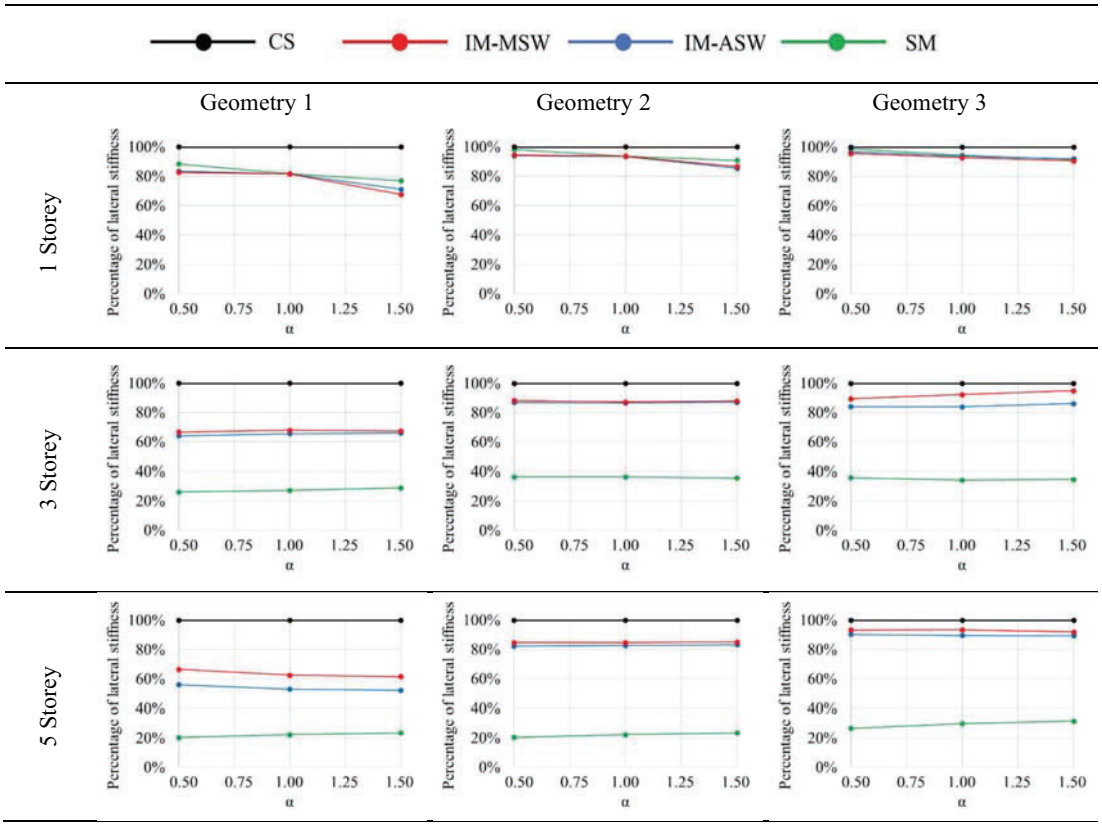

Figure 13: *Results in terms of lateral stiffness.*

The results about the lateral stiffness, depicted in Figure 13, align with those obtained for lateral storey displacements. The findings of Figure 13 demonstrate that IM-MSW and IM-ASW, which incorporate the structural interactions, have lateral stiffness between that of the SM and CS strategies. Specifically, the curves obtained from the monolithic and assembled shear walls (IM-MSW and IM-ASW, respectively) are much closer to those obtained from the comparison system (CS).

According to Figure 13, in case of one-storey systems, the curves representing the lateral stiffnesses lie approximately on the same level of the CS strategy. This is due to the fact that the systems deform with a predominant sliding mechanism and low rocking, generating negligible structural interactions.

Figure 13 shows that the overall lateral stiffness of multi-storey CLT shear walls is similar for both construction techniques depicted in Figure 2 (IM-MSW and IM-ASW). In this regard, the maximum differences between the IM-MSW and IM-ASW strategies are equal to 9%, for Geometry 3 and three-storey, and 11%, for Geometry 1 and five-storey.

Moreover, Figure 13 shows that, in case of Geometry 1, the monolithic and assembled shear walls modelled with interactions (IM-MSW and IM-ASW, respectively) have normalized lateral stiffness values all greater than 60% and 50% for three- and five-storey systems, respectively. However, in case of Geometry 2, these values are greater than 80% for both three- and five-storey systems. Whereas, in case of Geometry 3, the normalized lateral stiffness values are greater than 80% and 90% for three- and five-storey systems, respectively.

Figure 14 shows the structures in the deformed configuration obtained from the four modelling strategies, SM, IM-ASW, IM-MSW and CS, in case of Geometry 1. It can be observed that moving from SM to CS (from left to right of Figure 14), the rocking contribution decreases and the sliding contribution increases, due to the effects of the structural interactions. From Figure 14 it can be observed the significant effect of the interactions due to floors and lintels; in fact, the multi-storey systems with interactions deform similarly to multi-storey systems without openings (CS).

In particular, in case of SM strategy and CS strategy, the predominant deformation mechanisms were rocking and sliding, respectively, while in case of IM-MSW and IM-ASW a combination of sliding and rocking mechanism, with predominant sliding, were performed.

Results obtained from the elastic analyses, show that the interactions between lintels and wall segments and between floors and wall segments strongly influence the deformation mechanism of multi-storey CLT shear wall systems, which is closer to that of multi-storey shear wall systems without openings (CS) rather than that of multi-storey shear wall systems modelled with the SM strategy, in which these interactions are not taken into account.

4 CONCLUSIONS

This paper presented a numerical study that aims to examine how the lateral behaviour of multi-storey CLT shear wall systems, constructed using monolithic and assembled shear walls, is affected by structural interactions provided by floor diaphragms and lintels. In particular, the effects of the structural interactions were studied by considering both simplified modelling strategy (SM) and more advanced modelling strategies (IM), which consider these structural interactions. The numerical study was conducted considering nine structural configurations, consisting of one-, three- and five-storey systems, and including three multi-storey shear wall geometries and different mechanical properties of the connections placed at the base of the wall segments. The study was conducted by comparing the results, in terms of lateral storey displacements, lateral stiffness and deformation mechanisms, obtained from the advanced modelling strategies with interactions, in case of monolithic and assembled shear walls (IM-MSW and IM-ASW), with those obtained from the SM strategy. Moreover, an additional numerical model representing a comparison system (CS), which considers the same configurations of multi-storey CLT shear walls without openings, was developed only for purpose of comparisons.

Results of the elastic analyses show that the structural interactions due to floors and lintels modify the deformation mechanism of multi-storey CLT systems compared to the cases in which these structural interactions are neglected. In particular, these structural interactions reduce the rocking component of the lateral displacement and increase the overall lateral stiffness of the multi-storey systems, which becomes closer to that that of an equivalent system without openings.

Results of this study show that the simplified modelling strategies, often adopted in the design practice, may not always properly describe the behaviour of the multi-storey CLT shear walls subjected to lateral loads.

As result, this study suggests to take into account the contribution given by lintels and floors in the numerical modelling of multi-storey CLT shear walls, since they significantly modify the lateral performance of the system, which is typically modelled by means of simplified modelling strategy.

ACKNOWLEDGEMENT

The presented research was carried out during a research stay of the first author at the University of Kassel (Germany). The support of the scientific staff of the University of Kassel are gratefully acknowledged.

IN-PLANE DEFLECTION OF CROSS-LAMINATED TIMBER DIAPHRAGMS

Mahboobeh Fakhrzarei[1], Hossein Daneshvar[2], Ying Hei Chui[3]

ABSTRACT: Cross-Laminated Timber (CLT) is a reliable alternative to heavy structural components due to its dimensional stability and environmental benefits. However, there is currently no universally accepted design method for calculating the load-bearing capacity and deformation of a CLT diaphragm. The main objective of this study is to develop an analytical model for diaphragm deflection calculation when the major direction of panels is perpendicular to the load and confirm the results with the Finite Element (FE) analysis. In the absence of an experimental study aligned with the derived formula, an FE model was developed based on a full-scale diaphragm test subjected to loading parallel and perpendicular to the panel length. A parametric study was performed on the influence of the diaphragm length and the panel-to-panel connection stiffness. The contribution of bending, shear, and connection's slip to the total diaphragm deflection was quantified. The study reveals that the flexibility of the floor is primarily influenced by two factors: the shear deformation of the CLT panels when the load is perpendicular to the panel length and the stiffness of the panel-to-panel connection when the load is parallel to the panel length.

KEYWORDS: Cross Laminated Timber (CLT) diaphragms, Lateral load, Connections, In-plane deflection

1 INTRODUCTION

Floor diaphragms play an essential role in distributing the applied lateral load to the vertical elements of the lateral load-resisting systems of buildings. Cross Laminated Timber (CLT) panels have become more prevalent in recent years, such as diaphragm components in mid- to high-rise structures, primarily for sustainability reasons [1]. Several studies have investigated the impact of the rigidity or flexibility of CLT diaphragms on the distribution of lateral forces. A rigid diaphragm transmits loads to supports in proportion to the stiffness of the supports, whereas flexible diaphragms deformed in-plane through bending [2]. The lateral load distribution is influenced by the material properties and the load-slip behaviour of the connections between the adjacent panels (called panel-to-panel connections) and panel-to-beam connections [3]. Beairsto, in 2020 [4], evaluated the ductility of two large CLT diaphragms under monotonic and cyclic loads. The test indicated that the ductile design of the CLT diaphragm depended heavily on the panel-to-panel connections.

Pei et al. [5] conducted a series of experiments on a CLT building that was two-story high and 6.7 meters tall, using a shaking table to simulate seismic motions. The floors in this building were made up of 3-ply CLT panels, which were connected using a plywood surface spline and screws. The study found that the CLT diaphragms were significantly stiffer than wood frame floor diaphragms with wood-based sheathing panels, with satisfactory seismic performance. The researchers concluded that the design of a diaphragm needs to consider various sources of overstrength in the diaphragm components, e.g., the strength of the panel-to-panel connections, the stiffness of the boundary elements, and the strength of the fasteners used. Furthermore, Mohammadi [6] conducted experiments to evaluate the seismic performance of CLT diaphragms with multiple configurations. They found that the panel-to-panel connection stiffness significantly affected the in-plane stiffness of CLT diaphragms and recommended that the connections should be designed carefully.

Ashtari [7] investigated selected configurations of CLT floor diaphragm using a two-dimensional (2-D) FE analysis. The comparison between the FE and test results showed that the in-plane stiffness of CLT floors mainly depends on the panel-to-panel connection stiffness and shear modulus of the panels. It is important to note that CLT diaphragms can be loaded either parallel or perpendicular to the major panel axis, as shown in Figure 1. Spickler et al. [8] have provided a procedure for designing CLT diaphragms based on U.S. standards, assuming that the load is applied perpendicular to the panel length. The procedure covers diaphragm design for wind or seismic loads. However, their design approach has certain drawbacks that require attention, such as the failure to consider the impact of panel-to-panel connections on the overall behaviour of the diaphragm. Additionally, utilizing the chord width to determine the bending deflection of the diaphragm may not be a valid assumption.

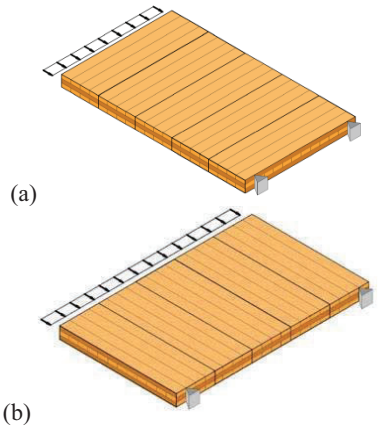

Figure 1: *CLT panels subjected to load (a) perpendicular and (b) parallel to the panel direction.*

Wallner-Novak et al. [9] conducted a technical investigation on the design of CLT floor diaphragms according to the Eurocode 5 specifications [10]. The report focused on diaphragms loaded parallel to the panel length and identified panel-to-panel connections that played a significant role in the diaphragm's performance. The study found that the diaphragm's deflection under shear force was primarily caused by the slip in the connections between the CLT panels, while the deflection due to bending resulted from the rotation of the panels. However, the study did not address scenarios where the applied load is perpendicular to the panel length.

Recently, Line et al. [11] conducted an experimental study to evaluate the current design provisions for CLT diaphragms in ANSI/AWC 2021 [12]. The study involved testing two CLT diaphragms that were loaded parallel and perpendicular to the panel length. The CLT panels were connected using plywood surface splines and fastened to glulam beams using self-tapping screws. Following the CLT diaphragm test [11], Line et al. [13] conducted a series of diaphragm connection tests to provide input data for models predicting the load-displacement response of the CLT diaphragms. The objective of the research was to analyse the behaviour of CLT diaphragms when loaded parallel or perpendicular to the panel length. The findings of the study provide helpful information regarding the different sizes and configurations of diaphragms which can contribute to the next edition of the Timber Design Standards in the USA.

This paper studies the effect of connections between CLT panels, assuming a simply supported diaphragm subjected to a uniformly distributed load perpendicular to the panel length. An analytical model is developed and validated using a finite element model. The effect of different connection stiffness values on the diaphragm's behaviour is evaluated.

The researchers also used a similar modelling technique to develop the FE model for CLT diaphragm loading in parallel and perpendicular directions and compared it with the experimental results. The findings show that the FE models agree well with the experimental results, confirming the effectiveness of the models in predicting the behaviour of CLT diaphragms.

This study has practical implications for the design of CLT diaphragms, as it provides a better understanding of the effect of connections on the diaphragm's performance. Additionally, it emphasizes the importance of incorporating different connection stiffness values and the size of the diaphragm length into the design process. Overall, this research contributes to the advancement of CLT diaphragm design and can potentially improve the performance of CLT structures.

2 ANALYTICAL MODEL DEVELOPMENT

When floor diaphragms are considered deep beams, their in-plane deformation can be separated into two components: deformation in the X and Y directions, as shown in Figure 2. The deflection in the X direction is primarily due to the slip between the panels. In the Y direction, deflection is caused by shear and bending in the CLT panels, as well as interlayer slip between the panels. Simple supports are assumed to be located at both ends of the diaphragm. The diaphragm centreline experiences an external in-plane load, q, which is then conveyed to the shear walls below by the CLT panels.

2.1 SLIPPING AMONG THE PANELS

Figure 2 shows an infinitesimal floor segment of finite length dx, the internal forces and moment, and the strain distribution in a typical floor diaphragm system cross-section.

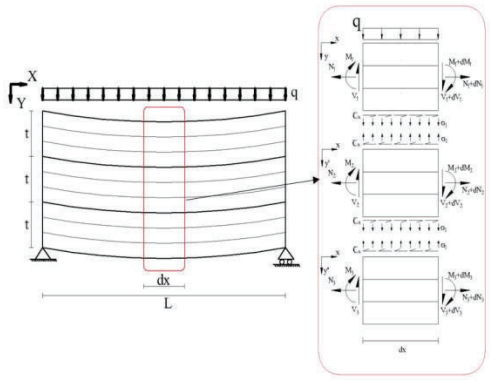

Figure 2: *CLT diaphragm internal force and strain*

The strain in the CLT panel cross-section near the interfaces is caused by the action of the bending moment and displacement in the X direction. First, a longitudinal displacement function (U^N) is assumed for each panel as Equation (1).

https://doi.org/10.52202/069179-0324

$$U_n^N(x,y) = A_n(x).{y_n}^2 + B_n(x).y_n + C_n(x) \quad (1)$$

The variable n = the panel number and y_n" = the reference point for the local coordinate system upper surface of each panel denoted as. Coefficients named "A_n", "B_n", and "Cn" are determined based on the boundary conditions. With the substitution of a derivative of Equation (1) into the distribution of shear stress throughout the depth of the panels, the shear stress for each panel can be written as:

$$\sigma_{xy(1)} = G_{xy}(2A_1y + B_1) \quad (2)$$

$$\sigma_{xy'(2)} = G_{xy}(2A_2y' + B_2) \quad (3)$$

$$\sigma_{xy''(3)} = G_{xy}(2A_3y'' + B_3) \quad (4)$$

where G_{xy} = the shear modulus, and $\sigma_{xy}(n)$ = shear stress throughout the depth of each panel. It is worth mentioning that, in this study, the analytical model was initially developed for a diaphragm system consisting of three panels. The local coordinates are centred on the upper surface of each panel and are represented as y for the top panel, y' for the middle panel, and y" for the bottom panel. By applying the boundary condition, the shear stresses in the panels can be calculated, and in turn, the shear strain in the panels is obtained as:

$$\gamma_{xy(1)} = \gamma_1 = \frac{\tau(x)}{G_{xy}t}y \quad (5)$$

$$\gamma_{xy(2)} = \gamma_2 = \frac{\tau(x)}{G_{xy}} \quad (6)$$

$$\gamma_{xy(3)} = \gamma_3 = \frac{\tau(x)}{G_{xy}}\left(1 - \frac{y''}{t}\right) \quad (7)$$

γ_{xy} = the shear strain of each panel. The longitudinal displacement function, U_n^N, due to longitudinal forces, is given by:

$$U_n^N = U_n^N(0) + \int_0^y \gamma_n(y)\,dy + U_n^N(t_n) \quad (8)$$

$U_n^N(0)$ and $U_n^N(t_n)$ indicate panel displacement at a panel's top and bottom edges, respectively, and can be calculated by subtracting the panel displacement at each interface from the connection displacement. The longitudinal force acting on each panel is equal to:

$$N_n = Eb\int_0^t \frac{dU_n^N}{dx}dy \quad (9)$$

where t = width (depth) of the panel, b = thickness of the panel, and E = Young's modulus. by substituting a derivative of Equation (8) into Equation (8), the strain at each panel edge is obtained. The shear stress between two adjacent panels can be expressed as Equation (10).

$$\tau(x) = \frac{K_s.n^*}{S}\left(u_{n+1}(x) - u_n(x)\right) \quad (10)$$

K_s = the shear stiffness of a fastener in units of (kN/mm). S = the distance between two fasteners and n* = the number of fasteners per row. The longitudinal displacements are described as $u_{n+1}(x)$ and $u_n(x)$, corresponding to the top of panel n+1 and the bottom of panel n, respectively.

The equations can be supplemented by the equilibrium equations assuming the same deflection for all panels. After some algebraic calculations, Equation (11) can be obtained for panel shear stress, where τ(x) is the shear stress at the interface.

$$\tau(x) = -m\frac{q}{\lambda}\left(\tanh\left(\frac{\lambda L}{2}\right)\cosh(\lambda x) - \sinh(\lambda x)\right) + mq\left(\frac{L}{2} - x\right) \quad (11)$$

Variables m and λ are determined in Equations (12) and (13), respectively. q = uniformly distributed load, and L = length of the CLT diaphragm.

$$m = \frac{1}{\left(\frac{1}{K_s} + \left(\frac{5t}{6G}\right)\right)\lambda^2}\left(\frac{t}{3EI}\right) \quad (12)$$

$$\lambda^2 = \frac{b}{\frac{1}{K_s} + \left(\frac{5t}{6G}\right)}\left(\frac{2t^2}{3EI} + \frac{1}{EA}\right) \quad (13)$$

where A = cross-sectional area of the panel, I = moment of inertia, and G = in-plane shear modulus. After substituting the value of τ(x) into horizontal equilibrium, the maximum amount of axial force can be calculated at the edge of the panels (x= 0 or L):

$$N(x) = \left(-m\frac{q}{\lambda^2}\left(tanh\left(\frac{\lambda l}{2}\right)Sinh(\lambda x) - Cosh(\lambda x) + 1\right) + mq\left(\frac{L}{2}x - \frac{x^2}{2}\right)\right) \quad (14)$$

2.2 DIAPHRAGM DEFORMATION

Diaphragm deformation corresponds to the conventional equation for a deep beam. However, it has an additional term to account for interlayer movement, including the panels' shear deformation. Using Timoshenko's theory [14] to establish the following relationship between the

bending moment, shear force, deflection, and rotation of the cross-section:

$$\frac{dw}{dx} = \theta - \frac{EI}{kAG}\left(\frac{d\theta^2}{dx^2}\right) \quad (15)$$

$$\frac{d\theta}{dx} = -\frac{M_T(x) - b\int \tau(x).2t}{3EI} \quad (16)$$

Where w = the deflection of the panels in the *y*-direction and θ = the cross-section angle of rotation and $M_T(x)$ = the applied moment. By substituting Equation (11) into Equation (16) to include the effect of shear stress on the deformation and adding the interlayered movement, we obtain Equation (17), which gives the mid-span deformation of the diaphragm.

$$w(x) = \frac{5qL^4}{384EI_s} + \frac{qL^2}{8kAG} + \frac{mqL^2}{4t}\left(\frac{1}{K_s} + \left(\frac{5t}{6G}\right)\right) \quad (17)$$

3 FE MODEL DEVELOPMENT

A three-dimensional (3D) model was created in Abaqus [15] to calculate the mid-span in-plane deformation of the diaphragm and replicate the layout illustrated in Figure 2. The model comprised a rectangular CLT floor consisting of three 10-meter-long and 2.4-meter-wide panels. Line springs were evenly distributed along the length of the panels to connect them. In addition, butt joint connections were strengthened by using screws oriented at a 45° angle relative to the edge face of the CLT panels to enhance the structure's load-carrying capacity. The comparison of the mid-span deflection of the floor between the FE and analytical models revealed a difference of less than 2%, with the deflection values of 3.3 mm and 3.36 mm, respectively. This indicates that the two models are in agreement with each other and can be relied upon to predict the behaviour of the floor accurately.

3.1 COMPARATIVE ANALYSIS OF CONNECTION STIFFNESS

The stiffness of connectors in the joints of CLT panels was determined through experimental tests from multiple sources, including studies [16-18], where 8mm screws were used. The stiffness values obtained were compared to the analytical model predictions, as shown in Figure 3. The comparison showed that the difference between the experimentally determined stiffness values and the predictions of the analytical model was less than 5%. The finding suggests that the developed formula is accurate for the assumed range of stiffness values. Hence, the analytical model can confidently predict the behaviour of CLT panel joints.

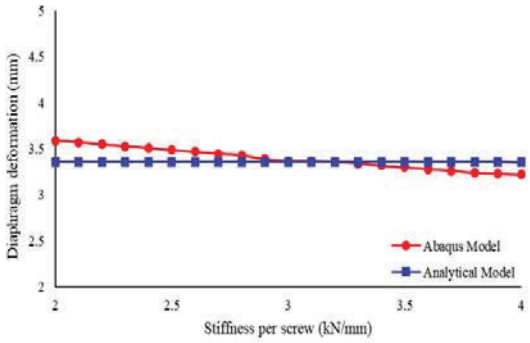

Figure 3: *The diaphragm deformation versus stiffness of the connection*

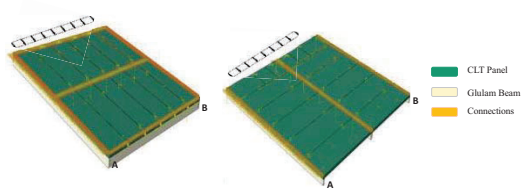
3.2 FE MODEL VALIDATION THROUGH EXPERIMENTAL STUDY

To the best of the authors' knowledge, no empirical investigations have been conducted to date on the behaviour of a CLT diaphragm subjected to a perpendicular load with the specific boundary conditions assumed in the developed analytical model. Therefore, to validate the modelling approach, the results of full-scale CLT diaphragm tests reported in [11] were compared with the FE model developed to ensure the accuracy of the proposed numerical models.

3.3 FE MODEL SETUP

The experimental study examined the behaviour of two diaphragms, one loaded parallel to the panel length and the other loaded perpendicular to the panel length, as shown in Figure 4.



(a) (b)

Figure 4: *Diaphragm assemblies when the load direction is (a) parallel to the panel length, (b) perpendicular to the panel length.*

For each diaphragm, twelve 1.22 × 3.66 m CLT panels were modelled with a proposed thickness of 105 mm using a three-ply layup. The panel-to-panel spline connection was made using 18.3 mm plywood and 8d common power-driven nails. To establish connections between panels and beams in the FE model, two-point spring elements were utilized. These spring elements were linked to the CLT panel at each fastener point by connector elements that tied the displacement and rotation

https://doi.org/10.52202/069179-0324

of each fastener point to the average displacement and rotation of the neighbouring nodes. As for the experimental study, the diaphragms were pinned at their far corners in the plane of loading (points A and B in Figure 4). The perimeter beams' edges were pinned, allowing the assembly to bend inward while restraining its movement in the direction of loading.

3.4 COMPARING THE RESULTS

The load-displacement curves at the mid-span of the diaphragms subjected to parallel and perpendicular loading to the panel length, obtained from both experimental and numerical analyses, are presented in Figure 5. The results demonstrate a close agreement up to the maximum force, suggesting that the numerical model was successfully validated and can be trusted to predict the behaviour of comparable CLT diaphragms under various loading conditions.

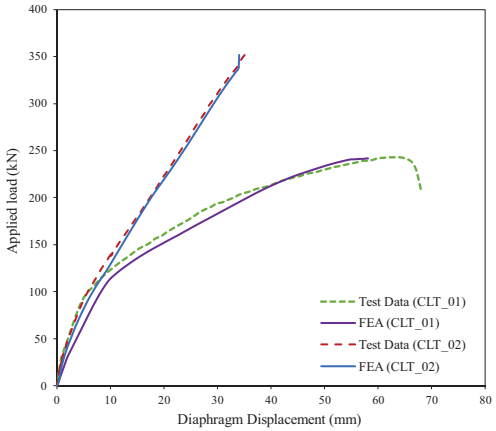


Figure 5: *The mid-span load-displacement curve for diaphragm under in-plane loading; numerical versus experimental.*

The numerical model was based on the assumption of linear-elastic behaviour of the wood components, with the connections exhibiting nonlinear behaviour. Plastic deformation was observed at a load of approximately 100 kN, leading to failure. However, due to numerical instabilities, the simulation was stopped once the load reached its maximum point, and the connections failed. Comparing the experimental and numerical load-displacement curves indicated that the developed numerical model effectively predicted the diaphragms' overall behaviour. These findings suggest that the numerical model can accurately simulate and predict the behaviour of similar CLT diaphragms under varying loading conditions.

4 THE PARAMETRIC STUDY

A comprehensive parametric study was conducted to augment the database on CLT diaphragms by varying parameters such as panel thicknesses and the Aspect Ratio (AR) of the CLT diaphragms, which is the ratio of the diaphragm length to its depth.

4.1 DIAPHRAGM LOADED PERPENDICULAR TO THE PANEL LENGTH

Table 1 presents six archetypes categorized based on the thickness of the CLT panels, with each group comprising three different panel sizes. Each configuration comprises six panels and three glulam beams placed underneath the panel joints.

Table 1: *Summary of characteristics feature of diaphragm loaded perpendicular to the panel length in FE models.*

Archetype No.	Diaphragm Size			Number of layers	Associated Sketch
	Length (m)	Depth (m)	Thickness (mm)		
1	9	7.2	175	5	
2	11	7.2	175	5	
3	13	7.2	175	5	
4	9	7.2	245	7	
5	11	7.2	245	7	
6	13	7.2	245	7	

The deformation of the CLT diaphragm under perpendicular loading to the panel length is illustrated in Figure 6. The results indicate an increase in the diaphragm deformation as the length increases. Interestingly, the study found that the thickness of the CLT panels did not significantly impact the deformation of the diaphragm in this configuration.

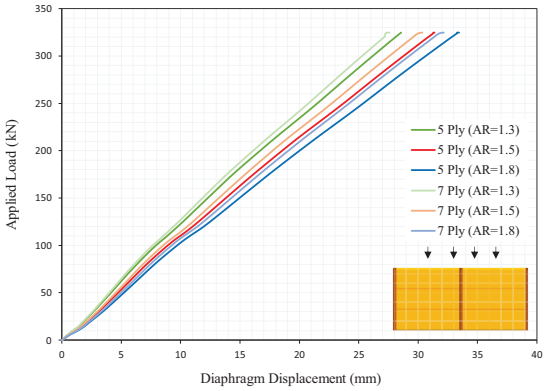

Figure 6: *Load-displacement curves for diaphragm with different diaphragm aspect ratios and thicknesses for loading perpendicular to panel length.*

4.2 DIAPHRAGM LOADED PARALLEL TO THE PANEL LENGTH

Table 2 summarizes the analysis results of six archetypes subjected to in-plane loads parallel to the panel length.

https://doi.org/10.52202/069179-0324

Similar to the analysis of perpendicular loading, the archetypes were divided into two groups based on the thickness of the panels.

Table 2: *Summary of characteristics of a diaphragm loaded parallel to the panel length in FE models.*

Archetype No.	Diaphragm Size			Number of layers	Associated sketch
	Length (m)	Depth (m)	Thickness (mm)		
1	9	7.2	175	5	
2	11	7.2	175	5	
3	13	7.2	175	5	
4	9	7.2	245	7	
5	11	7.2	245	7	
6	13	7.2	245	7	

The results presented in Figure 7 indicate that, for archetypes 1- 6, the diaphragm deflection decreased as the diaphragm length increased under loading parallel to the panel length. The panel thickness did not significantly affect the diaphragm deflection in this configuration. However, it was observed that, for loading parallel to the panel length, the chosen panel depth used in the parametric study, which was twice that of the experimental analysis, resulted in significantly less deformation than the experimental results. These findings highlight the importance of considering the appropriate panel depth to accurately predict the behaviour of CLT diaphragms under in-plane loads parallel to the panel length.

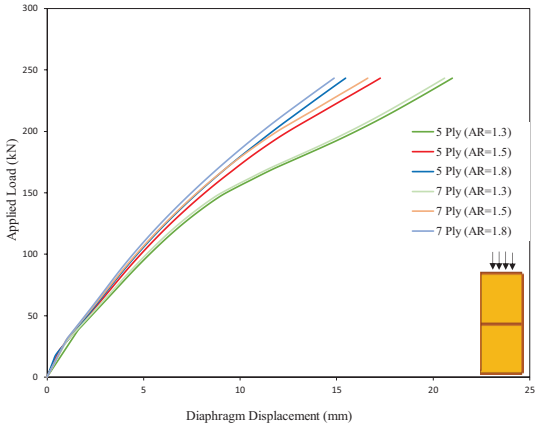

Figure 7: *Load-displacement curves for diaphragm with different diaphragm aspect ratios and thickness for loading parallel to panel length.*

5 DISCUSSION

Figure 8 summarizes the effect of diaphragm length and panel thickness on the behaviour of archetypes 1 to 6 under in-plane loading, both parallel and perpendicular to the panel length. The diaphragms loaded parallel to the panel length are denoted as "parallel," while those loaded perpendicular to the panel length are labelled as "perpendicular." The results reveal that the aspect ratio has the most significant effect on diaphragm deformation, particularly for aspect ratios below 1.5, while panel thickness is not an important parameter. For the diaphragm loaded parallel to the panel length, the stiffness was found to be unaffected by the panel thickness.

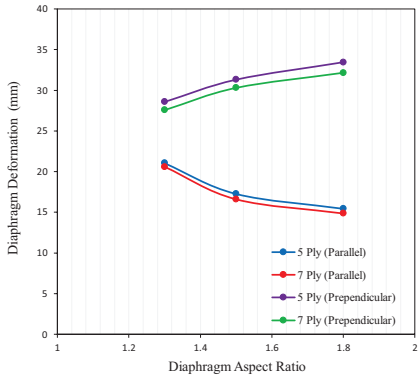

Figure 8: *The effect of the aspect ratio and panel thickness in diaphragm displacement for the archetype 1 to 6.*

6 CONCLUSIONS

This study presents an analytical model to calculate the mid-span deflection of a simply supported diaphragm and predict the force in the connection between adjacent CLT panels when the load is perpendicular to the panel length. The model accounts for the effect of bending and shear deflections of each panel and slip between the panels. To validate the analytical model, a FE model was developed and compared to the behaviour of CLT diaphragms under in-plane loading. The comparison showed good agreement between the predictions of the analytical and FE models, confirming the accuracy of the analytical model.

In addition, proposed FE models were compared to the results of full-scale CLT diaphragm tests to evaluate the modelling approach. A comprehensive parametric study was conducted to identify the most influential parameters contributing to in-plane deformation in CLT floor diaphragms. The behaviour of the employed diaphragm was investigated by varying the aspect ratio and thickness of the CLT diaphragm. It was found that when the load was perpendicular to the panel length, shear deflection in the CLT panels provided the most significant contribution to total diaphragm deflection, while the slip in the connections was the most influential parameter when the load was parallel to the panel length. The study also revealed that the thickness of the panels is not a key parameter in the deformation of the diaphragm under lateral loading.

https://doi.org/10.52202/069179-0324

The results of this study provide valuable insights into the behaviour of CLT diaphragms under in-plane loading that can be used by practitioners in the design of CLT diaphragms in both loading orientations. The developed analytical model can be applied to predict the mid-span deflection and force in the connections between adjacent CLT panels, enabling the more efficient and accurate design of CLT diaphragms.

ACKNOWLEDGEMENTS

The authors would like to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for the financial support of this study under the Industrial Research Chair Program. Financial support was also provided by the Landmark Group of Companies, FPInnovations, Canadian Wood Council, MTC Solutions, Rotho Blaas, Western Archrib, and Alberta Innovates. EVALUATION OF THE BEHAVIOUR FACTOR BY INCREMENTAL DYNAMIC ANALYSES FOR THE SEISMIC DESIGN OF LIGHT-FRAME TIMBER BUILDINGS

Alessandra Gubana[1], Alessandro Mazelli[1]

ABSTRACT: Light Frame Wood structures are today a valid alternative to Cross Laminated Timber structures for low and medium height buildings, both in terms of performance and environmental impact, given the lower volume of wood used. Light wood frames demonstrate a ductile behavior under seismic actions, linked to the plastic deformation of the connections, but uncertainties still regard the value of the behaviour factor associated to these types of structures.
This paper presents the evaluation of the behaviour factor 'q', used for the seismic design, based on Incremental Dynamic Analyses for Light-Frame Timber Buildings. Papers in literature regarding its evaluation are mostly based on static non-linear pushover analyses. Example buildings with 2, 3 and 4 storeys, were designed according to capacity design and then analysed by varying the displacement-ductility of the sheathing-to-frame connection. The results are then compared with the requirements provided by codes.

KEYWORDS: Light-frame timber buildings, Incremental Dynamic Analyses, Behaviour factor.

1 INTRODUCTION

Timber structures have a long tradition in several areas of the world, where residential balloon-frame and platform-frame houses constitute a large amount of the building stock. In the past, the carpenters' expertise drew the building construction process.
In the last years the use of timber in construction significantly developed, due to the growing attention to sustainability and environmental impact [1]. The appearance on the traditional market of new wood engineered products as Cross Laminated Timber (CLT) opened new technical possibilities and consequently also high multi-storey buildings can be built [2]. Thanks to prefabricated technologies, construction time can be strongly reduced with economic benefits on the real estate investment.
Light-frame wood (LFW) structures still represent a valid alternative to CLT structures for low and medium rise buildings, both in terms of performance and environmental impact, as the involved necessary timber mass is lower than in case of CLT. The advantages of the precast processes are also extended to LFW buildings, especially in Europe, where Light Frame Walls are built in prefabrication plants, often completed with the electrical and hydraulic systems and insulating materials and then connected in the building yards.
The good performance of timber buildings under earthquake excitations is well known and largely acquired, due to the limited mass and the high ductility ensured by, for instance, mechanical connections between sheathing to framing, wall to wall, wall to foundation. Besides, hysteretic behaviour of LFW structures were investigated by means of tests on shake tables in past years. [3-5]
It also well known that a reduction of seismic forces is possible due to the beneficial effects of energy dissipation in ductile structures and to inherent over-strength. This theoretical acquisition is considered in seismic design standards and codes, where force reduction factors (e.g. the 'behaviour factor' q in Eurocode 8 [6], or the 'response modification factor' R in US codes) are indicated to quantify the seismic design loads. The entity of these factors was initially based on empirical observations of the behaviour of common structural systems, but uncertainties still regard the value of q [7].
More recently, several numerical studies have been performed to determinate appropriate values, and most of them refer to non-linear static analyses results. A recent work by Rossi et al. [8] proposes the evaluation of q by static non-linear analysis, providing an important contribution to the calibration of the behaviour factor. However, static analysis does not consider the frequency of seismic input motion and the influence of higher vibration modes of the structure [9].
In the present work, a study for the evaluation of the behaviour factor q for LFW structures by means of Incremental Dynamic Analysis (IDA) is described.
Example buildings with 2, 3 and 4 storeys were designed according to capacity design and then analysed by varying the displacement-ductility of the panel. The results are then compared with the requirements provided by codes.

2 LIGHT FRAME WOOD WALLS MODELLING AND VALIDATION

Light Frame Wood (LFW) shear walls are made up of timber-based panels (typically Oriented Strength Board OSB or plywood) and a timber frame connected together by small diameter nails. Angle brackets are used for shear forces at the base and the top of the panel, while hold-downs are placed at the corners to absorb tension and compression induced by bending moment.

Recent codes provide analytical methods to evaluate the stiffness or the top displacement of a LFW wall subjected to a horizontal force. The New Zealand standard [10], the American International Building Code IBC [11] and the Canadian Standard Association CSA O86 [12] consider the top displacement of a LFW wall as the sum of four terms: the base rotation δ_c, the shear deformation of the wood panel δ_s, the shear deformation of the sheathing-to-frame connection δ_{ps} and the bending deformation δ_b. The total displacement of the wall δ_w is evaluated by means of equation 1.

$$\delta_w = \delta_c + \delta_s + \delta_{ps} + \delta_b \quad (1)$$

It is worth noticing that the contribution due to the deformation of the angle brackets is not considered in equation 1. The slip is negligible only if the connectors are extremely stiff, consequence of a Capacity Design approach. Otherwise, it is always possible to add the base slip contribution to equation 1.

In order to assemble the example buildings with parameterized sheathing-to-frame connections, two wall FEM models were built: a detailed model (Figure 1a) and a simplified model (Figure 1b). Both were then calibrated thanks to the results of a cyclic test on a real scale LFW (3 m × 3 m) Technical Report [13].

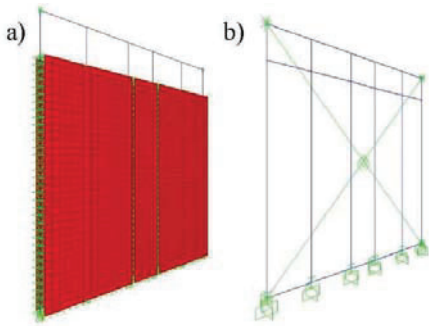

Figure 1: *Analysis models of the wall: complete (a) and with equivalent non-linear springs (b).*

The model of Figure 1a was built in SAP2000. OSB panel were modelled as *flat-shell* elements and timber studs as pinned *frames*. Non-linear links were used for hold-downs, angle brackets and for the nailed connection along the perimeter of the panels. It is worth noticing that the independent behaviour of the nail link in x and y directions leads to overestimate the strength of the connection in intermediate directions, and a squared rather than circular force domain is considered [14]. The detailed model was validated through a pushover analysis (Figure 2). This model was then used to create the set of parameterized walls, varying the displacement ductility of the sheathing-to-frame connection.

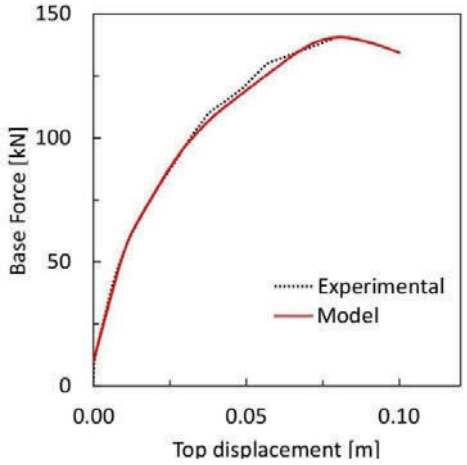

Figure 2*: Comparison between experimental and analytical monotonic behaviour of the wall.*

The model of Figure 1b was used to calibrate the pivot hysteresis parameters for non-linear uniaxial springs which represent the sheathing-to-frame connection, the hold-downs and the angle brackets separately. The walls were modelled by means of 5 non-linear springs each: two vertical springs for the hold-downs, one horizontal spring for the angle brackets and two inclined springs for the sheathing-to-frame connection. Their cyclic behaviour was validated by minimizing the difference with the experimental test in terms of dissipated energy (Figure 3). The simplified wall was then used in the modelling of the example buildings.

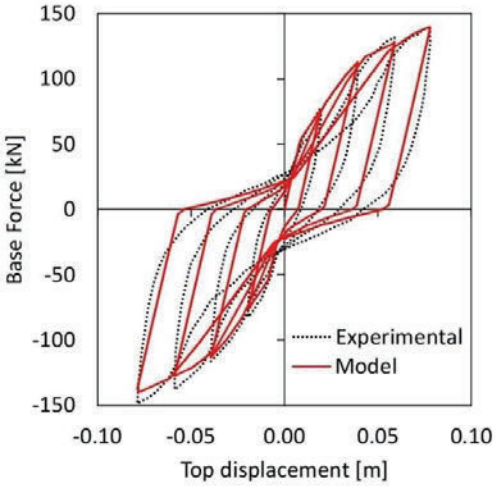

Figure 3*: Comparison between experimental and analytical cyclic behaviour of the wall.*

https://doi.org/10.52202/069179-0325

3 MULTI-STOREY TIMBER BUILDINGS

Example buildings with dimensions in plan of 6.50 m ×10.70 m with two up to four storeys, were built assembling 3 m × 3 m walls, in order to refer directly to the experimental test, and were calculated according to EN 1995-1-1:2005 [15] and EN 1998-1:2013 [6], following the Capacity Design (Figure 4). Each block can stand alone or be connected to other ones to have more surface area of the apartments.

The Life Safety ultimate state was verified by means of the Eurocode response spectrum with a PGA of 0.35 g, soil type A and q-factor equal to 3. The choice of q in the design procedure was necessary only to obtain realistic LFW wall structural dimensions, as the typical ones used in engineering design practice. The q equal to 3, in fact, affects the results only in term of resistance of the wall. The ductility of the nailed connection, in fact, will be parameterized. Furthermore, Rossi et al. [8] shows that the soil type has a negligible influence on the ductility evaluation.

An overstrength factor equal to 1 was chosen for the sheathing-to-frame connection, so that the nominal strength is equal to the design strength. On the other hand, hold-down and angle brackets were designed according to the Capacity Design approach [16], with an overstrength factor of 1.6. Because of this choice, the contribute to dissipation of hold-down and angle brackets was not considered, as they were over strengthened, and all the plastic deformation were concentrated in the sheathing-to-frame connection. Each wall of the example buildings was modelled with the simplified method (Figure 1b).

4 PARAMETRIZATION OF LFW WALLS

Starting from the validate detailed model of Figure 1a, a set of LFW walls was created, varying the ductility of the sheathing-to-frame connection. Three classes were selected: 4, 6 and 8. The yield limit and the ductility of the nailed connection was evaluated according to an Equivalent Energy Elastic Plastic EEEP approach.

Moreover, it was necessary to build set of walls that corresponds to the strength capacity required by the design procedure of the three example buildings. Thus, the connectors spacing and resistance was varied, and the OSB panels were placed on one or both sides. Table 1 reports the characteristics of the walls used to assemble the example buildings, obtained by means of pushover analyses.

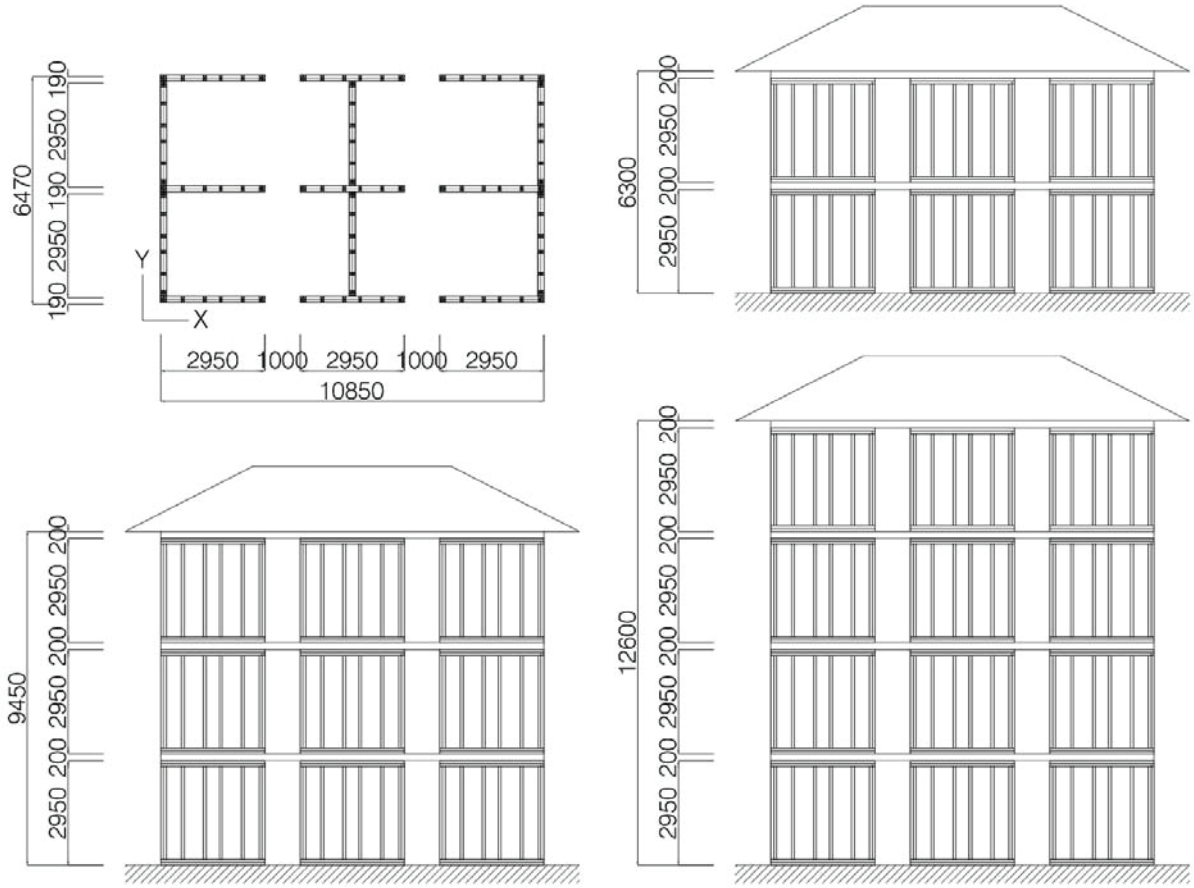

Figure 4: *Example buildings (dimensions in mm).*

https://doi.org/10.52202/069179-0325

F_{max} is the maximum resistant shear force of the wall, while d_y and d_u are the top horizontal displacement of the wall at yield and ultimate condition respectively. Each wall has a label that refers to the nail spacing (75 mm or 150 mm), the sides covered by OSB (1 or 2) and the resistance of the sheathing-to-frame connection, referred to only one nail (720 N or 1000 N).

Table 1: *Parameterized walls used in the assembling of example buildings.*

	LFW connection ductility 4		
Wall type	**F_{max} [kN]**	**d_y [m]**	**d_u [m]**
75(1)720	23.1	0.015	0.037
150(1)720	11.2	0.012	0.036
75(1)1000	29.9	0.017	0.039
150(1)1000	18.6	0.014	0.042
150(2)1000	36.5	0.012	0.030
	LFW connection ductility 6		
Wall type	**F_{max} [kN]**	**d_y [mm]**	**d_u [mm]**
75(1)720	25.6	0.017	0.058
150(1)720	12.3	0.013	0.048
75(1)1000	32.9	0.019	0.058
150(1)1000	20.6	0.015	0.055
150(2)1000	36.9	0.011	0.043
	LFW connection ductility 8		
Wall type	**F_{max} [kN]**	**d_y [mm]**	**d_u [mm]**
75(1)720	27.0	0.019	0.077
150(1)720	12.7	0.014	0.062
75(1)1000	35.5	0.021	0.078
150(1)1000	21.7	0.016	0.072
150(2)1000	37.1	0.012	0.056

The increasing of the ductility of the sheathing-to-frame connection affects slightly F_{max} and d_y, while it influences widely d_u.

The pushover curves of each wall of each set were transformed into multilinear relationship. Then, the behaviour was adapted to the non-linear diagonal springs of the simplified models. The procedure is shown in Figure 5, where F and d are the shear force and the top displacement respectively. The subscript 45 refers to the 45° inclined spring.

Hysteretic pivot parameters of the sheathing-to-frame connection were already calibrated in section 2.

An elastic behaviour was associated with hold-downs and angle brackets, since they were calculated according to the Capacity Design approach.

5 IDA PROCEDURE

The example buildings were analysed by means of IDA procedure [17].

The IDA consists in the execution of several non-linear dynamic analyses under a multiply scaled set of ground motion records. Every IDA curve represents the relationship between the Energy Demand Parameter (EDP) and the Intensity Measure IM. In the present study, the Peak Ground Acceleration (PGA) was chosen as IM and the ratio between the maximum roof displacement and the height of the building was selected as EDP (Mean Interstorey Drift Ratio MIDR). The choice of this couple (PGA, MIDR) allows to compare IDA curves at the same scale for each ductility class and for each number of storeys.

A set of 10 couples of records was chosen by means software REXEL [18] (Table 2).

Generally, the estimation of the q factor is obtained by means of non-linear static analysis via procedure present in the literature (e.g. Fajfar [19], Newmark and Hall [20]).

Table 2: *Record selected for IDA procedure.*

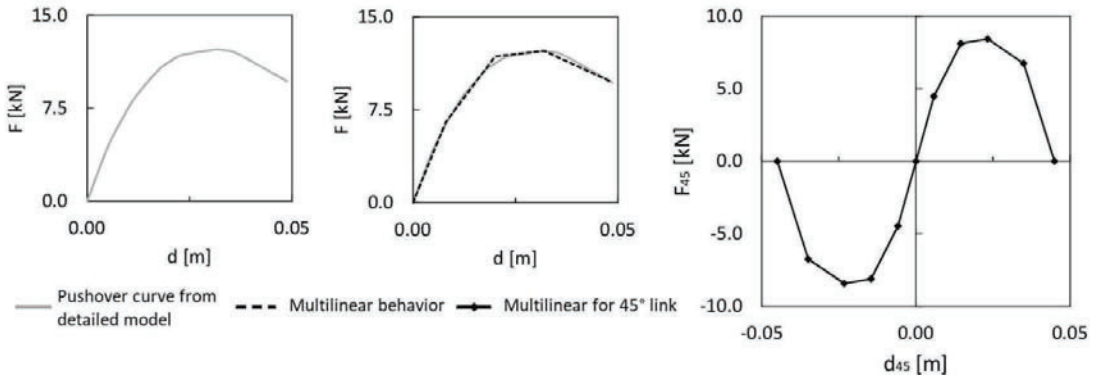

Figure 5: *Procedure to obtain multilinear behaviour for uniaxial non-linear springs of the simplified LFW wall model.*

https://doi.org/10.52202/069179-0325

Several methods to evaluate q by means on non-linear dynamic analysis are available, considering experimental, numerical or hybrid procedures [21]. Some were already used for CLT buildings [22,23] In this work, a numerical method to evaluate q was chosen.
In fact, the behaviour factor q was obtained as the product of a ductility factor q_μ, connected to the non-linear behaviour of the structure, and an overstrength factor q_D, which takes into account the post-elastic hardening and the structural redundancy [24]:

$$q = q_\mu \cdot q_D \tag{2}$$

The obtained q is intrinsic and code independent, because the design overstrength factor for the sheathing-to-frame connection was set to 1.
The two factors of equation 2 follow the expression (3) and (4) respectively.

$$q_\mu = \frac{V_{b(Dyn,e)}}{V_{b(Dyn,y)}} \tag{3}$$

$$q_D = \frac{V_{b(Dyn,y)}}{V_{b(St,s)}} \tag{4}$$

where $V_{b(Dyn,y)}$ is the base shear which corresponds to the collapse of the structure, and $V_{b(Dyn,e)}$ is the base shear obtained by an elastic analysis of the structure under the same records. $V_{b(St,s)}$ is the base shear corresponding to the first yield in the structure and it is evaluated by means of a static non-linear analysis.
The use of non-linear static analysis avoids the problem of yield point detection. In fact, in an IDA, there could be more IM intensities with only one wall that has reached the yield displacement. This solution was used in other literature works [25,26].
It is worth noticing that the choice of IM and EDP did not affect the final results, since the q-factors were evaluated by base shear force ratios.

6 RESULTS

In this section, the result of the 90 IDA are reported.
Figure 6 illustrates two examples of wall reaching the ultimate displacement for a ductility class equal to 6, one in X direction and one in Y, according to Figure 4.
The diagrams show the relationship between the shear force on the wall F and its top horizontal displacement d. The sheathing-to-frame connection reaches the ultimate displacement under the scaled Kalamata earthquake for a PGA = 0.13 g. (Figure 6a). In Y direction, the wall attains to its ultimate displacement under the South Iceland accelerograms for a PGA = 0.35 g (Figure 6b).
In Figure 7 the complete IDA study is reported. The curves for each example building and for each ductility class are illustrated at the same scale, in order to perform comparison. Each graph shows the Mean Interstorey Drift Ratio versus the PGA.

On the basis of these first results, for a fixed ductility class, the MIDR shows a decreasing tendency when the number of storeys increases. On the other hand, the MIDR increases for higher ductility classes.
Finally, to a higher ductility class corresponds a higher average PGA at collapse.

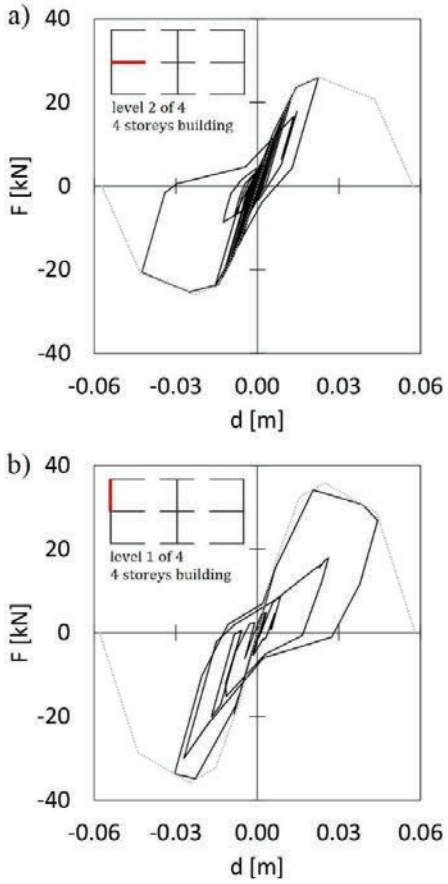

Figure 6: *Hysteresis cycles for two walls attaining the ultimate displacement for a sheathing-to-frame connection ductility equal to 6 under Kalamata (a) and South Iceland (b) earthquakes.*

Results of the IDA studies were used to evaluate the q factor, following equations 2, 3 and 4. Table 3 reports the minimum, mean and maximum values of the ductility factor q_μ, the overstrength factor q_D and the intrinsic factor q. Furthermore, the CoV is also reported for all the classes.
As expected, the ductility factor q_μ increases when increasing the ductility class of the sheathing-to-frame connection. Furthermore, the data are more scattered for higher values of ductility.
The overstrength factor q_D is higher as the ductility increases. Besides, the dispersion is lower with respect to the ductility factor.
The values of q reported in Table 3 are intrinsic and code independent. It can be noted that the value of 2.3 obtained for ductility class 6 correspond to the results reported in [8].

https://doi.org/10.52202/069179-0325

https://doi.org/10.52202/069179-0325

However, it is not possible to perform a direct comparison between these values and those provided by codes. In this study, the overstrength factor for the sheathing-to-frame connection was set to 1. Though, it is possible to multiply the intrinsic q by 1.5, which is the q-factor suggested by Eurocode 8 for a global non-dissipative behaviour, in order to calculate the q_{code} (code dependent q-factor)(Table 4).

Table 4: *Mean value of the q_{code} factor for each ductility class.*

Ductility Class	Storeys			global
	2	3	4	
4	3.6	2.6	2.4	**2.9**
6	4.3	2.8	3.3	**3.4**
8	5.6	3.6	4.0	**4.4**

For a ductility class equal to 4, a value of 2.9 was obtained, which confirms the q=3 provided by the Italian building code [27] for Low Ductility Class timber structures. On the other hand, a value of 3.4 was obtained for a ductility class 6, which is widely lower than 5, value suggested for Ductility Class High (DCH) by Eurocode 8 [6] and Italian Building Code [27]. Even a ductility class 8 is not sufficient to comply with Eurocode provision (a mean intrinsic q equal to 2.9, and a q-factor equal to 4.4). It is worth noticing that, in this work, all the dissipation is concentrated in the sheathing-to-frame connection, and the contribution of hold-downs and shear brackets are not taken in to account.

7 CONCLUSIONS

In this work, an Incremental Dynamic Analysis approach was used, in order to evaluate the behaviour factor for Light Frame Wood structures. Compared to the non-linear static approach, the dynamic analysis considers the cyclic behaviour of the walls and the frequency of the ground motion.

Three example buildings were calculated according to Eurocode and Capacity Design. Starting from an experimental test on a full-scale LFW wall, a set of walls was obtained, varying the ductility of the sheathing-to-frame connection, and an IDAs procedure was applied to the building assembled with parameterized walls.

The obtained results confirm the behaviour factor for Low Ductility Class according to the Italian building code. However, the q-factor for High Ductility Class is lower than that provided by Eurocode 8.

The results presented belong to a larger study. In the next phases, the influence of the non-regularity of buildings will be investigated and a greater number of accelerograms and ductility classes will be considered, in order to expand the dataset.

ACKNOWLEDGEMENT

MODULE FOR ANALYSIS AND CAPACITY-BASED DESIGN OF BRACED TIMBER FRAMES

Hossein Daneshvar [1], Brian Qi [2], Tahiat Goni [3] , Md. Abdul Hamid Mirdad [4], Marjan Popovski [5], Zhiyong Chen [6] Ying Hei Chui [7]

ABSTRACT: The National Building Code of Canada (NBCC) specifies values for the ductility-related force modification factor (R_d) for different seismic force resisting systems (SFRSs), which reflects their ability to dissipate energy during a seismic event. For braced timber frames (BTF), NBCC 2020 recognizes two ductility categories: braced frames with moderate and limited ductility, which are assigned an R_d value of 2.0 and 1.5, respectively. However, these values were primarily based on engineering judgment, qualitative comparisons, and experience rather than rigorous analysis using a recognized procedure. Additionally, the Canadian Standard for Engineering Design in Wood, CSA O86, needs to provide specific guidance on how to achieve these two ductility levels. To address this gap, the University of Alberta and FPInnovations are conducting an extensive study to develop specific design provisions for BTFs, including detailed procedures to achieve performance requirements for each level of ductility. This paper represents the first research stage, which involves developing software to analyse and design a range of archetype BTFs using capacity-based design principles.

KEYWORDS: Braced Timber Frame (BTF), Ductile End Brace Connections, Seismic Force Resisting System (SFRS), ductility-related force modification factors (R_d), ductile and moderately ductile connections.

1 INTRODUCTION

The National Building Code of Canada (NBCC) [1] specifies ductility-related force modification factors (R_d) and over-strength-related force modification factors (R_o) for different seismic force-resisting systems (SFRS) to account for a structure's ability to dissipate energy through inelastic behaviour and its dependable reserve strength, respectively. The NBCC 2020 considers Braced Timber Frames (BTFs) with two levels of ductility performance: moderate and limited ductility. The NBCC specifies values of 2.0 and 1.5 for R_d and R_o, respectively, for moderately ductile BTFs. The corresponding values for BTFs with limited ductility are 1.5 and 1.5 [1]. These recommended values were primarily based on engineering judgment, qualitative comparisons, and experience rather than rigorous analysis using a recognized procedure. In addition, no specific guidance is provided in CSA O86 [2] on achieving these ductility levels in terms of end brace connection details as the primary source of ductile behaviour in BTFs. Also, there is no specific design methodology and corresponding tool to design such frames to achieve the desired ductility levels. This project aims to contribute to developing seismic design provisions for BTFs that can be incorporated into the next edition of CSA O86, specifically provisions to achieve the stated R_d factors in NBCC.

2 METHODOLOGY

To achieve the project goals, the technical guide NRC-CONST-56478E published by Construction Canadian Construction Materials Centre (CCMC), National Research Council of Canada (NRCC), herein referred to as CCMC guideline, is used as the primary reference [3]. This guideline is a simplified version of the FEMA P695 guideline [4]. The procedure requires the study of various archetypes with different attributes that may affect the seismic performance of a building, such as storey heights, number of floors, number of bays, types of dowel-type connections, and earthquake intensities. The nonlinear time history analysis (NLTHA) approach at 100% and 200% of the Uniform Hazard Spectrum (UHS) is suggested to investigate whether the performance criteria are met for the designed archetypes [3]. To facilitate the required tasks, a computer platform is developed with the two modules shown in Figure 1. The first module is a BTF

linear analysis and capacity-based design module with an in-house developed analysis engine that can mass produce archetype models and the hysteresis loops of selected dowel-type connections necessary for performing NLTHA. These archetypes will be analysed using the OpenSeesPy program [5] and post-processed within module 2 to evaluate their responses to selected seismic motions, scaled according to NBCC [1]. As highlighted in Figure 2, this paper focuses on developing module 1 as a stand-alone software to create the necessary archetype buildings and hysteresis loops of selected dowel-type connections for performing NLTHA.

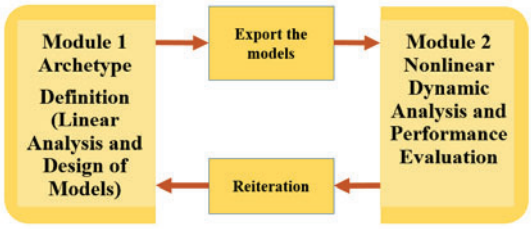

***Figure 1**: Modules 1 and 2 of the developed software to evaluate seismic force modification factors for BTFs*

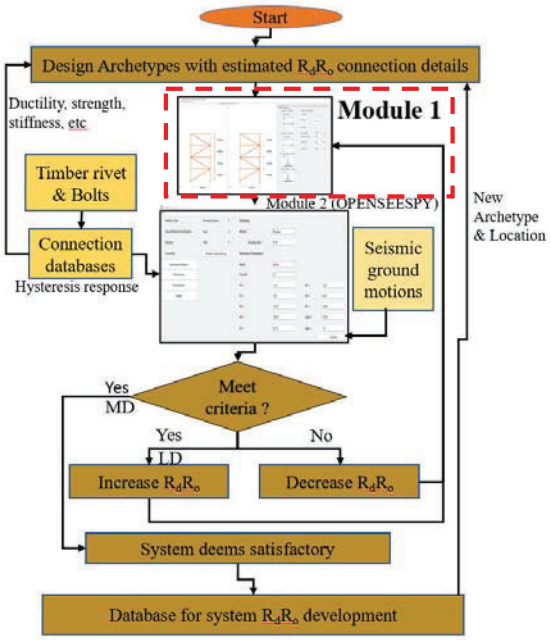

***Figure 2**: Process to evaluate seismic force modification factors for BTF (LD: Limited ductility; MD: Moderately ductile frames)*

3 FRAME ANALYSIS SOFTWARE

Module 1 was developed using Python [6] to calculate loading, analysis and design BTFs. The development of module 2 is in progress to perform NLTHA with the OpenSeesPy library using the exported file from module 1. Module 1 software interface includes a set of general and specialized tabs menus that enables users to create an archetype and, subsequently, analyze and design it in a step-by-step procedure. The steps followed are based on principles of the capacity-based design approach, as explained and demonstrated below in sections 3.1 to 3.9

3.1 PROJECT INFORMATION

In this section, the user is asked to input the model's name, description, revision number, the engineer's name, and the checker's name, as shown in Figure 3. The software automatically assigns the name to the file based on the input provided. It is noted that properly labelling the created archetypes is essential to help manage the large number of archetypes.

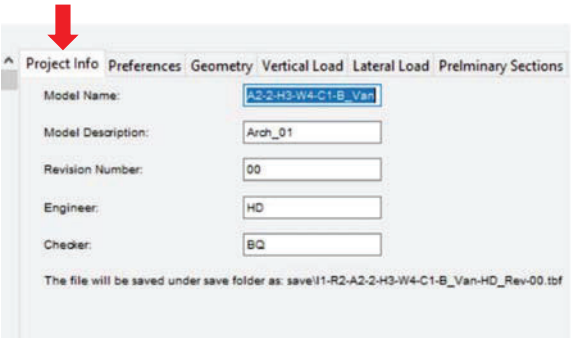

***Figure 3**: Software interface: project information*

3.2 PREFERENCES

In this section, the user selects the unit system (metric or imperial), design code (currently just CSA O86-19 [2]), the loading code (NBCC 2015 [7] or NBCC 2020 [1]), and the location of archetypes. The software currently incorporates four Canadian cities, as shown in Figure 4. Their associated design load values, such as 1-in-50-year ground snow loads, 1-in-50-year associated rain load, 1-in-10-year and 1-in-50-year wind reference velocity pressures, as well as 5% damped spectral response acceleration (S_a), are embedded and taken from NBCC 2015 [7] and NBCC 2020 [1]. More cities will be added later as the use of the module expands.

***Figure 4**: Software interface: preferences*

3.3 GEOMETRY AND BOUNDARY DEFINITIONS

This menu possesses two tabs. In the first one, the user inputs the required values to define the geometry of the archetype building, such as the number of storeys, the number of bays, their width in x- and y- directions, and the height of the first and subsequent stories, as shown in Figure 5. The user is also asked to input the type of braced frame in each direction (single diagonal versus cross bracing) and the kind of support condition at the bottom, either pinned or fixed (the pinned support is recommended for BTF). In the second tab, the user can select the locations of the braced bays within the interactive plan view (see Figure 6). The graphic interface will show a view of brace frames in each direction, as shown in Figure 7. By the end of this step, the archetype model's geometry is developed.

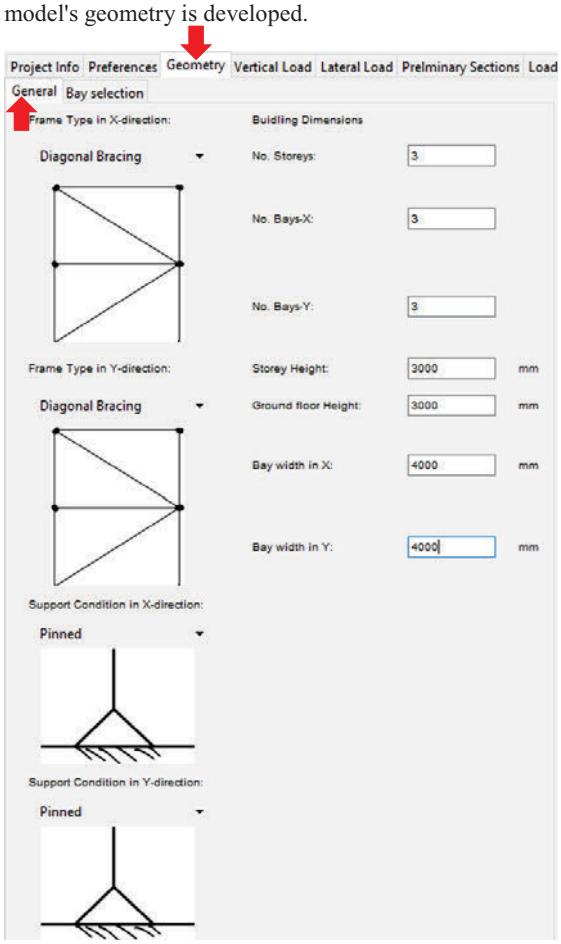

***Figure 5**: Software interface: geometry definition - braced frame specifications*

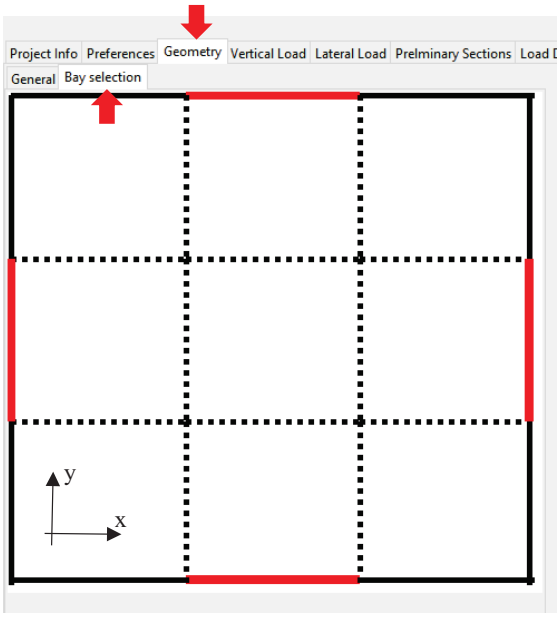

***Figure 6**: Software interface: geometry definition - braced frame locations*

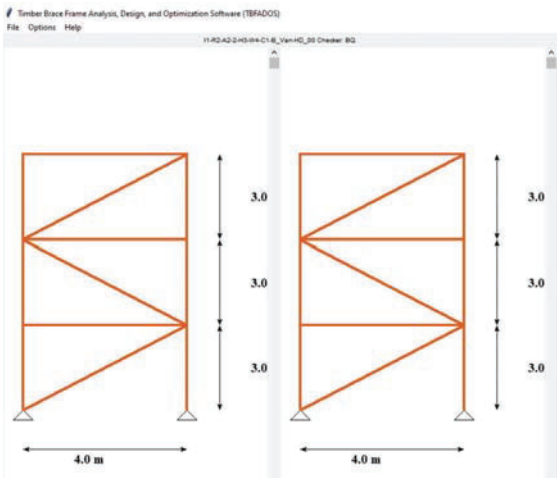

***Figure 7**: Software interface: geometry creation*

3.4 VERTICAL LOAD DEFINITION

In this section, the user inputs the distributed dead and live load with associated factors for calculating the snow load, i.e., wind exposure factor (C_b), slope factor (C_s), and accumulation factor (C_a), as shown in Figure 8. The software will calculate the share of each frame from the vertical loads considering the tributary area of each frame. The seismic weight of the archetype building is calculated based on the input provided in the section, according to the selected loading code. It is noted that the BTFs, as a part of SFRS, do not support any vertical load. The ability to support the vertical load in addition to the lateral load will be added in future revisions of the module.

https://doi.org/10.52202/069179-0326

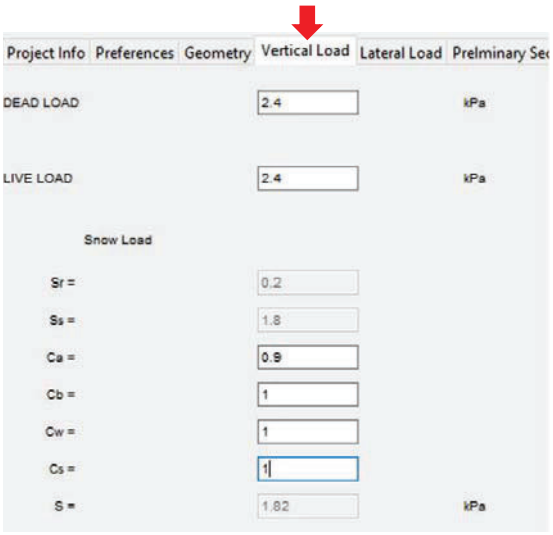

***Figure 8**: Software interface: vertical load*

3.5 LATERAL LOAD DEFINITIONS

This software section contains two tabs: one dedicated to wind load calculation and the other to seismic load, as shown in Figure 9 and Figure 10, respectively. To calculate the wind pressure, the user needs to select the importance category of the building, i.e., low, normal, high, or post-disaster, as well as the option to calculate the wind load; for either the ultimate limit state (ULS) or serviceability limit state (SLS). After that, the software will automatically select the appropriate values for the exposure, topographic, and external and internal pressure factors. The user can choose a factor of 2 or 2.5 for the gust factor. It is noted that the wind load calculation is used solely in period calculations based on the Rayleigh method in module 1 of the developed software.

In the seismic tab (See Figure 10 (a) to (c)), the user is asked to input the necessary values to calculate the induced lateral seismic loads based on the equivalent static load method according to NBCC 2015 or NBCC 2020, e.g., the soil type (Class A to E), importance category, and accidental eccentricities. The spectral acceleration values (S) are automatically calculated based on the archetype location, with reference values anticipated in the preference menu (S_a). One significant difference between NBCC 2015 [7] and NBCC 2020 [1] is the introduction of seismic design categories (SC) in the 2020 version of NBCC [1], which will be determined as shown in Figure 10 (c). Another difference is the substantially higher seismic design load adopted in NBCC 2020 for several major cities in Canada. In addition, the user can select ductility-related force modification, overstrength-related force modification factors, and the R_d and R_o factors, respectively, for each direction. The R_d and R_o factors are also used to calculate the estimated inelastic drifts of each floor. Additionally, the period of the structure is calculated using four different methods shown in Figure 10 (c); or can be overruled by the user. The period calculation method selected by the user will be used for base shear calculation (the default value is the NBCC's recommended relationship, depending on the height of the archetype solely). Finally, the software will calculate the base shear total force in each direction based on the information provided in this sheet.

***Figure 10**: Software interface: lateral load – earthquake*

3.6 SECTION DEFINITIONS

In this software interface section (See Figure 11), the preliminary sections and associated dimensions and materials are assigned to the braces, beams, and columns. The available products are sawn lumber and glulam, with different species and grades. In addition, the connection types for the end brace connections (dissipative connections) can be either timber rivet or bolted connection. The need to limit the choices to these two dowel-type connections is because background load-slip data on these connections have been obtained by experiments [8]. Other types of connections or fuses can be incorporated in the future.

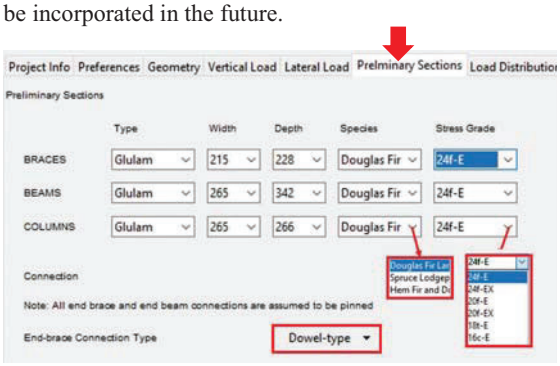

***Figure 11**: Software interface: preliminary sections*

3.7 DIAPHRAGM DEFINITION AND TWO-DIMENSIONAL (2-D) FRAME SELECTION

In this menu, as shown in Figure 12, the diaphragm type (flexible versus rigid) can be selected to distribute the seismic-induced forces among the frame within -z floors. The three-dimensional archetype produced at the beginning is loaded, while the analysis and design will be performed on the chosen 2-D frames, as suggested by CCMC [3] and FEMA P695 [4] guidelines. The BTFs are then analysed and designed based on the selected design loads. The load distribution and results are shown in Figure 12. Figure 13 shows the load distribution at different floor levels of the selected frame in the graphical interface. The period of the structure is calculated and reported using different methods, as shown in Figure 14. The variability of results for different period calculation methods indicates the need for investigating this issue more profoundly, as the current equation for the braced frames ($0.025h_n$; in which h_n is the building height) [1] is empirically obtained for the steel braced frames.

3.8 ANALYSIS

In this menu, as shown in Figure 15, running the analysis performs the linear static analysis with the option to include p-delta effects. The axial force for the braces is displayed in the graphical interface, along with the absolute elastic displacement. The elastic and plastic drift can be calculated (See Table 1) and compared with allowable values based on the importance category of the building specified in section 3.5. The analysis engine is created based on the matrix structural analysis method (displacement method), fully verified against third-party commercial software, SAP2000 [9].

3.9 DESIGN

This module segment has two tabs: one dedicated to designing dowel-type end brace connections; and the other for the design of members. The latter consists of three subsequent tabs devoted to braces, beams, and columns. Only the brace design interface is discussed in this paper.

3.9.1 End brace connections

For the end brace connection design, two types of fasteners are considered: bolts and timber rivets, due to the availability of the test results for these specific applications [8]. To keep the scope of the designed connection configurations manageable, four patterns for the bolted connections (C1-B, C1-B-R, C2-B, and C2-B-R) and two patterns for the riveted connections (G5-40-12 and G5-65-10) are selected as standard connection types, as shown in Figure 16 (a). The connection patterns for the C1-B and C2-B connection types are shown in Figure 17. C1-B-R and C2-B-R possess the same pattern as C1-B and C2-B, respectively, but were reinforced with self-tapping screws. G5-40-12 and G5-65-10 consist of twenty 5x40 and 5x65 timber rivets, respectively, with 25 mm spacing in both directions. The user can either revise the default design parameters for each type of standard connection, such as modification factors (Figure 16***Figure 16*** (b)), fastener specifications (Figure 16(c)), main and side member properties (Figure (d) and (e), respectively), or assign a scale factor (Figure (a)) to satisfy the strength requirement for the end brace connections, i.e., the strength of the end brace connection exceeds the force calculated in Section 3.8 (Figure 16 (f)).

An additional feature within this section is intended to perform a parametrization task in which the hysteresis loops of the connections are quantified by selecting a model. While this step is not vital for the archetype analysis and design within module 1, it is necessary to produce the required input to perform nonlinear dynamic analysis in module 2. The SAWS model, illustrated in Figure 18 ***Figure 18*** (a), available in OpenSeesPy [5], was selected to model both bolted and timber rivet connections, and is appropriate for modelling timber dowel-type connections in general. While this part of the module has been fully developed, it has not yet been discussed herein, as a thorough discussion of the subject is deemed outside the scope of this paper. However, the results of the parametrization exercise for the six types of standard connections mentioned above are summarized in Table 2. The test results compared to the SAWS model

with the obtained parameters are shown in Figure 18***Figure 18*** (b) and Figure 18 (c) as examples for C1-B and C2-B.

3.9.2 Members

After designing the end brace connections, where energy can be dissipated through yielding, it is necessary to design other components, namely braces, beams, and columns. The members are intended to remain elastic and undamaged, based on the capacity-based design principle. Figures (a) to (c) illustrate the details of designing a brace as an axial member for tension and compression, following CSA O86-19 [2]. Capacity protection is ensured by applying an over-strength factor, Figure 19 (b) and (c), for compression and tension, respectively. Although a factor of 1.1 is used in Figure 19 for demonstration purposes, this value could be increased based on the available test results and the design engineer's judgement. Work is currently underway to develop appropriate values for this factor based on a review of the typical coefficient of variation of connection test data that would meet the philosophy in CSA O86-19 [2] of designing capacity-protected elements based on the 95th percentile of ultimate strength of the energy dissipative connection.

4 RESULTS

After the results of the load distribution calculation, analysis, and design of connections and members are obtained; the last two tabs of the module should be accessed. They include the summary of the results and the export process of the model details and results to use in module 2 for performing NLTHA.

https://doi.org/10.52202/069179-0326

4.1 RESULTS

Figure 20 demonstrates a sample result summary of this module of the software. The geometry of the model includes the node coordinates (Figure 20 (a)), member types with their associated material types, section size, species, and grade, which the user can verify (Figure 20 (b)). The maximum governing stress ratio and status are also presented (Figure 20 (b)). Finally, the user can verify the number and type of end-brace connections with the scale factor used for design and the associated SAWS model parameters (Figure 20 (c)).

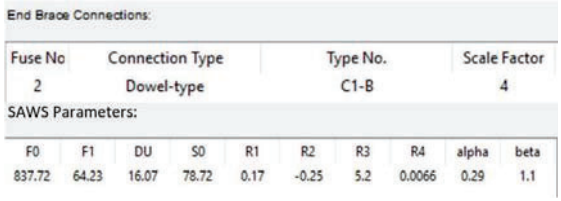
(b)



(c)

***Figure 20**: Software interface: results (a) node coordinates (b) members and their associated types, material, sections, stress ratios (c) end brace connection types and associated SAWS model parameters*

4.2 EXPORT TO MODULE 2

In the last section of the first module of the software, the results are exported as a file with the .py extension, which can be imported to module 2 to perform nonlinear dynamic analysis using the OpenSeesPy analysis engine [5].

5 SUMMARY AND CONCLUSIONS

This research project aims to contribute to developing design provisions on BTFs that could be implemented in the next edition of CSA O86-19 [2]. As the initial part of the research, a software module responsible for analysing statically (with the option to include p-delta) and designing a variety of archetype braced timber frames based on the principle of capacity-based design. The methodology established in the developed module provides specific connection details and system specifications permitted to use with the stated ductility-related seismic force modification factors specified in NBCC [1 & 7], namely limited and moderate ductility.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada (NSERC) through the Industrial Research Chair program as well as contributions of the Natural Resources Canada (NRCan) and the Canadian Wood Council (CWC). We also thank Dr. Dorian Tung of FPInnovations and Dr. Ali Mikael of CWC for their thoughtful insights.

INVESTIGATING THE EFFECTS OF THE INTERACTIONS BETWEEN FLOOR DIAPHRAGMS AND SEGMENTED CROSS-LAMINATED TIMBER SHEAR WALLS

Giuseppe D'Arenzo[1], Werner Seim[2]

ABSTRACT: This paper presents a study on the effects of the interactions between floor diaphragms and segmented cross-laminated timber shear walls. An analytical model of a beam on a bed of elastic springs is used to describe such an interaction for the case of two- and three-panel segmented shear walls. The analytical model is, firstly, validated by comparing its results with those of a numerical model developed in SAP2000 and, secondly, used for the definition of an equivalent spring which simulates the effects of the floor-wall interaction in a simpler yet reliable way. In the study, it is shown that the equivalent spring can be used to take into account the effects of the floor-wall interactions for the cases of two- and three-panel segmented shear walls. The internal actions of the floor element as well as the increase of rocking stiffness due to such interaction are discussed in the final part of the study.

KEYWORDS: Cross-Laminated Timber, Multi-Panel Shear Walls, Floor-Wall Interaction.

1 INTRODUCTION

Cross-laminated timber (CLT) is a structural typology which offers many advantages in terms of sustainability, speed of construction and structural performance. Given their excellent in- and out-of-plane structural properties, CLT panels are used in these structures as both vertical and horizontal load-bearing elements. The assemblage of the CLT panels is realized by means of mechanical joints, which permit the creation of structures with excellent lateral performance.

This assemblage represents a key aspect of the structural behaviour of CLT buildings, which, *inter alia*, entails structural interactions, such as those between perpendicular walls or vertical walls and horizontal floors. These structural interactions are usually not directly considered when the lateral performances of CLT buildings are assessed, as most of the attention is paid to the wall-base connections, namely, hold-downs and angle brackets. However, several experimental campaigns aimed at investigating the lateral behaviour of platform CLT buildings have revealed that these structural interactions modify the lateral response of the structure, leading to higher mechanical performance [1] or, ultimately, unexpected failure mechanisms [2].

This paper deals specifically with the problem of the interaction between floor diaphragms and segmented shear walls (see Figure 1). Among the several effects, the interaction between these structural components contributes to stiffening the lateral response of segmented shear walls and, under some conditions, can even lead to local failures of the floor panels.

In particular, the current paper provides a generalization of the methodology proposed by D'Arenzo et al. [3], in which an analytical model describing the interaction mechanism of two-panel segmented CLT shear walls and

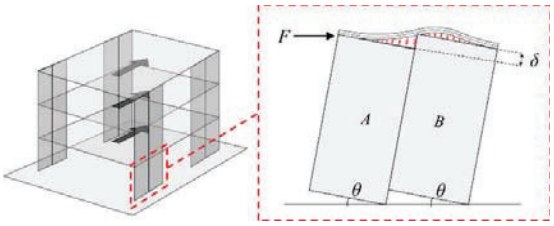

Figure 1: *Representation of the interaction between floor diaphragms and segmented CLT shear walls.*

CLT floors was presented. The analytical model, which is based on the theory of a beam on a bed of elastic springs, will be used in this study to describe the floor-to-wall interaction in the case of three-panel segmented walls. The reliability of the analytical model will be proved by means of numerical simulations and a parametric analysis, in which several wall geoemtries and connection stiffnesses are considered.

2 ANALYTICAL MODEL

The majority of the mechanical models available in the literature used for the prediction of the lateral response of CLT shear walls take into account the properties of the CLT wall segments and the wall base connections, yet do not consider the connections which are on the perimeter of the CLT panels, such as the connections between perpendicular walls or between floor and wall panels (see, for instance, Lukacs et al. [4]). In the model proposed by D'Arenzo et al. [3], the mechanical system is enlarged by considering the additional contribution of the floor elements and the floor-to-wall connections to account for

(a) (b)

***Figure 2**: Analytical model of floor-wall interaction.*

the effects of the interaction between segmented CLT shear walls and horizontal floor diaphragms. The effect of this interaction mainly contributes to reducing the slip between the vertical joints of the wall panels and, consequently, results in an increase of the rocking stiffness of the shear wall.

This interaction can be described by means of a mechanical model of a beam on a bed of springs, in which the beam represents the floor element and the springs represent the floor-to-wall connections. Figure 2 depicts the mechanical problem of this interaction, while Eq. (1) represents the differential equation governing the problem.

$$w^{IV}(x) + 4\lambda^4 w(x) = 0 \tag{1}$$

In Eq. (1), $w(x)$ represents the transversal displacement of the beam and λ is an elastic parameter, which takes into account the elastic properties of the system, i.e., the bending stiffness of the beam EI and the stiffness per unit length of the springs k, see Eq. (2).

$$\lambda = \sqrt[4]{\frac{k}{4EI}} \tag{2}$$

The solution to the differential Eq. (1) can be written as piecewise function defined over the two segments of length ηl and $(1-\eta)l$, see Figure 2 and Eq. (3).

$$w(x) = \begin{cases} w_A(x) = w_{g,A}(x); & 0 \le x \le \eta l \\ w_B(x) = w_{g,B}(x) + \delta; & \eta l \le x \le l \end{cases} \tag{3}$$

In Eq. (3), the functions $w_{g,A}(x)$ and $w_{g,B}(x)$ represent exponential functions solution of Eq. (1), which depend on constants to be defined in accordance to the boundary conditions of the system. δ represents the slip between the two wall panels, which triggers the resisting mechanism of the floor-wall interaction.

The boundary conditions of the system depicted in Figure 2 are reported in Table 1 and take into account the rotation, the bending moment, and the shear of the floor-beam, expressed as derivative of the transversal displacement.

It should be noted that the mechanical behaviour of the floor-to-wall connections is different for tensile and compressive forces. While the stiffness of the floor-to-wall connection is engaged in case of tensile forces, a contact mechanism takes place in case of compressive forces. This implies a nonlinearity of the mechanical behaviour of the floor-to-wall connections, which, however, cannot be described with the linear elastic model presented in this study. The solution adopted by D'Arenzo et al. [3] was to consider a linear behaviour of the floor-to-wall connections and to check downstream that the solution found is consistent with the real mechanical behaviour of the system.

***Table 1:** Boundary conditions of the analytical model of floor-wall interaction.*

$x = 0$	$x = \eta l$	$x = l$

	$w'_A(\eta l) = \delta$	
	$w'_B(\eta l) = \delta$	

3 EQUIVALENT SPRING

In D'Arenzo et al. [3], the expression of an equivalent spring to be placed between the vertical joints of two-panel segmented shear walls was presented, to provide a simple strategy to consider the effects of the floor-to-wall interaction (Figure 3). In this study, the equivalent spring will be validated for the case of three-panel segmented shear walls.

The mechanical system consisting of the floor and floor-to-wall connections provides stiffness that reduces the slip between the wall panels. This stiffness can be represented by a vertical equivalent spring in the joint of two wall panels, and can be calculated as the ratio between the shear force in the floor beam, $V(b_w)$, and the slip of the vertical joint of the wall, δ. This equivalent spring reproduces the effect of the floor-wall interaction for the rocking behavior of the segmented shear wall, based on the elastic properties of the floor beam and floor-to-wall connections, and independent of the kinematic behaviour of the segmented shear wall.

The stiffness of the equivalent spring, $k_{f-w,eq}$, can be determined using the polynomial function in Eq. (4), which depends on the bending stiffness of the floor beam, EI, the elastic parameter, λ, and the length of structural system, l (see Figure 2 and Figure 3).

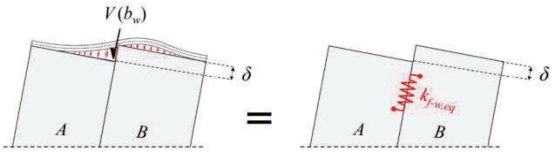

***Figure 3:** Representation of the equivalent spring.*

$$k_{f-w,eq} = \frac{V(b_w)}{\delta} = EI \cdot (p_{00} + p_{10} l + p_{01} \lambda + p_{11}\, l\, \lambda + p_{20} l^2 + p_{02} \lambda^2) \quad (4)$$

Table 2: *Polynomial coefficients for the calculation of the equivalent spring stiffness (Eq. (4)).*

$\lambda\ [m^{-1}]$	p_{00}	p_{10}	p_{01}	p_{11}	p_{20}	p_{02}
$0.5 \leq \lambda \leq 0.7$	0.73100	0.05060	-4.28300	0.21595	-0.01507	5.19500
$0.7 \leq \lambda \leq 1.2$	2.84650	0.12635	-10.2850	0.32880	-0.03467	8.91500
$1.2 \leq \lambda \leq 2.0$	8.02500	1.41600	-22.6350	0.06530	-0.14895	14.3100

The polynomial coefficients, p_{ij}, are listed in Table 2 for three different ranges of the elastic parameter, λ. Eq. (4) and the coefficients in Table 2 can be used to calculate the stiffness of the equivalent spring, $k_{f-w,eq}$, in $[kN/m]$ by using the bending stiffness, EI, in $[kNm^2]$, the system length, l, in $[m]$ and the elastic parameter, λ, in $[m^{-1}]$.

4 METHODOLOGY

To predict the floor-wall interaction for three-panel shear wall sytems, the analytical model is used to describe the shear force of the floor element by considering the three-panel system as the superimposition of two two-panel systems which share the central panel, see Figure 4. In particular, the analytical model is used to predict the shear force of the floor-beam in the region above the two vertical joints of the shear wall, as this represents the shear force value relevant for the definition of the equivalent spring. If the analytical model predict with sufficient accuracy the shear force in the region above the vertical joints of the shear wall, the equivalent spring can then be used for the case of three-panel shear wall systems.
The methodology used in this study involved comparison between the results obtained from the analytical model presented in the previous section and the numerical models presented in the next section. The numerical models were distinguished in deatailed models and simplified models. In the deatailed models, the floor-wall interactions was considered by modelling the floor and the floor-to-wall connections, while in the simplified models, the floor-wall interactions was considered through the equivalent spring.

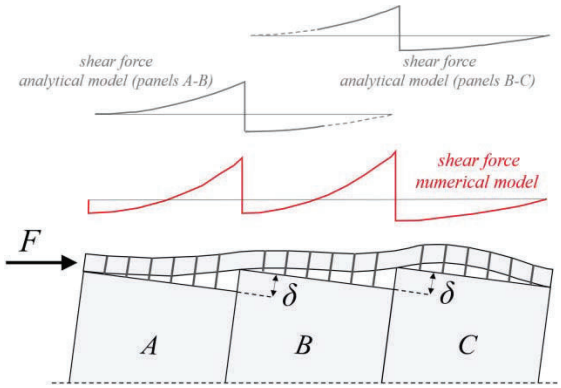

Figure 4: *Representation of the methodology adopted to use the analytical model for three-panel shear walls.*

Two types of analysis were considered: (i) local analysis, at floor level, to evaluate the capability of the analytical model to describe the internal actions of the floor, and (ii) global analysis, at wall level, to evaluate the capability of the equivalent spring to simulate the effect of the floor-wall interaction in three-panel shear wall systems. In the first analysis, the comparison is conducted by directly comparing the shear force functions of the floor, as shown in Figure 4. In the second analysis, the comparison is conducted by comparing the rocking stiffnesses of the shear walls, calculated as the ratio between the lateral force applied on the top of the wall, F, and the rocking displacement, Δ_{rock}, namely the lateral displacmenet on the top of the wall.

5 NUMERICAL MODELS

In this section the numerical models are presented. Three different numerical models were considered: (i) shear walls with floor-wall interactions considered through a detailed modelling of the floor and the floor-to-wall connections (Det-Model), (ii) shear walls with floor-wall interactions considered through the equivalent spring (EqSp-Model), and (iii) shear walls without floor-wall interactions (NoFl-Model). The last numerical model is considered for purpose of comparison, to evaluate the effects of the floor-to-wall interaction on the rocking stiffness of the shear wall. An illustration of the Det-Model for a three-panel shear wall system can be seen in Figure 5.
The same modelling strategy was used to model the wall segments and the base connections of the numerical three models considered. The wall panels were modeled as shell elements with orthotropic elastic material. To simulate the rocking behaviour of the shear walls, the external corner of the shell element under compression was hinged while the internal corner was restrained with a gap element. This allowed for free uplift of the internal corner while preventing displacement in the opposite direction to simulate the wall-to-foundation contact. The sliding mechanism of the shear-wall was disregarded as it has no influence on the rocking behaviour of the shear-wall. The external corner under tension was restrained with a vertical spring that represents the vertical stiffness of the hold down or the weighted vertical stiffness of all wall base connections. 2-joint links with high compression stiffness, no tension stiffness, and linear elastic stiffness in the transversal direction were placed between the two shell elements to prevent wall panel interpenetration and simulate the wall-to-wall connection flexibility in the transversal direction.

https://doi.org/10.52202/069179-0327

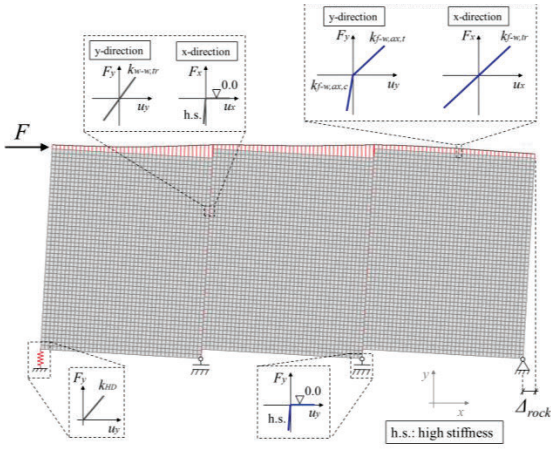

Figure 5: *Numerical model of floor-wall interaction (Det-Model).*

In the Det-Model, the floor was modeled as a linear elastic beam with an orthotropic material. The connections between the floor and the walls were modeled to account for their different behavior under tensile and compressive forces. While for tensile forces the behaviour of the floor-to-wall connection depends on the withdrawal stiffness of the connections, for compressive loads, the floor-to-wall contact takes place. This different behaviour for tensile and compressive forces was modelled with a 2-joint link with multilinear behaviour. For tensile forces the behaviour was assumed with stiffness of the floor-to-wall connection, while for compressive forces an equivalent stiffness that simulates the floor-to-wall contact was considered. Additionally, the horizontal stiffness of the floor-to-wall connection was considered in these links.

In the EqSp-Model, one equivalent spring was placed in the vertical joints between the shell elements representing the wall panels, in addition to the wall-to-wall connections.

A horizontal force was applied to the top of the wall panel, in all numerical models. Nonlinear static analyses were conducted to account for the multilinear behavior of the links simulating hold down, wall-to-wall, and wall-to-floor connections.

6 PARAMETRIC ANALYSIS

The analytical model is validated through a parametric analysis using common geometrical and mechanical parameters used in construction. The analysis considers two symmetric systems, each consisting of two or three wall panels of equal width anchored at both ends with two hold downs and an overlying horizontal floor with evenly spaced floor-to-wall connections, as depicted in Figure 6. For the validation, three wall panel aspect ratios were utilized, each with a height equal to $h = 2.5\ m$ and widths of $b_w = \{1.5 - 2.0 - 2.5\}\ m$. A 5-layer panel with a total thickness of $t_w = 120\ mm$ and individual layer thicknesses of **30**-20-**20**-20-**30** mm (with the thickness of the vertically arranged layers in bold) was considered in the analysis. Three different floor panels typologies with

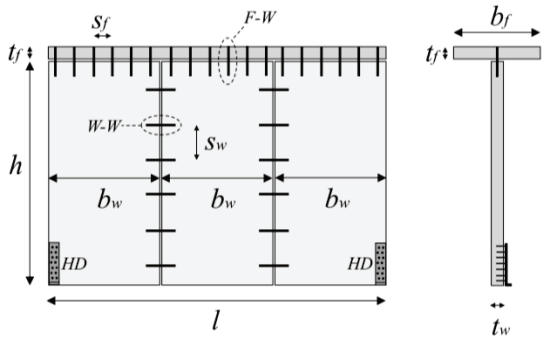

Figure 6: *Reference system used for the parametric analysis.*

total thickness equal to $t_f = \{140 - 180 - 220\}\ mm$ and layer thicknesses as shown in Table 3 were analysed. The floor width was not chosen a priori as it depends on the effective section that contributes to internal bending actions, as per composite section beam theory. The effective width was calculated using the methodology developed by Masoudnia et al. [21], which demonstrates that the effective width is dependent on the wooden layer structure of the CLT panel. The values obtained for the three floor-panels were $b_f = \{1006 - 479 - 636\}\ mm$.

Table 3: *Thickness (in mm) of the floor panels used in the parametric analysis.*

ID	t_f	t_1	t_2	t_3	t_4	t_5	t_6	t_7
1	140	**30**	25	**30**	25	**30**	-	-
2	180	**30**	**30**	20	**20**	20	**30**	**30**
3	220	**30**	**30**	35	**30**	35	**30**	**30**

The floor-to-wall connection spacing and withdrawal stiffness were selected to provide a broad range of stiffness per unit length k in the analytical model. The withdrawal stiffness of the screws was set at $k_{with} = 4kN/mm$, as reported in the experimental study of Gavric et al. [5]. This value is representative of floor-to-wall connections with partially threaded screws 10×260 mm. The screw spacing in the floor-to-wall connection was set at $s_f = \{900 - 300 - 100\}\ mm$. The shear stiffness of the floor-to-wall connections was set at $k_{sh} = 4kN/mm$, based on the experimental results from Gavric et al. [5]. The hold down stiffness was chosen as $k_{HD} = 10\ kN/mm$, as reported by Hummel et al. [6]. The CLT panels of both floor and walls were assumed to be made of wooden boards with an elastic modulus in the longitudinal direction of $E_0 = 11.6\ GPa$.

6.1 MECHANICAL PROPERTIES OF THE ANALYTICAL MODEL

The stiffness per unit length k of the analytical model was determined using Eq. (5), based on the withdrawal stiffness and the spacing of the floor-to-wall connections. The values presented in the previous section were utilized to calculate the stiffnesses per unit length as $k = \{4.4 - 13.3 - 40.0\}\ N/mm^2$.

https://doi.org/10.52202/069179-0327

$$k = \frac{k_{with}}{s_f} \tag{5}$$

The bending stiffness of the floor-beam was calculated based on the layered structure of the floor panel, as described by Blaß and Fellmoser [7], excluding the effect of the wooden boards in the transverse direction. Using the geometrical and elastic properties of the floor outlined in the previous section, the following bending stiffnesses were adopted for the floor beam in the analytical model: $EI = \{2197.7 - 2606.5 - 5947.6\}\, kNm^2$.

6.2 MECHANICAL PROPERTIES OF THE NUMERICAL MODEL

The wall panels were modeled as shell elements and their elastic properties were assigned based on the layered structure of CLT panels. Equivalent longitudinal and transversal elastic moduli of $E_{eq,l} = 7.7\ GPa$ and $E_{eq,t} = 3.9\ GPa$ were assigned to the orthotropic shell elements, based on the methodology proposed by Blaß and Fellmoser [7]. Equivalent shear modulus of $G_{eq} = 0.5\ GPa$ was assigned using the methodology proposed by Brandner et al. [8]. The floor-to-wall connections were modeled as links with spacing $a_f = 50mm$. The tensile stiffness of these links was calculated using Eq. (6), based on the stiffness per unit length of the analytical model and the spacing of the links in the numerical model.

$$k_{f-w,ax,t} = k \cdot a_f \tag{6}$$

The axial stiffnesses of the links simulating the floor-to-wall connections were determined using the values in the previous section, resulting in $k_{f-w,ax,t} = \{0.22 - 0.67 - 2.00\}\, kN/mm$.

The compressive stiffness of the links simulating the floor-to-wall connections, $k_{f-w,ax,c}$, was calculated using Eq. (7) as described by Schickhofer and Ringhofer [9] and Blaß and Görlacher [10].

$$k_{f-w,ax,c} = \frac{E_{90} \cdot A_{ef}}{t_f} = \frac{E_{90} \cdot l_{ef} \cdot a_f}{t_f} \tag{7}$$

The equation considers the effective area under compression in the floor element, A_{ef}, and the elastic modulus perpendicular to the grain of the floor, E_{90}. The effective area was determined by multiplying an effective length, l_{ef}, by the spacing of the link elements, a_f. The effective length was calculated based on a stress distribution line with an inclination of 1:3, according to Eurocode 5 [11] specifications. The resulting compression stiffnesses for the links simulating the floor-to-wall contact were $k_{f-w,ax,c} = \{45.7 - 40.0 - 36.4\}\, kN/mm$.

The transversal stiffness of the floor-to-wall connections was computed using Eq. (8), which considers the different spacings of the numerical model, a_f, and the reference system, s_f.

$$k_{f-w,tr} = \frac{a_f}{s_f} \cdot k_{sh} \tag{8}$$

Based on the values presented in previous sections, the following transversal stiffnesses were utilized for the floor-to-wall connections: $k_{f-w,tr} = \{0.22 - 0.67 - 2.00\}\, kN/mm$. The high stiffness of the wall-to-wall connections and gap element was set to $10^6 kN/mm$.

7 RESULTS AND DISCUSSION

7.1 ANALYSIS AT FLOOR LEVEL

The validation of the analytical model is carried out by comparing the displacement, the bending moment, and the shear force of the floor-beam obtained from analytical and numerical models. Figure 7 shows this comparison for the case of systems with two-panel shear walls with width $b_w = 2.0\ m$, floor bending stiffness $EI = 2606.6\ kNm^2$, and floor-to-wall connection stiffness per unit length $k = 13.3\ N/mm^2$. It can be observed that the analytical and numerical model results converge starting from a point of conjunction, located in the first half of the floor length.

For the case of three-panel shear walls, the analytical model is used to describe the shear force of the floor element. This is done by considering the three-panel system as the composition of two two-panel systems, as discussed in section 4. Figure 8 shows the comparison between the shear force obtained from the analytical and numerical model for the case of three-panel shear walls with width $b_w = \{1.5 - 2.0 - 2.5\}\, m$, floor bending

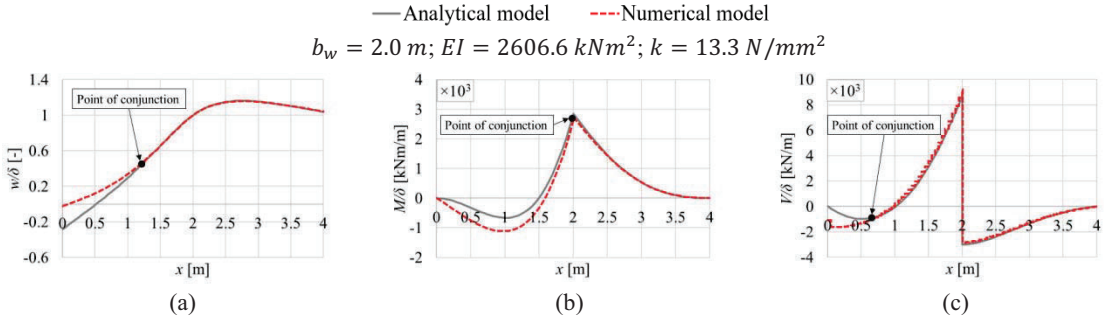

Figure 7: *Displacement, bending moment, and shear force function of the floor element for the two-panel shear walls.*

https://doi.org/10.52202/069179-0327

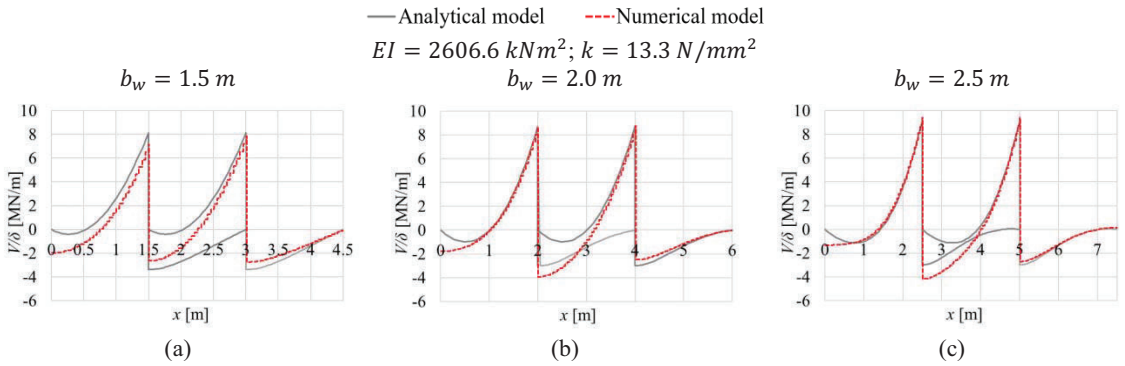

Figure 8: *Shear force function of the floor element for the three-panel shear walls.*

stiffness $EI = 2606.6\ kNm^2$, and floor-to-wall connection stiffenss per unit of length $k = 13.3\ N/mm^2$. It can be observed that the trend of the shear force for the three-panel system is similar to that of the two-panel system. In particular, the analytical and numerical models show a good agreement in the region above the vertical joints of the shear walls, with identical values for the cases with $b_w = 2.0\ m$ and $b_w = 2.5\ m$, and reasonably close values for the cases with $b_w = 1.5\ m$. This allows the equivalent spring defined for two-panel shear walls to be used for three-panel shear walls as well.

7.2 ANALYSIS AT WALL LEVEL

In this section the effect of the floor-wall interaction is evaluated at wall level. The results of the three numerical models described in section 5 are compared, (i) to evaluate the impact of the the floor-wall interaction on the lateral behavior of the shear wall, and (ii) to validate the equivalent spring in case of three-panel shear wall systems. In particular, the rocking stiffness of the models that consideres the floor-wall interaction (Det-Model and EqSp-Model) are compared with the rocking stiffness of the models without floor-wall interaction (NoFl-Model). Figure 9 shows the comparison of the dimensioneless rocking stiffness of the systems with width $b_w = \{1.5 - 2.0 - 2.5\}\ m$, floor-to-wall connection stiffenss per unit length $k = \{4.4 - 13.3 - 40.0\}\ N/mm^2$, and floor bending stiffness $EI = 2606.6\ kNm^2$. The dimensionless rocking stiffness, $\tilde{K}_{rock}$, was calculated as the ratio between the rocking stiffness of the models that consideres the floor-wall interaction and the rocking stiffness of the model without floor-wall interaction.

In general, the graphs show that the floor-wall interaction increases the rocking stiffness of the shear walls. The increase of rocking stiffness is primarily governed by the withdrawal stiffness of the floor-to-wall connections. For instance, for the systems with panel width $b_w = 2.0\ m$, the increase of rocking stiffness associated to the stiffness per unit length $k = \{4.4 - 13.3 - 40.0\}\ N/mm^2$ are equal to 24.8 %, 48.5 %, and 84.9 %, respectively. The panel width also affects the increase of rocking stiffness; for a floor-to-wall connection stiffness of $k = 13.3\ N/mm^2$, the increase of rocking stiffness associated to the panel widths $b_w = \{1.5 - 2.0 - 2.5\}\ m$ is equal to 43.8 %, 48.5 %, and 50.8 %, respectively.

The graph also reports the kinematic behaviour associated to each system. It is possible to see that if the effect of the floor-wall connection is neglected, the shear walls deform with a couple panel (CP) kinamtic behaviour, namely with

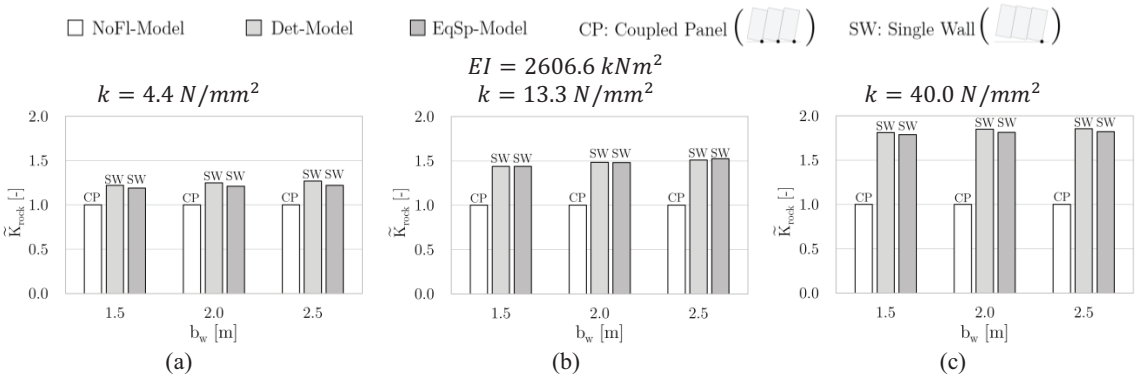

Figure 9: *Dimensionless rocking stiffness of the three-panel shear walls with and without floor-wall interaction.*

each wall panel being in contact with the foundation and the shear wall having multiple centre of rotations. On the other hand, when the floor-wall interaction is considered the kinamtic behaviour switchs to Single Wall (SW), meaning with only one panel in contact with the foundation and with the whole shear wall pivoting about one point. This is due to the fact that the floor-interaction fictitiously increases the overall stiffness of the wall panel vertical joints.

From Figure 9, it is also possible to observe the accuracy of the models with the equivalent springs (EqSp-Model). In fact, the values of rocking stiffness of these models are very close to those obtained from the models with detailed modelling of the floor-wall interaction. The largest discrepancy between these models is 3.8 % and is found in the case of system with $b_w = 2.5\ m$ and $k = 4.4\ N/mm^2$.

The results showed in Figure 9 reveal that the floor-wall interaction increases the rocking stiffness of segmented shear walls and may lead in some cases to modification of the kinematic behaviour, from coupled panel to single wall. This is particualry important to be considered in contexts of seismic design, when highly dissipative behaviours are expected from the vertical joints of segmented shear walls.

8 CONCLUSIONS

This paper presents a study on the effect of the floor-wall interaction on the rocking behaviour of multi-panel CLT shear walls. Previous research on two-panel wall systems conducted by D'Arenzo et al. [3] showed that the floor-wall interaction generates internal actions in the floor element and reduces the slip in the vertical joints of the wall panels. The internal actions can be described with an analytical model of beam on elastic springs, while the reduction of slip in the vertical joints of the wall panels can be simulated by means of an equivalent spring. In this study, the analytical model and the equivalent spring presented by D'Arenzo et al. [3] were used to describe the effects of the floor-wall interaction in the case of three-panel wall systems.

The results of this study showed that the analytical model can be used to describe the shear force of floor elements connected to three-panel shear wall systems. The comparison of the shear force obtained from the analytical and numerical models for three-panel systems showed a good agreement in the region above the vertical joints of the shear walls, with identical values for the cases with 2.0 m and 2.5 m panel width and reasonably close values for the case with 1.5 m panel width. This allowed the equivalent spring defined for two-panel systems to be used for three-panel systems.

At wall level, the results showed that the floor-wall interaction increases the rocking stiffness of the wall. It was found that the increases of rocking stiffness is primarily governed by the stiffness of the floor-to-wall connections and affected by the wall panel width. The increase of rocking stiffness was observed for all the systems, with the highest increase observed for the systems with the highest floor-to-wall connection stiffness and largest wall panels width.

These results demonstrate the significance of considering the interaction between floor diaphragms and segmented shear walls when evaluating the lateral response of multi-panel CLT shear walls. Nonetheless, further research is required to extend the findings of this study to the case of multi-panel systems with more than three panels both for linear elastic and nonlinear analyses.

The study provides valuable insights into the interaction between floor diaphragms and segmented shear walls in CLT buildings, demonstrating that these interactions can significantly modify the lateral response of CLT structures. The analytical model developed in this study provides a useful tool to account for the floor-to-wall interaction in the analysis of CLT buildings.

EXPERIMENTAL CHARACTERIZATION OF STIFF ALUMINIUM CONNECTORS FOR MULTI-PANEL CLT SHEAR-WALLS

Pietro Rigo[1], Andrea Polastri[2], Daniele Casagrande[3], Ernesto Callegari[4], Alvise Ramazzini[5], Luca Sestigiani[6]

ABSTRACT: Cross-Laminated Timber (CLT) shear-walls composed of multiple panels are nowadays a viable alternative to single-panel CLT walls in mid-rise construction sector. Prefabrication process, transport and erection limits are some of the reasons why short panels, vertically-jointed by means of mechanical fasteners, are preferred to CLT single-panel walls. When a significant amount of energy dissipation in the vertical joint is not required (i.e. low seismic prone areas), stiff vertical joints are preferred: the wall behaves mostly like a single-panel wall and vertical joints are designed to minimize the relative displacement between the panels. This paper presents an experimental campaign on aluminium stiff shear-key connector, as an alternative to traditional screwed connections for stiff vertical joints in multi-panels CLT walls. Monotonic tests were performed on shear-key connectors and full-scale tests on multi-panel CLT shear-walls were carried out. A numerical model was developed in order to extend the experimental results on full-scale tests by means of a sensitivity analysis.

KEYWORDS: Cross-laminated timber, Multi-panel, shear walls, Shear-key connectors, Hold-down, Vertical joints.

1 INTRODUCTION

Cross-Laminated Timber (CLT) shear-walls composed of multiple panels are nowadays a viable option for mid-rise buildings. Prefabrication process, transport and erection limits are some of the reasons for which short panels, vertically-jointed by means of mechanical fasteners, are preferred to CLT single-panel walls. The lateral load resistance of multi-panel walls is mainly provided by mechanical connections while CLT panels behave mostly like rigid elements. Either nailed or screwed connections are commonly adopted for connecting the panels.

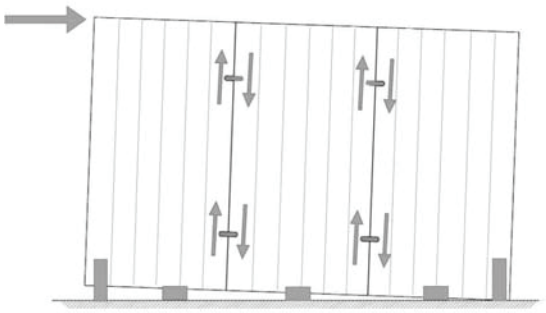

Figure 1: *Multi-panel shear wall with stiff connectors*

As derived by Casagrande et al. and Masroor et al. [1,20], the relative stiffness and strength capacity of vertical joints and hold-downs have a significant influence on the behaviour of multi-panel CLT shear-walls. When a significant amount of energy dissipation is not required (i.e. low seismic prone areas), relatively stiff vertical joints are preferred: the wall behaves mostly as single-panel wall, see Figure 1, and vertical joints are designed to minimize the relative displacement between the panels so that the stiffness and strength capacity of the wall is approximately equal to that of a single panel wall.

1.1 LITERATURE REVIEW

Several studies have been conducted in order to characterize the mechanical behaviour of CLT panel-to-panel joints. Monotonic and cyclic tests were carried out by Gavric et al. [2] on screwed half-lap and spline joints, showing high ductility and energy dissipation. Hossain et al. [3] performed monotonic tests on spline, half-lap and butt joints where fully- and partially-threated screws with different inclinations were adopted.

Loss et al. [4] presented an experimental campaign on butt joints with crossed self-tapping screws inserted in CLT panels with different inclinations. Half-lap and spline joints connected with partially- and fully-threated self-tapping screws were tested by Sullivan et al. [5], comparing the experimental results with the analytical preditcion in terms of strength and stiffness.

More recently, innovative steel devices have been presented as an alternative to traditional screwed connec-

tions. Schmidt and Blaas [6] developed a highly dissipative connection made with thin steel plate inserted perpendicularly to the vertical joint. Marchi et al. [7] performed cyclic tests on an innovative X steel bracket, showing high ductility, negligible strength degradation and a limited pinching behaviour.

A significant number of full-scale testes on multi-panel CLT shear-walls with vertical joints assembled with dowel-type fasteners has been conducted. Two-panel CLT shear-walls with half-lap and spline screwed vertical joints were tested by Gravic et al [8], showing an almost rigid behaviour of the CLT panels and a significant energy dissipation in the vertical joints. The cyclic behaviour of single- and multi-panel CLT shear-wall was also investigated by Popovski and Karacabeyli [9].

Conversely, a limited number of tests has been performed with the aim to characterise the behaviour of multi-panel shear walls with stiff vertical joints. This type of shear-walls, regardless the smaller energy dissipation capacity than shear-walls with flexible vertical joints, may be a viable alternative in low seismic prone areas.

1.2 OBJECTIVE

This paper presents an experimental campaign on a innovative stiff aluminium shear-key connector developed with the aim of providing an alternative to nailed or screwed connections for stiff vertical joints in multi-panel CLT walls. The connector is named "SLOT" and is produced by Rotho Blaas company [10]. SLOT connector is made with aluminium EN AW-6005A T6 (yield tensile strength equal to R_y = 225 N/mm^2 and ultimate tensile strength equal to R_u=270 N/mm^2). The length, the width and the thickness of the SLOT connector are equal to l_{SL} = 120 mm, b_{SL} = 89 mm and t_{SL} = 40 mm, respectively, see Figure 2.

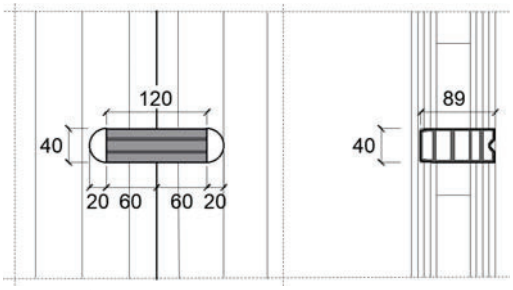

Figure 2: *Aluminium SLOT connector*

Monotonic shear tests were performed both at connector and shear wall level. Numerical finite element models were implemented to predict the mechanical behaviour of tested shear-walls.

2 MONOTONIC TESTS ON STIFF SHEAR-KEY CONNECTORS

2.1 MATERIALS AND METHODS

Monotonic shear tests were performed on CLT panel-to panel joints assembled with SLOT connectors.

Two grooves of dimensions equal to 90x60x40 mm were cut in the panels in order to insert each SLOT perpendicular to the vertical joint line and aligned to the outer face of CLT panels.

Different specimen configurations using different types of CLT panels were assembled for a total of 10 tests. The total thickness and the layout the of CLT panels are reported in Table 1. Tests on spline joints were also performed and the results were compared with those obtained in tests with SLOT connectors. The spline joints were made by connecting the CLT panels to a 27x150 mm LVL beech board by means of 6x70 mm screws, see Figure 3. For spline joints two different values of spacing (50, 100 mm) were tested, yielding a total of 4 tests (Table 1).

The mean value of the moisture content of the CLT panels was equal to 10.1% while the 5th percentile and the mean value of density of the CLT panels were equal to 402 kg/m^3 and 454 kg/m^3, respectively.

Table 1: *Test layout on SLOT connectors and screwed vertical joint*

Test on joints with SLOT connectors			
ID	Test	CLT thickness	CLT layout
SL01	I II III	90 mm	3s (24-42-24)
SL02	I II	100 mm	3s (33-34-33)
SL03	I	100 mm	3s (29-42-29)
SL04	I II III	100 mm	5s (20-20-20-20-20)
SL05	I	145 mm	5s (20+20-20-20-20-45)*
*Slot connector aligned to the outer layer with thickness equal to 20 mm			
Test on joints with screwed connections			
ID	Test	Screw spacing	CLT thickness	CLT layout
SP01	I II	50 mm	100 mm	3s (30-40-40)
SP02	I II	100 mm	100 mm	3s (30-40-40)

The inner panel of each specimen was vertically loaded, while the two outer panels were laterally restrained. The load was applied with a constant load rate equal to 0.1 mm/s and according to EN 26891 [11] the failure occurred within 300 seconds. The relative slip between the inner and the outer panels was measured by means of four LVDTs and the load applied was measured by a 250 kN load cell.

The results in terms of maximum shear load F_{max} and stiffness K_s are reported in Table 2 and 3.

For each specimen the slip value was determined as the average from four LVDTs. The shear load F acting on each single connector was obtained from the ratio between the total shear load measured by the load cell and

the number of connectors. The value of stiffness and shear load for spline joints is reported per couple of screws.

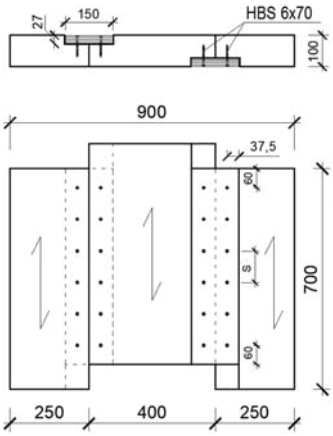

Figure 3: *Monotonic shear tests on spline joint*

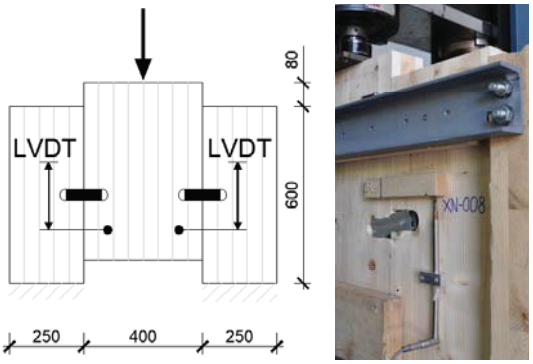

Figure 4: *Monotonic shear tests on aluminium CLT-to-CLT shear-key connector*

2.2 RESULTS AND DISCUSSION

Tests conducted on specimens with SLOTs showed a rigid body rotation of the connectors with no residual plastic deformation. A failure mode characterised by the localized crushing of the wood was observed. In spline joint tests, a plastic deformation of the screws and a local embedment crushing of the wood around the fasteners were detected.

The load-slip curves for test SL01-II and SP01-II are reported in Figure 5. The gap between the SLOT connector and the CLT panels caused an initial slip (0.3 and 0.5 mm) after which an elastic-almost perfectly plastic behaviour is observed. The initial slip was not observed in the tests on screwed joints where, conversely, a significant rope effect after the yielding of the fasters was detected.

The effective number of screws equal to a single SLOT connector in terms of strength and stiffness $n_{eff,Fmax}$ and $n_{eff,Ks}$ have been defined with the aim to compare the performance of joints with SLOT connectors to those with screwed joints. Using the average values of strength and stiffness determined from Table 3 and assuming an effective width $b_{eff,SL}$ of the SLOT connectors equal to 53 mm (see Figure 2, section), the effective number of screws $n_{eff,Fmax}$ and $n_{eff,Ks}$ are equal to 12.6 and 13.0 respectively.

Table 2: *Test results on SLOT connectors*

ID	Test	F_{max} [kN]	K_s [kN/mm]
SL01	I	60.35	13.99
	II	62.30	12.69
	III	58.74	14.75
SL02	I	53.83	14.91

3 FULL-SCALE TESTS ON MULTI-PANEL CLT SHEAR-WALLS

3.1 TEST-LAYOUT AND SET-UP

Two monotonic full-scale tests were carried out to investigate the mechanical behaviour of 3-panel 100 mm thick CLT [13] shear-walls with SLOT connectors, see Figure 6a and 6b. Either two or four connectors along each vertical joint were used. An additional multi-panel shear-wall with spline vertical joints was tested, see Figure 6c. As in shear tests on panel-to-panel joints, 6x70mm screws were used with a spacing of 50 mm.

Two typologies of hold-down (WHT 340 and WHT620) were used to limit the rocking of shear-walls, whereas the sliding of each panel was prevented by the contact of the panels bottom edges with properly designed steel devices. The same displacement was applied on the top of each panel according to the analytical model developed by Casagrande et al. (2018) [1]; no vertical load was applied. In accordance with EN 594 [14], displacement-controlled monotonic tests with load rate equal to 0.2 mm/s were adopted.

3.2 ANALYSIS METHOD

Two transducers (LVDTs) were used in order to measure the top lateral displacement of shear-walls, while another LVDT was used to measure the panel sliding.

The difference between the total lateral displacement and the sliding represents the lateral displacement Δ due to the rocking behaviour and the panel deformation.

Trilinear curves were drawn in order to approximate the experimental load-displacement curves. These curves were obtained by connecting the yield point Y, the maximum point M and the ultimate point U determined according to the procedure reported in EN 12512 [15]. The ratio between the yielding load F_Y and the yielding displacement Δ_Y represent the elastic stiffness K, while the ratio between the yielding displacement Δ_Y and the ultimate displacement Δ_U represent the ductility of the shear-wall μ.

Table 4: *Shear-wall test layout*

Test	N. of panels	Type of connector in vertical joint	N. of connector	Hold-down
Wall-I	3	SLOT connector	2	WHT 340
Wall-II	3	SLOT connector	4	WHT 620
Wall-III	3	Spline joint – 6x70 mm screws	44 / spacing 50 mm	WHT 340

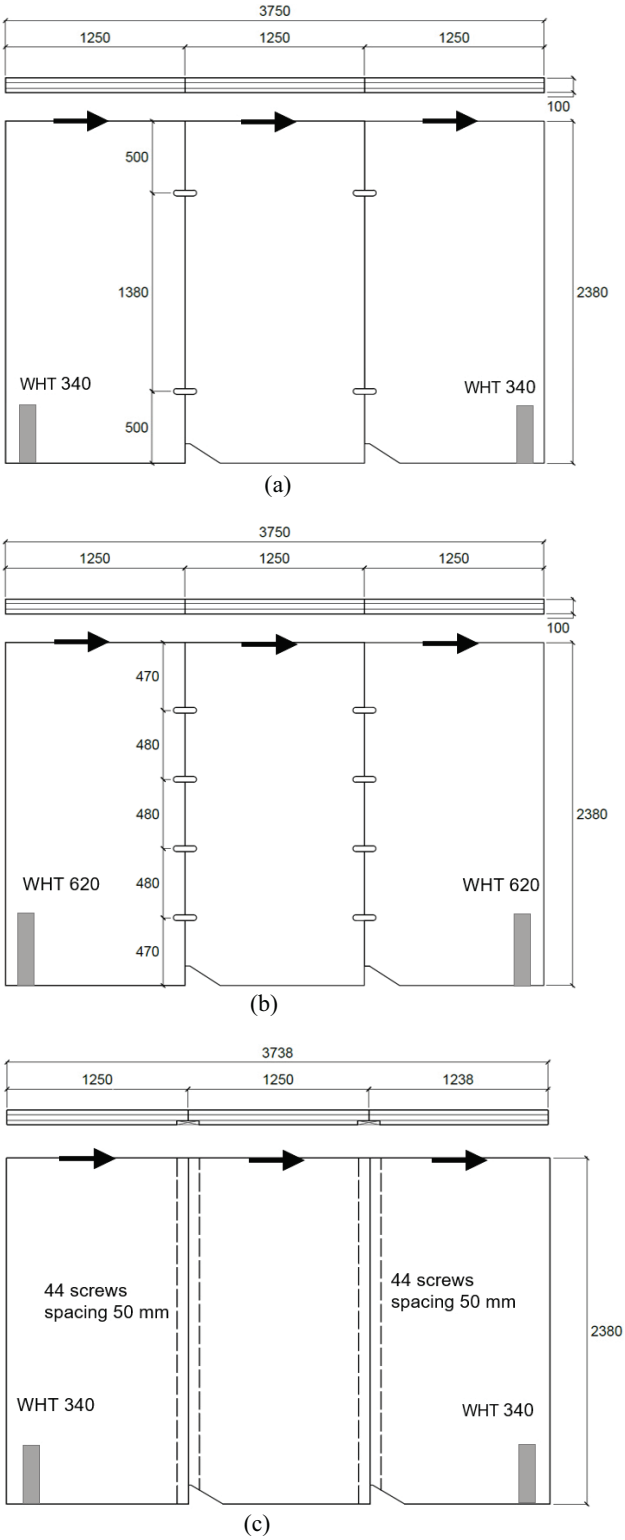

Figure 6: *Shear-wall test specimens (a) Wall-I, (b) Wall-II, (c) Wall-III*

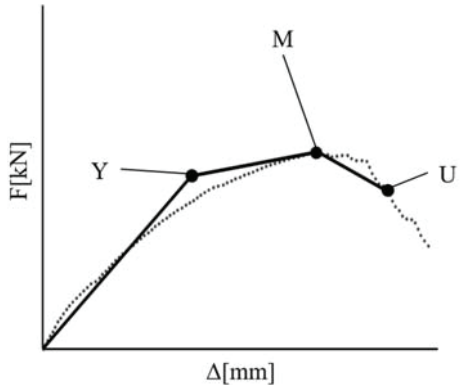

Figure 7: *Load F vs displacement Δ curves, trilinear approximation.*

3.3 RESULTS AND DISCUSSION

All the tested walls showed a kinematic mode characterised by a single global centre of rotation (see Figure 8), as also confirmed by a value of uplift of the hold-down greater than the panel-to-panel slip, see Table 5.

Table 5: *Uplift of hold-down and relative panel-to-panel slip corresponding to the maximum lateral load*

Test	Maximum load	Uplift hold-down	Slip panel 1-panel 2	Slip panel 2-panel 3
	F_M [kN]	v_{H-D} [mm]	$\delta_{1.2}$ [mm]	$\delta_{2.3}$ [mm]
Wall-I	115	19.5	2.0	2.0
Wall-II	167	16.0	1.1	1.2
Wall-III	120	20.8	2.4	3.5

The failure of the hold-down was achieved in all three tests: ductile failure with plastic deformation of nails was observed for WHT340 in Wall-I, while in Wall-III a brittle failure of the steel plate was observed. A brittle failure of the steel plate occurred also in the test on Wall-II, where WHT620 was used. Either SLOT connectors and screwed joints exhibited an almost elastic behaviour with no residual deformations. The force and displacement values related to the yield point Y, the maximum point M and the ultimate point U are reported in Table 6, whereas the experimental load-vs-displacement curve and the corresponding trilinear curve are reported in Figure 7.

Table 6: *Mechanical parameters obtained from tri-linear curves of shear-wall tests*

Test	F_Y	Δ_Y	F_M	Δ_M	F_U	Δ_U	K	μ
	[kN]	[mm]	[kN]	[mm]	[kN]	[mm]	[kN/mm]	[-]
Wall-I	101	9.4	115	17.4	92	21.8	10.7	2.3
Wall-II	141	5.9	167	13.5	167	13.5	23.8	2.3
Wall-III	86	5.0	120	19.5	116	20.2	17.3	4.1

As shown in Figure 9, the load-vs-displacement curves of the test on Wall-I and that on Wall-III are comparable. The maximum shear load reached in both tests is very similar, but due to the physical gap between the SLOT connector and the CLT panels, the stiffness of Wall-I is lower than that of Wall-III.

4 FINITE ELEMENT NUMERICAL ANALYSES ON SHEAR-WALLS

Finite Element (FE) numerical models were implemented with the commercial software SAP2000 [16] to predict the mechanical behaviour of the three tested shear-walls, see Figure 10. Orthotropic homogenous elastic 100 mm thick shell elements were adopted for the modelling of CLT panels. Effective modulus of elasticity $E_{eff.v}$ and $E_{eff.h}$ were defined along the vertical and horizontal direction. Respectively, according to the composite theory presented by Blass and Fellmoser [17] and adapted to CLT panels as expressed by Equations 2 and 3:

$$E_{eff.v} = \frac{E_0 \cdot \sum t_{v.i}}{t} = 7200MPa \quad (2)$$

$$E_{eff.h} = \frac{E_0 \cdot \sum t_{h.j}}{t} = 4800MPa \quad (3)$$

where E_0 is the modulus of elasticity of wooden boards equal to 12000 MPa, t is the total thickness of the panel equal to 100 mm, $\sum t_{v.i}$ and $\sum t_{h.j}$ are the total thickness of the vertical and horizontal layers equal to 60 mm and 40 mm, respectively.

An effective in-plane shear modulus G_{eff} equal to 479 MPa was assigned to shell elements according to the expressions proposed by Brandner et al. [18] to take into account the effective shear and torsional deformation of wooden boards. Rigid gap elements were adopted to model the contact of CLT panels with the ground. The shear-key connectors or the screwed connections along the vertical joints were modelled by 2-joint uni-axial multi-linear link elements.

https://doi.org/10.52202/069179-0328

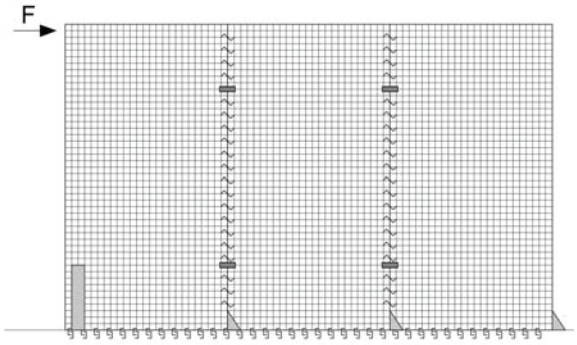

Figure 10: *FE numerical model for Wall-I*

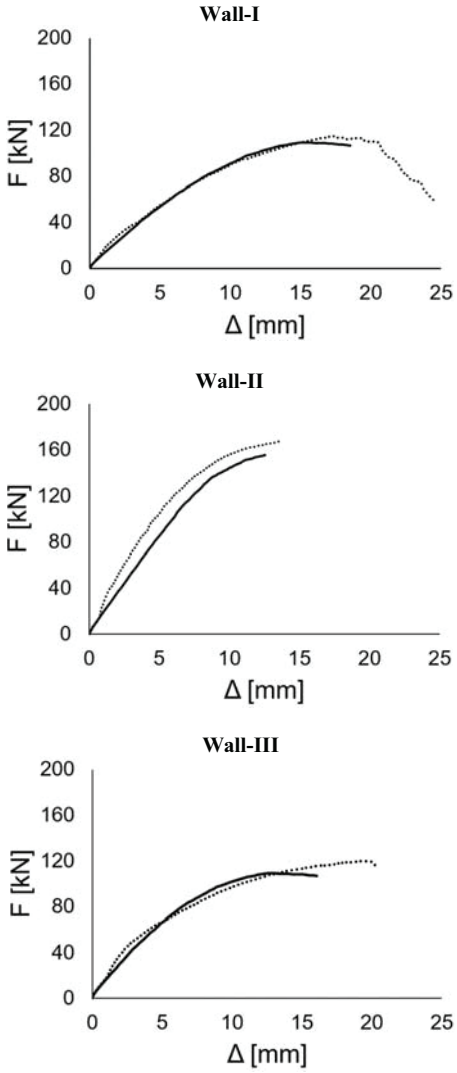

Figure 11: *Load-vs-displacement curves obtained from FE model (continuous line) and shear-wall tests (dot line)*

The multi-linear behaviour assigned to the link along the direction parallel to vertical joint was defined elaborating the experimental curves obtained from the tests on connectors presented in Section 3. In order to simulate the panel-to-paper contact, rigid gap elements acting along the direction perpendicular to the joint were used.

A multi-linear 1-joint uni-axial link element was adopted to model the hold-down when subjected to a vertical tensile load. In order to characterize the non-linear behaviour of hold-down link element, four monotonic tests were carried out on WHT 340 hold-down. The experimental curve for WHT620 is conversely available in Casagrande et. al 2021 [19].

A diaphragm constraint was applied at joints of the FE model on the top of each panel. Non-linear static analyses were performed by increasing the lateral displacement at the top of the wall from zero up to the value corresponding to the global failure condition.

The validation of the FE models with the experimental results was carried out in terms of load F vs displacement Δ curves as shown in Figure 11. It is noteworthy to mention that the values of the lateral displacement Δ were measured in the model at the same location of the LVDTs used during the tests to monitor the lateral displacement of the shear-wall. A reasonable fit is obtained for all analysed tests.

5 CONCLUSIONS

This paper presents an experimental campaign on aluminium rigid shear-key SLOT connectors. The tests were carried out both at connector and wall level. The curves related to connector tests, after an initial slip due to the gap between the connector and the CLT panels, showed an almost elasto-perfectly plastic behaviour.

At wall level, a single-wall kinematic mode with a single global centre of rotation was observed; all tested wall specimens showed a failure mode related to the hold-down.

The shear-wall with two SLOT connectors in each vertical joint (Wall-I) and the shear-wall with screwed vertical joints (Wall-III) showed similar behaviors: the maximum shear load was almost the same, but, due to the physical gap between the SLOT connector and the CLT panels, the stiffness calculated analytically was smaller in Wall-I than that in Wall-III.

The load-vs-displacement curves obtained from the FE numerical model reasonably fit the experimental curves obtained from the shear-wall tests. The numerical models can hence be adopted to predict the mechanical behaviour of multi-panel with rigid shear-key connectors for different geometrical dimensions and mechanical properties.

The results of the experimental and numerical investigations showed how these connectors can be considered to be a viable alternative to traditional connections for stiff vertical joints in multi-panels CLT walls.

6 ACKNOWLEDGEMENTS

Eng. Matteo Magelli is acknowledged for his great help in the processing of data of all tests.

REPRODUCTIVE ANALYSIS OF FULL-SCALE SHAKING TABLE TESTS OF WOODEN HOUSES USING QUALITY ENGINEERING

Tokikatsu Namba[1], Takafumi Nakagawa[2], Yuji Kado[3], Atsuo Takino[4], Hiroshi Isoda[5]

ABSTRACT: Since the Great Hanshin-Awaji Earthquake in Japan, many full-scale shaking table tests have been conducted for the purpose of analysing the seismic performance of wooden houses. Therefore, the knowledge obtained in the experiment needs to be fed back to the simulation such as structural analysis. However, as a premise that makes them possible, it is indispensable to be able to perform reproductive analysis. In this study, as reproductive analysis, we tried the data assimilation using quality for seismic response analysis of wooden houses engineering.

KEYWORDS: Data assimilation, Reproductive analysis, Full-scale shaking table test, Quality engineering

1 INTRODUCTION

Since the Great Hanshin-Awaji Earthquake in Japan, many full-scale shaking table tests have been conducted for the purpose of analysing the seismic performance of wooden houses [1]. The purpose of these experiments was to determine the seismic performance of the houses and to establish analysis methods. If there is an analytical method that can reproduce the behaviour, it will be possible to determine the seismic performance of the building without conducting experiments. However, if a time history response analysis is conducted in advance by simple addition of load-deformation relationships of individual walls, the response deformation tends to be larger, i.e., the performance of the building at the time of the experiment often exceeds the prediction. As a result, the parameters of walls and joints are reviewed to obtain parameters that match the experimental results, and the parameters will be compared before and after the review to consider the reason for the increase in the capacity. The review is performed manually while considering the reason for the increase, but it is a time-consuming process, and even if the failure process of the obtained solution is different, the inter-story displacement may happen to be similar to the experimental results.

This study discusses a data assimilation method, rather than trial and error, for the review process. Data assimilation is a method of finding parameters that are consistent with observations [2]. This method has been developed primarily in the field of weather forecasting, and it has also been applied to the development and validation of mathematical models in meteorology, climatology, geophysics, geology, and hydrology. In recent years, data assimilation has also been applied to numerical simulations in the fields of geophysics and biology to improve the reliability of numerical simulations [3,4]. In the fields of architecture and civil engineering, it is also known as "system identification," a theory for identifying the modal properties and analytical parameters of structures by observing their response to earthquakes and using microtremor measurements [5]. For example, Nakamura et al. (2000) proposed and validated method for identifying layer stiffness and damping of shear mass system structures using actual earthquake records [6]. In wooden houses, studies have been conducted to estimate layer stiffness by microtremor observation [7]. But there have been few research cases of system identification of nonlinear behaviour of wooden houses, which is the target in this study. As mentioned above, there are several studies on estimating seismic performance by analysis and reproducing experimental results that are closely related to the parameters. For example, Sugiyama et al. (1987), in a static load test of a two-story wood-frame frame house, compared the seismic capacity during a full-scale experiment with the estimated bearing capacity calculated from an experiment on a single wall, and reported that the capacity during the experiment was about 30% greater than the estimated capacity [8]. Miyoshi et al. (2001) reported that static loading force and shaking table experiments on a two-story wood-frame frame house estimated the load-deformation relationship in shaking table experiments by adding up wall experiment and found that it was possible to estimate about 90% of the stiffness up to 1/75 rad, but not the maximum capacity and toughness in the large-deformation region [9]. Comparing the results of shake table tests of several full-scale wooden houses with the calculation results of adding up the load-deformation relationships of all the walls of those structures, Isoda et al. (2021) reported that the capacity during full-scale

shake table tests was larger than the addition results, about 1.2 times larger at small deformations and about 1.5 times larger at large deformations [10]. It is not easy to accurately estimate the performance of a full-scale shaking table test from experiments for individual walls. In most of these previous studies, shear deformation of each floor is the target. In this study, on the other hand, a three-dimensional analytical model that includes the behaviour of joints, rather than a shear system model that only covers the response of the layers, was constructed to present the damage of each part in detail. In other words, the number of parameters to be considered is enormous.

Here, we focused on quality engineering to reduce the computational complexity in data assimilation and to more efficiently assimilate analytical parameters from shaking table tests. Quality engineering is a statistical method based on the design of experiment method and is sometimes called the robust design method [11]. Developed to improve product quality, orthogonal tables are employed to analyse a large number of variables with a relatively small number of experiments, for example [12]. And inferences obtained using orthogonal tables are said to yield results similar to those obtained by exhaustive examination, and have recently been applied in various fields, such as biotechnology. In the data assimilation method using quality engineering, parameters are defined by multiplying a correction factor with the nominal value set to 1 by the actual physical property value, and the parameters are reproduced by manipulating the correction factor [13].

Based on the quality engineering, this study attempted to establish a method for searching parameters in an analytical model that can accurately reproduce the response of a shake table test. By analysing the results obtained from the actual performance during the full-scale shaking table test and the results of elemental experiments for each seismic element, the main objective of this study is to discuss points and problems that have not been considered in previous studies and to help improve the accuracy of future seismic simulations.

2 EXPERIMENT

The full-scale shaking table experiment targeted in this study was conducted as part of the Ministry of Land, Infrastructure, Transport and Tourism-subsidized project "Design Method Verification Project for 3-Story Wooden Frame Construction" [14]. There were four specimens, each with different wall amounts, joints, and their arrangement, etc. The target specimens to be analysed in this study are specimens 1 and 2 (Figure 1), which have the same plan and elevation plan, but the design of the joints is different (Figure 2). Both are three-story wood-frame frame construction buildings with a plan dimension of 4.55 m x 10.01 m and an eave height of 8.905 m.

3 NUMERICAL ANALYSIS

3.1 Analysis model

In this study, we used “wallstat” [15], an analysis software based on the discrete element method, was used for the time history response analysis. The individual element method is an analysis method for discontinuous bodies such as collapsed bedrock, but the authors have proposed an analysis method using a three-dimensional framework model that can trace the collapse of a wooden house16). Figure 3 shows the analytical model. The number of nodes is 1716 and the number of springs is 3050. The shaft members were assumed to be beam elements, and the bending strength was set to 60 N/mm^2, considering the actual values of the glued laminated wood used in the test specimens. Young's modulus was set to the value based on JAS for each member, respectively.

(a) Beam and truss elements *(b) Overview*

***Figure 3**: Analysis model (1716 Nodes, 3050 elements)*

https://doi.org/10.52202/069179-0329

The shear resistance of the wall and brace were modelled as shown in Figures 4(a) and (b), with bracing substituted by truss elements for the walls and two truss elements for the fascia walls with separate load-deformation relationships on the tensile and compressive sides. Each spring acts only in the compression and tension directions. The joints were modelled with rotational springs, compressional and tensile springs (rigid against shear), as shown in Figure 4(c). The skeletal curves were defined based on the results of flexural and tensile tests of the joints. The tensile spring was assumed to be a spring with slip-type characteristics, and the compressional spring was assumed to be an elastic spring. The rotational spring acts independently in the strong and weak axial directions. Figure 5 shows the skeleton curve of the walls and braces, and the skeleton curves of the tensile and rotational springs. The resilience characteristics of the walls and braces are the bilinear + slip skeleton curve [15] (Figure 6), which is used as a simple modelling method for walls of wooden houses, while the tensile and rotational springs are defined as slip-type history characteristics.

The input seismic motion was the acceleration measured at the center of the shaking table; the time history of acceleration at 100% BSL and the acceleration response spectrum are shown in Figure 7. As in the experiment, the seismic motion was input in the order of 90% BSL to 160% BSL.

Numerical integration was performed using the average integration method with a step of every 10^{-5} seconds. Viscous damping was set to 2% with instantaneous stiffness proportional to the instantaneous stiffness, and zero damping was set when the instantaneous stiffness was negative. The weight of each layer was set to be equal to the weight measured in the full-scale shake table test by distributing half of the wall load to the upper and lower layers at the center of each floor height. 3.2 Analysis and experimental results

The time history response analysis was performed with analytical parameters based on the elemental tests. Figure 10 shows the test image of the BSL160% BSL and a simulation image of the same time in the time history response analysis. In the full-scale shaking table test, almost all of the column leg joints pulled out in specimen 2, and the entire building slid sideways. In specimen 1, the column legs did not pull out, but instead the damage was concentrated in the walls, resulting in the collapse of the building due to a 1F collapse. On the other hand, in the simulation, both specimens 1 and 2 collapsed and did not reproduce the experiment.

4 REPRODUCTIVE ANALYSIS

4.1 Outline of data assimilation

To analyse responses of the test, a 3-D simulation program "wallstat" was used. Figure 3 provides an overview of the data assimilation using orthogonal arrays. First, various skeletal curves are created by multiplying the parameters that simulate elemental experiments by correction factors (1. Definition of the parameters). These parameters are set as the skeletal curves for the springs in the analytical model, and multiple analyses are conducted (2. Numerical analysis). The results of the multiple analyses are compared with the experiments, and the correction factor range are analysed (3. Comparison). Then, the factor ranges are narrowed down by reviewing the initial range (4. Narrowing down the range of factor). Data assimilation was attempted by repeating this flow multiple times. In this study, we were able to obtain accurate results by repeating this process three times.

4.1.1 Definition of the parameters

In this study, mainly focusing on the input parameters for the walls, braces and joints, correction factors were multiplied to set the skeleton curve of the spring. The correction factor multiplied to the parameters are indicated in Figure 10.

Taguchi methods are statistical and based on the design of experiments (DOE), also called quality engineering to improve the quality of manufactured goods [16]. In the theory, the orthogonal array (OA) is a factorial-based approach combining statistical and engineering techniques [17]. The Taguchi technique employs OAs to analyze numerous variables with fewer experiments [18]. Moreover, inferences from the reduced number of experiments apply to the entire experimental region spanned by control factors and levels [19]. Therefore, this method allows data assimilation of many parameters without too much numerical analysis. Therefore, OAs in the Taguchi method was applied to conduct the time history response analysis. The OA is a type of general fractional factorial design. It is a highly fractional orthogonal design based on a design matrix proposed by Taguchi and allows one to consider a selected subset of combinations of multiple factors at multiple levels. OAs are balanced to ensure that all levels of all factors are considered equally. Therefore, the factors can be evaluated independently, despite the fractionality of the

design. In this study, 12 eleven-level factors and the orthogonal array, which is to examine the effects of those factors and called L121, were adopted. In L121, to clarify all effects of 12 eleven-level factors, 121 combinations are planned. Table 5 shows two orthogonal arrays (L121) that targets the 11 significant analytical parameters of rotational springs and young's modulus, along with the factor levels of the coefficient. The correction factors were set as 11 levels, equally spaced from minimum to maximum. In the numerical analysis, we multiplied the coefficient and the property. If we try to conduct all combinations, 9.85×10^{24} (= (1112)2) cases are simulated. Using combination of two OAs, 14641 (=1212) cases are needed.

4.1.2 Numerical analysis

The analyses planed in phase 1 were conducted using JAXA's HPC "JSS3" [20]. Using a common computer will take 600 days but using the supercomputer JSS3, it took 15 hours to complete 14,641 analysis cases.

https://doi.org/10.52202/069179-0329

4.1.3 Comparison

Focusing on the inter-story displacement, shear force, and uplifts deformation of walls measured in the full-scale shaking table tests, four model validation criteria related to the difference between the analytical and experimental results, shown below, were calculated for each case of analysis (14641 cases).

(i) Total distance of points on the graph in the load-deformation relationship for each layer

Draw the load-deformation relationship and sum the distances between the plots in the analysis and the plots in the experiment at all times. The interlaminar deformation was measured in 7 streets for each layer, but three streets, one at both ends and the center street, were targeted for the inter-story drift, and all the summed values were calculated. (Equation-(1))

$$nSm = \sum_{k=1}^{3}\sum_{i=0}^{20}\sqrt{({}_{anmk}D_i - {}_{exmk}D_i)^2 + ({}_{anmk}Q_i - {}_{exmk}Q_i)^2} \quad (1)$$

where *exmkDi*: inter-story drift in the *m*-story *k*-street in experiment at *i* second, *anmkDi*: inter-story drift in the *m*-story *k*-street in analysis at *i* second, *exmkQi*: shear force at in the *m*-story *k*-street in experiment, *anmkQi*: shear force in the *m*-story *k*-street in analysis.

(ii) Inter-story drift in each layer

The difference in Inter-story drift between the analytical and experimental results for all layers at all times when the earthquake motion was input was summed for each sampling period of 0.01 (s). The inter-story displacement was measured at seven streets in each layer, and calculations were made for three streets: the streets at both ends and the center street. (Equation-(2))

$$nDm = \sum_{k=1}^{3}\sum_{i=0}^{20}|{}_{anmk}D_i - {}_{exmk}D_i| \quad (2)$$

(iii) Shear force in each layer

The difference between the analytical and experimental results for the layer shear force was calculated at all times when the earthquake motion was input. (Equation-(3))

$$nQm = \sum_{k=1}^{3}\sum_{i=0}^{20}|{}_{anmk}Q_i - {}_{exmk}Q_i| \quad (3)$$

(iv) Uplift deformation of walls in 1F (14 locations)

The difference of uplift deformation of 1-story walls between the analysis and the experiment was summed up at all times. The difference of load-deformation curves between layers was evaluated in (1). However, if the results of the lifting of the legs were different, it could not be said that the three-dimensional behaviour during the experiment was reproduced, so the uplift deformation was also included in the evaluation. (Equation-(4))

$$nUD = \sum_{l=1}^{14}\sum_{i=0}^{20}|{}_{anl}UD_i - {}_{exl}UD_i| \quad (4)$$

Where, *anlUDi* : the uplift deformation of wall leg at point l in the analysis at i second, and *exlUDi* : the uplift deformation of wall leg at point l in the experiment.

These values are calculated separately for BSL90% and 160%, and the difference between the analytical and experimental results is evaluated to create a factorial effect diagram. For all criteria, the closer the values are to zero, the smaller the difference between the analytical and experimental results.

A comparison of the calculated results of each model validation for 14,641 analysis cases is shown in Figure 11.

The horizontal axis of each figure is 1S1, which is the distance between the points on the graph for the load-deformation curve in 1F at BSL90%, and the values on the vertical axis are changed. In (a), the vertical axis is 1UD targeting the uplift deformation at BSL90%, with values of 1UD greater than 40 x 10^6 shown in black and others in grey plot. The same trend can be seen in graphs (b) and (c), where the vertical axes are 1D1 and 1Q1 for inter-story drift and shear force in 1F, and the graphs are generally polarized with black values of 1UD greater than 40 x 10^6 and grey values for the other points. The positive correlation can be confirmed from (d) and (e). On the other hand, (f) shows that there is no significant correlation between 1S1 and 2S1.

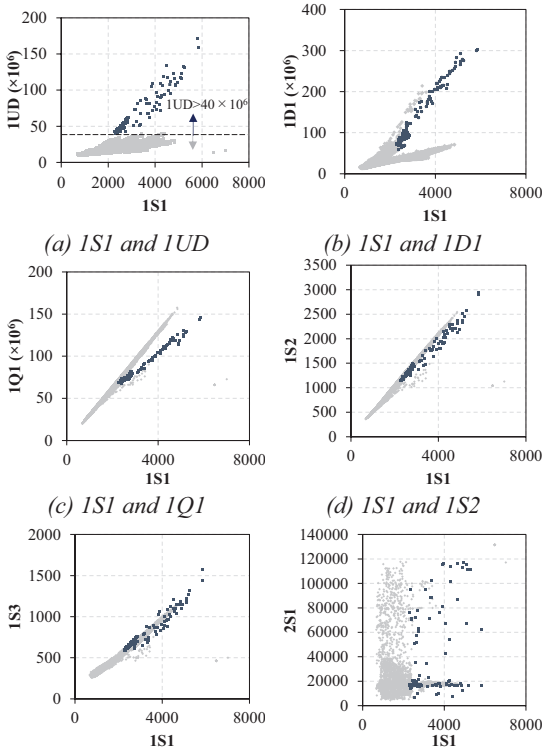

***Figure 11**: Comparison of evaluation (Wall_K_s1 of the Specimen No.1)*

4.1.4 Narrowing down the range of factor

The results of the analysis were evaluated using a factorial effect diagram in quality engineering. This figure is used to identify input parameters that are sensitive to output parameters and to analyse the range of correction factors that reduce the difference between experimental and analytical results. To minimize the difference between the analytical and experimental results, the next step is narrowing the factor range of each parameter. From the results in this phase 3, we can make the graph of factorial effect for each parameter, and we can narrow the ranges of other parameters to move to the second cycle. For the next, the same procedure was conducted, and the ranges were narrowed down using the figures. In the presentation, detailed results and the process will be discussed.

5 RESULT AND DISCUSSION

Figure 12 indicates comparison of the images from the full-scale shake table test, and reproductive analysis, respectively. In the test, almost all of the column legs were uplifted in specimen 2 and the entire building slid, while in specimen 1, the column legs did not pull out, but instead the damage was concentrated in the walls and the building collapsed. In reproductive analysis, the same behaviour of the test was confirmed and the proposed method in this study was verified. As for the load-deformation curves, similar results were got.

6 CONCLUSIONS

In this study, we tried the reproductive analysis of the full-scale shaking table test on two 3-story wooden houses to verify the validity of the proposed data assimilation method using quality engineering. The reproducibility of the analysis confirmed the validity of the data assimilation method, as it was able to track the experiment behaviour well.

ACKNOWLEDGEMENT

This research was conducted as part of a collaborative research by Kyoto University, Osaka Institute of Technology, and JAXA, "Examination of data assimilation method for simulation of collapse analysis of wooden houses using quality engineering". In the time-response analysis, we used the Japan Aerospace Exploration Agency supercomputer system "JSS3". The full-scale shaking table test targeted in this study was conducted as part of the Ministry of Land, Infrastructure, Transport and Tourism-subsidized project “Design Method Verification Project for Three-Story Wooden Frame Construction Methods”.

TIMBER-BASED SEISMIC RETROFIT TECHNIQUES FOR EXISTING MASONRY STRUCTURES IN NORTH EUROPE

Joakim P. Munden[1], Francesco Graziotti[2], Guido Magenes[3], Roberto Tomasi[4]

ABSTRACT: This paper presents the results of an application of seismic retrofitting techniques to an existing masonry structure in Oslo. Due to low seismicity, the Norwegian National annex of 1998-1 (EC8-1, Standard Norge, 2021) allows omission from seismic design of several structures. Furthermore, the EC8-3 Norwegian National annex (Standard Norge, 2013) states that, unless the probability of collapse in the case of an earthquake changes significantly as result of a general refurbishment of the structure, it is not necessary to perform seismic retrofitting of the building. However there are cases where, depending on the geographical site, intended use or changes to the lateral force resisting structure, it is necessary to perform seismic analysis and possibly strengthen the building's resistance to seismic forces. In this paper, a real case study is used to investigate how the effect of changes to shear walls due to a refurbishment intervention can reduce the capacity of a masonry building, and how two combined timber based retrofit systems can reduce the probability of collapse after the interventions: timber posts working as "strong-backs" with nailed OSB connected to the internal surface of the masonry walls; OSB panels applied to the timber floor.

KEYWORDS: Strengthening masonry structures; timber engineering; masonry shear walls; earthquake strengthening.

1 INTRODUCTION

The background of this study is the need to understand how seismic loads should be evaluated for changes such as renovation or change of use for existing masonry buildings, with a focus on a masonry type construction which is typical in Oslo. Oslo is located in an ancient deep rift zone corresponding to Oslofjorden, which is relatively active but with fairly low seismic loads [1]. The biggest recorded seismic event occurred in 1904, with the Ms 5.4 Oslofjorden earthquake. Masonry buildings constructed during the period 1850-1920 make up a significant part of the building stock in Oslo (Oslo Byleksikon [2], see Figure 1). The constructions are typically unreinforced masonry consisting of clay bricks and lime mortar. The floors are wooden beams.

Building standards for designing resistance to seismic forces were introduced with the Eurocodes in Norway in 2004. For certain buildings the codes require demonstration of capacity against earthquakes for both new buildings and changes in existing buildings. In cases where seismic design cannot be omitted according to EC8-1[3] , the construction must be demonstrated to be resistant to seismic forces.

EC8-1 has a set of criteria for when seismic evaluation is not necessary. The latest revision as of June 2021 has a new set of rules regarding omission of seismic evaluation of structures. According to the National annex of EC8-1, most structures in Oslo in seismic class II or lower, will no longer need to be evaluated for seismic loads. However, if ground conditions are unfavourable and the building project involves a change in use, masses and/or altering of stabilizing constructions, a seismic evaluation should be performed. EC8-3 guidelines are given for the design of existing structures. The National Annex, paragraph NA.2.1[4], states the following:

"*The reinforcement of existing structures that have not been exposed to earthquake damage can be limited to changes or additions that change the load effect and/or the carrying capacity in such a way that the probability of collapse during an earthquake increases significantly if the structure is not reinforced. In the assessment, NS-EN 1998-1 is used for calculation of load effect both before and after the change/addition (Standard Norge, 2013, page 2 in the National Supplement, authors' translation)*."

The standard does not provide provisions for what is considered a significant increase in the probability of collapse. However, RIF - The Norwegian Association of Consulting Engineering Firms has a published the paper "Dimensjonering for jordskjelv av eksisterende konstruksjoner" [5]). In this paper, a significant increase is defined as a 20% increase in the risk of collapse during an earthquake. The RIF guide reviews EC8-3 and EC8-1 for use in the design of existing buildings, and provides recommendations for calculation methods for demonstration of significant increase. However, the paper does not go into detail on the practical application for masonry buildings.

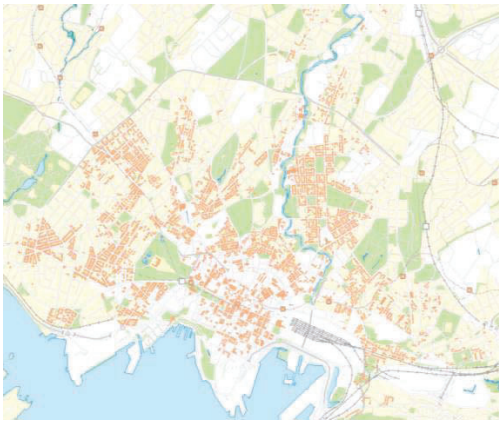

Figure 1: *Murbyen Kristiania, construction before 1915 (reproduced from Kart: Byantikvaren, 2011* [6]*)*

In Oslo (and probably Norway in general), seismic retrofitting of masonry structures is uncommon, and the perception amongst most building owners and people in general is probably that earthquakes don't impose a real threat in Norway. The aim of the study is therefore to look at simple seismic retrofitting strategies that are cost efficient and can improve the seismic resistance of the building structure so that the structure can withstand the design seismic load. For an existing construction where the lateral resistance is below seismic design loads, and the probability of collapse increases significantly after the changes have been made to the construction, the aforementioned guidelines are relevant to decide the need for retrofitting.

A large part of the building stock in inner Oslo consists of older masonry buildings that require repurposing or renovation.

The purpose of this study is to propose a retrofit technique when changes in masses, stiffness and/or strength constitute a significant increase for risk of collapse under seismic influence.

2 DESCRIPTION OF THE CASE STUDY

The project is a case study where a sample building is modelled with different situations where the walls' geometry is altered, introducing openings in lateral force resisting elements of the building.

The building in the case study is a typical masonry structure built around 1890 in the Grünerløkka quarter in Oslo, located in a densely populated residential area with buildings from the same era and with approximately equivalent geometry and construction methods.

The structures have a fairly consistent building design, with a load-bearing structure with piers and spandrels of unreinforced masonry of solid bricks and with timber floors and roofs. The floor slabs consist of floor joists that are supported by the façade wall, the central wall, and the back wall.

Normally, the timber floors have a dimension of approximately 170mm x 220mm, spaced 700mm–900mm. Dried clay, often from the construction site was used between the floor beams to increase the capacities for insulation, fire-resistance and sound insulation (see for example Figure 2).

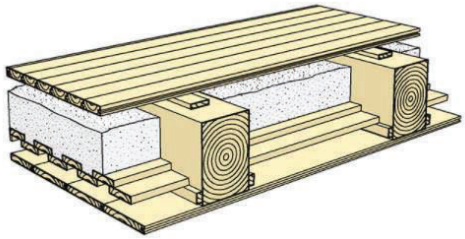

Figure 2: *Typical floor construction (Sintef Byggforsk 2017, reproduced from* [7]*)*

The building is relatively symmetrically designed, even if not completely regular on the ground floor. In the sample building, the structural design was changed in the 1960s by partially demolishing the load-bearing walls at the ground floor, to create more open spaces better suited for serving or retailing. All changes were in the main load-bearing walls in the X direction (façade wall, central wall, and back wall, see Figure 3). For the calculations, the existing/original situation is as it was before the renovation, while the new situation largely coincides with the actual changes in the load-bearing walls that were carried out in the 1960s.

The original (existing) and new situations for load-bearing walls in the X direction are shown in Figure 4. In the existing situation, the beams are dimensioned for the facade openings and the openings in the central wall. For changes in the new situation, both beams and columns are dimensioned.

The case study will be analysed both in the original situation and after the opening of the structure, in order to evaluate the effect of changes in terms of capacity of the building. The type of retrofitting techniques considered in this analysis will be the stiffening of timber floors and the application of timber strong backs with nailed OSB in the masonry walls in X direction.

A numerical model of the capacity of the structure is presented and the results are expressed in term of push-over curve, with respect to five design situations: original building; building after the opening; building with timber floors stiffened at the first storey; building with one wall retrofitted with timber strong-backs and OSB; building with timber floors stiffened at the first storey and one wall retrofitted with timber strong-backs and OSB.

The push-over capacity curve has been derived considering the mean mechanical parameters reported in Table 1 based on common practice in Norway for week mortar brick type of masonry with an assumption for cohesion value (i.e. 0.4).

3 PROPOSED RETROFIT TECNIQUES

3.1 ENHANCEMENT OF THE MASONRY

The proposed retrofit system is based on the strengthening solutions proposed and tested by Dizhur et al. [8], which involves the use of vertical timber posts connected to masonry walls to improve their out-of-plane capacity. The solution herein reported has been further developed by Guerrini et al. [9] and Miglietta et al. [10] to also improve the in-plane strength and deformation capacity of piers and the connection between masonry and floor systems. In fact, the lack of connections between masonry and flooring is a significant weakness in existing URM buildings and is addressed by the proposed retrofit system.

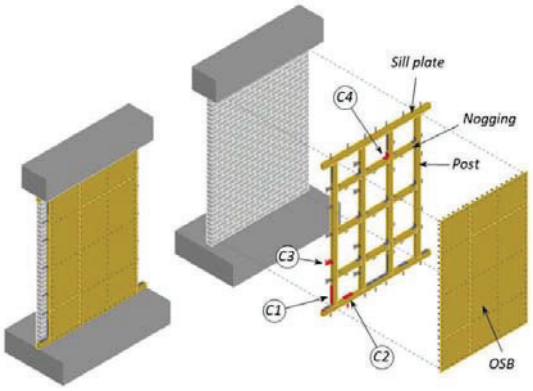

Figure 5: *Retrofit components and layout* [9]

The proposed retrofit system aims at improving the in-plane capacity of piers by adding horizontal timber members (nogging or blocking) between vertical posts to create a timber frame connected to the masonry. As shown in Figure 5, the frame is completed with top and bottom sill plates that connect to the floor and foundation. There are four different connection types: C1 (connections between posts and sill plates), C2 (anchorages between sill plates and floor/foundation), C3 (connections between timber frame and masonry wall), and C4 (connections between timber frame components).

The vertical posts improve the masonry wall's out-of-plane response by acting as strong-backs in flexure. The timber frame and OSB panels increase the pier's in-plane capacity by interacting with the masonry through connections C3. The posts and tie-down connections (C1) contribute to in-plane flexural strength, while the OSB layer and nailing contribute to in-plane shear strength.

The connection enhancement between masonry and floor offered by the retrofit system is critical in improving seismic performance as it promotes a global box-type response, preventing the onset of undesirable local mechanisms that can greatly reduce the building's seismic capacity. The system could be applied in one or both sides of the masonry, considering architectural limitations and required level of improvement.

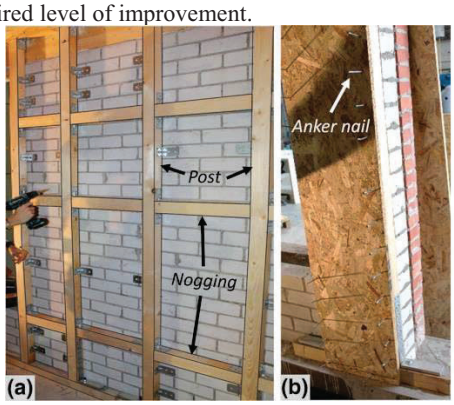

Figure 6*: Pictures of the retrofit system during the application on a building specimen tested on shake table: a) wall timber frame, b) nailing of a OSB for in-plane strengthening of longitudinal walls* [10]

This retrofit technique has been validated through components [9] and shake table tests on an entire URM building [10], as reported in **Error! Reference source not found.**. Analytical formulations to design this retrofit intervention are reported in Damiani et al. [11].

3.2 ENHANCEMENT OF THE FLOOR DIAPHRAGMS

Another structural element that may require to be stiffened and strengthened to transfer the shear between walls on different vertical planes and to assure a box-type response are the flexible timber diaphragms. Different strengthening techniques have been proposed in the past (see [12, 13]), but a typical in-plane floor reinforcement might use 18-mm thick OSB panels attached to the existing planks using anker nails and timber blocking beams inserted between joists. The blocking elements and joists have to be connected using steel angles and screws.

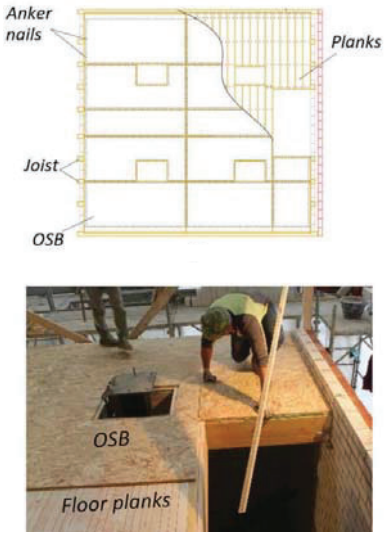

Figure 7: *OSB panels layout and picture of the diaphragm retrofit system during the application on a building specimen tested on shake table* [10].

The system could in principle be applied from underneath the diaphragm or on top of the diaphragm adapting the adequate detailing. Analytical formulations to design this retrofit intervention are reported in Damiani et al. [11]

4 MODELING OF THE RETROFIT INTERVENTIONS

4.1 STRUCTURAL ANALYSIS SOFTWARE

The commercial software selected for the analyses is 3Muri. It is based on the macro-element approach (with elastoplastic pier and spandrel behaviour) and allows execution of nonlinear static (i.e. pushover) and analyses of entire masonry buildings, by means of an equivalent-frame idealisation of the structure (Lagomarsino et al. [12]. This analyses allow to estimate the global capacity and behaviour of the structure.

The nonlinear static analyses were carried out with two different force distributions (e.g. mass proportional and first mode distributions), indicated by several codes (e.g. EN 1998-1, 2004, Eurocode [3]), to account for the dynamic response in the different phases of damage evolution.

The force distribution is applied along two orthogonal directions (both positive and negative), also taking into account accidental eccentricities introduced by the codes to account for uncertainties in the location of masses. Since the building originally has flexible timber floors, the position of the control node is critical. For this reason, one of the nodes belonging to the central wall at the top level was selected, as it was considered representative for the portion of the building with a higher displacement.

The proposed analyses are valid for evaluating the overall behaviour of the structure. Local analyses, such as the evaluation of out-of-plane mechanisms of masonry or the actual effectiveness of the steel beam inserted in place of the removed portion of masonry, should be evaluated with specific methods or software (these calculations are beyond the scope of this paper).

4.2 DEFINITION OF THE INTERVENTIONS

The building work carried out on the ground floor, such as the widening of openings, and in particular the central wall, worsens the seismic capacity both in terms of maximum shear at the base and displacement. Structural retrofit solutions must therefore be aimed at restoring the original structure's resistance and deformation capacity. In order to minimize the cost of the intervention, especially in terms of invasiveness for residents on the upper floors, it may be possible to intervene locally only on the ground floor.

The best solution from a seismic performance point of view would be to retrofit all the diaphragms and all the masonry piers and spandrels. Considering that this solution may be too expensive and also takes up valuable space, three more cost-effective solutions are investigated in this paper: (i) the first is to retrofit only underneath the first diaphragm above ground floor to redistribute the shear between walls and give the structure a more box-like behaviour; (ii) the second is to retrofit the main pier in the central wall on both faces, as the length of this structural element has been heavily reduced, and (iii) the third solution is to retrofit both the floor and the wall pier. A scheme of the retrofit solutions can be seen in Figure 8.

Regarding retrofit of the masonry (ii, iii), increasing the shear and deformation capacity on the shortened pier appears to be the only solution that maximizes the cost/benefit ratio. As shown in Figure 9 in section number 5 in the original structure (at the top), the pier remained undamaged (green) until the structure's ultimate capacity was reached, while after enlargement of the openings, (central figure), the remaining pier was the first to reach ultimate deformation (orange). Retrofitting it by increasing both its strength and deformation capacities

https://doi.org/10.52202/069179-0330

allows the entire structure to have beneficial effect both in terms of base shear and displacement capacity.

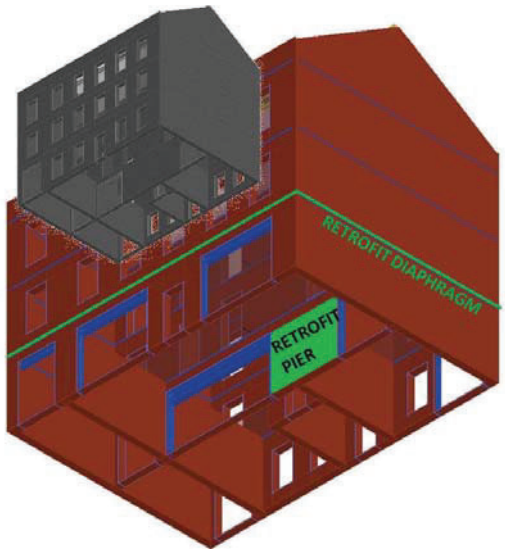

Figure 8: *Original and enlarged openings structures with scheme of the proposed structural interventions* [9]

4.3 MODELLING OF THE RETROFIT INTERVENTIONS

Detailed analytical formulations to design retrofit intervention are reported in Damiani et al. [13]. A detailed modelling of the same type of retrofit is also possible as reported in Damiani et al. [11]. For the preliminary study proposed in this paper, the retrofit was not designed in detail. The increase in shear strength and diaphragm stiffness was based on test results, and can therefore be considered plausible, but valid only for the specific details reported in Miglietta et al. [10]. The strength of the retrofitted masonry and the stiffness of the diaphragm may be increased or decreased depending on the nail spacing and/or on the thickness of the OSB or other detailing.

In particular, to model the presence of the retrofit for the masonry, the shear strength of masonry was increased by approximately 10 kN/m for the pier as experimentally assessed when retrofitting one side of the wall. As the pier is 3.6 meters in length, a retrofitting on both faces adds up to a shear strength increase of approximately 72 kN (about 1.5 times the strength of the non-retrofitted pier).

The ultimate shear deformation capacity of the retrofitted pier was increased from 0.5% to 0.8%. The latter value is conservative, as demonstrated by the physical testing described in [9]. For comparison 0.8% is the deformation capacity prescribed by Eurocode for reinforced masonry.

Concerning the diaphragm, the shear stiffness (expressed in terms of shear modulus times the thickness of the floor $G \cdot t$) was increased from 400 N/mm, a value assumed realistic for a flexible timber diaphragm with nailed planks, to 6300 N/mm for the diaphragm retrofitted with OSB, a value that can be considered plausible and valid for the specific detailing reported in Miglietta et al. [10]

5 RESULTS OF THE ANALYSES

As previously reported, the analyses were performed in all directions and for both force distributions (i.e. proportional to the first mode of vibration and proportional to the masses). For the sake of simplicity, only the results of the most critical analyses are reported here: parallel to the enlarged openings, with forces proportional to the masses and applying forces from left to right with no eccentricity.

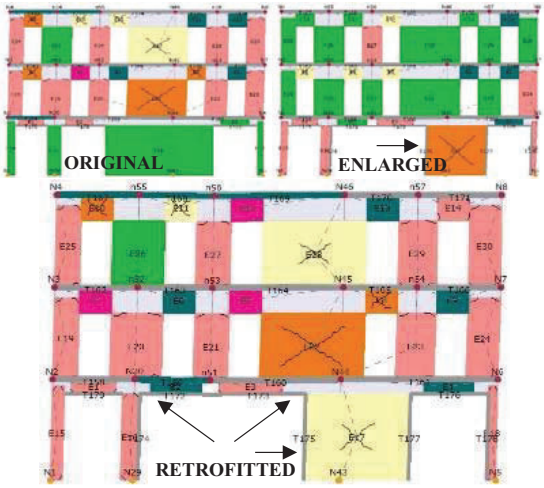

Figure 9: *Visualization of deformed shape and damage at ULS of the central wall for original (top left), enlarged openings w/o retrofit (top right) and retrofitted masonry and diaphragm (iii) (bottom) buildings.*

Figure 9 shows the deformed shape and damage at the ultimate limit state of the central wall (wall number 2 as per Figure 3) for the original (top left), enlarged openings without retrofit (top right), and retrofitted masonry and diaphragm (iii) (bottom). Analysing the top part of the figure, it is evident that the enlargement of the opening significantly affects the structure's behaviour. In the original building (top), the near-collapse condition is reached due to failures at the second storey, while the construction with enlarged openings collapses due to premature failure of the shortened pier at the ground floor, with walls in the upper floors almost undamaged. These results clearly suggest that a retrofit intervention should be focused on an enhancement of that particular portion of the building, both in terms of strength and deformation capacity.

The lower part of Figure 9 shows how the application of the retrofit to the masonry and diaphragm allows for more diffused damage through the storeys. In particular, the diffusion of damage throughout the storeys of the retrofitted structure is similar to the one obtained with the original one. This allows to avoid the soft-storey

mechanism of the building with enlarged openings increasing the displacement capacity of the building.
Figure 10 shows the deformed shape at ULS of the first diaphragm for enlarged openings without retrofit (left) and retrofitted masonry and diaphragm (iii) (right).

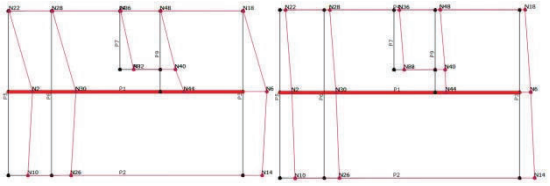

Figure 10: *Visualization of deformed shape at ULS of first diaphragm for enlarged openings w/o retrofit (left) and retrofitted masonry and diaphragm (iii) (right) buildings.*

The result of the analysis is shown in Figure 11. Firstly, comparing the original situation (black line) with the enlarged openings (red line) it is possible to observe a significant reduction both in terms of strength and displacement capacity (-16% both in terms of a_y* and d_u* according the bilinearization proposed by EC8).
Figure 11 reports the capacity (i.e. pushover) curves associated with the different models in terms of equivalent SDOF acceleration and displacement.

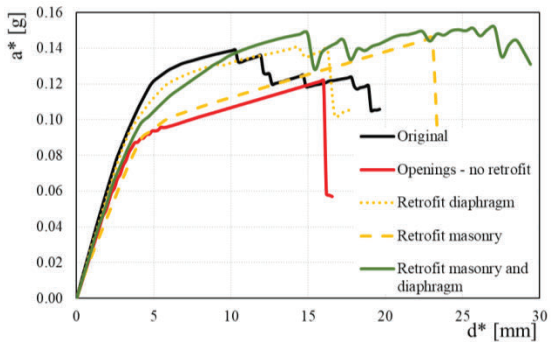

Figure 11: *Capacity curves associated with the different models in terms of equivalent SDOF acceleration and displacement.*

From the figure it is also evident that applying a retrofit intervention on the diaphragm alone (i) is beneficial for the overall strength, nearly restoring the capacity of the original situation. This is due to the inertia force primarily acting on the central wall with flexible diaphragm, while with the strengthened diaphragm loads are transferred also to the other walls, making use of their flexural/shear capacity. On the other hand, it is evident that this intervention does not restore the full displacement capacity of the original building. A representation of the difference between the behaviour of the original and the retrofitted diaphragm can be seen in Figure 10. Retrofitting only the central pier (ii) gives a different behaviour: this limited intervention is not able to restore the full strength of the building, but the displacement capacity is higher than the original situation (+21%); as visible in Figure 9, this is due to the combined effect of increase of displacement capacity of the ground floor pier and the increase of its strength, allowing for a better spread of damage throughout the storeys (i.e. avoiding the soft-story mechanism happening in the structure with enlarged opening but without retrofit interventions). Considering the positive effects of (i) and (ii), the best solution appears to be a combined retrofit of masonry and diaphragm. In this case (green line), both the strength and the displacement capacities were enhanced (+7% and +50% respectively from the original configuration).
Table 2 reports the SDOF parameters according EC8 [3]which summarize the results graphically represented in terms of capacity curves in Figure 11.

Table 2: *SDOF parameters associated with the different models according to the bilinearization proposed by EC8.*

	a_y* [g]	d_u* [mm]	Γ [-]
Original	0.13	19	1.31
Opening-no retrofit	0.11	16	1.28
(i) Retrofit diaphragm	0.13	16	1.26
(ii) Retrofit masonry	0.13	23	1.28
(iii) Retrofit masonry and diaphragm	0.14	29	1.29

6 CONCLUSIONS

Norway can be seen as a low to intermediate seismicity area, with a low seismic hazard and a low exposure level except the area around Oslo and on the west coast. The original motivation of this study is the need to understand how seismic capacity should be evaluated for changes such as renovation or change of use for existing masonry buildings, with a focus on a masonry type construction which is typical in Oslo. For that purpose, a case study of an existing brick masonry building has been analysed before and after a typical refurbishment intervention which introduces some opening in the lateral resisting masonry walls. The different design situations were investigated by means of a global analysis of the building through an equivalent frame macro-element model, using the commercial software 3Muri specific for masonry structures. The results of the analysis for the different cases were reported in terms of capacity curves.
The results showed that the intervention produced a significant weakening of the lateral capacity of the case study (around 16% both in terms of acceleration and displacement), even if, due to the low seismic input of Oslo area (PGA of 0.03g), the verification for seismic resistance could be still considered satisfied after the structural intervention. However, since these types of constructions are typical also of other area in Norway (and more generally in Northern Europe) where the conditions could be more unfavourable (higher seismic hazard, ground amplification), two retrofitting techniques, based on timber elements reinforcing the building structural elements, were investigated to reduce the probability of collapse after the weakening intervention: timber strong-backs with nailed OSB applied to both surface of a central masonry pier; OSB panels applied to the first floor level.

https://doi.org/10.52202/069179-0330

The results of the analysis showed both retrofitting solutions effectively improve the global performance of the building, and that a combined retrofit of floors and diaphragms produces the best performance both in terms of capacity and displacement.

ACKNOWLEDGEMENT

The execution of the analyses was partially funded by the DPC-ReLUIS within the framework of WP5 2022–2024 'Interventi di rapida esecuzione a basso impatto ed integrati'. The authors acknowledge Abdelghani Meslem for his suggestion and guidance during the preliminary analysis of the case study.

MODAL IDENTIFICATION AND MODEL UPDATING OF AN INNOVATIVE AUTOMATIC SELF-SUPPORTING TIMBER WAREHOUSE: THE CASE STUDY OF ROTHOBLAAS HEADQUARTERS EXPANSION

Ernesto Callegari[1], Roberto Girardi[2], Luca Gottardi[3], Andrea Incerti[4], Claudio Mazzotti[5], Luca Pozza[6], Sebastian Rodemeier[7], Luca Sestigiani[8], Mirko Tommasini[9]

ABSTRACT: Automatic Self-Supporting Timber Warehouse (ASSTW) is an innovative and sustainable structural system with a modal response strongly influenced by both the actual mechanical behaviour of structural elements and the load conditions. The structural analysis of ASSTW is typically carried out using numerical models calibrated referring to codified materials and connection properties. The reliability of the numerical simulations, used in the design phase, can be verified through modal identification on-site tests that also allow for a subsequent model update. This paper reports the main results of the modal identification on-site campaign, conducted by CIRI-EC laboratory of University of Bologna, of the new Rotho Blaas S.r.l. ASSTW in two different load conditions: unloaded warehouse with only the mass of the structural elements and partially loaded warehouse with eccentric mass. The subsequent model update phase is presented carrying out the most significant mechanical parameters to grasp the actual modal response of the structure.

KEYWORDS: Modal identification, Model updating, Self-Supporting Wooden warehouse, Timber structures.

1 INTRODUCTION

In recent years the use of wooden structural systems is increasingly widespread also for special building types typically made only of steel. Automatic self-supporting warehouse is a structural typology that can be profitably built using engineered wood-based products (EWP) allowing to optimize at the meantime: costs, sustainability aspects, aesthetic value and structural efficiency. This is due to the improved performances of the EWP and connection systems and to the use of advanced structural analysis and design methods [1].
Design of an Automatic Self-Supporting Timber Warehouse (ASSTW) can be developed in accordance with the current standard for the static and seismic actions [2,3] and for the fire safety [4].
The structural analysis of a ASSTW can be profitably carried out using numerical models calibrated referring to codified materials and connection properties [5]. Numerical models must be able to faithfully reproduce the static and dynamic response of structural systems characterized by significant plan dimensions and height. Modal identification on-site test represents a robust strategy for defining the actual building response and for the verification of the reliability of numerical simulations and for the subsequent model updating [6].
In this work, the case study of Rotho Blaas headquarters expansion, depicted in Figure 1, is used to describe both the innovative construction solution for ASSTW and the modal identification on-site tests adopted for the definition of modal response and for the model updating. Rotho Blaas ASSTW is one of the tallest wood warehouses in Europe, but also among the first to be fully automated, using conveyers, lifts and sliding shelving to speed and simplify the process (Figure 1-b).

2 DESCRIPTION OF ASSTW CASE STUDY

The ASSTW consists of a multifunctional timber skeleton: the shelving is part of the constructive system of the building together with the roofing and plugging elements. The shelves, which transfer the weights of the stored goods to the ground, also act as a load-bearing structure for the warehouse itself.

The Rotho Blaas ASSTW case study is schematically represented in Figure 2 and consists of three distinct volumes as follows:

- a main volume (1), to be used as an automatic warehouse, measuring 75 x 40 meters and 21 meters high;
- secondary volume (2), which will contain the goods entrance;
- an accessory volume (3), which will connect the new warehouse with the current one (4).

In the following the focus will be only on the main body of ASSTW (1).

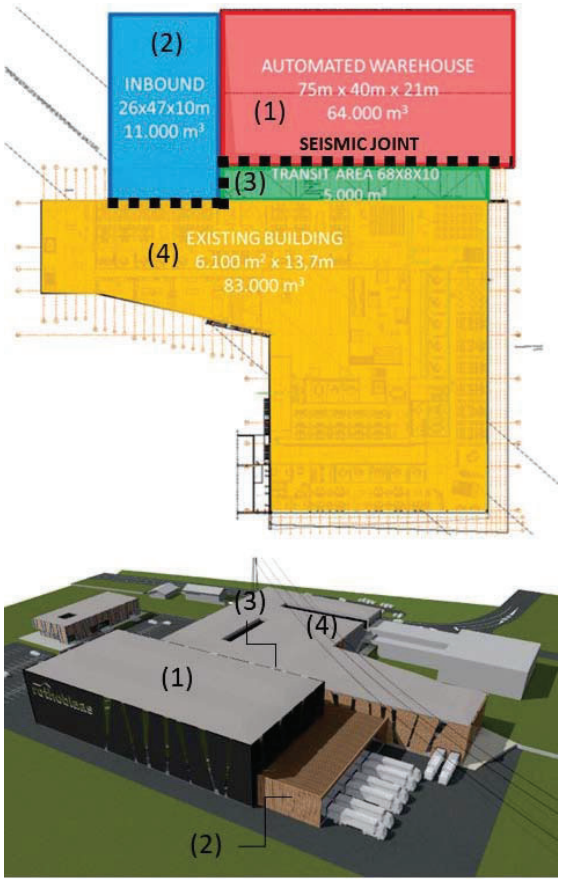

Figure 2: *3D scheme of the Rotho Blaas ASSTW*

3 MULTI-CRITERIA DESIGN

The architectural and compositional design recall the choices made for the existing buildings, which are characterized by large windows and a significant presence of timber, used both for structures and for flooring and coverings. Fire safety requirements, however, have imposed different solutions for the automatic warehouse which is almost entirely covered in aluminium, while the current sloping windows will be replaced by high-quality three-dimensional coatings made of larch strips, recalling the internal timber structures (Figure 3).

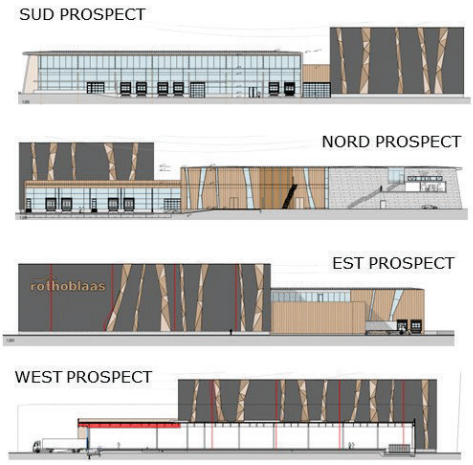

Figure 3: *External prospect of Rotho Blaas ASSTW*

As regard the structural layout, the Rotho Blaas ASSTW has a wooden skeleton (Glulam shelves and beams) enclosed by a CLT skin (roof and perimetral walls). More in details, the ASSTW is braced with two independent systems in the two directions (Figure 4).

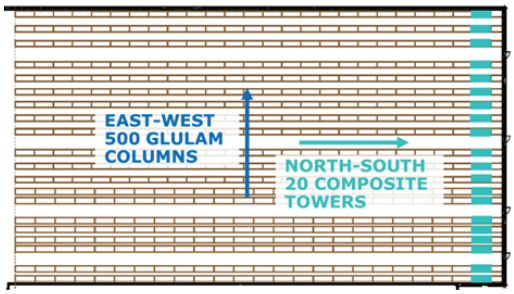

Figure 4: *Scheme of the bracing system for the north-south and East-West directions*

In the north-south direction (long side) twenty bracing towers consisting of a composite box section in LVL and glulam have been used (Figure 5). All the shelving is connected to the bracing towers in order to transfer the seismic forces onto them.

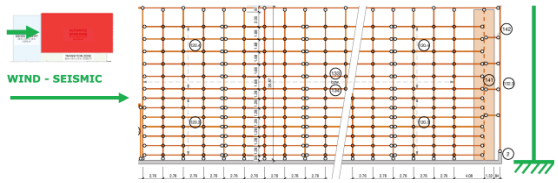

Figure 5: *Scheme of north-south bracing system.*

https://doi.org/10.52202/069179-0331

The composite box towers are embedded in the foundation by means of plates pre-inserted in the poured concrete (Figure 6).

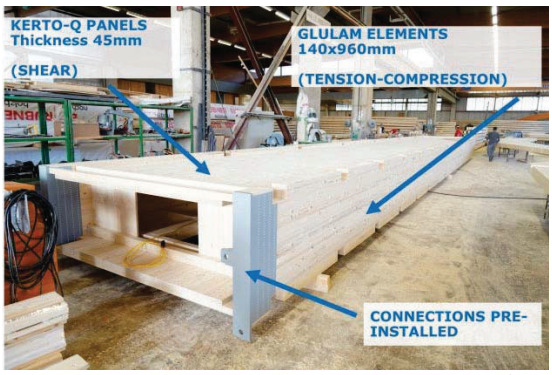

Figure 6: *View of the precast composite bracing tower during the manufacturing phase.*

In the east-west direction, the bracing system is constituted by the shelving itself (Figure 7), with the five hundred cantilevers interlocked at the base and connected to each other only at the roof (Figure 8). The roof is constituted by a framework of glulam beams and CLT panels, which create a limitedly deformable diaphragm.

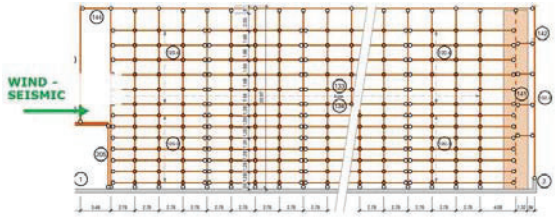

Figure 7: *Scheme of east-west bracing system.*

Figure 8: *Detail of the Glulam cantilever during the manufacturing phase.*

The main critical point of these structures is the deformability towards wind actions, which must be limited in order to allow the machines functionality. In fact, due to operational requirements, the project includes a displacement at the top (at a height of 20 meters) of only 19 millimetres in the east-west direction and 12 in the north-south direction (Figure 9).

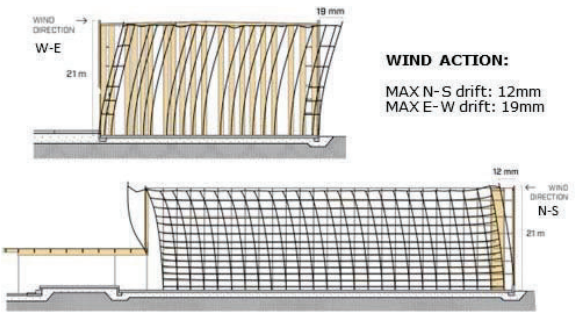

Figure 9: *Deformed shape and max drift of the ASSTW under the horizontal wind action in W-E and N-S directions.*

The ASSTW, is located in northern Italy, in an area classified as low seismic hazard. However, given the height of the building and the isostatic construction system, the seismic design was particularly challenging.
Therefore, a non-dissipative design was chosen, with a structure factor of 1.5 according to EN 1998-1 [3]. Since the building adheres to the existing building, it was necessary to create a seismic joint to decouple the dynamic behaviour between old and new structures (Figure 2).
Regarding to the fire safety, a R30 resistance for all the structures of the warehouse was adopted. It is worth nothing that, it is relatively easy to achieve the R30 requirement with properly designed timber structures. The R30 requirement also shifted the design of connections to solutions without exposed plates, using innovative timber-based materials instead of steel plates. Solutions with intumescent coatings to protect the steel were adopted where this was deemed unfeasible.
A further relevant aspect of warehouse design concerns the in-situ construction phases. In particular, the installation must ensure the stability of the structural system by exploiting the bracing elements of the system itself. Figure 10 shows some explanatory photos of the assembly sequence.

Figure 10: *In situ assembly phases – photo gallery.*

4 ON-SITE MODAL IDENTIFICATION

Goals of the on-site modal identification are:

- Characterization of the modal response of the warehouse in the initial post-construction configuration in order to verify over time, by means of periodic repetition of the dynamic tests, any

https://doi.org/10.52202/069179-0331

changes in the modal response and any system performance decay.

- Validation of the FE numerical model used for the seismic design and subsequent model updating for refined analyses to predict the warehouse response under different mass distribution.
- Identification of the interaction between the contiguous buildings and the stiffening effect of the external facade system.

On site modal identification tests were conducted by CIRI-EC laboratory of University of Bologna.

The modal identification on-site tests were performed installing 12 accelerometers (acc.1-12 in Figure 11) to measure the absolute accelerations of the structure along the longitudinal and transversal direction. Signal acquisitions were carried out when the ASSTW was subject to natural vibrations induced by wind or external vibrations [6].

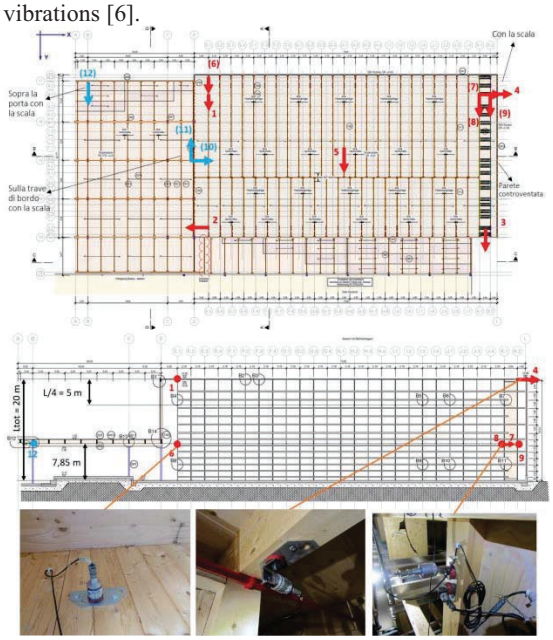

Figure 11: *Plan view and longitudianl section of the structural timber skeleton with indicated the localization of accelerometers employed for the modal identification.*

Two different load conditions were investigated: unloaded warehouse with only the mass of the structural elements and partially loaded warehouse with eccentric mass.

The Enhanced Frequency Domain Decomposition (EFDD) method [7,8] was used to process the on-site acceleration acquisitions obtaining an estimation of eigen frequencies and modal deformations of the Rotho Blaas ASSTW. The method derived from the on-site acceleration acquisition the power spectral density and subsequently the vibration eigenfrequency and modal deformed shape.

Results of modal identification are depicted, in terms of deformed shapes associated to the two principal eigen frequencies, in Figure 12 for the unloaded configuration and in Figure 13 for the partially loaded warehouse with eccentric mass.

Results demonstrate that the additional eccentric mass induces a variation in the principal eigen frequency and correspondent modal shapes. In detail it was observed a reduction of 1st eigen frequency value and modification of the modal response from translational to torsional. Moreover, a reduction of 2nd eigen frequency value was observed without significant modification of the modal response (translational in longitudinal direction).

Figure 13: *Partially loaded configuration - deformed shape associated to the: a) 1st mode; b) 2nd mode.*

5 MODEL UPDATING

The modal analyses of the ASSTW, in the different loading configuration, was carried out implementing a detailed Finite Element Model (FEM) considering both the main bracing elements and the stiffening contribution provided by the external massive walls made of CLT panels. The shelves were modelled as cantilever beam elements as well as the bracing towers while plate elements were used for the CLT outer skin panel and for the roof diaphragm. (Figure 14).

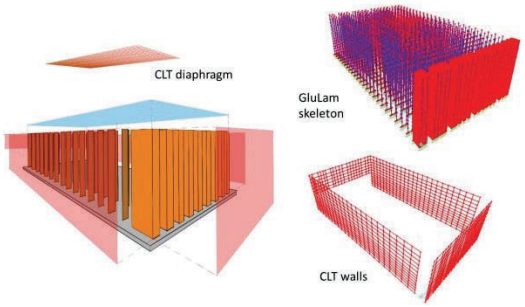

Figure 14: *Scheme of FE model components used for the model updating.*

Different modelling approaches [9] were used to predict the actual response of the warehouse: considering rigid or semi-rigid connections of the shelves and bracing tower; rigid or deformable diaphragm; considering all CLT walls, north and east wall, and no walls [10].
Results form analyses performed considering different modelling hypothesis demonstrate that, for the unloaded configuration, the most accurate model is the one with: fixed shelves and bracing towers; all external CLT walls and deformable diaphragm. This model ensures a good correspondence between FE analyses and identification results for both eigen frequency and modal shape. A comparison between updated FEM results and on-site identification test outputs is reported in Figure 15 for the 1st and 2nd vibration modes.

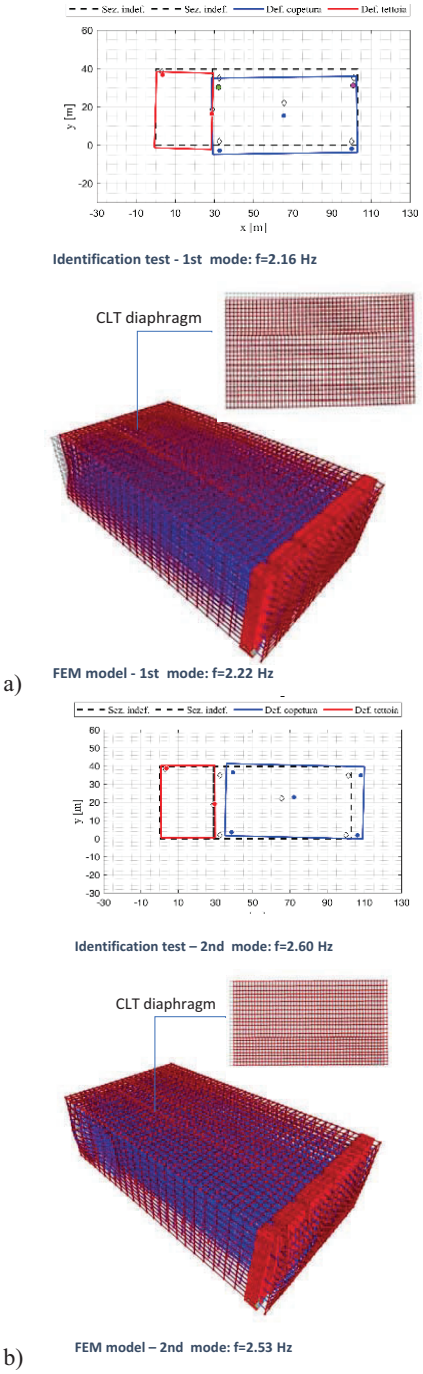

Figure 15: *Partially loaded configuration – comparison between FEM and on-site identification results: a) 1st mode; b) 2nd mode.*

Results substantially demonstrate that for small amplitude vibration (i.e. white noise) all the structural component are activated with a very stiff behavior. ***The*** FEM was also used to investigate the effect of the external CLT walls on the global response of the systems. It was observed that considering only the transversal walls the 1st eigen frequency is reduced from 2.22Hz to 1.46Hz. Otherwise, the system without CLT walls shows a 1st eigen frequency equal to 1.41Hz.

https://doi.org/10.52202/069179-0331

Comparative analyses demonstrate that external walls stiffen the system but do not modify the 1st deformed shape of the warehouse that is governed by the bracing tower. The in-plane stiffness of the roof diaphragm was also investigated. Results highlight that whit a rigid diaphragm the 1st eigen frequency is equal to 2.58 Hz and therefore greater than the reference one (deformable diaphragm - 2.22 Hz). It means that, despite the rigid panel to panel joint, the significant in plant dimension of the floor diaphragm requires a deformable modelling approach.Finally, the updated FEM was used to predict the response of the structure in different load cases: empty; 30% eccentrically loaded; 100% loaded. Figure 16 reports the results from the FE analyses.

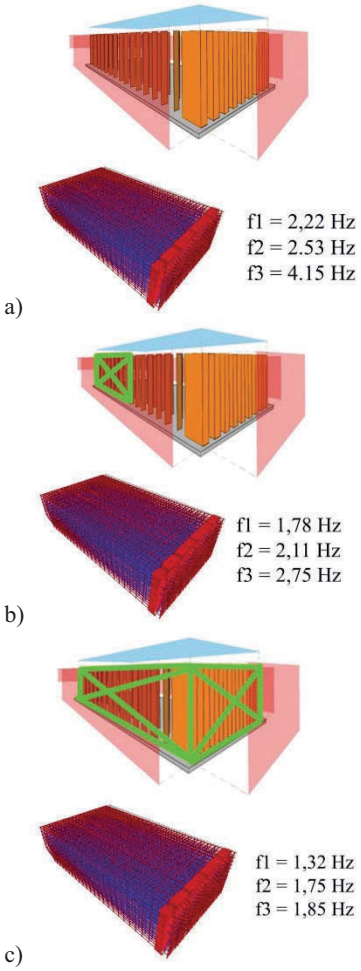

Figure 16: *principal eigen frequencies carried out with FEM analyses for different loading condition of the warehouse: a) empty; b) 30% eccentrically loaded and c) 100% loaded.*

It can be noted that for the 30% eccentrically loaded configuration, results demonstrate a good agreement with outcomes from on-site identification tests. Moreover, a significant reduction of the 1st eigenfrequency is observed for the 100% loaded configuration.

CONCLUSIONS

This work demonstrates the possibility to realize efficient and safe automatic self-supporting warehouse using EWP and high-performance connection elements.
Modal response of such special timber structure can be profitably verified using on-site model identification tests. The FEM can be therefore updated using results of on-site modal identification thus providing a more reliable simulation of actual structural response at global and local level.

EVALUATION OF THE STRUCTURAL PERFORMANCE OF SHEAR WALLS BUILT WITH MULTI-LAYER COMPOSITE LAMINATED PANELS

Lin Zheng[1], Sigong Zhang[2], Meng Gong[3],Ying Hei Chui[1]

ABSTRACT: An innovative multi-layer composite laminated panel (CLP), comparable to CLT, has been developed by combining Laminated Strand Lumber (LSL) and dimension lumber to overcome the rolling shear failure while maintaining high mechanical performance and the aesthetic appearance of natural wood. Experimental investigations have been conducted to assess the lateral resistance of CLP connections using self-tapping screws, as well as full-scale CLP shearwalls with varying connection layouts to achieve the target kinematic wall behaviour under both monotonic and cyclic loading. The findings indicate that incorporating Laminated Strand Lumber (LSL) in the laminations has a substantial impact on the mechanical properties of the connections. Replacing lumber with Laminated Strand Lumber (LSL) in the core layer exhibited a remarkable increase in stiffness and strength, and tended to fail in a ductile manner, while the utilisation of LSL in face layers enhanced stiffness and strength, but reduced ductility. Furthermore, the shear wall layout and the number of self-tapping screws in each connection were found to dramatically affect the overall structural performance of the shear wall.

KEYWORDS: Composite Laminated Panel (CLP), Shear walls, Connection properties, Mechanical properties.

1 INTRODUCTION

Over the past decade, mass timber panels (MTPs) have been increasingly implemented in construction as a sustainable and cost-effective building material. The best-known MTP product is cross-laminated timber (CLT), made from sawn lumber planks orthogonally glued together. As a viable product in the mid- and high-rise construction market, CLT offers a promising solution for a diverse range of structural applications in both all-wood and wood-hybrid buildings, including roof, floor, and wall assemblies, and is increasingly replacing other traditional materials such as steel and concrete. The panels can be easily connected to other structural members or materials using fasteners and connectors. The invention of CLT has significantly advanced panelised building technologies.

Although CLT possesses both good dimensional stability and the ability to transfer forces in two-way directions due to its crosswise lamination, its transverse layers are prone to rolling shear failure under out-of-plane loading. This is why new generations of MTPs are being driven forward. The prototype of the next generation of MTP is a combination of lumber and Structural Composite lumber. An innovative multi-layer composite laminated panel has recently been developed by combining laminated strand lumber (LSL) and dimensional lumber to overcome the rolling shear failure while maintaining the high mechanical performance and aesthetic appearance of natural wood, which is referred to here as composite laminated panel (CLP). Test results [14] show that the shear strength, bending stiffness, and moment resistance of CLP were up to 143%, 43%, and 87% higher than their counterparts of regular CLT, respectively, and the use of LSL in transverse layers could eliminate the potential rolling shear failure in CLT. The above promising performance of CLP has prompted researchers to further explore the potential for using CLP as a means of providing lateral load resistance in building systems.

Currently, the most commonly used approach for MTP walls is to consider the MTP as a rigid body and the lateral resistance of the whole wall is mainly governed by connection systems. This theory is based on a set of experimental investigations on full-scale CLT shear walls subjected to lateral loads. [3-4, 7-8] As there are presently no standardized provisions for determining the lateral resistance of CLP shear walls, it is necessary to further investigate this innovative engineered wood product, CLP, used as a lateral load resisting system (LLRS). Additionally, two types of LLRS are typically considered in CLT buildings: monolithic shear walls and multi-panel shear wall configurations. However, in North America, the multi-panel wall configurations are favoured over monolithic shear walls, primarily due to its transportation convenience and potential to enhance energy dissipation in the panel joint connections. (Masroor et al. [13]). Hence, the structural performance of full-scale CLP coupled-panel shear walls were fully evaluated through both monotonic and cyclic loading tests. Accurate quantification of the CLP screw connections was also presented, as it is essential for understanding the shear wall behaviours.

2 MATERIALS

2.1 SPECIMENS

In total, 21 three-ply MTPs were manufactured by InnoTech Alberta (Edmonton, AB), consisting of 19 three-ply CLP panels with 4 different layer arrangements, and 2 three-ply CLT panels. Figure 1 gives an illustration of the four CLP layups. All shear wall specimens were assembled by placing two panels of the same type side-by-side and connecting them to each other using splice connections. Four shear wall specimen types were fabricated with these four layups respectively. Two specimens were produced for each type with one subjected to a monotonic test and the other to a cyclic test. In addition, one CLT shear wall was also tested as a reference under cyclic loading. Afterwards, specimens for connection tests were obtained by cutting the CLP panels from the undamaged parts of the panels after the shear wall tests.

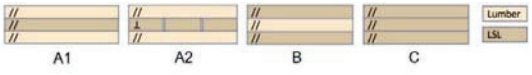

Figure 1: Illustration of CLP layups

2.2 FASTENERS

The study utilized SDS25300 self-tapping screws (STS) with a diameter of 6.35 mm and a length of 63.5 mm, as illustrated in Figure 2. They were made of SAE J403 low-carbon steel wire, possessing a bending yield strength of 1130 MPa (164000 psi), as stated by the manufacturer (SAE 2014). This type of screw has high strength in structural application with no-predrilling installation requirements, which is recommended for wood-to-wood and wood-to-steel connections.

Figure 2: SDS25300 wood screws (courtesy of Simpson Strong-Tie®)

2.3 STEEL PLATES

The steel side plate (HRS416Z) depicted in Figure 3 was manufactured from galvanized steel complying with ASTM A653, SS Grade 33, with a minimum yield strength of 227 MPa (33,000 psi) and a minimum ultimate tensile strength of 310 MPa (45,000 psi) based on the data provided by the supplier.

Figure 3: Steel side plate-HRS416Z (courtesy of Simpson Strong-Tie®)

3 EXPERIMENTAL PROGRAM

This section presents the experimental campaign conducted to investigate the mechanical properties of CLP screw connections as well as full-scale CLP shear walls. All tests were carried out at the Wood Science and Technology Centre, University of New Brunswick, in Fredericton, Canada.

3.1 CONNECTION TESTS

3.1.1 Test setup and procedure

The screw connection tests included 60 specimens with half being subjected to monotonic loading and the other half to reversed cyclic loading. CLP specimens with 4 different layups were tested, as well as a CLT specimen group used as a reference. Table 1 shows the connection specimen configurations. Three replicates were tested for each configuration.

The specimen dimensions were 200 mm × 120 mm × 107 mm for those with the load applied parallel to the face layer grain and 200 mm × 200 mm × 107 mm for those with the load applied perpendicular to the face layer grain. Each side of the CLP member had a 3mm thick steel plate attached using two STSs (SDS HEAVY-DUTY SDS25300), leading to a total of 4 STSs in 2 single-shear connections per specimen. The test setup is shown in Figure 4.

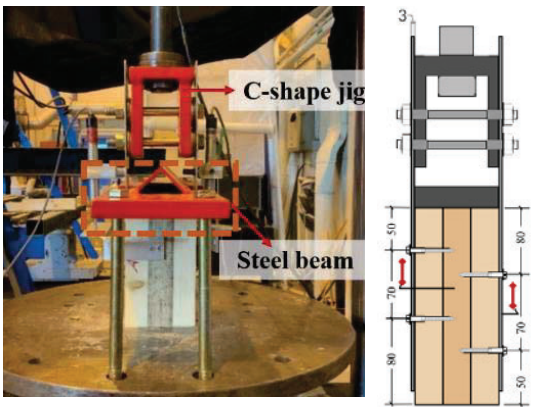

Figure 4: Connection test setup

The monotonic test was conducted at a loading rate of 5 mm/min prior to the cyclic test to obtain a reference displacement value for the cyclic test. The cyclic test was conducted using the reversed loading protocol based on the displacement-controlled loading procedure outlined in ASTM E2126 (Method B) [1].

https://doi.org/10.52202/069179-0332

Table 1: Test matrix for connection tests

Test series	CLP layup	Loading direction	Loading type
A1	L-LSL (par)-L	Par/Perp	m/c
A2	L-LSL (perp)-L	Par/Perp	m/c
B	LSL-L-LSL	Par/Perp	m/c
C	LSL-LSL-LSL	Par/Perp	m/c
CLT	L-L-L	Par/Perp	m/c

Note: "L" is lumber; "LSL" is laminated strand lumber. "Par" indicates the load applied parallel to grain, "Perp" indicates the load applied perpendicular to grain. "m" and "c" means monotonic and cyclic, respectively.

3.2 SHEAR WALL TESTS

3.2.1 Test setup

The CLP walls were anchored to a steel foundation using hold-downs and base shear connectors. As the rollers had horizontal translational and rotational degrees of freedom, four rollers (Ø 7 mm) were placed at the bottom of the panel in order to ensure that the movement of the panel was not restricted and also to prevent friction. A C-shaped channel was attached to the load cell and the actuator, transferring the lateral load through the pin joints to the CLP shear walls. The C-shaped channel was attached to the top of the CLP panel using two 25.4-mm bolts, evenly spaced. It should be noted that lateral supports were used in all the tests to prevent the out-of-plane movement of the wall by using parallel rigid bars and wooden blocks between the guides and specimen. Figure 5 illustrates the shear wall test setup. The shear wall test used Simpson Strong-Tie® steel brackets (Bracket AE116: 90 × 48 × 116 mm), hold-downs (HDU8: 422.5 × 90 × 35 mm). The steel plates used in the panel joint connections were identical to those used in the connection tests. Additionally, the same type of screw was used for all connections, as those tested in the connection tests. Table 2 describes all of the wall configurations tested.

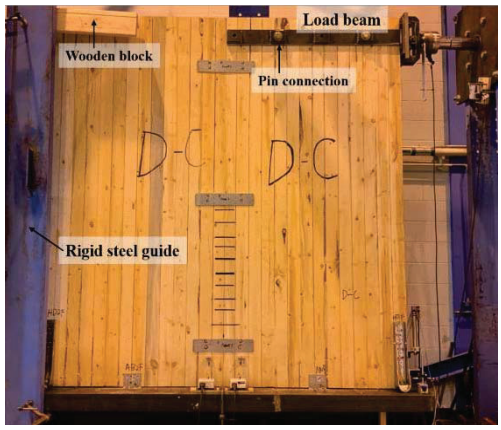

Figure 5: Shearwall test setup

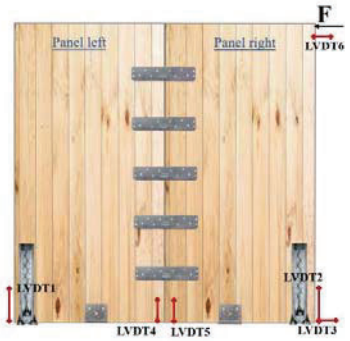
Six linear variable differential transformers (LVDTs) were installed on the specimen as shown in Figure 6.



LVDT1: Bottom left corner uplift (negative)
LVDT2: Bottom right corner uplift (positive)
LVDT3: Sliding
LVDT4: Central panel uplift (positive)
LVDT5: Central panel uplift (negative)
LVDT6: Top horizontal displacement

Figure 6: The shear wall sketch with measurement instrumentation

3.2.2 Test Configurations

In this study, three main connections in the shearwalls were panel-to-panel, hold-down, and base shear connections. All these connections share a common characteristic that they can be represented by a steel-to-wood screw connection.

To investigate the kinematic wall behaviour and aspect ratios of the wall panels, different connection layouts were designed by varying number of STS in these connections. Specifically, two target kinematic wall behaviours were considered according to [3]: (a) **Coupled wall** - the wall segments of the coupled wall are connected with a relatively weak panel joint (yielding of the panel joint occurs before yielding of the hold-down/base shear connections) and the wall segment can slide relative to each other under lateral loading; (b) **Single wall** - two panels are connected with a stiff and strong panel joint (yielding of the panel joint occurs after yielding of the hold-downs/base shear connections) and the wall would rotate as a single panel under lateral loading, as illustrated in Figure 7. Identical heights of 2400 mm and widths of 1200 mm were adopted for all CLP panel segments, resulting in an aspect ratio of 2:1 for coupled panel kinematic behaviour and 1:1 for single wall behaviour.

Table 2: Shearwall test matrix

Test Wall ID	No. of screws in brackets	No. of screws in Hold-down	No. of vertical joints	Kinematic behaviour
A1-m	6	9	10	Single
A1-c	6	9	10	Single
A2-m	6	8	6	Coupled
A2-c	6	8	6	Coupled
B-m	6	7	6	Coupled
B-c	6	7	6	Coupled
C-m	6	7	6	Coupled
C-c	6	6	6	Single
D-c	6	8	6	Coupled

A total of 9 shear wall tests were conducted, four of which were monotonic tests and the remaining five being cyclic tests. Table 2 provides a detailed overview of the wall

https://doi.org/10.52202/069179-0332

configurations tested. All the tests were performed with no vertical load applied.

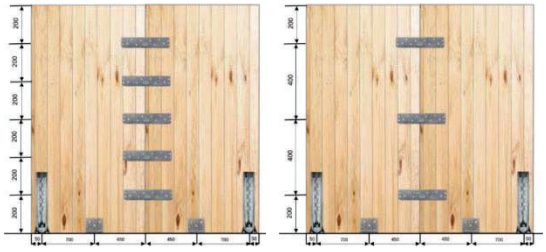


Figure 7: Kinematic wall behaviours: (a) Single wall behaviour (SW); (b) Coupled-panel behaviour (CP) (dimensions in mm)

4 RESULTS AND DISCUSSION

4.1 CONNECTION TESTS

4.1.1 Monotonic tests

Figure 8 and Figure 9 present the load-displacement curves (dashed lines) and their mean value curves (solid lines) of specimens subjected to monotonic loading parallel and perpendicular to the grain, respectively. The measured load values were divided by the total number of screws used to assess the capacity of an individual screw.

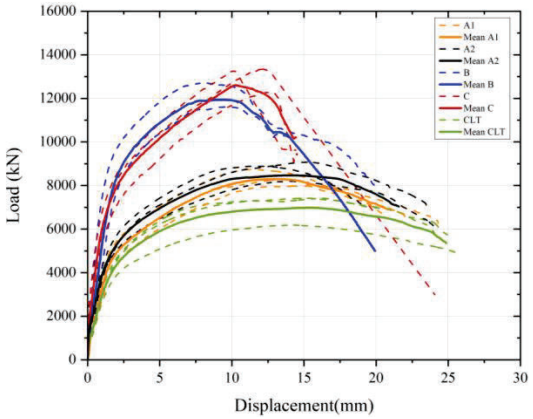

Figure 8: Load-displacement and mean value curves under monotonic load applied parallel to grain (per screw)

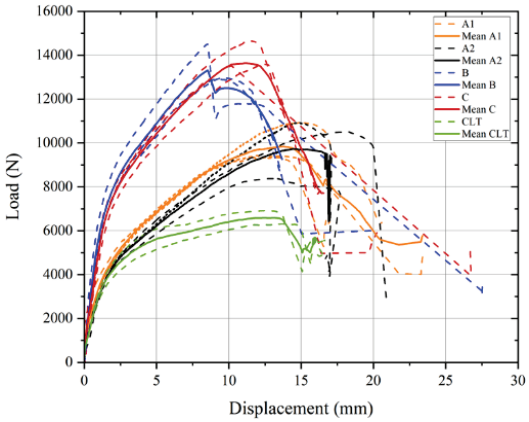

Figure 9: Load-displacement and mean value curves under monotonic load applied perpendicular to grain (per screw)

The presented figures highlight the distinctive behaviours of two test groups, categorized as layup A and traditional CLT in the first group, and layups B and C in the second. It can be observed that specimens A1, A2, and traditional CLT exhibited similar ductile behaviour, with comparable stiffness, yield strength, and ductility. Their load-displacement responses demonstrated that they could be loaded continuously beyond their yield point without significant loss of strength.

In contrast, the screws in specimens B and C demonstrated notably higher strength and stiffness but relatively low ductility. This phenomenon can be attributed to the use of LSL as the face layer of CLP. In other words, CLP with LSL on the face tends to have higher strength and stiffness than lumber on the face. This is because LSL had a higher density than sawn lumber. However, despite the higher strength of specimens B and C, the displacements at failure were extremely small. This observation becomes more apparent when the connection was loaded parallel to grain.

4.1.2 Cyclic tests

The cyclic test results are evaluated in terms of the peak load P_{peak}, yield strength P_{yield}, displacement at capacity Δ_u, displacement at yield load Δ_{yield}, stiffness K_e, ductility ratio μ and dissipated energy E_d according to the standard procedure ASTM E2126 [1]. The mechanical properties were analysed by considering both sides of the hysteresis loops. The mean values of the mechanical properties for each test group, together with the corresponding range of minimum and maximum values (values in brackets are the range of measured values), are presented in

Table 3. The cyclic mechanical properties of the testing group exhibit a trend similar to monotonic cases.

Table 3: Mechanical properties of CLP screw connections under cyclic loads

4.2 SHEAR WALL TESTS

4.2.1 Failure modes

The CLP shear walls behaved almost as rigid bodies during the test. The failure modes occurred mainly at the connections under both monotonic loading and cyclic loading, as displayed in Figure 10.

For monotonic loading cases, CLPA1-m failed due to both excessive uplift and shear of screws in the hold-down, resulting in slight plastic deformation of the hold-down (right corner), along with wood crushing and wood splitting around the hold-down and angle bracket were observed, while panel joint connection behaved elastically with no visible deformation or failure.

CLPA2-m failed mainly due to brittle failures occurring at the base shear connections (wood splitting and panel edge tear-out) (see Figure 10(d)). In addition, CLPB-m showed an obvious deformation in the hold-down (right corner) with screws pull-out (see Figure 10(a)). No failure was observed on CLPC-m due to the capacity of the test frame. The test was stopped before CLPC-m could fail.

In light of these observations, although CLPA2 and CLPB were designed to have flexible panel connections, the failures were predominantly localized at the hold-downs and base shear connections under monotonic loading. Nevertheless, it is noteworthy that the panel joint connection behaved in an almost elastic manner for all cases tested.

On the other hand, the dominant failure mode observed in the cyclic loading test was the screw yielding followed by screw withdrawal at the panel joint connections. The steel plate also exhibited some degree of plastic deformation, as shown in Figure 10(e) and (f).

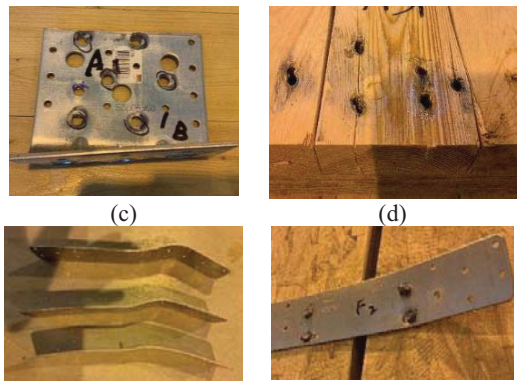

Figure 10: Typical failure modes of shear walls

4.2.2 Load-deformation response

The load-displacement response of each shear wall specimen under monotonic and cyclic tests was obtained. In addition, the envelope curve was generated from the cyclic load response by connecting the peak point of each load cycle. Figure 11 shows the monotonic and cyclic responses of the different wall layouts and the associated envelope curves. The EEEP curve analysis was performed in the same manner as the connection test data and the corresponding mechanical properties are given in

Table 4 and
Table 5.

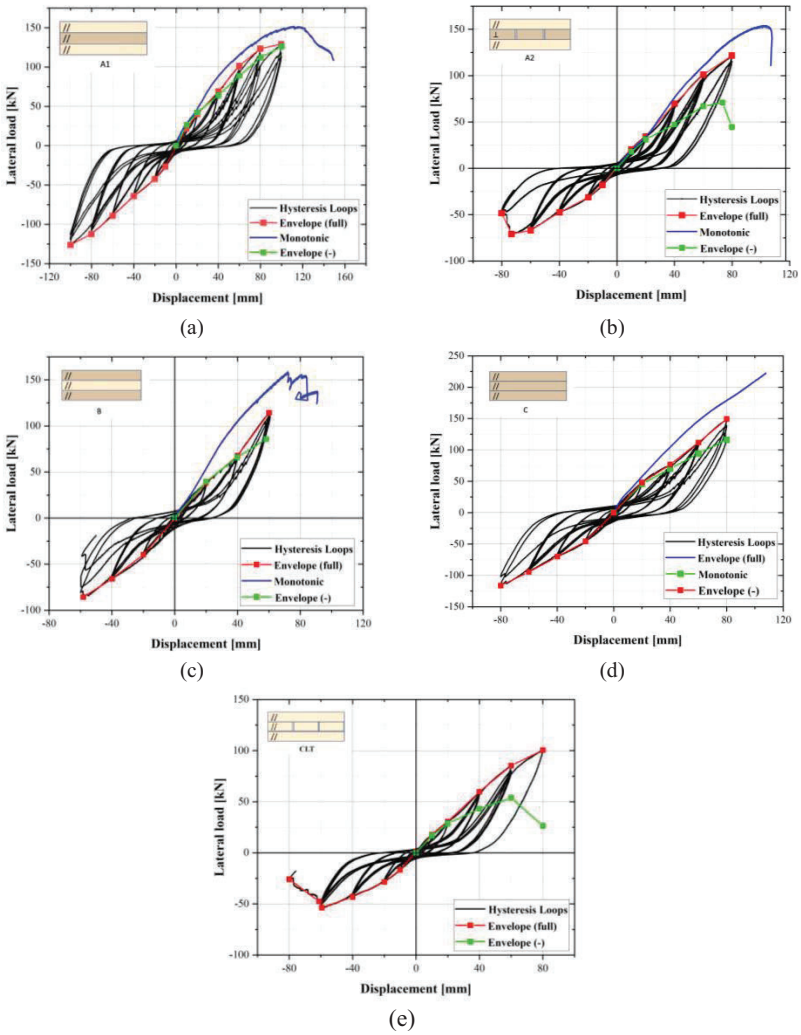

Figure 11: Comparisons of A1-c and A1-m(a), A2-c and A2-m (b), B-c and B-m (c), C-c and C-m (d) and CLT-c

Table 4: Test results of CLP shear wall tests under monotonic loading

Wall ID	K_e (kN/mm)	P_{yield} (kN)	Δ_{yield} (mm)	P_{peak} (kN)	Δ_{peak} (mm)	Δ_u (mm)	E_d (kJ)	$\mu = \Delta_u/\Delta_{yield}$
CLPA1-m	2.32	98.62	52.32	151.73	111.51	142.53	11.96	2.72
CLPA2-m	1.78	104.71	69.21	154.00	118.06	122.19	10.97	1.76
CLPB-m	2.39	80.28	57.25	158.89	91.1	157.77	12.12	2.75
CLPC-m	2.89	-	-	222.48*	95.59*	-	-	-

Note: * testing of wall CLPC was stopped before failure occurred.

Table 5: Test results of CLP shear wall tests under cyclic loading

Wall ID	K_e(+) (kN/mm)	K_e(-) (kN/mm)	P_{peak}(+) (kN)	P_{peak}(-) (kN)	Δ_{ult}(+) (mm)	Δ_{ult}(-) (mm)
CLPA1-c	1.81	1.90	129.18	126.17	99.59	100.1
CLPA2-c	1.78	1.73	121.77	70.92	79.85	79.53
CLPB-c	1.92	1.98	114.31	85.65	60.14	58.19
CLPC-c	2.38	2.26	149.33	116.32	80.03	80.01
CLT-c	1.49	1.65	100.66	53.77	79.97	77.53

The load-displacement response figures above clearly show the differences between the monotonic and reversed cyclic results. The peak loads from the monotonic tests were greater than the corresponding values for the cyclic tests, which was also observed by Popovski [8]. The peak loads from cyclic tests were reduced by 17.4%, 26.5%, 38.9%, and 48.9%, respectively, compared to the corresponding monotonic values. Furthermore, the ultimate displacements obtained from monotonic tests were also greater than the corresponding values obtained from cyclic tests.

In terms of initial stiffness, there is a reduction (20%) when compared to the monotonic test results. The largest difference was for the CLPC wall, with a 35% loss in stiffness under cyclic loading, which can be explained by the different connection details between the monotonic and cyclic tests. It should be noted that to reach the failure limit state of the CLPC wall under cyclic loading, the total number of screws in connection systems of the wall was reduced in the cyclic tests. Furthermore, it can be observed that CLPA1, CLPA2, and CLT walls showed progressively decreasing stiffness values before reaching the ultimate load, whereas a slight increase can be observed for wall CLPB and CLPC walls at displacements between 40 mm and 60 mm. This phenomenon further proves that the use of LSL in the face layer instead of lumber has made a difference.

In addition, the load-displacement responses of all the specimens appeared to exhibit relatively symmetrical load-deflection behaviour. The CLPA2 and CLT walls appeared to have some asymmetric response characteristics. A closer examination of the load-deflection responses would suggest that these walls exhibit apparent asymmetric load-deflection loops, as they failed in one direction before being able to reach the same level of displacement in the opposite direction. It should be noted that several previous studies (Popovski [8]; Dires et al. [5]) also observed the unsymmetrical lateral force-deformation curves for cyclic tests, and low-cycle fatigue may be one of the reasons.

5 CONCLUSIONS

Connection tests and full-scale shearwall tests were carried out for an innovative mass timber panel, CLP, to better understand their performance under lateral loads. From the connection test results, the core layer of the CLP had a non-negligible effect on the lateral strength of the STS connections but the overall performance of connections is less affected by the orientation of the core layer made of the same type of material. However, the face layer of LSL in the CLP significantly increases the stiffness and strength as the density of the face layer increased. Overall, it can be concluded that CLP had higher strength and stiffness than CLT regardless of whether LSL was placed in the face or core layer. However, specimens with lumber as the face layer and LSL as the core, i.e., A1 and A2, exhibited higher strength, stiffness and comparable ductility compared with CLT. This made them more suitable for seismic applications than traditional CLT and CLP with LSL as face layers (B and C).

Furthermore, the shear wall tests revealed that the resistance of coupled shear walls is mainly determined

https://doi.org/10.52202/069179-0332

by the panel-to-panel joints, as well as the hold-down and base shear connections reaching their respective yield strengths. The results indicated that the use of stiffer panel-to-panel connections may be difficult to realise the single wall behaviour in practice, but did make some difference to the entire wall behaviour. The panel-to-panel joint between adjacent panels is critical in determining the kinematic behaviour of the wall system. However, some unexpected brittle failures were observed in the connections during the shear wall tests. Therefore, it is necessary to implement a capacity-based design approach for CLP shear walls. The non-dissipative elements should be over-designed to remain elastic and prevent brittle failures.

TIMBER INTERACTIVE MODELLING AND POST-PROCESSING SOFTWARE (TIMPS)

Manuel Sánchez-Solís[1], Màxim Lliso[2], Fernando Ibáñez[3]

ABSTRACT: Timber Interactive Modelling and Post-Processing Software (TIMPS) is an internal programming routine implemented by Degree of Freedom for the scope of the analysis and design of timber structures acting as a plug-in for the most common commercial FEM software. Design timber codes and technical approvals from manufacturers are continuously being updated, therefore, design methods should also be adjusted to the latest equations. TIMPS is able to be customized for each project according to the current regulations and previous experiences in order to optimize the design of glulam members, CLT panels and connections specially for constructions with large amount of timber structural elements. The mechanical properties of the timber and its connections are calculated and transformed into typical inputs of commercial software, where the analysis is performed. Once the analysis is finished, TIMPS reads the software output and performs all verifications included in the codes. When the structure is optimized, final reports and graphics are printed.

KEYWORDS: Post-processing, Finite Element Method, analysis, timber, glued-laminated, CLT, cross-laminated, connections

1 INTRODUCTION

In the last two decades, the use of wood as a structural material in construction has experienced exponential growth all around the world. In some countries, structural timber is usually used in roofs, walkways, and single-family homes, limiting its use in big buildings which tend to have additional complexity, with a large floor volume or even a considerable height (up to 20-25 floors).

In this last application, the structural typology based on surface elements (walls and slabs) predominates globally, using panels of cross-laminated wood or CLT.

Regarding the structural design of this type of buildings, two great challenges appear compared to the calculation of conventional buildings: the modelling/verification of the linear elements and panels as structural elements and the modelling/design of the joints between panels.

One of the main characteristics of CLT panels is their orthotropy (both sectional and at the material level), which adds complexity to structural modelling in non-specific commercial calculation software, since a pre-process is required to transform the characteristics of the panel. to the characteristics of the finite element (different for each software).

Regarding its verification, again a specific formulation is required, not included in the usual software, which requires an external post-processing by the user to transform the forces of the finite element into stresses and demand/capacity ratios.

In relation to the joints between panels, the situation is analogous. It is possible to model them in conventional software with additional effort, while external post-processing is required to allow the joints to be dimensioned.

Regarding the first point, there are several programs aimed at sectional calculation and design of isolated elements of timber. The use of these programs is very useful in the design of small-scale buildings and in the pre-dimensioning of elements.

Among the commercial calculation software, there is a range of alternatives for the design of both linear and planar timber elements, however, not always the demands from the project are satisfied because of the available manufacturers of each region or the latest technical approvals or codes.

Furthermore, this software does not resolve all aspects of the design, since the results in joints between panels are limited to the mere obtaining of forces, also requiring external post-processing. Lastly, they do not have the versatility and power of other more advanced commercial software that allow for more complex applications to be carried out.

2 MODELLING SPECIFICITIES USING FEM FOR WOODEN STRUCTURES

FEM is a powerful extended tool in the structural professional practice regarding common structural elements (beams, shells) and materials (steel, concrete) thanks to its calculation capacity which translates to both precision and speed. However, important mechanical concepts need to be taken into account for the modelling of CLT panels and the adaptation of some aspects must be

[1] Manuel Sánchez-Solís, Degree of Freedom SLU, Valencia, Spain, m.sanchez@dofengineers.com

https://doi.org/10.52202/069179-0333

implemented in order to correctly represent and control the behaviour of this shell elements.

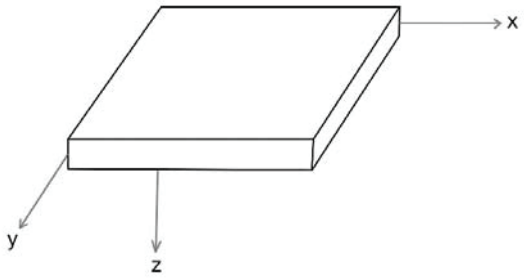

Figure 1: *Axes of orthotropic shells*

2.1 MATERIAL AND SECTIONAL ORTHOTROPIC PROPERTIES

CLT panels are shell elements constituted by different wooden layers which are orthogonally orientated with respect to the direction of their fibres. This fact consequently introduces two types of orthotropy: a material orthotropy in each layer and a sectional orthotropy in a given cross-section. In structural terms this has a particular impact on the shell stiffness since the double orthogonal symmetry of an orthotropic material originates a specific stiffness matrix shape.

In the case of isotropic shells in an elastic regime respecting the Infinitesimal Strain Theory, the stiffness matrix regarding stresses and strains is:

$$C = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{21} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{31} & C_{32} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & D_{11} & 0 & 0 \\ 0 & 0 & 0 & 0 & D_{22} & 0 \\ 0 & 0 & 0 & 0 & 0 & D_{33} \end{bmatrix} \quad (1)$$

In which the terms are:

$$C_{ii} = \frac{(1-\nu)E}{(1+\nu)(1-2\nu)} \quad (2)$$

$$C_{ij} = \frac{\nu\, E}{(1+\nu)(1-2\nu)} \quad (3)$$

$$D_{ii} = \frac{E}{2\,(1+\nu)} \quad (4)$$

Note the fact that only two parameters, the Young Modulus and the Poisson Coefficient, are required to define the stiffness matrix of an isotropic material.

As the study case is based on an orthotropic material, more parameters are needed to define the elastic properties of a cross-section. Those parameters are:

- Three Young Modulus:
  - E_{11}, E_{22} and E_{33}
- Three Poisson Coefficients:
  - ν_{12}, ν_{13} and ν_{23}
- Three Shear Modulus:
  - G_{12}, G_{13} and G_{23}

The stiffness matrix coefficients become then:

- Axial part:

$$C_{ii} = \frac{E_i(1-\nu_{jk}\nu_{kj})}{\Delta} \quad (5)$$

$$C_{ij} = \frac{E_j(\nu_{ij}+\nu_{kj}\nu_{ik})}{\Delta} \quad (6)$$

- Transverse part:

$$D_{ii} = \Delta G_{jk} \quad (7)$$

Where indices *i*, *j* and *k* are always different and vary from 1 to 3 and:

$$\Delta = 1 - \nu_{23}\nu_{32} - \nu_{31}\nu_{13} - \nu_{12}\nu_{21} - \nu_{12}\nu_{23}\nu_{31} - \nu_{32}\nu_{21}\nu_{13} \quad (8)$$

In the context of plate mechanics, no stress or strain is considered in the Z axe and a planar stress state occurs. Furthermore, it is possible to work with only one stiffness matrix with the shape of the one regarding the isotropic case if the cross-sectional orthotropy is physically represented in an equivalent single-layer shell. A method that fulfils this purpose is defined in section 3.1. By contrast, several coupled stiffness matrixes (one per layer) should be used to represent the global behaviour of the shell, which makes the analysis more complex.

These parameters are defined by the user in a later stage.

2.2 FINITE ELEMENT METHOD IMPLEMENTATION

As the FEM for static cases operates with force, stiffness, and displacement matrixes, these must be defined. The stiffness matrix of one layer is then computed in terms of force and displacement assuming the inexistence of work deformation in the Z axis (perpendicular to the plane of the shell). This matrix is introduced by the user into the calculation tool and will be called the elementary stiffness matrix hereafter.

Thus, external forces are:

$$F = \begin{pmatrix} M_x \\ M_y \\ M_{x,y} \\ V_x \\ V_y \\ N_x \\ N_y \\ N_{x,y} \end{pmatrix} \quad (9)$$

Where m_x and m_y are bending moments, $m_{x,y}$ is the torsional torque, V_x and V_y are the shear efforts due to bending, n_x and n_y are the membrane efforts and finally $n_{x,y}$ is the shear effort due to membrane loading. The associated stiffness matrix is:

https://doi.org/10.52202/069179-0333

$$K = \begin{bmatrix} k_x & k_v & 0 & 0 & 0 & 0 & 0 & 0 \\ k_v & k_y & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & k_{x,y} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & S_x & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & S_y & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & D_x & D_{x,y} & 0 \\ 0 & 0 & 0 & 0 & 0 & D_{x,y} & D_y & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & D_S \end{bmatrix} \quad (10)$$

These terms are calculated according to the Eurocode 5: Design of Timber Structures and Reissner-Mindlin plate theory, where K_z bending is not considered.
Finally, the displacement vector is given as:

$$U = \begin{pmatrix} \frac{\partial \Phi y}{\partial x} \\ -\frac{\partial \Phi x}{\partial y} \\ \frac{\partial \Phi y}{\partial y} - \frac{\partial \Phi x}{\partial x} \\ \frac{\partial uz}{\partial x} + \Phi y \\ \frac{\partial uz}{\partial y} - \Phi x \\ \frac{\partial ux}{\partial x} \\ \frac{\partial uy}{\partial y} \\ \frac{\partial ux}{\partial y} - \frac{\partial uy}{\partial x} \end{pmatrix} \quad (11)$$

Obviously, this formulation applies in the Continuous Medium Mechanics framework. The conversion into finite element exploitable objects is automatically done by the industrial calculation software by meshing the shells. Consequently, the size of the finite element stiffness matrix will depend on the level of discretisation reached.
All equations above are further simplified for frame finite elements (beams and columns).

2.3 STRUCTURAL JOINTS

The connection between different elements is modelled by the use of the finite element type "link" from industrial software, which connects two nodes with different properties. The stiffness for each degree of freedom is defined according to the slip modulus calculated for each connection.
For direct contact connections, a high stiffness value is defined to ensure that the loads are transferred as expected. For released degrees of freedom, a low stiffness value is used (instead of 0) to prevent from numerical errors during analysis.
The slip modulus to define the correct stiffness value of the connection is calculated according to Eurocode 5, chapter 7.1. The table below show the equations to obtain the shear stiffness of the connections based on the connector type, timber density and diameter of the screws. The axial slip modulus is not included in the Eurocode as these values are normally defined by the producers.

Table 1: *Values of k_{ser} for fasteners and connectors in N/mm in timber-to-timber and wook-based panel-to-timber connections. EC 5.*

Fastener type	K_{ser}
Dowels Bolts with or without clearance[a] Screws Nails (with pre-drilling)	$\rho_m^{1,5} \cdot d/23$
Nails (without pre-drilling)	$\rho_m^{1,5} \cdot d^{0,8}/30$
Staples	$\rho_m^{1,5} \cdot d^{0,8}/80$
Split-ring connectors A (EN 912) Shear-plate connectors B (EN 912)	$\rho_m \cdot d_c/2$
Toothed-plate connectors: - C1 to C9 (EN 912) - C10 and C11 (EN 912)	 $1{,}5 \cdot \rho_m \cdot d_c/4$ $\rho_m \cdot d_c/2$
[a]The clearance should be added separately to the deformation	

Th Eurocode states that for steel-to-timber connections, shear stiffness can be multiplied by 2.
The way in which screws are oriented along a CLT joint has an impact on both strength and stiffness of the connection. It is commonly assumed in the timber design references that only screws inserted perpendicular to the external force will work with a shear mechanism while any inclination of the fastener will make it work axially. Therefore, crossed-screws connections are very typical in timber industry. This concept is described in the following figure.

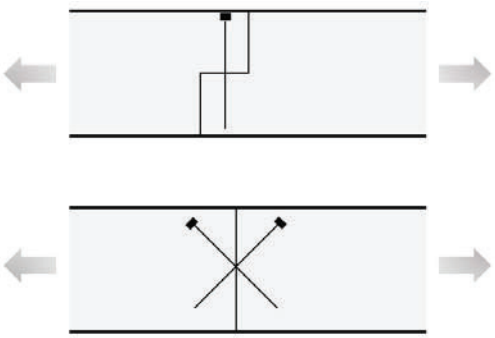

Figure 2: *Different screws resistance mechanisms*

3 TIMPS WORKFLOW

The improvement achieved in the logistical aspect of data processing is obvious. All the design process is now confined in two interfaces (the industrial FEM software and our self-elaborated routine) and the need of manually importing data sets is removed. The calculation stages are explained hereafter.

3.1 COMPUTATION OF THE ELEMENTARY STIFFNESS MATRIX

The elementary stiffness matrix is computed by using the Gamma Method for wooden structures developed in the Eurocode 5 or the Extended Gamma Method if the cross-section contains more than three longitudinal layers. By using this method, the shear stiffness of each layer is considered in the calculus by diminishing the second moment of inertia of the whole cross-section. This

https://doi.org/10.52202/069179-0333

approximation allows for the transition from a multi-layered material to a single-layered one, making it possible to build a single stiffness matrix for the complete orthotropic cross-section. Moreover, the coefficients of wood's transverse expansion ν_{ij} are often considered to be zero. This results in a diagonal matrix since $k_\nu = D_{x,y} = 0$ and therefore in a classical beam stiffness matrix for a generalised 3D situation.

3.2 STRUCTURAL MODELLING AND COMPUTATION

Structural modelling and computation are the only parts of the process elaborated by means of industrial FEM software. Therefore, the user defines the geometry, its boundary conditions, the loads and the load combinations of a given structure using wooden beams and CLT shells, which will be identified by groups. These shells are meshed and the model is computed. Various files containing the computation results are finally automatically created. Among data results, those of interest are the ones associated to nodal forces since they are needed in order to perform the stress analysis and verifications at the multi-layered element scale.

3.3 MODEL DATA ACCES THROUGH PROGRAMMING TOOLS

Once the FEM model is computed, several data packages are extracted using self-elaborated Python routines. Then, results can be selected, exported and manipulated. A significant improvement regarding post-processing computations is achieved by filtering datasets because the amount of data to be treated is well classified and defined. This improvement is appreciated when working with wooden buildings of more than ten floors since more structural effects and parameters, particularly linked to wind loading, need to be precisely considered. This translates into a relatively large amount of data to manage, so it is essential to only work with the necessary inputs with the aim of making post-processing approachable.
The extracted data is then:

- Connectivity chart: this chart identifies each finite element with the nodes that form it.
- Node properties: each node is identified with a number according to their group. Their degrees of freedom as well as their global coordinates are obtained.
- Nodal forces: forces at each node.

This data is stocked in text files.

3.4 MODEL DATA SELECTION BY STRUCTURAL GROUPS AND LOAD CASES/COMBINATIONS

As all data coming from the finite element model belongs to a certain node, it is possible to filter it by the group to which it belongs. As stated before, these groups are created by the user when modelling the structure by means of the industrial software. The advantage of working with group data is that it allows for the possibility to only analyse the selected CLT shells or glulam frames.
On the other hand, a load combination analysis is also feasible. Results of a certain load case or combination can be extracted as well as the results of all ULS or SLS combinations. It is also possible to determine the most unfavourable load combination for each structural element in ULS and SLS so the design calculus can be directly done.
Thus, not all the finite element model's generated data is used to further develop the post-processing analysis.

3.5 IMPLEMENTATION OF VERIFICATION EQUATIONS ACCORDING TO EUROPEAN STRUCTURAL REGULATION

Stress limits are stablished by the Eurocode 5: Design of Timber Structures for ULS. Deformation limits are stablished the same way for SLS.
These equations are implemented in the calculation tool. The ULS verifications carried out are listed below.
Axial and bending verification for timber elements:

- Tension:

$$\frac{\sigma_{t,0,d}}{f_{t,0,d}} + \frac{\sigma_{m,y,d}}{f_{m,y,d}} \leq 1 \tag{12}$$

- Compression:

$$\left(\frac{\sigma_{c,0,d}}{f_{c,0,d}}\right)^2 + \frac{\sigma_{m,y,d}}{f_{m,y,d}} \leq 1 \tag{13}$$

Axial and bending verification for walls and columns. Buckling:

$$\frac{\sigma_{c,0,d}}{k_{c,y}\, f_{c,0,d}} + \frac{\sigma_{m,d}}{f_{m,d}} \tag{14}$$

Shear:

$$\tau_{v,R,d} \leq f_{v,R,d} \tag{15}$$

In-plane shear for CLT panels:

- Shearing-off failure of the boards along a joint:

$$\tau_{v,s,d} \leq f_{v,CLT,d} \tag{16}$$

- Shearing failure of the glued surfaces in the intersection points:

$$\tau_{v,T,d} \leq f_{T,CLT,d} \tag{17}$$

- Shear failure of the entire plate:

$$\tau_{v,d} \leq f_{vgross,CLT,d} \tag{18}$$

With regards to SLS verifications, quasi-permanent and characteristic design situations are taken into account. The verifications are the following:

Deflection:

- Characteristic design situation:

$$w_{inst} \leq \frac{L}{300} \tag{19}$$

- Quasi-permanent design situation:

$$w_{fin} = w_{inst} + w_{creep} \leq \frac{L}{250} \tag{20}$$

Shear wall deformation:

$$w_{hor} = w_M + w_V + w_z + 2w_F \leq \frac{H}{300} \tag{21}$$

Where w_M is the bending deformation, w_V is the shear deformation, w_Z is the expansion of the tie rods and w_F is the displacement of the joints between wall and ceiling.

3.6 RESULT PLOTTING

Designing structures is an iterative process in which many parameters need to be considered. The variation of one of those parameters can significantly impact the results and it may not be easy to detect them, so a graphical representation is needed. Nodal displacements and stresses of the CLT shells or timber frames are plotted so that structural design judgement can be properly done.

As the TIMPS can work with several industrial software by interacting with their API, an interpolation module is provided for the cases in which data extracted is not interpolated so accurate plots can be done.

3.6.1 Examples

This section includes some of the outputs provided by this tool in different projects.

Results for planar elements, linear elements and joints between CLT panels are shown below.

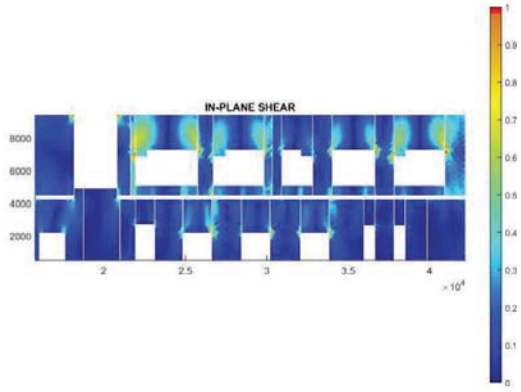

Figure 3: *In-plane shear verification of façade CLT walls*

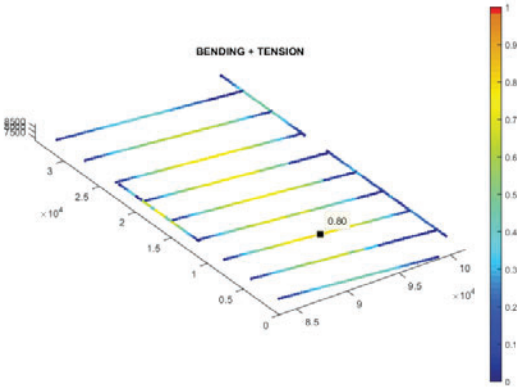

Figure 4: *Bending verification of roof timber beams*

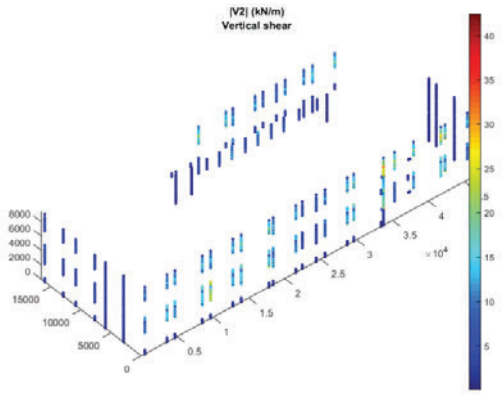

Figure 5: *Vertical shear forces in CLT joints*

3.6.2 Documentation generation

Once the iterative design process is finished, design reports and CAD files with required spacing of screws are exported.

The complete process performed by TIMPS is described in the following figure.

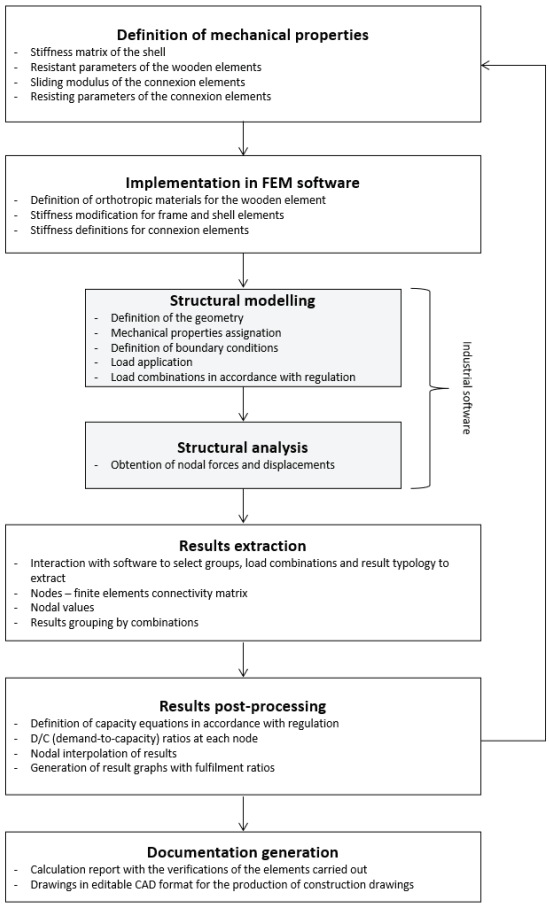

Figure 6: *TIMPS design workflow*

https://doi.org/10.52202/069179-0333

4 POTENTIAL IMPROVEMENTS

Several improvements are planned for the future of this tool. Some of them are listed below.

1) Predefinition of connection type catalogue with already calculated stiffness and strength to allow the user to check the most common joint solutions.
2) Connection to different software in the scope of the parametric design.
3) Improvement of CAD export function to minimize time consumed during detailed drawings production.
4) Evaluation of the transverse Poisson's Coefficients of the material in CLT shell computations. By considering them the results would be more accurate since the stiffness would be increased and best represented.

5 CONCLUSION

Timber Interactive Modelling and Post-Processing Software (TIMPS) is a design tool compatible with many of the commercial software for the purpose of the analysis, design and optimization of big timber structures based on the latest codes and technical approvals. The main goal of the application is to allow for quick updates of equations based on latest regulations and approaches from suppliers and producers in order to optimize future constructions by reducing the engineering time consumed for the verifications as a result of the iterative process inherent in the timber design sequence and the amount of data which needs to be evaluated by the structural engineer.

NUMERICAL AND EXPERIMENTAL INVESTIGATIONS ON THE STRESS STATE OF CLT-PLATES NEAR CONCENTRATED LOADS

Heinz Wimmer[1], Christoph Huber[2], Robert Eder[3]

ABSTRACT: Cross laminated timber (CLT), as a structural plate-like timber product has been successfully established in civil engineering practice as a load bearing product for walls, floor and roof elements. In a bending situation with transverse shear the cross section does not remain in a plane form due to the strong flexibility of crossing layers. The deformed cross section shows a significant warping which follows a zigzag pattern that influences the stress state. Comparative studies are worked out to investigate the efficiency of two different structural theories. It turned out, that the traditionally used First Order Shear Deformation Theory (FSDT) does not reflect satisfactorily the local stress state near concentrated loads. It is demonstrated that the relatively new Refined Zigzag Theory (RZT) is much better able to represent the stresses in different layers of CLT-plates in such a case. In particular, the rolling shear stress and the maximum bending stress will be strongly underestimated by FSDT, while RZT will provide accurate results. This finding was confirmed by alternative analysis with high-resolution FE continuum elements and by experimental tests using linear strain gauges and a digital image correlation system (DIC) to record the deformations in the area of interest.

1 INTRODUCTION

Cross laminated timber (CLT), applied as structural plate-like products has revolutionized timber construction for many years. The worldwide production volume is still increasing [1]. For floor systems, single-span strips are predominantly used, characterized by bending with uniaxial load transfer. For the analysis of these types of structural elements many methods exist. A well-known procedure is the Gamma-method [2], originally developed for composite beams with interlayer slip by Möhler [3], which can be modified for applications of CLT. The Shear Analogy (SA) method introduced by Kreuzinger [4] and worked out by Scholz [5,6] provides more capability concerning the local stress state. For beams and plates, the First Order Shear Deformation Theory (FSDT) [7,8] can be used when an appropriate shear correction factor is installed. For multi-span systems as well as for systems with concentrated loads most of the above-mentioned analysis tools are not sufficient to accurately predict the structural behavior, especially the local stress state. In these cases, a higher order plate theory which considers the specific warping phenomenon should be applied. While elaborate 3D analysis is indicated in cases of ultimate load determinations and predictions of damage histories [9], it is useful to resort to structural theories for everyday design tasks. The latter are less complex and easier to handle. In the wide field of theories of composite laminated structures, the following groups are distinguished: Equivalent single layer theories (ESL) [10], Layer-wise theories (LW) [11] and Zigzag Theories [12]. ESL models provide poor results of local variables when employed to highly heterogeneous laminates. The abrupt change of the mechanical properties between layers leads to a change in slope of the in-plane displacements. LW-theories, wherein kinematic assumptions are made for each layer, can reproduce these kinks very well, but the numerical effort increases with the number of plies involved. A good compromise between computational cost and accuracy is offered by the Zigzag models.

The Refined Zigzag Theory (RZT) [13] is an efficient structural theory based on the well-known First Order Shear Deformation Theory, enhanced by local kinematic terms, which allow for the particular attention of warping that arises in the cross section due to shear-elastic layers. The great accuracy of this approach was assessed by comparison with 2D and 3D analytical solutions and 2D-FE solutions as well [13,14]. In a recently published paper, the application of RZT to uniaxial spanned CLT-plates and other shear elastic timber structures like timber-concrete composite beams and timber beams with discrete shear dowels is demonstrated [15]. For single span beams with uniformly distributed loads, there is no significant difference in stress state between FSDT and RZT. In continuous beams and/or when concentrated loads are applied, there are considerable deviations that can no longer be ignored. The Refined Zigzag Theory can work out the qualitative differences that arise from the constrained warping deformations, while FSDT shows an unvarying stress pattern along the whole beam.

2 REFINED ZIGZAG THEORY

The Refined Zigzag Theory was founded in 2010 by Alexander Tessler (NASA) and co-workers from Politecnico di Torino [13]. Since that time many papers have been published, see e.g. references [16–19], showing the tremendous capability of this approach.

2.1 PLATE KINEMATICS

The plate is referred to a Cartesian coordinate system $(\boldsymbol{x}_\beta, z,\ \beta = 1,2)$ (Figure 1). Its thickness h consists of N completely bonded orthotropic layers. The normal surface load $q_z\ (\boldsymbol{x}_\beta)$ is acting on the mid-plane in the positive z-direction. The kinematic field in classical RZT-plate theory is written as

$$\boldsymbol{u}_\alpha^{(k)}(\boldsymbol{x}_\beta, z) = \boldsymbol{u}_\alpha(\boldsymbol{x}_\beta) + z.\theta_\alpha(\boldsymbol{x}_\beta) + \phi_{\alpha\rho}^{(k)}(z).\psi_\alpha(\boldsymbol{x}_\beta)$$
$$u_z^{(k)}(\boldsymbol{x}_\beta, z) = w(\boldsymbol{x}_\beta) \qquad (1)$$

$\boldsymbol{u}_\alpha^{(k)}(\alpha, \rho = 1,2)$ denote the in-plane displacements, $u_z^{(k)}$ the transversal deflection of the k-th layer. $\boldsymbol{u}_\alpha,\ w,\ \theta_\alpha$ represent the displacements of the mid-plane and the rotations of cross sections respectively. $\phi_{\alpha\rho}^{(k)}$ are the layer-wise linear zigzag functions (Figure 2), which are only dependent of the layer setup and the transversal shear moduli. Finally, ψ_α mean the zigzag rotations which are the two additional degrees of kinematic freedom, by which the warping of the cross section will be controlled. Transverse normal deformation (thickness stretching) is neglected. For angle-ply layers, additional coupling terms $\phi_{12}^{(k)}$ and $\phi_{21}^{(k)}$ should be used in the kinematic equations [20]. With these enhanced kinematic terms also diagonal laminated timber plates (DLT) [21] can be treated.

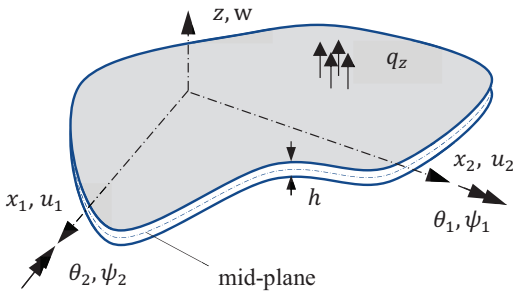

Figure 1: *General plate notation*

Using Green-Lagrange strain-displacement relations with limitation to moderate rotations (von Karman terms) we obtain for the in-plane strains (index p) of a laminated composite plate

https://doi.org/10.52202/069179-0334

$$\boldsymbol{E}_p^{(k)} = \boldsymbol{E}^{(m)} + z.\boldsymbol{E}^{(b)} + \boldsymbol{\Phi}_p^{(k)}(z)\boldsymbol{E}^{(\phi)} \qquad (2)$$

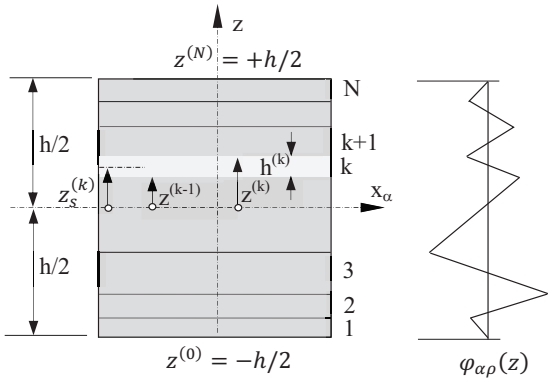

Figure 2: *General layer notation and zigzag function*

Split into the membrane part, the bending part and the zigzag part and with the abbreviation $(.)_{,\alpha} = \frac{\partial}{\partial x_\alpha}$ it follows

$$\boldsymbol{E}^{(m)} = \begin{Bmatrix} u_{,1} + \frac{1}{2}w_{,1}.w_{,1} \\ v_{,2} + \frac{1}{2}w_{,2}.w_{,2} \\ u_{,2} + v_{,1} + w_{,1}.w_{,2} \end{Bmatrix} \qquad (3a)$$

$$\boldsymbol{E}^{(b)} = \begin{Bmatrix} \theta_{1,1} \\ \theta_{2,2} \\ \theta_{1,2} + \theta_{2,1} \end{Bmatrix} \qquad \boldsymbol{E}^{(\phi)} = \begin{Bmatrix} \psi_{1,1} \\ \psi_{2,2} \\ \psi_{1,2} \\ \psi_{2,1} \end{Bmatrix} \qquad (3b, c)$$

$$\boldsymbol{\Phi}_p^{(k)}(z) = \begin{bmatrix} \phi_{11}^{(k)} & 0 & 0 & \phi_{12}^{(k)} \\ 0 & \phi_{22}^{(k)} & \phi_{21}^{(k)} & 0 \\ \phi_{21}^{(k)} & \phi_{12}^{(k)} & \phi_{11}^{(k)} & \phi_{22}^{(k)} \end{bmatrix} \qquad (4)$$

The transverse shear strains (index t) is given by

$$\boldsymbol{E}_t^{(k)} = \boldsymbol{E}_t^{(0)} + \boldsymbol{\Phi}_{t,z}^{(k)}(z)\boldsymbol{\psi} = \boldsymbol{E}_t^{(0)} + \boldsymbol{\beta}^{(k)}\boldsymbol{\psi} \qquad (5)$$

It can be split up into a constant averaged shear part and layer-dependent part

$$\boldsymbol{E}_t^{(0)} = \boldsymbol{\gamma}_t^{(0)} = \begin{Bmatrix} \gamma_1^{(0)} \\ \gamma_2^{(0)} \end{Bmatrix} = \begin{Bmatrix} w_{,1} + \theta_1 \\ w_{,2} + \theta_2 \end{Bmatrix} \quad \boldsymbol{\psi} = \begin{Bmatrix} \psi_1 \\ \psi_2 \end{Bmatrix} \qquad (6a, b)$$

$$\boldsymbol{\Phi}_t^{(k)} = \begin{bmatrix} \phi_{11}^{(k)} & \phi_{12}^{(k)} \\ \phi_{21}^{(k)} & \phi_{22}^{(k)} \end{bmatrix} \qquad \boldsymbol{\beta}^{(k)} = \frac{\partial}{\partial z}\boldsymbol{\Phi}_t^{(k)} = \begin{bmatrix} \beta_{11}^{(k)} & \beta_{12}^{(k)} \\ \beta_{21}^{(k)} & \beta_{22}^{(k)} \end{bmatrix} \qquad (7a, b)$$

Since the zigzag functions $\phi_{\alpha\rho}^{(k)}$ are chosen as layer-wise linear functions, the $\beta_{\alpha\rho}^{(k)}$ functions which influence the shear stresses (see Equation (7) and (8)) are constant for each layer, leading to mean values of shear stress. This means that in the classical RZT the local equilibrium condition of shear stresses at the interlayer and on top and bottom is violated, just like in FSDT. It has been shown by Tessler and co-workers [22,23], that by the application of Reissner´s mixed variational principle (RZT^m) this deficiency can be eliminated.

According to the assumption of plane stress state ($S_{33} = 0$) these strains are connected by the elastic Hookean law with the corresponding second Piola-Kirchhoff stress quantities

$$\boldsymbol{S}_p^{(k)} = \begin{Bmatrix} S_{11} \\ S_{22} \\ S_{12} \end{Bmatrix}^{(k)} = \bar{\boldsymbol{Q}}_p\boldsymbol{E}_p^{(k)} \qquad \boldsymbol{S}_t^{(k)} = \begin{Bmatrix} S_{13} \\ S_{23} \end{Bmatrix}^{(k)} = \bar{\boldsymbol{Q}}_t\boldsymbol{\gamma}_t^{(k)} \qquad (8a, b)$$

The matrices $\bar{\boldsymbol{Q}}$ contain the transformed plane stress reduced stiffness coefficients [7,8].

$$\bar{\boldsymbol{Q}}_p^{(k)} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix}^{(k)} \qquad \bar{\boldsymbol{Q}}_t^{(k)} = \begin{bmatrix} \bar{Q}_{44} & \bar{Q}_{45} \\ \bar{Q}_{45} & \bar{Q}_{55} \end{bmatrix}^{(k)} \qquad (9a, b)$$

To establish the discretized problem the principle of virtual work says

$$\delta W_{int} - \delta W_{ext} = 0 \qquad (10)$$

In detail the virtual work done by the inner forces reads

$$\delta W_{int} = \int \delta\boldsymbol{E}_p^T\boldsymbol{S}_p\, dV + \int \delta\boldsymbol{E}_t^T\boldsymbol{S}_t\, dV \qquad (11)$$

Integration over the thickness of the first part leads to

$$\delta W_{int} = \int \delta\boldsymbol{E}_p^T\boldsymbol{R}_p\, dA + \int \delta\boldsymbol{E}_t^T\boldsymbol{R}_t\, dA \qquad (12)$$

with the second Piola-Kirchoff-stress resultants

$$\boldsymbol{R}_p = \begin{Bmatrix} \boldsymbol{N} \\ \boldsymbol{M} \\ \boldsymbol{M}_\phi \end{Bmatrix} \qquad \boldsymbol{R}_t = \begin{Bmatrix} \boldsymbol{T} \\ \boldsymbol{T}_\phi \end{Bmatrix} \qquad (13)$$

2.2 CONSTITUTIVE RELATIONS OF THE WHOLE LAMINATE

From the above equations we get in summary the special plate constitutive equation. In full we have 14 strain components and stress resultants

$$\boldsymbol{R} = \begin{Bmatrix} \boldsymbol{R}_p \\ \boldsymbol{R}_t \end{Bmatrix} = \boldsymbol{C}\boldsymbol{E} = \boldsymbol{C}\begin{Bmatrix} \boldsymbol{E}^{(m)} \\ \boldsymbol{E}^{(b)} \\ \boldsymbol{E}^{(\phi)} \\ \boldsymbol{\gamma}^{(0)} \\ \boldsymbol{\psi} \end{Bmatrix} \qquad (14)$$

In detail we have

$$\begin{Bmatrix} \boldsymbol{N} \\ \boldsymbol{M} \\ \boldsymbol{M}^{(\boldsymbol{\phi})} \\ \boldsymbol{T} \\ \boldsymbol{T}^{(\boldsymbol{\phi})} \end{Bmatrix} = \begin{bmatrix} \boldsymbol{A} & \boldsymbol{B} & \boldsymbol{A}^{\boldsymbol{\phi}} & 0 & \boldsymbol{0} \\ \boldsymbol{B}^{\boldsymbol{T}} & \boldsymbol{D} & \boldsymbol{B}^{\boldsymbol{\phi}} & 0 & 0 \\ \boldsymbol{A}^{\boldsymbol{\phi}T} & \boldsymbol{B}^{\boldsymbol{\phi}T} & \boldsymbol{D}^{\boldsymbol{\phi}} & 0 & 0 \\ 0 & 0 & 0 & \boldsymbol{A}_t & \boldsymbol{B}_t^{(\phi)} \\ 0 & 0 & 0 & \boldsymbol{B}_t^{(\phi)T} & \boldsymbol{D}_t^{(\phi)} \end{bmatrix} \begin{Bmatrix} \boldsymbol{E}^{(m)} \\ \boldsymbol{E}^{(b)} \\ \boldsymbol{E}^{(\phi)} \\ \boldsymbol{\gamma}^{(0)} \\ \boldsymbol{\psi} \end{Bmatrix} \qquad (15)$$

https://doi.org/10.52202/069179-0334

The constitutive matrix **C** is built up by the following sub matrices, emerging from the integration of the weighted, reduced elastic stiffness coefficients over the thickness.

$$(\boldsymbol{A},\boldsymbol{B},\boldsymbol{D}) \equiv \int_{-\frac{h}{2}}^{+\frac{h}{2}} (1,z,z^2)\,\overline{\boldsymbol{Q}}_p^{(k)}\,dz \tag{16a}$$

$$\left(\boldsymbol{A}^{\boldsymbol{\phi}},\boldsymbol{B}^{\boldsymbol{\phi}},\boldsymbol{D}^{\boldsymbol{\phi}}\right) \equiv \int_{-\frac{h}{2}}^{+\frac{h}{2}} \left(1,z,\boldsymbol{\Phi}_p^{(k)T}\right)\overline{\boldsymbol{Q}}_p^{(k)}\boldsymbol{\Phi}_p^{(k)}\,dz \tag{16b}$$

$$\left(\boldsymbol{A}_t,\boldsymbol{B}_t^{(\phi)}\right) \equiv \int_{-\frac{h}{2}}^{+\frac{h}{2}} \left(1,\boldsymbol{\beta}^{(k)}\right)\overline{\boldsymbol{Q}}_t^{(k)}\,dz \tag{16c}$$

$$\boldsymbol{D}_t^{(\phi)} \equiv \int_{-\frac{h}{2}}^{+\frac{h}{2}} \boldsymbol{\beta}^{(k)T}\overline{\boldsymbol{Q}}_t^{(k)}\boldsymbol{\beta}^{(k)}\,dz \tag{16d}$$

The enhanced zigzag functions are established by layer-wise integration of the $\boldsymbol{\beta}^{(k)}$ functions. The latter are derived from a relaxed continuity condition of shear stresses at the interlayer and the assumption that the zigzag functions vanish at the top and bottom surfaces of the plate, see Sorrenti et al. [20]. The model allows for a piecewise constant distribution of transverse shear stresses that is accurate in an average sense.

The corresponding relations for the laminated beam in the x-z-plane can be found in [24]:

$$\begin{Bmatrix} N_x \\ M_x \\ M_\phi \end{Bmatrix} \equiv \begin{bmatrix} A_{11} & B_{12} & B_{13} \\ B_{12} & D_{11} & D_{12} \\ B_{13} & D_{12} & D_{22} \end{bmatrix} \begin{Bmatrix} u_{,x} \\ \theta_{,x} \\ \psi_{,x} \end{Bmatrix} \tag{17}$$

The stiffness coefficients are defined as

$$[A_{11},B_{12},D_{11}] \equiv \int_A C_{11}^{(k)}[1,z,z^2]b^{(k)}(z)\,dz \tag{18a}$$

$$[B_{13},D_{12},D_{22}] \equiv \int_A C_{11}^{(k)}\phi^{(k)}\left[1,z,\phi^{(k)}\right]b^{(k)}(z)\,dz \tag{18b}$$

which can be calculated analytically. For a beam in plane strain in width direction b, $C_{11}^{(k)} = E_x^{(k)}/\left(1-\nu_{xy}^{(k)}\nu_{yx}^{(k)}\right)$ and for beam in plane stress $C_{11}^{(k)} = E_x^{(k)}$, where $E_x^{(k)}$ is the Young´s modulus of the *k*-th layer in axial direction *x* and $\nu_{xy}^{(k)}$, $\nu_{yx}^{(k)}$ are the Poisson´s ratios. Beams with unequal ply width can also be analyzed when a modification of the shear modulus $G_{xz}^{(k)}$ is performed [15].

3 FINITE ELEMENTS

This section summarizes the main finite element developments of the last ten years based on refined zigzag kinematics.

3.1 BEAM ELEMENT

The first numerical implementation was presented by Gherlone et al. [25] using a C^0-element based on an anisoparametric interpolation scheme originally proposed by Tessler and Dong [26]. Di Sciuva et al. [27] has given an extension to a class of higher-order elements. Wimmer et al. [24] provided explicit representations for the stiffness, the geometric stiffness and the mass matrix and an exact version of the stiffness matrix has been worked out in [28]. Flores et al. [29] reflected some limitations of RZT when modelling delamination. Kefal and coworkers [30] presented an iso-geometric beam element based on RZT^m.

There are only a few papers that explicitly report on the experimental verification of RZT. Experimental evaluations of the static and dynamic response of sandwich beams are presented by Iurlaro et al. [31,32]. Buckling test are performed and reported by Ascione et al. [33].

It should be pointed out, that in FSDT beam analysis the shear stress pattern in the cross section does not vary along the beam axis, while in RZT it happens due to the additional kinematic degree of freedom ψ, as can be seen from Equation (5). The mean shear stress obtained by the corresponding constitutive equation of FSDT therefore underestimates the real value dramatically (see Figure 5). For this reason, the shear stress distribution is usually calculated by integrating the local equilibrium equation (Cauchy´s equation) [34]. An analogous procedure derived by Tessler [22] leads to

$$\begin{aligned}\tau_{xz}^{(k)}(x,z) = {} & \theta_{,xx}(x)\left[\frac{B_{12}}{A_{11}}\tau_u^{(k)}(z) - \tau_\theta^{(k)}(z)\right] + \\ & + \psi_{,xx}(x)\left[\frac{B_{13}}{A_{11}}\tau_u^{(k)}(z) - \tau_\psi^{(k)}(z)\right]\end{aligned} \tag{19}$$

with the integrals

$$\tau_u^{(k)}(z) \equiv \int_{-h/2}^{z} C_{11}^{(k)}\,d\bar{z} \tag{20a}$$

$$\tau_\theta^{(k)}(z) \equiv \int_{-h/2}^{z} \bar{z}\,C_{11}^{(k)}\,d\bar{z} \tag{20b}$$

$$\tau_\psi^{(k)}(z) \equiv \int_{-h/2}^{z} \phi^{(k)}(\bar{z})\,C_{11}^{(k)}\,d\bar{z} \tag{20c}$$

In case of shear stresses on the top and bottom side an additional term must be considered. When referring to FSDT all terms associated with ψ are omitted.

3.2 PLATE ELEMENT

A first application for bi-axial plate bending is given by Versino [16], who extended Tessler´s anisoparametric shape functions originally presented in the well-known homogeneous plate element MIN3 to RZT-kinematics. Recently Sorrenti et al. [18] reported a robust quadrilateral version which achieves reliable results even in the ultra-thin range. Wimmer et al. [17] has demonstrated the advantages that can be reaped when the so-called smoothed finite element technique is employed. Hasim et al. [35] has presented an iso-geometric variant that allows for plates with curvilinear fibers. Wimmer and co-workers [36] has recently shown the extension to buckling and geometrical-nonlinear bending.

4 NUMERICAL RESULTS

Two representative examples are given in this section. As a first example a continuous beam is investigated. In

another example, the biaxial bending state of a CLT strip intermediately supported by a column is treated.

4.1 UNIAXIAL BENDING

A two-span CLT-beam is investigated as a beam model (with RZT and FSDT) and as a 2D-continuum. The cross-section consists of five layers of equal thickness with $h^{(k)} = 0.04$ m.

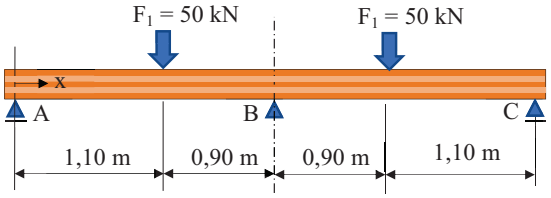

Figure 3: *System of a two-span continuous test beam under concentrated loads (uniaxial bending)*

The single boards are edge-glued. The beam has a width of b = 0.50 m and an overhang of 0.20 m at both ends. Two concentrated loads $F_1 = 50$ kN act approximately in the middle of the span (Figure 3 and 10). An additional force of $\Delta F_1 = 1.84$ kN was taken into account for the load transmission beam. As the structure is first analyzed as a beam model [24], the forces as well as the support reactions are applied via distributed loads with respect to the axis of the beam. At the force application point, a parabolic line load with amplitude $q_F = 243$ kN/m is modeled, acting over a length of 0.32 m, while the line load at the intermediate support has an amplitude of $q_B = -475.6$ kN/m, distributed over a width of 0.24 m, resulting in a reaction force B = 76.1 kN. In the 2D-continuum model the actions are located as uniform pressures on the top and the bottom side of the beam.

The material data for the numerical model were chosen as mean values from component tests of the single boards. To achieve the experimentally determined maximum deflection of $w_{max} = 2.85$ mm, the rolling shear modulus had to be adjusted concerning the experimental measure-ments (see section 5.3):

$E_x = E_0 = 11600$ MPa, $E_y = E_z = E_{90} = 370$ MPa, $G_{xz} = G_{090} = 560$ MPa, $G_{xz} = G_{yz} = G_{9090} = 120$ MPa.

4.1.1 Longitudinal Stress

The maximum bending stress distribution along the beam is given in Figure 4. It shows the significant influence of the cross sectional warping close to the load transfer zone.

In addition, the structure is modeled with 2D-continuum elements of high resolution (3 rows of solid elements for each layer). The maximum deflection must be corrected for thickness deformation when comparing with the beam solution. The peak values of RZT-beam solution are quite well confirmed by 2D-FE analysis. It should be noted that when using 2D continuum elements, no rotational degree of freedom at the nodes of the interlayer boundaries should be present (or it should be released). Otherwise, the typical kink is numerically cancelled, and the stress state could be locally distorted as a result. The measured values of the linear strain gauges (mean values of three specimens), which are attached to the tensile side of the load application points (Figure 10), impressively confirm the numerical values of the RZT.

4.1.2 Shear Stress

The standard method of RZT and FSDT as well provides only mean values of the shear stresses in each layer. It

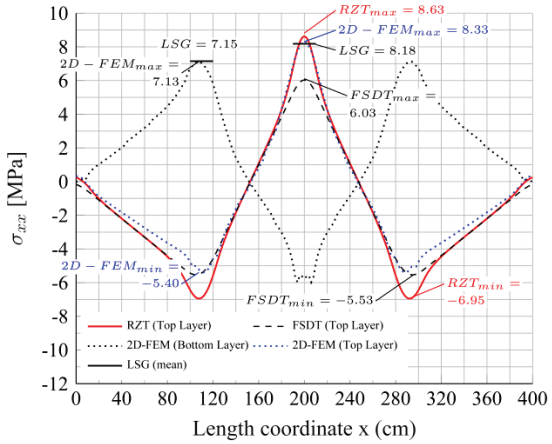

Figure 4: *Maximum bending stress along the axis of a two-span continuous beam for different composite beam theories, from 2D continuum analysis and experimental results.*

turned out that the standard FSDT is not able to reflect the stress state accurately. In particular, the rolling shear stress in the second layer is completely miscalculated qualitatively and quantitatively. It became apparent, that FSDT significantly underestimates the mean values of rolling shear stress (Figure 5) when using the constitutive equation. Figure 6 presents the shear stress distributions $\tau_{xz}(z)$ along several sections (see Figure 10) coming from

different calculation approaches. Figure 6 (upper graph) shows the mean values (FSDTm) recovered from the constitutive equations and the values which result from

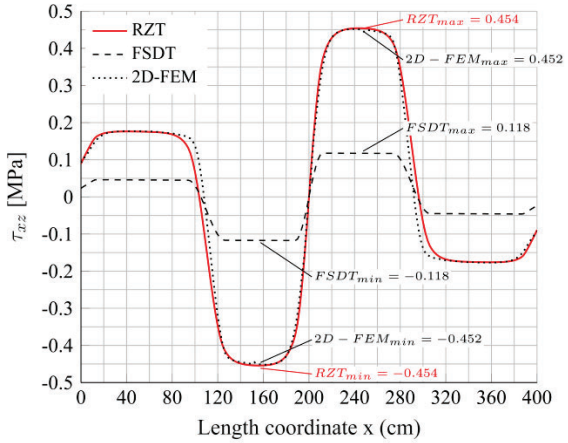

Figure 5: *Rolling shear stress in the second layer along the axis of a two-span continuous beam under concentrated loads for different composite beam theories and 2D continuum analysis.*

https://doi.org/10.52202/069179-0334

integration of Cauchy´s equation (FSDTc, Eq.19, 20). Figure 6 (lower graph) gives the corresponding results for RZT. It is noticeable, that RZT provides accurate values of the rolling shear stress in the second layer even if the constitutive equation is applied. Outside the warping zone, both theories give the same result when the integration technique is applied. In the load transfer zone, the symmetry is lost under the influence of the transverse normal stress σ_{zz}, as can be seen in section 0 - 0, but the maximum shear stress given by the RZT and the integration method reproduces the 2D solution quite well.

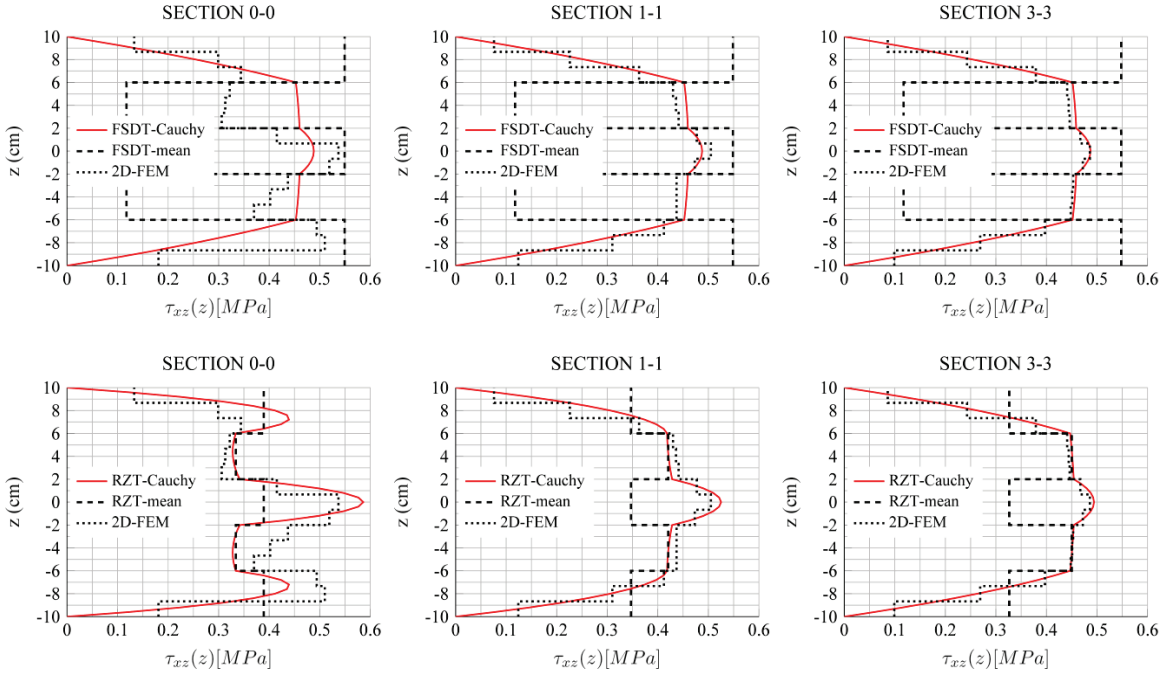

Figure 6: *Shear stress distributions $\tau_{xz}(z)$ (mean values, Cauchy-integrated and unsmoothed 2D-solution) for FSDT (upper graph) and for RZT (bottom graph) along different cross sections*

4.2 BIAXIAL BENDING

A double-symmetric, two-span rectangular CLT-plate (Figure 7) with dimensions 7.80 / 2.40 / 0.20 m, resting on a line support at both ends and a point intermediate bearing (30 x 30 cm) is studied with a plate model [17] considering the above two theories and a 3D continuum model. A quarter of the plate (3.90 / 1.20 m) is modeled and subjected by a constant surface load on the upper side of q_z = -10 kN/m^2. The contact area at the corner (0.15 / 0.15 m) has a subgrade reaction modulus of 3.3 10^6 kN/m^3. The cross section consists of 5 layers, each with equal thickness of 4 cm. The following material parameter were applied:

E_1 = 11500 MPa, $E_2 = E_3$ = 370 MPa, $G_{12} = G_{13}$ = 690 MPa, G_{23} = 50 MPa. ν_{12} = 0.38, ν_{13} = 0.22, ν_{23} = 0.203.

The material axis 1 coincide with the x_1-axis. The layer setup is 0/90/0/90/0°.

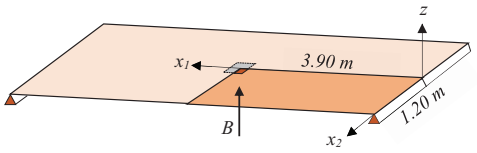

Figure 7: *Biaxial bending of CLT-plate with point intermediate support*

Table 1: *Maximum deflection and bending stresses in the upper two layers of a CLT-plate (symmetry point) under biaxial bending, 3D deflection corrected from thickness compression*

	FSDT	RZT	3D
max w [mm]	5.91	5.18	5.39
max σ_{11} [MPa]	5.68	9.23	9.71
max σ_{22} [MPa]	6.92	10.64	10.98

For comparison the plate is analyzed with the FE-program ABAQUS using more than 40 000 quadratic solids elements of type C3D20. Figure 8 shows the transverse deformation u3 = w and clearly the typical zigzag pattern arising from the heterogeneous cross section under high transverse shear stresses. In Table 1

https://doi.org/10.52202/069179-0334

essential results are presented. Figure 9 gives the through- thickness distribution of stresses at the center point of the whole plate in both directions. It demonstrates the superior accuracy of RZT against FSDT. As with the uniaxial example, it can be seen that FSDT significantly underestimates the maximum bending stresses.

5 EXPERIMENTAL RESULTS

In the following, the experimental configurations as well as the measurement systems for the test beam (see Figure 3) are described. Furthermore, the measured data are analyzed and compared with the results from the numerical analysis.

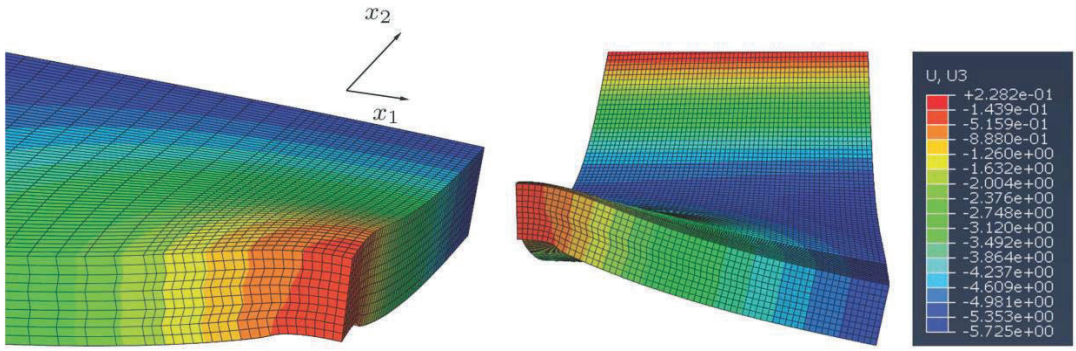

Figure 8: *Warping deformation near the point support along the planes of symmetry with typical zigzag pattern*

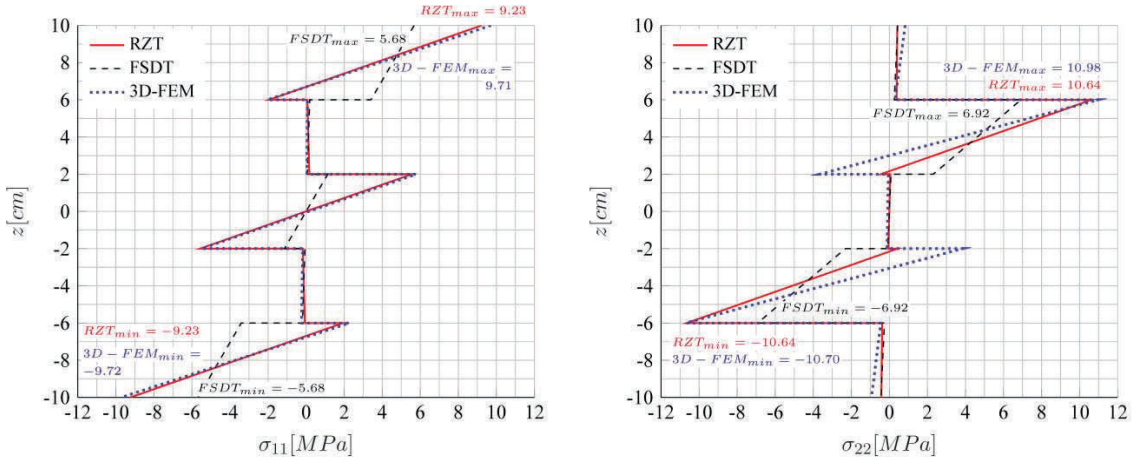

Figure 9: *Bending stresses distribution at the symmetry point by different structural theories*

5.1 EXPERIMENTAL SETUP

Figure 10 shows the experimental setup for the bending test. The hydraulic jack is fixed on a rigid loading frame. The latter is clamped to the rigid floor with anchor bolts. The load is applied via a crossbeam (HEM 280). The two-span beam has three roller supports. For dimensions and loads see section 4.1. The cross section of the test beam has a width of 50 cm.

The shear slenderness at the supports in both bays is a/d = 110/20 = 5.5 and concerning the inner support a/d = 90/20 = 4.5. The test program includes three test specimens. Figure 10 shows the four measurement methods used. A measuring box in the hydraulic jack reported the test load. In the range of the load application as well as above the intermediate support, linear strain gauges (LSG) were responsible for measuring the strains of the top and bottom fiber. To measure the vertical deflection, a displacement sensor was placed under the load application point. A DIC-System is used to detect strains in the area of interest (AOI). The load rate is determined at 0.5 mm/min. for all tests.

https://doi.org/10.52202/069179-0334

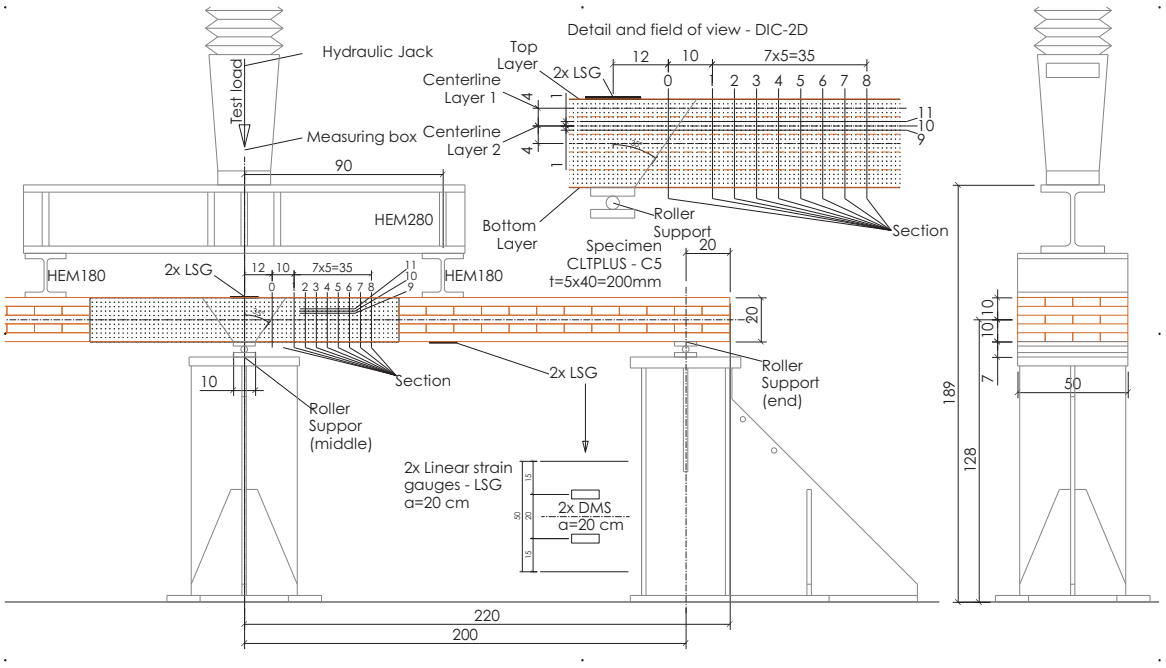

Figure 10: *Experimental setup of a CLT-beam*

5.2 Digital image correlation (DIC)

The DIC-System as an optical, contactless deformation measurement method combines image registration and tracking system for precise 2D measurements to reconstruct the strain state in a structural component. In this study, the DIC-System was used to monitor the strains and deformations near the intermediate support. Just left and right of this support the lateral surface of the beam was speckled randomly and 2D measurement method is employed. The strains and deformations are measured in the area of interest and compared with the numerical results.

5.3 Evaluation of strains

The DIC system provides Green-Lagrange strains. The evaluation of shear angles $\gamma_{xz} = 2\varepsilon_{xz}$ was carried out along vertical sections 0 – 8 (see Figure 10) and showed an unsteady distribution related to the strong inhomogeneity caused by the individual fibers. (Figure 11). Based on these distributions, mean values $\gamma_{xz,m}$ are calculated for each layer. Subsequently they were multiplied layer-wise by those shear moduli G_{xz} that lead to match with the results from 2D-FE analysis which in turn fulfil the equilibrium conditions.

The calibration procedure is performed for all vertical sections marked in Figure 10, separated according to layers, resulting in the following mean values: G_{9090} = 120 MPa, G_{090} = 560 MPa.

A comparison with extensive tests reported in [37] as well as numerical investigations [38] showed good congruence of these values.

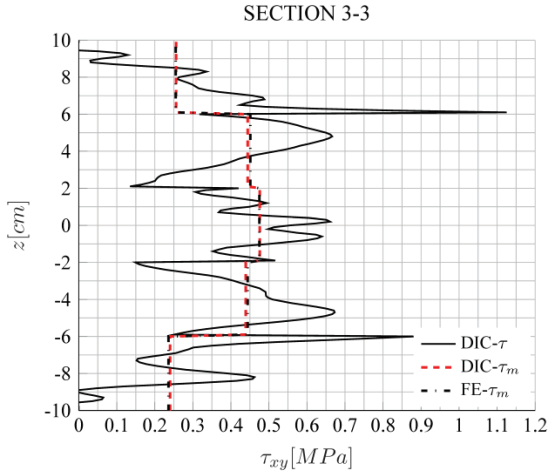

Figure 11: *Shear stress distribution measured by DIC and mean values per layer*

6 ULS-DESIGN

The clearly recognizable stress peaks in the examples shown have a non-negligible influence on the design process. The utilization factor with respect to the axial stresses in the grain direction, which is given in Tables 2, 3 and 4, was evaluated by the formula of Equation (21), where $\sigma_{t/c,0,CLT,d}$ and $f_{t/c,0,CLT,d}$ denote the design values of max/min. stress and strength parallel to the grain for

$$U_{t/c} = \frac{|\sigma_{t/c,0,mean,d}|}{f_{t/c,0,CLT,d}} + \frac{|\sigma_{m,CLT,d}|}{f_{m,CLT,d}} \qquad (21)$$

pure tension (t) or compression (c), respectively. $\sigma_{t/c,mean,d}$ represents the mean value of the linearly varying stress distribution in the uppermost or lowermost layer. The second part $\sigma_{m,CLT,d}$ is given by the nonuniform part of bending stress deviating from the above-mentioned mean value and the bending strength $f_{m,CLT,d}$. For the comparison we refer to the design format of Eurocode 5 and the following material parameters, proposed in [1]: $f_{m,CLT,k}$ = 24 N/mm^2, $f_{c,0,CLT,k}$ = 24 N/mm^2, $f_{t,0,CLT,k}$ = 16 N/mm^2. For the corresponding design values, $k_{mod} = 0.80, \gamma_M = 1.25$ was chosen.

7 CONCLUSIONS

Comparative studies on uniaxial and biaxial loaded CLT-plates under concentrated loads have shown the superiority of Refined Zigzag Theory over the traditionally used First Order Shear Deformation Theory. The bending and shear stresses predicted by the RZT are impressively confirmed by numerical comparative calculations with continuum elements and experimental measurements. It could be proven that using the FSDT-based axial stress values leads to an underestimation of the corresponding utilization factor of CLT-plates up to 50 % and more. When applying the FSDT the rolling shear stress must be determined by integration of Cauchy´s equilibrium equation otherwise it is dramatically underestimated. In case of uniaxial bending the RZT already reliably predicts the rolling shear stress in the standard procedure using the constitutive equation. The propagated RZT forms a good compromise in terms of computational effort and achieved accuracy. It does not require a shear correction factor. It represents a consistent extension of the FSDT showing a great similarity to that between Saint Venant's torsion and warping torsion. Since it is the simplest variant among the numerous higher-order shear deformation theories, it should be used as the new standard tool for the analysis of CLT plates and other shear-elastic structures in the everday design process.

ACKNOWLEDGEMENT

This work would not have been possible without the financial and technical support of the following involved parties, the Innovation Voucher - Program of the Austria FFG Funding Service, consultancy firm Poltnigg & Klammer ZT-GmbH & KASTNER ZT-GmbH, Carinthia, Theurl - Timber Structures GmbH and the Baulabor of the Carinthia University of Applied Sciences. Special thanks to Tamas Meszöly and Lukas Kepplinger for their contributions.

ANALYTICAL STUDY ON SEISMIC BEHAVIOR OF NEWLY BUILT FIVE STORY PAGODA IN TENDO-CITY JAPAN

Naohito Kawai[1], Mikio Koshihara[2], Iuko Tsuwa[3], Kohei Nakamichi[4]

ABSTRACT: A five story pagoda was built in Tendo-city Japan in 2019 using traditional construction method and structural calculation based on recent technology. First in this paper, the result of micro tremor measurement of the five story pagoda is summarized, next the result of lateral loading test on a shear wall with the same specification of the pagoda is summarized, and finally, the seismic performance of the pagoda is discussed based on the result of time history response analysis using a ten mass system model which is made with considering shear resistance of board walls, rotational resistance of joints between column and penetrating member, *nuki*, and column rocking resistance. As input earthquake waves, we used three artificial waves created with using the response spectrum of extremely rare ground motion stipulated in Building Standard Law of Japan. As the result of the analysis, the pagoda does not collapse even against the strong ground motion though the deformation angle of first story reaches 1/15 radian in some cases.

KEYWORDS: Micro tremor measurement, Time history response analysis, Ten mass system model

1 INTRODUCTION

It is said that there is no historical record that five story pagoda collapsed by earthquake. In the last 100 or so years, many discussions have been made on the seismic performance of five story pagoda in Japan. And even recently, five story pagodas are built using traditional construction method. As one of them, the five story pagoda of *Joan-ji* Temple was built in Tendo-city Japan in 2019 using traditional construction method and structural calculation based on recent technology.

First in this paper, the result of micro tremor measurement of *Joan-ji* five story pagoda is summarized, next the result of lateral loading test on a shear wall with the same specification of the pagoda is summarized, and finally, the seismic performance of the pagoda is discussed based on the result of time history response analysis using the ten mass system model which is made considering the results of the shear wall test.

2 *JOAN-JI* FIVE STORY PAGODA

Figure 1 shows the exterior photograph of the pagoda. Construction of the *Joan-ji* five story pagoda began in 2016 and was completed in August 2019. Height of the pagoda is 32.7 m and the side length of the first floor is 4.62 m.

Species of the structural members is cypress grown in Aomori prefecture. Although traditional construction method is used, engineered structural calculation was made to confirm structural safety according to the current Building Standard Law of Japan.

***Figure 1**: Exterior photograph of the pagoda*

3 MICRO TREMOR MEASUREMENT

3.1 MEASURING METHOD

Figure 2 shows the arrangement of measuring points in the pagoda. Total 14 velocity sensors are placed in sequence on the ground, beams and the center post of the pagoda to cover these 45 measuring points. Time length of one measurement is 500 sec with the sampling frequency 100 Hz. After measuring velocity twice at the same sensor placement we measured displacement also using integrator circuit built into the measuring system.

And after obtaining the values of natural frequencies, we conducted human power excitation at first and second natural frequencies by two persons pushing columns in fifth story for first natural frequency and in third story for second natural frequency, adjusting the pressing time interval to each natural frequency.

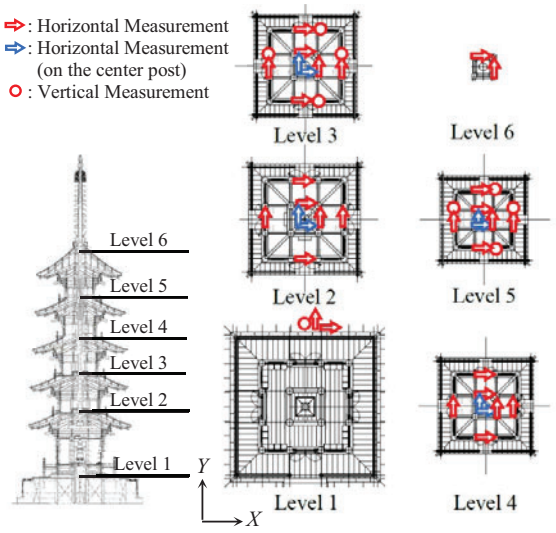

Figure 2: *Arrangement of measuring points*

3.2 RESULT OF MICRO TREMOR MEASUREMENT

By FFT analysis on the measured time history waves, we obtained some values of spectrum peaks. Figure 3 shows the result of FFT analysis. Values of frequency of main spectrum peaks are 1.12 Hz, 3.15 Hz and 5.88 Hz, which are regarded as first to third natural frequencies of the main structure of the pagoda. These observed values are the same in both the X and Y directions.

Figure 4 shows vibration modes in Y direction created by using the ratio of amplitude and the phase difference between measurement points. From Figure 4, we can see that the center column also vibrates with the main structure at first and second natural frequencies. At the third natural frequency, amplitude of the center column is far larger than that of main structure and it is omitted from Figure 4.

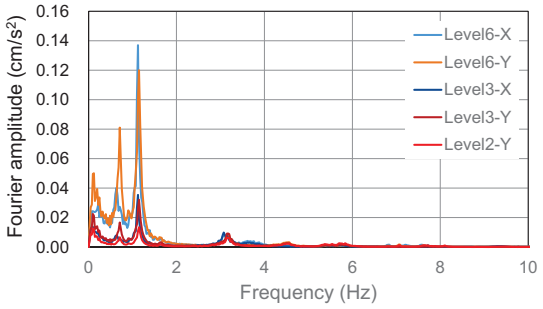

Figure 3: *Result of FFT analysis*

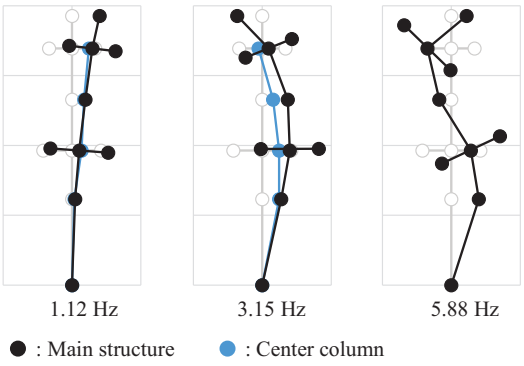

Figure 4: *Vibration mode*

Figure 5 shows the samples of time history waveforms obtained by human power excitation. And Table 1 shows the values of damping ratio at the first and second natural frequencies calculated as the values of logarithmic decrement from the time history waveforms.

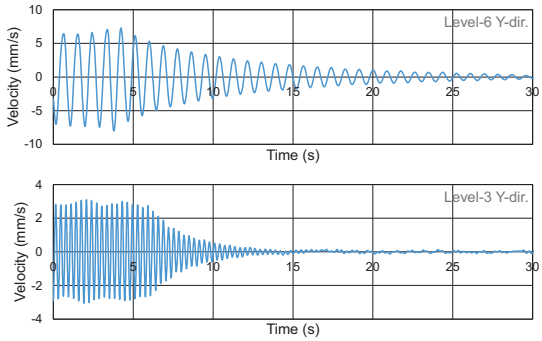

Figure 5: *Samples of time history wave forms obtained by human power excitation*

Table 1: *Values of damping ratio*

Natural frequency (Hz)		Damping ratio (%)

2nd	3.15	2.02

4 SHEAR WALL TEST

4.1 TEST SPECIMEN AND TEST METHOD

Figure 6 shows the whole view of the shear wall test, and Figure 7 shows the elevation of the test specimen. The specification of the specimen is same as the wall used in third story of the pagoda.

The species of the members, two column, a sill, a beam and wall boards is cypress. Boards with 50 mm thickness are dropped along the groove of the column and the boards are held together with 9 dowels in each layer. The dowels are made using zelkova. The section of dowels is square of 15 mm by 15 mm, and the length is 120 mm.

https://doi.org/10.52202/069179-0335

The sill of the specimen is fixed by bolts to the base structure and lateral load is applied to the beam using hydraulic actuator.

Lateral cyclic load is applied with 3 cycles at ten target deformation angles, 1/450, 1/300, 1/200, 1/100, 1/75, 1/50, 1/30, 1/20 and 1/15 radians, and finally the displacement reached 123 mm, which is about 1/10 radian in deformation angle.

Figure 6: *Whole view of the shear wall test*

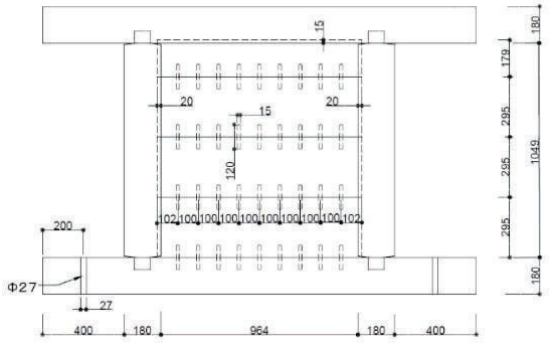

Figure 7: *Elevation of the shear wall specimen (unit: mm)*

4.2 TEST RESULT

Figure 8 shows the load-displacement relationship obtained by the loading test. The load keeps increasing even in a large deformation of 1/10 radian.

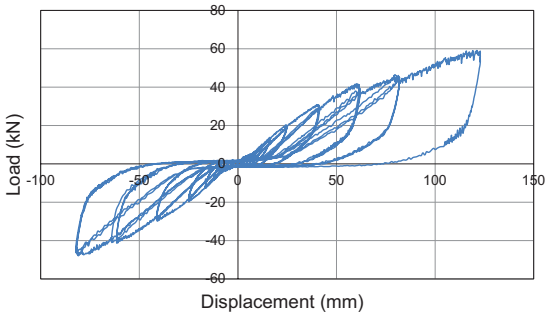

Figure 8: *Load-displacement relationship obtained by the test*

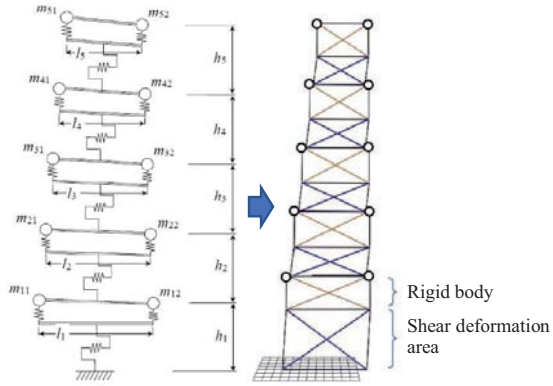
5 TIME HISTORY ANALYSIS

5.1 ANALYSIS METHOD

5.1.1 Overview of the vibration model

Figure 9 shows the concept of ten mass system model and the model for the software "wallstat" [1]. In the model for wallstat, each story consists of two layers. The lower part is is corresponding to the frames and walls and this area deforms by story shear force. The upper part is corresponding to the roof structure and is assumed to be a rigid body. Horizontal resistance of each story is calculated considering shear walls, rotation resistance of joints between column and penetrating member named *nuki* and column rocking resistance. P-Δ effect is also considered as it is built in by default in wallstat. The values of viscous damping is assumed to be 0.02 as instantaneous stiffness proportional type.



(a) Ten mass system model (b) Model for "wallstat"

Figure 9: *Vibration model*

5.1.2 Values of some parameters

Table 2 shows the values of masses which are obtained by accumulating masses of all the members and roof materials, and values of the length and the height used in the model.

In the roof structure of pagodas, there are some horizontally used timber members and it behaves like vertical springs. The vertical springs are located just below the masses and are assumed to be elastic in this analysis. The value of the spring constant is determined to be 1.81×10^4 kN/m with consulting the result of push over analysis on the three dimensional model which was used in structural calculation in the process of structural design.

Table 2: *Values of masses, length and height in the model*

Story	m_{i1} (ton)	m_{i2} (ton)	L_i (m)	H_i (m)
1st	15.08	15.08	4.62	5.12
2nd	15.21	15.21	4.20	3.65
3rd	13.17	13.17	3.78	3.65
4th	12.19	12.19	3.36	3.65
5th	13.02	13.02	2.94	3.57

https://doi.org/10.52202/069179-0335

5.1.3 Load displacement relationship of shear wall

In order to create the load-deformation relationship of the shear walls in the model, we planned to use theoretical equations for drop board walls given in a guidebook [3], and firstly confirmed the validity between the equations and the experimental results. According to the guidebook, initial stiffness and yield strength of the board wall can be calculated using Equations (1) and (2).

$$K = \frac{1}{\frac{1}{K_a}+\frac{1}{K_b}+\frac{1}{K_c}+\frac{1}{K_d}+\frac{1}{K_s}} \quad (1)$$

where,

K_a = stiffness of the boards as a compression brace,

$$K_a = \frac{E_\theta L t}{2\log\left(L\cos\theta\right)+\frac{1}{\cos^2\theta}-2}$$

K_b = embedment stiffness of the board to the beam,

$$K_b = \frac{L^3 t C_{yb} E_{\perp b}}{15 H d_b}$$

K_c = embedment stiffness of the board to the column,

$$K_c = \frac{aHtC_{yc}E_{\perp c}}{4d_c}$$

K_d = shear stiffness due to dowels,

$$K_d = an_d k_d$$

K_s = shear stiffness of the boards,

$$K_s = GLt$$

$$P_y = \min\left(P_{yd}, P_{ya}\right) \quad (2)$$

where,

P_{yd} = shear strength due to dowels,

$$P_{yd} = n_d \cdot \Delta P_y \left(1+\mu\frac{H}{L}\right)$$

P_{ya} = compression strength when the area of 5% of the diagonal length reaches yield strength,

$$P_{ya} = 0.05Ht\frac{F_\theta}{\sin^2\theta}$$

Parameters L, H, a, t, d_b, d_c, $E_{\perp b}$, $E_{\perp c}$, G, C_{yb}, C_{yc}, n_d, k_d, ΔP_y, μ, θ, E_θ and F_θ for the shear wall test specimen mentioned above are as shown in Table 3.

Figure 10 shows the comparison of load displacement relationship between the calculation result and the test result. The initial stiffness and the yield strength agreed well. As relatively large secondary stiffness was observed in the test result, we assumed secondary stiffness as 35% of the initial stiffness. Moreover, we added first broken point on the relationship of small displacement area to create the proper ratio of bilinear and slip in the hysteresis loop which is built in in the software wallstat as shown in Figure 11.

Table 3: *Values of parameters in Equations (1) and (2) for shear walls in 3rd story*

Symbol	Meaning	Value
L	Inner length of board wall (mm)	964
H	Height of board wall (mm)	1049
a	Board width (mm)	295
t	Board thickness (mm)	50
d_b	Beam height (mm)	180
d_c	Column width (mm)	180
$E_{\perp b}$	Young's modulus perpendicular to the grain of beam (kN/mm^2)	0.3
$E_{\perp c}$	Young's modulus perpendicular to the grain of column (kN/mm^2)	0.3
G	Shear modulus (kN/mm^2)	0.6
C_{yb}	Coefficient of end distance effect of beam	1.8
C_{yc}	Coefficient of end distance effect of column	1.8
n_d	Number of dowels	9
k_d	Shear stiffness of one dowel joint (kN/mm)	1.5
ΔP_y	Shear strength of one dowel joint (kN)	3.8
μ	Coefficient of friction	0.4
θ	Angle of diagonal (rad)	0.828
E_θ	Young's modulus in the direction of diagonal (kN/mm^2)	0.538
F_θ	Compression strength in the direction of diagonal (N/mm^2)	4.78

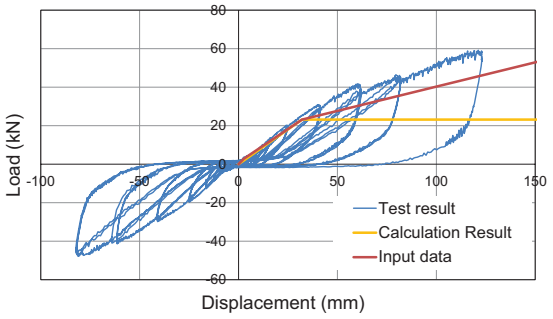


Figure 10: *Comparison of load displacement relationship between calculation result and test result*

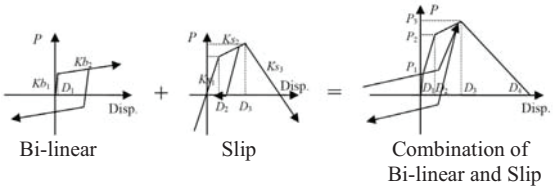

Figure 11: *Hysteresis characteristics of load displacement relationship in the software wallstat* [1]

Thus, we derived load displacement relationship of the shear wall in each story. Table 4 shows the values of parameters in each story. The obtained load value is multiplied by 4 as there located four shear walls in one direction in each story. Table 5 and Figure 12 show the load displacement relationships of the shear deformation

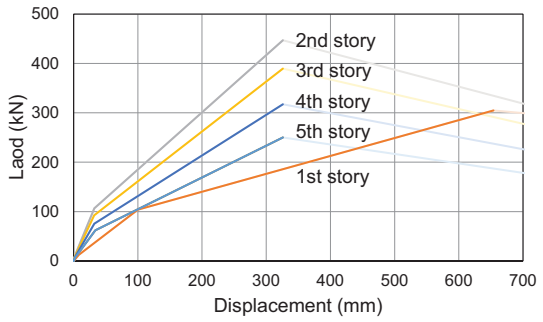

Figure 12: *Load displacement relationship of the shear deformation area in the vibration model due to shear walls*

5.1.4 Load displacement relationship due to rotational resistance of column-*nuki* joint

In order to create the load displacement relationship due to the rotational resistance of column-*nuki* joints, we used theoretical equations given in a design manual [4]. Initial rotational stiffness and yield moment of column-*nuki* joints can be calculated using Equations (3) and (4).

$$K_{\theta b} = {x_p}^2 y_p E_\perp \left\{ \frac{x_p}{Z_0}\left(C_{xm} - \frac{1}{3} \right) + 0.5\mu C_{xm} \right\} \quad (3)$$

$$M_{yb} = \frac{K_{\theta b} Z_0 F_m}{x_p E_\perp C_{xm} \sqrt{C_{ym}}} \quad (4)$$

where,

F_m = Embedment yield stress when end and edge distances are infinite

$$F_m \simeq \frac{2.4}{3} F_{cv}$$

F_{cv}: Embedment strength, F_{cv} = 7.8 (N/mm^2)

C_{xm}: Coefficient of end distance effect in length direction of *nuki*

$$C_{xm} = 1 + \frac{4Z_0}{3x_p}$$

C_{ym}: Coefficient of edge distance effect in width direction of *nuki*

$$C_{ym} = 1 + \frac{4Z_0}{3ny_p}$$

Table 6 shows the meaning of symbols, x_p, y_p, Z_0, $E_\perp$, n *and* μ, and Table 7 shows the values in each story. And Table 8 shows the calculated values of initial rotational stiffness $K_{\theta b}$ and yield moment M_{yb} in each story and of each column diameter.

Table 6: *Meaning of symbols in Equations (3) and (4)*

Symbol	Meaning
x_p	Half of column width or diameter (mm)
y_p	Width of *nuki* (mm)
Z_0	Height of *nuki* (mm)
$E_\perp$	Young's modulus perpendicular to grain of *nuki* (kN/mm^2)
n	Replacement factor of X and Y directions
μ	Coefficient of friction

Table 7: *Values of parameters in each story*

Symbol	Story	Value

https://doi.org/10.52202/069179-0335

To create the load displacement relationships due to the rotational resistance of column-*nuki* joints in each story, the load is calculated as the summation of moment of joints divided by the height of shear deformation area of the vibration model, and the displacement is calculated as the product of height of shear deformation area and rotation angle of joint. Though the diameter of column differs between the inner column and outer column in the same story, the difference of the rotation angle of yield point is small. Therefore, we used the summation of the initial stiffness and the summation of the yield moment in each story to derive the load displacement relationship of shear deformation area of each story.

Moreover, it is known that the relationship of moment and rotation angle of these joints has a relatively large secondary stiffness, so we assumed secondary stiffness of 1/12 of initial stiffness with reference to the result of the preceding study [5]. And we added first broken point on the relationship of small displacement area to create the proper ratio of bilinear and slip in the hysteresis loop.

Table 9 and Figure 13 show the load displacement relationships due to the rotational resistance of column-*nuki* joints in each story used in the shear deformation area of the vibration model. The last downward slope after the deformation angle 1/5 radian is a dummy for running the analysis.

Table 9: *Parameters of load displacement relationship for the shear deformation area in each story of the vibration model*

Story	P1 (kN)	P2 (kN)	P3 (kN)	D1 (mm)	D2 (mm)	D3 (mm)

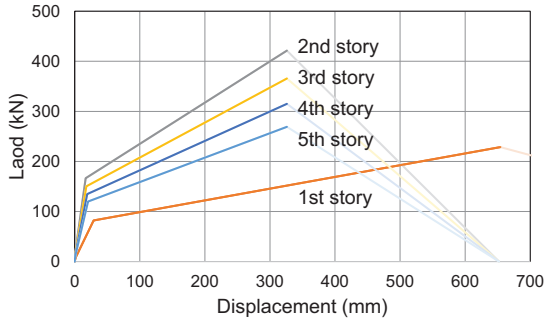

Figure 13: *Load displacement relationship of the shear deformation area due to rotational resistance of column-nuki joints*

5.1.5 Column rocking resistance

When a thick column tilts by lateral load, vertical load on the column works to reduce the tilting angle. This effect is called column rocking resistance and is one of the important seismic element of traditional timber buildings [6]. The function is built into the software wallstat to add column rocking resistance as the moment at the bottom of column.

Table 10 shows the parameters input to the vibration model. There are two columns in each story in the model, the values of vertical load in Table 10 are that of one column. And the values of vertical load from 2nd to 5th stories are decreased to 5/8 of the original values as these columns are surrounded by wood on top and bottom and the effect is smaller than the column on foundation stone. Figure 14 shows the load displacement relationship due to column rocking resistance calculated by Equation (5), which is based on the equation originally derived from the experiment result on circular section column by Ban [7], but does not contain the P-Δ effect as the P-Δ effect is considered for the whole model in the software wallstat.

$$P_c = \frac{b}{h} W \left(1 + 0.99625 e^{-0.03027\delta} - \frac{19.9625}{\delta + 10} \right) \qquad (5)$$

where, P_c = lateral load due to column rocking resistance (kN), b = column diameter (mm), h = column height (mm), W = vertical load (kN) and δ = displacement (mm).

Table 10: *Parameters of column rocking resistance of one column in the vibration model*

Story	Column diameter b (mm)	Column height h (mm)	Vertical load W (kN)
1st	340	3270	673.4
2nd	320	1630	328.5
3rd	300	1630	235.3
4th	280	1630	154.5
5th	260	1630	79.8

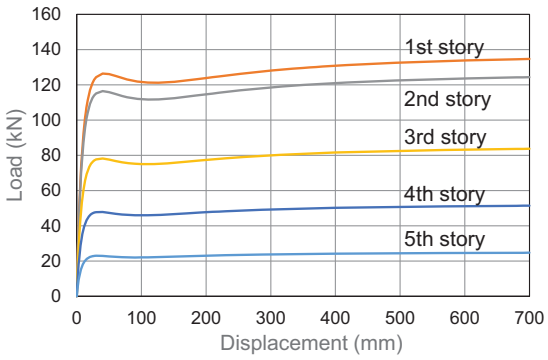

Figure 14: *Load displacement relationship of the shear deformation area due to column rocking resistance*

5.2 INPUT EARTHQUAKE WAVE

As the input earthquake waves, we used three artificial waves created with using the response spectrum of extremely rare ground motion stipulated in Building Standard Law of Japan. Figure 15 shows the acceleration response spectrum and Figure 16 shows the time history of acceleration of these waves.

https://doi.org/10.52202/069179-0335

Hachinohe-NS is created using an amplification factor of acceleration by surface ground G_s calculated by the boring data near the site and the phase spectrum of the observed wave at Hachinohe during the Tokachi-oki earthquake in 1968. Tendo-EW is also created using the boring data and the phase spectrum of the observed wave at Tendo during the 2011 off the Pacific coast of Tohoku earthquake. BSL1 is using G_s of type 1 ground stipulated in Building Standard Law of Japan and a random phase spectrum.

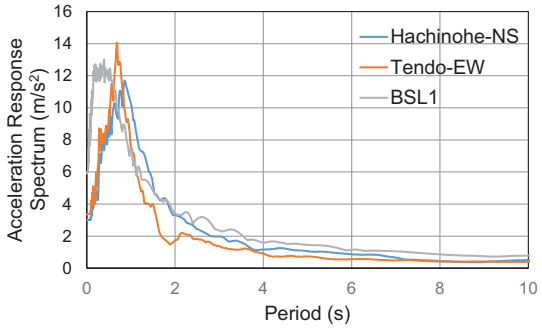

Figure 15: *Acceleration response spectrum of input waves*

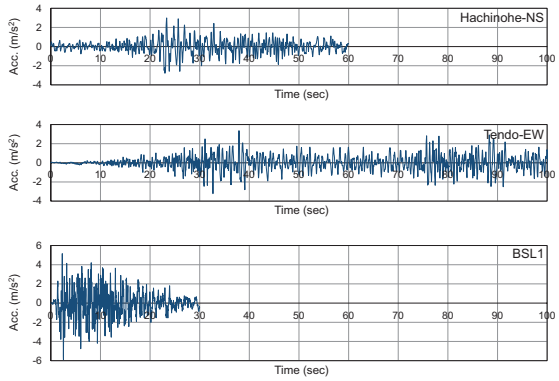

Figure 16: *Time history of acceleration of input waves*

5.3 ANALYSIS RESULT

As an example of the result of time history analysis, Figures 17 and 18 show the time history waveform of story drift and the relationships between story shear force and story drift, against the input wave using Hachinohe-NS phase. Table 11 and Table 12 show the maximum values of story drift δ_{max} and shear deformation angle γ_{max} against each input wave.

From Table 11 and Table 12 we can see that the maximum story drift of first story is far larger than other stories and it reaches 342.7 mm against BSL1, which is about 1/15 radian by story shear deformation angle. However, the pagoda does not collapse against the strong ground motion according to the requirement of Building Standard Law of Japan.

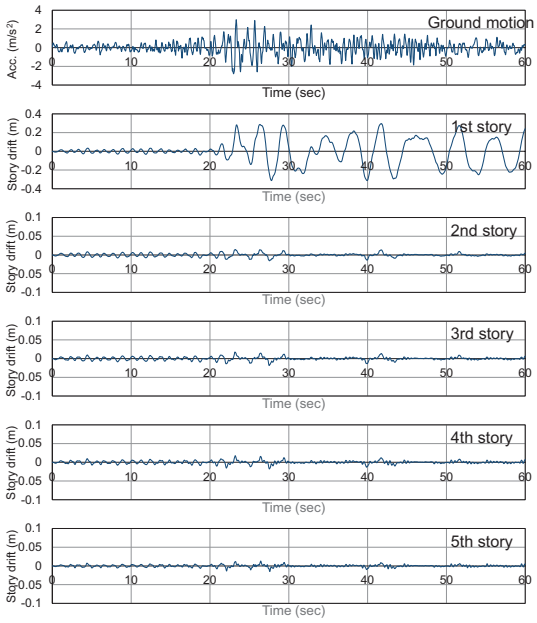

Figure 17: *Time history of story drift against Hachinohe-NS as an example of the analysis result*

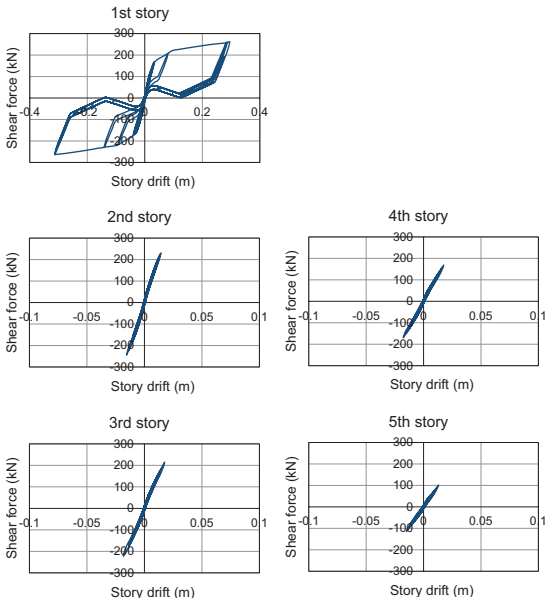

Figure 18: *Relationship between story shear force and story drift against Hachinohe-NS as an example of the analysis result*

Table 11: *Maximum values of story drift δ_{max} (mm)*

Story	Story drift δ_{max} (mm)		
	Input waves		
	Hachinohe-NS	Tendo-EW	BSL1
1st	312.9	295.0	336.5
2nd	15.6	16.3	15.8
3rd	18.4	18.9	16.3
4th	17.8	19.1	15.8
5th	15.0	15.0	15.1

https://doi.org/10.52202/069179-0335

Table 12: *Maximum values of shear deformation angle γ_{max}*

Story	Shear deformation angle γ_{max} (10^{-3} rad)		
	Input waves		
	Hachinohe-NS	Tendo-EW	BSL1
1st	61.1	57.6	65.7
2nd	4.3	4.5	4.3
3rd	5.0	5.2	4.5
4th	4.9	5.2	4.3
5th	4.1	4.1	4.1

In this analysis, only the main seismic elements are considered but there are other structural element that can be considered such as rotational resistance of many other joints. Especially, the ratio of shear stiffness of first story to other stories seems smaller considering the result of microtremor measurement. Therefore, actual maximum displacement may smaller than this analysis result and further study for more appropriate modeling seems necessary.

6 CONCLUSIONS

We conducted micro tremor measurement and performed time history response analysis on the newly built five story pagoda of *Joan-ji* temple in Tendo-city Japan. As the result of micro tremor measurement, we obtained natural frequencies and vibration modes. And the result of the time history analysis considering shear resistance of board walls, rotational resistance of the joints between column and *nuki*, and column rocking resistance, clarified that the pagoda does not collapse against the strong ground motion at the level of the requirement of standard though the deformation angle of first story reaches 1/15 radian in some cases.

ACKNOWLEDGMENT

Authors would like to thank Mr. Yasuo Matsuoka, the chief priest of *Joan-ji* Temple, for his full cooperation in this research, Dr. Takafumi Nakagawa, Associate Professor of Kyoto University, for his advice to use the analysis software wallstat, Mr. Takahiro Sato, who designed the structure of the pagoda, for his provision of technical data and all the members of Kawai laboratory in Kogakuin University who assisted with experiments, measurements and so on.

INNOVATIVE HIGH PERFORMANCE SEISMIC RESILIENT TIMBER WALL STRUCTURES WITH LOW DAMAGE FLOOR CONNECTIONS

Soheil Assadi[1], Ashkan Hashemi[2], Pierre Quenneville[3]

ABSTRACT: Rocking timber walls provide superior seismic performance in comparison with conventional light timber structures. Nevertheless, there is an uplift movement at the base of the wall that is translated as vertical displacement and rotation demands at the floor levels. With current conventional approach, not only floors and connections are prone to damage, but also the rocking movement is compromised. Presented in this paper is a new wall-to-floor and beam-to-floor solution for mass timber wall structures that not only transfer the lateral loads but also provide full self-centering while dissipating seismic energy without damage. A new shear key like system including friction dampers is proposed, to both safely allow wall uplift relative to floor and at the same time dissipate energy. Among the advantages of the new system are increased damping capacity of the system, elimination of bulky and expensive fastener connections, mitigation of displacement demands on the structure, reduction in the size and capacity of the hold-downs, and the possibility of reducing the size and number of walls. As a result, the design is more economical and cost-effective, while delivering a high-performance, competitive solution compared to conventional timber structures.

KEYWORDS: Low damage, Rocking wall, Cross Laminated Timber, Damage avoidance, Self-centring, Energy dissipation.

1 INTRODUCTION

There has been an increase in the use of engineered (mass) timber products in structures in the past decade due to the advantages they present over conventional light timber and concrete, such as construction speed, efficiency, sustainability, and reduced seismic loads due to their light weight. Shear walls (including rocking walls) are one of the most economical and efficient Lateral Load Resisting Systems (LLRS) to construct. They have been around for decades and have earned an excellent reputation. It has become increasingly popular among engineers and researchers to employ Cross Laminated Timber (CLT) rocking walls due to their reliability and efficiency in terms of seismic performance. In rocking walls, there is an uplift movement at the base of the wall that is translated as vertical displacement and rotation demands at the floor levels. So far, two general approaches have been taken to deal with these demands. Firstly, the coupled approach where the timber floors (or beams) are rigidly or semi-rigidly connected to the timber walls which are typically plywood shear walls. With this approach, not only floors and connections are prone to damage, but also the rocking movement is compromised. Secondly, the decoupled approach, where the floors are isolated from the walls. The extent of damage is relatively less with the decoupled approach; however, the gravity system is separated, and the wall capacity is not fully utilized. Conventionally, rigid or semi-rigid bracket plates and fasteners are utilized for either of these approaches, where not only the floors and connections are susceptible to damage, but also the overall seismic performance of the system is compromised. To date, there has been no solution to address the current shortcomings. This paper introduces an innovative system that addresses current shortcomings while taking advantage of the wall uplift at the floors to dissipate energy and increase the seismic resistance efficiency of the structure.

1.1 INADEQUACIES OF THE CURRENT WALL-TO-FLOOR DESIGN

To understand the performance of CLT walls in a variety of configurations, numerous numerical and experimental studies have been conducted [1-6]. Furthermore, extensive research and experimental tests have been conducted to assess the performance and failure modes of the conventional wall-to-floor connections [7-9]. Based on all of these studies, it can be concluded that CLT walls exhibit a reliable behavior, remaining intact with minimal damage, while plasticization and non-linearity occurring locally at the point of connections and fasteners (see Figure 1). Additionally, boundary conditions have been found to have a significant impact on the lateral resistance capacity of CLT walls. This includes bottom wall connections, i.e., hold-downs and shear keys, as well as the connections between walls and floors (diaphragms). In experimental tests, there were repeated instances of damage to CLT floor panels as a result of displacement incompatibility between the rocking motion and the

floor's swaying motion. Experimental and numerical studies using conventional rigid and semi-rigid connections with conventional hold-downs demonstrate pinching hysteresis and stiffness degradation after each cycle. The pinching hysteresis indicates yield and permanent damage to the rigid or semi-rigid connections and hold-downs, resulting in considerable residual drift and leaving the structure vulnerable to aftershocks. Thus, it is not desirable, nor is it consistent with mass timber structure's objective of seismic resilience and stainability. Presented in Figure 2 are the common failure modes associated with these conventional connections.

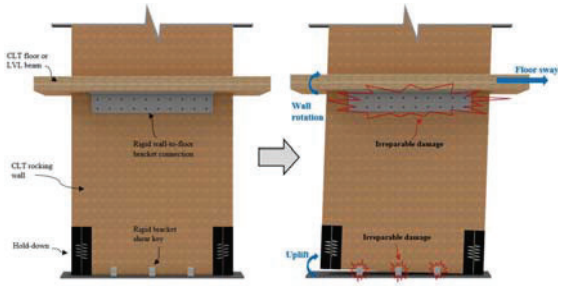

Figure 1. *Rocking wall motion and its interaction with the floor and the rigid connection, leading to irreversible and irreparable damage.*

Figure 2. *Connection failure modes: (a) fasteners withdrawal, (b) fasteners head pull-through, (c) metal bracket buckling, (d & e) timber panel brittle failure (tearing).*

2 CONCEPT OF THE PROPOSED SYSTEM

The new concept utilizes the established Resilient Slip Friction Joint (RSFJ) [10] as hold-downs to provide energy dissipation, self-centering, and allow safe rocking movement of the wall. It not only provides the necessary energy dissipation and complete self-centring behaviour, but also additional mechanism such as secondary fuse activation (collapse prevention) to ensure life safety during a major earthquake event. RSFJ consists of grooved cap plates, grooved middle plates, disk springs and pre-stressed bolts or rods. RSFJ is activated when force demand exceeds the slip force (resisting friction force between clamped plates). It is the friction between the grooved plates that dissipates energy as the cap plates slide onto the middle plates, while the pre-stressed bolts and disk springs are compressed together increasing the friction force required to slide the plates, and thus forcing the grooved cap plates to return to their original position, which leads to self-centering behavior. A more detailed description of the RSFJ mechanism can be found in [3, 11].

Experimental testing of a rocking CLT wall with RSFJ hold-downs demonstrated that these joints provide outstanding seismic performance while allowing damage-free deformation and ductility [3]. The RSFJ assembly and parameters of its flag-shaped load-deformation behavior are displayed in Figure 3.

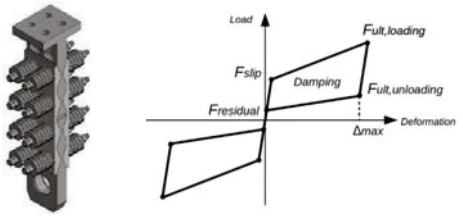

Figure 3: *Resilient Slip Friction Joint (RSFJ): (a) hold-down assembly (b) flagged shaped hysteresis.*

Additionally, slip friction dampers are employed at floor levels to take advantage of the uplift and enhance the damping capacity of the structure. Slip friction dampers are derivatives of symmetric slip-friction dampers introduced by Loo et al. [12]. The symmetric slip friction joint is composed of sliding steel plates clamped together with bolts, Belleville disks, and nuts (no shims are used). Friction dampers dissipate energy through friction between clamped plates, with the inner steel plate incorporating a slot to facilitate free movement of the outer plates without damage while providing Isotropic loop hysteresis behaviour (see Figure 4). The joint was successfully tested in an individual configuration as well as a hold-down for a LVL rocking wall, providing repeatable hysteresis while retaining strength and stiffness [12, 13].

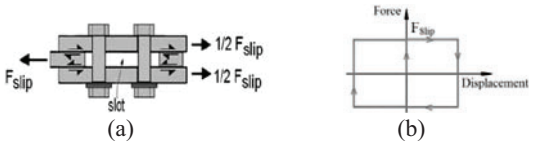

Figure 4: *Symmetric slip friction joint: (a) joint assembly (b) idealized joint isotropic hysteresis*

As an important component of this concept, the innovative shear key developed by Hashemi [3] is incorporated to ensure adequate shear transfer while accommodating the rocking of the CLT wall (Figure 5). It is further proposed to provide a similar shear key at the locations of wall-to-floor to subsequently transfer lateral demands from floor panel (essentially diaphragm) to wall and allow safe and damage free rocking motion. An illustration of the proposed concept assembly is shown in Figure 6. The proposed concept, in summary, utilizes RSFJs as hold-downs of the rocking CLT wall, while friction dampers are utilized at the locations of wall-to-floor, and the innovative shear key is employed at the base of the rocking wall as well as the locations of wall-to-floor.

3 METHODOLOGY

Through numerical analyses of case study structures with various number of storeys and configurations, this study provides a comprehensive assessment of the proposed CLT rocking wall system. Table 1 presents a summary of the case study structures and Figure 7 illustrates the assembly of the largest case study structure (seven storey K7-FD) as an example. As a means of highlighting the benefits of friction dampers, numerical analysis of each case study structure was conducted in two configurations, one with friction dampers at floor levels, the other without. It should be noted that the loading considerations are assumed to be for a commercial structure. While the first-floor measures 4.8 meters in height, all subsequent floors measure an equal 3.8 meters in height. Gravity is completely taken by the LVL gravity frame, hence the rocking CLT wall is decoupled from the gravity load resisting frame for the purposes of this study. CLT rocking walls are composed of Machine Stress Graded sawn timber with a modulus of elasticity of 8 GPa (MSG8) in the longitudinal direction and MSG6 in the transverse direction. ETABS software [14] is used for the numerical analysis. Non-linear pushover analyses are carried out to highlight the key performance characteristics of the proposed systems, followed by dynamic time history analyses that provide a wide range of variables suitable for comprehensive analytical study. Dynamic time history analyses are conducted by scaling seven ground motion records in accordance with NZS1170.5 guidelines [15].

Table 1: *Summary of the case study structures.*

Case study wall structure:	Configuration, Ki	Number of storeys	Structure height (m)
K2	K2 - FD K2 – R	2	8.6
K3	K3 - FD K3 – R	3	12.4
K4	K4 - FD K4 – R	4	16.2
K5	K5 - FD K5 – R	5	20.0
K6	K6 - FD K6 – R	6	23.8
K7	K7 - FD K7 – R	7	27.6

Configuration, Ki	Number of hold-downs	Number of shear keys	Number of friction dampers
K2 - FD K2 – R	2	2	4 -
K3 - FD K3 – R	2	3	6 -
K4 - FD K4 – R	2	4	8 -
K5 - FD K5 – R	2	5	10 -
K6 - FD K6 – R	2	6	12 -
K7 - FD K7 – R	2	7	14 -

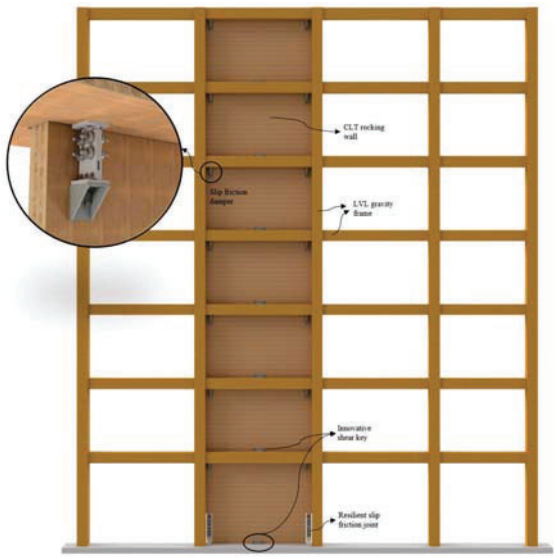

Figure 7: *Assembly of the case study structure (seven story K7-FD)*

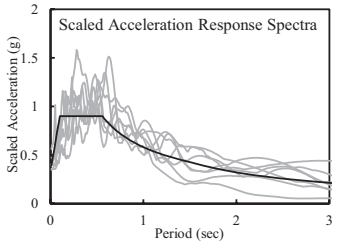

Figure 8: *Scaled ground motion accelerations*

The design envisages that there to be notches at both the bottom corners of the walls to fit the RSFJ hold downs, therefore, the rocking wall lever arm is from the rocking toe to the opposite RSFJ hold down. In practice, the RSFJ hold downs will be equipped with spherical swivel bearings at their base to allow rotation in line with the rocking wall. Thus, a pinned boundary condition is assigned to the bottom of the link elements representing the RSFJs in the numerical model. RFSJ hold downs are modelled using "Damper-friction spring" and slip friction dampers are modelled using "multilinear plastic" link elements in ETABS. The validity of the modelling techniques has already been confirmed by several studies [6, 16, 17].

4 PROPOSED SYSTEM PERFORMANCE

It is appropriate to use non-linear pushover analysis for this study since the case study structures are regular low- to mid-rise structures and the first mode of vibration is the governing mode (fundamental mode). In order to determine the optimal friction damper slip force for each case study structure, nonlinear pushover analysis iterations (tuning) were conducted. Each system was optimized by minimizing the residual force-displacement at the end of every quadrant cycle while maximising energy dissipation (damping). When the friction damper slip force is low, even though complete self-centering is achieved without any residual force, the flag-shaped hysteresis is narrow, and it is possible to increase the damping capacity of the system by increasing the slip force (capacity) of the friction damper in order to enlarge the hysteresis area. When the slip force of the friction damper is high, considerable residual displacement and force are experienced, which most likely result in significant residual deformation after an earthquake.

Hysteretic damping ($\xi_{hysteresis}$) is calculated via Jacobsen's simplified method (hysteresis area) [18] with the provided backbone curves from cyclic pushover analyses. In Figure 9, the load-deformation curve (hysteresis) of the system is shown for cases with friction dampers (Ki-FD series) versus cases without friction dampers (Ki-R series). Non-linear pushover results show that hysteretic damping capacity ($\xi_{hysteresis}$) has increased by 7% on average with the implementation of tuned friction dampers. Increases in damping capacity is correlated with an increase in stories, or in other words, an increase in friction dampers.

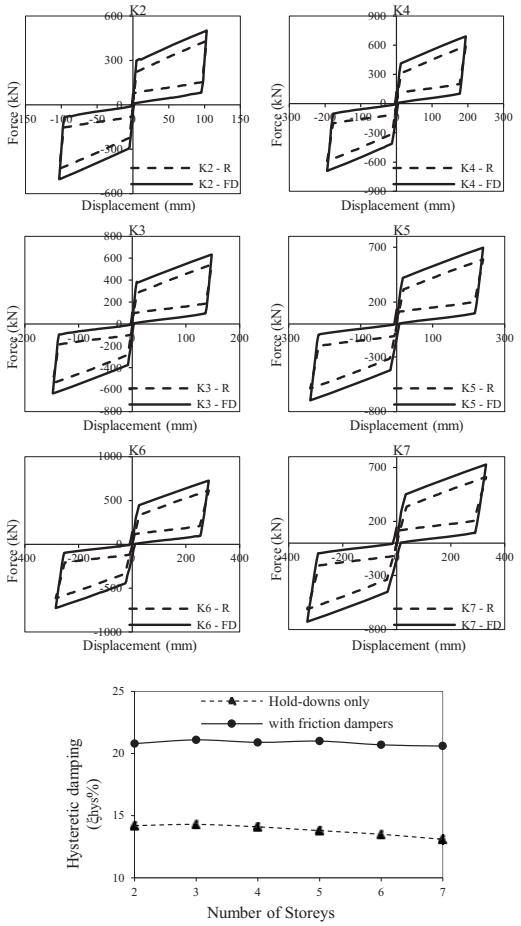

Figure 9: *Comparison of system load-deformation curves of cases with and without friction dampers.*

Dynamic time history offers not only a wide array of variables for this study, but also incorporates all modes of vibration, thereby capturing any dynamic effects that may have been overlooked in nonlinear pushover analysis. Furthermore, dynamic time history appropriately accommodates the non-linearity of members, links (dampers), and boundary conditions such as gaps with their respective inherent and hysteretic damping. For each case study "mean of seven" approach [19] is used as a means of interpreting the results. One of the most noticeable advantages of the proposed system is the reduction in displacement demands on the structure (as an important index); where roof drifts have been significantly reduced by an average of 35% (see Figure 10). It is observed that the greatest reduction in roof drift is about 65%, while the least reduction is about 10%. Based on these results, it is evident that the proposed system is effective in curtailing lateral displacement demands under a variety of cases.

https://doi.org/10.52202/069179-0336

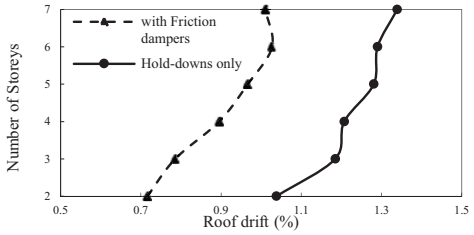

Figure 10: *Performance of the case study structures via dynamic time history analyses, roof drift comparison.*

Seismic force demands (base shear) have been reduced by about 15% on average. This decrease becomes more significant with taller structures, demonstrating an indication of the potential benefit of the proposed system on mitigating higher mode effects which have been of concern with tall wall structures [20, 21]. While complete self-centering behavior is observed in all cases, the proposed system appeared to be more effective in controlling residual drifts, especially for taller walls (see Figure 11). This provides further confidence in its likely performance during a major event in which ground motions exceeding the design level are experienced, developing force and displacement demands exceeding the design levels due to dynamic amplification caused by higher mode effects. All residual drifts fall well under the permissible residual drifts levels suggested by McCormick et al. [22] where 0.5% residual drift is a suitable threshold, after which the structure requires repairs to ensure structural soundness. Combined with RSFJ hold-downs, the concerns regarding self-centring of friction dampers, discussed in the previous section, are rendered irrelevant.

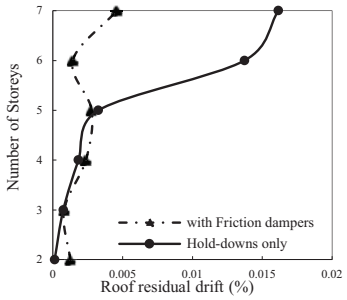

Figure 11: *Performance of the case study structures via dynamic time history analyses, roof residual drift comparison.*

Consequently, there is a reduction in both the force and displacement demands of the hold-downs, resulting in smaller hold-downs required. The reduction in force and displacement demands of the hold-downs is substantial, where force demand have been significantly reduced by an average of 40%, and displacement demand have been reduced by an average of 25%. Similar to the system, the hold-down force demand reduction becomes more evident with taller structures, validating that the presence of friction dampers helps control lateral demand, enhances lateral force distribution, and mitigates higher mode effects. These reductions entail a considerable decrease in capacity, size, and cost of the hold-downs. Figure 12 presents comparison of the hold-down load-deformation (hysteresis) obtained for El Centro (1940) ground motion. Furthermore, it is perceived that by utilizing smaller hold-downs, the stresses induced to critical points of CLT rocking walls can be reduced by approximately 20%. It is therefore possible to reduce the number of layers in the CLT wall or reduce the manufacturing grade of the CLT.

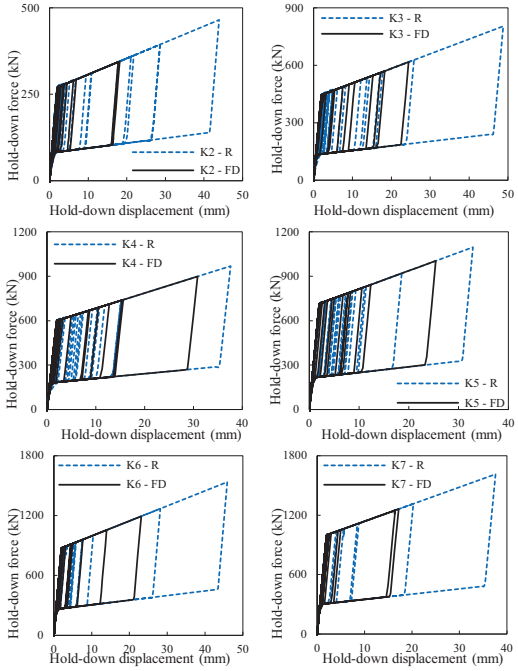

Figure 12: *Comparison of critical hold-down load-deformation (hysteresis) of the case study structures for El Centro (1940) ground motion.*

5 CONCLUSIONS

A new wall-to-floor and wall-to-beam system is presented in this paper that eliminates bulky rigid connections and addresses the shortcomings of existing conventional methods. A new shear key-like system, incorporating friction dampers, has been proposed to allow safe wall uplift, while dissipating energy at the same time. A numerical investigation of the proposed concept was conducted by selecting seven case study structures. By implementing friction dampers, the hysteretic damping capacity ($\xi_{hysteresis}$) has increased by 7% on average. According to the results of dynamic time history analyses, the most notable advantage of the proposed system is the reduction in displacement and force demand by about 35% and 15%, respectively. Furthermore, the force and displacement demand of the hold-downs has reduced noticeably by 40% and 25% respectively, leading to smaller capacity, reduced size, and more affordable hold-downs. The result is a more economical and cost-effective design as a whole, while delivering a high-performance, competitive solution compared to conventional timber structures. The cost of friction dampers can be offset by

eliminating the conventional bracket connections and reducing the number of fasteners.

EVALUATION OF SEISMIC PERFORMANCE FACTORS AND FRAGILITY FUNCTIONS FOR POST-TENSIONED MASS PLY PANEL ROCKING WALLS

Tu X. Ho[1], Patricio Uarac P.[2], Andre R. Barbosa [3], Arijit Sinha[4], Barbara Simpson[5], Gustavo A. Araújo R.[6], Gustavo F. Orozco[7]

ABSTRACT: This paper presents the statistical and numerical investigation of the seismic performance of a three-story post-tensioned mass ply panel (MPP) rocking wall lateral force-resisting system prototype whose main components are MPP, U-shaped flexural steel plates (UFPs), and high-strength steel post-tensioned rods. Uncertainties in material properties and geometry of the components are considered in the assessment of the performance of this lateral force-resisting system based on recent experimental data on MPP, experimental data available in the literature for the UFPs and post-tensioning rods, as well as some additional structural design considerations. In the assessment of the seismic performance factors, first, random realizations of the structural design are generated using Monte Carlo simulation. Second, for each realization, a nonlinear finite element model is developed. For each realization, two types of analysis are performed, nonlinear static analyses, and incremental dynamic analyses. Results of the nonlinear static and dynamic analyses are then used to estimate the seismic design factors (e.g., R-factor) and limit state-based fragility functions, the latter being based on exceeding limit states defined for each component based on existing experimental data.

KEYWORDS: Fragility function, incremental dynamic analysis, mass ply panel, post-tensioned rocking wall, pushover analysis, R-factor.

1 INTRODUCTION

Mass timber materials have gained public attention and are finding expanded uses in the building sector. The International Building Code [1] introduced new building types in the last code revision cycle, which now allows for the design and construction of mass timber buildings up to 18 stories tall. Innovative lateral force-resisting systems (LFRS), such as post-tensioned rocking walls coupled with different energy dissipation solutions, have been designed for use in buildings per (i) the equivalent lateral force procedure in ASCE 7 [2] assuming a conservative seismic response modification coefficient (R-factor) [3], or (ii) state-of-the-art performance-based design methods requiring the use of alternative means and methods of design and analysis, which were mentioned by FEMA P-58 [4]. However, even though a few buildings have been built using these LFRS [5], few studies have focused on the seismic performance of mass timber post-tensioned rocking walls, and therefore, the seismic design factors (e.g., R-factor) of the system, which is used in ASCE 7 and other seismic design standards, and fragility functions needed to fully adopt the FEMA P-58 methodology have been based on expert judgement [6] that have been largely conservative. Based on existing knowledge and recent experimental test data, this paper summarizes the nonlinear modelling of post-tensioned mass ply panel (MPP) rocking walls coupled with U-shaped flexural plates (UFPs) and presents the seismic performance assessment of a three-story building adopting this LFRS [7]. Effects of epistemic and aleatory uncertainties were explicitly accounted for in the seismic performance assessment of the rocking wall system, following a validated method available in the literature [8]. Results of the nonlinear analyses are presented in terms of collapse fragility functions and seismic performance factors, which may be used as a first step in the determination of low- and mid-rise building archetypes consisting of post-tensioned mass timber walls.

2 METHODOLOGY

2.1 DESCRIPTION OF STRUCTURE

The LFRS was designed for an occupancy consistent with that of an office building archetype located at a site in Seattle, Washington, USA with soil class D and seismic response spectral values, S_{DS} = 0.97 g, S_{D1} = 0.61 g. The direct displacement-based design (DDBD) method [9]–[11] was used for the design of the LFRS. The design base shear was determined by using the capacity spectrum approach [9] and was utilized to design shear wall dimensions, UFPs, and high-strength post-tensioned rods. In the design, a flag shape hysteretic model [11] was utilized to estimate the effective damping of the post-tensioned rocking wall, assuming a damping ratio of 10%. The LFRS was designed to meet requirements of three performance levels [Immediate Occupancy (IO), Life Safety (LS), and Collapse Prevention (CP)], each corresponding to an earthquake hazard intensity level [Service Level Earthquake (SLE), Design Earthquake (DE), and risk-targeted Maximum Considered Earthquake (MCE_R), respectively]. Table 1 lists the performance targets for each performance level. The targets are defined in terms of peak inter-story drift (D_{max}), strains in the post-tensioning rods (ε_{PTmax}), and MPP compression strains at the rocking interface (ε_{MPPmax}). The thresholds strains for the post-tensioning rods and MPP wall are defined such that they remain in the elastic range at IO and LS levels, while both tension rods and MPP are allowed to yield at CP level, but without exceeding their ultimate strains in tension and compression, respectively.

Table 1: *Performance levels and targets*

Performance Level	EQ Levels	Performance thresholds		
		D_{max}	ε_{PTmax}	ε_{MPPmax}
IO	SLE	1.0%	0.0044	0.0032
LS	DE	2.0%	0.0044	0.0032
CP	MCE_R	4.0%	0.0066	0.0075

The investigated post-tensioned rocking wall LFRS shown in Figure 1 (UFP wall) consists of an MPP shear wall (9144 mm × 2134 mm × 181 mm, F16 wall panel [12]), two pairs of post-tensioning rods (diameter 31.8 mm; ASTM A354 Grade BD [13]) connecting the top of the MPP shear wall to the foundation, and 20 UFP devices (152 mm wide, 12.7 mm thick and 102 mm bending diameter, ASTM A572 Grade 42 [14]). The UFPs are attached to the MPP and steel bounding columns that connect to the foundation. The steel bounding column is designed to remain elastic at MCE_R. The MPP walls are connected to the MPP floor slabs through one shear key at each floor level and two shear keys at its base. The MPP floor slabs are supported by laminated veneer lumber (LVL) beams and columns.

2.2 FINITE ELEMENT MODEL OF STRUCTURE

Two-dimensional (2D) finite element models were developed in OpenSees [15] to characterize the building geometry shown in Figure 1. For the gravity system, elastic beam-column elements (elasticBeamColumn) were used. The elastic beam-column elements were connected to the beam-column joint using zero-length, elastic elements to account for the rotational stiffness of the connection. For the LFRS, the MPP panel itself was modelled using elastic beam-column elements along the height of the building, with nonlinear springs placed between the base of the wall and the foundation to represent the rocking behaviour and any potential inelasticity due to panel crushing and gap opening at the base of the wall. The nonlinear base springs consisted of 19 zero-length, elastic-perfectly plastic (ElasticPPGap) elements that work only in compression, assuming the compression strength in the major direction of the MPP (f_{c_0}) as the elastic limit and considering a plastic hinge length of two times the thickness of the MPP [16]. The springs were located based on the Gauss-Legendre quadrature points along the width of the panel. The UFPs were also modelled with zero-length elements with a force-displacement relation based on the uniaxial material Giuffre-Menegotto-Pinto [17] model. Properties of the UFPs were calibrated to match available numerical models developed using a Ramberg-Osgood material model [18]. Finally, the post-tensioning rods were modelled as trusses with an initial strain based on the design post-tensioning force and a tension-only nonlinear material model. The model of the LFRS is shown graphically in Figure 2.

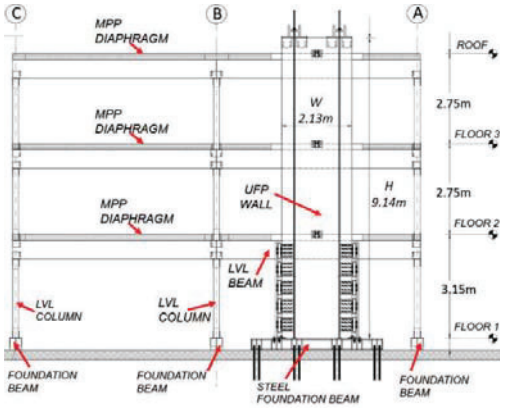

Figure 1: *Elevation of the LFRS archetype*

The finite element models were subjected to nonlinear static pushover analyses and nonlinear time history analyses (NLTHA). For each realization, the fundamental period (T_1) and the associated first-mode shape are computed and used as input parameters for the nonlinear static analysis, where at each floor level, a force is applied following this first-mode distribution with displacement control at the roof level. Each pushover realization is pushed until an 8% roof drift ratio or until is numerically unstable. For the NLTHA, the fundamental period is used to define the target damping ratios for the Rayleigh damping matrix, using committed stiffness and 2% damping associated with the elongated period $1.5T_1$ and short period $0.2T_1$.

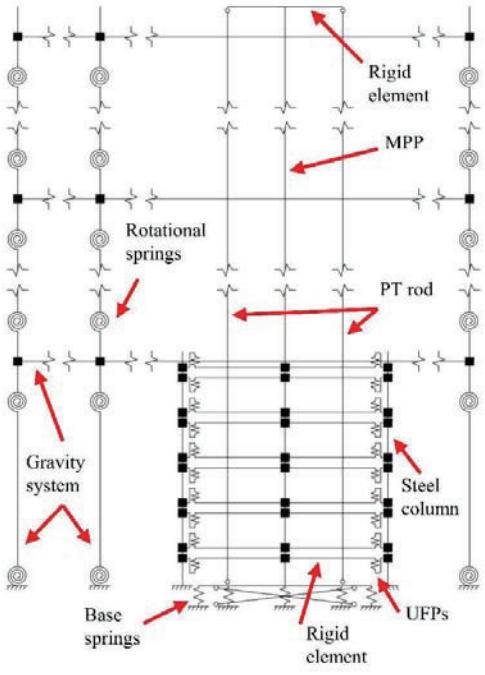

Figure 2: *Finite element model*

2.3 RANDOM VARIABLES AND THEIR STATISTICAL CORRELATIONS

The variability of component properties and dimensions affects the stiffness, strength, and dynamic properties of the structure, and, therefore, its response to loading. Based on the material properties described in this section, a set of 100 structural models were randomly generated. Each model represents a realization of the random variables defining the wall design. Considerations in the model development performed are described in the next subsections.

2.3.1 Material properties

Uncertainties in material properties were based on information available in the literature [19]–[25]. For MPP, Table 2 lists four random variables and their parameters, including mean and coefficients of variation (CoV) for density (ρ_w), modulus of elasticity (E_w), compressive strength in the major direction (f_{c_0}), and shear modulus (G). Expected values were based on the material testing results [24], [25]. Coefficients of variation (CoVs) were determined based on values and formula for glue-laminated timber [22], [23], because currently there is no reliable study on the CoVs of material parameters for MPP, which vary based on base materials, quality control, and material selection schemes implemented in the production of the panels. The density followed a normal distribution while the other properties are lognormally distributed. The four random variables were assumed to be correlated, based on data available for timber materials [22], as shown in Table 3.

Table 2: *Random variables for MPP material properties*

Variable	Dist.	Mean	CoV
ρ_w (kg/m^3)	Normal	34.0	0.10
E_w (MPa)	Lognormal	13626.0	0.13
f_{c_0} (MPa)	Lognormal	44.9	0.12
G (MPa)	Lognormal	509.7	0.13

Table 3: *Correlation coefficient matrix for MPP material properties*

Variable	ρ_w	E_w	$f_{c\ 0}$	G
ρ_w	1.0	0.6	0.8	0.6
E_w	0.6	1.0	0.6	0.6
f_{c0}	0.6	0.6	1.0	0.4
G	0.6	0.6	0.4	1.0

The probabilistic model parameters associated with the mechanical properties of the high-strength rod and other structural steel components are presented in Table 4 and Table 5, respectively. The random variables for the high-strength rods follow a normal distribution, while the structural steel follow lognormal distributions, including the elastic modulus (E_s) and yield strength (f_{sy}) for the UFP components, and on elastic modulus (E_s) and Poisson's ratio (v_s) for the steel bounding columns. The expected values and CoVs were derived from the literature [19], [20].

Table 4: *Random variables for high-strength steel rod properties*

Property	Dist.	Mean	CoV
E_p (GPa)	Normal	200	0.020
f_{pt} (MPa)	Normal	1075.6	0.025
e_u (mm/mm)	Normal	0.05	0.060

Table 5: *Random variables for structural steel properties*

Property	Dist.	Mean	CoV
f_{sy} (MPa)	Lognormal	423	0.105
E_s (GPa)	Lognormal	200	0.045
v_s	Lognormal	0.3	0.045

2.3.2 Component dimensions

Geometric deviations from specified dimensions that also contribute to model uncertainties were accounted for in the probabilistic modelling. For each considered variable, the distribution, mean value, standard deviation, and tolerance are presented in Table 6, where the mean values correspond to the dimensions used for the initial design. Tolerances were considered as the amount by which a measurement might change and still be acceptable [26]; this implies that no realization had geometric values outside the mean plus/minus the tolerance. Values from previous studies were used for the standard deviation and tolerances of each component. For the MPP, standard deviations and tolerances from [27] and [28] were used, respectively. For the UFP thickness, the standard deviation is assumed to be a third of the tolerance from [29]. For the other dimensions, the standard deviation is assumed as half of the tolerance from [30]. For the C-section steel column, the standard deviations are based on [31] and [32], along with tolerances from [30].

2.4 PERFORMANCE ASSESSMENT

2.4.1 Damage State Definition

Damage state thresholds were defined using the peak inter-story drift ratio limit as a proxy for damage based on drift limits estimated from component-based (UFP, wall, PT rod, etc.) strain limits developed from experimental data available in the literature. The damage states are associated with the building capacity curve. Three different damage state levels, including Immediate Occupancy (IO), Life Safety (LS), and Collapse Prevention (CP), are defined in this study. The IO damage state is associated with the effective yielding of any components in the building occurs. In the MPP wall LFRS, yielding of UFP devices usually happens at relatively small drift ratios; therefore, yielding of the UFPs is chosen as the indicator of IO damage state in this study. The LS damage state is associated with crushing of the MPP panel or yielding of the PT bar, whichever occurs first. Lastly, the CP damage states are associated with the first occurrence of the following cases: (1) the PT bar strain is greater than the ultimate capacity strain, (2) the peak inter-story drift ratio exceeds 0.1, or (3) the inter-story residual drift is greater than 0.015 [33].

2.4.2 Assessment of the seismic performance factors

The assessment of the seismic performance factors (R-factor, deflection amplification factor, and the over-strength factor) was implemented based on the nonlinear static analyses applied to the set of 100 generated structures. The pushover analysis was used to determine the damage state levels and impact of uncertainties on the R-factor and building capacity. The base shear versus roof drift ratio results were used to obtain the distribution of the building capacity. The mean (μ), mean minus standard deviation (μ-σ), and mean plus standard deviation (μ+σ) of each variable in Figure 3 are determined using the capacity curves. Overall, procedures followed in this study are described in [8] and [34]. The seismic performance factors include: (1) normalized reference yield force, F_y/W, where W is the weight of the structure, (2) reference yield roof drift ratio, d_y/H, where H is the height of the building, (3) displacement ductility factor $\mu = d_u/d_y$ (4) system overstrength factor $\Omega_s = F_y/F_d$, where F_d is the design base shear, and (5) both the seismic modification factor, R, and displacement amplification factor C_d , set equal to the product of the $R_\mu \cdot \Omega_s$., where R_μ is the seismic modification factor associated with the ductility of the system and, thus, set equal to the displacement ductility for this bilinear fitted model.

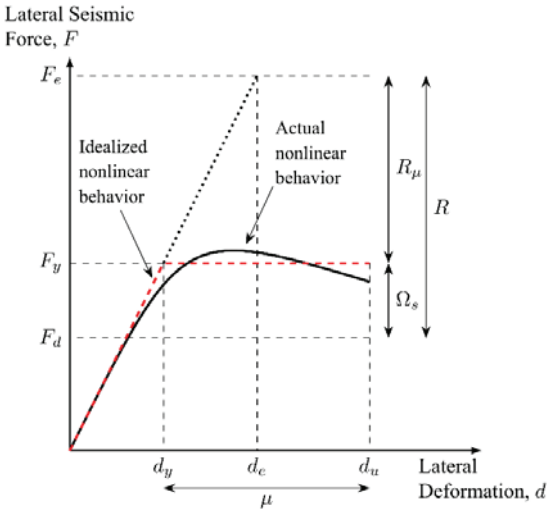

Figure 3: *Equivalent bilinear inelastic model*

2.4.3 Fragility functions

The uncertainties in seismic response were investigated using an incremental dynamic analysis (IDA) for the set of 100 structures. In the IDA, each structure is subjected to the suite of 44 far-field ground motions defined in FEMA P-695 [35]. To reduce computational cost, the 5%-damped response spectral acceleration at the first mode was scaled up to an upper limit of 5g, resulting in a truncated IDA [36]. For each ground motion (GM), increments of 0.2 g were used in the IDA, such that a total of 4,400 IDA was performed. At the IO level, the UFP yielding is chosen as indicator; however, since UFPs reach yielding at relatively small drift ratios, the nonlinear static analysis is used to identify the mean drift ratio where the first-yield of the system occurs, point associated with a 10% drop of the initial stiffness. Using the first-yield drift ratio as threshold on the IDA, a distribution of the amount of UFPs at yielding is obtained and its mean value is used to develop the component fragility function. At CP level, four collapse criteria were used: (1) maximum inter-story drift ratio greater or equal to 0.1, (2) maximum inter-story residual drift ratio greater than 0.015, as recommended by [33], (3) strain in the post-tensioned rods exceeding the maximum strain limit, and (4) numerical non-convergence. As part of the numerical model, the limit states of the UFPs and the MPP panels

https://doi.org/10.52202/069179-0337

were using the uniaxial material 'MinMax' in OpenSees but were not considered a collapse criterion. The use of this 'MinMax' material model means that for strains below or above the ultimate strain of the component, the component fails and returns zero stress.

Based on the IDA results, the fragility functions were fit to a lognormal cumulative distribution function (CDF) with an empirical section and a fitted-extrapolated section, as considered in [37].

3 RESULTS

3.1 SEISMIC PERFORMANCE FACTORS

Figure 4 shows the results of the nonlinear pushover analyses. The results for all 100 structures are shown in grey, while the black curve corresponds to the mean of all the pushover curves. The red line corresponds to a bilinear model calibrated using the Energy Equivalent Elasto-Plastic method [38] fit to the mean pushover curve. A similar calibration process was conducted to obtain the mean plus and minus standard deviation curves (not shown in the figure). Table 7 lists the normalized calibrated factors, reference yield force, and reference yield drift ratio (F_y/W, and d_y/H) for all three calibrated curves. In addition, Table 7 also lists the seismic performance factors. The base shear at the ultimate roof drift ratio of 0.07 represents the lowest force obtained in the mean pushover results.

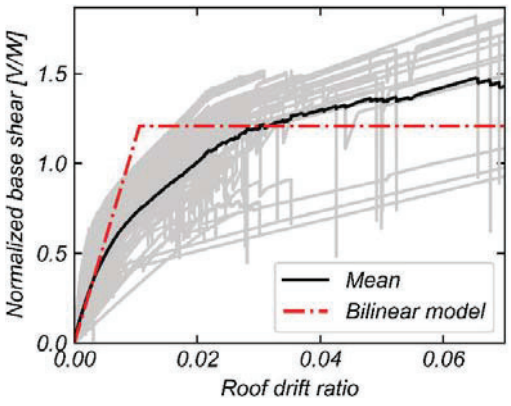

Figure 4: *Pushover results and fitted elastoplastic bilinear model.*

3.2 INCREMENTAL DYNAMIC ANALYSIS (IDA)

Figure 5 shows the results of the IDA, where each grey dot represents the maximum of the absolute peak inter-story drift ratios obtained for each NLTHA for a given realization and ground motion record scaled to the linear elastic, 5%-damped spectral acceleration at the fundamental period of the structure, $S_a(T_1)$. The blue curve represents a typical IDA curve for an individual ground motion and IM_{max} corresponds to the truncated value of the spectral acceleration considered. The mean curve indicates that the LFRS remains essentially elastic up to 0.02 maximum inter-story drift ratio, a soft transition occurs from this point before reaching the plateau of the system around 0.05 maximum inter-story drift ratio associated with IM of 3.3g, which is 3.6 times the S_{DS} value. Note, not all IDA reached the peak inter-story drift ratio of 10%, e.g. at 2%, 4% and 8% of peak inter-story drift ratio, 98%, 79% and 50% of the IDA reached or passed the values respectively.

Table 7: *Seismic performance factor statistics*

Variable	Mean – Std Dev	Mean	Mean + Std Dev
F_y/W	0.95	1.22	1.49
d_y/H	0.0083	0.0122	0.0161
$\mu = R_\mu = d_u/d_y$	4.35	5.74	8.45
$\Omega_s = F_y/F_d$	1.49	1.91	2.34
$R = C_d = R_\mu \cdot \Omega_s$	6.48	11.0	19.8

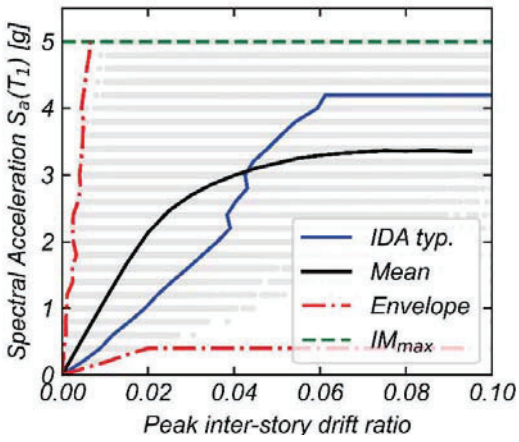

Figure 5: *IDA results for 100 realizations of the structure subjected to 44 FEMA P-695 far-field ground motions.*

As stated on the methodology, at the IO level, the UFPs yield at relatively small drift ratios. From the nonlinear static analysis, it was found that this occurs for an inter-story drift ratio of 0.001 (Figure 4) and the mean first-yield of the system is associated with the yield of one UFP.

Based on the IDA results, for each component, fragility functions were developed in terms of the spectral acceleration versus the normalized peak displacement over the yielding displacement of the UFP (d_u/d_y), normalized maximum stress over the crushing stress of the MPP wall (σ_u/σ_y), and normalized peak strain over the yielding strain on the PT rods ($\varepsilon_u/\varepsilon_y$), which are shown in Figure 6.

https://doi.org/10.52202/069179-0337

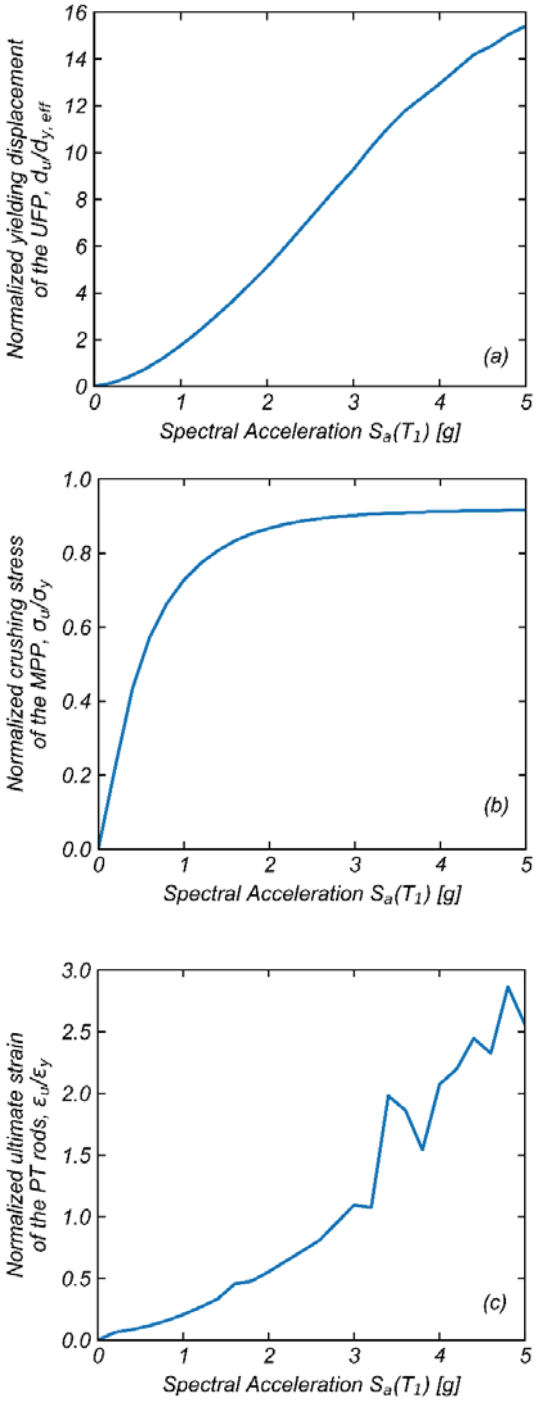

***Figure 6: Mean** empirical component fragility functions for: (a) UFP, (b) MPP panel, (c) PT rod.*

As stated previously, the UFPs reach yielding at small drift ratios compared with peak inter-story drift ratio limit on Table 1 for IO, and similar conclusions can be obtained from the fragility functions, where the IM at yielding is 0.708 g, which is 0.73 times S_{DS}. Between 1 g and 3.5 g, the fragility function is mostly linear and shows a large component displacement ductility of 15.4 at 5 g. The MPP fragility function shows that the MPP wall behaves in the elastic range for all considered IMs, although a plateau forms above 2 g (2.06 times S_{DS}) when the component can no longer resist additional stresses for all limit states. In the case of the PT rod fragility function, the function increases monotonically until yielding at 3 g (3.09 times SDS). After yielding, the function shows abrupt changes that could be related with the snap-back presented in typical IDA.

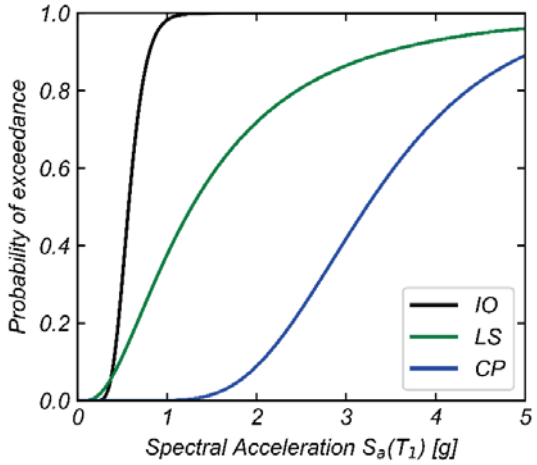

***Figure 7:** Empirical system fragility function for each damage state.*

***Table 8:** IM capacities for different damage states*

	IM		
Damage State	16th percentile	Mean	84th percentile
IO [g]	0.437	0.571	0.744
LS [g]	0.591	1.28	2.76
CP [g]	2.69	3.23	4.60

Table 8 lists the IM for the three damage states considered in this study fitted to a lognormal distribution, the values presented along with the Figure 7 show an overlap of the IO an LS damage for spectral accelerations below 0.5 g which is related to limit states used at each damage state. For IO, the only limit state considered was yield displacement of the UFPs, while for LS either crushing on the MPP or yield of the PT rods were used as limit states. The overlap implies that there is a probability below 5% that the system will sustain damage associated with either IO or LS damage state. Similarly, analysing the components that controls each of these states, UFPs for IO and MPP and PT rods for LS, the larger standard deviation at LS can be attributed to the MPP due its contribution to the nonlinear response at the base spring for each realization, which is a function of the elastic modulus (E_w) and its CoV, which is one order of magnitude greater than the other components. Similarly, at CP, the uncertainties on the MPP play a significant role on the standard deviation of the fragility function.

https://doi.org/10.52202/069179-0337

4 CONCLUSIONS

A statistical and numerical investigation of the seismic performance of post-tensioned MPP rocking walls on a 3-story building is conducted. The uncertainties in material properties of components are considered by generation of the basic random variables to model a set of 100 structures. Nonlinear static analyses and IDA are conducted for each structural realization. From the nonlinear static analysis, the seismic performance factors were estimated. The lower bounds and mean (listed in parentheses) are 6.48 (11.0) for the R-factor, 1.49 (1.91) for the system overstrength, and 4.35 (5.74) for the displacement ductility. From the IDA, empirical component fragility functions were developed as well as system fragility functions for different damage states. The component fragility function shows that the UFPs are the main ductility contributors to the system. The overlap on the system fragility functions for IO and LS damage state shows that there are gaps that must be addressed in the characterization of the uncertainties for mass timber products.

THE USE OF PARAMETRIC WORKFLOW ON TIMBER CONSTRUCTION AT SERVICE STATION TORGHATTEN

Paul Hufnagel[1], **Philipp Vehrenberg**[2], **Matthias Stracke**[3]

ABSTRACT: This paper deals with the planning and design process of the service station Torghatten which should provide better tourism infrastructure for one of the Norwegian scenic routes. It describes parametric and automated workflows used across the various project planning phases and their benefits. Based on the project presented, it will also be shown how using these workflows makes it possible to combine modern design and complex geometries even with traditional construction methods.

KEYWORDS: Timber log structure, solid timber structure, complex geometry, parametric modelling

1 INTRODUCTION

The project 'service station Torghatten' is a collaboration between the architecture studio Atelier Oslo AS and Bollinger+Grohmann on behalf of the road authority 'Statens vegvesen' of Norway.

As part of the 'Nasjonale turistveger', the Norwegian scenic routes, the project has a prestige character within the tourism industry in Norway. The Norwegian scenic routes deliver a scenic alternative to the main roads and is suited for tourists who want to explore unique natural qualities such as fjords, mountains or waterfalls by car. To make these natural sights more accessible, each stop provides parking spaces, sanitary facilities, or information boards. The service areas aim to combine beautiful Norwegian nature with Nordic architecture and art.

Today, the Norwegian authorities established 18 scenic routes totaling more than two thousand kilometres. The new service station is part of the section 'Helgelandskysten' and situated on an island in Brønnøy commune. The connected natural sight is Torghatten, a geological formation of a mountain with a hole going through from one side to the other, shown in Figure 1.

Figure 1: *Photography of Torghatten by Atelier Oslo*

The project will be located at the foot of this mountain. It contains parking lots, benches, and rooms for sanitary, technical and exhibition usage. The rooms share one cantilevered roof structure made of timber. In addition, there is a steel stair structure planned, which leads up to the hole. This structure is not part of this paper.

2 CONCEPT

The location of the service station forms a transition between the organised forecourt and the wild nature of Torghatten in the background (see Figure 2).

Three volumes where the cantilevered roof structure rests offer shelter and space for toilets and exhibition areas. The covered outdoor area below the canopy roof creates open spaces equipped with bicycle parking spaces and seating.

Figure 2: *Visualization of the service station by Atelier Oslo*

Except for the foundation, the whole building consists of solid timber beams arranged in layers on top of each other. The alternating overlapping of the layers of timber creates a log structure, which has a long tradition in Norway and is known as 'lafteverk'. This concept continues in the roof structure which is made of overlapping beams in several layers and irregular placement (see Figure 3). The construction method with its traditional roots represents a low-tech solution common in rural areas and differs from many high-tech solutions in urban construction. Due to this irregular placement of the timber beams and the glass roof around the structure, varied shadow plays can be observed throughout the day.

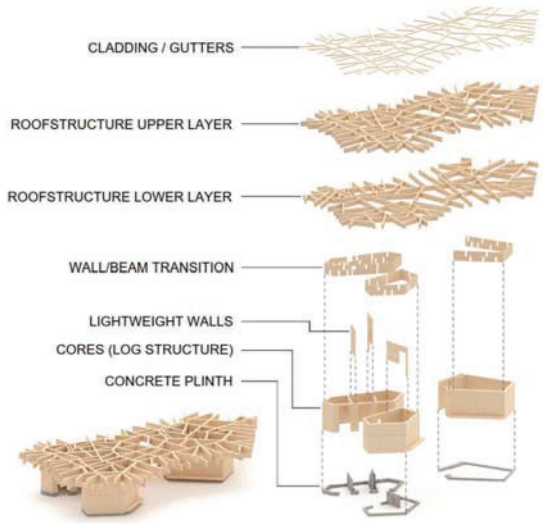

Figure 3: *Illustration of the service building components by Atelier Oslo (translated)*

The simple screw connections and the renunciation of glued timber connections allow the building to be easily dismantled at the end of its lifetime. Just in 2022 these regulations for the reuse of building materials were relaxed in Norway, making it easier to reuse the screws afterwards. A sustainable solution for the project could be found through the predominant use of renewable materials and consideration of the entire life cycle of the building.

3 STRUCTURE – WALLS

3.1 STRUCTURAL CONCEPT

The walls follow the traditionally used 'lafteverk'-concept, where each timber member is placed on top of the other. Each member interlocks on the top and bottom sides to create a horizontal shear connection between the layers.

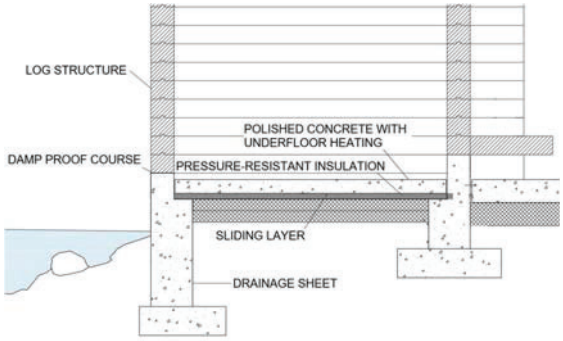

Figure 4: *Section through the service station by Atelier Oslo (translated version of an early presentation)*

In the intersections of two walls, the members alternately overlap in layers. This concept results in a structure of rigid wooden boxes that do not require any additional fasteners except for the door openings. Since the openings interrupt the interlocking principle, other timber dowels and vertical members were planned to ensure the stability of the walls.

3.2 ANCHORAGE/FOUNDATION

The cantilevers of the roof structure, the wind pressure from the passing wind underneath and the wind suction from above lead to uplifting forces that need to be anchored in the foundation. A detailed wind simulation was performed to estimate realistic values for the resulting wind forces that also take the blockage of the canopy roof into account (see Figure 5).

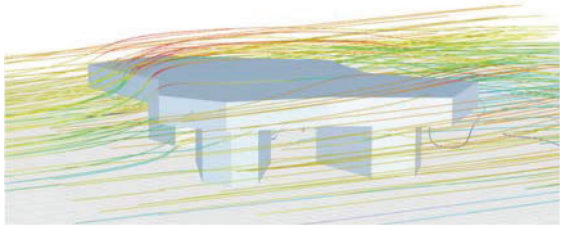

Figure 5: *Extract from the FE-wind calculation*

https://doi.org/10.52202/069179-0338

The resulting uplift forces are transferred by screws from the roof structure into the walls. As shown in Figure 6, the three upper beam layers are screwed to the three lower beam layers screwed to the upper members of the walls. A threaded rod that goes through all wall members is anchored in the foundation and receives a steel plate inside an opening in the top member of the walls. Through this threaded rod, the anchorage of the building can be adjusted according to the long-term deformations of the walls.

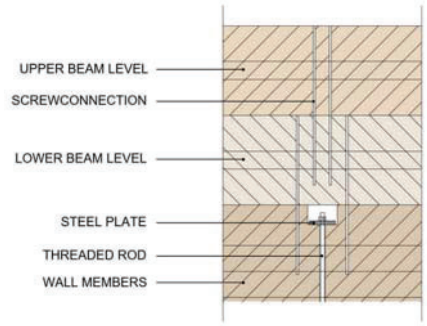

Figure 6: *Anchorage detail*

4 STRUCTURE – ROOF

4.1 STRUCTURAL CONCEPT

4.1.1 Lafteverk-concept within the roof structure

Like the walls, the roof structure also follows the 'lafteverk' principle. Each beam consists of three solid timber members, that are screwed together to create one stiffer member. In the intersections of two beams of the same level, the upper and lower layer of the primary beam (see Figure 7 in orange) continue. In contrast, the inner beam layer stops to give room for the inner layer of the secondary beam (see Figure 7 in green).

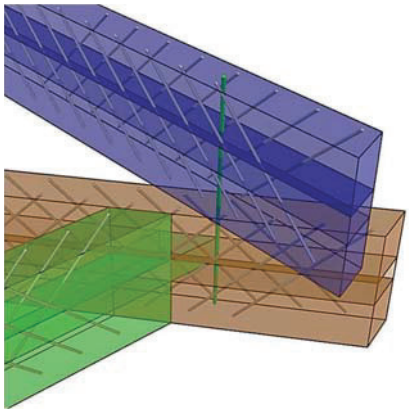

Figure 7: *Illustration of a connection of three beams*

This overlapping of the beam layers creates a vertical support for the secondary beam. This support is unsuitable for transferring moments, so it can be assumed to be hinged. To enable the cantilevers of the canopy roof, another level of beams has to be introduced (see Figure 7 in blue) to support the cantilevered beams that would be structurally unstable, with their only support being hinged. The beams must be placed so that every unstable secondary beam of one level can be supported by a structurally stable beam of the other level. This concept and the resulting structural systems are shown in Figure 8. As shown, it does not matter if a beam from the upper layer supports a beam from the lower layer or the other way around.

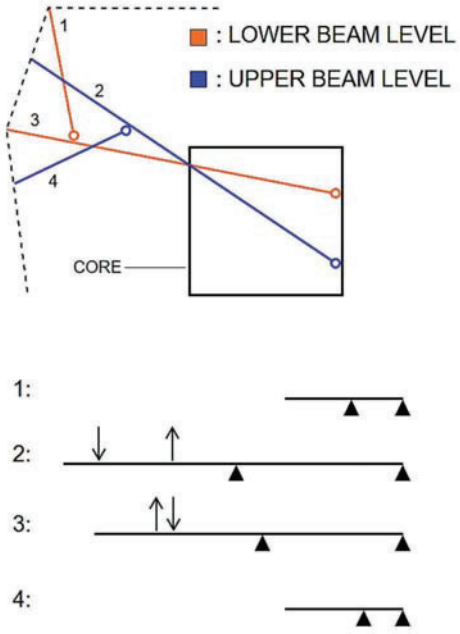

Figure 8: *Illustration of the structural concept of the roof*

Each level on its own would therefore be unstable. Only the combination of the two levels create a stable system where the acting forces travel up and down in the levels and end at the cores.

4.1.2 Form-finding

The architectural design showed the roof geometry as a disordered interaction of beams (see Figure 9).

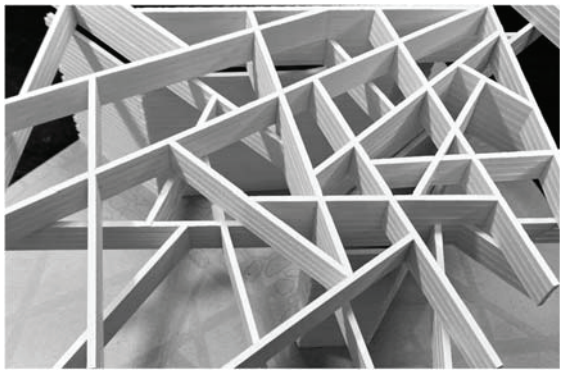

Figure 9: *Photography of an early model by Atelier Oslo*

The task was, therefore, to optimise the beam layout in a way that combines the architectural concept and an efficient structural design.

https://doi.org/10.52202/069179-0338

First, a variation of beam geometries was created using Rhino 3D and its plug-in Grasshopper. For this purpose, short lines were generated along the wall supports defined as fixed positions. Each of these were given a ranking. The short lines were then successively extended in the order of their ranking. If the lines meet the defined building boundary or hit another line, they are not extended any further. In the next step, the lines' ranking varied, which led to endless new patterns. The principle is shown in Figure 10. This approach made it possible to obtain various beam layouts that always sit on the supporting walls.

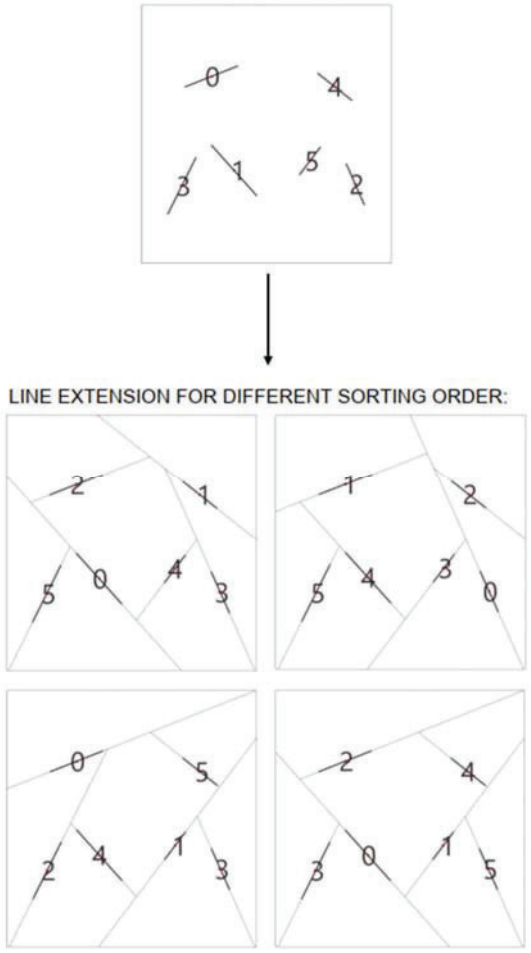

Figure 10: *Illustration of the form finding concept*

To get a tighter beam grid and to optimise the wall positions, additional lines and boundary conditions for the wall geometry were implemented.

In a further step, a structural analysis including FE-calculations was performed using the Grasshopper application Karamba in combination with a multi-objective optimization using the application Octopus. The results of the optimization were rated according to the three variation criteria "deformation", "deviation of the wall geometry" and "beam diversity". The architects used the optimisation variants (examples shown in Figure 11) as the basis for discussion and further development of the roof geometry.

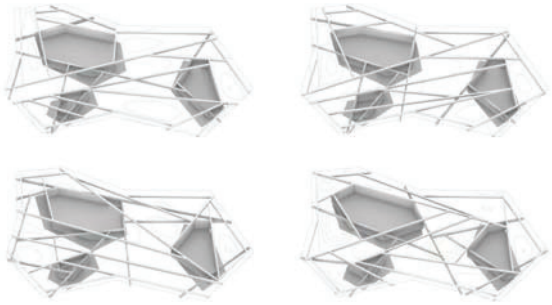

Figure 11: *Selection of results of the form-finding process*

The last adjustments, which led to the final geometry, were made in collaboration between Bollinger+Grohmann and Atelier Oslo based on more detailed FE calculation models using RFEM.

4.1.3 **Modelling**

The structural calculation model was created by using the FE-Software RFEM by Dlubal. The Eurocode refers to the gamma method in EN 1995-1-1 Annex B to model mechanically jointed beams. The gamma method is a simplified calculation in which the reduction factor gamma considers the resilience of the mechanical connection. This factor makes calculating an effective bending stiffness and the resulting deformation and inner forces possible. However, the calculation of the gamma values requires certain boundary conditions. For a mechanically jointed beam consisting of three members, the gamma values can be calculated as shown below:

$$\gamma_2 = 1 \qquad (1)$$

For i = 1 and i = 3:

$$\gamma_i = [1 + \pi^2 \, E_i \, A_i \, s_i / (K_i \, l^2)]^{-1} \qquad (2)$$

Ei Ai: axial stiffness

Ki: slip modulus

si: spacing between the fasteners

l: span

The shown equation (2) sets limits such as a uniform compound of the connection, constant cross-sections and simplified structural support conditions. Especially the last-mentioned limitation is hard to combine with the shown project. The span l can be defined as follows:

Single span beams with a span l: $l = l$

Continuous beams with a span l_i: $l = 0{,}8 \, l_i$

Cantilever with a cantilever length l_c = $2 \, l_c$

Even though RFEM offers the opportunity to define mechanically jointed beams according to their gamma values, each beam would have a different gamma value because of the varying support conditions. Furthermore,

https://doi.org/10.52202/069179-0338

the simplified structural systems used in the code to define the value for l are not feasible for more complex geometries like the roof structure. This premise meant that the gamma method was only used for preliminary calculations and as a plausibility check for individual beams.

A more precise approach was considered to model the stiffness reduction within the mechanically jointed beams, including the screws in the FE-model. The slip modulus of a mechanical connection influences the deformation behaviour of load-bearing systems. In addition, it directly affects the distribution of internal forces in the case of flexibly connected bending beams [1]. For this reason, each screw member had to be modelled according to its slip modulus.

Each combined beam's upper and lower beam layer was modelled for the calculation model according to their cross sections and material properties. Between these layers, the screws were added as spring members at a 45° angle and with a hinged connection to the beams. Each spring member was modelled with a capacity limit and a spring constant according to its slip modulus for the different limit states ULS and SLS and the time $t = 0$ and $t = \infty$. The resulting model acts as a truss system with realistic stiffness values. Additional vertical compression members, which fail if tension occurs, were added to simulate the beams laying on each other. As a simplification, the middle beam layer was only modelled as a load. To gain better control of the internal forces, every truss received a result beam that can show the combined inner forces of the upper and lower beam (see Figure 12).

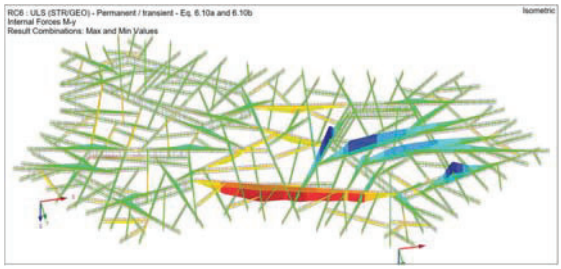

Figure 12: *Moment diagram of the result beams*

Figure 13 shows the FE model equivalent of a combined beam consisting of three individual beams screwed together.

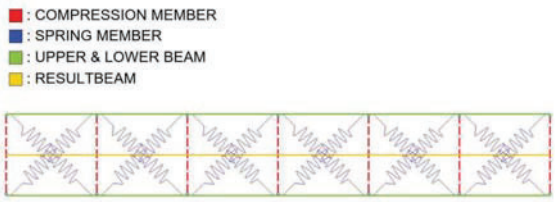

Figure 13: *Illustration of a beam in the structural model*

4.1.4 Interaction between FE-calculation model and parametric model

By having a representative member for each screw of the roof structure, the FE-model gained much complexity. To still react quickly and efficiently to changes in geometry or screwing, interfaces were created between the parametric 3D model and the calculation model.

The Rhino 3D plug-in Grasshopper made it possible to determine the centre lines of each beam for the calculation model from the architects' 3D model. Cross-sections and material properties could already be assigned to these centre lines. In a further step, the centerlines of the screws were generated, and for the screws fixed boundary conditions and variables were defined. One example for a variable parameter was the screw spacing. This made it possible to change the distances between screws in Grasshopper easily, and all the screw centre lines were automatically updated. Figure 14 shows an extract from the parametrically generated centre lines of the screws.

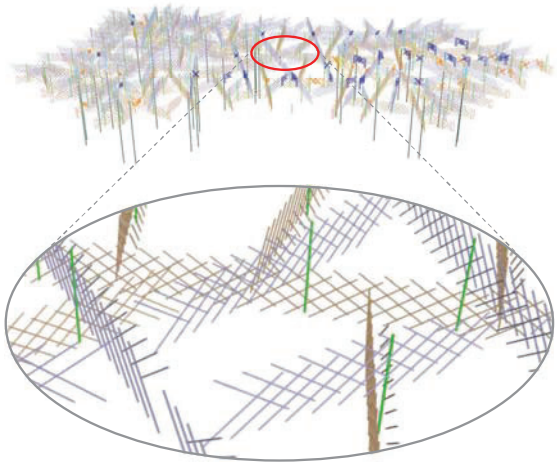

Figure 14: *Generated centre lines of the screws*

After the import into RFEM, only a few adjustments had to be made to get the results from the FE calculation.

5 PARAMETRIC COLLISION CHECK

The two super-positioned structural levels must be connected and also to the cores at particular points, thus creating constraints for the insertion of fasteners. Additionally, intertwining the beam layers within each level of the roof structure induces many potential clashing situations between fasteners and timber beam edges. Since the three beam layers of every level must create a stiff member, the density of necessary screws must be relatively high, increasing the complexity even further.

Over six thousand fasteners of at least eight different types varying in position, length, diameter, and angle had to be placed within this complex structure.

https://doi.org/10.52202/069179-0338

Some screws penetrate not only the three intertwining beams of one roof level but also those of the roof level beneath or the top layers of the walls. This posed a challenge for their modelling, but even more so for ensuring that all fasteners keep a minimum distance to each other and any other element, edge or opening.

By informing each element with a set of key and value properties, such as for the screws their type and beam affiliation, and for the beams their dimensions and beam group affiliation, they could easily be filtered and integrated into custom checks. For example, one review was to model a pipe around a set of screws, with the pipe's radius representing the minimum distance to other objects as defined in the code. Then, the pipe was used for clash detection towards another set of screws or towards beam or opening edges.

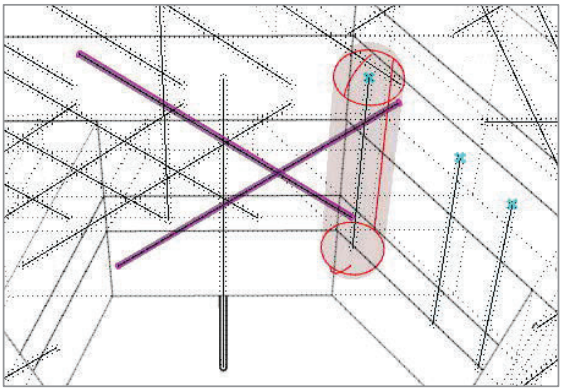

Figure 15: *Showcasing a collision check example*

Even with the 3-dimensional model at hand, it sometimes proved difficult to orient within the structure and avoid confusion. But without using both a 3-dimensional model and a parametric tool, this task for sure could not have been achieved within a reasonable timeframe.

6 PARAMETRIC SHOP DRAWINGS

By choosing a parametric workflow for this project, it was possible to automate almost the entire shop drawing process. This required setting up and maintaining a highly detailed, consistent, and data-informed 3D representation of the whole structure. Therefore, all structural parts, like beams, screws etc., were developed parametrically by Grasshopper scripts. Especially the complex intertwining beam layout proved to be an exciting challenge.

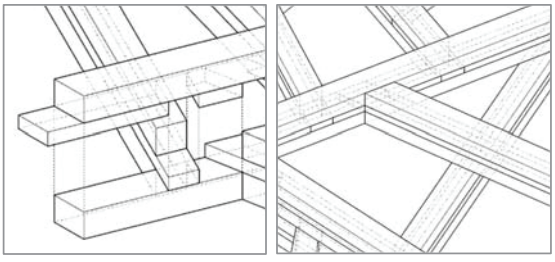

Figure 16: *Intertwined beam layers*

On the one hand, the beams were modelled as simple beams with rectangular plans, with each beam aware of its raw dimensions. On this basis, an excel sheet was exported containing all the necessary information to purchase the raw timber beams, since they had to be dried early on for the later construction process. On the other hand, the beams were also modelled in detail, with their heads cut according to their intersections to produce plans for their manufacture (see Figure 17).

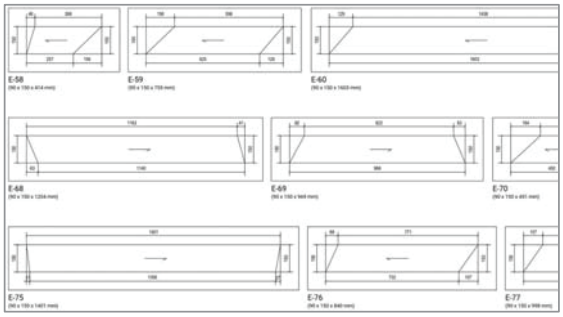

Figure 17: *Extract from the cutting drawing*

Since most elements for the drawings were extracted from or created based on the model, but also to enable an easy check of consistency between the 3D model and the 2D plans, they were made in 3D space at their actual location in the roof structure (see Figure 18). The geometrical elements of the drawing, dimensions, drawing titles, leaders and texts were generated in the parametric process. Once a set of elements was not supposed to change at a certain point in the design process, its final version was stored in the 3D model to reduce the number of elements in the scripting pipeline. To integrate them in the later stage plan production, they inherited the keys and values of their 3D parents and received new information on their purpose.

To conceive meaningful screw position plans, the almost one thousand beams making up the roof structure had to be sorted into roughly two hundred beam groups according to which beams were parallel and connected. Each resulting beam group received geometry and information from neighbouring groups, such as connecting beams and relevant screws that should be displayed along with themselves for orientation. Per beam group, one top view and one section plan were generated. For example, the model's 3D screw lines were transformed into 2D circles at their tips for the top views and to 2D offsets along their length for the sections. The diameter was retrieved from a table according to the screw type information each line contained.

https://doi.org/10.52202/069179-0338

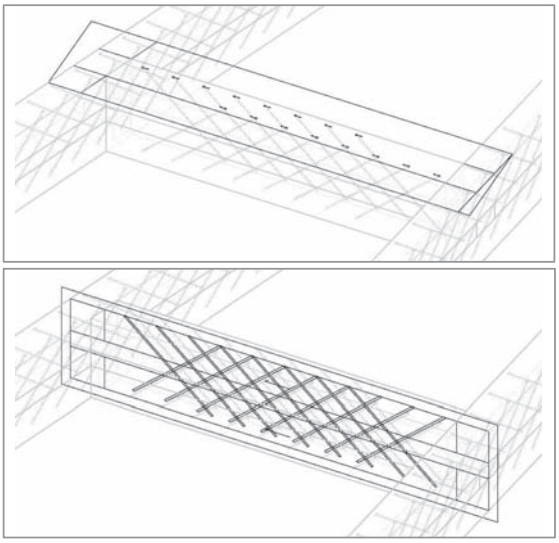

Figure 18: *'Raw' drawings at their origin within the 3D model*

In total, 16 A0 plans were produced for the beam cutting plans and 19 A0 plans for the screw position plans, plus a few more for overviews etc. Considering this number of plans and because every A0 sheet can contain up to one hundred beam cut drawings or up to twenty screw position drawings, it was a challenge to figure out a smart layout for each plan. Therefore, also this task was delegated to a computational tool: A nesting algorithm automatically distributed differently sized rectangles representing each drawing on A0 sheet boundaries, resulting in a spatially optimized layout (see Figure 19). The distributed rectangles contained information as to which drawing, they belonged, so the drawings could be placed on the A0 sheets accordingly.

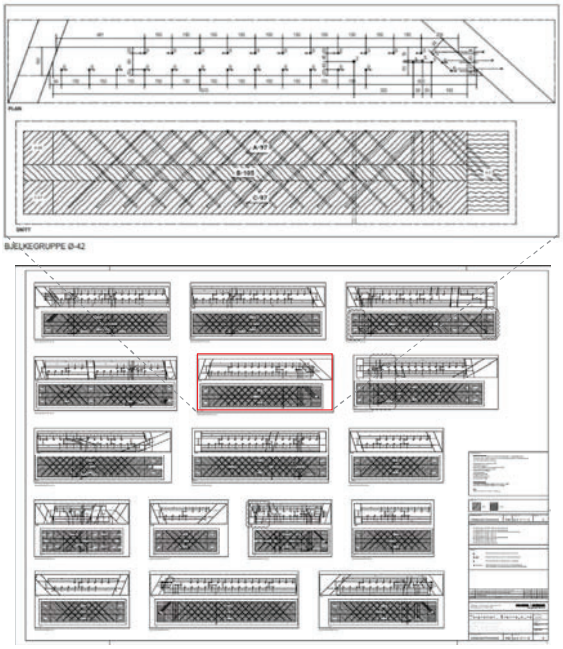

Figure 19: *Extract from the screw position drawings*

Since the entire workflow from modeling to plan production is parametric, changes to the structure or the drawings can be made relatively fast, and automated checks can be performed to enhance quality and oversight. Nevertheless, it was of course necessary to also double-check every plan manually in case of overlapping drawing elements or potential errors. These manual corrections alone proved to be so time-consuming due the number of drawings, that a manual production of all drawings in projects of this complexity can hardly be imagined.

7 CONCLUSION

The project 'service station Torghatten' presented several challenges for the planning architects and engineers due to its disorderly roof geometry and the chosen construction method resulting in an enormous number of fasteners. However, the successful course of the project showed how a parametrised workflow of the complex geometry in all project phases could help to overcome these challenges. The parametric form-finding process also made it possible to achieve an optimised solution in terms of costs, material consumption and sustainability. The interface between the parametric model and the FE software ensured that changes in the design could easily be imported into the analytical model. Custom scripts facilitated the handling of the geometry, for example, to automate edge distance control and collision checks of the screws. This led to more precise results and time savings. Thanks to the automated plan production process, hundreds of individual beams and thousands of screws could be transcribed with their exact position from a 3D model into 2D plans within a short time.

This project has shown that modern planning methods, such as the described parametric workflow, can give new input to traditional construction methods, such as the Norwegian 'lafteverk'.

TIMBER PAVILION CONSTRUCTED IN COMBINATION WITH PARAMETRIC DESIGN AND THE ZOLLINGER CONNECTION SYSTEM

Franziska Häuptle [1], **Camilla By Kampenes**[2], **Matthias Stracke**[3]

ABSTRACT: The engineering workflow in the pavilion project in Belgium has combined a particular connection / joint strategy to fulfil the architect's organic design intentions in a timber pavilion. The client and the architect set high artistic, cost, and environmental ambitions. The goal was to develop a grid-shell mesh consisting mainly of straight beams and continuous for both flat and double-curved surfaces. The structure was created by a combination of parametric engineering design and a grid-shell system called the Zollinger system, invented by Friedrich Zollinger in the 1920s. The paper describes the requirements and limitations set for the timber shell and gives specific features of the timber roof that influenced the design process. To consider all factors in the parametric workflow, a Grasshopper algorithm was set up and used in combination with the design software RFEM to analyse and optimise the grid shell structure efficiently. The paper shows that timber construction with high design ambitions by organic look can be achieved if the parametric design is combined with the Zollinger system. An outlook is provided on how using a parametric design tool can simplify the detailed design and generation of drawings.

KEYWORDS Zollinger system, timber structure, pavilion, parametric design

1 INTRODUCTION

A wooden pavilion for a private client should be designed mainly for the art exhibition. A gallery where the roof should be part of the exhibition, a work of art itself. Therefore, it will be exposed internally and some parts also externally. The Oslo-based architectural firm Snøhetta designed an organic shaped roof with flat, double-curved surfaces. Thus, a structural system needs to be created which sets not only high ambitions on aesthetics but also on the structural efficiency, costs, and environmental impacts. Consequently, the Zollinger system was chosen as a basis for designing a structural grid shell made of mostly straight beams with the help of parametrical design tools.

2 THE PAVILION

2.1 THE ZOLLINGER SYSTEM

The Zollinger system is named after the German architect Friedrich Zollinger who patented the structure during the recession in the 1920s. Rhombical arranged lamellas form a grid shell that can span large spans, using timber beams with a limited length and simple connection details. Both factors make prefabrication possible and an easy installation process on site. Mostly single-curved arched vaults were built for which the benefits of using the Zollinger structures show in general additional material savings.

Figure 2: *Interior view ©Snøhetta*

The main pattern of a Zollinger lamella roof is shown in figure 3. Beams are arranged at angles to each other so that two lamellas meet in the middle of one continuous lamella, forming a rhombus. The pattern enables the lamellas to be connected without moment transfer and still provides a stiff system. While the forces are transferred in several directions, the Zollinger system allows for large openings.

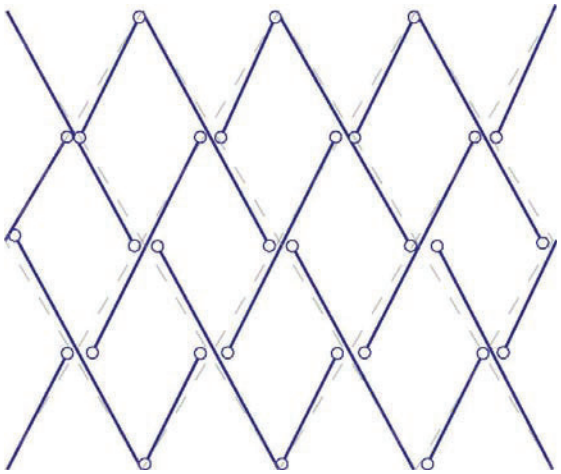

Figure 3: Principal pattern of the Zollinger lamella structure

The Zollinger system is not limited to the structures mentioned above, but it also allows to form double-curved structures out of straight beams while keeping the connection details simple. The system's disadvantages are that the installation process takes longer due to the many details. Therefore, it will be necessary to prefabricate larger elements in the workshop and assemble them on the construction site.

2.2 THE PAVILION'S GEOMETRY

The roof of the pavilion is a composition of double and single-curved surfaces; therefore, a definition for the grid must have been found, which allows a smooth transition between the different types of surfaces, see figure 4.

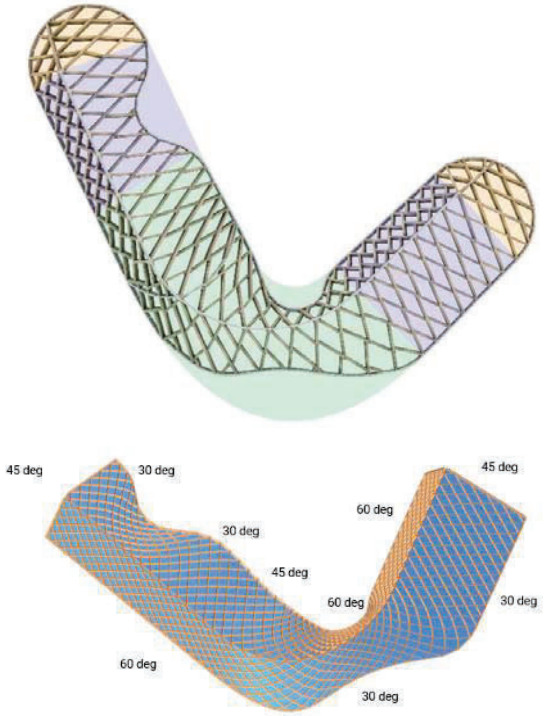

Figure 4: *Different types of surfaces (top) and roof angles (bottom). Top figure: blue: flat surface; green: double-curved surface; orange: double-curved, ellipsoid*

The roof can geometrically be split up into 3 different types. The first type, marked in blue, is a flat surface above the glass-roofed greenhouse and partially above the exhibition/living area. The second type is a double-curved structure marked in green. It represents the entrance area and parts of the residential/ exhibition area. Both pieces will be covered with timber plates and finished with the traditional Japanese shou sugi ban method to make it weather resistant. The areas at each end are part of an ellipsoid with a strong curvature. In addition to the double curvature, the geometry is not symmetrical to the top beam, and the vertical angles differ. This challenge could only be solved with the help of the parametric design described in chapter 3. Several geometries were studied to find an alternative meeting all requirements and limitations.

https://doi.org/10.52202/069179-0339

The requirements and limitations to design an efficient roof structure were:

- Straight beams for the whole roof structure.

- The grid should be as regular as possible to avoid many different node details and different types of beams

- The number of nodes should be kept to a minimum while still being able to establish the Zollinger system and the curved surfaces. With a denser mesh, the surface better approximates the curved architectural geometry, but requires more nodes and, in some areas, more complicated details.

- Simple design detail

- The maximum edge length of the rhombus is given by the glass elements and the plates of the roof membrane

- For each rhombus, a mostly flat surface must be established to mount the timber plates

- Double curved edge beams should be avoided due to the costs and complexity of the production

- The structure must be supported on rigid foundation walls

- The Zollinger system should be applied to all parts of the roof

2.3 SPECIFIC FEATURES FOR THE DESIGN PROCESS OF THE MESH

Specific features of the pavilion's geometry influenced the solution for the mesh.

2.3.1 Double curvature

The nodes in the areas of double curvature will have several different angles, which will influence the detail design. In addition, the mesh must be chosen, such as the timber plates for the roof membrane can be primarily flat or split up into triangulars.

2.3.2 Transition between cold (entrance and glass house) and warm (residential/ exhibition) area.

The roof above the exhibition area will be heated and therefore insulated, while the entrance area and the greenhouse will be uninsulated. Therefore, the thickness of the roof built-up differs. The offset should not be seen, and the top roof surface should be kept at one level. Therefore, the offset in the roof between the cold and warm areas must be handled in the structural system. The beams will be split and moved horizontally apart. Due to the vertical eccentricity, a moment-rigid connection is required, which is made using slotted steel sheets. To avoid complex details, the mesh was chosen so that the façade line (break line) generally does not go through a mesh node but through a continuous system beam.

2.3.3 Foundation

The timber roof will be based on cantilevering concrete walls. The influence of the horizontal deformations of the walls during the lifetime of the pavilion (creep) is considered in the support conditions in the calculation model. Those deformations will lead to vertical deformations of the roof and affect the force transfer.

2.3.4 Edge beams

The edge beams must gap the unsupported areas over the entrances. A double curvature of the beams should be avoided while, at the same time, their geometry should align with the architectural geometry. In addition, the edge beams must be contributed enough stiffness to the roof structure to avoid big deformations. This concerns mostly the long-spanning beam with big curvatures at the entrance area.

Therefore, an alternative geometry was developed that is close to the architectural geometry but only with single curved edge beams.

2.3.5 Half cones

Figure 5: *Alternative for ellipsoids with single curved beams*

The half-cone-shaped surfaces have a small radius of curvature which is challenging for the Zollinger system. Several alternatives were analysed in terms of the complexity of the details, the transition to the other roof areas, the curvature of the beams, the installation process, and the deviations to the architectural geometry.

The Zollinger system is applied but with single-curved beams. The advantages are that the same details can be used, and the visual impression of the main roof is retained. Using single-curved beams can keep the deviation from the architectural geometry to a minimum. Other alternatives were, e.g., a reciprocal frame with pinned connections or solutions with double-curved beams or straight beams spanning between the top and the edge beam.

https://doi.org/10.52202/069179-0339

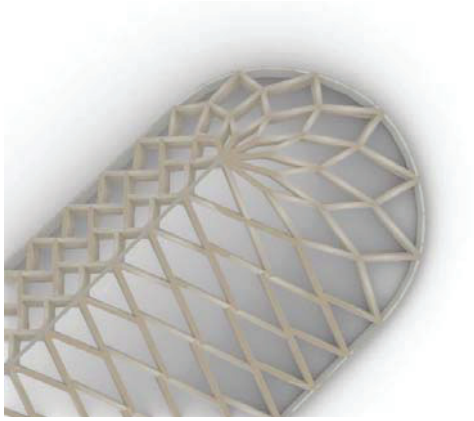

Figure 6: *Alternative for ellipsoids – reciprocal approach*

2.3.6 **Unsymmetrical roof geometry.**

Both parts of the roof must be split up in the same number of pieces to guarantee that the beams meet at the same position at the top beam. Since the outer edge line is longer than the inner one, the size of the mesh, especially over the double-curved entrance area, differs a lot. It needed to be ensured that the mesh of the inner part gets manageable since this will lead to many complex details and an enclosed look of the surface. At the same time, the mesh must be dense enough to establish rhombuses on the outer part. Several alternatives were studied. Two alternatives are shown in figure 7.

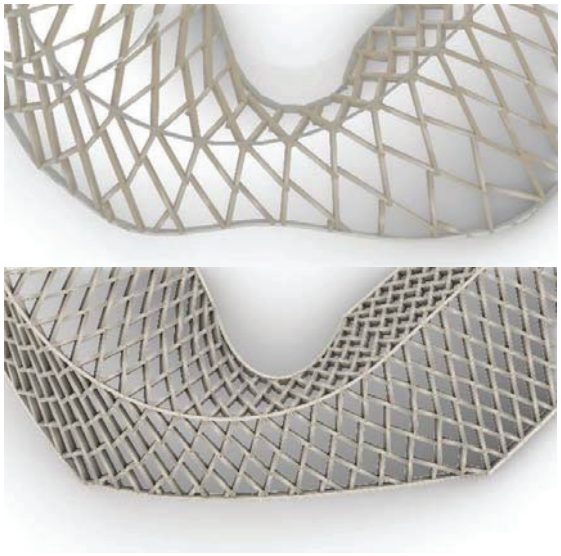

Figure 7: *Mesh above the entrance area – Top: wide mesh – Bottom: dense mesh with a single curved edge beam*

2.4 NODE DETAILS

Joints and connections are crucial points in timber structures and are generally critical to the structure's design. The strength of the connectors in the joint will dictate the strength of the timber structure [1].

Several types of details can be considered for the connection of the timber beams. Several factors influence the choice of relationship. Such as

-Types and sizes of internal forces which need to be transferred

-Geometry of the node. There are different angles in different directions, plus a possible eccentricity between the two ending beams

-The installation process. The number of nodes to be mounted on site must be considered, as what kind of angles are present and how much space is available.

- Collision between the connection elements of the two connecting lamellas.

2.4.1 **Zollinger pin**

The pin can transfer mainly axial forces. Its advantage is that it is easy and fast to install and has only one pin per node. The eccentricity required to install the pins can be large to use the pin for double curved surfaces. Especially at the inner area over the entrance where the mesh is denser, this will be problematic. Due to the shrinking of the timber elements, tightening the pin at regular intervals can be necessary.

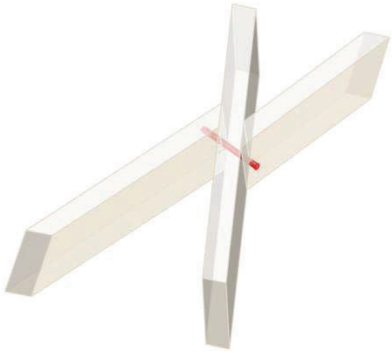

Figure 8: *Zollinger pin*

2.4.2 **Connection with slotted-in plates and dowels / screws**

A connection with steel plates will contribute more stiffness to the structure and allow the transfer of axial and vertical forces. Due to the different angles of the surfaces, this type of detail would lead to many different shaped steel plates, leading to a complicated planning and installation process.

https://doi.org/10.52202/069179-0339

Figure 9: *Detail with slotted-in steel plates of Frans Masereel Centrum in Kasterlee, Belgium*

2.4.3 Connection with screws

In this kind of connection vertical and axial forces can be transferred. To avoid a possible collision between the screws of the two end beams an eccentricity between the two ending lamellas is necessary. For the double-curved surfaces, the angles for the screws can be adjusted. Several screws will be required per node, leading to more connection elements than with the Zollinger pin.

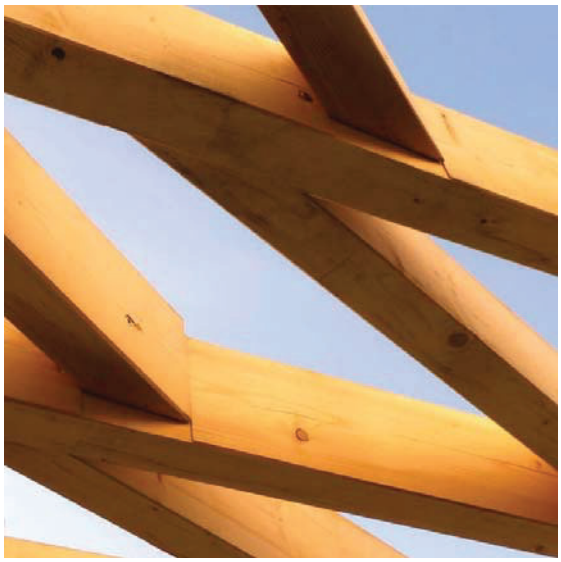

Figure 10: *General detail of Frans Masereel Centrum in Kasterlee, Belgium.*

2.4.4 Connection to the pavilion

For all the above connection requirements it has been determined to use a screwed connection for the general detail and where required by geometry or force a slotted plate as shown in figure 9.

3 PARAMETRIC DESIGN PROCESS

Parametric design tools are used to establish the mesh's geometry with the specifications and requirements mentioned in chapter 2. Unlike being designed directly, the parametric design method is shaped according to algorithmic processes. The aim is to be flexible with few basic parameters, to allow for fast analysis of different alternatives.

3.1 PARAMETRIC TOOLS

To define the geometry GRASSHOPPER was used. Once the boundary conditions were defined, an algorithm was set up that easily allows to adjust of the mesh size. It efficiently and quickly contributes to the study and identification of geometrical problems, such as collisions between the Zollinger roof and the facade line or the evenness of the roof membrane.

The definition was based on architectural geometry. The algorithm's input is the roof's outer lines, which represent the edge beams, and the top line, representing the ridge. In addition, the architectural surfaces of the roof were required, to define a mesh which is as close as possible to the architectural geometry. The input geometry was slightly adjusted to optimise the transition between the flat and double-curved surfaces.

In chapters 2.2 and 2.3 the geometrical specifics of the pavilion roof are given.

In the first step, the outer line without the end parts and the top line were split into the same number of segments. The reasons are given in 2.3.6. Also, the surfaces along the top line are split up normally to the plane in a specified number of segments. It applies the same design approach as for the outer and top lines. The designer chooses the number of segments but it must be a number that can be divided by 2 into a natural number. Only then a Zollinger grid can be established.

In the second step, a diagrid is set up. The nodes from the bottom lines are connected with the ridge nodes. In figure 11 the diagrid is shown as dashed lines.

To apply the Zollinger system the lines in the defined main direction of the diagrid are split at every second node. The received segments represent the continuous lamellas. The same way the second direction is handled but starting the segmentation at the first node, then every other. Now the principle of the Zollinger system is established.

Dependent on the design of the node detail, the eccentricity of the two ending lamellas is required. To study all consequences of the eccentricities on the mesh geometry and other design aspects, the definition of the eccentricities was included in the GRASSHOPPER definition. Therefore, the vectors of the lines of the diagrid are identified. Depending on the vector's direction, the line's end is moved upwards or downwards from the node on the continuous lamella. The principal can be seen in figure 11.

https://doi.org/10.52202/069179-0339

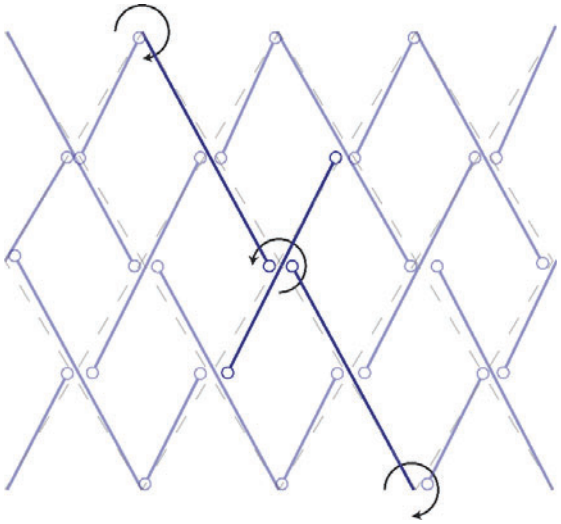

Figure 11: *Diagrid and set up of the eccentricities*

For the ellipsoids, the definition must be due to the strong curvature of the surface and the fact that the meshes of each side of the top line meet adjusted. Dependent on the chosen design approach.

Once the geometry is final, the model can be used to set up a calculation model. For the analysis, the software RFEM from Dlubal was used. Among others are the cross-section, beam hinges, support condition and loads defined in GRASSHOPPER and exported to RFEM.

3.2 CALCULATION MODEL

3.2.1 Geometry, node and support conditions

The geometry defined in GRASSHOPPER was used to set up a calculation model in RFEM. This way, it is possible to make changes to the geometry, such as optimising the curvature of the edge beams or changing the mesh size, without spending much time setting up a new model each time.

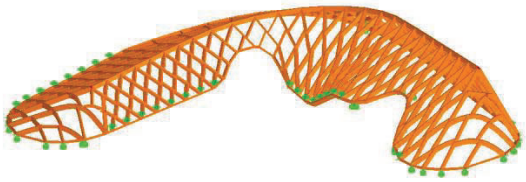

Figure 12: *RFEM Modell*

The connections between the lamellas are assumed as whole hinges. This represents the properties of the Zollinger pin. For other types of details, the stiffness of the connection is determined to check the influences on the roof system and the connection forces.

The vertical support is fixed, while the supports in the direction perpendicular to the concrete wall / outer beam are modelled as springs to account for the horizontal stiffness and long-term effects of the concrete wall.

3.2.2 Wind loads

The Eurocode only gives Cp-values for simple geometries of buildings; thus, the pavilion's plan geometry and the Eurocode assumptions do not cover the double-curved surface. Therefore, the add-on module RF-WIND was used to define the C_p-values for the wind loads for different wind directions. RF WIND is an add-on module to RFEM.

With the C_p-values and areas given from RF WIND the wind loads on each node of the structure were calculated within GRASSHOPPER and applied to the structure. The add-on module can also apply the wind loads directly to the structural model. Still, additional surfaces must be defined, which could adulterate the stiffness behaviour of the structure. In addition, the wind loads would need to be newly defined by RF WIND each time something was changed in the model. Using only the C_p- values can better control and check the load size.

To verify the C_p-values of RF WIND, they were compared to values from the EC 1-4 for a simpler roof geometry. It turned out that the values corresponded well and that the values from RF WIND could be used for the calculations.

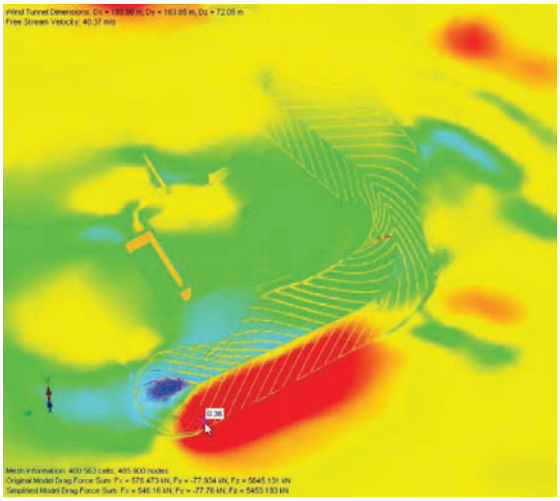

Figure 13: *RF WIND Simulation*

3.2.3 Analysis

With the calculation model, weak points of the structure were identified and optimised in cooperation with GRASSHOPPER according to the limitation and requirements given in chapter 2.2. For this purpose, among other things, the eigenforms of the roof were studied, and the force flow was analysed.

https://doi.org/10.52202/069179-0339

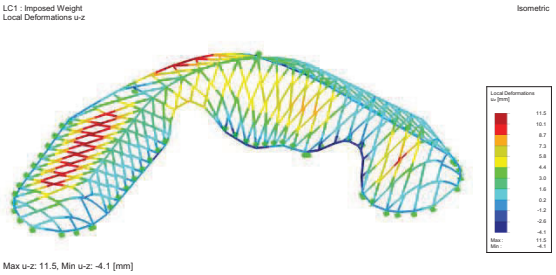

Figure 14: *Deformation print-out RFEM*

4 OUTLOOK

A parametric workflow could be developed to create drawings in a later design phase of the project. This will be especially helpful since, due to the complexity of the double-curved geometry, the length of the different beams and the angles of the connection details will differ. In addition, with the help of parametric tools, clashes of connection elements are quickly identified, and controls to guarantee the feasibility of each node are established.

The forces to transfer at each node can be retrieved from RFEM and checked in GRASSHOPPER for the governing combination. Especially with many different angles, it will take much work to identify manually relevant nodes for the calculation design.

5 CONCLUSION

The studies and analysis for this project show that a combination of a double-curved roof structure and flat surfaces made of straight timber beams using the Zollinger-System in combination with parametric design is possible.

Several factors must be included in the design process for the definition and the setup of the final mesh, such as the design of the nodes, evenness of the roof membrane, types of surfaces, base geometry (symmetrical, unsymmetrical, size of curvature, …), number of nodes, size and regularity of the mesh and the function of the building. All these factors can be included in the parametric design workflow.

The integration of a parametric workflow makes an efficient planning process possible. It helps to identify structural and geometrical problems early and allows quick adjustments in the structure's design.

GRASSHOPPER in combination with the calculation software RFEM from Dlubal allows changes in the geometry easily and therefore an optimised geometry which covers all requirements can be achieved.

DEVELOPMENT OF THE ANALYTICAL METHOD TO REPRODUCE SEISMIC BEHAVIOR OF CLT BUILDINGS AT LARGE DEFORMATION

So Momose[1], Tatsuya Miyake[2], Hiroshi Isoda[3], Takafumi Nakagawa[4]

ABSTRACT: Understanding the seismic resistance mechanisms and safety limits of cross-laminated timber (CLT) buildings is critical. However, the knowledge of shaking table tests of CLT buildings is limited. As a first step toward collapse analysis, in this study, it was attempted to reproduce full-scale two-story shaking table test results with maximum interstory drift of 8.77%. For that, the results which matched the experimental results were searched by performing data assimilation. Consequently, the analysis results after assimilation agreed well with the experimental results, indicating the validity of this study's analytical method, but the trend of the analytical results have to be addressed in the future.

KEYWORDS: CLT building, Large deformation, Reproductive analysis, Shaking table test

1. INTRODUCTION

The seismic performance of CLT buildings has been investigated using monotonic and quasistatic cycle tests on full-scale CLT buildings [1,2]. In 2007, full-scale shaking table tests of three-, and seven-story CLT buildings were performed as part of the Construction System Fiemme (SOFIE) project [3,4]. During the tests, no residual damage was observed after the destructive earthquakes. The maximum interstory drift of the seven-story building was 67 mm, which was 2.2% against the story height of 3.1 m between the second and third floors of the building during the Japan Meteorological Agency (JMA) Kobe 100%. Further, a five-story CLT building with narrowed panel CLT was tested on a shaking table [5]. During the JMA Kobe 100% test, the compressive rupture of CLT and yielding of all tensile bolts were observed, and a maximum interstory drift of 3.7% was measured on the Y0 plane on the second story. In the USA, a full-scale shaking table test of a two-story CLT building with replaceable components has been performed in a series of research projects on CLT buildings [6]. Interstory drift 4.29% during the Northridge of MCE+ hazard level was measured. In this study, we attempted to reproduce a shaking table test with a maximum interstory drift of 8.77% via numerical analysis, which was 263 mm for a floor height of 3 m at JMA Kobe 140% intensity, exceeding the abovementioned values.

In earthquake-prone areas, such as Japan, USA, and Italy, it is critical to clarify the safety limits and collapse mechanism of CLT buildings through collapse experiments and reproductive analysis as well as to achieve accurate seismic performance evaluation of CLT buildings to protect human lives in the event of a massive earthquake. Consequently, the authors developed the analysis software "wallstat" [7], which is based on the extended distinct element method (EDEM). In this study, the authors modified and developed "wallstat" for CLT buildings. Using the developed software, we attempted to reproduce the experiment results when CLT buildings encountered large deformation. Elemental experiments were used to define the mechanical properties of CLTs and joints. According to a previous study [8], the simple combinations of elemental experiments cannot accurately reproduce full-scale experimental results. An analysis called data assimilation [9] was performed. The process of data assimilation is shown in Fig. 1. First, spring and element parameters were multiplied by the correction factors to create various skeleton curves for the spring. Then, the analytical and experimental results were compared in terms of only the shear force–interstory drift of the first story; finally, the analytical results with the smallest error from the experimental results was extracted. Consequently, the experimental results were reproduced, and the validity of the analytical method was confirmed. Afterward, the analysis results before and after the data assimilation were compared, and the causes of the differences were discussed. This paper is part of the project funded by the Japanese forest agency and includes content that has been in press [10].

2. OUTLINE OF ANALYSIS METHOD

Previous research [11-14]. has widely used numerical calculations based on FEM, as represented using the matrix method, for the time history response analysis of buildings. However, FEM is a tool developed for the stress analysis of continuum, and geometric and material nonlinearities must be considered to trace a specimen to failure analytically. In particular, the problem of handling disproportionate forces in the calculation arises for extreme failures such as member rupture (wood fracture)

and crack propagation. The individual element method [15] is an analytical method that solves these problems and can trace the collapse process. The distinct element method, also known as the "discontinuity analytical method" (a method for calculating the behavior of discrete objects), was originally developed to calculate the collapse of soil and bedrock; hence, it can naturally analyse large deformations and collapse. EDEM [16] is an extended method in which the distinct element method's discontinuum elements are connected by springs, allowing the behavior of the continuum before failure to be tracked. To reproduce the behavior as continuum before failure as in FEM, "wallstat" uses beam elements. Shear, rotational, tensile–compressional, truss springs, and beam elements, which are commonly used in structural analysis in architecture, are incorporated between the elements as springs in EDEM. This has successfully reproduced the rocking and collapse behaviors of low-rise conventional-axle construction buildings [17-21]. "Wallstat" was used to analyse CLT buildings in this study by incorporating multiple-spring (described in Fig. 11) and shear spring models to account for the rocking behavior of CLT panels.

3. SHAKE TABLE TESTS

Fig. 2 shows the specimen of the shaking table test. The test specimen is a full-scale two-story CLT building with a narrow panel frame, consisting of a gravity frame and CLT wall, floor and roof. the floor plan of the second story (Fig. 3(a)), and its elevation in the Y2 and X1 planes where the CLT shear walls were located (Fig. 3(b, c)) are shown. The specimen size is 6.0 m long in the X direction, 2.5 m wide in the Y direction, and 6.0 m high. Two arrangements were made for the floor, one with the outermost lamina parallel to the X direction and the other with a perpendicular one, to verify various conditions. As the main seismic structure, two CLT shear walls were at the center along the X direction on the first and second stories. The strength grading of glulam, which is E95-F315, is specified in the Japan Agricultural Standard.

The meaning of E95 is the laminas in all layers have an average Young's modulus of 9.5 kN/mm^2 and above, whereas F315 means the bending strength of the glulam is 31.5MPa. The material of columns and beams was Glued Laminated Timber (Glulam) made of Scotch pine (*Pinus sylvestris*), which have 2 different strength grading of E95–F315 and E105–F300. The cross-section area was 120 (width) × 120 (height) mm, 120 (width) × 300 (height) mm, respectively. The horizontal diaphragm was made up of seven-layered 210-mm thick CLT panels of Japanese cedar (*Cryptomeria japonica*) grade Mx60 in JAS. The average Young's modulus of the lamina in the outer layers was equal to or more than 6.0 kN/mm^2, whereas it was 3.0 kN/mm^2 in the inner layers. The vertical diaphragm, e.g., shear wall, hanging wall, and orthogonal wall, comprised three-layered 90-mm thick CLT panels of Japanese cedar grade S60, meaning that the average Young's modulus of the lamina in every lamina was equal to or more than 6.0 kN/mm^2.

Fig. 4 shows details of the connectors and which spring corresponds to, and Fig. 5 shows images of the joints. Tensile bolts (ABR490, M16) and U-shaped connectors (TB-90) with holes for screws were used in the wall–foundation joints. Further, it is not common in Japan to install a stopper to resist shear force, but the purpose of this experiment was to excite up to a large deformation domain. Thus, stoppers were introduced to prevent the experiment from stopping early due to the shear failure of the CLT shear wall foot of the first story [Fig. 5(a)]. The metal protectors were attached between the wall panel and stoppers to prevent the shear wall from being embedded in the stoppers due to drifting during excitation. At the wall–wall and wall–roof joints, bolts (ABR490, M20) and U-shaped metal connectors (TC-90) with holes for screws were used as tensile connectors [Fig. 5(b)], and angle brackets (LST) with holes for screws were used as shear connectors [Fig. 5(c)]. Wall–hanging wall and floor–floor connections were made with steel plates secured with screws [Fig. 5(d)]. The screw STS6.5F was used for plywood and long steel plates in the floor–floor shear joint, and STSC65 was used for other joints. The specimen was designed according to "Route 1" provided in CLT manual [Japan Housing and Wood Technology Center Design and construction manual for CLT buildings, 2016]. "Route 1" was the simple method of allowable stress design against

https://doi.org/10.52202/069179-0340

0.2 base shear capacity for moderate earthquake and ultimate strength design against 1.0 base shear capacity for maximum considerable earthquake. The total seismic weight of the specimen was set to 175.95 kN based on the specimen specifications according to the Japanese building standard law (Notification 611 of the Ministry of Land, Infrastructure, Transport and Tourism (2016)).

As shown in Table 1, the specimen was subjected to sine wave of which the frequency was constant in Sequence 0, and the north–south (N–S) component of JMA Kobe waves, which was recorded during the Osaka–Kobe Earthquake in 1995, at 100% and 140% intensity in Sequence 1 and 2, respectively. The exciting direction was the X direction. The acceleration response spectrum of the three seismic waves is presented in Fig. 6.

The displacement where the stickers and LED lights as showed in **Fig. 5**((a)~(c)) were attached was measured with cameras, which is called "image measurement".

Fourier transformation was performed on the acceleration response time history on the shaking table and on the roof of the specimen in Sequence 0, Sequence 1, and Sequence 2; then, the Fourier spectrum was calculated. The Fourier spectrum of the roof was divided by that of the shaking table to obtain a spectral ratio (transfer function), and the lowest frequency among the peaks of the spectral ratio was defined as the natural frequency. In addition, the base shear capacity was derived from dividing the maximum shear force by the total seismic weight, in which the maximum shear force was determined from the acceleration observed during excitation. **Table 2** shows the natural frequency and base shear capacity. The specimen's maximum overall drift and interstory drift in Sequences 1 and 2 are listed in Table 3. During Sequence 1, the maximum roof displacement was 200 mm, corresponding to 3.33% overall drift. A split was seen at the edge of the CLT shear wall due to pulling by the hanging wall, but there was no significant damage other than the split [Fig. 7(a)]. During Sequence 2, the maximum roof displacement was 397 mm, corresponding to 6.62% overall drift, and the interstory drift of the first story was 8.77%. In addition, wall head embedment into the floor panel was observed [Fig. 7(b)]. No repair work was performed after Sequence 1. Some damage and deterioration in the specimen from Sequence 1 was considered in the analysis because the numerical models were subjected to Sequence 1 and 2 in a row.

4. MODELING METHOD

Fig. 8 provides the analysis model created according to the joint specifications of the specimen. The number of nodes is 382 and that of springs is 668. his model was fixed in the Y direction of translation because the twisting of the specimen was not observed in the shaking table test. Fig. 9 shows the spring arrangement on the Y2 plane. The analysis model included tensile, shear, and compression springs. Two tensile springs were used for the two types of tensile joints in "wall–foundation" (T1) and "wall–wall" or "wall–roof" (T2). Three types of shear springs were inserted corresponding to the stoppers in "wall–foundation" (S1) and shear joints with steel-plated screws in "wall–floor" or "wall–roof" (S2) and "wall–hanging wall" (S3). Three differently defined compression springs were inserted to express the embedment ability of CLT under loads applied to "wall–foundation" (C1), "wall–floor, wall–roof" (C2), and "wall–hanging wall" and "orthogonal wall–floor" (C3). Other planes, such as Y1 and X1, were modeled similarly.

The modeling method for the CLT shear wall is shown in Fig. 10: the CLT shear wall was replaced by a beam element with rigid beams at its top and bottom ends corresponding to the wall width. The joints at the wall head and foot were modeled with tensile springs, shear springs, and 11 compression springs. The 11 compression springs at equal intervals was called "multiple-spring"; this modeling method has been used in some numerical analyses of specimens with CLT to reproduce the rocking behavior of the CLT shear wall [22,23]. The orthogonal walls, hanging walls, and floor panels were all modeled with beam elements and rigid beams, similar to the CLT shear walls. The beam elements were given only one Young's modulus, which was applicable for both bending and compression. The Young's modulus was set to 4.0 kN/mm^2 for CLT shear walls and hanging walls because the major direction layer was seen as 0 kN/mm^2 according to CLT manual. In addition, it was set to 2.571 kN/mm^2 for the floor panels along the major direction, and 1.285 kN/mm^2 along the minor direction. When establishing the floor panel parameters, the cooperation width was considered. The gravity frame was modeled as a beam element with elastoplastic rotational springs at the element ends. The columns and beams' Young's modulus were set to 9.5 and 10.5 kN/mm^2, respectively, and the bending strength were set to 31.5 and 30.0 Mpa, respectively. This Young's modulus was applied for both bending and compression. Nonlinear tensile shear springs were used to simulate each joint, and nonlinear compression springs were used to model the CLT's embedment properties. Fig. 11 shows hysteretic rules of tensile–compressional and shear springs. The tensile–compressional spring was modeled as a slip type in tension and elastoplastic in compression. Shear springs were set to bilinear for blind prediction, and later wall–foundation shear springs were reset to slip type considering the load–displacement relationship of the experimental results.

The ultimate capacity for tensile springs at the wall–foundation joint (T1) were determined to be 59.3 and 93 kN, and the Young's modulus and effective area of tensile bolts (ABR490, M16) were 205 kN/mm^2 and 157 mm^2 according to JIS B 1220. In addition, the length between the nuts was 400 mm, therefore, the first stiffness and the ultimate displacement for the T1 spring were set to 26.0 kN/mm and 41 mm based on CLT manual. Similarly, for the wall–wall joint (T2), the Young's modulus and effective area of tensile bolts (ABR490, M20) were 205 kN/mm^2 and 245 mm^2 according to JIS B 1220, and the length between the nuts was 200 mm. Therefore, the first stiffness and the ultimate displacement for the T2 spring were set to 30.0 kN/mm and 20 mm according to CLT manual. For shear spring at wall–floor (S2), the yielding and ultimate capacity of the two angle brackets were determined to 54 and 90 kN, respectively, based on CLT manual. In addition, considering friction, the first stiffness was assumed to be like rigid, and the value obtained by multiplying the allowable (79.6 kN) and ultimate capacity (93.0 kN) of the tensile joint from JIS B 1220 by a friction coefficient of 0.3 were added to 54 and 90 kN, which is equivalent to 77.9 and 118 kN. As the four shear springs were distributed at the wall–floor joint as Fig. 10, the calculated yielding and ultimate capacity were divided by 2. Finally, yielding and ultimate capacity for the shear spring were set to 38.9 and 59.0 kN. The ultimate displacement was set to 23.86mm based on CLT manual. Skeleton curves of the wall–hanging wall shear spring (S3) and wall–foundation compression spring (C1) were determined from the element test results (Fig. 12(c, d)). The critical tensile–compressional and shear spring properties in this analysis model are presented in Table 4 and Table 5. All analytical results were generated using a time-integration step of 10^{-6} s. The numerical analysis used the measured acceleration at the center of the shaking table as ground motions. The model weights were equal to the seismic weights of the full-scale specimen, including members and loaded weights, and the weights of the first and second stories were set to 100.54 and 75.41 kN, respectively.

5. BLIND PREDICTION

In the push-over analysis (blind prediction), the skeleton curves of the springs were determined based on the elemental tests results of seismic elements. The analysis results and experimental results are shown in Fig. 13. The first stiffness agreed with the experiments for both the first and second stories, but the maximum capacity of the second story and the ductility of the first and second stories were insufficient, indicating that the analysis cannot reproduce the full-scale shaking table test results when the parameters of the springs were determined by element test results as described in previous papers [8]. Thus, reproductive analysis was performed to better match the experimental results.

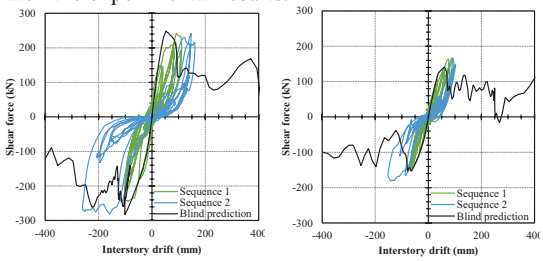

Fig. 13: *Push-over analysis (blind prediction)*

6. REPRODUCTIVE ANALYSIS METHOD

As previously stated, pushover analysis based on elemental tests and references could not reproduce the behavior of full-scale shaking table test at large deformation. The shaking table test results were used to calibrate the spring parameters for the wall–foundation tensile and shear joints (Fig. 14). For the tensile spring, the axial force–displacement relationship of the tensile bolts at the wall–foundation was traced and the skeleton curve was redefined by the slip-type hysteresis rules. In addition, a pretension load of 20 kN was added according to the experimental condition. Half of the shear force for the first story against wall–foundation relative displacement was traced for the shear spring skeleton curve. Half of that was used because there were two CLT shear walls on the first story. The skeleton curve was redefined by the slip-type hysteresis characteristics. Table 6 shows the two spring properties after calibration. Comparing the skeleton curve in blind prediction and after calibration, the tensile spring parameters after calibration matched well with those in blind prediction. For the shear spring, the difference in the first stiffness was large, indicating that the shear resistance ability of the stoppers was not rigid due to the embedment of the CLT shear wall even if the metal protectors were installed.

Further, to enhance reproducibility, the analytical method of this study [9], data assimilation, was performed for the reproductive analysis. Fig. 1 shows an overview of data assimilation executed as the reproductive analysis. The critical 24 parameters of springs and elements in **Table 7** were the target of data assimilation and multiplied by the correction factors to create various skeleton curves, and the parameter combinations when fit to the

experiment result were explored. The correction factors had the range to account for variations in materials and resistance factors which were not considered in the analytical model. Assuming the variation due to these uncertainties was expressed as the correction factors' coefficient of variation CV = 0.2 and the mean value of the correction factors μ was 1, the standard deviation σ = 0.2 was derived from Eq. (1). Assuming that the correction factor x was normally distributed, standardization was performed using the random variable z according to Eq. (2). In this case, $0.5 < x < 2.0$ accounts for 99.38% of the total, which can cover almost all patterns. Therefore, the correction factors were varied in the range of 0.5 to 2.0 with the interval of 0.15 for the Young's modulus, first stiffness, and first yield point. For the second stiffness, the correction factors were varied in the range of 0.0001 to 0.8 with the interval of 0.08, considering that the most possible values of the stiffness after yielding were covered.

$$CV = \frac{\sigma}{\mu} \quad (1)$$

$$\boldsymbol{z = \frac{x - \mu}{\sigma}} \quad (2)$$

With this method, various skeleton curves for the springs were created. Then, the experimental results and many analytical results were compared in terms of only the shear force–interstory drift of the first story through Sequence 1 and 2, not in terms of the time history of interstory drift and uplift displacement. Then, the analytical results with the smallest error from the experimental results was extracted. Later, when comparing the skeleton curves between before assimilation and after assimilation, five analysis results with the smallest five errors from the experimental results were extracted. Thus, assimilation was performed to match both Sequence 1 and 2. Therefore, the damage from Sequence 1 was also considered in the analytical results after data assimilation. In addition, because all springs and elements were free in all directions except the Y direction of translation, if multiple factors are included in the springs and elements, data assimilation of the parameters will result in an accurate analysis model.

7. REPRODUCTIVE ANALYSIS RESULT

The interstory drift time history for the first and second stories in Sequence 1 and 2 from data assimilation is illustrated in Fig. 15, together with the blind prediction and experimental results. The blind prediction did not agree with the experiment results except for the initial drift response to the excitation. Meanwhile, after assimilation, both the interstory drift and phase agreed well with the experimental results through Sequence 1. Even in Sequence 2, there was a slight error in interstory drift with the experiment results after the maximum drift, but the trends of the interstory drift and phase agreed well, implying a good reproduction result. Fig. 16 illustrates the shear force–interstory drift relationships for the first story in Sequence 1 and 2 in the experiment, in blind prediction, and after assimilation. For the blind prediction, the maximum load was nearly reproduced in Sequence 1, but not in Sequence 2. Nevertheless, the interstory drift and stiffness were not consistent with the experiment results. However, the analytical results after assimilation were almost identical to the experimental result, indicating that the overall behavior of the specimen could be tracked by reproductive analysis. Fig. 17 shows the uplift displacement time history at the CLT shear wall foot of the first story in Sequence 2 in the experiment and the analysis results after assimilation. The analytical result after assimilation agreed with the experimental results in drift and phase, demonstrating that the detailed behavior of the two-story CLT building was reproduced. Fig. 18 and Fig. 19 show the comparison of specimen's behavior in Sequence 1 and 2 between the experiment (red line and spheres depicted by image measurement data) and reproductive analysis (shown as Fig. 8) and the interstory drift time history (Fig. 15(a, c)) with the moment which the image exhibits. It could be seen that the analysis results agreed with the experiment results in appearance in Sequence 1 and 2. Therefore, it was verified that the analysis results were identical to the experiment results.

Fig. 20 shows the skeleton curves for the four springs before and after assimilation. The blue solid lines in each of **Fig. 20** (a)–(d) are skeleton curves in the analysis results with the five smallest errors from the experimental results. The five analytical results (smallest one was labelled (1), second smallest (2), third smallest (3), fourth smallest (4), and fifth smallest (5)) are shown to grasp the trend of how the skeleton curves changed.

For the wall–wall tensile springs (**Fig. 20**(a)), a clear trend of the first stiffness and yielding capacity was not seen. For the wall–floor shear spring (**Fig. 20**(b)) considering friction when determining the parameters, the skeleton curves tend to be the same before and after assimilation. For the wall–hanging wall shear spring (**Fig. 20**(c)) without considering friction, both stiffness and yield capacity tended to increase after assimilation. This implies that the friction between the shear connectors under suppressed force contributed to an increase in both stiffness and yielding capacity. However, it is recommended to reconsider the friction coefficient which is assumed as 0.3 in the paper. In addition, the difference in the loading speed between the dynamic loading during the full-scale shaking table test and the static loading in the element tests can be another reason because steel strength increases as the strain velocity increases. Also, for the (5), the yielding capacity of wall–floor shear spring was highest although the first stiffness and yielding capacity of wall–hanging wall shear spring were smallest, inferring that the wall–floor and wall–hanging wall shear springs were in a inverse relationship. An increasing trend of the first stiffness and yielding capacity was also seen in the case of compression springs (**Fig. 20**(d)). Similar to shear springs, the dynamic effects of loading can be a contributing factor to the increase in stiffness and yielding capacity. Another possible factor is that the dead weights were fixed to the floor with screws in the experiment, which increased the floor rigidity significantly and suppressed the vertical deformation caused by the rocking of the CLT shear walls." These inverse interaction and factors for increase of stiffness and capacity such as friction, dynamic effects, and increase of floor rigidity will be verified by comparing the detailed behavior and performing static loading tests in the future.

https://doi.org/10.52202/069179-0340

8. CONCLUSION

In this study, a model that can replicate the seismic behavior of CLT buildings up to a large deformation region is proposed using "wallstat," which was modified to consider the restoring force and P–δ effects due to the rocking behavior of CLT panels. The shaking table test on a two-story full-scale CLT building validated the analytical method.

- A split was observed at a wall–hanging wall joint. Despite the 8.77% interstory drift of the first story in Sequence 2, further damage, such as wall head embedment into the floor panel, was negligible.
- In pushover analysis, blind prediction agreed well with the experimental result in terms of the first stiffness but not the maximum capacity of the second story and the ductility of the first and second stories.
- The shaking table test results of the two-story full-scale CLT building were analyzed using "wallstat," which was modified to include multiple-spring and shear spring models, to account for restoring force and P–δ effects due to the rocking behavior of the CLT panels. Using wallstat, we attempted to replicate the seismic behavior of the two-story full-scale CLT building up to a large deformation domain. Blind prediction could not reproduce the experimental results in the time history interstory drift and hysteresis curves of the shear force–interstory drift of the first story. However, the analytical results after assimilation were consistent with the experimental results in interstory drift and phase in both the first and second stories although the discrepancy between the analysis and experiment after the maximum drift will be the subject of future research, demonstrating that the overall behavior of the CLT building specimen was reproduced with this analytical method even in the large deformation domain.
- The uplift displacement and phase trends of the CLT shear wall of the first story were analyzed for the uplift displacement time history. The outcomes suggest that our analysis model can even replicate the detailed behavior of a full-scale specimen at large deformation as well as the overall behavior.
- The overall behavior of analysis model could be seen identical to that of the specimen in appearance as well as on the graph.
- The skeleton curves of shear and compression springs after data assimilation tended to increase in both stiffness and yielding load compared with those before assimilation. For this, the suppression of deformation due to friction resistance, the difference in the loading speed between the element tests and the shaking table test, and the increment in floor rigidity due to fixed dead weights were considered to be the cause.

Hence, the analysis results after assimilation agreed well with the experimental results, indicating the validity of this study's analytical method. However, it is not possible to predict the responses of CLT buildings without experimental results from this study alone. In this study, as a result of varying the characteristic values for joints and members over the statistically determined range, analytical results that agree with the experimental results were obtained, and the trend of the analytical results was shown. Friction, dynamic effects, and an increase in floor rigidity due to fixed dead weights were thought to be the causes of the increase trend of stiffness and yielding capacity of shear and compression spring. In addition, as the inverse relationship between the properties of the shear springs was confirmed, the interaction among the tensile, shear, compression springs, and beam elements can also exist. These interactions in analysis models of this study have to be verified in the future through behavior comparisons of detailed part and static loading tests, and it is believed that the verification will lead to predict the seismic behavior of CLT buildings at large deformation without experimental results.

ACKNOWLEDGEMENT

This research was conducted as part of a Forestry Agency–subsidized project to study the relaxation of earthquake resistance standards by simplifying joints and reducing the number of walls, etc., based on an understanding of the seismic boundary performance of CLT panel construction method buildings. We would like to express our gratitude to all the parties involved. We used the Japan Aerospace Exploration Agency supercomputer system "JSS3" in the reproductive analysis. [24].

RACKING RESISTANCE OF CLT PANELS MANUFACTURED FROM C16 GRADE TIMBER

Conan O'Ceallaigh[1], Rimjhim Kashyap[2], Annette M. Harte[3], Patrick J. McGetrick[4]

ABSTRACT: This study examines the typical lateral/racking resistance of cross-laminated timber (CLT). The use of CLT in construction has grown in many regions of the world, not only due to its impressive structural properties but also the improved environmental performance achieved for this mass-timber system compared to more traditional construction materials. In Europe, CLT is primarily manufactured with C24 grade timber or a combination of C24 with small proportions of C16 grade material in internal layers. In many parts of the world, the supply of C24 timber is limited and it is important to establish the structural properties of CLT manufactured with lower-grade material. This study presents a numerical model developed to predict the load-displacement behaviour and structural racking resistance of CLT panels and will inform the experimental testing of CLT panels manufactured from C16 grade material in combination with typical connections utilised in structural mass timber systems.

KEYWORDS: Connections; Cross Laminated Timber (CLT); Engineered Wood Products (EWPs); Racking resistance; Sitka spruce

1 INTRODUCTION

In recent years, there has been a significant rise in the number of advanced engineered wood products (EWPs) coming to market. Cross-laminated timber (CLT) presented in Figure 1 is one of the most significant advances in EWP technology and has been responsible for the rise in timber structures and has the potential to significantly reduce the environmental footprint of the built environment in the fight against climate change [1].

Figure 1: *Typical cross laminated timber (CLT) panel.*

In Europe, this product is primarily manufactured using C24 grade [2] material with limited quantities of lower-grade material being used [3]. As the market interest in mass-timber increases, the demand for natural timber resources will benefit from increased knowledge of the structural properties of CLT manufactured from lower-grade materials. To date, there has been a significant amount of work carried out to establish the manufacturing properties of CLT from lower-grade materials [4–6] however, there is limited information on the racking resistance of C16-grade CLT panels [7]. In this study, a numerical model is developed to examine the racking resistance of CLT panels subjected to in-plane racking loads. The numerical model is validated against experimental tests on C24 grade CLT carried out by Hughes [8]. In the study by Hughes [8], a 5-layer CLT panel manufactured from C24 grade material was subjected to a racking test.

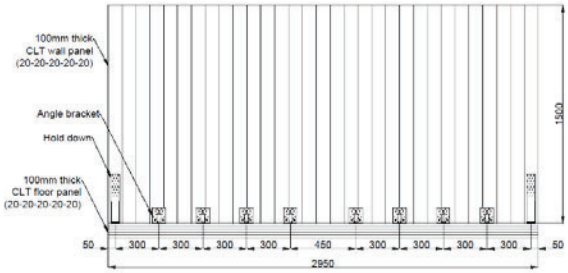

Figure 2: *CLT test set-up* [8] *(Dims. in mm).*

The CLT wall panel measured 1.5 m in height and 2.95 m in length as shown in Figure 2. The panel was connected to a CLT floor with a series of typical brackets (hold downs and angle brackets) and the floor panel itself was anchored to the ground at four fixing points. The vertical load was varied to understand its influence on the load-displacement behaviour of the CLT panel. The developed numerical model is validated based on the results presented by Hughes [8] and utilised to examine the

corresponding load-displacement behaviour of CLT panels manufactured from C16-grade timber. This numerical study will then inform the experimental testing programme of CLT subjected to racking tests in accordance with EN 594 [9].

2 RACKING RESISTANCE OF CLT

CLT wall panels are typically connected to floor panels through a combination of angle brackets and hold-downs. Angle brackets are used to resist shear and hold-downs are used to resist overturning. Dujic et al. [10] tested 2.44 m x 2.44 m glued lamellate panels subjected to monotonous and cyclic horizontal loads in combination with a constant vertical load. The tested wooden panels have relatively high stiffness and load-bearing capacity, therefore the influence of the anchoring system on the shear stiffness and strength of the wall was studied. It was observed that the racking behaviour of cantilever massive wood walls is very sensitive to the magnitude of vertical load and the type of anchorage system. Ceccotti et al. [11] performed a series of full-scale wall tests as part of the SOFIE project. 2.95 m x 2.95 m wall panels anchored using commercially available hold-downs and angle brackets were subjected to monotonic and cyclic tests to assess their racking behaviour. The panels were designed to behave rigidly and the connections were designed to exhibit ductile behaviour. Due to this, all forces and displacements were locally concentrated around the connections leading to local failure, confirming that the dissipated energy results from the connections. Subsequently, full-scale 3-storey and 7-storey buildings were designed as per Eurocode 8 [12] and tested for seismic loads using a 1D and a 3D shaking table respectively. Ductile failure modes with fastener bending and embedment were observed in these buildings. The buildings were observed to resist a whole series of earthquakes in 1D and 3D, keep their shapes and remain fully operational. Gavric et al. [13] investigated the behaviour of several configurations of single and coupled CLT wall panels subjected to cyclic loads according to EN 12512 [14]. Angle brackets and hold-downs were used to anchor the CLT walls to a steel foundation. The experimental results were then compared to advanced analytical models which were developed for nonlinear pushover analysis of the CLT wall system, which showed that angle brackets have sufficient tension capacity in addition to the shear capacity. However, hold-downs did not exhibit significant shear strength. Izzi et al. [15] proposed a numerical model to predict the mechanical behaviour and failure mechanisms of CLT wall systems. The CLT wall and the element to which it is anchored are modelled as 3D solid bodies using ABAQUS, while the connections are modelled as nonlinear hysteretic springs. Racking tests by Gavric et al. [13] were reproduced on the numerical models. The results of these analyses highlighted that in order to obtain a realistic prediction of the load-carrying capacity of the angle brackets, it is necessary to consider the axial load resistance of the angle brackets. Hughes et al. [7] studied the behaviour of tall CLT buildings under monotonic lateral loading. This was achieved by subjecting the CLT wall system to a constant vertical load replicating gravity loads at storeys within a 10-storey CLT building. Non-linear relationships between vertical load and total lateral displacement, and between vertical load and uplift were observed, which implied that vertical load has a significant influence on the behaviour of CLT wall systems.

3 FINITE ELEMENT MODEL

This section discusses the development of a 3-Dimensional finite element model (FEM) of CLT panels subjected to vertical loads and horizontal racking loads using ABAQUS FEM software.

3.1 MODEL GEOMETRY

The model was developed in line with the study presented by Hughes [7,8]. This comprised a 5-layer CLT wall and floor panel with dimensions of 1.5 m in height, 2.95 m in length and 0.1 m thick. The CLT panels were modelled as an orthotropic elastic material with each layer and corresponding grain direction (longitudinal, radial and tangential) being specified within the model. The CLT panels were meshed with 8-noded linear brick elements with reduced integration (C3D8R). The connections were not discretely modelled, however, connector elements with specified elastic and plastic stiffness were specified to mimic the hold-down and angle bracket behaviour.
A steel plate was utilised to apply the structural racking load and hard contact was defined between the surface of the timber and the steel plate with a tangential friction coefficient of 0.3. The vertical pressure was applied to the top surface of the CLT wall, and the base of the floor was fixed to mimic the experimental conditions.

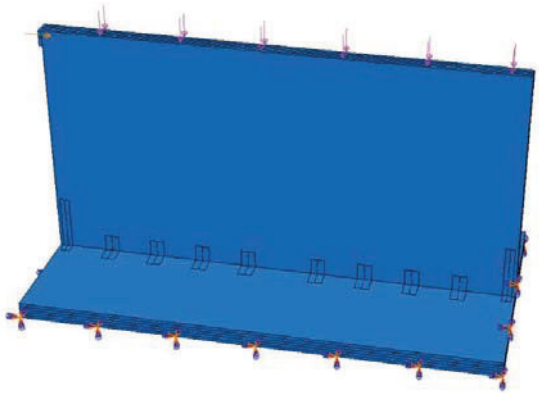

Figure 3: *FEM model geometry*

3.2 MATERIAL PROPERTIES

The material properties of the C24-grade CLT timber presented in Table 1 were sourced from a study by Uí Chúláin [16]. The subscripts *L*, *R* and *T* refer, respectively, to the directions of assumed elastic symmetry, longitudinal, radial and tangential directions. *E* and *G* represent the elastic modulus and shear modulus, respectively. The steel plate was modelled as a linear elastic isotropic material with an elastic modulus of 210 GPa and a Poisson's ratio of 0.3.

https://doi.org/10.52202/069179-0341

Table 1: *FEM material properties for C24 grade timber*

Property	Timber (C24)	Unit
E_L	12000	MPa
E_R	370	MPa
E_T	370	MPa
G_{LR}	690	MPa
G_{LT}	690	MPa
G_{RT}	50	MPa
ν_{LR}	0.511	-
ν_{LT}	0.511	-
ν_{RT}	0.203	-

4 FEM RESULTS

This section presents the result of the finite element model which is validated based on the study performed by Hughes [8]. The validated model is then used to examine the corresponding behaviour for C16-grade CLT.

4.1 MODEL VALIDATION

The simulated load-displacement behaviour of the finite element model results is presented in Figure 4. The results compare the lateral/racking displacement (U_{LAT}) and the lateral stiffness (k_{LAT}) of the panel. The lateral displacement is defined as the horizontal displacement of the top of the wall, measured on the top right corner, minus the horizontal displacement of the floor panel measured at the top of the floor panel directly under the wall panel at the right-hand end of the wall panel. This allows the relative movement of the wall panel to be examined. The numerically simulated horizontal movement of the CLT wall is graphically presented in Figure 5a. The simulated uplift of the wall was examined at the bottom left corner of the wall panel which can be graphically seen in Figure 5b. In Figure 4, the lateral displacement versus the applied lateral load is compared to the simulated results for a series of different vertical loads. The different vertical loads of 10.5 kN/m, 31.5 kN/m and 84.0 kN/m correspond to the associated structural loads of a 2-storey (T1 [8]), 4-storey (T6 [8]) and 9-storey (T8 [8]) CLT building, respectively. It can be seen that the behaviour for different vertical loads can be relatively well predicted. The behaviour of the T8 specimen [8] with a vertical load of 10.5 kN/m was found to have the largest lateral deflection when subjected to a lateral load of 50 kN. This was found to be 4.00 mm and the numerical model demonstrated good agreement and predicted a lateral displacement of 4.24 mm for a common vertical load. The connection properties of the hold-down and angle brackets utilised in this study were based on results presented by Hughes [8]. It was stated in this study that the vertical load had a significant effect on the stiffness behaviour of the individual connections and the associated load-displacement behaviour. This was also noted upon increasing the vertical load within the numerical model and utilising common properties for the connections. It was observed that the load-displacement behaviour deviated from that observed experimentally. It can be seen in Figure 4 that the load-displacement behaviour of Specimen T6, which is subjected to a vertical load of 31.5 kN/m, does not match that of the experimental curve initially as a much stiffer response was simulated than that observed for T8 which was only subjected to a vertical load of 10.5 kN/m. The yielding of the connections was also observed in the numerical model. Similarly, a stiffer response was simulated for Specimen T1 which had a vertical loading of 84 kN/m (equivalent to a 9-storey building).

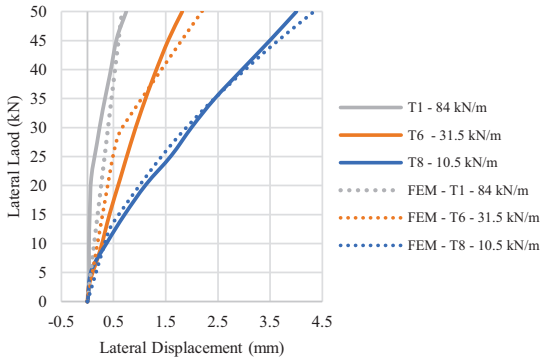

Figure 4: *Load-displacement behaviour of CLT tests [8] compared to the FEM model results.*

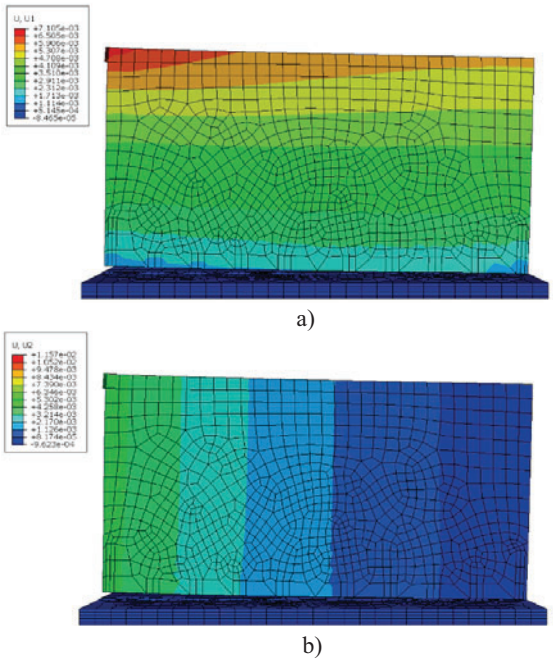
The model was also utilised to compare the experimentally determined lateral stiffness of the panel under different vertical loads. The results are presented in Table 2 and graphically presented in Figure 6. It can be seen that with increasing vertical load, the lateral stiffness of the panel increases as expected and the numerical model predicts the trend observed experimentally.



a)

b)

Figure 5: *CLT Racking FEM displacement results at a horizontal load of 100 kN: a) horizontal slip/movement (U1) and b) Vertical uplift (U2). Dimensions are presented in meters and a deformation scale factor of 10 was applied.*

In all cases examined in this study, the predicted lateral stiffness is greater than that observed experimentally. The experimental values of T1, T6 and T8 were found to be 13.5 kN/mm, 26.8 kN/mm and 45.0 kN/mm, respectively.

https://doi.org/10.52202/069179-0341

The results of the model which were taken between 10% and 40% of the maximum load were found to provide values of 15.8 kN/mm, 31.3 kN/mm and 51.7 kN/mm, for T1, T6 and T8, respectively.

Table 2: *Experimental results [8] vs numerical model (FEM)*

FEM Model	Vertical Load (kN/m)	Experimental		FEM	
		U_{LAT} (mm)	k_{LAT} (kN/mm)	U_{LAT} (mm)	k_{LAT} (kN/mm)
FEM-10.5	10.5	4.00	13.5	4.24	15.8
FEM-31.5	31.5	1.82	26.8	2.17	31.3
FEM-84.0	84.0	0.74	45.0	0.62	51.7

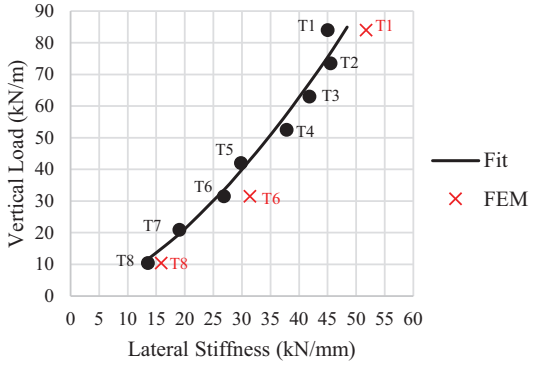


Figure 6: *Vertical load versus the mean lateral stiffness presented by Hughes [8] and the FEM results.*

4.2 RACKING OF C16 GRADE CLT

The developed model was subjected to similar structural loads, however, the structural properties of the CLT were changed from C24-grade material properties to C16-grade properties in accordance with O'Ceallaigh [17] to examine the influence of the grade of timber used to manufacture the CLT. The material properties are presented in Table 3.

Table 3: *FEM material properties for C16 grade timber*

Property	Timber (C16)	Unit
E_L	9222	MPa
E_R	663	MPa
E_T	415	MPa
G_{LR}	659	MPa
G_{LT}	619	MPa
G_{RT}	66	MPa
ν_{LR}	0.529	-
ν_{LT}	0.333	-
ν_{RT}	0.558	-

The results of both models are presented in Figure 7. It can be seen that the stiffness of the CLT has an insignificant effect on the overall lateral displacement and the connections govern a significant proportion of the behaviour. The connection properties are not varied in this study but will form a significant component of future testing on typical bracket connections under tension and shear loading. The developed model will inform the experimental test programme for C16-grade CLT connections.

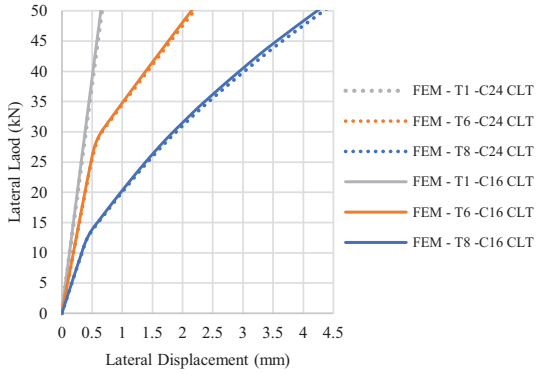

Figure 7: *Comparison of the load-displacement behaviour of CLT manufactured from C24-grade timber and C16-grade timber under different vertical loading situations.*

5 FUTURE EXPERIMENTAL TESTING

This section discusses the planned manufacture and experimental testing of C16-grade CLT under racking loads in accordance with EN 594 [9]. The further development of a suitable numerical model for the prediction of the behaviour of C16-grade CLT connections requires a series of experimental tests to be carried out. While a significant amount of research has been carried out for CLT connections, most of the testing has been carried out for C24-grade CLT. Only a limited number of studies focused on C16-grade timber. O'Ceallaigh & Harte [5] used C16 grade CLT panels to study the behaviour of commonly available steel-to-timber angle bracket connections. The connections were subjected to monotonic and cyclic loadings and were tested for different fastener lengths. The experimental results were compared to analytical models developed using the provisions of Eurocode 5 [18] and the analytical model developed by Blaß & Uibel [19,20]. The results were shown to perform well for C16-grade material. Therefore, it is proposed to test C16-grade CLT connections comprising individual brackets which will allow for an improved numerical model to be developed for C16-grade CLT. It is proposed to extend upon this testing to examine a series of brackets/connections in racking wall systems.

5.1 C16 CLT MANUFACTURE

For the proposed testing, the CLT will be manufactured in accordance with EN 16351 [1]. Two different sizes and test configurations of CLT panels will be manufactured, namely a 3-layer (40-40-40) and a 5-layer (40-20-20-20-40) panel. Boards of C16 Irish Sitka spruce (*Picea sitchensis*) with nominal cross-sectional dimensions of 100 mm × 35 mm (for panels comprising 20 mm thick layers), and 175 mm × 47 mm (for panels comprising 40 mm thick layers), will be used to manufacture the CLT panels. The boards will be initially stored in a conditioning chamber at a relative humidity of 65 ± 5% and at a temperature of 20 ± 2°C, before specimen preparation. Prior to fabrication, all of the sides of the boards will be planed to the desired board thickness (20

https://doi.org/10.52202/069179-0341

mm and 40 mm) and width (80 mm and 160 mm). All of the panels will be bonded using a one-component PUR adhesive (PURBOND HB S309), with a spreading rate of 160 g/m^2, and a pressure (face bonding only, no edge bonding) of 0.6 N/mm^2.

5.2 CONNECTION TESTING

It is proposed that typical CLT bracket connections are to be subjected to compression and shear testing. The influence of three different fastener lengths is to be studied to establish the elastic and ductile behaviour of these connectors for C16 grade CLT. Five sets of tests for each fastener length are proposed for both compression and shear loads. In addition to angle brackets, timber plates or stud rails connected using self-tapping screws is an alternate method for floor-to-wall connections and will be investigated.

5.3 RACKING TEST SET-UP

The connection testing will inform the racking tests. Racking panels, measuring 2.4 m x 2.4 m, will be manufactured in accordance with EN 16351 [1] and tested in accordance with EN 594 [9], which governs the test procedure for determining the racking strength and stiffness of timber frame wall panels. The test protocol allows for comparative performance values for the materials used in the manufacture of the panels to be determined and provides evidence in the form of experimental data for use in structural design. The racking frame in the University of Galway can be seen in Figure 8.

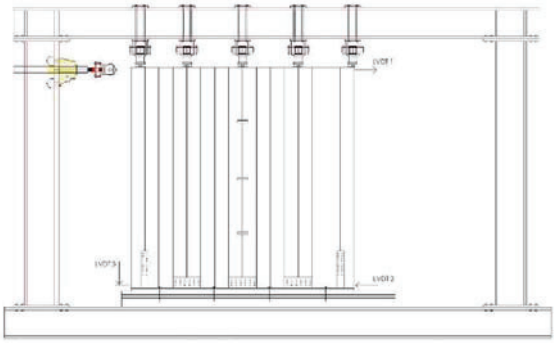

Figure 8: *Racking frame test set-up*

The self-restraining racking frame has the capability to apply a horizontal racking load of up to 200 kN and a series of vertical loads ranging from 1-5 kN. The lateral or racking load (F) is applied via a contact roller to the top left of the panel. The panels will be tested with no vertical load and with the vertical loads (F_v) set to apply a maximum vertical load of 5 kN at five different points along with the top of the wall panel. The five vertical loads are equally spaced along the top of the panel allowing for 100 mm from the leading edge of the wall in accordance with EN 594 [9]. For the purpose of this testing, the leading edge of the panel is the left edge (Figure 8) and the lateral/racking load is applied to the top of the leading edge of the wall panel. The right edge of the panel (see Figure 8) is referred to as the trailing edge.

The displacements of the panel will be monitored using linear variable differential transducers (LVDTs) at locations indicated LVDT 1, LVDT 2 and LVDT 3 (see Figure 8). The deformation (v) for the calculation of the lateral/racking displacement is taken as displacement at LVDT 1 minus the displacement at LVDT 2. The displacement at LVDT 3, which represents the vertical displacement or uplift of the panel is reported separately.
The horizontal racking load will be applied at an appropriate rate to ensure the rate of loading achieves 90 % of the maximum racking load (F_{max}) within 300 ± 120 s in accordance with EN 594 [9].
The lateral/racking displacement of the panel is calculated as shown in Eq. (1).

$$v = v_{LVDT1} - v_{LVDT2} \tag{1}$$

Where v_{LVDT1} is the lateral displacement at LVDT 1 and v_{LVDT2} is the lateral displacement at LVDT 2 (see Figure 8). The racking strength of the panel is the maximum load attained during the test as shown in Eq. (2).

$$F = F_{max} \tag{2}$$

where F_{max} = the maximum load attained.
The lateral/racking stiffness (R) is calculated as shown in Eq. (3).

$$R = \frac{F_{40} - F_{10}}{v_{40} - v_{10}} \tag{3}$$

where F_{10} and F_{40} = are the loads corresponding to 10% and 40% of F_{max} and v_{10} and v_{40} = are the displacements corresponding to 10% and 40% of F_{max}. Essentially, the Racking Stiffness (R) is the slope of the line between 10% and 40% of F_{max}.

6 CONCLUSIONS

A finite element model capable of replicating the load-displacement behaviour of wall-floor CLT connections has been presented. The model has been shown to perform well when examining the load-displacement behaviour and lateral stiffness of C24-grade CLT. The model was also utilised to examine the influence of the timber grade used in the manufacture of the CLT. The numerical results have demonstrated the potential for significant lateral/racking resistance to be achieved from CLT panels manufactured from C16 grade material but it was shown that the stiffness of the CLT itself may not be as important as the defined connection behaviour. This finding must be examined experimentally and is a key focus of future work which will further calibrate the connections utilised in the developed model to better predict the behaviour not only under monotonic loading but also under cyclic loading situations. The development of a refined model will allow a series of different configurations of connections to be examined utilising different grades of CLT. The model and its findings will provide designers with confidence in this product and may encourage producers to incorporate C16-grade material into the production of CLT.

NUMERICAL ANALYSIS OF BIAXIAL HOLLOW TIMBER SLAB ELEMENTS

Dominik Bissig[1], Marcel Muster[2], Andrea Frangi[3]

ABSTRACT: The inventions of the company Timber Structures 3.0 (TS3) facilitate the construction of point supported flat slabs made of cross laminated timber (CLT) elements. The CLT of the entire slab area is designed to bridge the largest span and to resist the largest forces at the point supports. Thus, major portions of the flat slab are overdesigned and much of the built-in structural timber is wasted. To tackle this problem, a biaxial hollow timber slab element is developed, to replace the CLT elements wherever their high performance is not needed. The hollow elements consist of a grid of notched, linear timber beams, covered on both sides with thin CLT plates. The notches in the timber grid cause stress concentrations perpendicular to the grain that can lead to an early brittle failure in regions with large shear forces. Therefore, possibilities to optimise the hollow elements' shear resistance are analysed with the help of finite element (FE) models. The models are compared to experimental results and the chosen methods are validated. The geometry of the FE model is parametrised, and the results of 1024 geometry combinations are analysed to study the influence of the geometry parameters on the structural properties of the hollow elements. The results show that geometries with multiple smaller notches have a significantly higher shear resistance than those with only one notch. Furthermore, the shear resistance can be increased by using a wider web with a smaller spacing. Contrary to the initial assumption, the use of CLT instead of glued laminated timber (GLT) in the web grid does not lead to a significant increase of the shear resistance.

KEYWORDS: TS3, point supported flat slab, biaxial hollow slab elements, FEM, Abaqus, parameter study

1 INTRODUCTION

Point supported flat slabs are often used to build modern office buildings and apartments, allowing for versatile floor plans. Most of these slabs are built with reinforced concrete, a low-cost building material that is well known and widely available. The goal of the company Timber Structures 3.0 (TS3) is to provide a cost efficient and sustainable timber alternative to concrete flat slabs. Thus, TS3 has initiated several research projects to develop a point supported timber flat slab. It consists of cross laminated timber (CLT) elements, which are connected on site with the TS3 resin [1]. The timber flat slab has been realised in several projects in Switzerland [2], but the high strength and stiffness of CLT is not needed in all areas of the point supported slab. Thus, the idea of a biaxial hollow timber slab was presented in [3]. An additional research project was launched in 2021 to investigate the biaxial hollow slab. The goal of the project is to replace the CLT elements in those parts of the slab, where the mass timber solution is not needed from a structural point of view. The conceptual idea of the new hollow slab system is illustrated in Figure 1. The new hollow elements aim to optimise the material usage and to be even more economically competitive than the current TS3 slab system by reducing the amount of valuable structural timber needed. The aim is for the hollow elements to contain at least 30% less timber than CLT elements of an equivalent thickness.

The biaxial hollow slab elements are composed of a bottom and a top CLT plate that are glued to a grid of

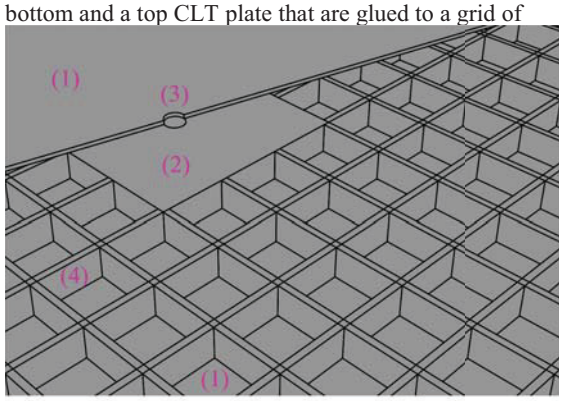

Figure 1: *Sketch of the conceptual idea for a biaxial hollow timber flat slab. (1) upper and lower CLT plate, (2) column head made of CLT, (3) connection and load transfer support, (4) hollow slab grid for biaxial load carrying action.*

linear glued laminated timber (GLT) beams, as illustrated in Figure 1. Figure 2 shows three possibilities how the intersection points of the grid can be accomplished with notches. As presented in many publications of the past decades (summarised e.g. in [4]), the notches cause stress concentrations in the timber beams. The stress concentrations can lead to an early, brittle failure of the timber beams, especially in regions of high shear forces. Therefore, the high shear forces occurring around the load

https://doi.org/10.52202/069179-0342

introduction of the point supported flat slabs can become the governing design parameter of the new hollow slab. A lower shear resistance of the hollow elements requires larger CLT elements introducing the loads into the point supports. The goal is to reduce the size of the CLT areas, to cut back on the usage of timber as much as possible. Therefore, a high shear resistance of the new hollow element is needed, and the optimisation of the grid intersection points is a crucial task in the current research project.

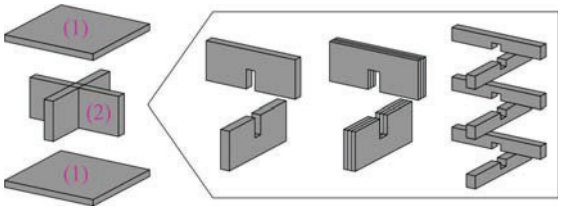

Figure 2: *Layout of the different compounds of the biaxial hollow slab elements and the different web intersection designs tested in* [5]. *(1) CLT plates, (2) GLT / CLT beams with the different notched intersection options.*

A first experimental investigation on biaxial hollow timber elements with different intersection types (as illustrated in Figure 2) was performed in 2021 at ETH Zurich [5]. The uniaxial 4-point bending tests were performed to find the bending stiffness, the shear stiffness and the shear resistance of the different element types. The experiments showed, that multiple smaller notches or the use of a wider CLT instead of a slimmer GLT beam grid increases the shear load bearing capacity of the element by 35% on average [5]. After the experiments, the three intersection types illustrated in Figure 2 were chosen to further investigate with finite element (FE) models.

To investigate the influence of the different geometrical properties on the different structural properties of the elements, the FE-models are parametrised, and a parameter study is performed. The main goal of the parameter study is to find an option with large shear resistance due to the reasons mentioned before. The bending resistance, bending stiffness and shear stiffness are also investigated, but are assumed to be less important. It is assumed that the bending resistance and the bending stiffness can easily be controlled with the hight of the element and the thickness of the CLT plates. According to previous experiences with the TS3 slab system, the shear stiffness has only a minor influence on the global deformations and vibrations in comparison to the bending stiffness. However, the influence of the notch geometry, the web width and web material on the shear resistance is of special interest for this investigation. It is assumed, that these are the most efficient parameters to be manipulated to enlarge the shear resistance. A literature review and the experimental campaign suggest that multiple smaller notches enlarge the shear resistance of all element geometries. Since the production of multiple small notches is more expensive than the production of one larger notch, the parameter study has to proof the structural benefits of the smaller notches over a variety of geometry combinations. Also, the influence of the web width on the shear resistance has to be investigated. A wider web (the same width is used in both directions) enlarges not only the webs cross sectional area, but also the width of the notch. The parameter study should also show, whether the use of CLT in the web is generally beneficial for the shear resistance. Finally, the findings from this parameter study are needed to further optimise and finalise the cross section geometry of the new slab elements.

2 MATERIAL AND METHODS

2.1 FRAMEWORK AND MODELLING

The parameter study was performed in the FE program Abaqus [6]. A Python script was used to generate and execute a volumetric, linear elastic model in Abaqus Standard. The script reads deformations and stresses from the output database generated by Abaqus and stores the information in text files. The text files were read and visualised with the help of a Matlab [7] script.

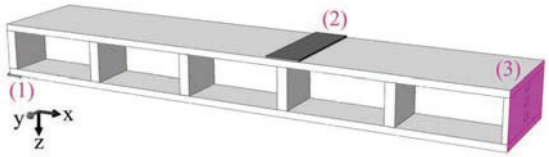

Figure 3: *Illustration of the FE model in Abaqus. (1) steel plate support, (2) steel plate load introduction, (3) symmetry plane.*

The 4-point bending test was modelled in Abaqus with volumetric timber elements. The timber plates were modelled as single parts and the timber webs were modelled as single parts with openings. To model CLT, the parts were partitioned, and each layer was assigned the correct material orientation. Side face gluing of all layers was assumed. The plate and web parts were connected rigidly with each other to form the assembly shown in Figure 3. A hard contact with a tangential friction coefficient of 0.3 was applied between timber and steel plates (support and load introduction), as well as between all timber parts that are not glued together. No glued connection was modelled at the notched intersection of the longitudinal and the cross web parts. The notches were modelled with 1 mm air around all three edges to account for the production. Each steel plate was constrained in all degrees of freedom to a reference point lying centrically below/above the plate (see Figure 4). The reference point at the support was fixed in the directions u_y, u_z (deflections), r_x and r_z (rotations), to model a rolling support. The reference point at the load introduction was fixed in u_x and u_y direction. A point load of $F_{cyl} = 10$ kN was introduced to the reference point above the load introduction steel plate. The symmetry plane in the middle of the specimen was fixed in the directions u_x, r_y, r_z.

The Abaqus mesh element type C3D8 (brick element with 8 integration points) was chosen. A preliminary investigation showed, that this element type has the best result quality to computation time ratio for the on hand study. The mesh size was chosen according to the CLT plate layer thickness h_h. For $h_h \leq 20$ mm, a mesh size of 20 mm was chosen, for $h_h > 20$ mm a mesh size of 30 mm was chosen. A mesh refinement region was

https://doi.org/10.52202/069179-0342

implemented around the notch nearest to the support and at the symmetry plane. In the refinement region, a mesh size of 10 mm was chosen. The refinement region stretched 60 mm from the cross web, followed by a mesh transition zone of 40 mm, as illustrated in Figure 4.

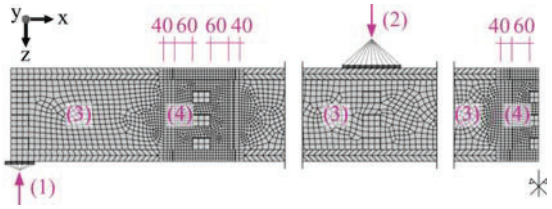

Figure 4: *Longitudinal section of a specimen in Abaqus with the mesh of C3D8 elements, generated according to the defined restrictions. (1) support on reference point, (2) load introduction to reference point, (3) general mesh 20..30 mm, (4) fine mesh 10 mm.*

The elastic material parameters for the longitudinal (L, 1), tangential (T, 2) and radial (R, 3) direction shown in Table 1 were used to model the timber parts. The material model does not distinguish between radial and tangential properties (transversely isotropic material model). Average values of the Poisson's ratio after [8] were used.

Table 1: *Elastic properties of the modelled timber parts for a moisture content of 12%.*

E_1 $E_2 = E_3$	11'500 MPa 300 MPa	Elastic modulus [9]
$G_{12} = G_{13}$ G_{23}	650 MPa 65 MPa	Shear modulus [9]
$\nu_{12} = \nu_{13}$ ν_{23}	0.395 0.41	Poisson's ratio [8]

To verify the FE-model with the experimental results, the actual average timber moisture content of 9% was taken into account. The moisture dependent stiffness parameters after Neuhaus [10] were used to scale the stiffness parameters listed in Table 1 according to Equation (1).

$$E_{FE} = E_{EN} \cdot \frac{E_{NH}(9\%)}{E_{NH}(12\%)} \quad (1)$$

with: E_{FE} Elastic modulus used in the FE-model
E_{EN} Elastic modulus defined in Table 1
E_{NH} Elastic modulus after [10] in dependence of the timber moisture content

2.2 GEOMETRY

The geometric properties of the modelled elements were parametrised to study their influence on the structural properties of the slab elements. The parameters illustrated in Figure 5 were varied with the values listed in Table 2.

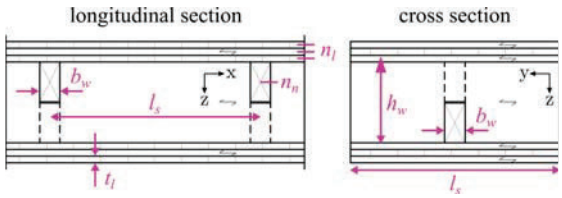

Figure 5: *Illustration of the geometric parameters that are varied within the scope of the parameter study (see Table 2). Longitudinal and cross section of one element configuration modelled with the setup of a uniaxial 4-point bending test.*

Table 2: *Parameters of the hollow elements that are varied within the scope of the parameter study (see Figure 5 for an illustration of the geometric parameters).*

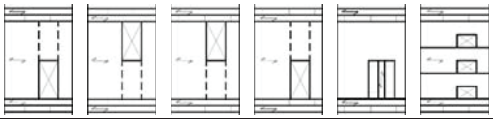
Name	Range	Description
b_w	60, 120, 180 mm	web width
h_w	80, 180, 280 mm	web height
l_s	375, 500, 625 mm	web spacing
n_n	1, 3	number of notches
t_l	20, 40 mm	thickness of CLT layers
n_l	2, 3	number of CLT layers
PN	top, bottom	position of notch
GD	0°, 90°	grain dir. CLT top layer
MW	GLT, CLT	material web

The width of the element was chosen equal to the web spacing l_s to model a representative section of the slab. The number of openings between the cross web parts was kept at a constant number of $n_o = 5$. Thus, the total length of the specimen varied with the chosen web spacing l_s.
A total of 1728 combinations result from the parameters listed in Table 2. The following combinations were excluded from the analysis, since they are not viable either from a productional or from a structural point of view:

- $b_w = 180$ mm and $l_s = 375$ mm
- $h_w = 80$ mm and $n_n = 3$
- MW = CLT and $n_n = 3$

Thus, a total of 1024 geometry combinations result, which leads to the same number of models to be created.
Furthermore, six models with the geometric parameters given by the experimental analysis (see [5]) were created. These models were used to verify the FE results of the failure load and the stiffness by comparing them to the corresponding experimental results. The geometry and the naming of the verification models is summarised in Table 3 and described in detail in [5].

Table 3: *Names and geometry of the verification models. All verification models had a web hight* $\boldsymbol{h_w = 240}$ *mm, a web spacing* $\boldsymbol{l_s = 625}$ *mm, a CLT layer thickness* $\boldsymbol{t_l = 20}$ *mm and a number of CLT layers* $\boldsymbol{n_l = 2}$.

	NL-LX	NL-XL	NX-LX	NX-XL	CL-LX	LL-LX
						


b_w	60 mm	60 mm	60 mm	60 mm	80 mm	60 mm
n_n	1	1	1	1	1	3
PN	B	T	T	B	B	B

GD	0°	90°	0°	90°	0°	0°
MW	GLT	GLT	GLT	GLT	CLT	GLT

2.3 DATA OUTPUT AND CALCULATIONS

The deflections were evaluated in the pure bending region at the symmetry plane and at a distance of 250 mm from the load introduction point, as illustrated in Figure 6. The bending and shear stiffness can be calculated from the two deflections after Equation (2) and (6).

$$EI_{eff} = \frac{F_{cyl}\, a\, l_w^2}{8\,(w_2 - w_1)} \tag{2}$$

With the assumption that only bending deformations occur in the whole specimen, the apparent bending stiffness can be calculated from Equation (3).

$$EI_{app} = \frac{F_{cyl}}{24\, w_2}\,(3\, a\, l^2 - 4\, a^3) \tag{3}$$

Since the total deformation in the middle of the specimen compounds of bending and shear deformations, the shear stiffness GA_v can be calculated as follows.

$$w_2 = w_2(M) + w_2(V) \tag{4}$$

$$w_2 = \frac{F_{cyl}}{24\, EI_{eff}}(3\, a\, l^2 - 4\, a^3) + \frac{F_{cyl}\, a}{GA_v} \tag{5}$$

$$GA_v = \frac{F_{cyl}\, a}{w_2 - \frac{F_{cyl}}{24\, EI_{eff}}(3\, a\, l^2 - 4\, a^3)} \tag{6}$$

with:
- EI_{eff} Bending stiffness
- GA_v Shear stiffness
- EI_{app} Apparent bending stiffness, assuming $GA_v \to \infty$
- F_{cyl} Force applied per cylinder (10 kN)
- a Distance between support and load introduction (see Figure 6)
- l_w Distance between third point deformation measurements (see Figure 6)
- l Distance between supports (see Figure 6)
- w_i Deformation (see Figure 6)

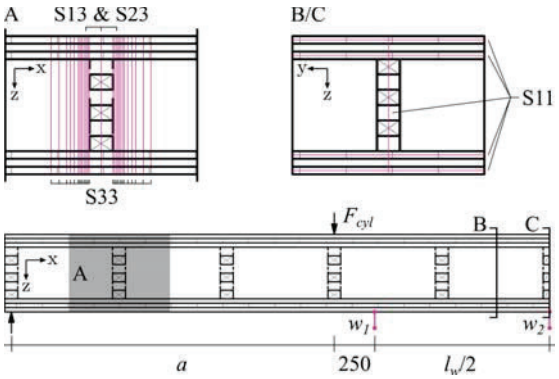


Figure 6: *Evaluation positions of the shear stress (S13, S23), stress perpendicular to grain (S33) and stress parallel to grain (S11) as well as the deformations w_i.*

The bending tension and compression stresses (S11) parallel to grain were evaluated in the pure bending region in the cross sections B and C illustrated in Figure 6. They were evaluated in the centre of each longitudinal layer of the plates and along a vertical section in the middle of the model. The shear (S13) and rolling shear (S23) stresses were evaluated along three vertical lines in the middle and 10 mm to the left and right of the notch next to the support as illustrated in Figure 6. The stresses perpendicular to grain (S33) were evaluated at the same notch, but along 12 vertical lines left and right of the notch. Since the self weight is neglected in the parameter study, the shear force between support and load introduction is constant. Hence, the shear stresses and the stresses perpendicular to grain were not measured at the support to avoid the local influence of the supporting steel plate. For the specimens with a GLT web, the vertical evaluation lines were placed in the centre of the web. To capture the stress perpendicular to grain in the specimens with a CLT web, the vertical evaluation lines in these models were placed in the layer with horizontal grain direction 1 mm from the edge of the web.

The evaluated maximum stresses were compared to the corresponding strength to estimate the load bearing capacity. Preliminary investigations showed that the peak stress positions of the different stress directions do not coincide. Thus, the load bearing capacity of each linear elastic model was estimated after Equation (7) and no stress interactions were considered.

$$F_R = \min\left\{F_{cyl} \cdot \frac{f_i}{\sigma_i}\right\} \tag{7}$$

with:
- F_R Load bearing capacity
- F_{cyl} Applied cylinder force
- f_i Strength in direction *i*
- σ_i Maximum stress occurring in direction *i*

To estimate the load bearing capacity, the average strength values for GL24h listed in Table 4 were used. The compression strength perpendicular to grain was neglected since the tension strength perpendicular to grain is decisive in every case due to symmetry. The tensile strength perpendicular to grain was chosen after the glulam specimens tested by [11] for a small reference volume of 0.75 to 1.5 dm^3.

Table 4: *Mean strength values for GL24h used to estimate the load bearing capacity.*

Name		Value (MPa)	Source
S11	$f_{t,0,m}$	27	[12]
	$f_{c,0,m}$	40	[12]
S13	$f_{v,m}$	4.1	[13]
S23	$f_{r,m}$	1.88	[14]
S33	$f_{t,90,m}$	1.5	after [11]

2.4 EVALUATION METHODS

The stress and strain output database of the verification FE-models was analysed manually in Abaqus' 3D viewer and compared to the automatically produced result data vectors to ensure the quality of the automated data output.

https://doi.org/10.52202/069179-0342

Due to the number of models used in the parameter study, only the automated data output was used for its analysis. The Kendall rank correlation coefficient [15] was used to get an overview of the relations between the different geometry parameters and the structural properties. Furthermore, box- and scatter plots were used to validate the correlation numbers visually and to get a quantitative overview of the results. The boxplots show a box between the 25th and the 75th percentile. All values lying outside the boundaries of 1.5 times the interquartile range are marked as outliers. The median is marked by the centre line and the notches indicate the 5% significance range of the median after [16].

3 RESULTS AND DISCUSSION

3.1 VERIFICATION

Figure 7 shows the force displacement diagrams from the experiments and from the corresponding linear elastic FE models. A longitudinal section and the short name in each diagram indicate the corresponding specimen type. The first two failures estimated by the FE model are indicated in the diagrams with circles.

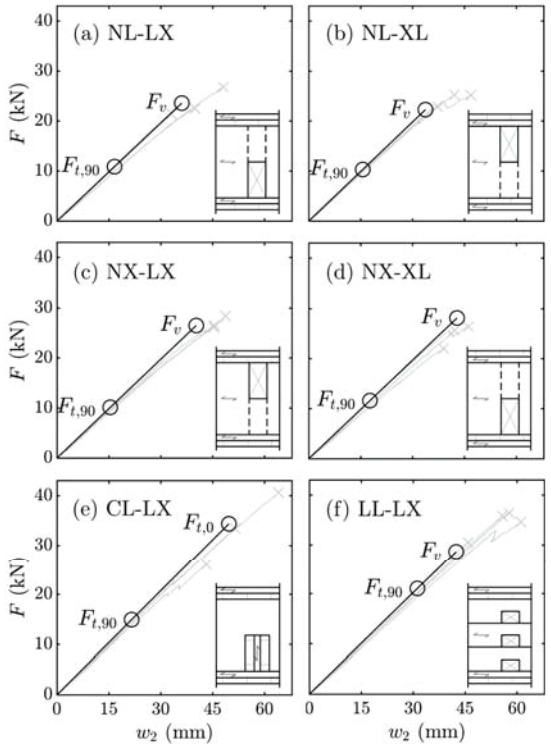

Figure 7: *Force displacement diagrams of the verification models. Results from the FE analysis (black) and the experimental analysis (grey). The circles indicate the first two failures estimated by the FE model.*

Only a negligibly small difference between the grey lines and the black line can be seen between 10% and 40% of the estimated failure load. This indicates that the model predicts the stiffness well in the region of interest. Towards the end of the curve, the grey lines show larger deflections than the black line. This softening is probably caused by the cracks propagating from the notch's corners along the web, which is not reproduced by the linear elastic FE-models. Since the softening occurs in a late state of the experiment, it is not relevant for the derivation of the stiffness parameters and the chosen method is assumed to be suitable. The estimation of the failure load is less straight forward. As observed in the experimental campaign, the first failure occurs in tension perpendicular to grain ($F_{t,90}$) for all specimen types. The magnitude of the first failure load also corresponds well with the observations made during the experiments. It was observed that the cracks formed at the notches corners and expanded until a shear failure occurred. The shear failure (F_v) is also predicted as a second failure by the FE model for the types NL, NX and LL. Although the cross section reduction by crack propagation is not taken into account by the FE model, the magnitude of the shear failure load for these types fits the observed failure load well. The second failure load of the CL type is predicted to be in tension parallel to grain ($F_{t,0}$) in the bending region. No bending failure was observed in the experimental campaign, however, a shear and rolling shear failure in the glue line was observed after the crack propagation. Nevertheless, the first failure type is predicted well for all specimen types. Thus, the first failure type is chosen for further comparisons of the shear resistance. Although this failure does not necessarily correspond to a global failure of the specimen, it still allows for a relative comparison of the models analysed in the parameter study.

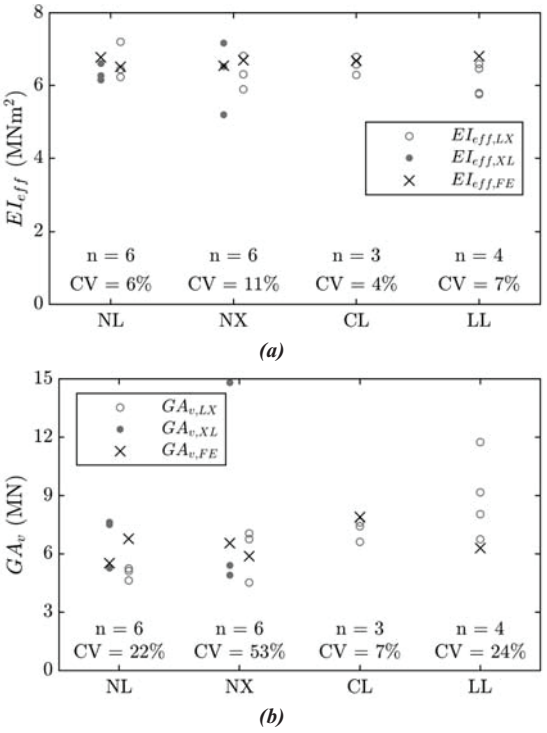

Figure 8: *Bending stiffness* ***(a)*** *and shear stiffness* ***(b)*** *of the different element types, derived from the experimental campaign and the FE-models.*

Figure 8 compares the experimentally determined and numerically predicted bending (EI_{eff}) and shear stiffness

(GA_v). The experimentally determined shear stiffness shows a large scattering for the element type LL. This can partly be explained by the fact, that for two of the LL specimens, only one of two LVDTs measuring w_1 was used due to a malfunction of the other one. The outlier shear stiffness measurement of the specimen type NL showed a large longitudinal crack in the web in the pure bending region already before the test. It is assumed that the specimen cracked due to swelling and shrinking and that the larger deformations in the pure bending region lead to an underestimation of the bending stiffness and an overestimation of the shear stiffness. Given the small number of experiments and the scattering of the results, it still can be stated that the FE-model predicts both stiffnesses accurately for all specimen types. Thus, the chosen material parameters, the element type and the mesh size are assumed to be suitable.

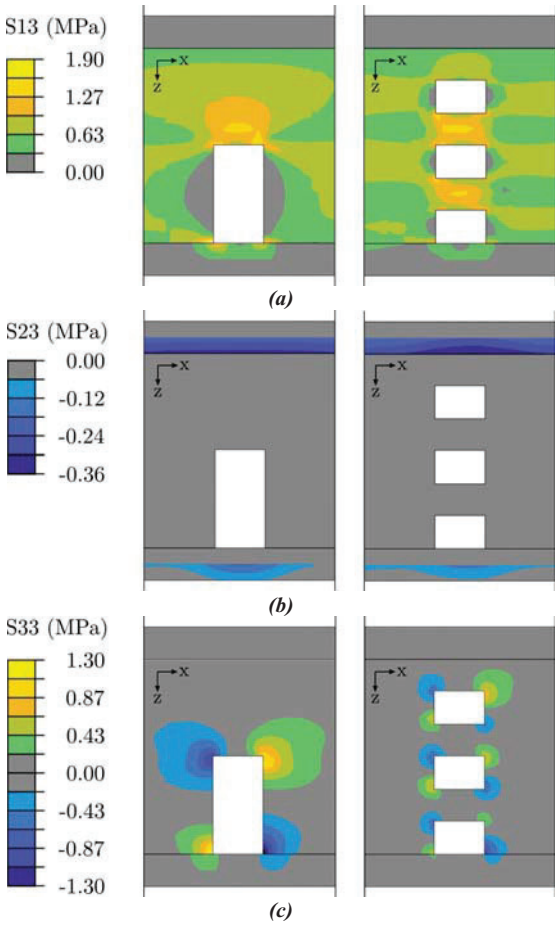

Figure 9: *Stresses acting near the first notch after the support of the specimens NL-LX (left) and LL-LX (right). Acting on the sections: shear load V = 10 kN, bending moment M = 6.3 kNm.* ***(a)*** *shear stress (S13 =* $\boldsymbol{\sigma_v}$*),* ***(b)*** *rolling shear stress (S23 =* $\boldsymbol{\sigma_r}$*),* ***(c)*** *stress perpendicular to the grain (S33 =* $\boldsymbol{\sigma_{t/c,90}}$*).*

Figure 9 illustrates the shear and rolling shear stress as well as the stress perpendicular to grain in the NL-LX and the LL-LX models at the notch next to the support (section A as illustrated in Figure 6). Figure 9 (a) and (b) show, that the largest shear and rolling shear stresses occur in the centre line of the notches. The magnitude and the volume subjected to large shear stresses is similar for both the NL and the LL model. Figure 9 (c) shows, that the NL specimen experiences a higher peak in stresses perpendicular to grain than the LL specimen. Additionally, the timber volume subjected to stresses perpendicular to grain is larger for the NL specimen. Figure 10 illustrates the bending stress of the NL-LX and the LL-LX models at the symmetry plane. It shows, that the tension stress parallel to grain is largest near the web and a stress peak forms under the notch. This peak is higher for the NL model than for the LL model. Nevertheless, the full width of the flange is activated in tension and compression in both models.

It can be concluded that the chosen positions for the evaluation of the stresses as illustrated in Figure 6 cover the maximum stress peaks for all stress directions. This can also be shown for the other reference specimens NX and CL.

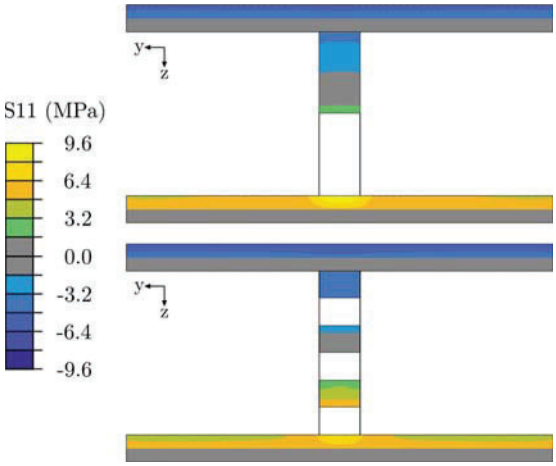

Figure 10: *Bending stress (S11 =* $\boldsymbol{\sigma_{t/c,0}}$*, resp.* $\boldsymbol{\sigma_m}$*) at the symmetry plane of the specimens NL-LX (top) and LL-LX (bottom). Acting on the sections: bending moment M = 18.75 kNm.*

3.2 PARAMETER STUDY

The Kendall rank correlation coefficient for the different geometry parameters and the different structural properties of the elements is shown in Figure 11. This coefficient can only be used to get a first overview of the results, since the coefficient was calculated over the whole dataset and some geometry combinations were excluded from the analysis from the beginning (see Section 2.2). The presented results were normalised for one meter width.

The absolute value of all correlations over the whole dataset is smaller than 0.6, which can be explained by the fact, that all structural parameters are influenced by multiple geometry parameters. Nevertheless, the figure shows, which geometrical parameters can be tackled to manipulate the different structural parameters efficiently. As expected, the bending resistance and the bending stiffness show the largest positive correlation with the height of the web and the thickness of the CLT plates

https://doi.org/10.52202/069179-0342

defined by the number (n_l) and thickness (t_l) of the single CLT layers. They also show a small negative correlation with the grain direction, which can be explained by the modelling of three-layered plates, which are stronger in one direction. Both parameters show little to no correlation with the web width and the web spacing. Since the bending resistance and the bending stiffness can easily be manipulated with the geometry parameters mentioned and since they are not decisive for the success of the hollow slab system, they are not discussed further.

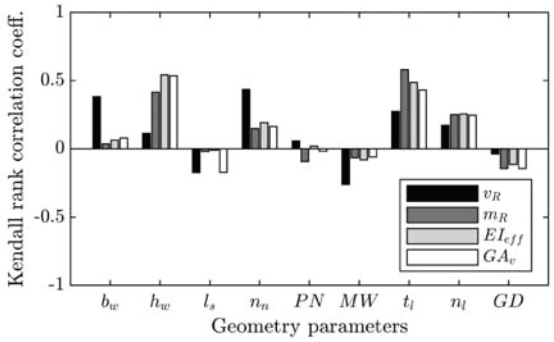

Figure 11: *Kendall rank correlation coefficient for the geometry parameters explained in Table 2 (positive correlation with respect to the values listed in Table 2 from left to right) and the structural parameters* $\boldsymbol{v_R}$ *(shear resistance),* $\boldsymbol{m_R}$ *(bending resistance),* $\boldsymbol{EI_{eff}}$ *(bending stiffness) and* $\boldsymbol{GA_v}$ *(shear stiffness). All structural parameters are evaluated per meter width.*

The shear stiffness also shows the largest positive correlation with the hight of the web and the thickness of the CLT plates, which have a direct influence on the cross-sectional area. It is assumed that the web width shows only a small positive correlation with the shear stiffness due to the exclusion of the mentioned parameter combination of a web width of 180 mm and a web spacing of 375 mm. The web spacing and the shear stiffness show a small negative correlation, which implies that a smaller web spacing is beneficial for the shear stiffness. Since the shear stiffness has only a minor impact on the global deformations of the hollow timber slab, it is not discussed further.

The position of the notch shows little to no correlation with any of the structural parameters. The negligible influence of the position of the notch can also be shown with more detailed scatter- and box plots and the findings coincide with the experimental investigations. The grain direction shows no correlation with the shear resistance and it shows only a small negative correlation with the other structural parameters. Therefore, these parameters are not discussed further.

The shear resistance is mainly influenced by the web width and the number of notches. The width of the web shows a positive correlation with the shear resistance. Thus, the positive effect of a wider web seems to dominate the assumed negative influence of a wider notch (see also Figure 12). The hight of the web does not correlate with the shear resistance, which is an indicator that the shear resistance is dominated by a failure in tension perpendicular to grain. A closer examination shows, that all 1024 models first fail in tension perpendicular to grain. The web spacing and the shear resistance show a small negative correlation, which implies that a smaller web spacing is beneficial for the shear resistance. It is assumed that this correlation would even be larger, if the combination with a web width of 180 mm and a web spacing of 375 mm would not have been excluded from the analysis. As assumed, the number of notches correlates positively with the shear resistance (see Figure 12). The thickness and number of the CLT plate layers also show a positive, but smaller correlation with the shear resistance. Since the plate thickness should stay as small as possible to save as much timber as possible, these parameters are not predestined to enlarge the elements shear resistance. The influence of web width, web spacing, number of notches and thickness of CLT plate layers on the shear resistance is illustrated in Figure 12. The figure confirms the previously stated assumptions and findings.

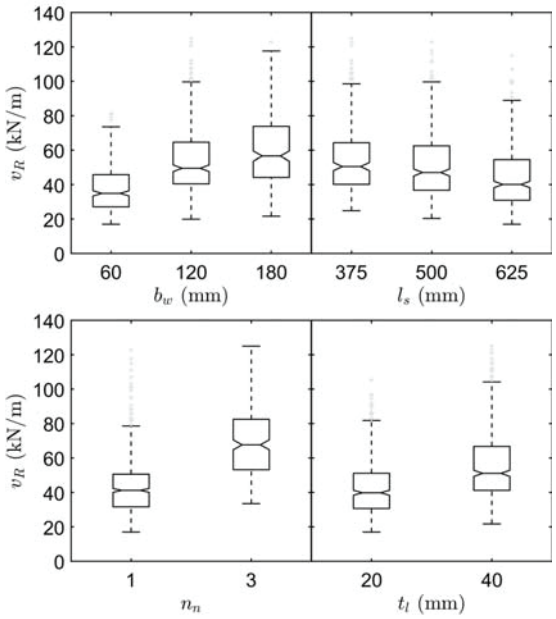

Figure 12: *Boxplots that show the relationship between the shear resistance and the web width (*$\boldsymbol{b_w}$*), the web spacing (*$\boldsymbol{l_s}$*), the number of notches (*$\boldsymbol{n_n}$*) and the thickness of the CLT plate layers (*$\boldsymbol{t_l}$*) for all models analysed within the parameter study.*

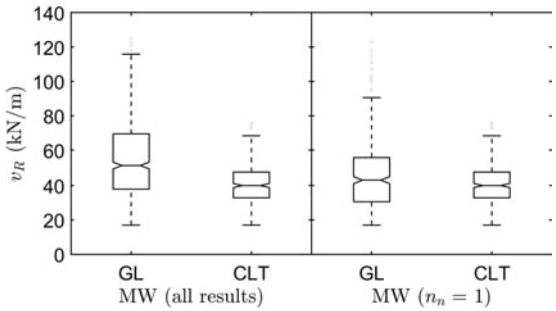

Figure 13: *Boxplots that illustrate the influence of the different web materials (MW) on the shear resistance. Two datasets are illustrated: all results (left) and only specimens with one notch (right).*

https://doi.org/10.52202/069179-0342

The material of the web shows a negative correlation with the shear resistance, which implies that using CLT to build the web does not bring benefits. As illustrated in Figure 13, the effect of a CLT web disappears in the statistical evaluation due to other, more important geometry parameters. The height of the notch dominates the influence on the shear resistance and the negative correlation partially originates from the fact, that the combinations with CLT web and three notches were excluded from the analysis. Figure 13 illustrates the relationship between the shear resistance and the material of the web for two different sets of results. If all results are considered, a negative correlation and a significantly smaller median follows for the CLT web specimens. If only the results for specimens with one notch ($n_n = 1$) are plotted, no significant difference between the medians can be found. Additionally, a smaller scattering of the CLT web specimens can be observed. This may arise from the measuring method of the stresses perpendicular to grain. It is possible that the stress measured only 1 mm from the edge of the CLT web captured a numerical stress peak and thus leads to more conservative shear resistance estimations. But even if the CLT web specimens showed a slightly higher shear resistance, they should not be preferred over the glulam option with one notch, since the stress concentration between web and plate will be the same for both options. The reinforcing vertical middle CLT layer can only be activated in the centre of the web, not at the boundary between plate and web.

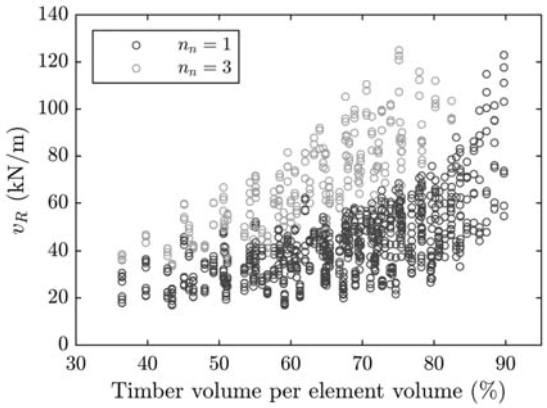

Figure 14: *Shear resistance of all geometry combinations plotted over their average timber volume per element volume. The number of notches ($\boldsymbol{n_n}$) of the individual specimens is illustrated by the marker's brightness.*

The correlations indicate that the shear resistance of the biaxial hollow slab elements is most efficiently maximised by using multiple notches, a wider web and a smaller web spacing. Figure 14 shows a plot of the shear resistance of each geometry combination over its average timber volume per element volume. The two groups of elements with only one notch and elements with three notches represented in black and grey can easily be distinguished. It can be seen, that the elements with three notches have a larger shear resistance overall. The plot clearly illustrates that multiple notches outrival the single notched web specimens in terms of shear resistance over the whole range of geometry combinations. It also shows that the largest shear resistances are achieved by using 70% of timber per element volume or more. As described in Section 1, the timber volume of the hollow elements should be as small as possible, and it should not exceed 70% of the total volume of the element. Thus, a geometry with multiple notches should be chosen in favour of an option with only one notch to build a biaxial hollow slab system.

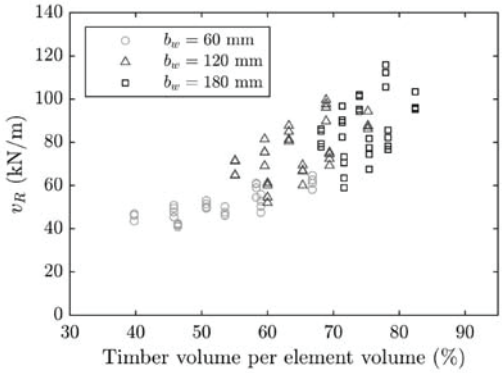

Figure 15: *Shear resistance of the specimens with three notches ($\boldsymbol{n_n = 3}$) and a web spacing ($\boldsymbol{l_s}$) of 500 mm. The web width ($\boldsymbol{b_w}$) of the individual specimens is illustrated by the markers shape and brightness.*

Enlarging the web width also leads to higher shear resistances, as illustrated in Figure 15 for specimens with three notches ($n_n = 3$) and a web spacing (l_s) of 500 mm. The overall smallest shear resistance is achieved with a web width of 60 mm, whereas the overall largest shear resistance is achieved with a web width of 180 mm. The figure also illustrates that less timber can be saved with wider webs. Since the timber volume of the hollow elements should be as small as possible, the results suggest, that web widths larger than 120 mm are not efficient.

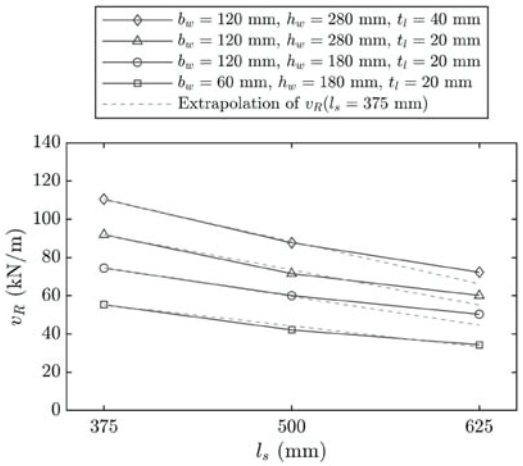

Figure 16: *Shear resistance over web spacing for four example geometry combinations with the common parameters $\boldsymbol{n_n = 3}$, $\boldsymbol{n_l = 2}$, $\boldsymbol{PN = bottom}$, $\boldsymbol{GD = 0°}$, $\boldsymbol{MW = GLT}$ and the varied parameters listed in the legend. The dashed line shows the shear resistance estimated by linear extrapolation of the shear resistance per web with $\boldsymbol{l_s = 375}$ mm.*

https://doi.org/10.52202/069179-0342

Figure 16 illustrates, how the web spacing influences the shear resistance on four different geometry combinations on which only the web spacing was varied. The shear resistance varies linearly with the web spacing. The dashed line in the graph was calculated with the shear resistance per web of the specimens with $l_s = 375$ mm. This shear resistance was linearly extrapolated to get the shear resistance per meter width for web spacings of 375 mm, 500 mm, and 625 mm. The results only marginally deviate from the dashed lines. Thus, it is assumed that the shear resistance varies directly proportional with the web spacing for values within the analysed boundaries and no mentionable stress interactions resulting from smaller web spacings occur.

4 CONCLUSIONS AND OUTLOOK

As expected, the bending resistance and the bending stiffness of the hollow elements can easily be enlarged by enlarging the thickness of the CLT plates and the total thickness of the elements. The same parameters have a positive influence on the shear stiffness too, which is however, less important than the bending stiffness for the serviceability limit state design. Multiple notches, a wider web and a closer web spacing have a positive influence on the shear resistance of the elements. The shear resistance of elements with multiple notches is significantly larger than the one of elements with one single notch over the whole set of geometry combinations. The number of notches proves to be the parameter with the largest influence on the shear resistance of the elements. Web widths larger than 120 mm lead to larger shear resistances, but also consume more timber and are consequently not to be used. The shear resistance per meter width of the element is directly proportional to the web spacing. In opposition to the initial assumption, no positive influence of a CLT web was found.

The different geometry combinations have been compared to each other and the relative best solutions and methods to optimise the mechanical properties were found. To find the absolute best solution for different point supported slab layouts, further studies are needed. Only by comparing different slab layouts, the total timber saving and the impact of the production cost on the total slab cost can be estimated. Hence, different examples of point supported slab arrangements should be analysed. Furthermore, a suitable analytical calculation method is of great importance to allow for an easy and efficient design process. Different analytical models for the calculation of bending and shear resistance and stiffness will be analysed and compared to the data achieved with the FE parameter study.

EFFICIENT FINITE ELEMENT MODELS FOR ADHESIVE-FREE MULTI-LAYERED TIMBER STRUCTURES

J. Paroissien[1,2], T.A. Bui[3], M. Oudjene[1], P. Lardeur[2]

ABSTRACT: This paper presents finite element models to assess the vibration performance of multi-layered timber structures assembled through compressed wood dowels. Starting from a solid model which is considered as a reference, a new methodology using a solid-beam approach for the dowels and a solid-shell approach for the layers is described. Kinematic assumptions are applied throughout the cross-section of the dowels and the thickness of layers, leading to a significant reduction of the number of variables. The models are assessed for the calculation of frequencies and mode shapes of multi-layered timber beams and timber panels. The efficiency of this approach, in terms of quality of results and model size, is highlighted.

KEYWORDS: timber construction, wood dowels, finite element, solid-shell, solid-beam.

1 INTRODUCTION

The construction sector faces an increasing need for more sustainable materials. This is brought together by institutions that impose increasingly stringent standards and consumers who transform the market through their more ecological demands.

Adhesive-free multi-layered timber structures aim to replace glue-laminated timber structures as an eco-friendly alternative by improving their durability and recyclability. Indeed, at high temperatures, glue emits toxic gases, especially formaldehyde which is carcinogenic to humans [1].

A concern for timber construction is the vibration serviceability of timber floors, glued or not. Human activity and children jumping in a residential or commercial building induce annoying vibrations in timber floors since they are lightweight structural elements.

Bui et al. [2,3] performed an experimental and numerical investigation on the vibration performance of Adhesive-Free Laminated Beams (AFLB) (Figure 1) and Adhesive-Free Cross-Laminated Timber (AFCLT) panels (Figure 2) assembled through compressed wood dowels.

Namely, this study highlighted a high variability level of frequencies. A finite element model made of solid elements was proposed for the layers and the dowels. Bui et al. [4] developed the Modal Stability Procedure (MSP) for the evaluation of the variability of frequencies, using this solid finite element model. This model is satisfactory in terms of quality of results but is time-consuming, particularly in the context of variability assessment or optimization where a large number of analyses may be necessary.

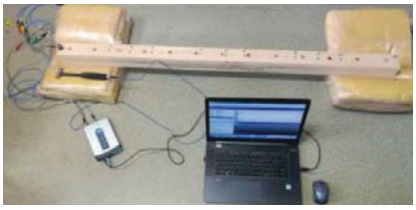
Models using classical beam elements for the dowels and classical shell elements for the layers were tested by Bui [5]. These models lead to several difficulties, namely due to the complex deformation of dowels and the specific geometry representation, and are finally unsatisfactory.
Solid-shell and solid-beam approaches were developed by Wei et al. [6,7]. These approaches have the advantages to use solid elements and to reduce the number of degrees of freedom in a model by applying beam or shell theories.
These approaches are applicable to AFLB and AFCLT panels to reduce the model while keeping the solid geometry of the structure. However, adapting the solid-shell and solid-beam approaches to industrial structures is a novelty.
In this paper, we first recall the main experimental results obtained for AFLB and AFCLT panels. Then we present the reference finite element model of multi-layered timber beams and timber panels for modal analysis in free-free conditions. To reduce computational time using these reference models, reduced models using solid-beam and solid-shell approaches are also presented. Finally, a method to calculate variability is described.

2 SUMMARY OF EXPERIMENTAL DATA

In Bui et al. study [2], two wood species were considered for the layers: spruce and oak. The experimental campaign and the results were obtained in free-free conditions to minimize boundary conditions effects, with the hammer impact technique. The experimental set-up for the assessment of vibration behavior of AFLB and AFCLT panels is shown in Figure 3.

(a)



(b)

Figure 3: *Experimental set-up for (a) AFLB, (b) AFCLT panels [5]*

For the beams, 11 measurement points are chosen along the longitudinal axis, and for the panels 15 measurement points are distributed over the whole surface.
In this paper, we consider AFLB and AFCLT panels composed of oak for the layers and compressed spruce for the dowels. The moisture content during the experiments was 9 %.
The first three bending modes for both types of structures are presented.
The AFLB pictured in Figures 1 and 3a is composed of three oak layers and 27 compressed spruce dowels. The beam has a length of 1450 mm for a width of 70 mm and a height of 67.5 mm.
The results for the experimental mean natural frequencies, damping ratios and their respective coefficients of variation are summarized in Table 1 for five AFLBs and Table 2 for five AFCLT panels.

Table 1: *Experimental natural frequencies and damping ratios [2] for five AFLBs*

		Mean value	CoV (%)
f1	frequency (Hz)	118.2	6.0
	damping (%)	4.3	9.0
f2	frequency (Hz)	281.0	5.3
	damping (%)	2.1	4.6
f3	frequency (Hz)	471.1	4.2
	damping (%)	1.9	13.7

The vibrational serviceability performance of AFLB was demonstrated by comparison to their glued counterparts by Bui et al. [5]. It was proved that while the difference between frequencies increase slightly with higher modes, the damping ratio is much higher for AFLB.
The AFCLT panels pictured in Figures 2 and 3b are composed of three oak layers, 28 boards and 196 compressed spruce dowels in total. Each external layer contains 7 boards, while the interior one contains 14 boards in the perpendicular direction. These panels have a length of 2100 mm for a width of 1050 mm and a height of 75 mm.

Table 2: *Experimental natural frequencies and damping ratios [2] for five AFCLT panels*

		Mean	CoV (%)
f_2	frequency (Hz)	54.5	2.5
	damping (%)	0.72	10.8
f_3	frequency (Hz)	56.3	8.5
	damping (%)	0.87	13.7
f_7	frequency (Hz)	110.3	3.0
	damping (%)	0.97	6.9

The vibrational characteristics for the assembled beams and panels show high variability levels as stated before. This highlights the need for a complete variability assessment of the structures.

3 REFERENCE FINITE ELEMENT MODEL

3.1 FINITE ELEMENT MODEL

The models for both AFLB and AFCLT panel using the Verification and Validation methods [8] are presented.
Finite element models are created using the software Abaqus/Standard©, and the twenty-node hexahedral solid element with reduced integration (C3D20R of Abaqus [9]) is exploited. After testing several solid elements, this choice has been made as it is the most efficient for convergence of frequencies and leads to a minimization of model size for these timber structures.
As finite element models must be as close as possible to the physical reality, assumptions based on experimental observations [2] related to the connection between the different parts, are made. On the one hand, in the following models, there are no interactions between the boards or the layers with each other. On the other hand, as the dowels are densified and tend to expand to keep their shape memory, contact without sliding is considered. Because meshes of layers and dowels are not coincident at their interfaces, the interaction between dowels and layers must be modelled. To stick the surfaces of the dowels and holes of the boards, the *Tie* option in Abaqus is chosen.
Finally, the mechanical properties of the oak boards, are a mix of experimental results from [2] for the density and the longitudinal modulus. For all the other elastic properties, empirical relations from Jodin's book [10] are used. For the compressed wood that constitutes the dowels, the properties were identified using a quasi-inverse problem by Bouhala et al. [11].

3.2 VERIFICATION STEP

The Verification process is completed when the convergence of frequencies to the accurate solution is achieved. For the Verification stage, a highly accurate solution is obtained with a very fine model as no analytical solution exists.
For the AFLB the results of the convergence study given in Figure 4 lead to an optimal mesh with about 13 000 elements and 220 000 degrees of freedom.
This model is described in Figure 5. It is important to note that in the dowels the mesh is refined near the interfaces between layers as shear stress gradients are high in these areas.
The same method is applied to the AFCLT panel. In particular, the same refinement technique is applied to the dowels. The convergence study illustrated in Figure 6 leads to an optimal mesh with about 86 000 elements and 1 500 000 degrees of freedom. This mesh is shown in Figure 7.

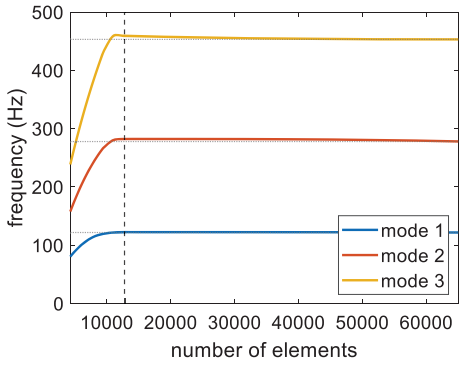


Figure 4: *Convergence study for AFLB*

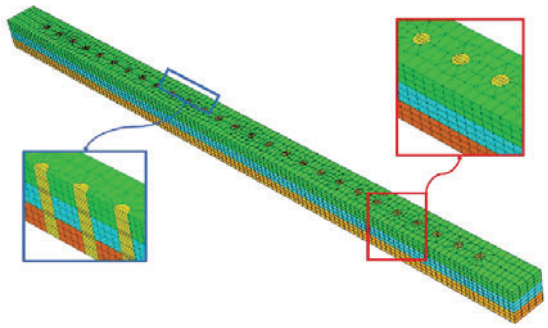

Figure 5: *AFLB finite element model*

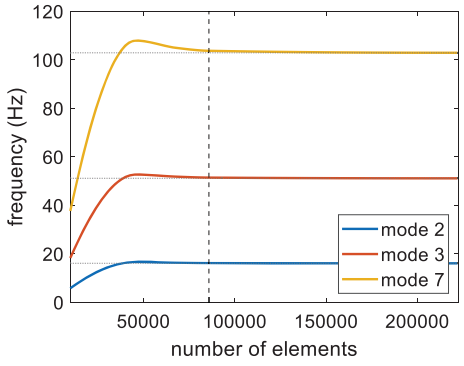

Figure 6: *Convergence study for AFCLT panel*

Table 3: *Elastic mechanical properties for dowels and layers*

	E_1 (MPa)	E_2 (MPa)	E_3 (MPa)	G_{12} (MPa)	G_{13} (MPa)	G_{23} (MPa)	ν_{12}	ν_{13}	ν_{23}
Oak [2,10]	11 380	1 045	1 871	977	1 275	361	0.4	0.32	0.43
Compressed spruce [11]	26 000	1 033	1 082	800	800	100	0.41	0.41	0.37

https://doi.org/10.52202/069179-0343

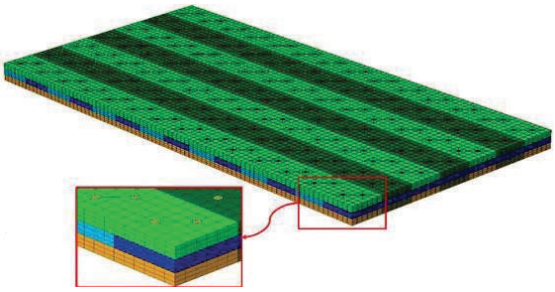

Figure 7: *AFCLT panel finite element model*

3.3 VALIDATION STEP

The Validation stage deals with the comparison between the numerical results obtained with the verified finite element model (from the previous Verification step) and the experimental results. As stated in section 2, we consider three frequencies that correspond to the first three bending modes illustrated in Figure 8 for the beam and Figure 9 for the panel.

Here, the Validation concerns only the mean behaviour of the structures, so numerical frequencies are compared to the mean experimental frequencies. Results are shown in Table 4 for AFLB and Table 5 for AFCLT panel.

Table 4: *Frequencies comparison between mean experimental data [2] and finite element model for AFLB*

	Mean experimental frequencies	Numerical frequencies	Diff.
f_1	118.2 Hz	119.1 Hz	0.7 %
f_2	281.0 Hz	278.2 Hz	-1.0 %
f_3	471.1 Hz	459.6 Hz	-2.4 %

Table 5: *Frequencies comparison between mean experimental data [2] and finite element model for AFCLT panel*

	Mean experimental frequencies	Numerical frequencies	Diff.
f_2	54.5 Hz	54.3 Hz	-0.3 %
f_3	56.3 Hz	55.9 Hz	-0.7 %
f_7	110.3 Hz	108.6 Hz	-1.6 %

Numerical and mean experimental results are in good agreement both for AFLB and AFCLT panel.

The small errors between numerical and experimental frequencies demonstrate that the adopted interaction assumptions are relevant despite that they may be questionable with regard to the complex physics involved in the connections.

This finite element modelling may lead to large-size models. In order to reduce the model size, a new methodology based on specific solid-beam and solid-shell approaches was developed.

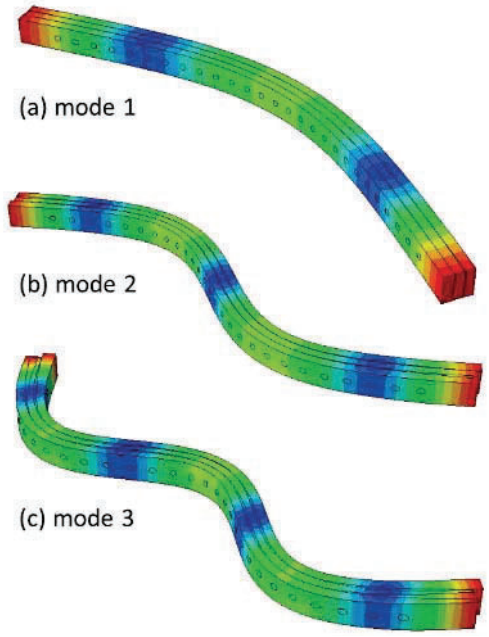

Figure 8: *Mode shapes for AFLB finite element model*

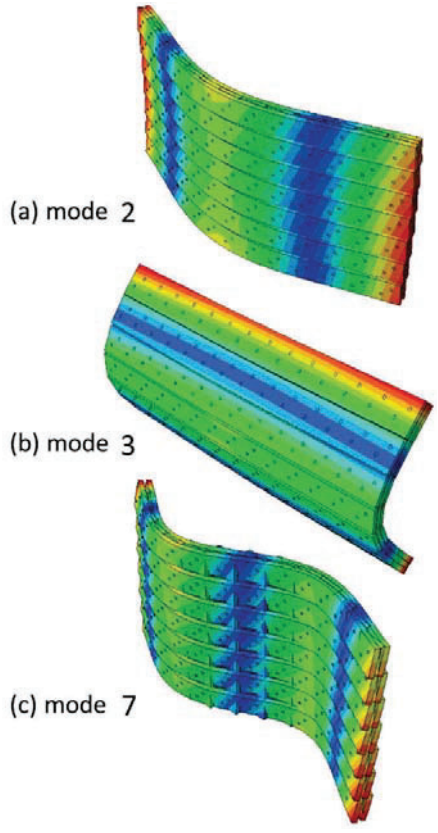

Figure 9: *Mode shapes for AFCLT panel finite element model*

4 SOLID-BEAM AND SOLID-SHELL BASED MODELS

4.1 PRINCIPLE OF SOLID-SHELL AND SOLID-BEAM APPROACHES

The solid-beam and solid-shell approaches used to build a reduced model exploit a methodology that was initially developed by Wei et al. [6,7].

The structure is first modelled with solid finite elements, for layers as well as dowels. Shell theory is considered for the layers and beam theory for the dowels. Then for layers, through-the-thickness shell equations are applied directly to the solid model. In the same way, through-the-section beam equations are applied for dowels. The concept of master and slave nodes is used, only master nodes are kept in the final model and slave nodes are eliminated. This process modifies the system of algebraic equations and leads to a reduction of the model size compared to the initial solid model.

First-order, as well as higher-order theories, can be considered. In this paper, we only use modified first-order theories.

A MATLAB© code produces the set of linear equations. In the Abaqus input file, these equations are introduced using the keyword 'EQUATION' [9].

4.2 DISTRIBUTIONS AND NODE LOCATIONS FOR SOLID-SHELL APPROACH

For the layers, the displacement field in Equation (1) was exploited by Wei et al. [7], using the Reissner-Mindlin theory [12,13], modified to correctly consider the Poisson effect through the thickness. The displacement field is linear through the thickness for *u* and *v* and quadratic for *w*.

$$\begin{cases} u(z) = za_1 + a_2 \\ v(z) = zb_1 + b_2 \\ w(z) = z^2c_1 + zc_2 + c_3 \end{cases} \quad (1)$$

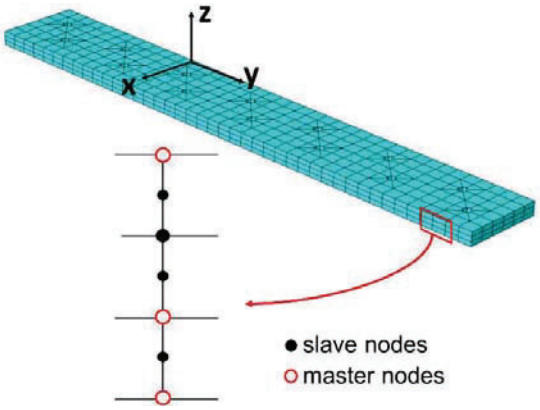

Figure 10: *Master and slave nodes locations for the modified first-order solid-shell approach*

The displacement field is applied through the thickness of a layer as represented in Figure 10. The coefficients in Equation (1) are identified using the coordinates of nodes and displacements at degrees of freedom of master nodes. Then this displacement field is applied to the degrees of freedom of slave nodes which are eliminated. The location of master and slave nodes is described in Figure 10.

4.3 DISTRIBUTIONS AND NODE LOCATIONS FOR SOLID-BEAM APPROACH

For the dowels, the displacement field in Equation (2) was exploited by Wei et al. [6], using the modified Timoshenko theory [14,15]. The reader can find complementary information in the paper by Wei et al. [6].

$$\begin{cases} u(y,z) = ya_1 + za_2 + a_3 \\ v(y,z) = y^2b_1 + z^2b_2 + yzb_3 + yb_4 + zb_5 + b_6 \\ w(y,z) = y^2c_1 + z^2c_2 + yzc_3 + yc_4 + zc_5 + c_6 \end{cases} \quad (2)$$

The displacement field in Equation (2) is applied through the cross-section of each dowel. The distribution is linear for *u* (longitudinal displacement) and quadratic for *v* and *w* (transverse displacement).

The same principle using slave and master nodes is applied again. Figure 11 describes the location of master and slave nodes.

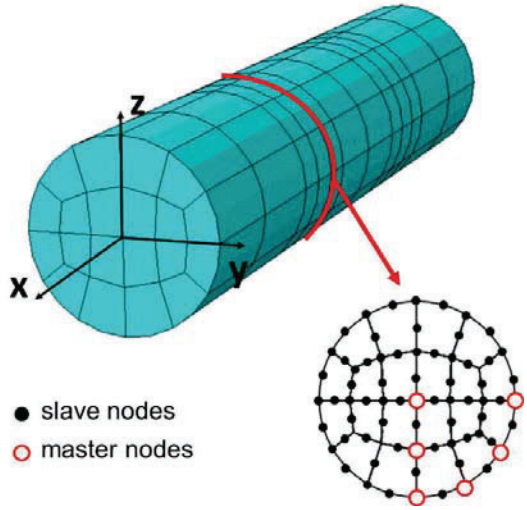

Figure 11: *Master and slave nodes locations for the modified first-order solid-beam approach*

4.4 RESULTS WITH REDUCED MODELS

The reference models respectively for AFLB and AFCLT panel are the ones described in section 3.2 and obtained with the Verification and Validation process. Reduced models for both AFLB and AFCLT panel are created using the methodology presented in sections 4.2 and 4.3. In this section, the reduced models are compared to the reference models. The quality of results and cost reduction are also highlighted.

4.4.1 AFLB reduced model

Table 6 compares, for AFLB, the numerical frequencies obtained with the reference and the reduced finite element

https://doi.org/10.52202/069179-0343

models. The difference between the two models in terms of quality is acceptable with a maximum difference of 5.8 % for the highest frequency.
The comparison of model size and computational cost is summarized in Table 7. The reduction in number of floating-point operations is 97 %. The number of degrees of freedom (d.o.f.) is reduced by 76 %.

Table 6: *Comparison of frequencies between the reference and the reduced models for the AFLB*

	Reference model	Reduced model	Diff.
f_1	119.1 Hz	121.1 Hz	1.7 %
f_2	278.2 Hz	290.0 Hz	4.2 %
f_3	459.6 Hz	486.4 Hz	5.8 %

Table 7: *Comparison of size and computational cost between the reference and the reduced models for the AFLB*

	Reference model	Reduced model	Reduction
Number of d.o.f.	221 220	53 553	76 %
Number of floating point operations	1.34×10^{11}	4.13×10^{9}	97 %

4.4.2 AFCLT panel reduced model

Table 8 compares, for AFCLT panel, the numerical frequencies obtained with the reference and the reduced finite element models. The frequencies obtained with the reduced and solid models are very close to each other. The maximum difference is 3.5 % for the highest frequency.
The comparison of model size and computational cost is summarized in Table 9. The number of d.o.f. and number of floating-point operations are reduced by 77 % and 96 % respectively.

Table 8: *Comparison of frequencies between the reference and the reduced models for AFCLT panel*

	Reference model	Reduced model	Diff.
f_2	54.3 Hz	55.6 Hz	2.4 %
f_3	55.9 Hz	56.2 Hz	0.5 %
f_7	108.6 Hz	112.4 Hz	3.5 %

Table 9: *Comparison of size and computational cost between the reference and the reduced models for the AFCLT panel*

	Reference model	Reduced model	Reduction
Number of d.o.f.	1 460 256	335 356	77.0 %
Number of floating point operations	1.49×10^{12}	6.03×10^{10}	96.0 %

The reduction level is comparable for beams and panels models. However, for cross-laminated timber panels, the size of the numerical models is much larger than for beams. Consequently, reducing the size of the model is even more interesting in this case, especially for a variability or optimization assessment.

4.5 DISCUSSION ON REDUCED MODELS BASED ON HIGHER-ORDER THEORIES

The difference between the reference models and the reduced models for both the AFLB and the AFCLT panel is acceptable in terms of quality. However, some might find it too high for a comparison between two finite element models. The reason for this slight discrepancy is due to the fact that only first-order theories are used here and applied to the totality of the layers and dowels.
Higher-order beam and shell, as well as a mix between beam, shell and solid theories, have also been considered. These other approaches allow us to obtain a better quality of results between the reference and reduced models but in that case, the reduction level is lower. In this paper, only modified first-order theories, which lead to the largest reduction level, are presented.

5 CONSIDERING VARIABILITY WITH A PROBABILISTIC APPROACH

Bui et al. [4] assessed the variability of the vibration frequencies of AFLB and AFCLT panel using the Modal Stability Procedure (MSP). Here, and based on this previous study, we recall the principle of the MSP. Then we apply it to calculate the variability of two frequencies of the AFCLT panel and compare it to the direct Monte Carlo Simulation (MCS).
One way to assess the variability is to use a probabilistic approach which assumes that statistical laws (distribution type, mean value, standard deviation) define the input parameters. Then, statistical characteristics of the output quantities are obtained.
The direct MCS is a robust probabilistic method. In this method, a large number of trials is required with random input values to estimate the statistical characteristics of the output quantities. The computational time of one analysis is multiplied by the number of trials. Consequently, this approach is very computationally time-consuming.
The MSP, a less time-consuming variability assessment methodology, is investigated here.

5.1 THE MODAL STABILITY PROCEDURE

The MSP methodology was developed by Arnoult et al. [16]. Its efficiency in terms of quality of results and computational cost has been proven in multiple studies.
MSP assumes that the mode shape does not change between the original structure (subscript 0) and a perturbated one (subscript p), so $\phi_p = \phi_0$. Consequently, this methodology requires only one finite element analysis in the nominal configuration to extract the mode shapes ϕ_0 and modal strains ε_0.
Thanks to the previous assumption, we obtain the perturbed natural angular frequency for a given mode

using the perturbed stiffness matrix K_p and the perturbed mass matrix M_p:

$$\omega_p^2 = \frac{\phi_0^T K_p \phi_0}{\phi_0^T M_p \phi_0} \quad (3)$$

Equation (3) can be transformed as a summation over all n elements of the finite element model. The elementary internal strain energy of an element j can be expressed as the integration over the elementary volume V_j of the product of the stresses by the strains. Using the generalized Hooke's law to developpe the stress, we then obtain our metamodel as follows:

$$\omega_p^2 = \frac{\sum_{j=1}^{n} \int_{V_j} \varepsilon_{0j}^T C_{pj} \varepsilon_{0j} dV}{\sum_{j=1}^{n} \phi_{0j}^T m_{pj} \phi_{0j}} \quad (4)$$

with C_{pj} the constitutive law matrix and m_{pj} the perturbed mass matrix of the j^{th} element.
The metamodel in Equation (4) is used in a fast MCS, allowing the evaluation of perturbed natural frequencies for each trial. The variability (mean value, standard deviation, coefficient of variation and distribution) of natural frequencies can subsequently be obtained.
Figure 12 presents a flowchart explaining the whole methodology.

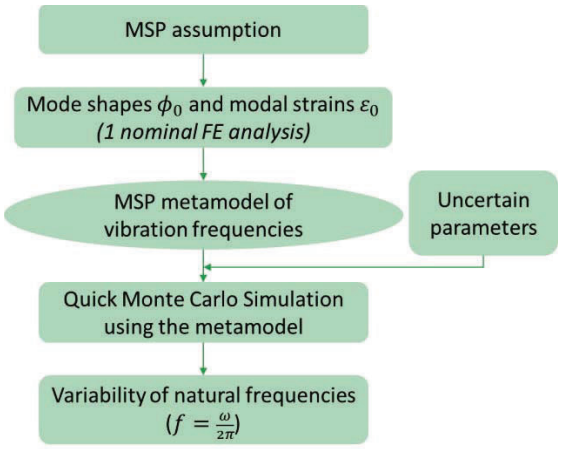

Figure 12: *MSP flowchart*

5.2 VARIABILITY OF AFCLT PANEL FREQUENCIES

The MSP results are presented for two frequencies of the AFCLT panel f_2 and f_3. The reference model is exploited here.

5.2.1 Inputs variability

Uncertain parameters are the material properties of dowels and boards. The parameters distribution is assumed to be Gaussian, however, the distribution law is truncated (±3σ) in order to avoid non-physical values.

Table 10 gives the mean value and coefficient of variation of the uncertain parameters. Four uncertain parameters are defined for each of the 28 boards and 3 uncertain parameters for each of the 196 dowels, leading to 700 independent uncertain parameters.

Table 10: *Variability levels of uncertain parameters*

		Mean value	CoV
board	ρ (kg/m^3)	624	6.5 %
	E_1 (MPa)	11400	13.6 %
	G_{12} (MPa)	1200	14 %
	G_{13} (MPa)	920	14 %
dowel	ρ (kg/m^3)	1133	4.2 %
	E_3 (MPa)	1100	9.5 %
	G_{13} (MPa)	800	10 %

5.2.2 Results

Simulations with 2000 trials using the MSP metamodel and the direct MCS are performed. Figure 13 illustrates the distribution of two frequencies.

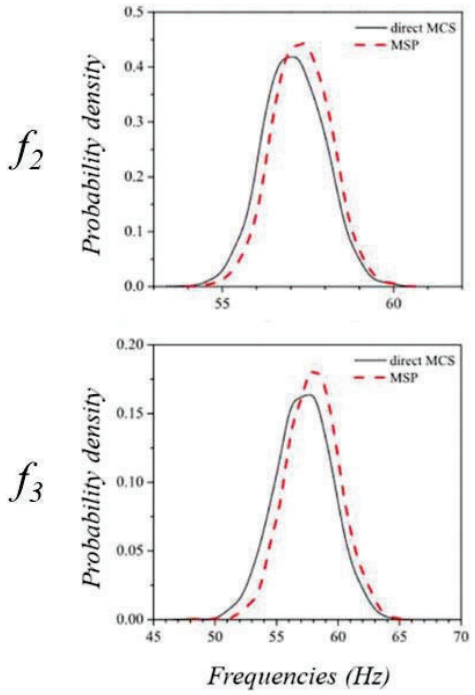

Figure 13: *Distribution of frequencies of AFCLT panel obtained with 2000 trials*

There is a good correlation between results obtained with MSP and direct MCS, even if limited shifts are observed. The maximal difference, observed for mode 3, is about 1 % for the mean value and 8 % for the standard deviation. MSP computational time is divided by about 1000 compared with direct MCS. We can thus conclude that MSP is satisfactory for the assessment of variability of frequencies of a AFCLT panel.

https://doi.org/10.52202/069179-0343

6 CONCLUSION AND PERSPECTIVES

Finite element models to assess the vibration behaviour of AFLB and AFCLT panel have been presented. The Verification and Validation approach shows that the reference model, composed of solid elements, is able to correctly reproduce the experimental frequencies.

A reduction technique, based on the application of solid-beam and solid-shell approaches for dowels and boards respectively, has been introduced. First-order beam and shell theories have been exploited, but higher-order theories can also be considered. The reduced finite element models show good results in terms of quality and significant model size and computational cost reduction compared to the reference models.

The MSP has been presented and applied to evaluate the variability of frequencies of a AFCLT panel using the reference models. The MSP is satisfactory in terms of quality and is much less time-consuming than the classical direct MCS approach.

A next step of this study will be to couple the MSP with reduced models.

Investigating the confrontation between experimental and numerical variability more deeply is also a perspective.

ACKNOWLEDGEMENT

The authors would like to thank the Hauts-de-France Region (France) and the Natural Sciences and Engineering Research Council of Canada (NSERC) for funding this work.

STUDY ON THE STRUCTURAL PERFORMANCE OF PLYWOOD BEARING WALL WITH THE RUSTED NAIL AND DECAYED WOOD

Yuki Ota[1], Hiroki Ishiyama[2], Shigefumi Okamoto[3]

ABSTRACT: In this study, based on the study of the past, deterioration degree of nail and wood is classified because there is a correlation between the maximum load and not only the deterioration degree of the nail by visual inspection but also the penetration depth by pilodyn measurement in the decayed part of wood[1)2)].
And the formula which predicts characteristic of a deformation-load relation when the nail rust and wood decay is developed. Also, using the result and analysing, the structural characteristic of the plywood bearing wall with the nails rusted wood decayed according to the degree of deterioration of the nail and wood can be predicted. As a result,

1. It is revealed that the maximum strength doesn't decrease remarkably when only the sill of plywood bearing wall deteriorates.
2. When the column deteriorates, the rigidity after yield is remarkably reduced.
3. even if the wood decay a little, the strength increases due to the influence of rusting of the nail, and it decreases when further deterioration progresses.

KEYWORDS: Wooden structure, Nail joint, Biological deterioration, Shear strength, Durability, Pull-out force

1 INTRODUCTION

Wooden houses may be required to ensure their safe and long-term use as living spaces. In the deterioration diagnosis currently used, bearing capacity of wall magnification is reduced based on the results of the determination of some deteriorated conditions, such as balconies. And wooden houses may not be adequately repaired according to the degree of deterioration.
So, the shear resistance of the nail joint with rusted nail and decayed wood is formulated based on the study of the past, and the structural characteristic of the plywood bearing wall according to the degree of deterioration of the nail and wood is estimated using the results.

2 ESTIMATION OF THE SHEAR CAPACITY OF JOINT

2.1 CLASSIFICATION OF DETERIORATION DEGREE

The deterioration degree is divided to concisely calculate the shear capacity of nail joint according to the deterioration degree. There is a correlation between the maximum load and the deterioration degree of the nail by visual inspection (Table 1[1)], Fig.1[2)]). And according to Fig.2, it is found that the same behaviour is shown in the case of the same deterioration degree of the nail. Also, there is a correlation between the maximum load and the penetration depth by pilodyn measurement in the decayed part of wood (Fig.3)[3)]. The degree of decay of wood is divided into four stages: pilodyn driving depth of less than 23.5 mm, 23.5 mm or more and less than 27.5 mm, 27.5 mm or more and less than 35 mm, and 35 mm or more. Separated in this way, from Fig.4, the test specimen at the same stage exhibits generally similar behavior. Therefore, the deterioration degree division is Table 2. However, in this study, it is dealt with the degree of deterioration shown in the shaded part of Table2, because moisture is the main cause of both rusting of nails and decay of wood and it is unlikely that only either of them is deteriorate significantly.

Table 1: *Standard of the deterioration grade*

Rating	Standard	Example
1	Scarcely rusted	2	Partially rusted, no visible defect	3	Totally rusted, no defect inside	
4	Partially defect, with original length	
5	failure

		Deterioration degree of nail					
		1	2	2.5 ~3.5	4 ~4.5	4.5~	
Penetration depth[mm]	~23.5	Aa	Ba	Ca	Da	Ea	Fa
	23.5~27.5	Ab	Bb	Cb	Db	Eb	Fb
	27.5~35	Ac	Bc	Cc	Dc	Ec	Fc
	35~	Ad	Bd	Cd	Dd	Ed	Fd

2.2 ESTIMATION OF TENSILE STRENGTH WITH DETERIORATED NAIL AND WOOD

It is believed that when a shear load is added to the nail joint and the displacement increases, the deflection angle of the nail increases, and resulting in nail pull-out, punching out, or braking. Therefore, it is a breaking point where the axial force of the nail is reached either the pull-out stress intensity of the nail, the nail head penetration bearing capacity of plywood, or the tensile strength of the nail. And the nail head penetration strength of plywood and the tensile strength of nails are determined in the same manner as in previous studies [2]. So, the penetration strength is determined as a stress intensity of 1404 N/mm^2 based on the experimental results of previous study[2] and the tensile strength is calculated by multiplying the lower limit of the tensile strength ($690N/mm^2$) of the iron wire for nail (JISG3562 SWM-N) by the cross-sectional area of the nail body diameter. On the other hand, the pull-out stress intensity of the nail is determined by equation (1).

$$P_d = 4r \int_{\theta_1}^{\theta_2} F(\theta)\mu_{sta}(\theta)d\theta \quad (1)$$

Where, $F(\theta)$ =uniaxial compressive strength of wood [kN], $\mu sta(\theta)$ = static friction coefficient, θ = angle [°] and r = nail radius [mm].
Therefore, the uniaxial compressive strength of wood, the coefficient of statin friction between the rusted nail and the wood, and the range which involved in pull-out resistance of nail (Fig.5) is determined from the study of the past[2)4)5)]. The method is shown below.

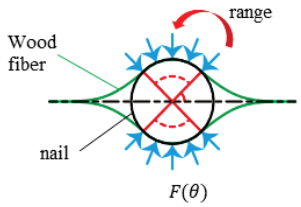

Figure 5: *Range which involved in pull-out resistance of nail*

2.2.1 Uniaxial compressive strength of wood

As for the uniaxial compressive strength, based on the research results[4)], the supporting strength of the wood in the parallel direction of the fiber and the direction in the direction of the fiber perpendicular is adopted. So, the uniaxial compressive strength of wood in fiber

https://doi.org/10.52202/069179-0344

equilibrium direction and the fiber orthogonal direction is represented by the formula (2) and (3), respectively.

fiber equilibrium direction:

$$F_l = -0.7867(x - 20.5) + 35.655 \quad (2)$$

fiber orthogonal direction:

$$F_r = -1.0316(x - 20.5) + 41.271 \quad (3)$$

Where, x =penetration depth by pilodyn.

2.2.2 The coefficient of statin friction between no damage nail and wood

The coefficient of statin friction between no damage nail and wood is adopted by the study[5]. So, coefficient of statin friction between no damage nail and wood in fiber equilibrium direction and the fiber orthogonal direction is represented by the formula (4) and (5), respectively.

fiber equilibrium direction:

$$\mu_{sta_l} = -0.325r_u + 0.409 \quad (4)$$

fiber orthogonal direction:

$$\mu_{sta_r} = -0.386r_u + 0.318 \quad (5)$$

Where, r_u =specific gravity of wood.

2.2.3 The range which involved in pull-out resistance of nail

Using the Hankinson's equation, $F(\theta)$ and $\mu_{sta}(\theta)$ are presented by equation (6) and (7), respectively.

$$F(\theta) = \frac{F_l \times F_r}{F_l sin^2(\theta) + F_r cos^2(\theta)} \quad (6)$$

$$\mu_{sta}(\theta) = \frac{\mu_{sta_l} \times \mu_{sta_r}}{\mu_{sta_l} sin^2(\theta) + \mu_{sta_r} cos^2(\theta)} \quad (7)$$

Further, by substituting into equation (1), the following equation (8) is obtained.

$$P_d = 4r \int_{\theta_1}^{\theta_2} \frac{F_l \times F_r}{F_l sin^2(\theta) + F_r cos^2(\theta)} \times \frac{\mu_{sta_l} \times \mu_{sta_r}}{\mu_{sta_l} sin^2(\theta) + \mu_{sta_r} cos^2(\theta)} d\theta \quad (8)$$

From previous research[2], since the pull-out resistance of the CN65 nail (P_d) is 627.2[N], the required range is θ_{65}~90[°] satisfying equation (9).

$$627.2 = 4r_{65} \int_{\theta_{65}}^{90°} \frac{F_l \times F_r}{F_l sin^2(\theta) + F_r cos^2(\theta)} \times \frac{\mu_{sta_l} \times \mu_{sta_r}}{\mu_{sta_l} sin^2(\theta) + \mu_{sta_r} cos^2(\theta)} d\theta \quad (9)$$

Where, r_{65}=CN65 nail radius [mm]=1.665.
Here, when $\theta_{65} = 89.65°$ and when $\theta_{65} = 89.7°$, the value of equation (9) is 629.9 and 539.9, respectively. So, θ_{65} is found to be about 89.65°.

Then, a range of 89.95 ~ 90 [°] related to the extraction resistance in the case of CN65 nail is applied to the N50 nail. Assuming that the state of the wood when the wood fibers are pushed apart by driving a nail is the same as in the case of CN65 nail and N50 nail, the nail joint at that time is considered to be as shown in Fig.6.

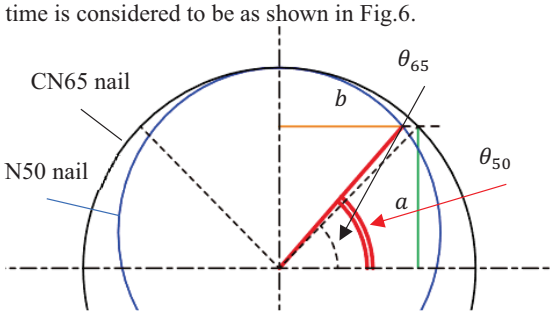

Figure 6: *Schematic of the nail joint when CN65 and N50 nails are driven into wood*

At the time, the range of θ_{50} ~90[°] that affects the extraction resistance in the case of the N 50 nail is represented by the formula (10).

$$\theta_{50} = \tan^{-1}\left(\frac{a}{b}\right) = \tan^{-1}\left(\frac{r_{65} \sin\theta_{65}}{\sqrt{{r_{50}}^2 - (r_{65}\sin\theta_{65} - r_{65} + r_{50})^2}}\right) \quad (10)$$

Where, r_{50}=N50 nail radius [mm]=1.375.
Therefore, when $\theta_{65} = 89.65°$ is substituted into equation (10), $\theta_{50} = 89.7°$, so the range which involved in pull-out resistance of N50 nail is revealed that 89.7~90[°].

2.2.4 The coefficient of statin friction between rusted nail and no damage wood

The coefficient of statin friction between rusted nail and no damage wood is determined based on the results of the pull-out experiment about CN65 nail in previous study[2]. The method is shown below. First, it is calculated how many times the static friction coefficient between rusted nail and no damage wood is that between no damage nail and wood in the case of CN65 nail. Assuming that the rate of increasing static friction is expressed by equation (11), the weight remaining rate of the nail and the rate are shown in Table 3 from the experimental study[2].

$$R = M_R / M_N \quad (11)$$

Where, R =rate of increasing static friction, M_R = maximum pull-out strength with rusted nail and M_N = maximum pull-out strength with no damage nail.
And, assuming that the corrosion depth of the nails when the degree of deterioration of the nails is the same, the weight residual rate of N50 nails having a corrosion depth equivalent to that of CN65 nails with a certain weight residual rate is calculated. The schematic diagram of the rusted nail looks like Fig. 7, so if the nail rust occurs uniformly throughout the nail, the corrosion depth is expressed by formula (12).

https://doi.org/10.52202/069179-0344

Table 3: *static friction (CN65 nail)*

Weight Residual rate	Maximum pull-out strength	Rate of Increasing static friction
100.00[%]	627.2[N]	1.00
97.3[%]	1821.8[N]	2.90
93.4[%]	3011.5[N]	4.80
83.5[%]	3405.1[N]	5.43

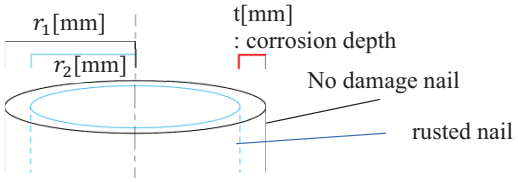

Figure 7: *Schematic of rusted nails*

$$t = r_1\left(1 - \sqrt{q}\right) \tag{12}$$

Where, r_1=body diameter of no damage nail, r_2=body diameter of rusted nail and q=weight residual ratio = $\frac{{r_2}^2}{{r_1}^2}$.
Therefore, when the corrosion depths of the CN65 nail and the N50 nail are equal, the weight residual ratio of the N50 nail is expressed by Equation (13).

$$q_{50} = \left\{1 + \frac{r_{65}}{r_{50}}\left(\sqrt{q_{65}} - 1\right)\right\}^2 \tag{13}$$

Where, q_{65} =weight residual ratio of CN65 nail, q_{50}=weight residual ratio of N50 nail, r_{65}= body diameter of CN65 nail and r_{50}= body diameter of N50 nail.
And the rate of increasing static friction of N50 nail at the time of nail rusting is shown in Table 4.

Table 4: *static friction (N50 nail)*

Weight Residual rate	Rate of Increasing static friction
100.00[%]	1.00
96.74[%]	2.90
92.03[%]	4.80
80.21[%]	5.43

2.3 THE FORMULA OF DEFORMATION-LOAD RELATION

2.3.1 Creating formula on two-later ground

The formula which predicts change of a deformation-load relation when the nail rust and wood decay is developed by expanding the study of the past[2]. In other words, assuming that wood is a two-layer configuration of the decay part and the no damage part, using the horizontal resistance calculation formula of piles[6], the wood is regarded as the ground and the nail is regarded as the piles, and formulas are created for each protruding and fixing conditions of the nail head on two-layer ground. Therefore, equations (14), (15) and (16) are solved for the boundary conditions in the assumed nail head state, and constants A_n, B_n, C_n, and D_n satisfying these conditions are calculated.

$$\begin{aligned} y_1(x) = {} & A_n e^{\beta_1 x}\cos(\beta_1 x) + B_n e^{\beta_1 x}\sin(\beta_1 x) \\ & + C_n e^{-\beta_1 x}\cos(\beta_1 x) \\ & + D_n e^{-\beta_1 x}\sin(\beta_1 x) \end{aligned} \tag{14}$$

$$\begin{aligned} y_2(x) = {} & A_{n+1} e^{\beta_2 x}\cos(\beta_2 x) + B_{n+1} e^{\beta_2 x}\sin(\beta_2 x) \\ & + C_{n+1} e^{-\beta_2 x}\cos(\beta_2 x) \\ & + D_{n*1} e^{-\beta_2 x}\sin(\beta_2 x) \end{aligned} \tag{15}$$

$$y_3(x) = A_{n+2} + B_{n+2}x + C_{n+2}x^2 + D_{n+2}x^3 \tag{16}$$

Where, fixed numbers are shown in Table 5~8.

Table 5: *Fixed number (1)*

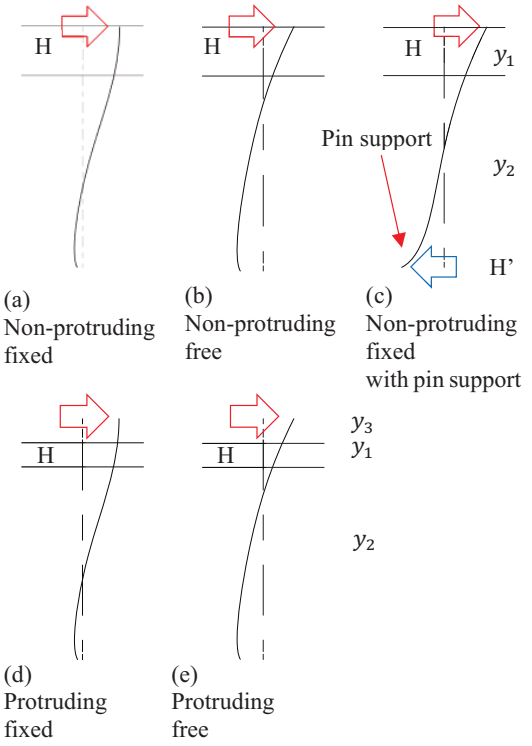

Figure 8: *Schematic diagram of the nail joint under all nail head conditions*

2.3.1.1. Non-protruding and fixed

Fig. 8 (a) shows a nail joint when the nail head condition is non-protruding and fixed. The boundary conditions at this time are that θ_0=0 $[rad]$ and the horizontal load at the nail head is $H[N]$. And the calculations are equation (17) and (18).

$$y_1(0) = \frac{b_2h_1 + 8h_3}{4EI{\beta_1}^3b_3h_1}H \tag{17}$$

$$H_0 = -\frac{2\beta_1b_3h_1}{b_1h_1 - 8h_2}M_0 \tag{18}$$

2.3.1.2. Non-protruding and free

Fig. 8 (b) shows a nail joint when the nail head condition is non-protruding and free. The boundary conditions at this time are that M_0=0 $[N \cdot mm]$ and the horizontal load at the nail head is $H[N]$. And the calculations are equation (19) ~ (22).

$$y_1(0) = \frac{b_4h_4 + 4h_5 - 4h_6}{2EI{\beta_1}^3b_2h_4}H \tag{19}$$

$$\ell_m = \frac{1}{\beta_2}tan^{-1}\left(-\frac{f_5sin(\beta_2\ell) + f_6cos(\beta_2\ell)}{f_6sin(\beta_2\ell) - f_5cos(\beta_2\ell)}\right) \tag{20}$$

$$H(\ell_m) = \frac{\beta_1M(\ell_m)(f_5sin(\beta_2\ell) + f_6cos(\beta_2\ell))h_4}{2{\beta_2}^2({f_3}^2 + {f_4}^2)sin(\beta_2\ell_m)}e^{\beta_2\ell_m - \beta_2\ell} \tag{21}$$

$$H(0) = \frac{\beta_1M(0)h_4}{2{\beta_2}^2f_4} \tag{22}$$

2.3.1.3. Non-protruding and free with pin support

Fig. 8 (c) shows a nail joint when the nail head condition is non-protruding and free with pin support in no damage part of wood. The boundary conditions at this time are that M_0=0 $[N \cdot mm]$, $M(\ell_m) = 0$, the horizontal load at the nail head is $H[N]$ and the horizontal load at $\ell_m$is $H'[N]$. And the calculations are equation (23) ~ (25).

$$y_1(0) = \frac{{\beta_1}^2b_4 + R_1 + R_3}{2EI{\beta_1}^5b_2}H + \frac{R_2 + R_4}{2EI{\beta_1}^2{\beta_2}^3b_2}H' \tag{23}$$

$$\theta(0) = \frac{{\beta_1}^2b_1 + 2R_5 - 2R_7}{2EI{\beta_1}^4b_2}H + \frac{R_6 + R_8}{2EI\beta_1{\beta_2}^3b_2}H' \tag{24}$$

$$\theta(\ell_m) = \frac{S_1 - S_3}{2EI{\beta_1}^3} \times \frac{\beta_2\sin(\beta_2\ell_m)}{f_5\sin(\beta_2\ell) + f_6\cos(\beta_2\ell)}H + \frac{S_2 + S_4}{2EI{\beta_2}^2} \times \frac{sin(\beta_2\ell_m)}{f_5sin(\beta_2\ell) + f_6cos(\beta_2\ell)}H' \tag{25}$$

2.3.1.4. Protruding and fixed

Fig. 8 (d) shows a nail joint when the nail head condition is protruding and fixed. The boundary conditions at this time are that $M(-h)$=0 $[rad]$ and the horizontal load at

the nail head is $H[N]$. And the calculations are equation (26) ~ (29).

$$\ell_m = \frac{1}{\beta_2} tan^{-1}\left(\frac{W_1}{W_2}\right) \tag{26}$$

$$H_{\ell_m} = \frac{4{\beta_1}^3 M(\ell_m) t_1 (\beta_1 h T_1 + T_2) W_1 e^{\beta_2(\ell_m - \ell)}}{Y_1 sin(\beta_2 \ell_m)} \tag{27}$$

$$y_3(-h) = \frac{H}{12EI{\beta_1}^3 t_1(\beta_1 h T_1 + T_2)} \times \begin{Bmatrix} {\beta_1}^4 h^4 t_1 T_1 + 4{\beta_1}^3 h^3 t_1 T_2 \\ +3{\beta_1}^2 h^2 (t_1 T_3 + t_2 T_2 + t_3 T_1) \\ +3\beta_1 h(t_2 T_3 + t_4 T_1) + 3(-t_3 T_3 + t_4 T_2) \end{Bmatrix} \tag{28}$$

$$H_\ell = -\frac{4\beta_1 M(\ell) t_1 (\beta_1 h T_1 + T_2)}{{\beta_1}^2 h^2 U_2 + \beta_1 h U_4 + U_6} \tag{29}$$

2.3.1.5. Protruding and free

Fig. 8 (e) shows a nail joint when the nail head condition is protruding and free. The boundary conditions at this time are that $\theta(-h)$=0 $[rad]$ and the horizontal load at the nail head is $H[N]$. And the calculations are equation (30) and (31).

$$y_3(-h) = \frac{1}{12EI{\beta_1}^3 t_1 T_1}\{4{\beta_1}^3 h^3 t_1 T_1 + 12{\beta_1}^2 h^2 t_1 T_2 + 6\beta_1 h(t_1 T_3 + t_2 T_2 + t_3 T_1) + 3(t_2 T_3 + t_4 T_1)\} H \tag{30}$$

$$y_3'(-h) = -\frac{{\beta_1}^2 h^2 T_1 + 2\beta_1 h T_2 + T_3}{2EI{\beta_1}^2 T_1} H \tag{31}$$

2.3.2 The formula deformation-load relation

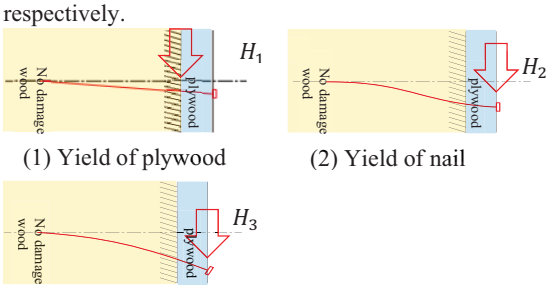
Fixed numbers are shown in Table 9.

Table 9: *Fixed number (5)*

H_n	Horizontal load of the nail head at the nth change point of the load-deformation relationship
y_n	Horizontal displacement of the nail head at the nth change point of the load-deformation relationship
σ_{yp}	Yield stress of plywood to the nail side =4105
A_p	Cross-sectional area of plywood to the nail side
Z_n	Section modulus of nail
σ_n	Yield stress of nail =734.6
P_d	Pull-out stress intensity of the nail
P_h	The nail head penetration bearing capacity of plywood
P_n	The tensile strength of the nail

2.3.2.1. No damage wood and rusted nail

Fig.9 is a schematic of no damage wood and rusted nail using plywood as the side material. In this case, first, the wood yield in the state where the nail head is non-protruding and fixed, then the nail yield in the state of nail head protruding and fixed. And the finally, the nail is pulled out, the nail is broken, or the nail head is punching out in the state of nail head protruding and free. The horizontal load and horizontal displacement of the nail head at these times are expressed by equation (32) ~ (37), respectively.



(1) Yield of plywood (2) Yield of nail

(3) Pull-out, punching out or break of nail

Figure 9: *No damage wood and rusted nail*

$$H_1 = \frac{\sigma_{yp} \times A_p}{2} \tag{32}$$

$$y_1 = \frac{H_1}{4EI{\beta_1}^3} \tag{33}$$

$$H_2 = \frac{2\beta_1 Z_n \sigma_n}{\sqrt{1 + (\beta_1 h)^2} exp[-tan^{-1}(1/\beta_1 h)]} \tag{34}$$

$$y_2 = \frac{(1 + \beta_1 h)^3 + 2}{12EI{\beta_1}^3} H_2 \tag{35}$$

$$H_3 = \sqrt{\frac{6/\alpha^2 - \sqrt{36/\alpha^4 - 24N/\alpha^3}}{2}} \tag{36}$$

$$y_3 = \frac{(1 + \beta_1 h)^3 + 1/2}{3EI{\beta_1}^3} H_3 \tag{37}$$

Where, $\alpha = \frac{(1+\beta h)^2}{2EI\beta^2}$.

2.3.2.2. Decayed wood and no damage nail

Fig.10 is a schematic of decayed wood and no damage nail using steel plate as the side material. In this case, first, the nail head yields in the state where the nail head is non-protruding and fixed. Then the nail body yields in the no damage part of wood or at the boundary between the no damage part and the decay part of wood in the state where the nail head is non-protruding and free, and finally the nail pulls out. The nail head conditions for pulling out are protruding and free when the yield of nail body occurs in the no damage part of wood, and non-protruding and free when it occurs at the boundary between the no damage part and the decay part of wood. The horizontal load and horizontal displacement of the nail head at these times are expressed by equation (38) ~ (50), respectively.

2.3.2.3. Decayed wood and rusted nail

Table 10 shows the nail head conditions and joint behavior at the situation of no damage wood and rusted nail and decayed wood and no damage nail. And Fig. 11 shows experimental results and estimates at the situation. From Fig.11, the formulas are correct because the experimental result and the estimated value match. Therefore, considering these results, nail head conditions and nail joint behavior are expected when wood decay and nail rust occur in combination. The first change point of the load-deformation relationship is the point where the plywood yields when the nail head condition is non-protruding and fixed. This is because, in wooden houses, plywood is used as the side material, so the nail head will not yield. Next, the second change point is the point where the nail yields in the no damage part of the wood or at the boundary between the no damage part and the decayed part of the wood when the nail head condition is protruding and fixed. The reason why the nail head condition is protruding is that the deflection angle of the nail head increase due to the yield of the plywood, and it is thought that it protrudes. Finally, the third change point is the point at which the nail pulls out, breaks, or punching out when the nail head condition is protruding and free. The horizontal load and horizontal displacement of the nail head at these times are expressed by equation (51) ~ (58), respectively. There are summarized as shown in Fig.12. Fig. 13 shows the behavior of the nail joint for each degree of deterioration calculated using these results.

3 MODELING AND ANALYSIS

3.1 OUTLINE

Based on the estimated value by the formula in 2.3.2, the elastoplastic analysis of the plywood bearing wall model is carried out using the analysis software SNAP. The model is shown in Fig.14. To analyze the strength of the plywood bearing wall based on the estimated shear resistance of the nail joint, two frame models are connected with a spring 1, and the estimated value calculated in 2.3.2 is input to spring 1. Further, one of the frame models a wooden frame in the plywood bearing wall and the other models a frame when the structural plywood is expanded using brace expansion.

Spring2: plywood
Rigidity:16.5[kN/mm]
Elastoplastic property: elasticity

Table 11: *Pattern of deterioration position*

Pattern	Deterioration position
(α)	No damage
(β)	4
(γ)	5,6
(ω)	1,2,6

https://doi.org/10.52202/069179-0344

3.2 LOCATION OF DETERIORATION

The plywood bearing wall is divided into areas as shown in Fig14, and the deterioration position that is likely to occur is divided into patterns assuming deterioration in the house. This is shown in Table 11. The analysis is carried out when the nail joint at these 4 pattern positions become about 13 levels of deterioration shown in the shaded portion of Table 2.

3.3 ANALYSIS RESULT

Fig.15(α) shows the analysis result and the experimental result of the past[7] with the no damaged nail and wood. The analysis result agrees well with the experimental result. Next, the analysis results of patterns (β), (γ) and (ω) are also shown in Fig.15. In the case of (β), the load-deformation relationship is almost the same regardless of the degree of deterioration of the foundation. In the case of (γ), the deformation increases as the deterioration progresses, but there is no significant effect on the maximum strength. In the case of (ω), the maximum strength and rigidity after yield decreases remarkably as the deterioration progresses.

4 CONCLUSIONS

The structural performance of plywood bearing wall with the nails rusted and columns decayed can be predicted by deterioration degree of nails and columns. The maximum strength doesn't decrease remarkably when only the foundation of plywood bearing wall deteriorates. On the other hand, when the pillar deteriorates, the rigidity after yield is greatly reduced. In addition, even if the wood decay a little, the strength increases due to the influence of rusting of the nail, and it decreases when further deterioration progresses.

ACKNOWLEDGEMENT

This study was carried out with support from the Asahi Glass Foundation.

DEVELOPMENT OF A NUMERICAL MODEL TO CONSIDER THE FOUNDATION FLEXIBILITY EFFECTS IN CLT ROCKING WALLS

Irshad Qureshi[1], Gustavo Acuña[2], Daniel Dolan[3],

ABSTRACT: This work developed a numerical model to consider the effects of foundation flexibility in cross laminated timber rocking wall structures. The model was validated against the test results of a quasi-static cyclic and dynamic tests. In both tests, the foundation behaved as a flexible member with significant yielding. A multi-spring model was used in the study and two different approaches for solid and steel section beam foundations were employed to calculate the axial stiffness of contact springs. The proposed techniques were found to be not only able to consider the foundation flexibility but to also omit the need to use empirical relationships or calibration with experiments to calculate plastic hinge length to be used for calculation of axial stiffness for the base springs. Following the validation of the numerical model, a parametric study was performed to study the effects of foundation flexibility on the shear-drift response of rocking wall structures.

1 INTRODUCTION

Recently, there has been an increasing focus on the use of sustainable materials in construction. A global effort to reduce carbon emissions has instigated renewed interest in the use of engineered timber like cross laminated timber (CLT) and mass plywood for building structures, which promise a green construction material with higher strength-to-weight ratio, comparable stiffness and ductility, faster installation, and improved thermal performance. CLT rocking wall structures have been in a development phase as a resilient and sustainable alternative to conventional concrete and steel structures. Rocking structures promise damage avoidance design with minimal residual drift and decent energy dissipation.

The U.S. National Science Foundation funded NHERI Tall wood project is a major research initiative [1]. As an initial step, a series of CLT rocking walls with varying design parameters like area and initial force of post-tensioning, single and coupled walls, and varying flexibility of foundation were used [2]. A uniaxial shake table test of a 2-story CLT rocking wall structure followed [3], and a 10-story rocking wall structure is being tested on the NHERI shake table at the University of California-San Diego [4]. During the testing of the 2-story structure, it was observed that the base beam, used as a foundation for the rocking wall, yielded with significant permanent deformation. This unintended inelastic behavior of foundation increased the fundamental period of the building [5], resulting in lower-than-expected damage in the structural members especially at the wall toes; however, the displacement demand on members increased. Based on these results, it is important to explore the effect of foundation flexibility on the overall lateral behavior of rocking wall structures and develop guidelines to achieve optimum solutions with minimal damage and manageable drift demands. To achieve this, numerical models capable of incorporating the effects of foundation flexibility are required, which can then be used to further investigate different aspects of this rocking wall-foundation interaction.

This study is focused on the development of a numerical model to account for the foundation flexibility effects in rocking wall structures. Two different modeling approaches are proposed in this study to model two different tests from literature where the foundation of rocking wall behaved nonlinearly with significant yielding/crushing, one was a static [2] while the other was a dynamic test [3]. A multi-spring model was used in this study to model the rocking behavior along with two different approaches to model contact stiffness at the interface of rocking wall and flexible foundation. A parametric study was then performed to understand the effects of foundation flexibility on the seismic force and displacement demands against two levels of initial post-tensioning.

2 CASE STUDY STRUCTURES

Ganey [2] tested single and coupled CLT rocking walls using quasi-static cyclic lateral loading and the response of these rocking walls were numerically modelled in several studies [2,6,7]. However, to the best of the authors' knowledge, Specimen 4 from the testing has been

[1] Visiting Fulbright Scholar, Washington State University, m.qureshi2@wsu.edu

[3] Professor, Washington State University, Pullman WA, USA jddolan@wsu.edu

https://doi.org/10.52202/069179-0345

modeled in the past studies. Specimen 4 consisted of a single CLT rocking wall resting on a CLT foundation. Since the rocking wall rested on the weaker axis of the CLT foundation, the nonlinear behavior was confined to crushing of the foundation only, resulting in a flexible foundation condition. The CLT rocking wall consisted of two Hem-Fir 5-ply CLT panels joined by steel plates using SDS screws. Cross-sectional dimensions were approximately 1.22 m by 0.17 m while the wall height was 4.43 m. Lateral loading was applied at a height of 4.1m. A 31.5 mm rod with an initial post-tensioning force of $0.4f_{pt,u}$ was used, where $f_{pt,u}$ was the ultimate stress of PT rod. The material properties of CLT and PT are shown in Table 1 while the testing setup for Specimen 4 is shown in Figure 1.

Table 1: *Properties of CLT and PT used for Specimen 4*

CLT Property (Units)	Value	PT Property (Units)	Value
E_1 (MPa)	3042	E_{pt} (GPa)	220
E_2 (MPa)	900	$f_{pt,y}$ (MPa)	929
E_3 (MPa)	2080	$f_{pt,u}$ (MPa)	1091
G_1, G_2, G_3 (MPa)	345	$F_{pt,i}$ (kN)	338
ν_1, ν_2, ν_3	0.3		
f_y (Direction 1*) (MPa) (For rocking wall)	24.8		
f_y (Direction 2*) (MPa) (For CLT foundation)	5.93		

*Directions 1, 2 and 3 coincide with the height, length, and thickness of the CLT wall panel

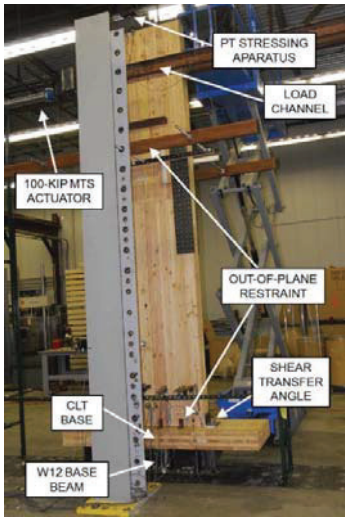

Figure 1: *Testing setup for Specimen 4 (CLT wall) resting on CLT foundation* [2]

The dynamic test considered was the full-scale 2-story CLT rocking wall structure with two rocking shear walls in the direction of shaking [3]. The rocking wall panels were 5-ply having grade E2-M1 CLT. The modulus of elasticity, shear modulus and yielding stress for CLT were 8536 MPa, 552 MPa and 25 MPa, respectively. For each wall, two balloon framed CLT panels were used. The CLT panels in each wall were joined by five equally spaced U-shaped flexural plates along the height of the wall to provide a minimum energy dissipation ratio of 0.3. Modulus of elasticity and yielding stress of each U-shaped plate were $2x10^5$ MPa and 414 MPa. Post-tensioning was provided by using four 19 mm bars in each wall with an average initial post-tensioning force equal to 40% of yield strength (53 KN for each bar). Each wall had a height, length, and thickness of 7.32 m, 1.52 m, and 0.17 m, respectively. Shear transfer angles were used at the wall ends to transfer shear and avoid lateral slip. Wall-to-diaphragm shear transfer connections were used to transfer lateral demands while out-of-plane movement was constrained using bracing. As explained earlier, the steel foundation of the 2-story building, which was expected to behave as rigid, exhibited nonlinear behavior with permanent deformations right below the wall ends (i.e., at the center of rotation during the rocking motion.) A total of 14 excitations were used for the dynamic testing of the structure, with effective PGA for the excitations varying from 0.13g to 0.85g representing service level earthquake (SLE), design basis earthquake (DBE) and maximum considered earthquake (MCE). Details of the test structure, rocking wall and foundation are shown in Figures 2 and 3. Further information about the structure, testing setup and dynamic testing can be found in [8].

3 PROPOSED NUMERICAL MODELS

Several techniques have been used to model the behavior of rocking walls including monolithic beam analogy, lumped plasticity model, multi-spring model, fiber model, and finite element model. Except for finite element models, all the above-mentioned models need iterative procedures or calibration using experimental results to determine the compression zone/plastic hinge length, and do not consider foundation flexibility. In the current study, a multi-spring (MS) model has been used, as shown in Figure 4, for the 2-story coupled rocking wall with energy dissipation mechanisms, that was tested on the shake table. The MS model for the quasi-static test on single rocking wall without any external energy dissipation mechanism was also based on the same principles for the modeling of the wall, PT steel, contact modeling, placement of rigid links, etc., but it is not shown here for brevity. The rocking wall was modeled using a beam-column element, the post-tensioning was modeled using axial springs with prestress force, and the contact was modeled using 50 compression-only springs at the base. Adjusting the stiffness of the contact springs is an active area of research. Several empirical formulas have been proposed in the past to determine the length of the plastic hinge (L_e), which is used to find the contact stiffness by equating it to EA/L_e where, E and A are modulus of elasticity of wall and contact area. [9,10] proposed empirical relationships to find out the plastic hinge length for rocking timber walls. A plastic hinge length of two times the wall thickness has also been proposed and used in the past [5,11] while for concrete rocking connections, a plastic hinge length equal to the half the length of the walls has been proposed [12,13]. All these empirical relationships try to a provide a measure for the axial stiffness of the rocking wall assuming the foundation to act as rigid, however, both the case study structures selected in the current work showed a permanent deformation due to yielding in the foundation, rendering the available empirical formulas unsuitable. Therefore, different techniques were proposed in this study.

The stiffness of the contact springs was calculated using principles of contact mechanics. [14] argued that the volume with dimension of the contact length in all three spatial dimensions represents the maximum stress concentration region and should be used to find different parameters of contact. It has been shown that although it's an assumption, it gives results within a 10% margin of error [14]. If the indentation at contact interface of a length $2a$ against a force F is d, then axial stress and axial strain are $\frac{F}{(2a)^2}$ and $\frac{d}{2a}$, respectively. Solving for the equation $\sigma = E\varepsilon$ results in

$$F = 2aEd \tag{1}$$

where, $2aE$ represents contact stiffness and E is the modulus of elasticity of elastic half space. However, this formulation is valid for solid foundations only and a different technique is used to model the 2-story rocking wall test on shake table.

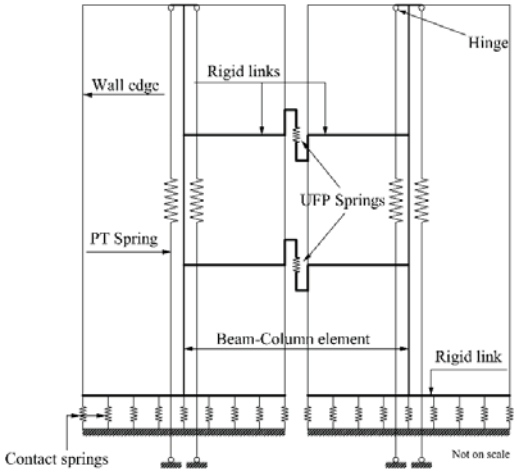

Figure 4: *Multi-spring model*

A steel beam was used as foundation in the dynamic test which showed yielding and permanent deformation. To quantify the contact stiffness at wall-foundation interface, a finite element model for the steel base beam resting on the ground was developed in ABAQUS [15]. Solid 8-noded linear brick elements (C3D8R) with reduced integration were used to model the base beam. A mesh sensitivity study was conducted before choosing the mesh size. Self-weight of the base beam was ignored. Yielding stress for the steel beam was assumed to be 414 MPa. To simulate contact behavior during rocking motion, a triangular force pattern was applied at the expected contact area on the steel beam. The problem was considered as a two-dimensional and the axial stiffness for the contact springs was determined by dividing the force in the tributary area of each spring divided by the average deformation in that region. The finite element model, and the stress distribution in the steel base beam after applying the loading is shown in Figure 5. It is important to mention that the finite element model showed yielding in the base beam even for the loading corresponding to the service level earthquakes. Using the MS model described earlier with contact stiffness from the results of finite element analysis, all 14 ground motions were applied to the 2-story rocking wall in the sequence used during the experiments and the yielding observed in any test in the contact springs was used as initial condition for those springs in the next

https://doi.org/10.52202/069179-0345

tests. However, it was observed that assuming an undamaged base beam for each test did not alter the analysis results significantly as the beam started yielding at the corners at the start of the test, and the condition of the beam against the maximum response time span was almost same.

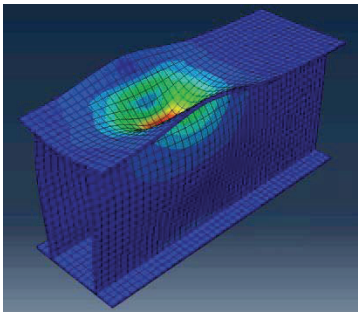

Figure 5: *3D Finite element model of base beam after applying loading*

4 NUMERICAL MODEL VALIDATION

Loss in PT force against increasing drift demand was observed in the test for Specimen 4; however, the model used here cannot account for it. Therefore, a maximum drift of 4% is considered for the comparison purpose as the losses in PT steel during the test were within reasonable range up to this drift. Equation 1 was used to model the stiffness of the foundation which is considered to dominate the contact behavior at the wall-foundation interface because of a much lower modulus of elasticity of CLT in transverse direction of the foundation when compared to the in-plane direction in wall. This stiffness is, therefore, used as axial stiffness for contact springs. The experimental results for only one 5-ply CLT panel was available in the out of plane direction; therefore, an average value of yield stress for four 3-ply and one 5-ply CLT panels in the direction of interest were used to adjust the yielding stress of the CLT foundation.

Wall Specimen 4 was modeled using the MS model explained in earlier sections. Initially, a single layer of axial springs representing a flexible foundation was used. However, two layers of springs can also be used representing the axial stiffness of wall and transverse stiffness of foundation. An important point in this regard is the use of a plastic hinge length for the springs representing the rocking wall. Equating Equation (1) with the expression EA/L_e gives an effective length of the wall equal to the thickness of wall. It's important to mention here that several past studies have proposed an effective length of two times the wall thickness for CLT walls [7, 11, 16]. Results with one and two layers exhibited almost identical results in this study and are not shown here for brevity.

Comparison of force-drift behavior from the experimental results and numerical model is shown in Figure 6. The CLT rocking wall showed slightly different behavior in positive and negative direction of motion. As the first cycle of lateral deformation was provided in positive direction, the comparison in the positive direction of response is considered and discussed here. The numerical model was found to model the initial stiffness accurately. Since the yielding stress for the 5-ply CLT in the transverse direction was taken as average of different samples, a monotonic response considering the CLT wall to be linear elastic is shown. The nonlinear behavior in monotonic response is purely due to geometric nonlinearity. Comparing these two responses shows that the CLT wall showed yielding before gap opening behavior which also caused a softening of post gap-opening stiffness. The numerical model was able to predict this response accurately and the assumed average yield stress value was found to be reasonable. The hysteretic behavior, on the other hand, showed some mismatch with the numerical model showing lower energy dissipation than the experimental results. It's important to mention here that this is due to unavailability of a reliable hysteretic model for the transverse direction response of CLT and future works need to focus on this. Single and coupled rocking walls tested by Ganey were also modeled using this approach and results showed a similar or better accuracy compared to some of the earlier works that calculated plastic hinge length by using trial-and-error approach; however, these walls had rigid-like footing condition and their results are not presented here for brevity and for the reason that this work is focused on the response of rocking structures on flexible foundations.

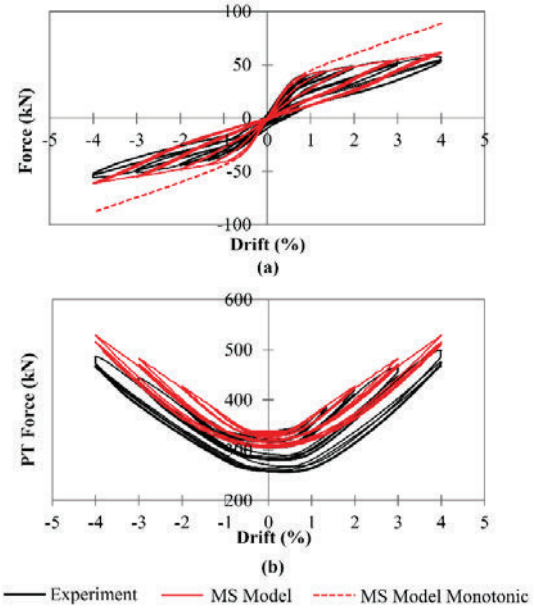

Figure 6: *Comparison of (a) force-drift and (b) PT force-drift response from experiment and MS model for Specimen 4*

As explained earlier, the stiffness of the base springs for the dynamic test was calibrated using a finite element model. All the other aspects of the MS model were same except for the calculation of contact stiffness as described

earlier. Results from two SLE (Tests 2 and 4), one DBE (Test 6) and one MCE (Test 12) level ground motions are shown in Figure 7. The MS model was able to predict the displacement demands in terms of pattern and maximum values with significant accuracy. Barring some under-prediction in a few cycles, the numerical model was found to be efficient in simulating the displacement results of rocking wall resting on flexible foundation. Although not shown here, the results of roof acceleration and base shear, however, showed underprediction for most tests. Two different techniques were used in the current study to model the foundation flexibility effects in solid and steel section beam foundations, and the proposed techniques have shown promising results. Further verification of the proposed techniques is needed in the future to develop a more generalized approach for modeling contact behavior in rocking walls with or without rigid foundations, omitting the need to calibrate the numerical models with experimental results.

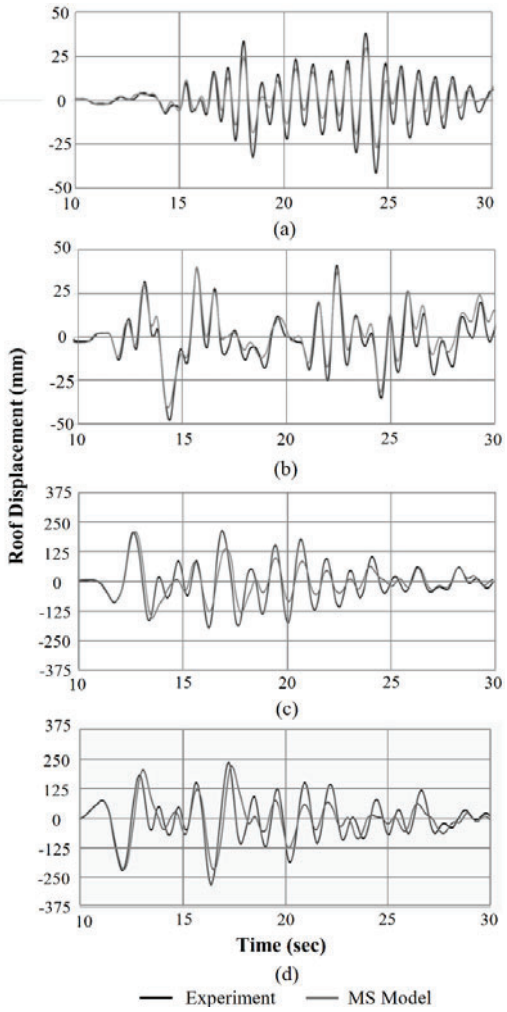

Fig 7: *Comparison of roof displacements from experiment and MS model for (a) Test 2, (b) Test 4, (c) Test 6 and (d) Test 12*

As the proposed MS model can include the effects related to foundation flexibility, a parametric study was conducted to further explore these effects on the base shear demands of rocking walls against different levels of foundation flexibility.

5 PARAMETRIC STUDY

To further explore the effects of foundation flexibility on the lateral behavior of rocking walls, the validated numerical model was used to simulate different combinations of wall and foundation stiffness. Ganey used two levels of initial post-tensioning for different specimens (i.e., 10% and 40% of ultimate strength of PT steel.) In this part, the Ganey wall was used with different foundation stiffness values, ranging from rigid to a stiffness value equal to 10% of the axial stiffness of the wall against two levels of initial post-tensioning, as shown in Table 2. Axial springs representing stiffness of wall and foundation were considered to be acting in series to calculate equivalent interacting stiffness. All the other parameters were kept constant for all the iterations. In this part, both the wall and the foundation were assumed to be linear elastic with geometric nonlinearity acting as sole contributor for inelastic behavior. As the foundation flexibility increased,
the decompression rotation increased while the forces against any particular drift decreased, as shown in Figure 8. When the foundation stiffness was one tenth of the axial stiffness of the wall, the maximum force demands against 3% drift reduced by 30% and 27% for the cases with initial PT force equal to 10% and 40% of the ultimate PT force, respectively. There was also a visible decrement in initial stiffness of the rocking system which will change the modal properties of the system with a lengthened fundamental period, modified mass participation and changes in modal force patterns along the height.

Table 2: *Variables used in parametric investigation*

Initial PT	Parameter studied	Parameter variations				
$f_{pt,i} = 0.1f_{pt,}$	Ratio of foundation to wall stiffness	Rigid	1	0.5	0.25	0.1
$f_{pt,i} = 0.4f_{pt,}$	Ratio of foundation to wall stiffness	Rigid	1	0.5	0.25	0.1

Although the modeling techniques proposed in the current work were focused on the timber rocking walls, future works need to ascertain their general applicability by using them for the modeling of concrete and steel rocking structures. Furthermore, the proposed contact mechanics technique for solid foundations suggests that a concrete rocking wall resting on a concrete foundation with a similar value of modulus of elasticity, as is usually the case, should not be considered rigid as the real contact stiffness value would be lower than the axial stiffness of the wall in the contact region.

https://doi.org/10.52202/069179-0345

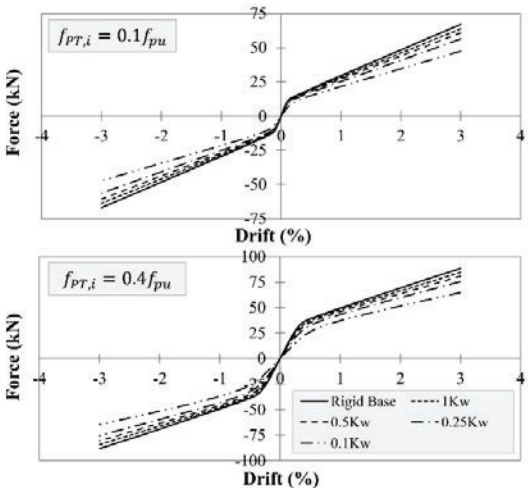

Figure 8: *Effect of foundation stiffness on the force-drift response.*

6 CONCLUSIONS

This study was focused on the development of a simple numerical model to account for the foundation flexibility effects in rocking wall structures. Results from a static and a dynamic test of rocking walls with flexible foundations were used in the current study. Two different approaches for the modeling of contact behavior at wall-flexible foundation interface were proposed. For the solid flexible foundation, a technique based on the principles of contact mechanics was used. Albeit some mismatch in the hysteretic response, the proposed technique was found to predict the force and displacement responses of the case study rocking wall resting on a yielding foundation with significant accuracy. On the other hand, using the results of foundation stiffness from a finite element model to adjust the contact stiffness in the multi-spring model proved to be an effective technique, and accurately predicted the displacement responses of the structure against varying levels of seismic intensity. A decrease in foundation stiffness is found to reduce the initial stiffness and the force demand in rocking structures. Future works are needed to check the general applicability of proposed techniques by modeling the concrete and steel rocking walls.

PRESCRIPTIVE SEISMIC DESIGN PROCEDURE FOR POST-TENSIONED MASS TIMBER ROCKING WALLS IN THE UNITED STATES

Aleesha Busch[1], Reid B. Zimmerman[2], Shiling Pei[3], Eric McDonnell[4], Philip Line[5], Da Huang[6]

ABSTRACT: This paper describes a prescriptive seismic design procedure for a lateral force-resisting system composed of post-tensioned mass timber rocking walls. This procedure utilizes techniques and analysis methods routinely adopted by industry and adheres to force-based approaches found in the current U.S. seismic loading standard. Unlike performance-based design approaches that are more complex and require peer review, this design procedure targets future adoption into model codes by providing a basis for the prescriptive design of mass timber rocking wall lateral force-resisting systems. To illustrate this procedure, a series of example buildings were designed using the methods described in this paper.

KEYWORDS: Tall wood building, Seismic design, Mass timber rocking wall, Cross-laminated timber

1 INTRODUCTION

With the recent growth and popularity of mass timber in the United States, the number of mass timber building projects is expected to multiply. Although there has been increased traction for mass timber lateral force-resisting systems (LFRSs)—which utilize mass timber panels such as cross-laminated timber (CLT), laminated veneer lumber (LVL), and mass plywood panels—in research and development, the U.S. building code and its reference design standards provide limited options for mass timber seismic force-resisting systems as of the end of 2022. The one currently permitted system comprises platform-framed, conventionally connected CLT walls.

Out of the many potential mass timber LFRSs, post-tensioned mass timber rocking walls are thought to be the competitive choice for mass timber building projects in regions with high seismicity, particularly because they are considered a low-damage lateral system. The mechanism of this system is very similar to that of a precast concrete rocking wall system, which was heavily researched and tested in the 1990s and then codified via ACI ITG-5.1-07 and ITG-5.2-09 [1,2]. Researchers in New Zealand conceptualized the first timber version of this system, using LVL walls, and continued the development with several real building project applications [3]. The U.S. also adopted this system and has had real projects that were either permitted [4] or built [5,6]. However, all of these existing designs and analyses were conducted using advanced tools and procedures (performance-based design and nonlinear response history analysis), which are not typically used in average design offices. This situation calls for a prescriptive design method for post-tensioned mass timber rocking wall systems.

2 MASS TIMBER ROCKING WALL SYSTEM

The design procedure described in this paper is suitable for post-tensioned mass timber rocking wall LFRSs like those shown in Figure 1.

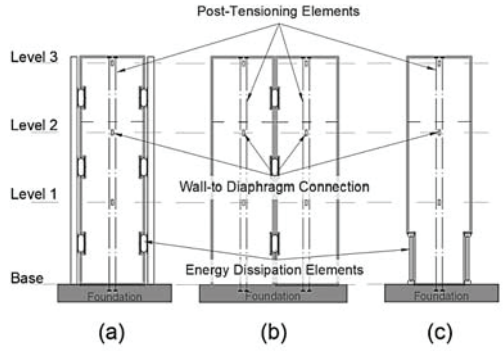

Figure 1: *(a) Conceptual configuration of a post-tensioned mass timber rocking wall with bounding columns; (b) conceptual configuration of coupled post-tensioned mass timber*

https://doi.org/10.52202/069179-0346

rocking walls; and (c) conceptual configuration of an uncoupled post-tensioned mass timber rocking wall.

The walls consist of mass timber panels attached to the floor diaphragms in a balloon-framing configuration, and the panels can either be coupled or uncoupled. The material of the wall panels can be of the engineer's choice, given they meet the requirements of the National Design Specification (NDS) for Wood Construction's Chapter 8 for structural composite lumber or Chapter 10 for cross-laminated timber [7]. The wall panels are post-tensioned (P/T) at the center of the wall with high-strength steel strands or threaded rods. Energy dissipation (ED) elements, which can be yielding or frictional devices or specialized friction dampers, must also be part of the system to help absorb the earthquake input energy during the rocking motion. These damping elements can include, but are not limited to, U-shaped flexural plates (UFPs) or buckling restrained devices (BRBs). Connections between the walls and the diaphragms, and between the wall and the foundation must also be detailed to complete the lateral load path.

3 SEISMIC DESIGN APPROACH

This design methodology was created to be used by practicing engineers in the United States to design post-tensioned mass timber rocking walls as a lateral force-resisting system [8]. To accomplish this, a prescriptive design method using either the Equivalent Lateral Force (ELF) method or Modal Response Spectrum Analysis (MRSA) from ASCE 7 Chapter 12 [9] was created. The overall design is completed at the design basis earthquake (DBE) with some additional checks at the maximum considered earthquake (MCE_R). The approach can be broken into the five major steps described below:

3.1 PRELIMINARY DESIGN

This section contains the architectural design and the creation of a linear analysis model of the building.

3.2 DRIFT ANALYSIS

This section calls for the calculation of the building drifts and checking them against the allowable story drifts in ASCE 7 Chapter 12 [9].

3.3 ROTATIONAL DEMAND AT THE ROCKING INTERFACE

This section addresses the calculation of the gap opening at both DBE and MCE_R levels. This is done for each of the hazard levels by following Equations 1 and 2, respectively:

$$\theta_{design} = \frac{C_1 * \delta_x - \delta_{xe,y}}{h_w} \quad (1)$$

$$\theta_{maximum} = \frac{1.5 * C_1 * \delta_x - \delta_{xe,y}}{h_w} \quad (2)$$

Where δ_x is the elastic roof displacement from a fixed-base, elastic model, C_1 is a factor that relates displacements from a linear model to expected inelastic displacements, $\delta_{xe,y}$ is displacement due to the elastic flexibility of the wall panel itself, and h_w is the height of the wall.

3.4 SYSTEM LEVEL DESIGN AND CHECKS

This section contains the determination of the system moment and shear demands from the fixed-based model and their scaling, when appropriate. In addition, the calculation of the system capacity using sectional analysis is also determined. Following the determination of the demands and capacities, a check is performed to ensure the strength of the system is sufficient. The moment capacity of the system shall be determined at the center of the wall for a single wall panel, and at the center of the system for a coupled rocking wall. The moment check can be determined using Equation 3.

$$M_{u,rm} \leq \phi_{rm} * M_{n,rm} \quad (3)$$

Where $M_{u,\ rm}$ is the moment demand of the rocking mechanism from ASCE 7 LRFD factored load combinations, excluding overstrength load combinations, φ_{rm} is the strength reduction factor for the rocking mechanism, and $M_{n,rm}$ is the nominal moment capacity of the rocking mechanism and can be calculated following Equation 4a for single wall panels and Equation 4b for coupled wall panels.

$$M_n = M_{ed,comp} + M_{wood,comp1} + M_{wood,comp2} + M_{ed,tens} \quad (4a)$$

$$M_n = M_{ed,comp} + M_{wood,comp1} + M_{wood,comp2} + M_{ed,tens} + M_{PT\Delta} \quad (4b)$$

Where $M_{ed.comp}$ is the moment due to the ED elements at the wall toe (i.e., compression end of the wall), $M_{wood,comp1}$ is the moment due to the compression of the wood in the linearly varying stress portion, $M_{wood,comp2}$ is the moment due to the compression of the wood in the constant stress portion, $M_{ed,tens}$ is the moment due to the ED elements at the wall heel (i.e., tension end of the wall), and $M_{PT\Delta}$ is the moment due to the incremental force from elongation of the P/T elements during rocking (i.e., total force in P/T elements minus initial P/T force). Each of these moments is defined further in Equations 5 through 9. It should be noted here that the following equations are derived for when the moment is being taken about the center of the wall. When the moment is being taken about a different point (e.g., in a coupled wall system), adjustment to the equations is required. In addition, Equation 9 is only needed for the coupled wall as indicated in Equation 4b.

$$M_{ed,comp} = \frac{F_{ed,comp} * - L_w}{2} \quad (5)$$

$$M_{wood,comp1} = F_{wood,comp1}\left(-\frac{L_w}{2} + c_2 + \frac{c_1}{3}\right) \quad (6)$$

$$M_{wood,comp2} = F_{wood,comp2}\left(-\frac{L_w}{2} + \frac{c_2}{2}\right) \quad (7)$$

$$M_{ed,tens} \ \frac{F_{ed,tens} * L_w}{2} \quad (8)$$

$$M_{PT\Delta} = F_{PT\Delta} * \frac{L_w}{2} \quad (9)$$

Where $F_{ed,\ comp}$ is the force due to the ED elements at the wall toe (i.e., compression end of the wall), $F_{wood,comp1}$ is the force in the wood in the region of linearly varying stress, $F_{wood,comp2}$ is the force in the wood in the region of constant compressive stress, $F_{ed,tems}$ is the force due to the ED elements at the wall heel (i.e., tension end of the wall), $F_{PT\Delta}$ is the force due to the elongation of the P/T elements during rocking (i.e., total force in P/T elements minus initial P/T force), L_w is the length of the wall, c_1 is the length of the linearly varying stress portion in the wall toe, and c_2 is the length of the constant compressive stress in the wall toe. It should be noted that c_1 and c_2 summed together will give c, the neutral axis depth of the wall. These forces are illustrated in the free body diagram in Figure 2 and can be calculated using sectional analysis. The probable moment of the system will be calculated using the same process but using the gap opening rotation at the MCE_R and expected/ultimate material properties.

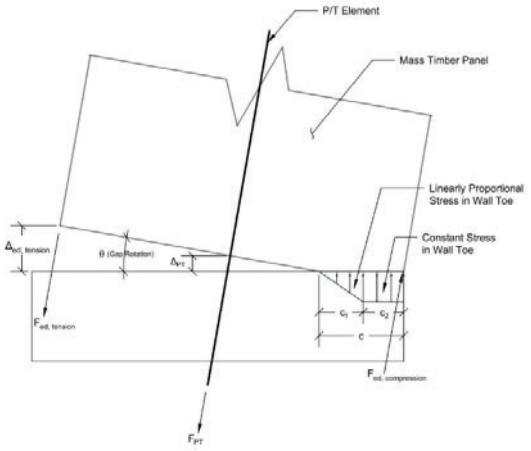

Figure 2: **Free body diagram of mass timber panel at the rocking interface.**

The shear check can be determined using Equation 10 which is also found in the NDS [7].

$$F_v' \geq f_v \tag{10}$$

Where F'_v is the adjusted shear design capacity determined per the NDS and f_v is the in-plane shear capacity of the mass timber panel. It should be noted that dynamic shear amplification may need to be accounted for due to the reduction of yielding in modes other than the fundamental mode for the wall.

3.5 LOCAL COMPONENT DESIGN AND CHECKS

The steps in this section are responsible for the determination of the wall hardware including the P/T and ED elements. Following the determination of these elements, several local checks—detailed below—are completed.

3.5.1 Restoring Ratio

This ensures the rocking wall will re-center after shaking up to and including the design basis earthquake. This is done by comparing the resisting force provided by the initial P/T force plus the additional dead load to the force provided by the ED components on the tension end of the wall at their ultimate capacity. This can be done following Equation 11 below.

$$F_{PTi} + 0.9 * P_u > 2 * F_u * A_{ed,tens} \tag{11}$$

Where F_{PTi} is the initial post-tensioning force in the P/T components, P_u is the vertical dead load in the wall at its base including the wall self-weight, F_u is the ultimate strength of the energy dissipation elements, and $A_{ed,tens}$ is the area of the energy dissipation elements on the tension end of the wall.

3.5.2 Energy Dissipation Ratio

This ratio enforces that there will be some energy dissipation from the system. To calculate this, a ratio of the moment capacity resulting from the energy dissipation devices to the total moment capacity is compared to a minimum limit. This ratio can be calculated using Equation 12 detailed below.

$$\frac{(M_n - M_{noed})}{M_n} \geq 0.25 \tag{12}$$

Where M_n is the nominal moment capacity of the wall and M_{noed} is the nominal moment capacity of the wall if there were no energy dissipation elements in the system.

3.5.3 Limited Wall-Toe Crushing at DBE

This ensures minimal damage occurs at the toe of the rocking wall for shaking up to and including the design basis earthquake and is completed by checking the strains in the wood. This can be calculated using Equation 13 detailed below.

$$\varepsilon_{wood,compr} \leq 0.9 * \varepsilon_{mtmax} \tag{13}$$

Where $\varepsilon_{wood,compr}$ is the strain in the extreme compression fiber and ε_{mtmax} is the maximum useable strain of the mass timber panel. The maximum useable strain shall not be taken greater than the strain at which the post-peak stress reaches 80 percent of the peak compression stress determined from an edgewise compression stress-strain curve.

3.5.4 No P/T Yielding at DBE

This is another check to ensure that re-centering will occur after shaking up to and including the design basis earthquake since P/T yielding compromises re-centering capability. This check is done by comparing the demand to yield stress of the P/T and can be calculated using Equation 14 detailed below.

$$f_{PT} \leq 0.9 * f_{yPT} \tag{14}$$

Where f_{PT} is the stress demand in the P/T elements at DBE and f_{yPT} is the yield stress.

3.5.5 No P/T Failure at MCE_R

This check is to ensure the P/T system will not fail at MCE_R. This is determined by calculating the strain in the P/T elements using Equation 15 detailed below.

$$\varepsilon_{PTf} \leq 0.85 * \varepsilon_{PT,u} \tag{15}$$

https://doi.org/10.52202/069179-0346

Where ε_{PTf} is the strain demand in the P/T elements at the MCE_R and $\varepsilon_{PT,u}$ is the ultimate strain capacity of the P/T element.

3.5.6 No ED Failure at MCE_R

This check is to ensure the ED elements will not fail at MCE_R. This is determined by calculating the strain or deformation in the ED elements using Equations 16a or 16b detailed below.

$$\varepsilon_{ed,tens} \leq 0.85 * \varepsilon_{ed,u} \quad (16a)$$

$$\Delta_{ed,tens} \leq 0.85 * \Delta_{ed,u} \quad (16b)$$

Where $\varepsilon_{ed,tens}$ or $\Delta_{ed,tens}$ is the strain or deformation of the ED elements in tension due to elongation, and $\varepsilon_{ed,u}$ or $\Delta_{ed,u}$ is the ultimate strain or deformation capacity of the ED elements.

4 DESIGN EXAMPLES

To illustrate the use of the proposed design approach, two design examples will be presented. The first example is a six-story mixed-use building featuring post-tensioned mass timber rocking walls with bounding columns. The second example features a three-story academic building with coupled post-tensioned mass timber rocking walls.

4.1 SIX-STORY EXAMPLE

4.1.1 Preliminary Design

This example features an office building located in Seattle, WA on Site Class C and a Seismic Design Category of D. The building features a 6.1m first story with the remaining stories being 3.7m in height. The floor plan of the building is shown below in Figure 3.

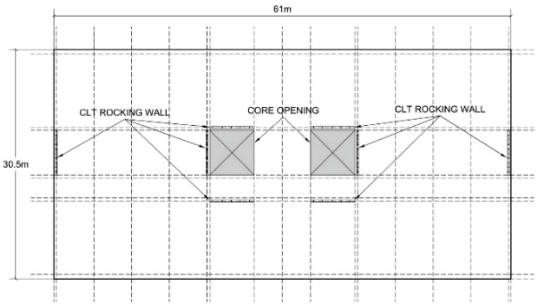

Figure 3: *Floor plan of the 6-story example building.*

The lateral system is composed of eight, 5.9m post-tensioned mass timber rocking walls consisting of 7-ply E1M1 CLT in a bounding column configuration. The wall components for this example are shown in Figure 4. Since this system's response modification factor was not yet available, it was assumed to be equivalent to that of a special reinforced concrete shear wall, giving an R = 6. Additionally, C_d was taken equal to R based on the recommendations made by Uang et. al [10]. Furthermore, the CLT panel material is isotropic and therefore needs to be modeled with appropriate stiffness parameters.

The linear elastic model for this example was built in ETABS with the seismic ground motion parameters listed in Table 1, which were determined using the ATC Hazards by Location Tool [11,12].

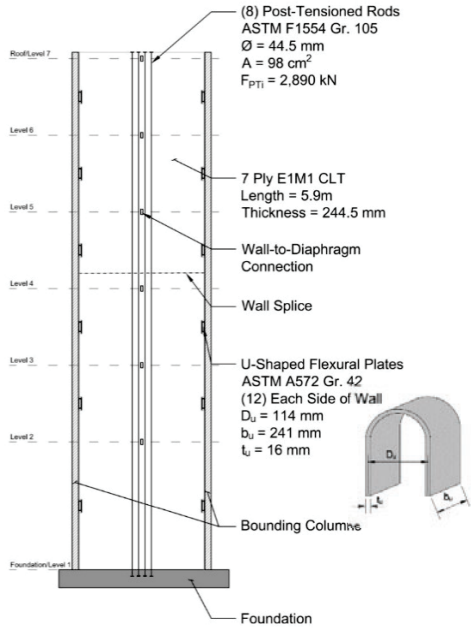

Figure 4: **Description of wall components, including UFP dimensions, for the 6-story example.**

Table 1: *List of seismic ground parameters for the 6-story example.*

Seismic Ground Motion Parameters	
The mapped MCE_R spectral response acceleration parameter at short periods, S_s	1.38
The mapped MCE_R spectral response acceleration parameter at a period of 1s, S_1	0.48
Short-Period Site Coefficient, F_a	1.2
Long-Period Site Coefficient, F_v	1.5
The MCE_R spectral response acceleration parameters for short periods, S_{MS}	1.65
The MCE_R spectral response acceleration parameters at a period of 1s, S_{M1}	0.72
The design spectral response acceleration parameter at short periods, S_{DS}	1.10
The design spectral response acceleration parameter at a period of 1s, S_{D1}	0.48

4.1.2 Drift Analysis

The drift of the building was determined using the linear elastic ETABS model and is shown in Figure 5. ASCE 7-16 Table 12.12-1 gives the Allowable Story Drift [9]. With the classification of "All other structures" and a Risk Category of II, the allowable story drift is 2%. Based on the data presented in Figure 5, it is evident that the drift in both directions does not exceed the 2% limit, therefore validating the current building layout and allowing for the design of the wall to continue.

https://doi.org/10.52202/069179-0346

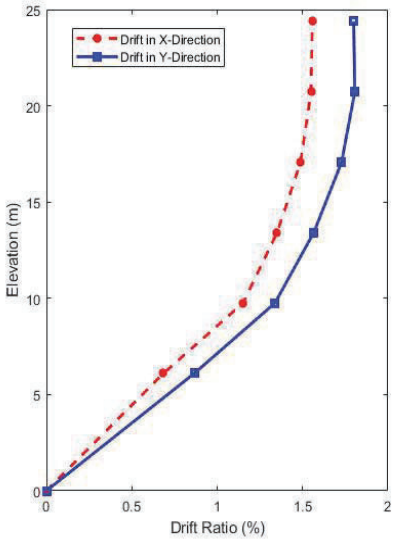

Figure 5: *Drift responses at each story for the 6-story example.*

4.1.3 Rotational Demand at the Rocking Interface

Using the analysis from the linear structural model created in the previous step, the deflections needed to calculate the rotations at the rocking interface can be determined. The design rotation at the rocking interface was given by Equation 1 and can be calculated as follows:

$$\theta_{design} = \frac{1.0*0.273m-0.093m}{24.4m} = 0.007\ rad$$

The maximum rotation at the rocking interface was given by Equation 2 and can be calculated as follows:

$$\theta_{max} = \frac{1.5*1.0*0.273m-0.093m}{24.4m} = 0.013\ rad$$

4.1.4 System Level Design and Checks

The nominal moment capacity of the wall system is calculated using Equation 4a, and subsequently Equations 5 through 8. The forces needed to calculate the moment capacity of the wall were determined using sectional analysis and are listed in Table 2.

Table 2: *Parameters needed to calculate moment capacity for the 6-story example.*

Parameter	Value
$F_{ed,\ comp}$	924 kN
$F_{wood,comp1}$	-472 kN
$F_{wood,comp2}$	-3513 kN
$F_{ed,tems}$	924 kN
c_1	0.22m
c_2	0.81m

Using the values populated in the table above, the individual moment capacities can be computed following Equations 5 through 8.

$$M_{ed,comp} = \frac{-924\ kN*-5.9m}{2} = 2{,}747\ kN*m$$

$$M_{wood,comp1} = -472\ kN\left(-\frac{5.9m}{2} + 0.81m + \frac{0.22m}{3}\right) = 986\ kN*m$$

$$M_{wood,comp2} = -3513\ kN\left(-\frac{5.9m}{2} + \frac{0.81m}{2}\right) = 9017\ kN*m$$

$$M_{ed,tens} = \frac{924\ kN*5.9m}{2} = 2{,}747\ kN*m$$

Following the individual moment capacity calculations, the nominal moment for the wall system can be calculated following Equation 4 as the following:

$$M_n = 2{,}747\ kN*m + 986\ kN*m + 9{,}017\ kN*m + 2{,}747\ kN*m = 15{,}497\ kN*m$$

The probable moment for this system would also be computed using the same equations, but with the maximum gap opening rotation and expected/ultimate material properties. For this example, the probable moment was calculated to be 19,421 kN*m.

Following the nominal moment capacity calculation, Equation 3 can be used to determine if the capacity is sufficient for the demand taken from the ETABS model.

$$13{,}367\ kN*m \leq\ 0.9*15{,}497\ kN*m = 13{,}947\ kN*m$$

Based on the calculation above, the strength of the rocking mechanism is satisfied.

The shear check for this example can be computed following Equation 10 and is detailed below.

$$4.0\ MPa \geq 2.9\ MPa$$

Based on the calculation above, the in-plane shear capacity of the wall is sufficient. It should be noted that the in-plane shear at any section of the mass timber panel shall be calculated using the wall shear demand from ASCE 7-16 factored load combinations (excluding overstrength load combinations) [9]. For this example, the shear demand was determined considering amplification due to flexural overstrength and higher mode effects as reported elsewhere [8].

4.1.5 Local Component Design and Checks

4.1.5.1 Restoring Ratio

Based on Equation 11 and the wall components, the restoring ratio can be determined as the following:

$$2891\ kN + 0.9*0 > 2*\frac{110\ kN}{UFP}*12\ UFPs$$

This then gives the following:

$$2891\ kN > 2640\ kN$$

It should be noted that since this wall is in a bounding column configuration there is no additional dead load from the floors. Furthermore, the self-weight of the wall is conservatively neglected. Based on the calculation above, the system will be able to re-center.

https://doi.org/10.52202/069179-0346

4.1.5.2 Energy Dissipation Ratio

Based on Equation 12 and the wall components and the previous calculations, the energy dissipation ratio can be determined as the following:

$$\frac{(15{,}497 kN*m - 10{,}002\ kN*m)}{15{,}497\ kN*m} = 0.35 \geq 0.25$$

Based on the calculation above, the energy dissipation of the system is sufficient.

4.1.5.3 Limited Wall-Toe Crushing at DBE

Based on Equation 13 and the wall components, the following can be computed:

$$0.0118 \leq 0.9 * 0.015 = 0.0135$$

Based on the calculation above, the strain of the extreme compression fiber of the mass timber panel is satisfied.

4.1.5.4 No P/T Yielding at DBE

Based on Equation 14 and the wall components, the following can be computed:

$$407\ MPa \leq 0.9 * 724 MPa = 652\ MPa$$

Based on the calculation above, there is no yielding of the P/T bars during DBE.

4.1.5.5 No P/T Fracture at MCE_R

Based on Equation 15 and the wall components, the following can be computed:

$$0.0024 \leq 0.85 * 0.05 = 0.043$$

Based on the calculation above, there is no fracturing of the P/T bars at the MCE_R.

4.1.5.6 No ED Fracture at MCE_R

For UFPs, the critical design property is the distance from the start of the 180-degree bend to the nearest attachment point (e.g., weld or bolt) on the straight portion. Based on Equation 16b and the wall components the following can be computed:

$$71.8\ mm \leq 0.85 * 127\ mm = 108\ mm$$

Based on the calculation above, there is no ED fracture at the MCE_R.

Since all the system and local level component checks are satisfied, the overall design of the wall is complete.

4.2 THREE-STORY EXAMPLE

4.2.1 Preliminary Design

This example features an academic building located in Seattle, WA on Site Class C and a Seismic Design Category of D. The building features story heights of 3.7m. The floor plan of the building is shown below in Figure 6.

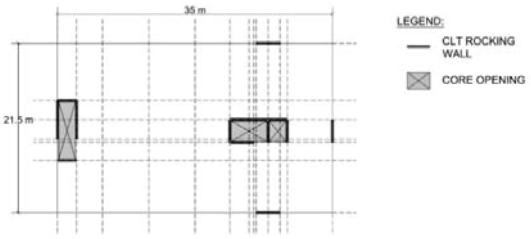

Figure 6: *Floor plan of the 3-story example building.*

The lateral system is composed of eight, 2.44m post-tensioned mass timber rocking walls consisting of 9-ply E1M1 CLT in a coupled wall configuration (not all walls in the floorplan are coupled). The wall components for this example are shown in Figure 7. The response modification factor for this system, since not yet available, was assumed to be equivalent to that of a special reinforced concrete shear wall, giving an R = 6. Additionally, C_d was taken equal to R based on the recommendations made by Uang et. al [10]. Furthermore, the CLT panel material is isotropic and therefore needs to be modeled with appropriate stiffness parameters.

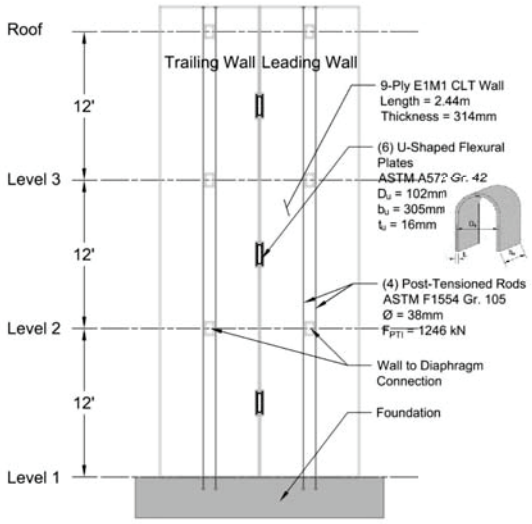

Figure 7: *Description of wall components, including UFP dimensions, for the 3-story example.*

The linear elastic model for this example was built in ETABS with the seismic ground parameters listed in Table 1.

4.2.2 Drift Analysis

The drift of the building was determined using the linear elastic model and is shown in Figure 8. ASCE 7-16 Table 12.12-1 gives the Allowable Story Drift [9]. With the classification of "All other structures" and a Risk Category of III, the allowable story drift is 1.5%. Based on the data presented in Figure 8, it is evident that the drift in both directions does not exceed the 1.5% limit, therefore validating the current building layout and allowing for the design of the wall to continue.

https://doi.org/10.52202/069179-0346

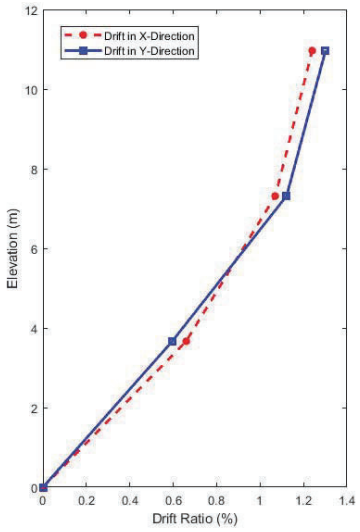

Figure 8: *Drift responses at each story for the 3-story example.*

4.2.3 Rotational Demand at the Rocking Interface

Using the analysis from the linear structural model created in the previous step, the deflections needed to calculate the rotations at the rocking interface can be determined. Since the coupled wall is symmetric in the linear analysis model, the design rotations at the rocking interface will be the same for both walls. The design rotation at the rocking interface was given by Equation 1 and can be calculated as follows:

$$\theta_{design} = \frac{1.1*0.094m-0.028m}{11.0m} = 0.007\ rad$$

The maximum rotation at the rocking interface of each wall was given by Equation 2 and can be calculated as follows:

$$\theta_{max} = \frac{1.5*1.1*0.094m-0.028m}{11.0m} = 0.013\ rad$$

Note that it is a coincidence that the design and maximum rotations at the rocking interface for this example match those of the 6-story example presented in Section 4.1.3.

4.2.4 System Level Design and Checks

For a coupled wall system, the subsequent calculations are broken down into the values for the trailing wall (subscript Tw) and leading wall (subscript Lw). The orientation of these walls is illustrated in Figure 7. The nominal moment capacity of each wall is calculated using Equation 4b, and subsequently Equations 5 through 9, with some modifications to the moment arm as mentioned previously and detailed below. Following the calculation of each wall's nominal moment capacity, the moment for the wall system will be determined following the summation from each wall. The forces needed to calculate the moment capacity of each wall were determined using sectional analysis and are listed in Table 3.

Table 3: *Parameters needed to calculate moment capacity for the 3-story example.*

Parameter	Value
Trailing Wall	
$F_{ed,\ comp}$	-657 kN
$F_{wood,comp1}$	-590 kN
$F_{wood,comp2}$	-368 kN
$F_{ed,tens}$	N/A
$F_{PT\Delta}$	411 kN
c_1	0.22 m
c_2	0.069 m
Leading Wall	
$F_{ed,\ comp}$	N/A
$F_{wood,comp1}$	-590 kN
$F_{wood,comp2}$	-1583 kN
$F_{ed,tens}$	657 kN
$F_{PT\Delta}$	312 kN
c_1	0.22 m
c_2	0.29 m

Using the values populated in the table above, the individual moment capacities can be computed following Equations 5 through 9. As previously mentioned, these equations need modifications to reflect the moment arm for summing moments about the center of the coupled wall system (rather than the center of each respective wall) and are reflected below:

$$M_{ed,comp_TW} = F_{ed,comp_TW} * 0 = -657\ kN * 0\ m = 0\ kN * m$$

$$M_{wood,comp1_TW} = F_{wood,comp1_TW} * \left(c_{2_{TW}} + \frac{c_{1_{TW}}}{3}\right) = -590\ kN\left(0.069\ m + \frac{0.218\ m}{3}\right) = -83.4\ kN * m$$

$$M_{wood,comp2_TW} = F_{wood,comp2_TW} * \left(\frac{c_{2_{TW}}}{2}\right) = -368\ kN\left(\frac{0.069\ m}{2}\right) = -12.6\ kN * m$$

$$M_{PT\Delta_TW} = F_{PT\Delta} * \frac{L_w}{2} = 411\ kN * \frac{2.44\ m}{2} = 501.1\ kN * m$$

$$M_{ed,tens_TW} = N/A$$

$$M_{ed,comp_LW} = N/A$$

$$M_{wood,comp1_LW} = -F_{wood,comp1_LW} * \left(L_w - (c_{2_{LW}} + \frac{c_{1_{LW}}}{3})\right) = 590\ kN\left(2.44\ m - \left(0.29\ m + \frac{0.218\ m}{3}\right)\right) = 1{,}223\ kN * m$$

$$M_{wood,comp2_LW} = -F_{wood,comp2_LW} * \left(L_w - \frac{c_{2_{LW}}}{2}\right) = 1583\ kN\left(2.44m - \frac{0.29\ m}{2}\right) = 3{,}628.1\ kN * m$$

$$M_{PT\Delta_TW} = -F_{PT\Delta} * \frac{L_w}{2} = 312.3\ kN * \frac{2.44\ m}{2} = -380.7\ kN * m$$

https://doi.org/10.52202/069179-0346

$$M_{ed,tens_LW} = F_{ed,tens_LW} * 0 = 657\ kN * 0\ m = 0\ kN * m$$

Based on the calculations above, the moment capacity for each wall can be computed following Equation 4b as the following:

$$M_{n_TW} = 0\ kN * m - 83.4\ kN * m - 12.6\ kN * m + 501.1\ kN * m = 405.1\ kN * m$$

$$M_{n_{LW}} = 1{,}223\ kN * m + 3{,}628.1\ kN * m - 380.7\ kN * m + 0\ kN * m = 4{,}470.4\ kN * m$$

$$M_{n_tot} = 405.1\ kN * m + 4{,}470.4\ kN * m = 4{,}875.5\ kN * m$$

The probable moment for this system would also be computed using the same equations, but with the maximum design values. For this example, the probable moment was calculated to be 6,070 kN*m.

Following the determination of the moment capacity of the wall system, Equation 3 can be used to determine if the capacity is sufficient compared to the demand determined by the linear analysis model.

$$3{,}510.4\ kN * m \leq 0.9 * 4{,}875.5\ kN * m = 4{,}388\ kN * m$$

Based on the calculation above the strength of the rocking mechanism is satisfied.

The shear check for this example can be computed following Equation 10 and is detailed below.

$$4.0\ MPa \geq 1.2\ MPa$$

Based on the calculation above the in-plane shear capacity of the wall is sufficient. It should be noted that the in-plane shear at any section of the mass timber panel shall be calculated using the wall shear demand from ASCE 7-16 factored load combinations (excluding overstrength load combinations).

4.2.5 Local Component Design and Checks

The restoring and energy dissipation ratios will be checked at the system level for the coupled walls. However, all other local component checks will be broken down by the individual wall panel.

4.2.5.1 Restoring Ratio

Equation 11 will be used to determine the restoring ratio for the wall system. Since there are two walls in the system, the restoring force provided by each wall will need to be considered in the calculation. This can be done by summing the two forces as follows:

$$(1245.5\ kN + 0.9 * 42.3\ kN) + (1245.5\ kN + 0.9 * 42.3\ kN) > 2 * \frac{156.4\ kN}{UFP} * 6\ UFPs$$

This then gives the following:

$$2567.1\ kN > 1876.8\ kN$$

Based on the calculation above, the system will be able to re-center.

4.2.5.2 Energy Dissipation Ratio

Equation 12 will be used to determine the energy dissipation ratio for the wall system. Since there are two walls in the system, the moment contribution from both walls will need to be considered in the calculation. This can be done by summing the moments as follows:

$$\frac{(405.1\ kN*m - 204.4\ kN*m) + (4470.4\ kN*m - 3138.4\ kN*m)}{405.1\ kN*m + 4470.4\ kN*m} = 0.314 \geq 0.25$$

Based on the calculation above, the energy dissipation of the system is sufficient.

4.2.5.3 Limited Wall-Toe Crushing at DBE

The strain in the extreme compression fiber of the trailing wall can be calculated following Equation 13. This check is calculated below:

$$0.0032 \leq 0.9 * 0.015 = 0.0135$$

The strain in the extreme compression fiber of the leading wall can be calculated following Equation 13. This check is calculated below:

$$0.0058 \leq 0.9 * 0.015 = 0.0135$$

Based on the calculations above, the strain in the extreme compression fiber of both mass timber panels is satisfied.

4.2.5.4 No P/T Yielding at DBE

The stress in the P/T components of the trailing wall can be computed following Equation 14 and is shown below:

$$481\ MPa \leq 0.9 * 724MPa = 652\ MPa$$

The stress in the P/T components of the leading wall can be computed following Equation 14 and is shown below:

$$451\ MPa \leq 0.9 * 724MPa = 652\ MPa$$

Based on the calculations above, there is no yielding of the P/T bars during DBE in either wall panel.

4.2.5.5 No P/T Fracture at MCE_R

The strain in the P/T elements for the trailing wall can be calculated following Equation 15 and is shown below:

$$0.00295 \leq 0.85 * 0.05 = 0.043$$

The strain in the P/T elements for the leading wall can be calculated following Equation 15 and is shown below:

$$0.00259 \leq 0.85 * 0.05 = 0.043$$

Based on the calculations above there is no fracturing of the P/T elements during MCE_R in either wall panel.

4.2.5.6 No ED Fracture at MCE_R

The strain in ED elements between the trailing and leading wall can be calculated following Equation 16 and is shown below:

$$33.5mm \leq 0.85 * 127mm = 108mm$$

Based on the calculations above, there is no fracturing of the ED elements during MCE_R.

Since all the system and local-level component checks are satisfied, the overall design of the wall system is complete.

5 CONCLUSIONS

This paper describes a prescriptive design procedure for post-tensioned mass timber rocking walls. Based on the existing design procedure for precast concrete walls, this design procedure was developed with a prescriptive format so that it can be integrated into the provisions of ASCE 7 [8] and the National Design Specification (NDS) for Wood Construction [9]. The design procedure includes an assessment of drift limits and an estimation of gap openings. It also checks the wall's ability to re-center, the minimum energy dissipation, and several local element checks. In addition to the ideology of the checks and calculations, two full building examples highlighting different wall configurations are also presented.

ACKNOWLEDGEMENT

The authors would like to acknowledge funding support for the development of the design procedure by the US Forest Services through the Wood Innovation Grant. The use of ETABs software was provided by Computers and Structures Inc. (CSI). The numerical model used for validation in this study was supported by research funding from the National Science Foundation through grant CMMI 1636164. The opinions and conclusions presented in this article are of the authors themselves but not the sponsors. The authors would also like to acknowledge Jonathan Heppner and Thomas Robinson at LEVER Architecture for coordinating an architectural floor plan, which worked with the 6-story example building used in this study.

EFFECT OF THE ASPECT RATIO ON THE SEISMIC PERFORMACE OF POST-TENSIONED CROSS-LAMINATED TIMBER ROCKING WALL SYSTEMS

Gustavo Acuña[1], J. Daniel Dolan[2], Irshad Qureshi[3].

ABSTRACT: With the increased interest on the use of Cross-Laminated Timber (CLT) rocking walls as primarily lateral resistance system, some challenges arise, and special considerations might be considered in the design and structural analysis of this type of system. The influence in the dynamic response of the CLT panel aspect ratio is a parameter that has not been thoroughly studied, nor regulated by current codes and standards. The use of narrower panels leads to an amplification of higher-mode effects, due to the lower flexural stiffness of these elements, negatively affecting both the seismic performance and serviceability of this structural system. The objective of this investigation was to determine the variation in the dynamic behavior of a set of mid-rise Post-Tensioned Cross-Laminated Timber rocking wall structures, considering CLT panels with various aspect ratios. Nonlinear time-history analyses, including P-Δ effects, were performed to predict the seismic behavior. The results clearly showed that the use of wider panels improved the dynamic performance of these type of systems, highlighting reductions in the acceleration and seismic demands, as a consequence of a decrease in the higher-mode amplitudes. Lower aspect ratios also were associated with better displacement, drift ratio, and damage performances.

KEYWORDS: Cross-Laminated Timber, Rocking Walls, Aspect Ratio, Higher-Mode Effects, Nonlinear Analysis.

1 INTRODUCTION

The use of Post-Tensioned Cross-Laminated Timber (PT CLT) walls as primarily lateral resistant system brings both benefits and challenges. It has been demonstrated that CLT rocking wall systems can potentially withstand major earthquake events, and at the same time represents a viable sustainable construction alternative, which makes it very attractive to the designers. However, one of the major concerns with rocking systems and CLT construction is the important presence of higher modes in their dynamic response, including in low- and mid-rise structures.

Past research (Wiebe and Christopoulos [1], Ceccotti [2], Wiebe et al. [3-4], Qureshi [5], Li [6]) have found and shown the significant contribution of higher modes through testing and numerical simulations. The higher-mode contribution increases the acceleration demand in the entire structure, with a more noticeable effect at the upper stories, producing a whip-action. This increase in the acceleration response also increases the internal forces during seismic excitations, as well as the observable damage at the CLT wall toes. This structural drawback, combined with a drop in the serviceability due to excessive floor accelerations, can potentially reduce the overall feasibility of these type of systems in the mid-rise range. Hence, it is crucial to determine the main factors that affect the higher-mode amplification in PT CLT rocking wall structures.

One of the factors that can affect the dynamic performance of these rocking systems is the wall aspect ratio. Even the ever-increasing research in rocking systems, the current state-of-the-art has not evaluated its influence on balloon CLT rocking structures as far as the authors can determine. Moreover, the current codes and standards in the United States only provide guidelines for the wall aspect ratio for platform construction in light-frame wood construction. This aspect ratio limitation is provided by the National Design Specification for Wood Construction [7], and naturally, it is tied to the inter-story wall dimensions, rather than its global dimensions.

Therefore, the objective of this investigation was to quantify the difference in the seismic performance of a set of 6-story PT CLT walls with various global aspect ratios. The mean maximum responses of floor accelerations, floor displacements, inter-story drift ratios, shear and moment in the CLT walls, and damaged volume on the CLT wall toes were used as metrics to evaluate the effect of wall aspect ratio. In addition, the higher-mode influence was investigated by analyzing the roof acceleration time-history results.

The results presented, herein, are part of the investigation developed by Acuña [8] and are valid only for the structural configurations defined in later sections of this manuscript. These results must be complemented with further research and experimental testing to determine the maximum practical height-to-length ratio for this type of system.

2 METHODOLOGY

2.1 GENERAL PROCEDURE

The main steps used in this investigation are briefly described in this section. First, the general rocking wall properties were defined, including the number of stories, wall dimensions, seismic weight, and position of the post-tensioned rods. Next, the initial estimates of the seismic demands were computed, following the Equivalent Lateral Force Method (ELF) described by the ASCE 7-16 [9] guidelines.

To determine the number, size, and initial force on the post-tensioned rods, the Cross-Sectional Analysis, developed by Ganey [10] for PT CLT walls, was followed. This method solves the equilibrium equations and stress distributions iteratively to estimate the moment capacity of the post-tensioned rocking wall, given a fixed displacement.

The structures were then evaluated through nonlinear time-history analysis using SAP2000 [11], considering P-Δ effects. Each individual structure was subjected to forty-four far field traces, scaled to Design Basis Earthquake level, according to ASCE 7-16 [9] procedures.

To determine the frequency content of the roof acceleration time-history responses, Fourier analysis was used with the time trace of the roof response from the program. This approach allowed the amplitude, and therefore the influence, of each mode detected on the acceleration response to be calculated. The Discrete Fourier Transform (DFT) and the Amplitude Spectrum were computed using the MATLAB [12] Function "fft", corresponding to the "Fast Fourier Transform" algorithm.

2.2 MODEL CHARACTERIZATION

The CLT rocking walls were modeled with a simplified 2D model, consisting of a linear elastic frame element to represent the wall panel, and two nonlinear rotational springs at the base of each rocking wall to characterize the rocking behavior. This is a computationally efficient and accurate method of modeling CLT rocking systems, developed by Wilson [13], and it is shown in Figure 1. The modeling technique was further validated against the shake table test results carried out by Pei et al. [14] in a full-scale 2-story post-tensioned CLT rocking wall building. Additional details about the model validation can be found on Acuña [8] and Wilson [13].

U-Shaped Flexural plates (UFPs) were utilized to couple adjacent CLT wall panels and to connect the outer CLT panels to the bounding columns. A rigid foundation was assumed for all the cases. A representation of a 3-panel wall model is illustrated in Figure 2.

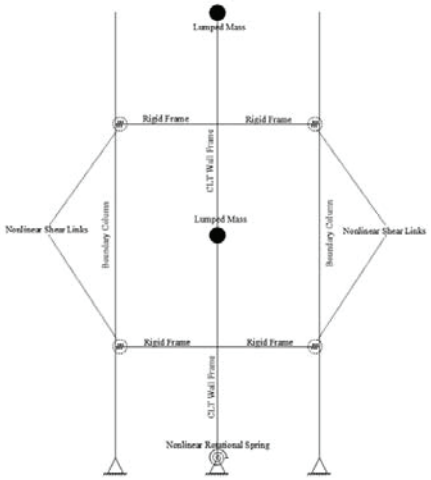

Figure 1: *Simplified CLT rocking wall model*

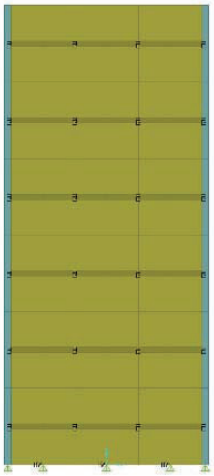

Figure 2: *Coupled wall model*

2.3 SELECTION AND SCALING OF GROUND MOTIONS

Twenty-two far-field acceleration record pairs from the PEER database [15], typically used for FEMA P-695 [16] analyses, were selected for numerical evaluation. Scaling of the traces was carried out following the Amplitude Scaling process, according to ASCE 7-16 [9]; where one single scale factor is used for all the acceleration traces to match the average maximum direction spectrum (RotD100) with the target spectrum at the target period.

https://doi.org/10.52202/069179-0347

The target spectrum was defined assuming the buildings to be in Downtown Seattle, WA (47.622, -122.337). Site Class C and Importance Factor II were assumed for the building, according to ASCE 7-16 [9]. The Modified Response Factor (R-factor) was selected as 6, based on the observations presented by Pei et al. [17], Ganey [10], and Wilson [13]. The design moment demand for all of the structures was 3,192 kN-m. The target spectrum, the mean RotD100 spectrum, and the individual RotD100 spectra for the 22 ground motions are shown in Figure 3.

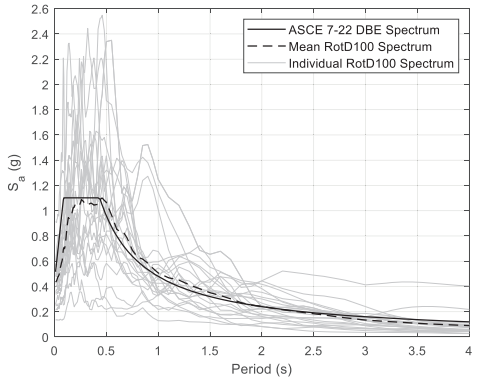

Figure 3: *ASCE 7-22, mean RotD100, and individual RotD100 acceleration spectra*

3 CASE STUDY

3.1 MATERIAL PROPERTIES

3.1.1 Cross-laminated timber

E1M5 rated panels, according to the Structurlam [18] specification, were selected for the CLT rocking walls. The properties of a 9-ply CLT panel were derived from crushing and shear tests performed in a 5-ply CLT panel by OSU and PSU [19]. The adjusted properties for a 9-ply panel were: 7,037 MPa for the modulus of elasticity in the longitudinal direction, 4,520 MPa for the modulus of elasticity in the transverse direction, 552 MPa for the shear modulus, 18.2 MPa for the yield stress, 0.0026 mm/mm for the yield strain, and 0.0082 mm/mm for the crushing strain. The Poisson's ratio was assumed as 0.3 in all directions. The post-yield behavior of the wood crushing was assumed as elastic-perfectly plastic.

3.1.2 Post-tensioned rods

Fully threaded, high-strength steel rods were selected for the PT rods, with denomination ATS-HSRX, according to Simpson Strong-Tie [20]. ATS-HSRX rods use ASTM F1554 Gr.105 steel for diameters equal or greater than 28.58 mm; with modulus of elasticity of 200,000 MPa, yield strength of 724 MPa, and tensile strength of 862 MPa.

3.1.3 U-shaped flexural plates

ASTM A572 Gr.42 steel plates were selected for the UFPs. The elastic modulus was 200,000 MPa, and the yield stress was 290 MPa.

3.2 SPECIMEN DESIGN

Four CLT panel lengths were selected for the numerical evaluation. These panel lengths were chosen to contain the practical range of the CLT panel manufacturing (up to 3.05 m), while an additional length (4.57 m) was included in the analyses for numerical purposes (it is understood that field connecting multiple CLT panels to construct the walls longer than can be manufactured is currently problematic, but for this analysis the connectivity to construct a continuous 4.57 m panel was assumed to be perfect).

For comparison reasons, a target wall length of 9.14 m was defined, and the required number of panels to cover the target length was calculated. These wall segments were connected by using UFPs. The panel length, aspect ratio, and the required number of segments are shown in Table 1.

The number of stories, inter-story height, wall thickness, story weight, roof weight, and position of the post-tensioned rods were held constant throughout all the cases, assuming 6 stories, 3.66 m, 31.43 cm, 333.6 kN, 166.8 kN, and wall centerline respectively. The UFP's size was also held constant; the bend diameter, width, and thickness were set to 15.24 cm, 6.35 cm, and 0.953 cm, respectively.

Table 1: *Wall Length and Aspect Ratio*

#ID	Wall Panel Length (m)	Aspect Ratio (H:L)	# Segments
1	1.52	14.4 : 1	6
2	2.29	9.6 : 1	4
3	3.05	7.2 : 1	3
4	4.57	4.8 : 1	2

To conduct the performance comparison, the rocking wall structures were designed to provide a similar moment capacity at 2.0% drift ratio. The required PT size, number, and initial force were determined using the Cross-Sectional Analysis. The PT properties are summarized in Table 2, and the moment-drift ratio relationship for the wall specimens are shown in Figure 3.

Table 2: *Post-tensioning properties*

#ID	ϕ_{PT} (mm)	#PT Rods	Segment Initial PT Force (kN)	Specimen Capacity (kN-m)
6-5	28.58	4	667	3,452
6-7.5	28.58	4	489	3,553
6-10	28.58	4	311	3,557
6-15	34.93	2	111	3,510

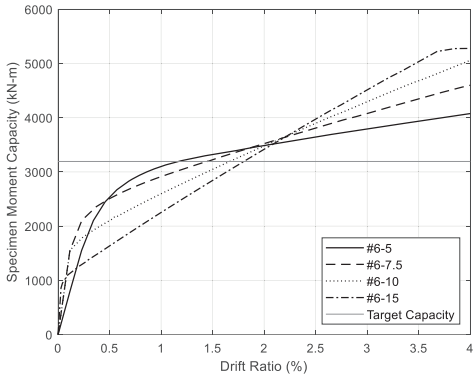

Figure 4: *Specimen capacities and target capacity*

4 RESULTS

The main results from the nonlinear time-history analyses are presented in this section. These results include acceleration, displacement, inter-story drift, shear force, and moment envelopes, modal amplitudes, and damage on CLT walls. The relative differences presented in this section were computed considering the results for Specimen #6-5 as baseline.

4.1 ACCELERATION RESPONSE

The time-history analysis results showed that the magnitude of the peak floor acceleration is directly related to the wall aspect ratio. The mean maximum profiles, presented in Figure 4, indicate a reduced acceleration response for specimens with lower global panel aspect ratio, essentially in the entire structure. A decrease in the whip-action at the upper stories is also noticeable, indicating less influence of the higher vibration modes.

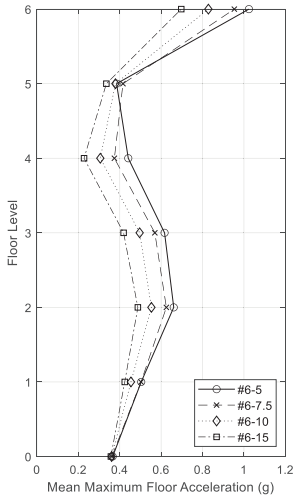

Figure 5: *Average peak floor acceleration*

It was observed that the largest average peak roof acceleration in Specimen #6-5, had a mean value of 1.02 g, while the smallest peak roof acceleration response was obtained in Specimen #6-15, with a value of 0.70 g. This is a respective difference reduction of 31.4%. The remaining average peak roof accelerations and differences are summarized in Table 3.

Table 3: *Average peak roof acceleration*

#ID	Average Peak Roof Acceleration (g)	Difference (%)
6-5	1.02	-
6-7.5	0.95	-6.9
6-10	0.83	-18.6
6-15	0.70	-31.4

4.2 FREQUENCY ANALYSIS

The 90th percentile Fourier amplitude spectra are presented in Figure 5. It is observed that both the first and second mode amplitude increase as the aspect ratio of the wall segment increases, showing the largest amplitudes in Specimen #6-5 and the smallest in Specimen #6-15. A significant shift in the second mode frequency is also exhibited, moving from the 3.5-4.0 Hz range for Specimen #6-5 to the 7.0-7.5 Hz range for Specimen #6-15; this change in the second-mode frequency can potentially reduce the seismic demands by moving the dynamic response out of the plateau region of the design spectrum.

The first and second mode amplitudes for Specimen #6-5 were 0.108 g and 0.145 g, respectively. For comparison, the first and second mode amplitude for Specimen #6-15 were 0.061 g and 0.067 g, respectively. The relative comparison between these two structures yielded an amplitude reduction of 43.5% and 53.8% for first and second mode, respectively. The Fourier amplitudes for the structures considered in this study are shown in Table 6.

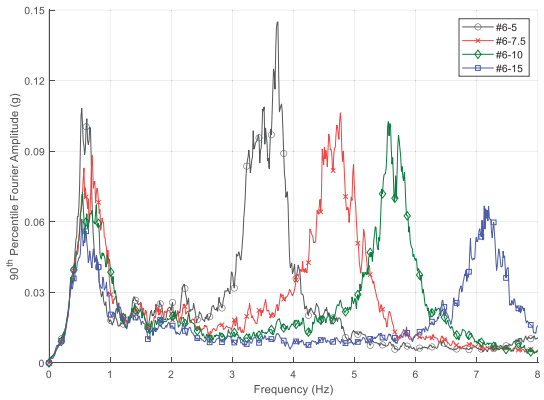

Figure 6: *90th percentile Fourier amplitude spectra*

https://doi.org/10.52202/069179-0347

Table 4: *90th percentile Fourier amplitude spectra*

#ID\ Mode	Frequency (Hz)		90th Percentile Amplitude (g)		Amplitude Difference (%)	
	1	2	1	2	1	2
6-5	0.54	3.75	0.108	0.145	-	-
6-7.5	0.70	4.77	0.088	0.106	-18.5	-26.9
6-10	0.55	5.55	0.072	0.103	-33.3	-29.0
6-15	0.54	7.12	0.061	0.067	-43.5	-53.8

4.3 DISPLACEMENT RESPONSE

The average peak floor displacement profiles, shown in Figure 6, increases with the aspect ratio. It can also be observed that the wall aspect ratio impacts the shape of the displacement envelope, indicating a relative change between the different displacement mechanisms.

The largest peak roof displacement was obtained in Specimen #6-5, with an average of 28.7 cm. While, the minimum average peak roof displacement in Specimen #6-15 was averaged 23.1 cm. The displacement difference between these two structures showed a reduction of 19.5%. The remaining peak roof displacements are presented in Table 5.

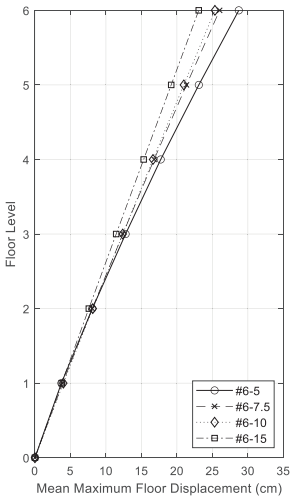

Figure 7: *Average peak floor displacement*

Table 5: *Average peak roof displacement*

#ID	Average Peak Roof Displacement (cm)	Difference (%)
6-5	28.7	-
6-7.5	25.9	-9.7
6-10	25.4	-11.5
6-15	23.1	-19.5

4.4 INTER-STORY DRIFT RESPONSE

Similar to the displacement results, the average peak inter-story drift ratio increased as the wall aspect ratio increased. Additionally, it was verified that the rocking behavior governed the displacement response of the structure with the lowest aspect ratio panels, given by its relatively uniform deformation pattern. In contrast, the structure with the highest aspect ratio panels presented a non-uniform drift ratio distribution, with higher drifts in its upper section, indicating an important presence of bending relative to the rocking motion. The average peak inter-story drift profiles are shown in Figure 7.

The analysis results showed that the maximum inter-story drift ratio was produced in Specimen #6-5, with an average of 1.59%. The lowest drift ratio was observed in Specimen #6-15, with an average of 1.07%. Their relative difference resulted in a drift reduction of 32.7%. The rest of the average peak inter-story drift values and differences are presented in Table 6. Note that these peak values are the maximum observations, regardless of where it was produced (i.e., they are not bound to a specific story.)

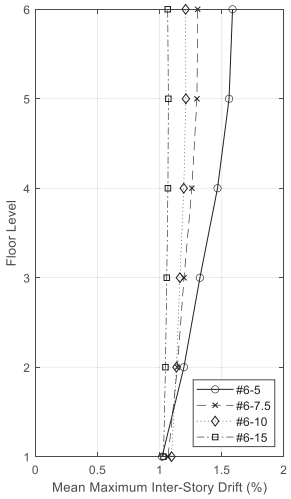

Figure 8: *Average peak inter-story drift ratio*

Table 6: *Average peak roof displacement*

#ID	Average Peak Inter-Story Drift Ratio (%)	Difference (%)
6-5	1.59	-
6-7.5	1.31	-17.6
6-10	1.21	-23.9
6-15	1.07	-32.7

4.5 SHEAR RESPONSE

The shear force results, shown in Figure 8, indicate that the use of longer CLT wall segments reduced the seismic forces into the structure. This patter is observed essentially in the entire structure, and it follows a similar trend as the acceleration envelopes, presented in previous sections. The seismic shear reduction is also a

https://doi.org/10.52202/069179-0347

consequence of the difference on the higher-mode amplitudes.

The largest base shear was observed in Specimen #6-5, with a peak average of 490 kN, while the smallest seismic base shear was on Specimen #6-15 with a maximum average of 358 kN. Their relative difference was a reduction of 26.9%. The rest of the mean maximum base shears are summarized in Table 7.

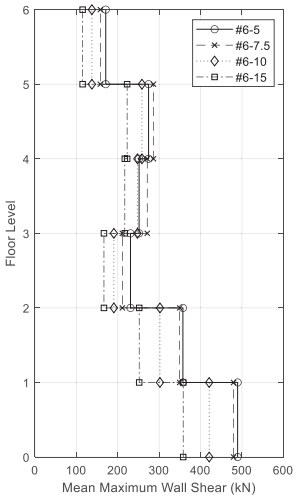

Figure 9: *Average peak wall shear*

Table 7: *Average peak base shear*

#ID	Average Peak Base Shear (kN)	Difference (%)
6-5	490	-
6-7.5	480	-2.0
6-10	421	-14.1
6-15	358	-26.9

4.6 MOMENT RESPONSE

The moment results followed a similar pattern compared to the shear force distribution, as shown in Figure 9, presenting the lowest seismic demand in Specimen #6-15. This performance difference was expected, based on the acceleration and modal amplitude results.

The largest average peak base moment was obtained in Specimen #6-5, with a moment of 3,111 kN-m, while the smallest peak moment was observed in Structure #6-15, with a mean maximum base moment of 2,306 kN-m. The improvement in the response was a reduction of 25.9%. The remaining average maximum base moments are summarized in Table 8.

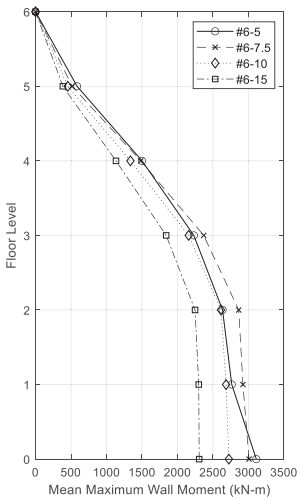

Figure 10: *Average peak wall moment*

Table 8: *Average peak base moment*

#ID	Average Peak Base Moment (kN-m)	Difference (%)
6-5	3,111	-
6-7.5	3,008	-3.3
6-10	2,724	-12.4
6-15	2,306	-25.9

4.7 DAMAGED CLT

The damage analysis also continued with the trend observed for the other performance indicators, showing larger damage in the CLT wall toes in structures with higher aspect ratios. This is a direct consequence of the increase of displacements and moment demands for structures with higher wall aspect ratios, as well as for the reduction in their internal lever arm (to achieve a similar moment, there are required higher strains and stresses at the toes, hence more damage is expected).

The maximum average damage was observed on Specimen #6-5, while the minimum damage was obtained on Specimen #6-15. The average damaged volumes for these two configurations were 18,108 cm^3 and 4,097 cm^3, respectively. The damage difference was a reduction of 77.4%. The remaining CLT damage and their respective percentage differences are summarized in Table 9.

Table 9: *Average damaged volume on CLT wall toes*

#ID	Average Damaged Volume (cm^3)	Difference (%)
6-5	18,108	-
6-7.5	11,930	-34.1
6-10	7,833	-56.7
6-15	4,097	-77.4

https://doi.org/10.52202/069179-0347

5 CONCLUSIONS

The effect of wall segment aspect ratio on the seismic behavior of CLT rocking walls was determined. The results showed that structures with lower aspect ratios (i.e., wider wall segments) have a better seismic performance than structures with narrower segments, due to a reduction of the higher-mode influence on its dynamic behavior, as demonstrated through the Fourier amplitude spectrum. The mean maximum acceleration, displacement, and drift ratio envelopes reduced as the aspect ratio decreased. The internal forces (story shear and moments) presented identical trends as mentioned before. The aspect ratio of the segments also affected the local performance of the rocking walls, exhibiting less damage on the CLT wall specimens with lower aspect ratios.

Based on the findings of this investigation, it is highly recommended to use longer wall panels rather than a series of slender panels coupled with UFPs. However, further investigations are needed to determine the overall upper bound of the wall aspect ratio for this type of systems, also considering the effect of the total building height. This would be crucial to develop new code regulations for CLT rocking wall systems and potentially fully develop its use in mid-rise construction.

The acceleration results showed the highest response in Specimen #6-5, with an average peak roof acceleration of 1.02 g. The structure with the lowest acceleration response was Specimen #6-15, with an average maximum of 0.70 g. Their relative difference was 31.4%. The shape of the acceleration distributions showed a reduction in the whip-action at the upper stories in structures with lower wall aspect ratio.; this also suggested a reduction on the higher-mode contribution, which was confirmed through the frequency analysis.

The Fourier amplitude spectra showed the difference in the frequency content on the roof acceleration response. It was verified a reduction in both the first- and second-mode amplitude in structures with lower aspect ratios. The relative differences between Specimens #6-5 and #6-15 were reductions of 43.5% and 53.8% for the first and second mode, respectively.

Both the displacement and inter-story drift ratio distributions showed that the increase on the wall aspect ratio increased the influence of bending deformation, relative to the rocking motion. It was also verified that structures with higher aspect ratio presented higher displacements and inter-story drifts. The maximum roof displacement and inter-story drift were found for Structure #6-5, with an average displacement of 28.7 cm and 1.59%, respectively. Structure #6-15 presented the lowest average peak displacement and drift ratios, with mean maximum values of 23.1 cm and 1.07, respectively. Their respective relative differences were 19.5% for displacements, and 32.7% for drift ratios. It was also verified that the structures presented in this study did not exceed the drift limit of 2.0% specified in ASCE 7-22 for design level earthquakes.

The internal forces presented similar trends, showing a general decrease as the aspect ratio decreases. The maximum base shear and base moment were observed in Specimen #6-5, with values of 490 kN and 3,111 kN-m. The minimum base shear and moment were found on Structure #6-15, with values of 358 kN and 2,306 kN-m. Their relative differences were reductions of 26.9% and 25.9% for shear and moment, respectively.

The damage on the CLT walls increased as the aspect ratio increased. Specimen #6-5 exhibited the largest average damage, with a volume of 18,108 cm^3, while Specimen #6-15 presented the lowest damage, with an average of 4,097 cm^3. Their relative difference was 77.4%.

THE ROLE OF INTERMODULAR CONNECTIONS IN THE GLOBAL BEHAVIOR OF HIGH-RISE MASS TIMBER BUILDINGS

Juan S. Zambrano Jaramillo[1] and Erica C. Fischer[2]

ABSTRACT: The use of mass timber as a pre-engineered product combined with prefabrication processes to assemble volumetric modular units contributes to optimizing the construction by reducing time, waste, and the weight of the structures for high-rise buildings located in high seismic regions. The performance of modular buildings subjected to lateral loads demonstrated that the connections between the modules play an important role in the diaphragm behavior and the structural response of the buildings. To study the building response, a parametric analysis was performed on 9-, 12-, and 18-story mass timber modular buildings simulated in OpenSees, to identify the influence of the stiffness of the intermodule connections and their location between the modular units. The analysis identified key parameters that govern the diaphragm behavior and how it affects the building's performance. The results demonstrated that the horizontal translational stiffness of the intermodular connections controls the diaphragm behavior thereby controlling the classification of the diaphragm as rigid, semi-rigid, and flexible diaphragm ranges for modular buildings. Additionally, the location of the intermodular connection modifies the diaphragm deflections and the envelope of the column force demands for the gravity system.

KEYWORDS: Mass timber, modular construction, intermodular connections, stiffness, high-rise buildings.

1 INTRODUCTION

1.1 INTRODUCTION TO MODULAR CONSTRUCTION AND MASS TIMBER

The architecture, engineering, and construction industry has acknowledged a shared commitment to increasing the speed of construction [1]. With the emergence of fabrication technology, including robotics, pre-fabrication of structural members and systems is possible. This results in the ability of structural frames or modules to be fabricated prior to arrival on site. Modular building construction takes advantage of this pre-fabrication ability and has been increasing in popularity to reduce the housing demands [2]. In most cases, these modular buildings use light steel frames to assemble modular units for residential buildings, and their dimensions are mainly limited by transportation requirements [3].

The benefits of modular buildings are reduction in construction waste, noise, and cost. Research has shown that 43% of the manufacturing waste can be recycled in a factory environment, resulting in waste of 5% of the total weight of the building compared to traditional construction with an average of 10 - 13% [4]. The use of modular units results in a 70% reduction in the number of trucks used to deliver construction materials to the site, which reduces the construction noise. Lastly, there is a 25 - 50% reduction in construction time of a mass timber building as compared to conventional building construction materials [4,5]. For all these reasons, mass timber modular buildings have the capability of increasing the speed of construction, reduction of waste, and reduction of noise during construction.

Modular building construction requires additional planning during the schematic design and design development phases to coordinate the floor plan such that it meets the functionality requirements of the building based on different arrangements of the modular units. Because of this additional planning, researchers have investigated optimal designs of the modular units for different occupancies [6,7]. Previous research shows that buildings with both office and residential occupancies can be developed using steel modular construction.

Connections are key elements that define the performance of modular buildings and modular units have three main types of connections [8]: intramodule, intermodule, and module to foundation connections. Intramodule connections connect the structural components within the module and are used to assemble the volumetric unit. These connections are designed to provide module stability during transportation and construction and to resist the gravity load demands. Intermodule connections constitute the module to module connection and transfer horizontal and vertical forces. These connections are designed for ease of construction and maintenance. Previous researchers have investigated the behavior of

[2] Dr. Erica Claire Fischer, Oregon State University, United States, erica.fischer@oregonstate.edu

https://doi.org/10.52202/069179-0348

these types of connection in steel modular buildings and concluded that they can greatly influence the global behavior of the building [9,10]. The last type of connection is the module to foundation connection which transfers the vertical and lateral loads of the gravity system to the foundation. These connections are designed to restrain displacements and give support at the base of the building so each column can have the required conditions to develop its full strength. Concrete is mainly used for the foundation, and based on previous studies in steel modular buildings, these connections require additional on-site work due to welding and precautions to avoid corrosion [8].

Mass timber as a construction material is becoming more popular as a building construction material. From an analysis by Svatoš-Ražnjević et al. [11], the number of mass timber buildings and the number of stories in those buildings has increased between 2000 - 2021. Of the mass timber buildings constructed during this time, 7.3% of the buildings were classified as using volumetric units [11]. Fernandes Carvalho et al. [12] performed a case study analysis of nine modular mass timber buildings. These structures are used as schools, apartments, and hotels. All of them use either linear, planar, or volumetric modular units to assemble the mass timber structures. A hybrid high-rise hotel building was assembled using CLT panels, glulam beams and columns, and reinforced concrete walls up to 24 stories [13]. One of the major barriers to constructing more modular buildings using volumetric units is data on the behavior of inter and intramodular connections, how to simulate the building under lateral load demands, and proof-of-concept connection types, particularly for high-rise modular buildings.

1.2 PREVIOUS RESEARCH ON MODELING DIAPHRAGMS MASS TIMBER BUILDINGS

To simulate high-rise mass timber buildings under varying lateral force demands, researchers have used finite element (FE) modeling methodologies. However, previous researchers have utilized different methods of modeling mass timber diaphragm behavior.

Ávila et al. [14] simulated CLT diaphragm seismic behavior in a high-rise building with reinforced concrete shear walls. They concluded that using a rigid versus flexible diaphragm impacted the demands in the shear walls and the diaphragms themselves such that a rigid diaphragm produced larger demands in the walls than a flexible diaphragm; however, a rigid diaphragm produced smaller diaphragm demands than a flexible diaphragm [14]. Blomgren et al. [15] also studied CLT diaphragm behavior under seismic loads using the data from a two-story mass timber building tested at the University of California San Diego shake table. The conclusions of this research were that the ratio of the lateral stiffness of the CLT panels to the rigidity of the lateral system can influence whether the diaphragm behaves like a rigid, flexible, or semi-rigid diaphragm.
In general, diaphragms are designed as elastic elements so they can resist gravity loads and transfer the lateral loads without any substantial damage [16]. For code-based design, the diaphragm flexibility must be defined to simulate force distribution and to account for differential displacements of the diaphragm that may occur depending on its flexibility. For modular systems, diaphragms play an important role in the building behavior. During the construction stage, they provide stability to the module while as part of the building they transfer the force to the lateral system [17]. However, there is limited research on how to simulate modular building diaphragms, particularly considering the stiffness of the intermodular connections.

Diaphragms are classified based on their deformation capacity. Specifically, diaphragms are classified by the ratio between the maximum computed in-plane deflection of the diaphragm when subjected to lateral loads and the average drift of the elements of the seismic force-resisting system of the story below the diaphragm under consideration [18]. This ratio can be used to classify the diaphragm as rigid, semirigid, or flexible. The code-prescribed limit for rigid diaphragms is the ratio less than or equal to 0.5, flexible diaphragms greater than 2.0, and semirigid or stiff diaphragms between 0.5 and 2.0. While this diaphragm classification was developed for conventional construction, it has been applied to modular steel buildings in previous research of steel modular buildings [19] and therefore used by the authors.

Previous researchers have explored how intermodular connections can have an impact on the global behavior of a building. Chen et al. [20] developed and tested a steel intermodular connection that was later simulated by Peng et al. [21] to identify the behavior of steel modular buildings under seismic demands. They concluded that the fundamental period of the structure is 14% smaller when the intermodular connections are assumed to be rigid compared to the stiffness obtained from the tested steel connection that add more flexibility to the frame model.

Lacey et al. [22] and Fathieh [23] explored how the stiffness of the intermodule connections affected the structural response of modular buildings. Both researchers used individual spring elements to simulate the horizontal and vertical components of the connections and concluded that the translational stiffness of the intermodule connection had the biggest influence on the global structural behavior of the building. A connection with high translational stiffness resulted in a building with a smaller period and larger base shear forces, while a connection with smaller translational stiffness resulted in larger inter-story drifts. In addition, the translational stiffness of the intermodule connections has shown to increase the modal periods of the structure and cause higher mode participation [19]. The rotational stiffness of the intermodule connection showed to have little effect on the global building behavior [22,23].

This paper aims to explore how to simulate and design mass timber high-rise modular buildings by examining how the structural behavior was influenced by the stiffness of the intermodular connections, the

https://doi.org/10.52202/069179-0348

intermodular connection location, the geometric transformation type, and the diaphragm property definition. Specifically, the objectives of this research are to: (1) develop a numerical modeling methodology to simulate mass timber high-rise modular buildings; (2) explore the influence of the stiffness of the intermodular connections on the diaphragm behavior of mass timber modular buildings; and (3) investigate the influence of intermodular connection and its location on the global structural response of mass timber modular buildings.

2 DESIGN DETAILS AND MODEL DESCRIPTION

2.1 BUILDING DESIGN

To achieve the research objectives, the authors used 9-, 12-, and 18-story modular buildings designed per to ASCE 7 [18] and IBC [24]. The buildings were assumed to be located in Seattle, Washington with site class D. Residential occupancy was considered to calculate the seismic design loads and a risk category II was assumed for the analysis. The gravity system of the structure used mass timber modular elements designed as volumetric units (Figure 1), and for the lateral force-resisting system double core reinforced concrete shear walls were located at the quarter points of the structure length (Figure 2). The building was designed with nine load combinations (Table 1), including seismic load cases. The loads considered are dead load (D), live load (L) due to residential occupancy and at the roof level (Lr), snow load (S), and earthquake load (Eh). The earthquake loads were calculated based on the equivalent lateral force method (ELF).

Table 1: *Load combinations for Allowable Stress Design (ASD)*

Comb	Load Combinations
1	D
2	D + L
3	D + Lr
4	D + S
5	D + 0.75L + 0.75Lr
6	D + 0.75L + 0.75S
7	$1.0D + 0.7E_h$
8	$1.0D + 0.525E_h + 0.75L + 0.75S$
9	$0.6D + 0.7E_h$

The gravity system was designed considering a corner-supported modular system, similar to previous research [4,7]. Each module consisted of four glue-laminated (glulam) columns, four perimeter glulam beams at the floor level, and four at the ceiling level. The floor was a cross-laminated timber (CLT) panel which spanned between the glulam beams and which was assumed to behave as a discrete diaphragm for each module. At the ceiling level, ponderosa pine CLT panels were used to ensure the stability of the module during the transportation and building construction. Since this panel did not resist gravity or lateral load demands, the authors chose a low grade CLT panel. Ponderosa pine is a biproduct of forest restoration for wildfire mitigation in the western states and exploring its usage within building construction would improve the sustainability of the building itself [25].

The superimposed dead load was 0.48 kN/m2 considering finishes at the floor levels. Live load was 2.40 kN/m2, which corresponds to a residential live load per IBC [24], 0.48 kN/m2 was applied at the ceiling level, and 0.96 kN/m2 for a non-occupied roof. The snow load for Seattle was 1.20 kN/m2 [26]. All the mass timber elements were Douglas-Fir and the dimensions were selected from commercially available material [27].

The frame elements used to assemble the modular units of the gravity system were designed per the National Design Specification (NDS) [28]. The centerline dimensions of the volumetric modules (Figure 1) were 3048 mm wide and 6096 mm long, with a total height of 4572 mm. For the 9- and 12-story buildings, the columns were 216 mm by 222 mm. The 18-story building used 260 mm square columns. The floor beams were 130 mm by 337 mm, while the ceiling beams were 130 mm by 298 mm. The floor beams and the ceiling beams were located such that there was a clear distance of 305 mm between the top of the ceiling and the bottom of the floor beam of the module above. This interstitial space was for plumbing and HVAC ductwork throughout the building and a common design for modular buildings. The CLT panel for the floor level was a 5-ply V2M1.1 grade 175 mm thick, and the ceiling panel was a 3-ply 105 mm thick CLT panel.

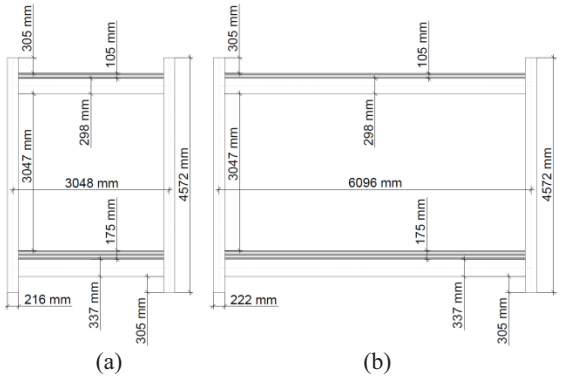

Figure 1: *Module elevation a) in the short direction, b) in the long direction*

Using the designed mass timber modules, a floor plan was proposed based on a double-core shear wall system, similar to the Brock Commons Student Residence project [29]. The proposed floor plan and layout consisted of 41 modules per story, arranged in three rows in the E – W direction (Figure 2). The first and third rows contain 15 modules each while the second row contains 11 modules. At the quarter point along the length of the building, the concrete cores were located in a space equal to that of two modules (Figure 2). All the building cases have 457 mm thick concrete shear walls arranged in a C shape with an opening toward the center of the building. The wall thickness was selected to satisfy the drift limit

requirements in both directions [18]. The modules are oriented with the longest side in the N – S direction, creating a space for the cores with a width-to-length ratio close to unity. The goal of the modular arrangement was to distribute the modules in a way to avoid structure irregularities or inherent torsion while still maintaining functionality of the building.

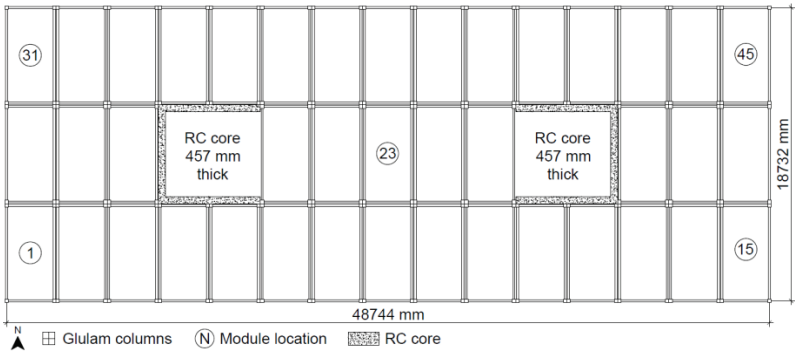

Figure 2: *General plan configuration for modular buildings*

2.2 NUMERICAL MODELING

2.2.1 Modeling geometry

Three-dimensional (3D) finite element models were developed for the 9-, 12- and 18-story mass timber modular buildings using the open-sourced finite element program, OpenSees [30]. All of the mass timber elements were simulated using elastic beam-column elements for the beams and the columns. Zero-length elements were used at the base of the columns to simulate different boundary conditions and three elastic beam-column elements were used to simulate the interstitial space (Figure 3). The beams of the module used zero-length elements at the ends to provide a pinned boundary condition representing the intramodule connection. Finally, a rigid diaphragm property was assigned to the floor level of each module.

To connect the modules together throughout each floor, the intermodule connections were simulated using two-node link elements. This modeling methodology was similar to the modeling methodology implemented by previous research on steel modular buildings [7,22,31]. The two-node link spanned between the column nodes of each module on the same floor. To connect modules together between floors, a rigid zero-length element was used thereby assuming that load was always transferred vertically between the floors and continuity of the module columns was achieved through the connection. In addition, all intermodule connections remained elastic throughout the analysis. The benefit of considering link-type elements in the modeling process was the capacity to explore the impact of each DOF on the global behavior of the building. In addition, each DOF can be defined by assigning elastic materials that can be updated to include material nonlinearity.

Two locations for the intermodule connection were considered (Figure 3). The first location (Figure 3a) considers the intermodule connection (and two-node link) coinciding with the location of the floor beams. The second location (Figure 3b) considers the intermodule connection (and two-node link) located at the column joint. Both locations were considered to compare how the location of the intermodule connection influences the building behavior. For the remainder of the paper, the location shown in Figure 3a will be referred to as *the case with the link at the diaphragm level* and Figure 3b will be referred to as *the case with the link at the column joint location*.

The concrete shear wall elements were simulated using elastic beam-column elements with a fixed base. The dimensions of the walls depended on the location, for the E-W walls two elements were used for each side of the core, while in the N-S direction only one element was used. Connections between the modular elements and the concrete walls were modeled with two node link elements. Because the main objective of this study is to examine how the stiffness of the intermodular connections influences the global behavior of the building, the concrete walls were assumed to be undamaged and uncracked throughout the analysis. Therefore, only the elastic concrete material properties were utilized with an inertia reduction ratio of 0.70. For the purposes of this research, the intramodule connections were considered rigid enough to remain elastic and satisfy the gravity demands for the applied loads in each module

Second-order effects were included through corotational geometric transformation for all elements to take into account the influence of the tolerance limits of the modular elements during the construction process [32].

All the buildings were modeled using elastic uniaxial materials and manually adjusting the stiffness of the two-node link elements used to simulate the intermodule connections to perform the parametric analysis and evaluate the influence of each DOF of the connection on the modular building behavior. Glulam properties for elastic beam-column elements were used from commercial providers [27].

https://doi.org/10.52202/069179-0348

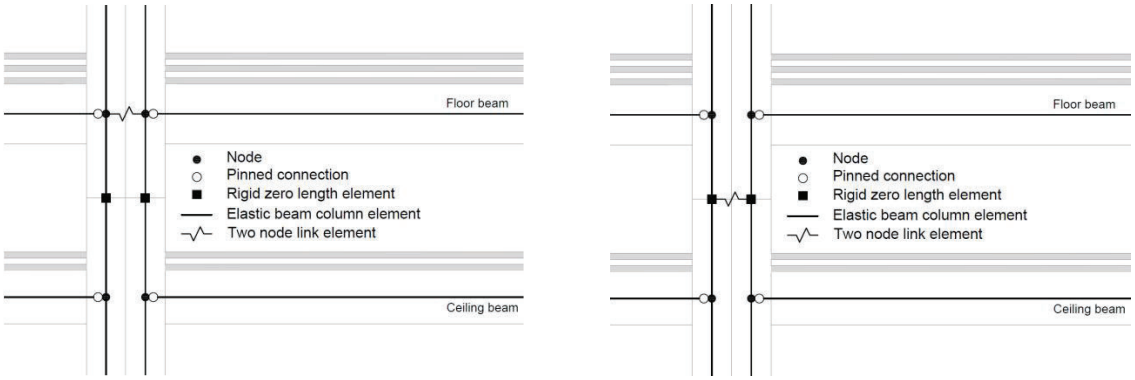

Figure 3: *Horizontal link located a) at the diaphragm level, and b) at the column join level*

2.2.2 Diaphragm modeling

The diaphragm of the case study buildings was assumed to be located at the floor level of the modules. The ceiling level had lower stiffness than the floor because ponderosa pine CLT was utilized for the ceiling panels. CLT diaphragms were considered to behave as rigid elements under design-level earthquake loads [33]. Therefore, the floor panels for each module were considered discrete elements with a rigid diaphragm property to avoid in-plane deformation. This modeling methodology also contributed to the analysis of the structural behavior of the entire floor diaphragm based on the stiffness of the intermodule connections.

The authors assumed a symmetric connection in the X and Y direction. With a parametric analysis the stiffness of the connections was modified in the translational and the rotational DOF to measure the diaphragm deflections. ASCE 7 [18] methodology was used to classify the building diaphragms according to their in-plane deflection compared to the lateral system deflection when both are subjected to lateral loading. The authors used the maximum deflection ratio to classify the diaphragm of each one of the simulations.

2.2.3 Gravity and lateral loads

The gravity loads were included in the model as distributed loads along the module beams based on an equivalent tributary area at the floor and the ceiling beams. Self-weight was assigned as concentrated loads directly to the nodes for columns and the reinforced concrete shear walls. The structure effective mass was considered to be the total structure self-weight plus the superimposed dead load. The mass was assigned to the nodes at the floor and the ceiling level as concentrated mass. Lateral loads were assigned to the model based on the approaches used to simulate the diaphragm. When discrete diaphragms are assigned to each module, the lateral loads were uniformly distributed between the nodes of the columns located at the floor level. This approach allows to simulate the loading distribution required for semi-rigid or flexible diaphragms. In the case of a rigid diaphragm, the same uniform load distribution was applied.

2.3 SENSITIVITY ANALYSIS

A sensitivity analysis was performed to examine the influence of the intermodular connection location (Figure 3) and the influence of the stiffness of each DOF of the intermodular connection. This sensitivity analysis was also performed to increase computational efficiency. The results of the sensitivity analysis were carried through in the remainder of the investigation described in this paper. To perform this sensitivity analysis, a base model was defined. The base model consists of a building with rigid intermodular connections and a rigid diaphragm property assigned to each module in the building. The ranges of considered stiffnesses of the column links are summarized in Table 2.

Table 2: *Parameters analyzed in the sensitivity analysis*

Properties	Direction	Condition/Range
Link location	--	Diaphragm or Column joint
Horizontal links	X, Y	Range: 1.75×10^{-1} – $1.75 \times 10^{+8}$ kN/mm
Rotational links	θX, θY, θZ	Pinned or Fixed

The ranges of stiffnesses provided in Table 2 were used to evaluate the influence of intermodule connection stiffness on diaphragm behavior, specifically the influence of the translational DOF stiffness. The horizontal translational stiffness (X and Y) was adjusted manually to fixed values while the remaining DOF of the connections were assumed to be rigid. The deformation ratio of the diaphragm, the modal periods, and the inter-story drifts of the buildings were calculated for each stiffness value.

3 RESULTS AND DISCUSSION

3.1 INTER-STORY DRIFTS

For all case study buildings and both locations of the intermodular connections (Figure 3), the maximum inter-story drift was below 1.5% (Figure 4). The inter-story drift increased when the intermodular connections were located at the column joint location. Analyzing each location independently, the buildings with connections at the diaphragm level, had higher inter-story drifts in the X direction than in the Y direction, while the buildings with

connections at the column joint locations had larger drifts in the Y direction than in the X direction. The intermodule connection location also influenced the location of the maximum inter-story drift (Figure 4). For the buildings where the intermodular connections are located at the column joints, the maximum inter-story drift ratio was located at about 60% of the height of the building (Figure 4); whereas when the intermodular connection was located at the diaphragm, the maximum inter-story drift ratio was located at about 80% of the height of the building (Figure 4).

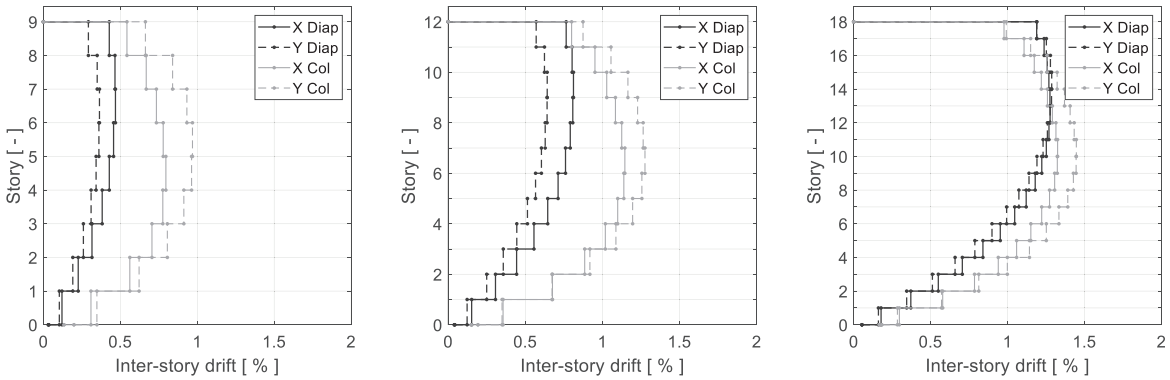

Figure 4: *Design inter-story drifts for the diaphragm and column joint link cases: a) 9-story, b) 12-story, and c) 18-story*

3.2 DIAPHRAGM BEHAVIOR

Regardless of the location of the intermodule connection, as the translational DOF stiffness of the connection decreased, the diaphragm deflection increased exponentially (Figure 5). Based on static analysis results (Figure 5), the 9- and 12-story building required high translational stiffness for the intermodule connection to obtain the same diaphragm deflection ratio as the 18-story building with a less stiff connection. This horizontal stiffness of the intermodular connections influence the deflection of the diaphragms and requires a connection with larger translational stiffness to reach a certain deflection with shorter buildings. This response is opposite to the common behavior of the stiffness of traditional lateral force resisting systems (LFRS) that requires higher stiffness for taller buildings to satisfy the building drift demands.

The difference in diaphragm deflection based on the location of the intermodular connection is more pronounced for the 9-story building (Figure 5a), than for the 18-story building (Figure 5c) and for stiffer connections, than for more flexible connections. In general, buildings with intermodular connections at the column joint location require higher connection stiffness to obtain a rigid diaphragm property definition. On the contrary, regardless of the intermodular connection location, similar connection stiffnesses were required to obtain a semi-rigid or flexible diaphragm definition. Based on the diaphragm behavior shown in Figure 5, the authors assumed a rigid diaphragm could be obtained with an intermodular connection stiffness of 100 kN/mm, regardless of the building height as this connection stiffness results in diaphragm deflection less than 0.5.

The building in-plane configuration, particularly of the LFRS, was observed to have some influence over the diaphragm stiffness. All the cases were analyzed with the same building geometry, however, in the Y direction, when the lateral loads are applied on the long side of the building, the diaphragm deflection is greater than the deflection in the X direction for the same translational stiffness. This is because for the case study building, in the X direction, the lateral displacements are controlled by four shear walls, while in the Y direction, two shear walls control the displacements.

In addition to diaphragm deflection, the authors explored the impact that intermodular connection translational stiffness and location has on the model translational periods in each direction (Figure 6). The results (Figure 6) show that the translational periods are constant for connection stiffnesses greater than 100 kN/mm, which correspond to a rigid diaphragm (deflection ratio less or equal to 0.5). At connection stiffnesses less than 100 kN/mm, the building periods increase with small reductions in the translational stiffness of the intermodule connections. The location of the intermodule connection also has an impact on the translational period of the building. When the intermodule connection is located at the column joint, the buildings have a larger period than when the intermodule connection is located at the diaphragm. This result was observed regardless of building height.

Further analysis considered the modal shapes of the buildings to determine the direction of the translational modes and define if they are affected by the translational stiffness of the connections. Comparing the translational period in the X and Y direction, the same behavior occurred in all the story cases such that the buildings with the connections at the diaphragm change the direction of the fundamental period to the orthogonal direction in the semirigid range. For instance, in Figure 6 the influence of the location of the connection and its stiffness was important over the structure period. For the values at the

https://doi.org/10.52202/069179-0348

bottom of the curve the differences in the periods of the buildings were in some cases more than 1s while for the stiffer cases at the top, the differences remain in less than 0.5 s for all the buildings. For the column joint connection cases, the direction of the fundamental period remained the same for the entire range.

While Figure 5 and Figure 6 show the results of modifying the translational stiffness of the intermodule connections, Figure 7 shows the results of modifying the translational stiffness and the rotational DOF of the intermodule connections. The translational stiffness of the intermodule connections were varied in addition to the rotational DOF varying between pinned and fixed. This variation was performed in in both directions and with both locations of the intermodule connection. In the case of the fixed rotational DOF, the results shown in Figure 7 are the same as those shown in Figure 5 for comparison.

In the X and Y directions (Figure 7), there were small differences between the models with fixed and pinned rotational DOF when the connections were located at the diaphragm level (17.6% for the X direction and 13.2% for the Y direction, on average). However, when the intermodule connection is located at the column joint, the models with pinned rotational DOF had larger diaphragm deflections, on average 25.3% larger in the X direction and 29.8% larger in the Y-direction than models with fixed rotational DOF. In some cases, the location of the intermodular connection changed the diaphragm classification from rigid to semi-rigid. This effect was less pronounced for the 18-story building than for the 9-story building.

The simulation results in Figures 5 – 7 demonstrate that the translational stiffness of the intermodular connections had more of an influence on the diaphragm behavior than the rotational stiffness. This conclusion was consistent with previous research on modular buildings [22]

3.3 ELEMENT FORCES

The modular building design was implemented using an envelope of forces within the structural elements for the two intermodular connection locations (Figure 3). The envelopes of the design forces are shown in Figure 8 for the 12-story building. The forces in the other two buildings were proportional to their height.

The location of the intermodular connection did not substantially influence the axial force demands in the gravity columns (Figure 8a). Rather, there was an 8.7% difference between the axial force demands when the intermodular connections were located at the diaphragm as opposed to the column joint. However, the intermodular connection location did influence the shear demands within the gravity columns (Figure 8b and c). The shear force envelopes in the connection region for when the intermodular connection was located at the diaphragm was on average 33.6% lower in the strong axis (Figure 8b) and 66.8% lower in the weak axis (Figure 8c) than when the intermodular connection is located at the column joint. Similarly, the moment demands in the gravity columns were on average 13.2% lower in the weak axis (Figure 8d) and 26.4% lower in the strong axis (Figure 8e) when the intermodular connection was located at the diaphragm than at the column joint. Columns strong axis is located parallel to E-W direction (Figure 2).

4 CONCLUSIONS AND FUTURE WORK

This paper presented the results of the analysis of a 9–, 12-, and 18-story mass timber modular building with two reinforced concrete cores. 3D elastic models were developed in OpenSees and used to evaluate the influence of the stiffness and location of intermodule connections on the global response of modular buildings under combined gravity and lateral loads. The modeling methodology developed in this research and summarized within this paper can be utilized to simulate high rise mass timber modular buildings. The numerical simulation approach with beam and column elements to assemble the volumetric units, generated similar response for mass timber modular buildings compared to steel modular buildings reported in previous studies. Therefore, the authors can conclude that the structural behavior described in this paper and the conclusions made herein can be generalized for modular construction independent to the material used to simulate the modular units.

The stiffness of the translational DOF of the intermodular connections showed an inverse exponential relation with the diaphragm deflections for all the building heights. However, taller buildings required a less stiff connection than shorter buildings to have a rigid diaphragm behavior. Figure 5 can be utilized by designers to determine the required connection stiffness to obtain specific diaphragm flexibility given a building height. Simulations demonstrated that the period of mass timber modular buildings remains constant if the diaphragm can be classified as rigid (Figure 6) regardless of the building height, however the building period increases with small reductions of the translational stiffness of the intermodule connections when the diaphragm is classified as either semi-rigid or flexible.

https://doi.org/10.52202/069179-0348

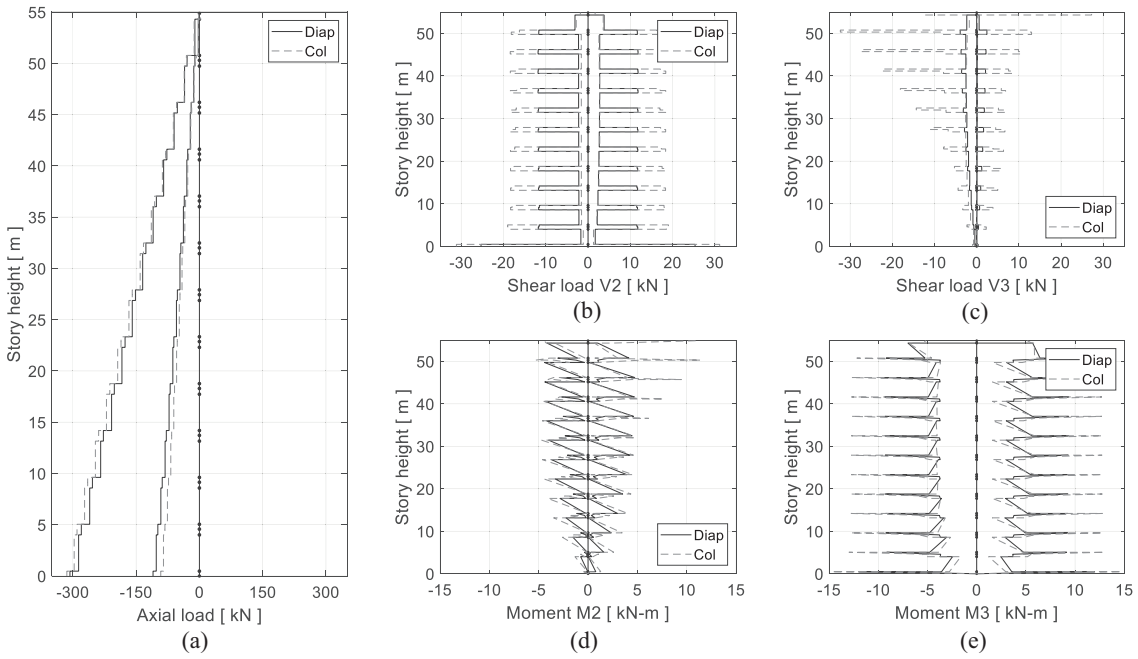

Figure 8: *Design element forces for 12-story buildings: a) axial load, b) shear load in the strong axis, c) shear load in the weak axis, d) moment around the weak axis, e) moment around the strong axis*

The rotational DOF of the intermodule connections has little effect on the diaphragm deflections compared to the influence of the translational stiffness. When the location of the connections was considered, the rotational DOF of the intermodule connections showed a slight increase of the diaphragm deflections for the buildings with the connections at the column joint.

Two different locations of the intermodule connections for the modular buildings were explored in the analyses. The building performed better when the connection was located at the diaphragm level. Specifically, the periods and drifts distribution were influenced by the location of the connection. When the intermodule connection was located at the column joint, the connection required larger translational stiffness to obtain lower diaphragm deflections in all the buildings. In addition, when the intermodule connection was located at the column joint, the shear and moment demands in the column elements were higher.

To identify a better relation between the diaphragm flexibility and the in-plane configuration of the building, additional analyses should be performed to compare different model geometries, however, it is considered out of the scope of the current research. Future research on this topic should also explore the dynamic response of the structures to verify the building behavior under earthquake hazards and define the required strength to design and test the inter-modular connections.

A Comparison of Punching Shear Design Approaches for Point Supported CLT Panels

Christian Slotboom[1], Carla Dickof[2], Robert Jackson[3]

ABSTRACT: The following study examines different methods of punching shear design for point supported Cross Laminated timber (CLT) panels. A literature review was completed, summarizing CLT rolling shear capacity, as determined in both European and North America research as well as code and material standard documents. Analysis methods for calculating internal stresses in CLT slabs were then reviewed, with an emphasis on simplified design equations. Several design checks were then completed by comparing predicted capacity to tested strength for CLT panels from existing experimental programs. Predictions from each method were compared to actual panel capacities from testing, and it was found the methods used predicted failure at approximately 3x the input load or higher for the specific panel examined. A parametric study was completed where a number of panels were analysed using the different analysis methods outlined. The parameters studied include panel number of spans, length, width, grade, thickness, and support size. It was shown that simplified analysis methods make predictions that were comparable to FEM predictions, but FEM results varied more with respect to these parameters. It was also shown that the support stiffness was a significant parameter on the distribution of shear forces and the peak model forces observed.

KEYWORDS: Tall wood buildings, CLT Floors, Point-supported floors, two-way floor action, Punching Shear, Rolling Shear.

1 INTRODUCTION

Recent changes to the National Building Code of Canada [1] and International Building [2] have increased height limitations on tall timber buildings up to 12 and 18 storeys respectively. These tall timber provisions accommodate a quickly growing segment of the market, one with many benefits such as decreased embodied carbon in buildings and shorter construction times. One structural system gaining popularity is point supported Cross Laminated Timber (CLT) a gravity system where panels are supported directly on columns without intermediate beams. Buildings using the point supported CLT structural system minimize floor assembly depth. They also reduce material volumes and construction timelines due to the limited components.

The force distribution of point supported CLT differs from typical CLT on beams, and shear forces near the supports are much higher. As such, this type of system is more frequently governed by shear design instead of bending or deflection. While CLT has been studied significantly over the past 20 years, there is minimal code guidance for the design of CLT in this condition. One prominent building in North America using point supported CLT panels is TallWood House at the University of British Columbia [3], where physical testing of full scale CLT panels [4] was used to validate the design of the point supported structural system.

Since the UBC TallWood House was completed, a number of research programs have studied point supported CLT, evaluating both the rolling shear strength of CLT and analysis methods to assess internal stresses. However, few studies to date have compared the predictions made by different design methods. To help address this knowledge gap, the following paper reviews various methods to determine the capacity and demands for CLT punching shear, and compares their predicted results. The analysis and capacity methods examined were applied to a design example where a number of design cases are considered on an experimentally tested panel. Finally, a parametric study was used to examine the effect a wide range of variables on panel response.

2 CLT PUNCHING SHEAR CAPACITY

There are two significant parameters for point supported CLT: the rolling shear strength (f_s), which describes the strength of the base CLT fibre; and the punching shear amplification factor (k_s), which increases the base strength of CLT near columns to it's punching shear strength (f_p). A summary of the rolling and punching shear amplification of CLT is outlined in the following section.

2.1 ROLLING SHEAR STRENGTH

In North American material standards and CLT fabrication standards "specified strength in rolling shear, fs, is taken as approximately 1/3 of the specified strength in shear, f_v, for the corresponding species combination" [5,6]. The rolling shear strengths specified in the fabrication standards are consistent with this rule instead

of being developed based on test results in material studies.

The rolling shear strength of CLT can be determined experimentally using either inclined direct shear test or four point bending test. Inclined shear tests load a small specimen of CLT in shear directly through a single layer oriented for rolling shear. Many tests on different European species of wood were completed by Erhert et al. [7,8]. It was noted that the strength of CLT was influenced by the aspect ratio of the boards used. Other studies using inclined shear tests include Wang et al. [9], Mestek [10], and Muster [11]. Four-point bend tests load a CLT specimen in bending to failure. The internal stress is indirectly determined using an analytic or numerical assessment of the CLT beam based on the known shear failure load and the CLT layup. Several studies used this method on European [12], Asian [13], Oceanic [14] CLT. While the experimentally measured rolling shear strength varies, impacted by parameters such as species, width-to-depth ratio of the lamella, etc., strengths reported for softwood have been shown within the range of 0.8MPa to 2.0MPa. Table 3 summarizes the 5th percentile strengths observed in different studies and compares them to the characteristic rolling shear strength specified by the material standard CSA O86. To be compared with the short-term test results with the CSA O86 [5] values have a short term load duration factor of 1.15 applied to the standards specified value.

Table 1: *Comparison of 5th percentile strength with CSA 086 code values.*

Reference	f_s (MPa)
CSA O86 SPF [6]	0.50
Wang et al. [9]	0.76
Ehrhart (2015) [7]	1.51
Mestek (2011) [10]	1.47

2.2 PUNCHING SHEAR STRENGTH

Point supported CLT is loaded with a more complex load path than those used in rolling shear tests. The punching shear strength of CLT can be predicted using direct punching tests where a point load is applied to a CLT panel supported or 3 or 4 sides. Based on the ultimate strength observed in testing, the internal shear stresses are determined using analytical methods or numerical methods such as FEM models. Recent studies [10,11,15] have shown that the stress predicted at failure corresponds to a higher shear capacity than the observed base rolling shear strength. Mestek [10] noted that point supported CLT specimens failed at internal stress 1.6 times the predicted capacity associated with base rolling shear strength. Similar increases in strength were noted by Bogensberger et al. [15] and Muster [11].

Possible factors contributing to the observed strength increase include additional confinement from compression, the restraining effect of top and bottom layers, and nonlinear redistribution of forces at failure. Bogensberger proposed a nonlinear strength model of CLT model that could account for the observed higher shear stress [15]. The effect of compression on rolling shear strength was observed by Mestek [10], where the shear strength observed where compression was applied to inclined shear specimens was consistently higher.

Based on the observed data, a draft Eurocode document [16] proposed a factor, k_p=1.6, to increase the base rolling shear strength for punching shear in CLT. In a later study, Muster [11] proposed decreasing k_p to 1.3 at supports at panel edges.

3 POINT SUPPORTED CLT ANALYSIS

Internal stresses can be estimated using ether finite element models, or simplified design equations. The following sections highlight existing methods used to predict demands in CLT panels.

3.1 FINITE ELEMENT MODELS

Three types of Finite element models (FEM) have primarily been used for analysis and design of CLT in punching shear:

- Solid 3D element models.
- Shell 2D element models.
- Beam models using the shear analogy.

Solid 3D models are the most detailed analysis approach of the above three. Each layer of wood is modelled with interaction properties between layers defined. These models can show complex behaviour such as the effect of edge glue, the contact stresses between layers or supports, and the interaction between bending and shear forces. Internal stresses are generally read directly from FEM models. Solid models have been used in a number of studies [10,11,15] to predict internal panel stress, or compare to other design methods in research.

Shell element 2D models represented the CLT with either an orthotropic shell element with equivalent section properties, or a layered shell element. In layered shell elements, stresses can be extracted from layers directly, and some software products, such as Dulbal's RFEM, have layered shell representations of CLT [17]. Stresses through the depth of the panel are then calculated based on established analytical models such as beam shear models. If orthotropic shell elements are used, then stresses are calculated using a section analysis.

Muster [11] presents a modelling approach where 2D shell provided similar stresses to 3D finite element models. In this approach, the supports are modelled as springs with a spring stiffness tuned so that bending stresses were similar between the two models. The simplicity of 2D shell element modelling makes this method attractive to practicing designers.

A grid of beam elements in conjunction with the shear analogy method can also be used to model point supported CLT. This method was used by Mestek [10] to determine the distribution of shear forces on column supports, in lieu of the solid 3D model or a calibrated 2D shell element model. Girder-girder models avoid the extreme stress concentrations that can occur in solid or shell element models.

https://doi.org/10.52202/069179-0349

3.2 SIMPLIFIED MODELS

In addition to FEM, a number of simplified analysis methods have been proposed. Simplified analysis methods typically first determine shear forces on each face of a column, then find internal stress using those forces. The accuracy of these methods is generally determined by comparing to FEM analysis. Three simplified analysis methods were considered in this study:

- Tributary Area simplified method [3].
- Mestek's simplified method [10].
- Muster's simplified method [8].

The Tributary Area simplified analysis method was proposed in a study for the UBC TallWood House [3]. This method determines column face forces (V_i) using associated tributary area. Internal stresses, (τ_i) are then evaluated based by evenly distributing force across the width of the effective support, then using beam bending equation as described in equation 1. The effective depth (d_i) is taken as the height of CLT between layers longitudinal to CLT face being evaluated. The effective width of the support ($b_{i,eff}$) is as half the effective depth (d_i) from the respective face of the column.

$$\tau_i = \frac{1.5V_i}{b_{i,eff}d_i} \quad (1)$$

Mestek's simplified analysis method was developed and calibrated from a parametric study using FEM grid-beam CLT models used to determine forces at the face of column supports. From the support forces, the internal stress across the effective support width and through the depth of the panel are based on equations from DIN 1052 [18]. Conditions for supports at corners of panels, and another for supports in the centre of a panel were considered.

To determine the distribution of forces, a FEM based parametric study was implemented considering:

- Three ratios of strong-to-weak axis lamella thickness, 1, 1.5, and 2
- depths of CLT from 100mm to 220mm with 5 to 11 symmetrical layers depending on thickness and layup
- A single span with a span length-to-width ratio between 1-3

Support size and bay size were not considered in the parametric study. The study also assumes no narrow side edge gluing. Based on outputs from these parametric studies, equations for calculating the force on the strong axis face (V_x) and the force on the weak axis face (V_y) were determined using regression equations. The study found that the distribution of force on each support face had a strong correlation with both number of CLT layers, and the ratio between CLT layer thicknesses. Two equations are developed for both columns at edges and columns away from any panel edge.

Given the support shear force(s), an equation simplified from the German design code [18] is used to calculate peak stress (τ_i) as described in equation 1. This equation is based on the lamella thicknesses in each direction (t_x, t_y), effective support width ($b_{i,eff}$) and two modifications factors: a stress concentration factor (k_A) and a pre-calculated modification factor (k_R). The effective support widths ($b_{i,eff}$) was taken as 35° from the face of column support.

$$\tau_i = \frac{K_{A,i}1.5V_i}{k_{R,i}b_{i,eff}(t_x + t_y)} \quad (2)$$

The stress concentration factor (k_A) accounts for the ratio between the peak stress and average stress across the effective support width in the FEM model for panels supported at their edge. The factor ranges from 1.35 to 1.6 depending on effective support width and panel thickness, but is taken as 1.0 for panels supported away from their edge. The factor k_R is a coefficient precalculated from the section analysis method presented in DIN. Table 2 summarizes values of k_R for a corner support.

Table 2: *Values for K_R in the x and y direction for a corner support.*

Factor	Number of Lamella			
Orientation	5	7	9	11
$k_{R,x}$	2	2.5	3.3	3.89
$k_{R,y}$	1	2	2.5	3.3

Mestek also compared the proposed simplified equation to the FEM results of the parametric study. The predictions from the simplified equations were typically higher than the FEM results, with most in the range of 20% higher. One exception was the weak axis CLT shear stress for 5ply CLT, which was 40-70% higher than the FEM results.

Muster also developed a simplified analysis method, where column face forces (V_i) were calculated using a strip method modified from Hillerborg [19]. Once column face forces were determined, beam bending equations on an effective section were used to determine internal stresses, as shown in equation 3. Two k factors were included in this equation. The stress concentration (k_A) was taken from Mestek and accounts for the ratio between the peak and stress. The stress concentration factor (k_{edge}) was derived from comparisons with FEM data, and represent additional stress concentrations resulting from openings through the panel at supports at panel edges. The effective width is calculated by taking a combination of 45° and 15° angles from the column support for through parallel and perpendicular to grain shear loading respectively.

$$\tau_i = \frac{k_A K_{edge}1.5V_i}{b_{i,eff}d} \quad (3)$$

Muster compared the simplified equation to 3D FEM models, and it was found that both models had similar trends, but a large scatter between the Muster's simplified analysis method and 3D solid FEM stresses.

4 POINT SUPPORTED DESIGN METHODS

The following section compares several design cases for point supported CLT in a design case study using test data

from the UBC TallWood House building. Each design case was completed by choosing an approach for calculating panel capacity as presented in Section 2, to internal stresses predicted by an analysis method from Section 3.

4.1 OVERVIEW OF CONSIDERED DESIGN METHODS

The analysis methods chosen for use in each design case were a mix of FEM and simplified methods. For the simplified analysis methods, both the Tributary Area and Muster simplified analysis method from Section 3.2 were chosen because of their simplicity and flexibility. While the tributary method does not account for centre span hogging, it has no limitations on panel configuration and column locations. Muster's method accounts for hogging of centre columns and panel stiffness, and can analyse any number of panel spans. Mestek's simplified analysis method was excluded because it is limited to single span panels with columns at corner, or columns located at the middle of panel.

For the FEM analysis methods, only the 2D shell analysis were examined due to the complexity associated with making 3D solid modelling and grid-beam models. Several hybrid analysis methods are also examined, where the FEM models are used to calculate V_i on each column face, then simplified analysis equations are used to calculate internal stresses.

Three types of capacity methods were used in the design cases considered: the base code strength, the code strength amplified by k_p, and 5th percentile characteristic strength from test data presented in Table 1. The code strength represents the most conservative assumption, while using test data with k_p is the least. The design cases considered are summarized in Table 3, which describes the methods used to both analyse and determine the capacity of each panel.

Table 3: *Design methods considered.*

Design Case	Analysis Method	Capacity Method
D1	Tributary Area	PRG
D2	Muster's simplified method	PRG & k_p
D3	Hybrid approach, FEM with Muster simplified	PRG & k_p
D4	FEM RF-Laminate	PRG & k_p
D5	Hybrid approach, FEM with Muster simplified (support stiffness x10)	PRG & k_p
D6	FEM RF-Laminate (support stiffness x10)	PRG & k_p
D7	Hybrid approach, FEM with Muster simplified	Test data & k_p

Design case D1 uses the Tributary Area simplified method compared against O86/PRG rolling shear values without punching amplification factors. Case D2 uses the Muster simplified analysis method and compares peak stresses against O86/PRG rolling shear values amplified by the Muster punching shear amplification factors. Case D3 is a proposed hybridized method, which used a FEM 2D shell model of the system with spring supports as presented by Muster to predict column face forces (Vi) [11]. The equations from Muster's simplified method were used to predict peak stress in the system, and compared with the amplified O86/PRG capacities. Case D4 is a full FEM approach using a similar model to the one used in D3. Peak stresses in individual lamella from the RF-Laminate module were extracted from the model and compared with amplified O86/PRG capacities. Cases D5 and D6 used similar models and capacities to D3 and D4 respectively, but with support spring stiffness increased by a factor of 10 to evaluate the sensitivity of the model to stiffness. Finally, design case D7 used a similar model to that in D3, with unchanged spring stiffness, but compares the peak stresses against a 5th percentile base rolling shear strength of 0.75Mpa, along with Muster amplification factors. The base strength value for this case more closely aligning with results from testing [9],

4.2 COMPARISON WITH PREVIOUS TESTING FOR UBC TALLWOOD

The design cases presented in Table 3 were evaluated by comparing their design strength to internal stress for point supported panels in the UBC TallWood House testing [3]. For this evaluation, the panel from Manufacturer III was used, which was a two-span continuous 5ply panel, 169mm thick. Failure occurred in punching shear at the middle support in the strong axis. An average ultimate load of 402kN (201kN per bay) was applied to the system. Figure 1 shows the geometry of the panel tested.

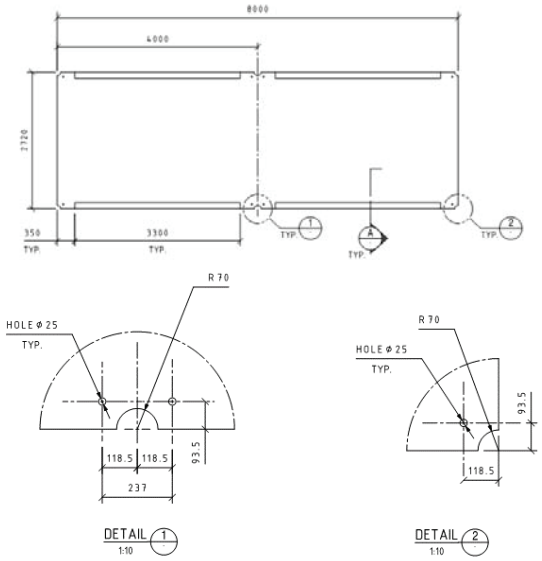

Figure 1: *Geometry of panel considered for Testing.*

For each design case from Table 3, the CLT panel from experimental was analysed using it's failure load to determine the stress demands at failure. For the case D1 and D2, the load was simplified as an equivalent uniform load. For the remaining series the loads were applied as discrete area loads to match the true test setup as shown

https://doi.org/10.52202/069179-0349

in [3]. Table 4 summarizes predicted column face shear for the middle the column, where V_x is the maximum force on the left and right face (i.e. face perpendicular to primary span), and V_y is the shear on the top or bottom face (i.e. face parallel to primary span).

The column face forces predicted by each design case was similar with a few exceptions. In D1 the force in the weak axis was smaller than all other design cases. There was also a notable difference between FEM models with 10x support stiffness used, where stiffer models (D5/D6) attracted more force in the weak axis.

A significant spread is observed in the stress predicted by each design case. Case D1 predicted lower shear stresses than other methods, likely because of not including any stress concentration factors. Comparing design cases that used hybrid analysis (D3, D5) with design cases that used pure FEM (D4, D6), the hybrid methods predicted higher stresses for the baseline model, but lower stresses when the support stiffness was increased. When similar design cases that used different support stiffnesses (D4 vs. D6, D5 vs. D7) were compared, it was found that the spring stiffness significantly impacts the load distribution between column faces, with stiffer supports leading to more force in the y axis and higher stress peaks.

Table 4: *Design Demands*

Design Case	V_x (kN)	V_y (kN)	τ_x (Mpa)	τ_y (Mpa)
D1	32	33	1.55	1.3
D2	33	55	2.81	1.5
D3	34	60	2.94	1.65
D4	34	60	2.28	1.8
D5	26	71	2.25	1.98
D6	26	71	3.05	2.24
D7	34	60	2.94	1.65

Table 5 summarizes the shear strength(s) considered in each design method (D1-D7) for the strong and weak axis faces. The characteristic strength used was multiplied by a phi factor of 0.9 from CSA O86 to determine the design rolling shear strength (f_s'). The punching shear strengths in each direction (f_{px}, f_{py}) were determined based on amplifying the design rolling shear strength by punching factors where applicable. An Overstrength Factor (OF), defined as the ratio between the punching shear stress at failure and the capacity, is also shown. Lastly the predicted failure axis, where the predicted shear stress and the punching capacity the closest, is presented.

Table 5: *Capacity and Overstrength Factor (OF) for design cases considered.*

Design Case	f_s' (Mpa)	f_{px} (Mpa)	f_{py} (Mpa)	OF	Governing Axis
D1	0.45	0.45	0.45	3.44	strong
D2	0.45	0.585	0.72	4.79	strong
D3	0.45	0.585	0.72	4.96	strong
D4	0.45	0.585	0.72	3.90	strong
D5	0.45	0.585	0.72	3.85	strong
D6	0.45	0.585	0.72	5.21	strong
D7	0.68	0.884	1.088	3.33	strong

In all design cases, the strong axis governed the shear capacity, which matched observations from testing [3]. In addition, all design cases using PRG based rolling shear strength had an OF above 3.4, with the series D1 showing the lowest predicted value. For series D7, where a larger rolling shear strength was used, there was still a significant margin of safety in the system, with an overstrength of 3.33.

5 PARAMETRIC STUDIES

To further understand how the analysis methods presented in Section 3 compare, a parametric study was completed. The output column face shear forces from simplified analysis methods were compared with outputs from FEM. The impact of different parameters on outputs of the shell FEM approach presented in Muster were also examined.

5.1 STUDY OVERVIEW

For simplified methods, the parametric study uses 175mm thick CLT panels 5 layers of 35mm thick laminates, 1950f-1.7E SPF in the strong axis and No.1/No.2 SPF in the weak axis. The parameters considered include:

- number of spans (1,2,3)
- span length (3.6m – 4.4m, increments of .2m)
- span width (2.7m – 3.5m, increments of .2m)

For FEM models, the panel was modelled using the 2D shell elements and support conditions as specified by Muster. Near supports a mesh refinement was used. The following parameters were varied in addition to those above in each trial analysis:

- Effective width of support along the weak axis face (0.3m-0.5m, increments of 0.05m, strong axis face is half this value.)
- Spring stiffness (0.1x, 1x, 10x the stiffness equation proposed by Muster)
- CLT panel type (139, 175, 191, 245)
- Grade (E and V)

The 175mm and 245mm thick panels had 5 and 7 layers of 35mm. These panels used 2100f -1.7E SPF in the strong axis and No.1/No.2 SPF in the weak axis for E rated panels, while V rated panels used No.1/No.2 SPF in both directions. The 139mm and 191mm had layers 35mm thick in the strong axis and 18mm thick in the weak axis. These panels used 2100f-1.7E SPF in the strong axis and No.3 and better SPF in the weak axis for E rated panels, while V rated panels used No.1/No.2 SPF in the strong axis, and No.3 and better SPF in the weak axis.

https://doi.org/10.52202/069179-0349

All panels have an edge cantilever of 0.3m on either side of the first and last column. In FEM, the effective dimension of the strong axis face is taken to be half the width of the weak axis face. All panels were loaded with a unit 1kPa load, and results were presented in kN/kPa. A total of 150 trials were run for each simplified method panel, and 2250 trials for each FEM model.

5.2 SIMPLIFIED METHODS COMPARISON

The column face shear forces were compared for the Tributary Area analysis method, Muster simplified analysis method, and FEM models. Because there were multiple columns, each plot shows the shear force for the worst-case column. Figure 2 shows the strong axis column face forces (V_x), and Figure 3 shows the weak axis column face forces (V_y). Width had a small effect on V_x and similarly, changes in length had a small effect on V_y. For this method number of spans had a moderate effect on V_x, but a large effect on V_y.

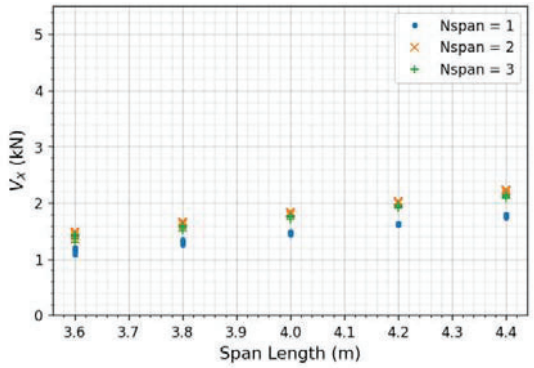

Figure 2: *Shear on X column face for Muster Simplified method.*

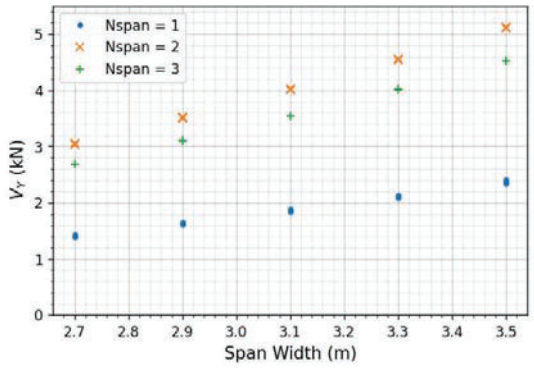

Figure 3: *Shear on Y column face for Muster Simplified method.*

Figure 4 and Figure 5 show the column face forces for the Tributary Area analysis method. Like the Muster analysis method, changes in width had a small effect on V_x and changes to length had no effect on V_y. Similarly, the number of spans had no effect on V_x, and only effects V_y, going from one to two spans. As such, results are only presented for two span panels.

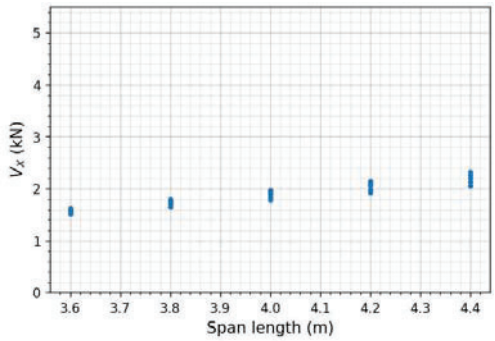

Figure 4*: Shear on X column faces for Trib. Area Method.*

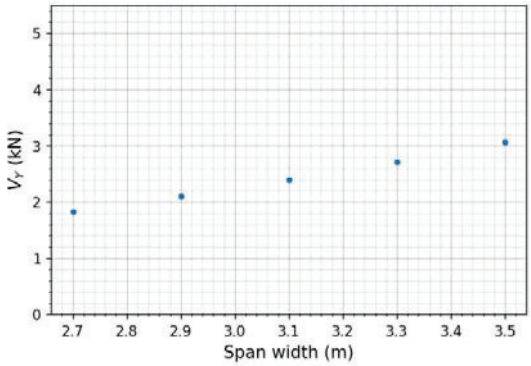

Figure 5: *Shear on Y column faces for Trib. Area Method.*

Results for the Tributary Area and Muster simplified analysis methods were also compared to results from FEM models. The shear force at each column face was extracted from the model for each combination of input variables, and the largest value from all columns was reported. For the FEM models, there was a much larger spread in results, indicating that factors like the out of plane grid dimension (width in this case) or support size had a larger impact on the distribution of forces. Table 6 summarizes the spread in V_x observed, where length is fixed at 3.6m and 4.4m, the number of spans is fixed at two, three or four, and all other parameters were allowed to vary. For the spread of values at each length/span combination, the smallest (min) and largest (max) values from all other combination of parameter were reported, as well as the average value observed. For the Tributary Area simplified analysis method, values were the same for every number of spans, and so not separated out.

Table 6: *Comparison of V_x from simplified methods and FEM*

L (m)	Analysis Method	N_{span}	V_x (kN)		
			Min.	Avg.	Max.
3.6	Muster	2	1.09	1.16	1.20
		3	1.35	1.44	1.49
		4	1.35	1.38	1.43
	Trib. Area	-	1.52	1.58	1.62
	FEM	2	1.10	1.29	1.45
		3	1.39	1.65	1.97
		4	1.39	1.58	1.87

https://doi.org/10.52202/069179-0349

		2	1.74	1.78	1.80
	Muster	3	2.17	2.21	2.23
		4	2.17	2.13	2.15
4.4	Trib. Area	-	2.06	2.20	2.32
		2	1.37	1.64	1.86
	FEM	3	1.75	2.07	2.46
		4	1.75	1.98	2.31

5.3 EFFECT OF PARAMETERS ON SHEAR FORCE

Data from the parametric study was also used to understand how the studied variables change the shear force predicted by FE models. As with the data from section 5.2, it was found that there was a large spread in predicted shear force when comparing applied shear with the span length in that direction (V_x vs. span length, V_y vs. span width). Correlations on the dataset were calculated to highlight which variables are most significant when predicting shear force. Table 7 summarizes the correlations coefficient determined for span length (L), span width (w), number of spans (N_{span}), effective support dimensions (d_{sup}), lamination grades (V or E Grade), and support stiffness (k_s) on the output shear (V_x, V_y).

In Table 7 the shear force generally correlated strongly with the span direction perpendicular to the support face, but there was also a strong correlation with the opposite span length as well. Grade and support size had less of an effect on the distribution of shear force. Strong correlations were also noted for support stiffness and number of spans.

Table 7: *Correlations of various parameters on Shear forces.*

Panel	Correlation Coefficient with V_{xh}					
	L	w	N_{span}	d_{sup}	Grade	k_s
139	0.23	0.08	0.11	-0.11	-0.05	-0.51
175	0.25	0.21	0.22	-0.06	-0.06	-0.35
191	0.27	0.24	0.28	-0.07	-0.06	-0.31
245	0.25	0.27	0.32	0.02	-0.07	0.00
Panel	Correlation Coefficient with V_y					
	L	w	N_{span}	d_{sup}	Grade	k_s
139	0.15	0.35	0.49	0.02	0.01	0.41
175	0.19	0.32	0.53	0.00	0.02	0.34
191	0.18	0.31	0.50	0.03	0.02	0.35
245	0.23	0.30	0.57	-0.01	0.02	0.18

The strong correlation of V_x with support stiffness, but not support width was highlighted below in Figure 6, where a 175 V rated panel with two spans and a 4.2mx2.9m grid has been examined. In this small subset of the data, a large difference between the shear force for different support stiffnesses values (x0.1, x1, x10) was shown. However, shear force was relatively constant for different values of effective support width.

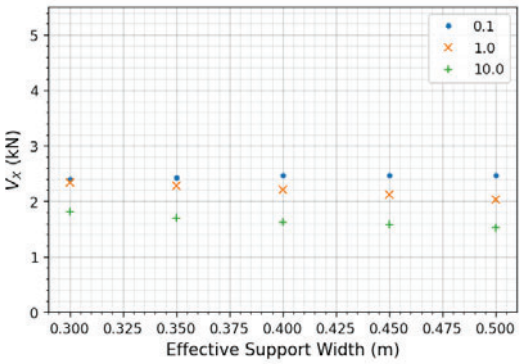

Figure 6: *V_x vs. support width for a trace of data on a 175 V rated panel, and different factors applied ot the support stiffness.*

5.4 FEM MODEL MEASURED K_A

Another quantity measured in the parametric study was the ratio between the peak and average shear force observed in FEM models across a wide variety of panels. In Figure 7-Figure 10, these values were compared to the baseline K_A value proposed by Mestek. The parameters of the parametric study were as presented in Section 5.2.

For each of the panels considered, two series were presented: the baseline formula for spring stiffness from Muster, and x10 the spring stiffness proposed from Muster. For all FEM models the peak value in V_x/m was extracted from the model, and compared to the average value of V_x/m. A large spread in peak/average can be observed that for some series, with thinner panels having a larger distribution in stresses. This may be because Muster's formula for the spring stiffness changes at a negative third power of the panel thickness, so the base stiffness for each panel can be significantly different. The difference in stress ratio suggests significantly different behaviour at supports between the 139mm panels and 245mm panels. Despite the large differences observed between different panels, K_A was lower than the values proposed by Mestek for many panels.

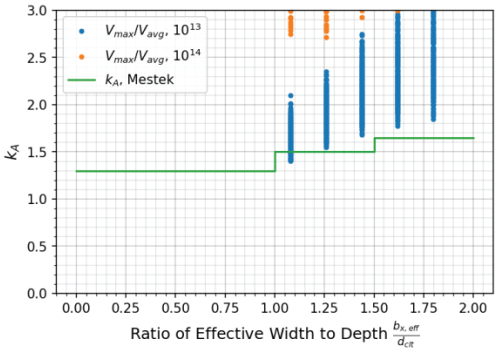

Figure 7: *Calculated K_A for 139 panels.*

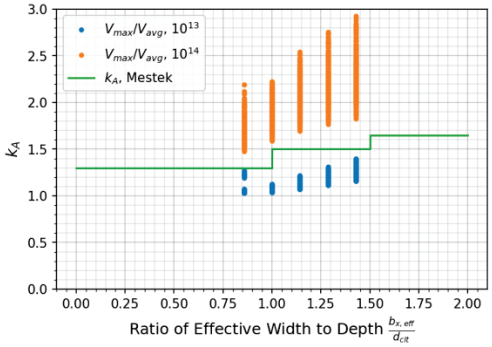

Figure 8: *Calculated K_A for 175 panels.*

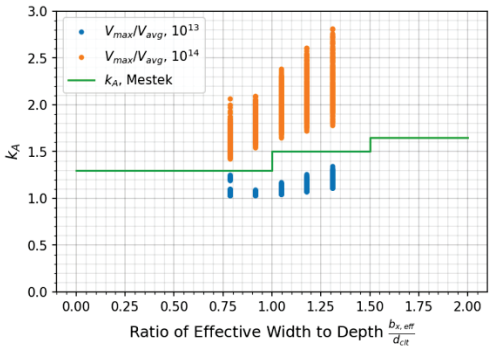

Figure 9: *Calculated K_A for 191 panels.*

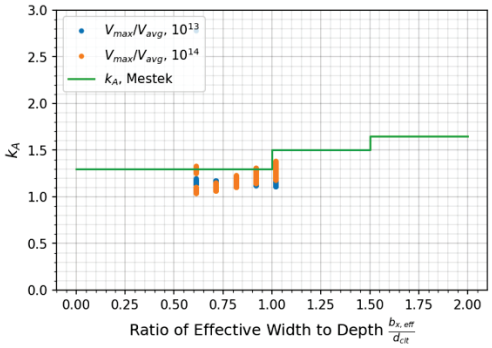

Figure 10: *Calculated K_A for 245 panels.*

The effect of support stiffness as predicted by Muster [11] can also be qualitatively observed in Figure 11 for a single data point. Here a set of four panels is shown where the top pair was 139E rated, the bottom pair was 245E rated, and all other variables are the same between panels. For each pair, the bottom panel uses the baseline formula's constant of 10^{13} (1x stiffness), and the top panel uses 10^{14} (10x stiffness). For these panels, there is a significantly different deformation profile over column supports for the baseline model of 245E vs. 139E, with the 245 behaving much more flexibly.

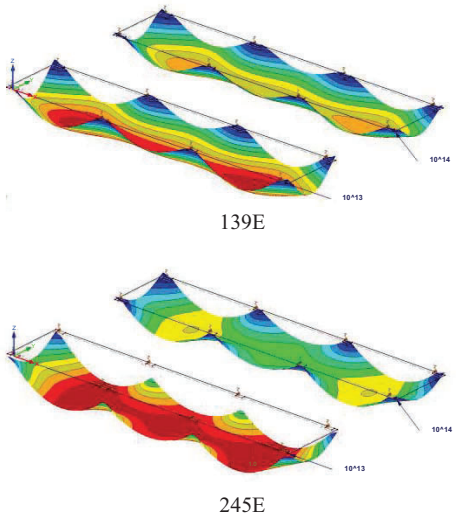

Figure 11: *Deformation over supports for 139E and 245E panels, colour indicates vertical deflection with red being the highest and blue the lowest.*

6 CONCLUSIONS

Reviewing the code and North American material standards for determining capacity of point supported CLT, it was observed that PRG specified shear strength values were generally lower than characteristic strengths determined in experimental test. Several simplified analysis methods were reviewed, with the method presented by Muster [11] being the most flexible.

The capacity and analysis methods were applied to CLT panel tests in a number of design cases. In addition to the simplified analysis methods examined, a Hybrid analysis method was also examined, that takes forces from column faces in the FEM model, and the stress formula from the Muster simplified analysis method. When compared to test data from the UBC TallWood House testing program, the design cases assessed had a significant margin of safety when using current strength specified values in the PRG 320, with ratios of strength to capacity in the range of 3.4-5.2. Even using strength values from experiment, the ratio between failure load and predicted capacity was 3.3 for the Muster Simplified method.

In both the sample design and parametric study, it was noted that the stiffness of column supports had a significant impact on the FEM predicted forces and stresses. In the parametric study it was noted simplified methods predicted column face shears that were comparable to FEM predictions, however, it was observed that FEM predictions had a larger spread in data. This indicates that parameters like the out of span width affect results more than simplified methods. In general FEM results were more sensitive to the span perpendicular to load, e.g. width on V_x, than the simplified models.

The parametric study also showed that the support stiffness was the parameter that had the most influence on support shear forces. The length, width, and number of spans also had a significant effect on shear force, while the type of panel used and support size did not. The parametric study showed that the support stiffness also

https://doi.org/10.52202/069179-0349

had a significant effect on the peak model shear forces of all studied parameters. The ratio of peak to average stress varied significantly for different panel layups and support stiffnesses. A large difference in behaviour at the supports was observed between different panels in the parametric study. Because support stiffness was observed to have a significant influence on shear stress distribution in FEM models, further study is recommended to refine this stiffness for a wider set of parameters and ensure its interaction with factors such as k_A is appropriate.

SEISMIC AND ENERGY RETROFIT OF MULTIFAMILY LIGHT-FRAME TIMBER RESIDENTIAL BUILDINGS USING MASS PLY PANEL (MPP) WALL FAÇADE SYSTEM

Gustavo F. Orozco O.[1], Andre R. Barbosa[2], Mark Fretz[3], Judith Sheine[4], Jason Stenson[5], Kevin Van Den Wymelenberg[6], Payton Narancic[7], Flynn Casey[8]

ABSTRACT: The most common type of construction in the US for single and multifamily housing is known as Light-Wood-Frame (LWF). This system has been widely used for decades, following prescriptive design rules and usually without an engineered-based analysis. Due to the evolution of knowledge on the seismic hazard in the Pacific Northwest, retrofitting these structures built before the 1990s has become a necessity. In addition, these buildings also lack the energy efficiency required to reduce our global carbon footprint. This paper presents a novel façade retrofit solution consisting of prefabricated mass ply panels (MPP) that can be rapidly applied on-site over existing building cladding to upgrade older LWF one- to three-story buildings. The structural design of an existing prototype two-story LWF building in Portland, OR is presented. Custom steel connections resist design forces following the Equivalent Lateral Force (ELF) method from ASCE 7-16. Nonlinear displacement validation is performed using analytical models (AM) and finite element models (FEM), obtaining lateral drifts of 0.50% for the design earthquake (DE) reducing the expected damage in the building. Over-strength factors are calculated, considering the contribution of existing LWF walls and steel connections. A follow-up experimental setup is described for future validation of the initial assumptions.

KEYWORDS: Façade, Light-Wood-Frame, Mass Timber, Retrofitting, Seismic Vulnerability.

1 INTRODUCTION

In the US, the majority of low-rise residential buildings consist of Light-Wood-Frame (LWF) lateral force-resisting system (LFRS). The LWF structural system makes use of dimensional lumber elements equally spaced forming walls, floor diaphragms, and roofs. These elements are generally joined together using nails and panelised sheeting, such as plywood, oriented-strand board (OSB), or gypsum wallboard (GWB). Even though this solution has been prevalent and overall well-designed buildings tend to perform well under seismic loading, the 1994 Northridge Earthquake resulted in many residential buildings sustaining damage due to excessive lateral drifts [1,2]. In addition, in the Pacific Northwest, the Cascadia Subduction Zone, which drives the high seismic risk of existing structures in the region [3] was only recognized in the early 1990s, and buildings in the region constructed prior to this date were designed to sustain relatively low levels of seismic loading.

Besides the inadequate seismic resistance of many existing buildings constructed before the 1990s, many US buildings were constructed before the advent of building energy codes. In 1975, the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) promulgated Standard 90-75, which is widely recognized as the first US residential energy code. Since that time, housing energy efficiency has significantly improved in many states. However, pre-code housing remains a significant fraction of the nation's housing stock. According to the Northwest Energy Efficiency Alliance (NEEA) Residential Building Stock Assessment, 88% of this housing stock in the Pacific Northwest is one- to three-story light-wood-frame structures and were constructed between 1960-1994 with very low wall insulation levels (64% had R8-R12 wall insulation) [4]. In addition, the majority of the 88% of the housing stock was constructed with 2x4 studs (38 mm x 76 mm) at 406 mm (16") on-centre [4].

Such outdated buildings can benefit from a retrofit solution that minimizes impact on the interior of the units, thus minimizing downtime, combining increase energy and seismic performance. The solution proposed in this study involves performing most, if not all, interventions on the exterior of the building through the development of a façade retrofit solution. While other successful energy façade retrofit programs exist in Europe, such as the *Energiesprong* [5] method that provides many lessons for the US, energy façade retrofits on the Pacific Northwest must also contend with seismic upgrades, which are often automatically triggered with the mass of an existing building increases by 10% relative to the mass of the existing building.

In the development of a novel façade retrofit solution, this study adopts a recent product known as mass ply panel (MPP) [6] in the development of structural and non-structural retrofit façade panels that enable seismic and energy retrofit of LWF buildings. Specifically, this paper proposes a structural design methodology for the structural façade panels, considering custom-designed connectors that attach the façade retrofit solution to the existing concrete foundation and existing LWF structure. In addition, considerations needed for the design of the non-structural façade panels are also presented.

1.1 EXAMPLE CASE STUDY

An existing two-story LWF structure built in 1971 in the city of Portland, Oregon (45.51179, -122.67563) is selected as an application example to demonstrate the seismic design retrofit procedures and dimensioning of structural elements of the retrofit façade system and considerations for non-structural elements.

Figure 1: *Visualization of case study multifamily building used for façade retrofit study, pre-retrofit [7].*

The two-story building shown in Figure 1 consists of multiple two-unit modules illustrated in Figure 2a and b. For the existing building, based on the NEEA study [4], it is assumed that there are two types of walls, including (1) exterior walls consisting of 8x8 plywood sheathed wood structural panels (WSP) with 6d nails spaced a 150 mm and (2) interior walls consisting of gypsum sheathed walls.

1.2 FAÇADE RETROFIT SOLUTION

A façade system is proposed, formed by two different types of MT panels. First, the non-structural MPP with slotted-hole connections resisting out-of-plane loads only (highlighted in yellow in Figure 2 and Figure 3), and second the structural walls that resist lateral forces (highlighted in red in Figure 2 and Figure 3).

The MPP structural walls have increased over-turning capacity due to the steel plate hold-downs that transfer overturning tension and compression forces caused by lateral loads to the foundation. A shear steel plate is installed at the base of the MPP transferring the base shear reaction to an upgraded foundation. Fasteners distribute the tension forces from the steel plates to the MPP, and expansion bolts connect the steel plates to the concrete foundation. The MPP walls are connected to MPP transfer joists that transfer the load from the existing LWF to the retrofit system (see Figure 4a).

Insulation layers are attached to both structural and non-structural MPP panels, including wood fibre insulation infill and siding. Windows, doors, field-installed foundation insulation with vertical siding elements used to conceal the hold-downs and other panel-to-panel joints on the completed façade.

2 STRUCTURAL DESIGN PROCEDURES

The design of the new lateral force resisting system (LFRS) follows a capacity-based design approach, where hold-downs are designed as structural fuse elements, while shear transferring elements are designed to remain essentially elastic by considering an over-strength factor (Ω), precluding brittle failures and allowing the wall to develop large deformations without loss of structural capacity.

The design of the structural wall panel followed existing standards, including ASCE 41-17 [8] and ASCE 7-16 [9], and consisted of determining: (1) the tributary seismic weight to be resisted by the structural wall panel, (2) the design seismic base shear, (3) design of the components of the structural wall and connections, (4) a drift analysis, and (5) capacity-based design of elements that are designed to remain essentially elastic. For the non-structural walls, the design consisted of displacement compatibility checks, namely through the design of slotted connections in panel-to-panel, panel-to-transfer joist, and panel-to-foundation connections. The existing and upgraded concrete foundation requires the design of epoxied dowels, shear transfer between the upgraded foundation and the existing foundation, and geotechnical foundation stability checks.

2.1 SINGLE WALL ANALYSIS

In a single structural wall, lateral design forces are calculated and distributed assuming a triangular distribution of forces (see Figure 4b).

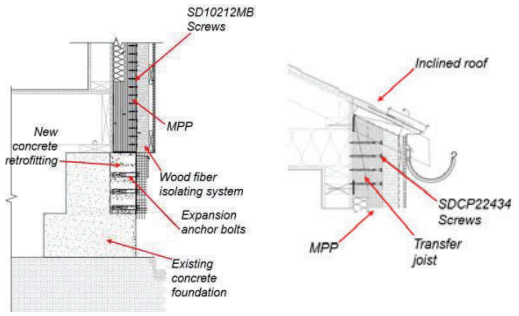
Tension and compression reaction forces generated at the base of the wall, T and C, respectively, are determined using the following expression:

$$T = C = \frac{(V_3 \times H_2) + (V_2 \times H_1)}{L_1 + \frac{2}{3}a} \quad (1)$$

where V_3 is the lateral load at floor level 3, H_2 the height at floor level 3, V_2 is the lateral load at floor level 2, H_1 is the height at floor level 2, L_1 is the length between the center of the hold-down connection and the initial point where the wall starts lifting, and a is the length of the compression zone. Additional details on these dimensions are shown in Figure 6a.

The foundation will most probably need to be retrofitted since typical stem walls in existing buildings will not have the bearing area needed to support the new façade panels. Also, due to the addition of extra walls on the façade, the existing diaphragm needs to be evaluated to verify if additional retrofit elements are needed to resist added capacity provided by the façade panels. Upon determination of the diaphragm forces, it may be necessary to provide additional floor sheathing and/or steel coiled straps that may work as collectors or diaphragm tension chords. The need for these elements will vary from project to project, and are therefore not detailed in this paper. Example cross-sections on how the MPP is attached to the existing façade and additional non-structural insulation materials are shown in Figure 5a and b for foundation and roof heave connections, respectively. Additional details on other necessary considerations are provided elsewhere [7].

https://doi.org/10.52202/069179-0350



(a) (b)

Figure 5. *Section cut of (a) MPP to the concrete foundation, (b) MPP to transfer joist connection.*

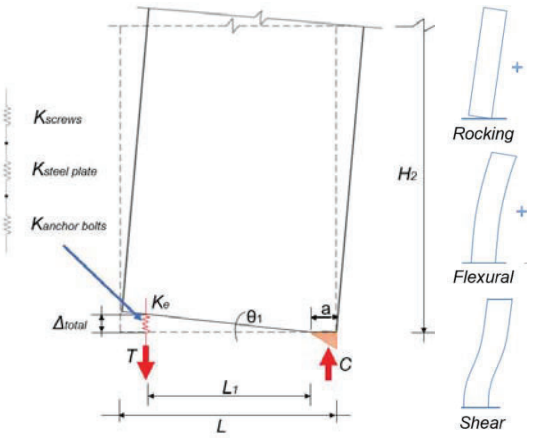
2.2 LATERAL DEFORMATION ANALYSIS=

Lateral deformations of the new LFRS can be verified using a nonlinear analytical model, that considers three types of deformation types in the wall: (1) lateral deformation due to the rocking of the panel, (2) lateral deformation due to the flexural deformation of the panel, (3) lateral deformation due to the shear deformations of the panel (see Figure 6b).

Figure 6a illustrated a simplified model to capture the effects induced by the rocking of the wall. As the wall rocks about one end, the opposite end tends to uplift resulting in compression and tension of either hold-down. For the hold-down that goes into tension an equivalent stiffness K_e for the hold-down connection is given by:

$$\frac{1}{K_e} = \frac{1}{K_{sc}} + \frac{1}{K_{sp}} + \frac{1}{K_{ab}} \qquad (2)$$

where $\boldsymbol{K_{sc}}$ is the stiffness provided by the screws, $\boldsymbol{K_{sp}}$ is the stiffness of the steel plate, and $\boldsymbol{K_{ab}}$ is the stiffness provided by the anchor bolts.



(a) (b)

Figure 6. *(a) Simplified model for rocking deformation analysis, (b) Types of lateral deformations in the wall.*

The lateral displacement at the top of an MPP wall D_{total} is given by:

$$D_{total} = D_{hold-down} + D_{flexure} + D_{shear} \qquad (3)$$

$$D_{hold-down} = H \times \theta_1 \qquad (4)$$

$$\theta_1 = 90^o - \cos^{-1}\left(\frac{\Delta_{total}}{L_1}\right) \qquad (5)$$

$$D_{flexure} = \frac{V_2 {H_1}^3}{3E_{app}I} + \frac{V_3 {H_2}^3}{3E_{app}I} \qquad (6)$$

$$D_{shear} = \frac{V_2 H_1}{G_{app}A} + \frac{V_3 H_2}{G_{app}A} \qquad (7)$$

where $D_{hold-down}$ is the lateral displacement due to hold-down deformation, $D_{flexure}$ is the displacement due to wall flexure, and D_{shear} is the displacement due to wall shear; θ_1 is the rotation at the base of the wall; Δ_{total} is the opening at the base of the wall; H is the height of the wall, $E_{app}I$ is the apparent wall's flexural stiffness (I = 1/12 $t_w L^3$), and $G_{app}A$ is the wall's apparent shear stiffness (A = $t_w L$).

2.3 NONLINEAR CAPACITY OF LWF WALLS

The capacity-based design methodology requires the calculation of any source of over-strength that can affect the new LFRS. In the present application, the main contributor to over-strength in the system is the existing LWF structure. To obtain the lateral stiffness of these walls, simplified backbone curves can be calculated from experimental tests, considering different types of sheathing and length of walls [10]. Structural walls are considered the ones with proper sheathing, with WSP. Infill walls are initially not considered in the lateral resistance of the exiting LWF, and are only considered for over-strength factor calculation. Nevertheless, depending on the contribution of the nonstructural walls, they may be considered structural for structural assessment.

3 EXAMPLE BUILDING APPLICATION

The loads considered to act on the structure are: (1) Dead loads, including self-weight and over-imposed loads of 1.05 kN/m^2 and 0.72 kN/m^2 for intermediate floors and roof, respectively, and (2) live loads of 1.91 kN/m^2 and 0.96 kN/m^2 for intermediate floors and roof, respectively. The performance level for existing structures defined in ASCE 41-17 (BSE-1E) requires an earthquake with a 20% of probability of return in 50 years. For existing structures, ASCE 41-17 and local design codes [11] allow for the use of a design limit of 75% of the seismic demand used for new buildings (BSE-1N), or 10% in 50 years, also known as Design Earthquake (DE).

The design approach included the following steps. First, the two-unit structure shown in Figure 2a was assumed to

https://doi.org/10.52202/069179-0350

be retrofitted by six MPP structural wall segments for the LFRS, for the direction of the building with more openings. The other direction of the building is not presented in this paper, since the more critical direction is analysed. Each MPP structural wall segment has dimensions: 1.20 m wide, 6.10 m height, and 76.2 mm thick. Second, a seismic modification factor (R-factor) of 3 is assumed for the MPP walls [12]. The building is a risk category II structure, therefore a base shear (V_b) of 22% of the seismic weight is determined for the BSE-1N design level earthquake (DE). Applying the limit of 75% the BSE-1E design base shear of 16.8% is obtained. Note that this level is higher than what would be needed for the existing structure with light-frame-wood walls, which would be allowed to be designed for a corresponding R-factor value of 6.5. This would result in a BSE-1N force value of 10.1% of the buildings seismic weight and a corresponding BSE-1E force value of 7.6% of the seismic weight.

Note that this increased level of design force for the façade retrofit solution compared to a retrofit solution of existing LWF walls using additional and stronger sheathing, the façade retrofit solution enhances building performance by reducing drifts and mitigates soft-story failure modes, thus allowing for an enhanced resilient design. Nonetheless, the solution may raise questions from structural engineers and some building owners since it does require that the existing structure be retrofitted to a higher seismic force level.

For the example building, a seismic weight of 400 kN was determined, considering the dead load and 25% of live load. Following allowable stress design (ASD) [9] combinations (with 0.70 factor for seismic forces), a horizontal force of 7.87 kN is obtained for each of the MPP walls, and tension and compression forces of 36.61 kN are obtained for the hold-downs and MPP structural wall panel, respectively.

3.1 HOLD-DOWN CONNECTION DESIGN

The number of screws needed to resist the tension forces is determined following the NDS yielding modes [13], considering a modifying factor $C_d = 1.6$, a group factor $C_g = 0.86$, and additional factors equal to 1.0. The steel plate is sized following the requirements in AISC 360-16 [14], including tension and shear checks. The design checks for the expansion bolts follow the design manual provided by the manufacturer [15]. Shear and compression stresses on the MPP structural wall are checked to verify the thickness of the panel. The ASTM A572-50 [16] steel plate hold-downs obtained are 3.2 mm thick, 101 mm wide, and 1460 mm high, and require a total of 60 screws type SD10212MB [17], and three carbon steel expansion bolts with a diameter of 16 mm (see Figure 7).

To determine the hold-down equivalent stiffness (K_e in Figure 6), the stiffness used for an individual fastener is obtained from shear tests of angle bracket connections using nails with similar diameters [18]. For the steel plate, an axial stiffness relationship, E_sA/L, is used, where E_s is the steel Young's modulus, A is the cross-section area, and L is the effective length of the steel plate. Elastic and plastic shear stiffness and yield forces for an anchor bolt are assumed following engineering first principles. Backbone values per component are shown in Table 1.

Table 1: *Backbone parameters for the hold-down connection.*

Element	Yield force (kN)	Yield disp. (mm)	$K_{elastic}$, (kN/mm)	$K_{plastic}$, (kN/mm)
Bolts	345	38	9	12
Steel plate	122	2	52	3
Screws	96	9	11	4

3.2 SHEAR TRANSFER CONNECTIONS

For this example, an overstrength factor, Ω, of 4 is initially considered. Based on this assumption, the ASTM 572 shear plate connection is 3.2 mm thick, 171 mm wide, 889 mm long, and requiring a total of 46 SD10212MB screws, and seven carbon steel expansion bolts with a diameter of 9.5 mm.

For the transfer joists, 16 screws type SDCP22434 [17] are needed. Note that these are designed with slotted hole connections that allow the wall to rock relative to the transfer joist without inducing uplift forces on the joist. Details are shown in Figure 7.

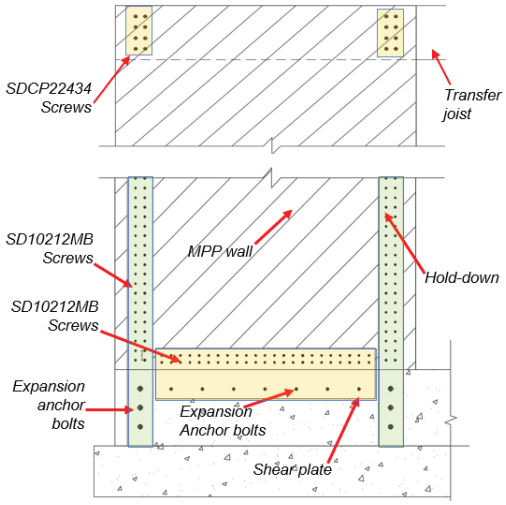


Figure 7. *Hold-down, shear plate connections, and transfer joist details.*

3.3 LWF CONTRIBUTION TO STRENGTH AND STIFFNESS

The exterior and interior walls of the existing structure contribute to the performance of the building by increasing its apparent strength and stiffness. For each MPP structural wall, a tributary length of existing exterior and interior walls and type of sheathing are considered. For the interior gypsum board walls, a tributary length of 3 m is assumed. For the exterior walls, which are assumed to be wood structural panels with 6d nails spaced at 150 mm on-center (8x8 WSP 6d @ 150 mm), a length of 1.20

https://doi.org/10.52202/069179-0350

m is assumed. The contribution of the existing exterior walls with window or door openings was neglected. The resulting backbone curves based on the considerations described in this paragraph are shown in Figure 8 based on experimental data available in [10].

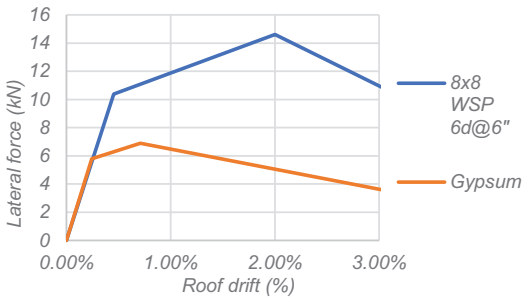

Figure 8. *Nonlinear backbone capacity of existing LWF walls based on their tributary length assigned to an MPP structural wall panel for this façade retrofit example.*

4 FINITE ELEMENT MODEL

Figure 9 illustrates a detailed Finite Element Model (FEM) that was developed to predict the response of the retrofitted building and validate the analytical methodology described in the previous sections. The FEM software used is ETABS [19]. The MPP structural walls are modelled using elastic shell elements for the panel and nonlinear fiber shell elements for the steel plate, both with a mesh size of 50 mm x 50 mm. Orthotropic material properties for the MPP are assumed, based on experimental data [20], using 12362 MPa for Ex, 2979 MPa for E_y, 206 MPa for Ez, 861 MPa for Gxy, 820 MPa for Gyz, and 145 MPa for Gzx. Multilinear elastic links are used to model the nonlinear behavior of screws and bolts. Compression-only nonlinear elastoplastic contact springs are assigned to the FEM to simulate the uplift/contact behavior of the panel with the foundation, considering a yield stress for MPP of 42.95 MPa, a corresponding yield strain of 0.0032, and ultimate strain of 0.007, with the tributary area for each spring and a plastic hinge length of twice the panel width (152.4 mm) [21].

The existing LWF structure is modelled using X-braced frames that can deform axially only and capture the horizontal story force-displacement response shown in Figure 8. Compression and tension plastic hinges are assigned for two braced frames acting in parallel to capture the shear response of the exterior and interior walls. The vertical and horizontal elements are assumed to be nearly rigid elements with moment releases at the ends.

A nonlinear static analysis is performed, using a displacement-controlled analysis, until reaching a target displacement at the top of the MPP wall of 244 mm, which corresponds to 4% roof drift ratio. The nonlinear parameters used in the software are: Newton-Raphson for positive iterations, Constant-Stiffness for negative iterations, solution scheme is Event-to-Event Only, event lumping tolerance (relative) of 0.001, maximum events per step of 200, minimum event step size of 0.001, and the maximum number of null events per step of 5.

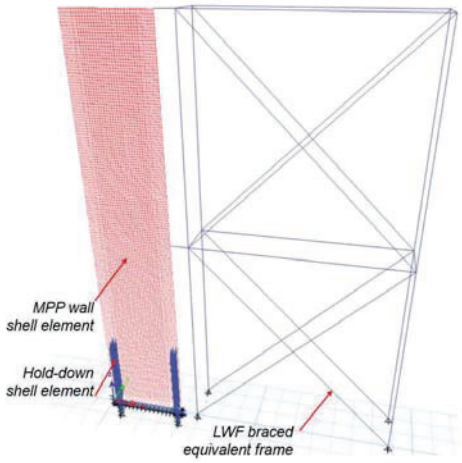

Figure 9. *Two-dimensional FEM developed in ETABS. The MPP structural wall is modelled as shell elements. Steel connections are discretized with shell elements with nonlinear materials. Screws, bolts, and contact elements are modelled as nonlinear multilinear springs. The existing LWF exterior and interior walls are modelled using equivalent braced frames.*

5 RESULTS AND DISCUSSION

5.1 CAPACITY CURVES AND OVER-STRENGTH FACTORS

Figure 10 shows the response for different models. The black line shows the FEM pushover analysis response of a model consisting of only the existing LWF structural walls (WSP walls). The yield force of this system is reached at approximately 11.9% of the seismic weight. After the system yields, damage concentrates on the first floor of the existing building, creating a soft-story mechanism. For reference, the ASCE 41-17 BSE-1E required design force (7.79%) of the LWF walls, shown as a green dash-dot line, is slightly smaller than the yield force of the existing structural wall. Using a typical NDS safety factor of 3.0, the yield point of the capacity curve should be equal to 23.4%. It can be seen in the figure that the LWF structural capacity curve is below this value, therefore the existing LWF structure requires retrofit.

Note that the nonstructural components such as the interior walls should be classified as structural elements if stiffness or strength exceeds 10% of the exterior structural walls [8]. In this case study, including the contribution of the interior walls, the yield force increases 82% from just considering exterior walls to 21.7%. Therefore, even accounting for the nonstructural elements, this LWF structure requires retrofit.

Additionally, Figure 10 shows three different FEM results. The FEM-1 curve is the capacity curve for the MPP structural wall where only the contact springs and

hold-down steel plate and screw connections are modelled explicitly, or in other words, where the horizontal shear steel plate is not modelled. FEM-1 shows a higher ductility than the WSP walls, reaching the first yield point at 1.50% drift. The FEM-2 results show the capacity curve of the model with the shear steel plate and thus illustrate the effect of adding the shear plate at the base of the MPP relative to FEM-1. The addition of the shear steel plate at the base of the wall increases the lateral stiffness and strength of the system. Finally, FEM-3 corresponds to the model shown in Figure 9. The results indicate the increase in capacity required in terms of base shear (over-strength) when the contribution of the existing exterior and interior LWF, WSP, and gypsum walls, respectively, are also added to the model.

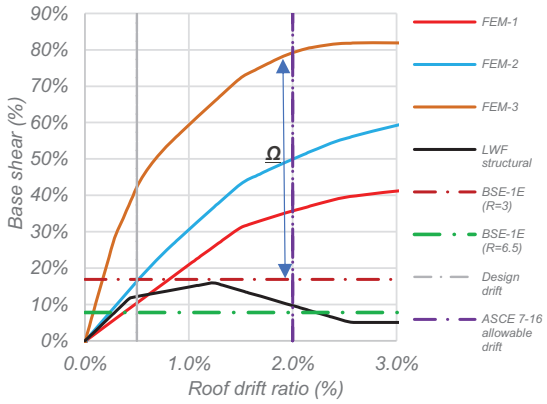

Figure 10: *Capacity curves for the following systems: WSP structural capacity (black), MPP structural wall (red), MPP structural wall with shear plate connection (blue), MPP structural wall with shear plate connection, and existing LWF (orange). The horizontal dashed-dot lines correspond to the BSE-1E force levels.*

The analysis results presented in Figure 10, illustrate that the over-strength in the system originates from two main sources. First, through the engagement of the shear plate connection at the base of the MPP, and second through the lateral stiffness provided by the existing LWF exterior and interior walls. At 2% drift, the over-strength from the shear plate contribution is approximately 143%, while the over-strength originating from the existing LWF walls is 476%.

5.2 STRESS ANALYSIS OF MPP AND STEEL PLATES

MPP walls need to resist the stresses induced by the lateral loads at higher drifts, allowing the connections to develop their nonlinear capacity. Using MPP allowable stresses: tension F_{t0} = 8.96 MPa, bending F_{b0} =13.1 MPa, compression F_{c0} =16.55 MPa, and shear F_{v0} =1.76 MPa [6]. The stress distribution in the MPP and steel plates, at the design force level (7.87 kN), is shown in Figure 11. At this level, the steel plates and the MPP show elastic properties, satisfying one of the initial assumptions in the design process. Nevertheless, the FEM shows shear stress concentration at the base of the wall at higher deformations, shown in Figure 12 for 2% drift. A follow-up experimental test will provide further validation of these results.

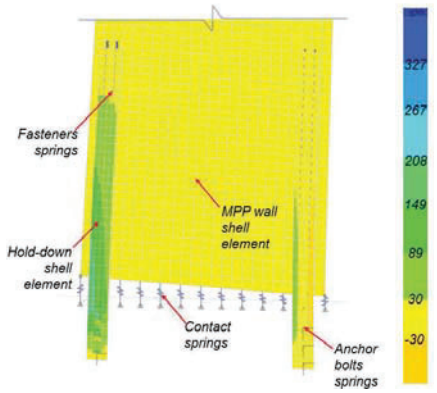

Figure 11: *Axial stresses (F22) for design level (MPa), for hold-down and MPP shell elements. Non-linear springs representing the fasteners and rocking effect at the base of the wall.*

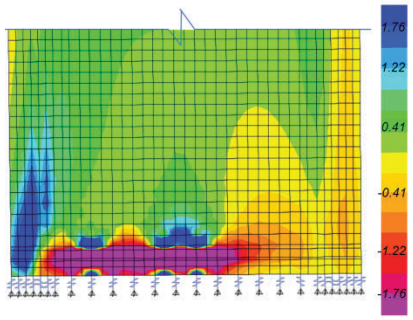

Figure 12: *Shear stress (F12) concentration in MPP at 2% drift ratio.*

5.3 ANALYTICAL MODEL AND FEM COMPARED.

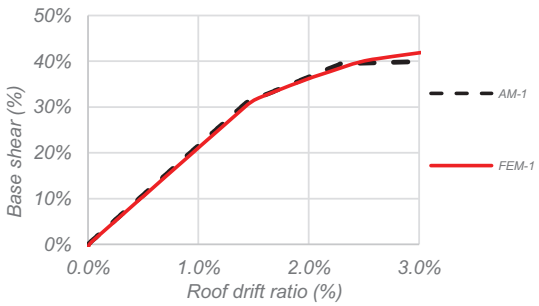

Figure 13. *Capacity curves for AM and FEM for MPP wall with hold-down connections only.*

After applying Equations 3 to 9, the analytical model describes the capacity curve of the LFRS and the yielding points of the components. Compared with the detailed FEM, the results were practically identical, obtaining the yielding points for fasteners and steel plates (see Figure 13).

https://doi.org/10.52202/069179-0350

6 CONCLUSIONS

The implementation of a combined energy and seismic façade retrofit system using MPP provides a practical solution for existing LWF buildings.

A force-based lateral load calculation (ELF) from ASCE 7-16 can be used to size steel connections in a retrofit system. In addition, the lateral stiffness of the existing LWF is an important factor to consider when developing over-strength factors. The lateral transfer system from the existing structure to the new LFRS needs to be designed following capacity-based design demands, increasing the ductility of the system.

A simplified analytical model can be used to obtain the nonlinear capacity curve of the LFRS, following the geometric and mechanical properties of the wall, which was later validated by a detailed finite element model.
An experimental test is needed to validate the assumptions made in the design and the modelling of the LRFS.

7 FUTURE WORK AND EXPERIMENTAL TEST

The analytical model presented in this document presents the equations for the MPP wall only, a future implementation of the existing LWF structure is planned, with the development of the stiffness matrix describing the behavior of 2- and 3-story buildings.

This project has been accompanied initially by the construction of a mock-up, real-scale specimen, built to verify the connections matched with the panels and the foundation. A follow-up experimental test is being developed in parallel, where a real-scale MPP with steel connections attached to a concrete beam will be subjected to a quasistatic lateral protocol load. From the experiment, a validation of the stiffness of the connection is expected, also showing the probable damage at the base of the MPP.

Based on ASCE 41-17, further performance assessment of the system is planned, determining performance points and implementing the methodology from this standard. Response history analysis will be also implemented to determine ductility factors and dynamic effects in the behaviour of the LFRS.

CROSS-LAMINATED TIMBER FLOORS WITH OPENINGS – SERVICEABILITY LIMIT STATE VERIFICATIONS

Martin Schenk[1], Anja Husel[2], Philipp Dietsch[3], Pablo González-Serna[4], José Manuel Cabrero[5], Stefan Winter[6]

ABSTRACT: This paper contributes information about the influence of openings in cross laminated timber (CLT) floors in serviceability limit state (SLS) design. SLS verifications according to the European structural design standard for timber structures - Eurocode 5 - comprise functionality, appearance and the user's comfort. The verifications are based on deformation and vibration criteria. The investigation presented describes the influence of openings on the basis of experimental and theoretical investigations. Rectangular centralized openings in CLT elements were tested. The experimental results were used for the calibration of the numerical models used for theoretical investigations. The numerical models were geometrically parameterized. Towards application for practice, modification factors were derived to enable determination of the respective deformation and first natural frequency.

KEYWORDS: mass timber, cross laminated timber, serviceability, openings in floors, deformation, vibration

1 INTRODUCTION

Structural design of openings in walls and floors is of crucial interest to enhance the competitiveness of cross-laminated timber (CLT) with other building materials [1]. Already for spans larger than 4 m – 5 m, serviceability limit state design (SLS) is decisive for the height of floor constructions in timber buildings [2]. Openings, e.g. for staircases or passages of technical building equipment (pipes, ventilation, etc.) locally reduce the mass and stiffness of floors and have therefor an influence on this important design situation. The verifications of serviceability limit states according to the European structural design standards [3], the Eurocodes, ensure (a) the functionality under typical conditions of use, (b) the appearance of the structure and (c) the comfort of intended users. According to the European design rules for timber structures [4] those verifications comprise criteria on deformations for (a-b) and on vibrations for (c). Research results on the performance of CLT floors with openings are available in e.g. [5, 6]. As presented in [7], simplified rules for the assessment and design of openings in CLT floors seem to vary significantly worldwide.

Striving towards a harmonization of rules, the aim of the present investigations is to contribute to existing studies on the influence of openings in CLT floors on SLS design. To achieve this, static load and vibration tests of 6 CLT elements by one single manufacturer without and with openings were carried out at the laboratories of the Technical University of Munich, Germany (MPA BAU), see Figure 1. Four-point bending tests were conducted to obtain the (i) stiffness, (ii) strength, (iii) deformations, and (iv) failure modes of the single span CLT elements. Vibration tests were conducted to derive the (v) natural frequencies of the system. The influence of openings was investigated for two sizes of openings, see Figure 2 and Figure 3. The test results, presented in Chapter 2 and in the companion paper [8], not only gave an insight into the structural behaviour of the system, but also provided data that has been used for the calibration of a numerical model, see Chapter 3, followed by a parametrized

numerical study on the influence of openings on deformations and frequencies in the system, see Chapter 4.

2 EXPERIMENTAL INVESTIGATIONS

A total of six non-edge-glued CLT specimens according to ETA-06/0138 [9] with an element height of 100 mm were tested in bending to determine the element stiffness and natural frequencies. The test set-up for bending corresponded to the test provisions of EN 16351 [10] in conjunction with EN 408 [11]. The lamination height of the five layers of the elements was 20 mm each with the outer layers oriented in span direction, see Table 1 and Figure 4. The strength class of the sorted laminations corresponded to C24 according to EN 338 [12]. The elements had a length of 2,50 m and width of 1,20 m. The span of the simple supported test set-up was 2,40 m. The ratio of plate thickness t to span L was 1/24.

Table 1: *Layer thickness and orientation relative to the x-axis of the element and total element thickness*

layer	1	2	3	4	5	Σ	unit
thickness	20	20	20	20	20	100	[mm]
orientation	0	90	0	90	0	–	[°]

The panels where tested in three series: (i) without opening, (ii) with an opening size of 300 mm x 300 mm and (iii) with an opening size of 600 mm x 300 mm, each in the centre of the elements, see Figure 2. Thus, the opening size corresponded to 12,5 % of the span and to 25 % of the panel width in case (ii) and to 50 % of the panel width in case (iii). In the test series with small opening (ii), the edge distance of the opening was 450 mm. In the test series with bigger opening (iii), the edge distance was 300 mm. Four panels (A2, A3, A4, A6) were tested in all opening stages while two panels (A1, A5) served as reference panels without openings. In this evaluation, the series with openings are presented. All CLT specimens were stored in standard climate until moisture balance with a temperature of around 20 °C and a relative humidity of about 65 % in the test laboratory. The mass of all panels and the moisture content of the CLT panels was determined according to EN 13183-2 [13], see Table 2. The elements had a mean density of 437,5 kg/m^3 (COV: 10,2) and an average moisture content of 11,3 m-% (COV: 0,083). Three different load configurations were tested: (a) two uniformly distributed linear loads over the full element width, (b) two concentrated point loads, both for deformation investigations and (c) an unloaded state for vibration investigations (self-weight only), see Figure 2. The loads F were applied with a displacement-controlled hydraulic actuator in the distance of 900 mm to the supports. The hydraulic cylinder was jointed to a self-contained steel frame, fixed to the ground. The point loads were applied via steel plates of 200 mm x 200 mm width, the linearly distributed loads via two respective spreader beams (HEB), which were linked with a steel coupler. To avoid compressive deformations perpendicular to the grain in the outermost layers, a hardwood lamella was placed as load distributing element onto the roller supports, see Figure 4. Via nine displacement transducers (w1-w9 in Figure 2), global and local deformations were recorded.

Table 2: *Average moisture content according to EN 13183-2 [13] and total element mass without opening*

specimen	A2	A3	A4	A6	unit
moisture	11,3	11,2	11,6	10,9	m-%
mass	132	132	130	131	[kg]

Figure 6: *View on displacement transducer arrangement*

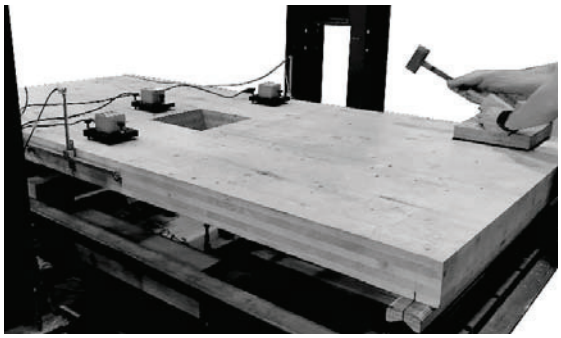

Figure 7: *View on the vibration test set-up*

Spherical bearings at the cylinder and at the concentrated loads ensured uniformly orthogonal load application, see Figure 5. Each concentrated load corresponded to the load $F/2$. An estimated failure load $F_{max,est}$ was determined by numerical calculations according to [14]. In order to achieve deformations in the elastic range and also to reduce the risk of damage such as cracks or plastic deformations to the specimen, a conservative load limitation $F_{lim,est}$ to 40 % of the estimated maximum load $F_{max,est}$ was made for the non-destructive deformation tests. The non-destructive tests were stopped manually when the estimated limit load was reached. For, e.g. panel A2, the estimated limit load $F_{lim,est}$ reached approximately 34 % of the destructively tested limit load $F_{max,test}$, see Figure 8 and Figure 9. Figure 10 shows the evaluated moduli of elasticity in span direction x as average between the left panel edge (transducer w1) and the right panel edge (transducer w2) for all test series in load configuration (a) and (b). The specimens in this series were tested without opening. The in total smallest evaluated value of the modulus of elasticity was $E_{net,x,min} = 12.468$ N/mm^2. The in total largest evaluated value of the modulus of elasticity was $E_{net,x,max} = 14.558$ N/mm^2. The mean values were evaluated as $E_{net,x,mean} = 13.596$ N/mm^2 in case (a) and $E_{net,x,mean} = 13.243$ N/mm^2 in case (b), see Figure 10. The corresponding value according to the manufacturer was 12.000 N/mm^2. One reason for the relatively high tested values could be the inclusion of higher quality boards in

* see Chapter 3

the grading process. While the laminations have a stiffness more than 10 % higher than stated in declaration of performance, the resulting values for series (a) and (b) are at similar level. The averaged modulus of elasticity $E_{net,x,mean}$ in the case of testing according to [10] (a) is 2,6 % higher than the respective value in the case of concentrated loading (b). To obtain the dynamic characteristics of the elements, the CLT panels were excited at midspan, in the quarter points and at the opening edge by a falling impact hammer in all test stages, see Figure 7 and E1 – E5 in Figure 3. The response was read via accelerometers fixed to the panels in midspan and in the quarter of the span, see Figure 7 and R1 – R3 in Figure 3. The time history acceleration responses from the hammer impacts were converted into frequency domain using the Fast Fourier Transform algorithm, see Figure 11. Table 3 shows the first natural frequency of the elements with and without openings. In general, the first natural frequency of the CLT panels without openings was relatively similar in all elements. The mean fundamental frequency of the CLT panels without opening was 27,4 Hz. With opening, the scatter of the measured fundamental frequencies was a little wider, see Table 3. Due to an opening of 300 mm x 300 mm in the elements, the mean value for the natural frequency of the panels dropped by 2,2 % to 26,8 Hz. An extended opening width of 600 mm x 300 mm lead to a further decrease of the mean value of the fundamental frequency to 25,1 Hz and thus by 8,4 % compared to the condition without opening. For an in-depth view into the determination of values according to EN 384 [16], destructive test-results and further test- set ups, their execution and evaluation see the companion paper [8].

3 NUMERICAL INVESTIGATIONS

There are numerical or analytical methods for solving the plate differential equations, see e.g. [17 – 19], the latter usually being valid for very special cases only. In the present study, a linear elastic finite element (FE) analysis with the software SOFiSTiK 2020 (version 2020.13-1) [20] was used for numerical evaluations.

There are various ways of representing the material and load-bearing behaviour of cross laminated timber elements in finite element models. Figure 12 shows the considered models: (A) modelling of each individual lamination as 2D Timoshenko-beam element, (B) modelling as a multi-layered structure with shell elements and (C) modelling as an equivalent single layered shell element with adjusted material values. For the discussion of further structural models of CLT elements with openings, see [8]. For an overview of the advantages and disadvantages of the investigated model types (A) – (C), see [15].

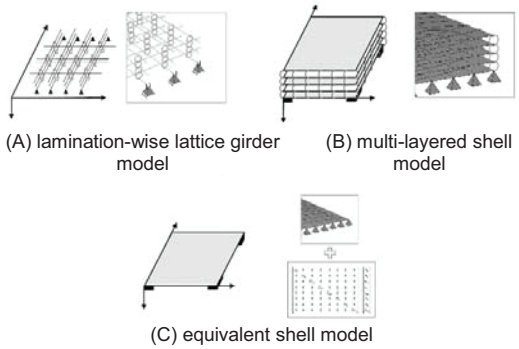

Figure 12: *Overview of considered FE models [13]*

https://doi.org/10.52202/069179-0351

The investigation on hand was carried out using 4-noded Bathe-Dvorkin shell elements, to avoid locking effects [20], with adapted stiffness properties (type C in Figure 12). Further information on locking effects can be found in [21] and [22]. A regular mesh size of the finite elements with a maximum width of 50 mm was chosen. For a convergence study on the mesh size, see [15]. In the applied models, the support conditions were fixed against translation in the *y*- and *z*-directions on one side of the span and against translations in *x*-, *y*- and *z*-directions on the other side. Both support conditions did not fix torsional deformations. A uniformly distributed load of 5 kN/m² was applied to the model for the evaluation of parametrized deformations.

Due to ratio of the investigated total panel thickness t to the span L, it might be assumed that deformations due to shear would not contribute considerably to the calculation results and might be neglected according to Kirchhoff's plate theory. According to Mestek [23], shear deformations of the cross-laminated timber panels may be neglected in the mechanical modelling for threshold ratios $t/L = 1/20 \ldots 1/30$. Additionally, Mestek [23] recommends to always consider shear deformation in serviceability limit state verifications. For the investigation on hand, shear deformations were considered throughout the models. The examined cross-laminated timber panels did not have edge bonding on the narrow edges of the laminations. Therefore, the Poisson's ratios were generally set to zero. For the same reason, the modulus of elasticity perpendicular to the grain in plane was set to zero as well. The adjustment of the torsional stiffness B_{xy} was made according to the declarations specified by the manufacturer [9]. For an in-deep view into the material properties of cross laminated timber, see e.g. Brandner et al. [24]. The applied stiffness values based on the test results are shown in Table 4. For a deeper insight into the evaluation of these stiffness values by calibration on the test results according to Chapter 2, see [15]. For the evaluation of the natural frequencies under dead load, the method according to Lanczos [25] was used. For an in-depth view into modelling of natural frequencies of CLT and respective model uncertainties, see e.g. Labonnote and Malo [26]. The numerical model was parameterized in the geometries span of the element $L_x = 3.000 \ldots 7.000$ mm, width of the opening $l_y = 0{,}10 \ldots 0{,}80 \cdot L_y$ and length of the opening $l_x = 1.000 \ldots 1.500$ mm according to Figure 13.

Table 4: *Material parameters for the model evaluated in [15]*

B_x [kNm/m]	B_y [kNm/m]	B_{xy} [kNm/m]	S_{xz} [kN/m]	S_{yz} [kN/m]
792	208	33,8	7.980	4.420

B_x; B_y = bending stiffness
B_{xy} = torsional stiffness
S_{xz}; S_{yz} = shear stiffness

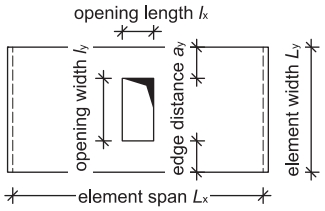

Figure 13: *Definition of geometries according to [15]*

4 RESULTS

The results of the calibrated and parameterized FE analysis were internal forces and deformations, each in the respective element nodes, as well as natural frequencies. The post-processing of the data was carried out with SOFiSTiK, Microsoft Excel and a Python script. Under the two concentrated loads, the CLT elements deformed in both the longitudinal and transversal direction, see Figure 14. The deformed shape of the CLT panels with and without openings was similar under the uniformly distributed load of 5 kN/m². The maximum deflection occurred usually in the area of transducer w4 respectively w7, see Figure 2. The first eigenmode, each with and without opening, reflected an expected semi-sinusoidal shape, see Figure 15.

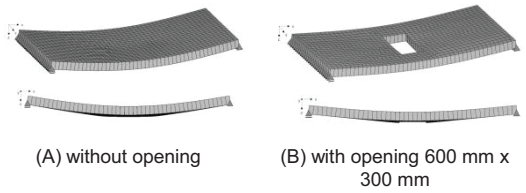

Figure 14: *Deformed shape of the CLT element with visualized element height [15]*

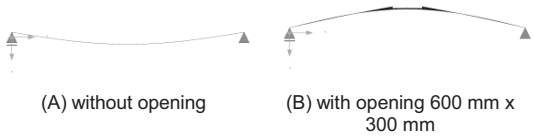

Figure 15: *Semi-sinusoidal eigenmode of the CLT element*

Figure 16 shows the non-normally distributed scatter of the maximum deformation expressed as increase factor k_w, normalized on the deformation without opening for centralized rectangular openings with a fixed opening length of $l_x = 1.000$ mm, see Figure 16 (A), and length of $l_x = 1.500$ mm, see Figure 16 (B), respectively, and a span parametrized between $L_x = 3.000 \ldots 7.000$ mm according to equation (1). Table 5 lists the respective mean values.

https://doi.org/10.52202/069179-0351

$$k_X = \frac{X_2}{X_1} \quad (1)$$

with
$X = w$ for the deformation (2)
$X = f_1$ for the first natural frequency (3)

where
k_X = influence factor of the opening on an effect of action named X;
X_1 = value of the effect of action without opening;
X_2 = value of the effect of action with opening.

It was noted that the relative influence of the opening width l_y on the deformation increases exponentially with the increase of the same in the investigated set-up. As expected with a uniaxial load-bearing system, increasing the opening length l_x in span direction has positive effect on the deformations in case of large opening widths, see Figure 16. From the data obtained, it also appears that the influence of the opening width l_y increases as the span increases. The observations on the deformation can be transferred to the eigenvalues, see Figure 17. Here, too, the influence increases more with increasing opening width compared to increasing opening length. In addition to the stiffness, the influence of the reduced self-weight due to the opening on the natural frequency should not be neglected.

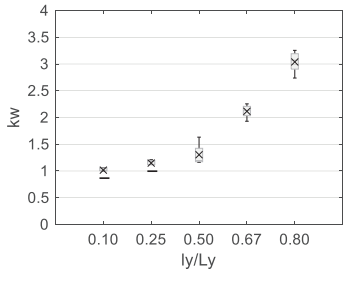
Table 5: *Mean values of influence factor k_w according to [15] and k_{f1} for a span in the range of L_x = 3.000…7.000 mm and for an opening length l_x = 1.000 mm*

l_y/L_y	0,10	0,25	0,50	0,67	0,80
k_w	1,02	1,15	1,54	2,12	3,04
k_{f1}	0,99	0,94	0,83	0,72	0,60

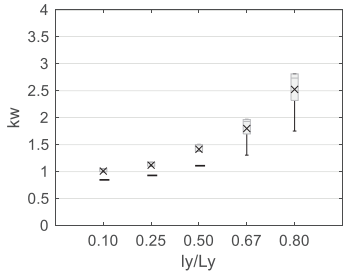
l_y = opening width
L_y = element width

5 CONCLUSIONS AND OUTLOOK

Eurocode 5 provides SLS design verifications for functionality, appearance and the user's comfort in form of deformation and vibration criteria [4]. According to the current draft of the second generation of Eurocode 5 [27], deformations have to be verified using the characteristic, frequent, or quasi-permanent combination of actions given in Eurocode 0 [28]. Based on the investigations of e.g. [29 – 31], vibration verification according to prEN 1995-1-1 [27] comprises frequency criteria, stiffness criteria, velocity and acceleration criteria which are adapted to human perception. The investigations presented showed that openings in CLT floors have a decisive influence on the deformations and the natural frequencies and hence influence the respective verifications in SLS design. Simplified design rules for the verification of deformations of CLT floors with openings do not yet exist in the European design standard.

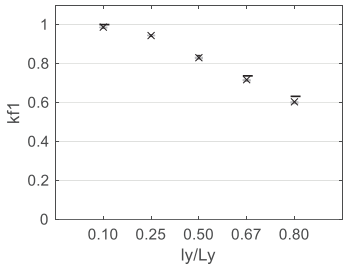


(A) l_x = 1.000 mm

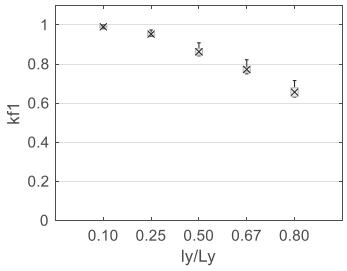


(B) l_x = 1.500 mm

Figure 16: *Non-normally distributed scatter of the increase factor k_w for a span in the range of L_x = 3.000…7.000 mm under uniformly distributed load of 5 kN/m² according to [15]*



(A) l_x = 1.000 mm



(B) l_x = 1.500 mm

Figure 17: *Non-normally distributed scatter of the increase factor k_{f1} for a span in the range of L_x = 3.000…7.000 mm under self-weight*

https://doi.org/10.52202/069179-0351

According to prEN 1995-1-1 [27], under certain boundaries, openings in floors may be generally neglected in the vibration verification provided that the plan area of the opening area and that no individual opening dimension is greater than 40 % of the respective floor dimension.

Further introduction of simplified rules for SLS design of CLT floors with openings would not only strengthen the competitiveness of timber structures but could also support the resource-efficient use of the material in general. Subsequently, with further harmonisation of its structural design, application of CLT will become more and more user-friendly and attractive globally [32].

ACKNOWLEDGEMENT

Project InnoCrossLam was supported under the umbrella of ERA-NET Cofund ForestValue by MIZŠ, INNOVA, FORMAS, STEM, BMLFUW, FNR and MINECO-AEI and has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N° 773324.

The financial support provided by Fachagentur Nachwachsende Rohstoffe e. V. (FNR) of the German Federal Ministry of Food and Agriculture (BMEL) and the Spanish Ministerio de Ciencia, Innovación y Universidades – Agencia Estatal de Investigación under contract PCI2019-103591 AEI is gratefully acknowledged.

TIMBER-FRAMED SHEAR WALLS WITH LARGE OPENINGS AS PART OF THE LATERAL FORCE-RESISTING SYSTEM - OPTIMIZATION OF THE SHEATHING-TO-FRAMING CONNECTION LAYOUT

Nadja Manser[1], René Steiger[2], Martin Geiser[3], Lukas Kramer[4], Andrea Frangi[5]

ABSTRACT: For lateral force-resisting systems of multi-storey timber-framed buildings, the usual policy of current standards is to only consider timber-framed shear wall segments ranging continuously from the ground floor to the top edge of the building and to neglect wall elements with openings. Developing a design method that allows taking wall elements with openings into account, would make the lateral force-resisting system more efficient and respective buildings more economic. This paper presents investigations of the combination of sheathing thickness and arrangement of the fasteners connecting the sheathing to the framing to maximize the load-carrying capacity of the wall while guaranteeing a ductile failure of the connection. The results of the study provide the basis for further experimental investigations on one- and two-story wall elements with large openings with the final goal of developing a design method for timber-framed shear walls with openings.

KEYWORDS: Timber-framed walls, shear walls, sheathing, OSB/3, openings, lateral stiffness, design

1 INTRODUCTION

Timber-framed shear walls are commonly used for the construction of buildings of low to medium heights. It is the usual policy in several current design standards, e.g. SIA 265, 2021 [1], DIN 1052, 2008-12 [2], EN 1995-1-1, 2008 [3], to adopt the so-called segmentation approach for the design of timber-framed shear walls contributing to the lateral force-resisting system (Figure 1, left). Thus, only wall segments, which continuously range from the ground floor to the top of the building can be considered to contribute to the lateral force-resisting system.

Figure 1: *Segmentation approach in the design of timber-framed shear walls with openings (left) versus considering all parts of wall elements with openings (right).*

However, modern architectural designs often demand flexible interior room arrangements, making exterior wall stiffening more important. Since modern architectural designs are characterized by numerous and in particular large openings (Figure 2), designing the lateral force-resisting system of a building using timber-framed shear walls gets very challenging, and sometimes even becomes impossible, since not enough continuous wall segments may be available to resist the lateral forces. The efficiency of the lateral force-resisting system could be enhanced by mobilizing wall segments with openings in the design (Figure 1, right). A beneficial side effect of this design approach is that the number of expensive anchorages is reduced.

Figure 2*: Buildings showing the recent trend in modern architectural design towards façade walls with large openings. [4]*

The objective of an ongoing research project in Switzerland, which forms the basis for the subsequent investigations and findings presented in this paper, is to develop a design method for timber-framed shear walls with openings. This will be accomplished by executing full-scale experiments on such walls and by an analysis of their behaviour under lateral loading. In order to come to an efficient design of wall specimens with openings, it is necessary to first of all define an appropriate and optimized sheathing-to-framing connection layout. This particular

https://doi.org/10.52202/069179-0352

first-step investigations were performed on wall elements *without* openings.

In seismic active areas, timber-framed shear walls are typically designed to exhibit ductile failure of the sheathing-to-framing connection. This requires that buckling and shear failure of the sheathing and a failure of the framing elements is prevented in order to ensure that ductile failure of the sheathing-to-framing connection remains the governing failure mode. An optimal sheathing-to-framing connection layout allows for the maximization of the load-carrying capacity of the wall, while ensuring that the fasteners undergo ductile failure when the load-carrying capacity is reached and avoiding brittle failure of the sheathing.

2 STATE OF THE ART

2.1 TIMBER-FRAMED WALL CONSTRUCTION

The regional differences in the construction of timber-framed shear walls can be observed comparing the dimensions of the framing elements, the thickness and the materialization of the sheathing, and the type of fasteners utilized. In Europe, the dimensions of the framing elements are generally larger compared to e.g. North-America and the thickness of the OSB/3 sheathing is commonly 15 mm. The typical construction of timber-framed shear walls in Switzerland and in other European countries involves the application of staples for the sheathing-to-framing connection. In Switzerland, more than one row of fasteners is not an uncommon practice. Since the study presented in this paper is a part of a research project in Switzerland, the focus is on the type of timber-framed shear walls prevalent in Switzerland and Europe.

2.2 RULES FOR THE DESIGN OF WALLS WITHOUT OPENINGS

2.2.1 Swiss standard SIA 265, 2021

In the Swiss standard, SIA 265, 2021, some general specifications for the design of timber-framed shear walls without openings are provided but no specific design rules are available. Hence, design rules taken from either EN 1995-1-1, 2008 or from DIN 1052, 2008-12 are applied.

2.2.2 European standard EN 1995-1-1, 2008

According to EN 1995-1-1, 2008, the design shear capacity of a timber-framed shear wall $F_{\mathrm{i,v,Rd}}$ can be determined from Formula (1).

$$F_{\mathrm{i,v,Rd}} = \frac{F_{\mathrm{f,Rd}} \cdot b_{\mathrm{i}} \cdot c_{\mathrm{i}}}{s} \tag{1}$$

where $F_{\mathrm{f,Rd}}$ = design load-carrying capacity of a single fastener, b_{i} = width of a single shear wall element, s = distance between fasteners, $c_{\mathrm{i}} = 1.0$ if $b_{\mathrm{i}} \geq b_0$ and $c_{\mathrm{i}} = b_{\mathrm{i}}/b_0$ if $b_{\mathrm{i}} < b_0$, where $b_0 = h/2$ with h = height of the shear wall element.

In EN 1995-1-1, 2008 it is assumed that the load-carrying capacity of the sheathing-to-framing connection is the governing factor for any wall geometry. This corresponds to the assumption that the resistance of the fasteners is always lower than the resistance of the sheathing. However, this assumption may not be valid when multiple rows of fasteners are used.

2.2.3 German standard DIN 1052, 2008-12

According to DIN 1052, 2008-12 the design shear strength of a timber-framed shear wall without opening can be calculated using Formula (2).

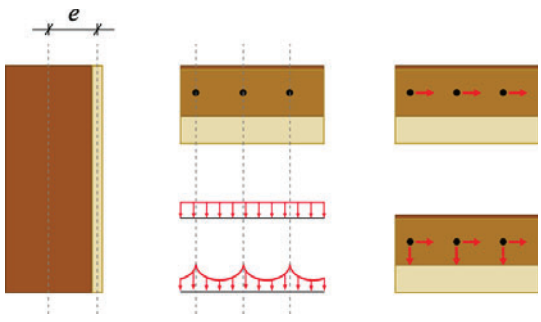
$$f_{\mathrm{v,0,d}} = \min \begin{cases} k_{\mathrm{v,1}} \cdot R_{\mathrm{d}}/a_{\mathrm{v}} \\ k_{\mathrm{v,1}} \cdot k_{\mathrm{v,2}} \cdot f_{\mathrm{v,d}} \cdot t \\ k_{\mathrm{v,1}} \cdot k_{\mathrm{v,2}} \cdot f_{\mathrm{v,d}} \cdot 35 \cdot t^2/a_{\mathrm{r}} \end{cases} \tag{2}$$

where $k_{\mathrm{v,1}}$ = factor to account for the arrangement and the way of connecting the panels ($k_{\mathrm{v,1}} = 1.0$ if the sheathing is connected to the framing on all edges in a sufficiently stiff manner in terms of transferring of shear stresses), $k_{\mathrm{v,2}}$ = factor to account for additional stresses (influences described in the next paragraph), R_{d} = design load-carrying capacity of a single fastener, a_{v} = distance between the fasteners, $f_{\mathrm{v,d}}$ = design shear strength of the panel, t = thickness of the sheathing, a_{r} = distance between the studs.

The first line in Formula (2) considers the limit given by the resistance of the sheathing-to-framing connection. The second line describes the limit given by the resistance of the panel and the third line the limit given by the buckling resistance of the panel. The $k_{\mathrm{v,2}}$ factor serves in accounting for additional stresses, which lead to a reduction of the shear strength of the sheathing. These stresses may originate from:

- the distance between the axis of the framing elements and the sheathing (Figure 3, a)),
- a discontinuous shear flow (Figure 3, b)),
- forces acting perpendicular to the axes of the framing elements (Figure 3, c)).

In DIN 1052, 2008-12 the $k_{\mathrm{v,2}}$ factor is set to 0.33 for the design of sheathing placed on only one side of the wall and to 0.50 for sheathing placed on both sides of the wall.



a) *b)* *c)*

2.2.4 Current working draft of Eurocode 5, prEN 1995-1-1, 2022

The rules for the design of wall diaphragms in the current working draft of Eurocode 5, prEN 1995-1-1, 2022 [5] are based on the design procedure specified in DIN 1052, 2008-12. The $k_{v,2}$ factor was renamed to $k_{p,model}$ and increased to 0.5 for sheathing placed on one, and to 0.67 for sheathing placed on both sides of the wall. In addition to the three influences listed in DIN 1052, 2008-12, along with the design rules in prEN1995-1-1, 2022 two additional influences which need to be accounted in shear wall design (via the $k_{p,model}$ factor) are mentioned:

- Model assumption of pinned connections between ribs while the actual connections are often weaker (Figure 4, a)),
- Eccentricity of the axes of the framing if the framing elements are of different depth in cross-section (Figure 4, b)).

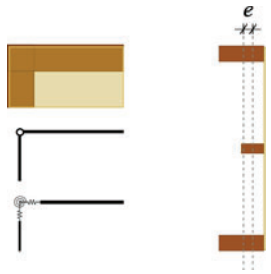

***Figure 4**: Influences reducing the shear strength of the sheathing in timber-framed shear walls compared to DIN 1052, 2008-12 additionally described in prEN 1995-1-1, 2022. a) Deviation from the model assumption of pinned connected framing elements (top: model assumption, bottom: reality), b) eccentricities within the framing elements.*

3 GOAL OF THE STUDY

The $k_{v,2}$ factor specified in DIN 1052, 2008-12 seems to have been introduced to overcome the problem of unaccounted additional stressed in the shear wall designs, which can reduce the shear strength of the sheathing. When looking at literature, it is unclear, to what extent these values are based on experimental research. Up to now, no results from experiments on timber-framed shear walls using OSB panels as sheathing material are available. This leads to the conclusion that the basis in terms of experimental data for the determination of the $k_{v,2}$ factor (or $k_{p,model}$ factor, respectively) is still poor.

In Switzerland, it is common practice to design the fasteners (i.e. the staples) of the sheathing-to-framing connection in multiple rows. In consequence, the need for a more accurate quantification of the $k_{v,2}$ factor needed for an accurate calculation of the shear strength of the sheathing of timber-framed shear walls arises. The results of this study will help in defining the optimal combination of sheathing thickness and fastener layout in order to maximize the load-carrying capacity of the wall element, while avoiding brittle failure of the sheathing.

An experimental campaign was conducted to investigate the shear resistance of OSB/3 panels in timber-framed shear walls without openings. The resulting shear resistance of the OSB/3 panels was compared to analytic estimations based on the design rules available in the standards mentioned above. The ratios calculated from a comparison of experimental data and estimate from design code formulae correspond to the reduction of the shear strength of the OSB/3 sheathing for applications in timber-framed shear walls.

4 MATERIALS

4.1 SHEATHING PANELS

The panels investigated were of type OSB/3 with thicknesses of 12 mm, 15 mm, 18 mm and 25 mm, and dimensions (i.e. width and height) of 1250 mm and 2500 mm. The panels for all test specimens originated from one single production batch for each panel thickness. The moisture content was determined by using the oven-dry method in accordance with the test procedure specified in EN 322, 1993 [6] and was $7.2 \pm 0.4\%$, which fulfils the requirements of EN 300, 2006 [7].

4.2 FRAMING ELEMENTS

The framing elements were composed of Swiss-grown Norway spruce (*picea abies*) glulam GL24h (EN 14080, 2013 [8]). The moisture content was determined by measuring the electic resistance and was $10.3 \pm 0.7\%$.

4.3 SHEATHING-TO-FRAMING CONNECTION

For the sheathing-to-framing connection, two different types of fastener were used:

- resined staples with a diameter of 1.53 mm and a length of 50 mm (Haubold, KG 700),
- threaded nails with a diameter of 3.10 mm and a length of 90 mm. (Haubold 3.10 x 90 Ring Wire Weld).

5 METHODS

Experiments on wall elements, as well as on OSB/3 panels were carried out. The latter aimed at determining the mechanical properties of the OSB/3 panels.

5.1 TESTS ON OSB/3 PANELS

The shear strength of the OSB/3 panels was determined in accordance with the test procedure specified in the European standard EN 789, 2005 [9]. Five specimens were tested for each sheathing thickness for both parallel and perpendicular strand orientation of the top layer.

5.2 SHEAR WALL TESTS

In order to evaluate the shear resistance of OSB/3 panels when applied as sheathing in timber-framed shear walls, full-scale wall elements were tested. The study focused on wall configurations where the OSB/3 sheathing was placed on one side only. The test setup, including the terminology used for the framing elements and the definitions of fastener distances, is depicted in Figure 7.

https://doi.org/10.52202/069179-0352

5.2.1 Design of the specimens

The specimens were designed to ensure that failure would occur in the sheathing, rather than in the sheathing-to-framing connection. To provoke this particular failure mode, sheathing-to-framing connection, anchoring, and framing elements were over-designed in comparison to the shear resistance of the sheathing. The shear resistance and the resistance against buckling of the panels (as described in the second and third line of Formula (2)) were evaluated on design level, using:

- $k_{v,1} = 1.0$,
- $k_{v,2} = 1.0$, assumption as starting point for the factor to be investigated,
- $f_{v,d} = k_{mod} \cdot f_{v,k}/\gamma_M = 6.23\ N/mm^2$, where k_{mod}, γ_M, and $f_{v,k}$ are 1.1, 1.2, and 6.8 N/mm^2, respectively, according to EN 1995-1-1, 2008,
- t: Thickness of the sheathing (nominal values).

Due to lack of information the over-strength factor to design the sheathing-to-framing connection and the anchoring was conservatively selected 1.5. This resulted in a high number of fastener rows. The space needed to arrange the fasteners influenced the width of the edge studs and the top and the bottom rail. In consequence, the framing elements compared to the sheathing, have an over-strength higher than 1.5.

The panels with thicknesses 12 mm, 15 mm, and 18 mm, were connected to the framing elements by means of resined staples. For the 25 mm thick panels, threaded nails were used, since the resined staples used in practice are technically difficult to insert in the 25 mm thick OSB/3 panel and the penetration depth in the framing members would be critically low.

The size of the specimen was governed by the dimensions of the panels (2.50 m and 1.25 m) and an offset of 20 mm (Figure 7 d_1) on all edges to prevent local crushing of the sheathing due to increasing deformations during the tests. The width and the height of the specimen were 1.29 m and 2.54 m respectively. To ensure comparability, the geometric configuration of the three stapled wall types was kept identical. The layout of the sheathing-to-framing connection and the dimensions of the framing elements as well as of the anchoring were taken based on the test specimens with the 18 mm thick sheathing, while the number of inner rails was taken based on the test specimens with the 12 mm thick panel since the resistance against buckling failure is minimal for the thinnest panel. Three specimens were tested for each wall type. In Table 1 the materials used and the geometrical properties are listed for all the four wall types investigated.

In order to prevent compression failure parallel to the grain of the edge studs and the top and the bottom rail, the corners of the walls were designed in such way that the rails and the edge studs both ranged continuously to the edges of the wall elements (mortise and tenon joints). The top and the bottom rails were constructed overlapping in order to simplify the installation of the test specimens in the test rig as well as the force transfer from the hydraulic jack to the specimen. (Figure 5)

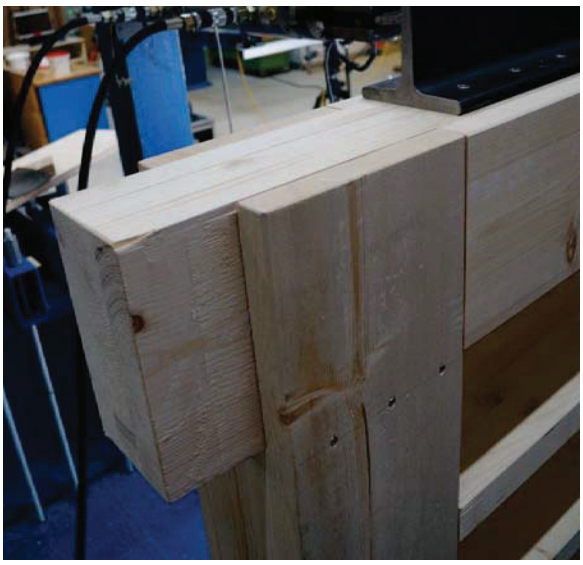

***Figure 5**: Construction detail of mortise and tenon joints at the corners of the tested timber-framed shear wall elements.*

5.2.2 Loading protocol

The walls were tested according to the testing standard ISO 21581, 2010 [10], using the force controlled testing protocol shown in Figure 6. $F_{max,est}$ was determined by estimating the shear capacity of the wall element resulting from the shear resistance of the panel (as described in the second line of Formula (2)) taking the parameters as follows:

- $k_{v,1} = 1.0$,
- $k_{v,2} = 1.0$, assumption as starting point for the factor to be investigated,
- $f_{v,mean,est} = 9.4\ N/mm^2$ [1],
- t: Thickness of the sheathing (nominal values)

5.2.3 Realization in the lab

The force was applied centrically on the top rail of the specimen using a 1000 kN hydraulic jack (Figure 8 and Figure 9). Due to the non-perfect stiffness of the test rig, small test rig deformations in direction of the applied force could not be prevented. Since the effective deformation ($d_{\mathrm{max,rel}}$) of the timber-framed shear wall was determined in accordance with the procedure given in the standard ISO 21581 as the difference between the deformation in direction of the applied force on the top rail and the bottom rail, these small test rig deformations were neglected. The horizontal displacement in the centre of the bottom edge of the wall was measured using a mechanical displacement sensor with a measuring range of 10 mm and a precision of 0.04 mm, the horizontal displacement in the centre of the top edge of the wall was measured using a laser distance sensor with precision of 0.11 mm.

The anchoring of the vertical tensile and compressive forces and the resulting horizontal force is shown in Figure 9 and in Figure 10. Due to the asymmetry of the wall elements with sheathing on one side, out-of-plane forces developed during loading. To prevent tilting of the wall, a steel support was attached to the top rail of the wall and a 50 kN hydraulic jack was used to stabilize the wall (Figure 11). By forcing the stroke of this hydraulic jack to a displacement of 0 mm, tilting of the wall was avoided.

***Figure 8**: Timber-framed shear wall specimen mounted in the test rig and ready for investigation of the shear resistance of the OSB/3 panels applied as sheathing material.*

***Figure 10**: The horizontal reaction force was transferred to the test rig via a massive steel angle bracket. The vertical compressive force was transmitted through contact.*

***Figure 9**: The force was applied by the red hydraulic jack. The rail construction on top of the specimen is freely movable in horizontal direction. The tensile reaction forces were transmitted through the edge studs to the top edge of the specimen, where they were then transferred to a steel plate and brought back to the specimen via four steel rods.*

***Figure 11**: Tilting of the specimen was prevented by means of a 50 kN hydraulic jack maintaining the out-of-plane displacement on the top rail at a value of 0 mm.*

6 RESULTS AND DISCUSSION

6.1 TESTS ON OSB/3 PANELS

The results of the shear tests performed on the OSB/3 panels are presented in Table 2. The coefficients of variation (CoV) of the shear strength were in the range of 3.6% to 10.8%. The mean value of the shear strength of OSB/3 panels reported in the literature (9.4 N/mm^2, [11]) was not confirmed by the results obtained from the tests conducted in this study. The 5% fractile values calculated from the test data according to the procedure in the European Standard EN 14358, 2016 [12] were lower than the value specified in EN 1995-1-1, 2008 and in the declaration of performance (6.8 N/mm^2) for all test series except for the 12 mm and 15 mm thick panels tested perpendicular to the strand orientation of the top layer. Investigations are planned to identify the causes of the insufficient shear strengths of the panels.

***Table 2**: Mean values, standard deviations and coefficients of variation (CoV) of the shear strength obtained from the tests on the OSB/3 panels. The 5% fractile values were calculated in accordance with the procedure given in EN 14358, 2016.*

12, ∥	5	6.97	0.38	5.5	6.08
15, ∥	5	7.40	0.42	5.6	6.41
18, ∥	5	7.28	0.46	6.3	6.21
25, ∥	5	6.37	0.27	4.3	5.62

6.2 SHEAR WALL TESTS

In all the 12 tests performed on timber-framed shear wall elements, the sheathing failed in a brittle manner, in direction of the force flow, connecting the point of the applied force and the point where the horizontal force is transferred to the test rig. The initial failure occurred either along one of the fastener rows (Figure 12), or in diagonal direction in the field of the sheathing (Figure 13).

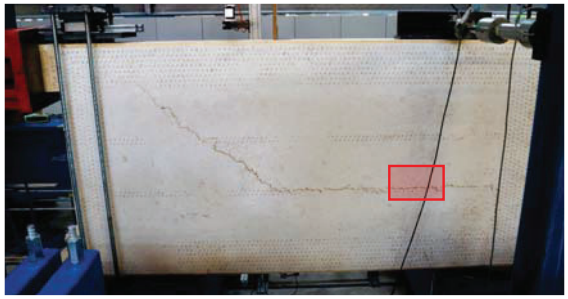

***Figure 12**: The initial failure in the 12-S-2 shear wall test occurred along the fastener row on the lower inner rail (marked in red).*

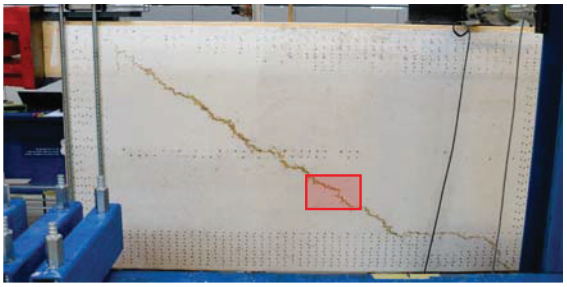

***Figure 13**: The initial failure of the 25-N-3 shear wall test occurred in diagonal direction in the field of the sheathing (marked in red).*

The applied maximum force and the respective maximum of the relative horizontal displacement ($d_{max,rel}$, see 5.2.3) are listed in Table 3 for each of the specimens tested. Since the displacement and the resulting stiffness of the tested wall elements are important for the comparison of numerical calculations with test results, the displacements are given for the sake of completeness, without being further discussed in this paper.

***Table 3**: Applied maximal horizontal force F_{max} and respective maximal relative displacement $d_{max,rel}$ at failure for each of the timber-framed shear wall specimens tested.*

	Specimen	F_{max} [kN]	$d_{max,rel}$ [mm]
12-S	12-S-1	181	9.5
	12-S-2	186	10.1
	12-S-3	178	9.5
15-S	15-S-1	241	12.5
	15-S-2	221	10.6
	15-S-3	229	10.6
18-S	18-S-1	299	11.9
	18-S-2	290	11.7
	18-S-3	305	12.9
25-N	25-S-1	394	16.6
	25-S-2	405	16.3
	25-S-3	379	14.5

The $k_{v,2}$ factor can be determined by equating the shear resistance of the OSB/3 panel in timber-framed shear walls estimated using the second line in Formula (2) multiplied by the length of the wall, and the maximum force F_{max} at failure determined in the experiments. Solving for $k_{v,2}$ leads to Formula (3).

$$k_{v,2} = \frac{F_{max}}{F_{max,est}} = \frac{F_{max}}{k_{v,1} \cdot f_{v,est,mean} \cdot t \cdot l} \qquad (3)$$

where F_{max} = applied force at failure, $k_{v,1} = 1.0$, $f_{v,est,mean}$ = estimated shear strength of the panel on mean level, t = nominal thickness of the sheathing, l = length of the wall.

The mean value of the shear strength of OSB/3 panels $f_{v,est,mean}$ was estimated starting from the characteristic shear strength specified in EN 1995-1-1, 2008 (i.e. $f_{v,k} = 6.8\ N/mm^2$). Based on the assumption of a

log-normal distribution, the mean value was calculated using the definition of the moments and the cumulative distribution function of the log-normal distribution (Formulae (4) - (6)).

$$\mu_X = e^{\lambda+\zeta^2/2} \tag{4}$$

$$\mathrm{CoV}_X = \sqrt{e^{\zeta^2} - 1} \tag{5}$$

$$F_X(x) = \Phi\left(\frac{\ln(x)-\lambda}{\zeta}\right) \tag{6}$$

where ζ and λ = distribution parameters, μ_X = mean value of the population, CoV_X = coefficient of variation of the population.

In the JCSS Probabilistic Model Code [13], there is no information about the CoV of the shear strength of OSB/3 panels. In the present study, it was decided to use a CoV of 15% as the upper bound for the investigations, a value equal to the one specified in the JCSS Probabilistic Model Code for the shear strength of glued laminated timber (GLT). The mean CoV determined from the tests carried out to assess the shear strength of the OSB/3 panels was 6%. This low value can be explained by the fact that all panels tested were part of one single production batch. Hence, in the investigations, the 6% CoV was chosen as the lower bound. Additionally, calculations were also performed using a CoV of 11%. The $k_{v,2}$ factors resulting from these calculations (i.e. from the comparison between estimates and experimental data) are listed in Table 4. In the presented study, the $k_{v,2}$ factors for timber-framed shear walls sheathed with OSB/3 panels on one side were found to range between 0.69 and 0.88, depending on the thickness of the panels and the CoV outlined above accounted for in the calculation. The results show that the $k_{v,2}$ factor of 0.33 given in DIN 1995-1-1, 2004-08 for sheathing placed on one side is very conservative. However, the specified value of 0.5 specified in the working draft of prEN 1995-1-1, 2022 matches the experimental results of this study better.

***Table 4**: $k_{v,2}$ factors determined by applying Formula (3) and using the estimated shear strength $f_{v,est,mean}$ evaluated by assuming different* CoV*'s for the distribution of the shear strength of the OSB/3 panels.*

CoV*	$f_{v,est,mean}$	$k_{v,2}$			
		12-S	15-S	18-S	25-N
6%	7.52 N/mm²	0.81	0.82	**0.88**	0.84
11%	8.19 N/mm²	0.74	0.75	0.81	0.77
15%	8.78 N/mm²	**0.69**	0.70	0.75	0.72

* CoV 6%: Lower bound value based on the mean value of the shear strength measured in the experiments on OSB/3 panels, CoV 15%: Upper bound value based on the CoV given for GLT in JCSS.

In addition to the influencing factors, which induce additional stresses as listed in DIN 1052, 2008-12 (see 2.2.3) and in prEN 1995-1-1, 2022 (see 2.2.4), there are additional influences, which may reduce the shear resistance of OSB/3 panels when applied as sheathing material in timber-framed shear walls. These factors include:

- Additional stresses resulting from eccentricities in the connection of the ceiling to the wall.
- Weakened sheathing due to the attachment of steel bracket angles as anchoring.

These influences were not considered in the experiments, and hence, also not considered in the calculated $k_{v,2}$ factors in Table 4.

When investigating the maximum number of fasteners that can be applied while still ensuring a ductile failure of the connection, an over-strength factor of 1.6 was assumed [14]. By comparing the resistance of the sheathing-to-framing connection and the shear resistance of the panel (first and second line in Formula (2)) and using the over-strength factor 1.6, the minimum distance $a_{v,min}$ between the fasteners can be calculated with different assumptions in terms of $k_{v,2}$ factor with Formula (7):

$$a_{v.min} = \frac{1.6 \cdot R_d}{k_{v,2} \cdot f_{v,d} \cdot t} \tag{7}$$

where $k_{v,2}$ = factor to account for additional stresses, $f_{v,d}$ = design shear strength of the panel, t = thickness of the sheathing, R_d = design load-carrying capacity of one single fastener.

The characteristic load-carrying capacity $F_{v,Rk}$ of a single nail and a single staple was calculated according to the standard EN 1995-1-1, 2008 (Clause 8.2.2, Equation 8.6). The design load-carrying capacity R_d according to EN 1995-1-1, 2008 is $R_d = k_{mod} \cdot F_{v,Rk}/\gamma_M$, where k_{mod} and γ_M are 1.1 and 1.2, respectively, according to EN 1995-1-1, 2008. For a single nail, the design load-carrying capacity R_d is equal to 0.66 kN and for a single staple the respective value is 0.52 kN.

Taking the data and $k_{v,2}$ factors listed in Table 4 and applying Formula (7), the minimum fastener distances were calculated for $k_{v,2}$ values between 0.55 and 0.75. The resulting minimum distances $a_{v,min}$ are listed in Table 5.

***Table 5**: Resulting minimal fastener distances $a_{v,min}$ for the four investigated sheathing thicknesses (12 mm, 15 mm, 18 mm and 25 mm) assuming different $k_{v,2}$ factors.*

$k_{v,2}$	$a_{v,min}$			
	12 mm	**15 mm**	18 mm	25 mm
0.60	18.6	**14.8**	12.4	11.2
0.65	17.1	13.7	11.4	10.4
0.70	15.9	12.7	10.6	9.6
0.75	14.8	11.9	9.9	9.0
0.80	13.9	11.1	9.3	8.4

For example, for a 15 mm thick sheathing and assuming a conservative value of 0.6 for the $k_{v,2}$ factor, based on the results listed in Table 4, the minimum $a_{v,min}$ distance between the staples was calculated to be 14.8 mm (→ 15 mm). When arranging two rows of staples, the minimum distance between the staples would be 29.6 mm (→ 30 mm). According to the Swiss standard SIA 265/1,

https://doi.org/10.52202/069179-0352

2018 [15] the minimum distances of the connection need to be increased by a factor of 1.5 to ensure a ductile behavior. The minimum distance between the staples in Switzerland would be 34.4 mm (→ 35 mm)

7 CONCLUSIONS AND OUTLOOK

The factor $k_{v,2}$ specified in DIN 1052, 2008-12 (0.33 for sheathings placed on one side), which accounts for additional stresses that are reducing the shear resistance of the sheathing in timber-framed shear walls seems to be quite conservative, compared to the results from the experiments conducted in the presented study. The values for $k_{v,2}$ resulting from the experiments range between 0.69 and 0.88 depending on the estimated mean value $f_{v,est,mean}$ of the shear strength of the panels. The value for $k_{v,2}$ (renamed to $k_{p,model}$ in prEN 1995-1-1, 2022) matches the experimental results of this study better.

The test results indicate that by specifying reasonable minimum distances a_v between the fasteners (i.e. for instance 30 mm for two rows of staples in a 15 mm thick OSB/3 sheathing and choosing a $k_{v,2}$ factor of 0.60), multiple rows of fasteners can be planned while ensuring a ductile failure of the fasteners and avoiding a brittle failure of the sheathing.

Further investigations (i.e. additional experiments accompanied by numerical analyses) are required to determine the accurate value of the $k_{v,2}$ factor used in the calculation of the shear resistance of OSB/3 sheathings in timber-framed shear walls. The study presented here only investigated wall elements with OSB/3 sheathing placed on one side of the wall. Additional experiments recently performed on OSB/3 sheathed timber-framed shear walls can be taken into consideration to determine the values of the $k_{v,2}$ factor more reliably. An increase of this factor compared to the values currently specified in prEN 1995-1-1, 2022 (i.e. 0.50 for sheathings on one side and 0.67 for sheathings on both sides) would lead to an increased load-carrying capacity of timber-framed shear walls.

This study represents the first step of a series of investigations in a research project where further experiments will be performed on one- and two-storey wall elements with large openings, with the ultimate goal of developing a design method for timber-framed shear walls with openings as part of the lateral force-resisting system in timber buildings. The use of timber-framed shear walls with openings in the lateral force-resisting system has the potential to provide more economical design solutions in timber construction.

EXPERIMENTAL AND NUMERICAL INVESTIGATION ON THE EFFECT OF CIRCULAR HOLES ON GLULAM COMPOSITE BEAMS

Dag Pasquale Pasca[1], Yuri De Santis[2], Angelo Aloisio[3], Andreas Stenstad[4], Karl-Christian Mahnert[5],

ABSTRACT: This paper presents an extensive experimental investigation on the effect of circular holes with and without reinforcement on glulam joists' behaviour. The tests consider the variability of hole position, number and strength class of the beam. Furthermore, a finite element model based on fracture mechanics was developed and validated against the experimental force-displacement curves of thirteen configurations. The model reproduces crack initiation and propagation through the adoption of cohesive contact layers. The satisfactory agreement with the experimental data has been the base of extensive parametric analyses considering multiple beam and hole geometry selections and two load arrangements at the upper and lower side of the beam. Finally, the results of the parametric analyses, initially used for a qualitative understanding of the structural behaviour, are used for calibrating probabilistic capacity models of the capacity of simply-supported beams with circular holes. The mechanics-based probabilistic model calculates the capacity as the product between the analytical capacity associated with the reduced cross-section and an adimensional correction factor. The factor is expressed as a linear combination of a set of explanatory variables selected after a step-wise deletion process.

KEYWORDS: Holes; Glulam; Reinforcement; NLFM; Experimental tests; FEM.

1 INTRODUCTION

The use of holes in timber beams is a widespread structural solution, especially in the case of interference with pipeline services. The occurrence of tensile stresses perpendicular to grain due to holes, shrinkage, external loads, or a combination of these factors in timber beams can significantly impair the bearing capacity, given the low tensile strength perpendicular to grain [1-3].
Most existing research on beams with holes focuses on experimental tests rather than numerical modelling [4-6]. Experimental tests [7], finite element analysis [8, 9], analytical modelling and design provisions [10] demonstrated the detrimental impact of the holes and notches on the load carrying capacity of the bare timber beams (without slabs) as well as timber composite I-joist with oriented strand board (OSB) webs [11].

The failure of timber beams with openings is typically associated with cracks initiated from the top quarter of the holes (towards mid-span) and/or from the bottom quarter of the holes (towards the support). Similar failure modes and delamination and shear failure of the flanges have been observed in the timber I-joists with web openings [11-13]. The results of laboratory testing and FE modelling have been used to develop empirical equations for estimating the load-carrying capacity of the timber I-joists with web openings [14, 15]. Moreover, for the practical design of OSB webbed timber I-joists with openings, critical (minimum) spacing between the web openings was determined based on the results of FE analyses [15]. To minimize the impact of openings and notches on the peak load of the timber beams, different methods such as externally bonded plywood/OSB and steel plates [12, 13], and fully threaded screws or glued-in rods have been proposed. Their performance has been experimentally and analytically examined by [16, 17].

Karimi and Valipour [18] tested eleven different types of Laminated Veneer Lumber- Cross Laminated Timber (LVL-CLT) and Glued Laminated Timber (GLT)-CLT beams and four types of bare LVL-GLT beams without and with circular and square openings in the LVL-GLT webs under three-point bending to produce benchmark experimental data required for assessing the effect of the web openings on the failure mode and load carrying capacity of the Timber-Timber-Composite (TTC) beams. In addition, digital image correlation (DIC) was used to capture the strain profile around the holes up to the initiation of cracks (onset of fracture) and shed light on failure mechanisms generated by the combination of bending, shear, and tension perpendicular to the grain.

Several capacity models underestimate the peak loading capacity of timber beams or maybe only applicable to the beams with specific details or cross-section dimensions. For instance, Danielsson [3] showed that the empirical method adopted in the Swedish glulam handbook [10] tends to underestimate the experimental load-bearing capacities of the GLT beams with rectangular openings.
Karimi and Valipour [19] numerically investigate the structural behaviour of the LVL and GLT beams with openings and highlight the importance and need for applying robust localization limiters (regularisation technique).
Recently, Gilbert et al [20] carried out tests on timber Circular Hollow Section (CHS) beams showing failure modes not usually encountered in timber structures.

Fracture mechanics approaches are needed for accurate predictions of the post-elastic behaviour of beams with holes [21]. Therefore, complex mechanical formulations are required, like those based on linear elastic fracture mechanics (LEFM) [22-24] and Weibull theory-based damage model [25].
Nonetheless, the predictions with LEFM might lead to conservative results, as highlighted by Adalany et al. [26], who considered LVL beams with holes.

Guan and Zhu [27] developed a nonlinear finite element model capable of simulating crack propagation based on stress monitoring. The model eliminates the structural contribution by setting the stiffness to zero when the yield strength is reached. However, despite the mentioned improvement, the model does not allow sudden crack propagation, typical of the shear failure of beams with holes.

More recently, methods based on nonlinear fracture mechanics (NLFM) proved to be more effective and capable of simulating the post-failure behaviour with crack propagation [21, 28].
Ardalany et al. [21] developed an NLFM-based tridimensional FE model to investigate the effect of shape, size and position of the openings of a glulam beam and to derive an optimal reinforcement strategy. Continuum damage models (CDM) were developed by Sandhaas [29] and modified by Gharib et al. [30] who enriched it with an anisotropic non-local integral-type model. The non-local CDM is implemented in FE software and then is employed to predict the nonlinear behaviour and capture failure of timber under complex multiaxial stress states generated by the presence of holes/openings.

This paper presents an experimental and numerical study on composite glulam joists with one or two circular holes in different positions. The experimental campaign aims at identifying the influence of hole position, hole number and distance on the reduction of the joist capacity. Furthermore, a finite element model, which accounts for crack initiation and propagation, is developed and validated against the experimental results. Differently from what has been done by [21], cohesive contacts have been used to reproduce the crack formation. The efficient tridimensional FE model has been parameterized and used to extend the results of the experimental campaign.

In synthesis, the main aspects of novelty and originality of this research are:

- Extensive experimental campaign on glulam joist with different hole geometry, position and reinforcement.
- Validation of a nonlinear finite element model based on fracture mechanics.
- Parametrization of the model and extensive analyses to assess the dependence of the capacity of beams with circular holes by varying the following parameters: hole diameter and position, beam geometry, the position of the load (upper side and lower side).

The main limitations of this research are twofold. The first relates to the experimental tests, where only one value for the hole-depth ratio was considered. Therefore, the FE model has only been validated for a specific hole/depth ratio. The second aspect relates to the computational burden of the analyses. The authors only varied the geometric parameters of the beam, assuming deterministic mechanical parameters, which were validated against the experimental tests. Future research efforts will assess the effect of the fracture mechanics properties by considering suitable probability distributions, thus providing a probabilistic estimate of the capacity for given geometric configurations.

2 EXPERIMENTAL TESTS

2.1 MATERIALS AND CONFIGURATIONS

The experimental campaign involved glue-laminated timber joist of length l=5700 mm, with a cross-section width b of 36 mm or 48 mm and with a cross-section height h of 300 mm (Figure 1).
In addition to the reference configurations without holes, joists with one or two holes of diameter d=170 mm in different positions along the joist axis were tested. The tests include configurations with a hole at mid-span and configurations with one or two holes near the supports or under the loading point. The position of the holes of each configuration is shown in Table 1.

Two different series have been considered to assess the glulam class influence on the mechanical properties reduction due to holes. The joists of both series are combined glulam with 19 mm thick ungraded internal lamellae and 47 mm thick external lamellae. The external lamellae of the first and second series are made of C30 and C40 lamellae, respectively. The mean density of the specimens is 460 kg/m^3
The tests covered both unreinforced beams and beam reinforced by glulam or plywood plates glued to the outer faces of the beams. Figure 2 shows the geometry and dimensions of the specimens with exterior reinforcements of the holes.

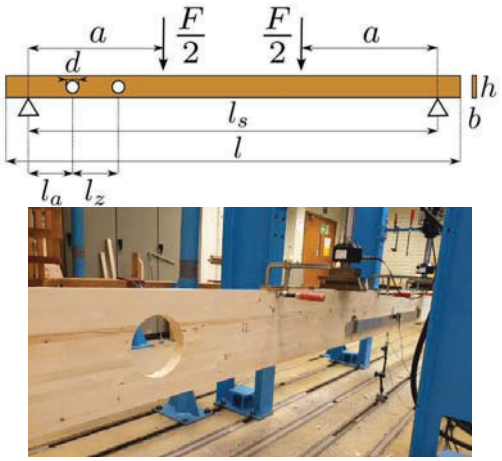

Figure 1 - *(up) Geometric configuration of the beam; (down) Experimental setup*

The plywood plate reinforcement has a length b_r of 1200 mm, a height h_r of 290 mm and a thickness t_r of 12 mm. The employed plywood has 5 layers and belongs to strength class F20/15 and MOE class E 45/25 according to EN 13986 and EN 636. The glulam reinforcement is made of the same material as the reinforced joist with the timber grain parallel to the joist axis. In both cases, the reinforcement has been glued to the joist with a phenol-resorcinol adhesive together with self-tapping screws d=5 mm and l=50 mm. Also, a specimen with non-structural glue was tested. Different quantities of glue and number of screws were tested (Table 1).

2.2 TEST METHODS

The glulam joists were tested according to the four-point bending test procedure outlined in the EN-408 standard [31]. The distance between the base supports was set to l_s=18h=5400 mm, and the distance between a loading points position and the nearest support has been set to a=6h=1800 mm (Figure 1).

The bending strength f_m has been determined with the following equation:

$$f_m = \frac{F_{max} a}{2W} \quad (1)$$

Where F_{max} is the overall maximum load applied by the two jacks, a is the loading points distance from the nearest support and $W=bh^2/6$ is the section modulus.

The global modulus of elasticity in bending $E_{m,g}$ has been calculated from the load-deflection linear regression between F_1 and F_2 and the corresponding deflections w_1 and w_2. The global displacement was measured using LVDT placed under the beams at mid-span, as outlined by the standard. According to EN 408 $F_1=0.1F_{max}$ and $F_2=0.4F_{max}$ or at least $F_2=0.3F_{max}$ with $R2>0.99$, and $w_1=w(F_1)$ and $w_2=w(F_2)$.

The following equation gives the global modulus of elasticity in bending:

https://doi.org/10.52202/069179-0353

$$E_{m,g} = \frac{l^3(F_2 - F_1)}{bh^2(w_2 - w_1)}\left[\left(\frac{3a}{4l}\right) - \left(\frac{a}{l}\right)^3\right] \quad (2)$$

where l is the beam span and $a=6h=l/3$ is the distance from support to the nearest load application point.
The shear strength of the glue line parallel to the direction of the grain of glulam-glulam and glulam-plywood specimens has been tested according to EN-392. The shear test was carried out on specimens with rectangular parallelepiped shapes with two sides of length b=50 mm and the third of t=36 mm or t=48 mm. The offset between each half of the specimen was b_o=5 mm (Figure 3).

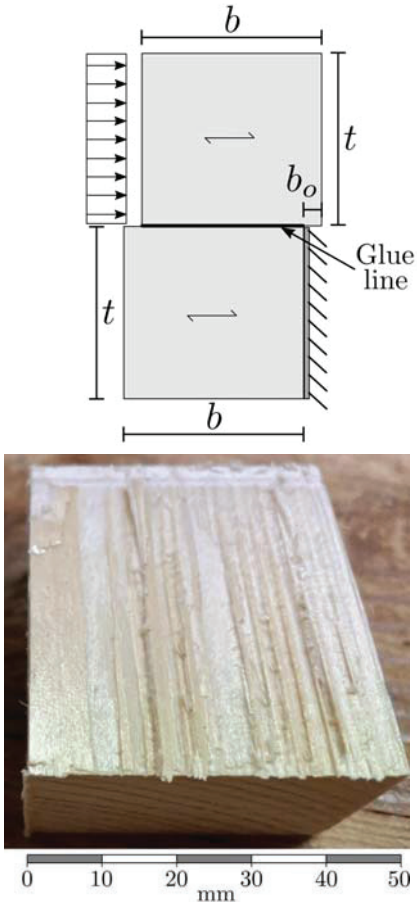

Figure 3 - *Shear tests: (up) dimension and setup; (down) failure surface*

2.3 TEST RESULTS

The overall applied force-midspan deflection results are reported in Figure 4 and Figure 5. The maximum load, the ultimate displacement, the global modulus of elasticity in bending and the bending strength are reported in Table 2. In the reference configurations without holes and configurations with holes in the constant moment area, the joists fail in bending. In contrast, in the joists with one or two holes in the constant shear area, the failure happens due to the longitudinal cracks around the holes (Figure 6).

No appreciable maximum load reduction was observed in configurations with a single hole at midspan (l_a=*2.7 m*). An appreciable decay of the strength of the joist was observed for single hole configurations with l_a=*0.6 m* or l_a=*1.7 m*. The double hole configurations with $l_a=l_z$=*0.6 m* led to the greater reduction in strength of -27% and -33% for C30 and C40 test series, respectively.
The reinforcement of the joists with $l_a=l_z$=*0.6 m* led to a total recovery of the resistance. No significant differences were found in the percentage of strength recovery for varying reinforcement configurations.

Regarding the shear tests, the shear strength and the percentage of timber and glue failures are reported in Table 3. It is worth noting that since the percentage of the timber failure is predominant, the τ_{max} is intended as the shear strength of timber in the direction parallel to the grain.

2.4 PREDICTED LOAD VIA STANDARD FORMULATION

The experimental results have been compared with the predicted load of the formulation prescribed in the DIN-1052. According to the formulation given by this standard, the failure load can be predicted by superposing the effects in terms of traction perpendicular to the grain of the shear and moment component as in the following equation:

$$F_{t,90} = F_{t,V} + F_{t,M} \quad (3)$$

where the shear component $F_{t,V}$ is calculated by integrating the shear tension according to the Euler-Bernoulli theory over the section area delimited by the crack. This area is conventionally defined by the intersection of a 45° line from the hole centre with the hole circumference itself:

$$F_{t,V} = \frac{Vh_d}{4h}\left[3 - \left(\frac{h_d}{h}\right)^2\right] \quad (4)$$

where V is the shear force in the beam, h_d is equal to $d{\cdot}cos(\pi/4)$ for circular openings, d is the diameter of the hole, h the height of the section of the beam.
The moment component $F_{t,M}$ is calculated by an empirical equation by Kolb and Epple [32]:

$$F_{t,M} = 0.008\frac{M}{h_r} \quad (5)$$

where M is the bending moment in the beam and h_r depends on the remaining height above (h_{ro}) or underneath (h_{ru}) the hole crack and can be assumed equal to $h_r=min(h_{ro}+0.15h_d;\ h_{ru}+0.15h_d)$.

PRF Plywood	14	97	3	5.8	23.6
PRF Glulam	10	74	26	7.8	12.3

The load of Eq.3 is then compared to the tensile strength of the area subjected to stresses perpendicular to the grain. It is worth noting that according to this model when the crack is located nearest to the mid-height of the section of the beam, the shear contribution defined in Eq.4 increases while the bending contribution defined in Eq.5 decreases. The results in terms of predicted load and percentage deviations from the experimental load are shown in Table 4. The formulation provides accurate predictions in almost all cases that experimentally exhibit failure due to crack propagation around the holes.

3 FINITE ELEMENT MODELLING

A three-dimensional finite-element model capable of reproducing the joist failure mode due to tensile crack formation was implemented in ABAQUS. The model assembly, analysis and post-processing were performed through a Python script to automatise the process and allow for extended validation and parametric analyses.

3.1 MODEL DESCRIPTION

Due to the symmetry of the joist and holes (see Table 1) in the vertical-longitudinal *yz* plane, it was possible to reproduce only half of the actual geometry. On the symmetry plane, the displacement in the out-of-plane direction was restrained $u_x=0$. The hinge support restraint has been reproduced by imposing $u_y=u_z=0$ on the contact line nodes, whilst the roller restraint has been reproduced by imposing $u_z=0$ on the contact line nodes (Figure 7).
An imposed linearly increasing displacement was applied to the nodes of the contact areas between the beam and the distribution plate under the hydraulic jacks ($u_{imp}=100$ *mm*).
The joist has been discretized through C3D8R general-purpose linear brick element, with reduced integration (ABAQUS/Standard library). The mesh dimensions are approximate $m_s \approx b/4$.

A linear elastic constitutive law has been assigned to outer and inner lamellae domain portions. The material has been modelled as orthotropic and the elasticity moduli and the shear moduli were related to the elastic module in the direction parallel to the grain according to EN-338 [33]. The elastic moduli in the direction perpendicular to the grain have been assumed as $E_x=E_y=E_z/30$, and the shear modules have been assumed as $G_{zy}=G_{zx}=E_z/16$ and the rolling shear moduli has been assumed as $G_{xy}=G_{zy}/10$. Similarly, the plywood reinforcement mechanical properties have been chosen according to EN 13986 and EN 636 and are reported in Table 5.

Cohesive contacts are assigned to surfaces explicitly introduced into the model to reproduce the crack formation and propagation around the hole. No stress interaction was considered for the cohesive layer; the damage is initiated where and when the stresses in the main local direction reach their relative strength values. Conventionally, the crack around the hole is assumed to be at an angle of 45° to the longitudinal axis of the beam. In the finite element models herein developed, the position of the cohesive contacts has been assumed coincident with the point of attainment of the maximum tensile stress perpendicular to the grain on the hole circumference. This position has been determined using preliminary elastic analyses conducted on a single-hole beam} for varying hole positions and both the case of

https://doi.org/10.52202/069179-0353

four-point bending and uniformly distributed load (Figure 8).

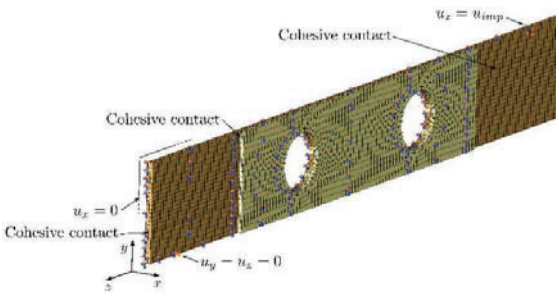

***Figure 7**: Finite element model*

In the case of uniformly distributed load, the maximum stress around the hole is reached between 30° and 40° to the longitudinal axis of the beam with a descending trend if the hole moves towards the mid-span (increasing l_a). Beams with a hole close to the mid-span exhibited lower stresses than those with hole close to the end support. In the four-point bending configuration, tension perpendicular to the grain increases in the part of the beam subjected to linearly increasing bending moment, while a stress drop and a sudden change of the maximum stress location is observed immediately after the loading point location which is at $l_a=6h=1800$ *mm*. Due to the local effect of the loading point, when the hole is under the external load, the maximum stress is reached near the bottom part of the hole.

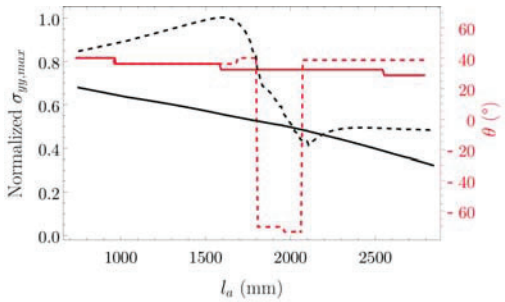

***Figure 8:** Normalized maximum stress and attainment position on the hole circumference for varying hole-support distance l_a (**Figure 1**) (Continuous lines: uniformly distributed load; Dashed lines: four-point bending).*

The interaction between the beam lateral surface and the reinforcement has also been modelled with cohesive contacts to make the model able to predict the failure on the reinforcement-joists contact surface. The screws used to restrain the reinforcement to the beam during the glue curing are neglected in the model. This assumption is made since the stiffness of screws perpendicular to the sliding plane is much lower than the stiffness of the glued connection and therefore, when the reinforced system fails, the contribution of the screws in terms of forces is negligible [34, 35].

The cohesive contacts are specialized constitutive laws used to simulate crack initiation and propagation [21]. Despite timber exhibiting exponential softening behaviour in experimental fracture tests, a bilinear curve is commonly used for this traction-separation curve [36].

The cohesive contacts behaviour is governed by a damage initiation criterion and a traction-separation curve, which relates element traction (stress) to *mode I* (opening) and *mode II* (shearing) displacement.
The bilinear traction-separation relationship consists of an initial elastic region showing the interfacial strength; and a subsequent softening region where zero stress is reached (see Figure 9). *D* is the damage parameter, which changes from *D=0* in the undamaged state to *D=1* in the fully damaged state:

$$D = \frac{\delta_e(\delta - \delta_c)}{\delta(\delta_e - \delta_c)} \quad (6)$$

δ_c indicates the separation corresponding to damage initiation, and δ_e is the final separation corresponding to the full fracture of the element. The total area under the curve is the fracture energy of the material. The stress-strain relationship is assumed for material outside the fracture process zone, and the stress versus separation curve is used for the material in the fracture process zone. However, the traction-separation laws become active only after a damage initiation criterion is met, e.g., when the stress exceeds the material's strength. When it comes to damage evolution, Wu's mixed mode fracture criterion was used [37, 38]:

$$\left(\frac{G_I}{G_{IC}}\right)^m + \left(\frac{G_{II}}{G_{IIC}}\right)^n = 1 \quad (6)$$

G_I and G_{II} indicate the fracture energies for mode I and II, respectively, and G_{IC}, G_{IIC} instead their critical energy release rate values, m and n denote the power of the equation.
The damage initiation parameters σ_n and τ_l have been chosen equal to the inner lamellae tensile strength in the direction perpendicular to the grain and inner lamellae shear strength in the direction parallel to the grain, as explained in the following paragraphs. The shear strength is assumed from experimental tests. In contrast, the tensile strength perpendicular to the grain derives from the model calibration using the experimental test results of the beams in terms of ultimate load. The propagation parameters of the cohesive contact have been chosen according to the results of [21] and are reported in Table 6.
According to [39], the critical fracture energy G_{IC} for mode I varies between 150-600J/m^2 for softwood species. In contrast, the critical fracture energy for mode II can be assumed as $G_{IIC}=3G_{IC}$.

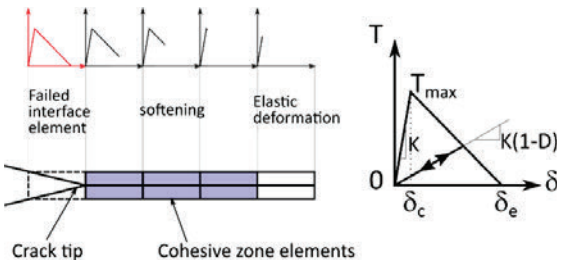

***Figure 9**: Cohesive elements and traction separation curve.*

3.2 MODEL CALIBRATION AND VALIDATION

Firstly, the elastic properties (i.e. the MoE perpendicular to grain, and the shear modulus) of the external and internal lamellae were calibrated according to the reference test series without holes. A sensitivity analysis was conducted on the numerical model to investigate which combination of parameters would minimise the difference with the experimental results. The investigated parameters were the elastic moduli perpendicular to grain and the shear modulus of both the external and internal lamellae. The bounds of the sampling domain were set to $E_{z,ol}$=*13 GPa ±25%*, $G_{zy,ol}=G_{zx,ol}$=*0.75 GPa ±25%*, $E_{z,il}$=*9 GPa ±25%*, $G_{zy,il}=G_{zx,il}$=*0.56 GPa ±25%*. The domain was sampled adopting Saltelli's sampling scheme [40, 41]. The error between the experimental and numerical results was assessed by the squared difference of the ratio of the applied force to the displacement at mid-span (SS).
A graphical representation of the results is shown in Figure 10. Here each point is a triplet of values $E_{z,il}$, $E_{z,ol}$ and the squared differences in terms of stiffness between the experimental and finite element model results) with the two MoE shown on the two horizontal axis. The figure clearly shows that a combination of values that minimises the error exists. By imposing a low threshold value for the error and fitting with linear regression, a relation between $E_{z,il}$ and $E_{z,ol}$ were found. The analysis confirmed also that the shear moduli $G_{zy,il}$ did not have any effect on the results.

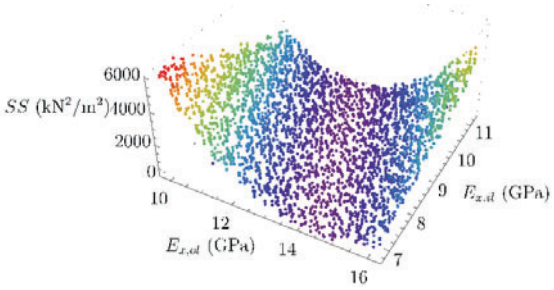

***Figure 10**: Squared differences in terms of stiffness between the experimental and finite element model results for various combinations of $E_{z,ol}$, $E_{z,il}$ and $G_{zy,il}$.*

Experimental tests carried out on the outer lamellae provided a mean value for $E_{z,ol}$ equal to 14.5 and 12.5 for the C40 and C30 timber. Therefore, assuming the above values for the MoE of the outer lamellae, the estimated value of the MoE of the inner lamellae is $E_{z,il}$ ≈10.5 GPa. The resume of all mechanical parameters is shown in Table 5.

In the second stage, the parameters governing the cohesive contact of the beam and the reinforcement were studied. Since the results of the shear test of glued specimens had demonstrated that the failure happens mainly on the timber side, the shear damage initiation parameter τ_l was assumed equal to the experimentally determined value, which corresponds to the actual shear strength of glulam (Table 3 and Table 6).

https://doi.org/10.52202/069179-0353

***Table 5**: Mechanical properties.*

Material name	E_z (Gpa)	$E_x = E_y$ (Gpa)	$G_{zy} = G_{zx}$ (Gpa)	G_{xy} (Gpa)	ν
C40	14.5	0.48	0.91	0.091	0.4
C30	12.5	0.42	0.78	0.078	0.4
Inner lamellae	10.5	0.35	0.66	0.066	0.4
Plywood	8	6	0.35	0.05	0

The tensile strength perpendicular to the grain σ_n and the fracture energy G_{IC} was estimated by minimizing the error between the numerical and experimental result of the unreinforced beams in terms of ultimate load.
The parameter G_{IIC} was derived from the previously mentioned relation according to [39].

A comparison between the results of the calibrated models and the test results is shown in Figure 4 and Figure 5 and Table 4.

***Table 6:** Mechanical properties of the choesive contacts.*

	σ_n (MPa)	τ_I (MPa)	G_{IC} (J/m^2)	G_{IIC} (J/m^2)	m	n
Inner lamellae	1.2	7.9	400	1200	0.5	0.5
Reinforcement Joist	5.4	5.8	400	1200	0.5	0.5

Overall a good agreement between experiments and numerical simulations is achieved. The elastic analyses confirmed that the crack starts at about 28-40° with respect to the longitudinal axis of the beam (Figure 8), which is a well-known result in literature [1, 39] and also confirmed by the experimental outcomes Figure 6.
In some cases (e.g. hole at mid-span, reinforced holes) the cohesive layer failed when the stress perpendicular to the grain on the outermost fibre had already passed values that would have led to a bending failure of the beam. For this reason, an additional failure criterion based on the tensile stresses reached in the outermost elements was introduced. The ultimate tensile stress was assumed to be equal to the one found by the tests on the reference beam, and namely f_m=33.9 MPa and f_m=39.9 for C30 and C40 test series respectively.

3.3 PARAMETRIC ANALYSES

In this section, the results of some parametric studies performed to identify the parameters that have the greatest impact on the ultimate load of the joists are reported.
It is assumed in the finite element models of all studied cases that the external lamellae are strong enough to avoid the bending failure of the joist. In this way, the finite element model can only account for the combined shear-tension perpendicular to the grain failure, so the hole is always the weak point from which the cracks that lead to the failure of the joist propagate.\\
The following plots show the failure load associated with the hole crack propagation determined through the parametric finite element model (contour of Figure 11, Figure 12 and). On the same plots, the analytically determined flexural limit loads of the joist mid-span section (grey surface) and of the hole section (magenta surface) are reported. The flexural limit loads have been determined as the loads which cause the tensile failure of the outermost lamella accounting for the heterogeneous section and the hole in the section modulus calculation (W_{ef} and $W_{ef,hole}$ respectively). The associated maximum forces have been determined from Navier's equation. For the mid-span failure load:

$$f_m = \frac{M_{max}\left(\frac{l}{2}\right)}{W_{ef}\left(\frac{E_{ol}}{E_{il}}, h_{ol}, h_{il}\right)} \tag{8}$$

and for the hole-section failure load:

$$f_m = \frac{M_{max}(l_a + l_s)}{W_{ef,hole}\left(d, \frac{E_{ol}}{E_{il}}, h_{ol}, h_{il}\right)} \tag{9}$$

By substituting in Eqs. 8 and 9 the expression of bending moment M_{max} as function of F_{max} for uniformly distributed load or four-bending configuration and solving for F_{max} the corresponding expressions for the analytically determined bending capacity F_a were found:

$$F_{max} = \begin{cases} \frac{2f_m W_{ef}}{l} \; mid\ span, unif.dist. \\ \frac{2f_m W_{ef,hole} l}{(l_a+l_z)(l-l_z-l_z)} \; hole, unif.dist \\ \frac{2f_m W_{ef}}{a} \; mid\ span, 4\ p.b. \\ \frac{2f_m W_{ef,hole}}{l_a+l_z} \; hole\ and\ l_a + l_z \le a, 4\ p.b. \\ \frac{2f_m W_{ef,hole}}{a} \; hole\ and\ l_a + l_z > a, 4\ p.b. \end{cases}$$

The first parametric study identifies the influence of hole diameter and hole position for a four-point bending configuration. As can be seen from Figure 11 (up) which shows the results for joists similar to that of configuration UNR-C30-0.6-0.6, moving the two holes closer to the load application point causes a slight increase in strength of the hole-failure mechanism. As shown in Figure 8, when the hole is about at 1_d from the load application point l_a=*1.5 m*, the external load-induced compression perpendicular to the grain causes a significant reduction of the tensile stresses (Figure 8).

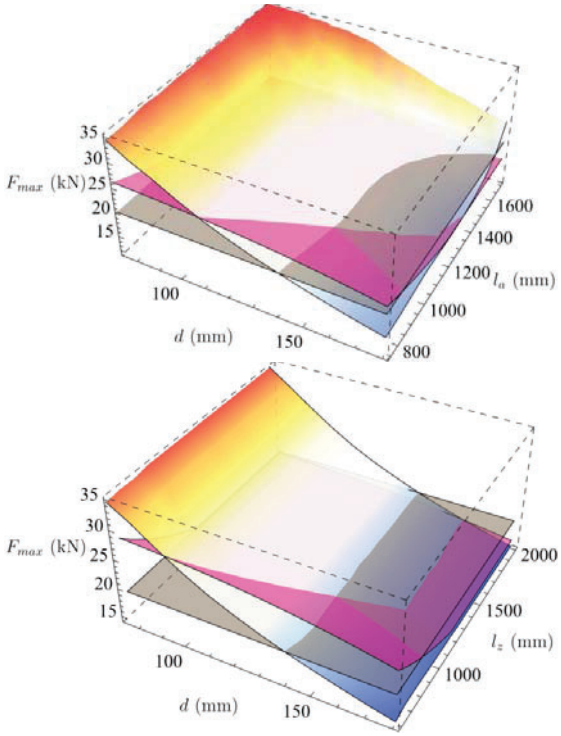

***Figure 11**: Failure load for varying hole diameter and hole position in four-point bending configuration: (up) varying the position of both holes simultaneously (l_a), (down) varying second hole position (l_z) (Contour: FEM hole crack failure load, gray: failure load of mid-span section without hole, magenta: failure load of hole-section).*

Keeping fixed the position of the hole nearest to the support l_a=*0.6 m*) and moving the position of the second hole does not affect the capacity associated with the hole failure because the limit load is related to the failure of the first hole (Figure 11 (down)). In both cases, the hole diameter has a strong influence on the strength reduction.

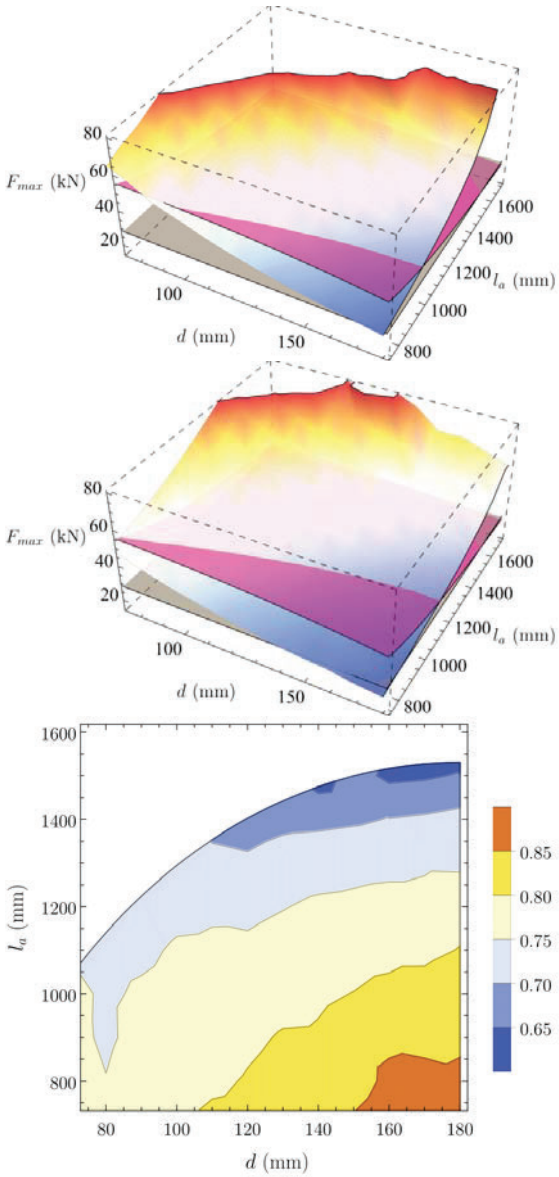

***Figure 12**: Failure load for varying hole diameter and hole position in the uniformly distributed configuration: (up) load at the upper side, (mid) load at the lower side, (down) ratio between the failure load of the lower side and upper side. (Contour: FEM hole crack failure load, grey: failure load of mid-span section without hole, magenta: failure of hole-section*

The second set of parametric studies deals with the case of uniformly distributed load. In both the cases of load applied at the lower side of the beam and load applied at the upper side of the beam, the hole position has proven to be a more significant parameter than in four-point bending configuration in determining the ultimate load for hole area-cracking failure mode (Figure 12). This behaviour is justified by the different arrangements of the internal forces. In the four-point bending configuration, the hole position was varied along the part of the beam in constant shear and linearly increasing bending moment, whilst in uniformly distributed load configuration the beam is subjected to linearly decreasing shear towards the mid-span and parabolic bending moment. As a

https://doi.org/10.52202/069179-0353

consequence when increasing l_a in a four-point bending configuration the tensile stresses perpendicular to the grain due to the combined shear and bending effect increases and reduce only when the local effect of the external load is significant, whilst in uniformly distributed load configuration an almost linear reduction of tensile stresses perpendicular to the grain for increasing l_a can be observed (Figure 8).

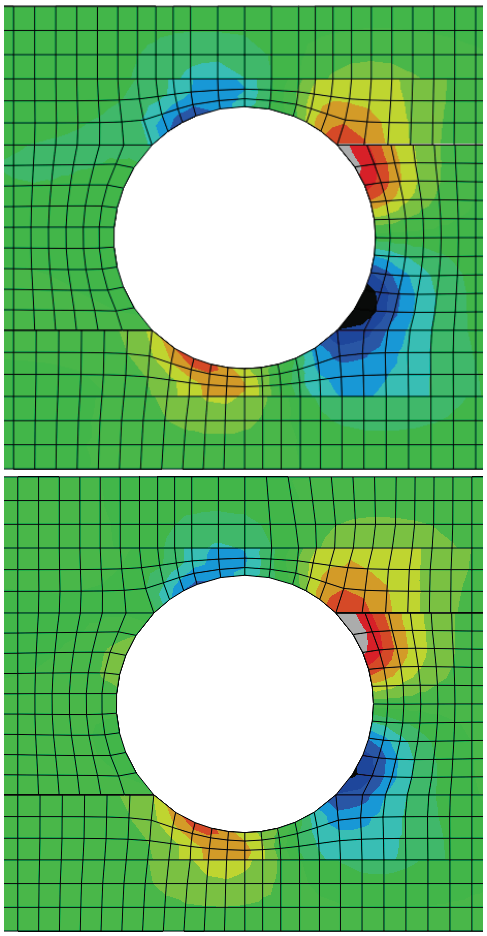

***Figure 13**: Tensile stresses perpendicular to the grain: (up) upper side load, (down) lower side load.*

Applying the load at the lower side causes a reduction in the ultimate load comprised between 40% and 15%. For fixed hole position the reduction is higher for lower diameters. The closer the hole is near the midspan, the higher the reduction. It was observed that applying the same load at the lower side causes an increase in the tensile stresses perpendicular to the grain around the hole (Figure 13).

In the last parametric study, the height of the beam h=300 mm and the relative position of the hole $l_a/l = 0.1$ were maintained constant while varying the length of the beam l and the hole diameter d. This study revealed how for shorter-span beams, the influence of the hole diameter is higher with respect to longer-span beams (Figure 14).

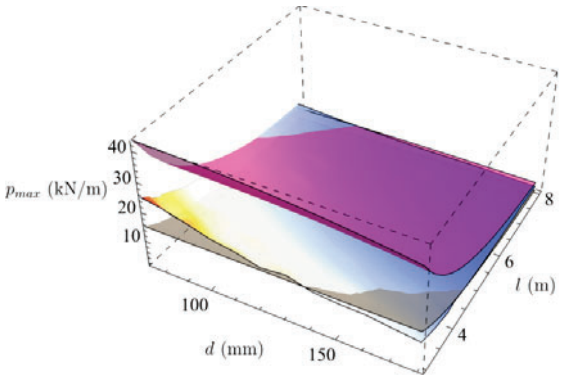

***Figure 14**: Failure load for varying hole diameter and beam length. (Contour: FEM hole crack failure load, grey: failure load of mid-span section without hole, magenta: failure load of hole-section).*

4 CONCLUSIONS

An extended experimental investigation has been conducted on composite glulam joists. The tests highlighted strength reductions up to 33% when in a four-point bending configuration the hole is located in the constant shear zone. No significant differences were found between plywood and glulam reinforcements or between PRF and non-structural glue types. In all cited cases a complete restoration of the joist bending strength was observed.

The developed finite element model provided accurate results in terms of strength and stiffness. The results of the parametric study can be itemized as follow:

- the hole position is a more relevant parameter in beams loaded by a uniformly distributed load than in beams under four-point bending;
- in four-point bending configuration the applied load prevents crack formation; so when the hole is under the load application point the failure load increase;
- applying the load at the lower side causes a reduction in the ultimate load comprised between 40% and 15% with respect to applying the load at the upper side;
- the strength reduction caused by the hole is more pronounced for shorter span beams

Although a satisfying correspondence was found between the formulation provided by the DIN-1052 and the experimental results, the authors proposed a mechanics-based probabilistic formulation for the determination of the strength reduction of beams with holes. Both the case of uniformly distributed load applied at the upper side and lower side have been considered. The proposed formulas are elementary and therefore could be implemented in codes or easily used by practitioners as a possible improvement of the current experimentally derived formulation.

EVALUATION OF HARDENING MODELS TO SIMULATE JOINTS IN TIMBER SHEAR WALLS

Rajan Maharjan[1], Johan Vessby[2], Le Kuai[3]

ABSTRACT: The properties of sheathing-to-framing joints considerably affect the load carrying capacity of a light-frame timber shear wall. A fastener with isotropic or kinematic hardening properties is modelled for the sheathing-to-framing joints with a zero-length element, with coupled properties in two perpendicular (orthogonal translational) directions to avoid the overestimation achieved with an uncoupled alternative. A single fastener experiment is performed to determine the elastic and plastic properties. For both fastener level and wall level modelling, monotonic as well as cyclic loading scheme is analysed. A concept of modelling the elasto-plastic coupled behaviour with hardening of the connector model for the fasteners is suggested. A damage response of the fastener is also studied to estimate the failure in load capacity of the connector model and decrease in the wall capacity after the maximum loading.

KEYWORDS: Light-frame timber shear wall, Sheathing-to-framing joints, Single fastener test, Connector model

1 INTRODUCTION

A timber shear wall is built by timber frame members, studs and rails, and sheathing panels attached together by means of mechanical fasteners. The walls are common in multi-story timber buildings since they act as structural diaphragms and transfer lateral loads like wind and seismic loads to the foundation by in-plane action. Furthermore, they are lightweight and can be pre-fabricated at highly automated indoor facilities at high speed in an efficient manner.

From previous studies e.g. [1, 2], it is observed that the mechanical fasteners used as sheathing-to-framing connections are the most important elements affecting the in-plane stiffness and load carrying capacity of the light-frame timber shear wall. To fully comprehend the response of the wall subjected to the in-plane loading, it is essential to study the behaviour of the fasteners used in such connections, a topic that has been addressed by several researchers during the last decades. These include studies with assumed linear elastic response [3] and plastic response [4] of the fastener as well as simulations based on characteristics from Eurocode expressions [5].

The laterally loaded sheathing-to-framing connections are generally timber-steel-timber connections that undergo elasto-plastic deformation when subjected to the loading. A typical mechanical fastener initially behaves elastic up to the yield force and a plastic displacement develops beyond that force. Further displacement beyond the yield initiation is referred to as 'hardening' if the force is increased and 'softening' if the force decreases.

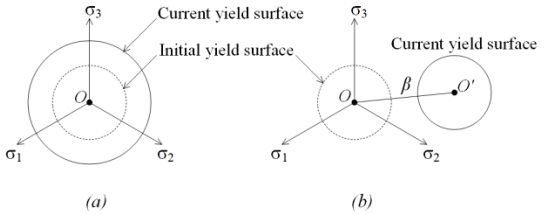

Figure 1: *Initial and current yield surfaces for (a) isotropic and (b) kinematic hardening in the deviatoric plane.*

Hardening can be classified as isotropic hardening or kinematic hardening [6] and they may both be used to simulate the plastic behaviour of the fasteners. The initial yield surface and current yield surfaces for isotropic and kinematic hardening are shown in Figure 1 in the deviatoric plane, perpendicular to the hydrostatic axis.

With an increase in loading, if the subsequent yield surface expands uniformly in all direction in the stress space, the hardening is isotropic. When the yield surface shifts in the stress space, without change in the shape while loading and unloading, the hardening is kinematic. In Figure 1(b), the shift perpendicular to the hydrostatic axis of the current yield field space β is termed as back-stress. For a typical fastener of the type studied, plastic deformation proceeds the failure of the joint. The failure in turn may occur pre or post the average peak load of the fastener type. The peak load is the maximum load registered in the fastener during an experimental test.

Several studies were performed previously on various fasteners to study the performance of mechanical fasteners under monotonic or cyclic loading. Models for

https://doi.org/10.52202/069179-0354

both monotonic and cyclic lateral behaviours of the nail connection was established in the 1990s e.g. [7]. A hysteresis model, based on modification of the Bouc, Wen, Baber and Noori model, was used [8] in non-linear dynamic analysis of a single-degree-of-freedom wood systems. It was modified to a non-linear and history dependent hysteretic behaviour of a nailed joint [2] which was performed using an user defined element in the finite element (FE) based software ABAQUS.

A recent study on modelling the fastener with a coupled zero-length element was applied on seismic analysis of wood-frame structures [9]. The coupled properties of the zero-length element were implemented to avoid an overestimation of the forces when the load is applied in two orthogonal directions simultaneously. Such coupling may be performed in various ways and some of those are scrutinized by [10]. As previously stated, an accurate model of the fastener is crucial for a correct simulation of a whole shear wall. Many of the previous studies on fasteners also include simulations of different types of shear walls and conclude that the fastener model works well for the wall level e.g. [11].

The aim with the current paper is to evaluate any possible effect in the load-displacement response of choosing an isotropic or kinematic hardening model for the fasteners. To do so, they are modelled in a FE-software using a zero-length coupled element under monotonic and cyclic loading in a 2-D space. The study is performed for a single fastener and for a three panelled shear wall unit. The pinching effect in the cyclic loading is not considered in the simulations performed. An analysis of the damage response of the fasteners is also performed both for the single fastener level and the shear wall level.

2 MATERIAL AND METHODS

2.1 EXPERIMENTAL STUDY

For the experimental study, a timber frame, 45·120 mm in cross-section and of strength class C24 are used. Furthermore, a 12 mm plywood sheathing panel of quality K20/70 and a 3.9·55 mm screw were used for the single fastener test. Monotonic and cyclic tests were performed according to EN 12512 [12] for a single fastener to obtain the load displacement curves and to study a typical loading cycle of the fastener which is loaded parallel to the fibre direction of the timber member.

2.1.1 Monotonic test of a single fastener

A screw was fastened to the sheathing panel (plywood 250·100·12 mm) and the frame (C24 and cross section dimensions 120·45 mm) at the distance of 50 mm from the closest edge in the loading direction, see Figure 2 . The timber frame was fixed to the steel frame by using four Ø 8 mm and 250 mm long steel threaded rods and bolts. The sheathing panel was connected with four bolts, Ø = 4 mm, to the 45·3 mm steel plate that was clamped to the hydraulic wedge grip of the MTS machine having a capacity of ± 100 kN and ± 0.1% linear tolerance interval. The relative displacements between the frame and the panel were acquired by means of two linear variable

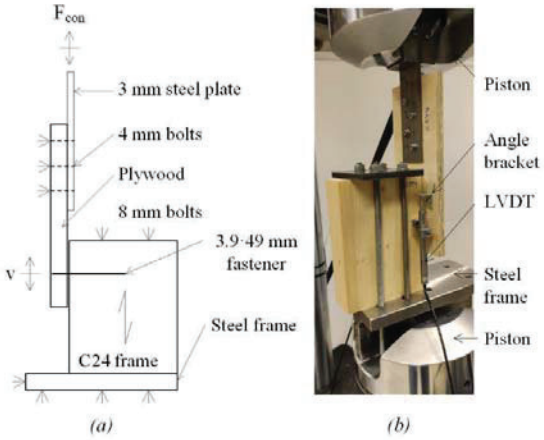

Figure 2: *(a) Setup of the single fastener test and (b) on-going test of the single fastener.*

differential transformers (LVDTs) that were placed at each side of the frame member. The LVDTs were mounted, to the closest possible location of the fastener, on the frame and measured relative to a 15 mm aluminium angle bracket in turn secured to the panel. The monotonic tests were performed under displacement control at a rate of 0.2 mm/sec and from the load-displacement plot of the test the yield displacement v_y was calculated. For the load displacement curve having two clearly linear components, the yield values are determined from the intersection of the two lines according to the procedure suggested in EN 12512 [12].

2.1.2 Cyclic test of a single fastener

The cyclic tests were also performed in the same setup with the load protocol illustrated in Figure 3 where v_y is the yield displacement determined from the monotonic test. The first cycle consists of compression load (towards the steel frame) until the LVDT displacement of $0.25 \cdot v_y$, followed by unloading to zero displacement,

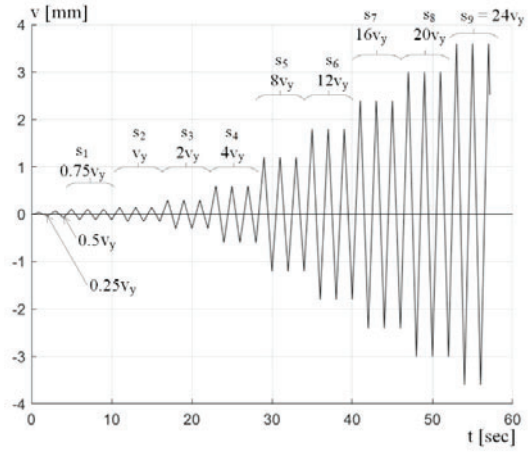

Figure 3: *Loading protocol for the cyclic test where v_y is estimated yield displacement calculated from monotonic test.*

reloading to tensile load (away from the steel frame) up to the LVDT displacement of $0.25 \cdot v_y$ and followed again by unloading to the zero displacement. The second cycle consists of similar loading scheme but this time to the maximum displacement of $0.5 \cdot v_y$. A series (s_1) of three cycles are introduced thereafter with the maximum displacement of $0.75 \cdot v_y$ and so forth with increasing factors for the maximum displacement until failure or until a maximum displacement of v = 30 mm is reached. For both monotonic and cyclic tests, the test frame and the sheathing panel were placed inside a climate chamber with controlled temperature of 20°C and relative humidity of 65% prior to the test, to secure a moisture content around 12% in the timber. The screw was driven by an electric screwdriver after the test setup was prepared.

2.2 NUMERICAL STUDY

2.2.1 FEM model of the single fastener

A two-dimensional connector model of the zero-length element consisting of two orthogonal coupled springs was developed for simulation of the fastener in the commercial FE software ABAQUS. The linear elastic and the non-linear plastic hardening properties of the connector model were assigned based on the results from the cyclic experimental tests. A comparative study on isotropic hardening and kinematic hardening during cyclic loading was performed.

For the isotropic hardening, the yield surface F^0 is a function of equivalent plastic relative displacement $\bar{u}^{pl}$ that can be expressed as:

$$F^0 = \bar{F}_0 + Q_{inf}(1 - e^{-b \cdot \bar{u}^{pl}}) \qquad (1)$$

where, $\bar{F}_0$ is the yield force value at zero plastic relative displacement, and Q_{inf} and b are material parameters affecting the shape of the hardening curve.

Similarly, for the kinematic hardening, the change in the backforce over a half cycle of a unidirectional tension or compression experiment is expressed as:

$$F_j = (F_j{}^0 + \beta_j), \qquad \beta = \frac{C}{\gamma}\left(1 - e^{-\gamma \cdot u^{pl}}\right) \qquad (2)$$

where, $F_j{}^0$ is the initial yield force value, β is the backforce, u^{pl} is the plastic relative displacement, and C and γ are material parameters that are calibrated from the test [13]. The backforce for the connector model is interpreted similar to the back stress in Figure 1(b). The values of Q_{inf} and b for isotropic hardening and C and γ for kinematic hardening were determined by plotting the best fit curve to the envelope curve of the cyclic experimental load-displacement relation.

Since the fasteners in the shear walls experience forces in both orthogonal directions, a coupled behaviour of the fastener is desirable. Therefore the plastic properties of the connector model were modelled as coupled for both hardening models studied. The linear elastic stiffness of the connector was defined as $k = 2 \cdot 10^6$ N/m in both orthogonal directions. The yield force for the cyclic test denotes the boundary between linear elastic and non-linear plastic hardening behaviours studied.

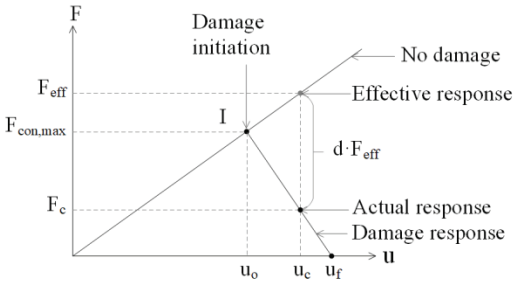

Figure 4: *Damage initiation and damage response.*

When the force in the connector model that is under plastic hardening exceeds its critical value, an irreversible damage is initiated and additional loading leads to further evolution of damage, eventually leading to failure of the fastener. The force response of the connector component i when damage take place is determined as

$$F_i = F_{effi}(1 - d_i), \qquad 0 \le d_i \le 1 \qquad (3)$$

where, d_i is a scalar damage variable and F_{effi} is the effective response in the available connector component under assumption of no damage.

Figure 4 illustrates a simple linear elastic response of a fictive connector with and without damage response. If damage is not defined, the effective response is when the force in the connector is F_{eff} at a displacement u_c. When a damage initiation is introduced at point I by using a damage criteria, the corresponding displacement is u_o. After the connecter is loaded more so that the displacement increase to u_c, the connector force reduces to the current force as determined in Equation (3) depending upon the value of d. Further loading of the connector gradually reduces the response, leading subsequently to the ultimate failure displacement u_f. At the failure displacement, d = 1, which is its maximum value, and at this point the connector loses the ability to carry any load [13].

A force-based damage initiation criterion was specified by defining the lower or compression limit $F_{con,min}$ and the upper or tension limit $F_{con,max}$ for the damage initiation force values. The limits were determined from the maximum load carrying capacity of the fastener from the cyclic tests. Since coupled connector are used, when the resultant of the forces in the connector between two orthogonal directions is outside the range of the two limit values for the first time, the damage initiation occurs. In addition, a linear evolution law is defined by specifying a relative displacement u_{dam} which is the difference between the relative displacement at ultimate failure and the relative displacement at damage initiation $u_{dam} = u_f - u_o$. It describes the additional linear deformation after the damage initiation for the connector to reach the zero force level. A small value of u_{dam} indicates that the connector has brittle property and on the contrary if u_{dam} is large the failure behaviour in the connector is more ductile.

https://doi.org/10.52202/069179-0354

2.2.2 FEM model of simple light-frame shear wall

A shear wall 3.6·3.0 m^2 with three wall panels of width 1.2 m was modelled in a 2-D space with C24 timber frames (cross section 45·120 mm) as beam elements and 12 mm plywood panels as shell elements. The sheathing-to-framing joints for 3.9·55 mm mechanical fasteners were modelled by using one of the two aforementioned connector models. The centre-to-centre spacing between the fasteners at the outer edges of the sheathing panels was assigned as s = 100 mm and that for the intermediate stud at the middle of the panel was assigned as s_{mid} = 200 mm, see Figure 5. The connections between the rails and the studs, which generally consist of 2-3 nails of dimensions 3.1·90 mm, were modelled as a hinge joint so that only the effect of sheathing-to-framing fasteners could be assessed for the global behaviour of the wall. The bottom rail of the wall was fixed to the ground and a displacement controlled horizontal load F_w was applied at the left end of the top rail. A monotonic loading up to a prescribed displacement u_{pres} and a cyclic loading with different displacement amplitude were applied to analyse the global behaviour and the local fastener behaviour. Results from the models were used to compare load-displacement curves for the two hardening models, and to illustrate forces from all fasteners acting on the wall panel at a current load stage and force history during the whole load event for some selected fasteners.

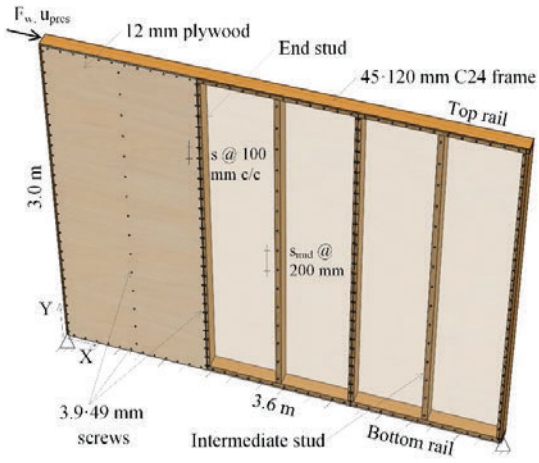

Figure 5: *A simple shear wall model with geometry and spacing of fasteners.*

3 RESULT AND DISCUSSION

3.1 EXPERIMENTS OF A SINGLE FASTENER

The result of single fastener experimental test is illustrated in terms of load-displacement diagram. The force value is taken from the MTS load cell and the displacement value is taken as an average of the two LVDTs that were placed on each side of the fastener.

Among many monotonic tests performed, a typical test result is illustrated to show the calculation method of the yield displacement. From the single fastener monotonic test, the yield load F_y = 588 N and yield displacement v_y = 0.15 mm were determined from the intersection of the two clearly visible linear components (indicated with dotted lines), see Figure 6. The maximum force experienced by the screw in the load-displacement curve is 2340 N at the displacement 10.4 mm.

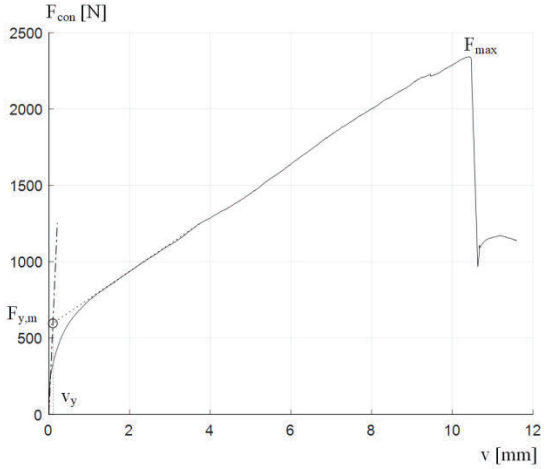

Figure 6: *Load displacement curve from a monotonic test of single fastener showing the yield force F_y from the intersection of two linear components (dotted lines) of the curve.*

Similarly a typical test result from the cyclic loading experiment is shown in Figure 7, which illustrates the load-displacement response for the loading protocol with the yield displacement v_y = 0.15 mm. The experimental data is shifted by + 50 N to the tension zone to adjust the centre of the hysteresis curve about the force axis. The black curve illustrated in the figure is the envelope curve for the test, which is obtained by connecting the force values from the first cycle of each series of the cyclic test, see Figure 3. The envelope response from the cyclic test is observed to yield at F_y = 490 N at a displacement of 0.135 mm, and thus, the elastic modulus is calculated as k_E = 3630000 N/m.

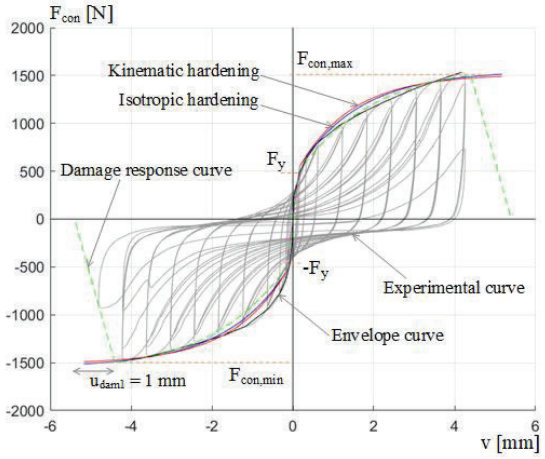

Figure 7: *Load displacement curve for a cyclic loading of the single fastener test with an envelope curve, hardening curves and curves with damage response for v_y = 0.15 mm.*

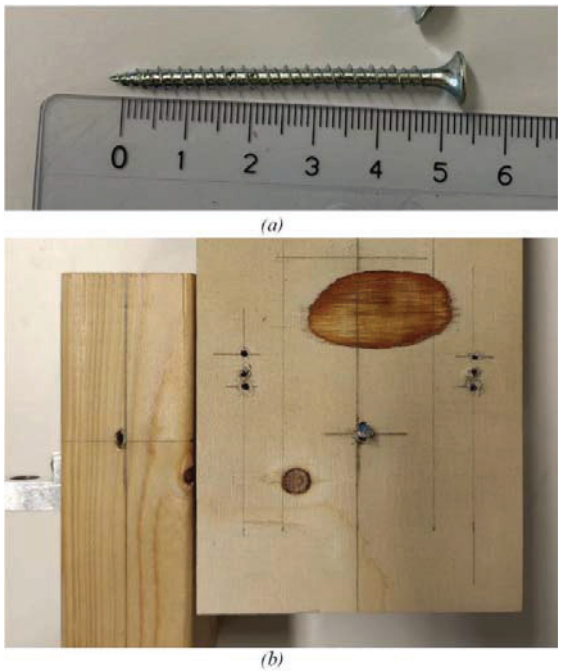

Figure 8: *The screw (a) before the test and (b) after the ultimate failure in the cyclic test.*

The isotropic hardening parameters are obtained by adjusting the parameters in Equation (1) so that the response fits the envelope curve from the experimental results which occurs for Q_{inf} = 1100 and b = 630.
Similarly the kinematic hardening parameters C = 660000 and γ = 590 in Equation (2) are used to fit the experimental results. The lower half-cycle curve for the both hardening properties are obtained by using F_y = - 490 N so that a symmetry in the force-displacement curve is obtained.
From Figure 7, it is observed that during the cyclic test, the screw reached the maximum load carrying capacity $F_{con,max}$ = 1500 N at the cyclic displacement v = 4.2 mm, which is the 10th series of the loading protocol. Therefore, the damage initiation limits, $F_{con,max}$ = 1500 N and $F_{con,min}$ = -1500 N are used for both hardening models. Moreover, two alternate relative displacements u_{dam1} = 1 mm and u_{dam3} = 3 mm are assumed for the connector model which is an estimation of the further deformation of the fastener after the peak load up to the ultimate failure displacement u_f of the fastener. The test screw before and after the ultimate failure from the cyclic test is shown in Figure 8.

3.2 MODELLING OF A SINGLE FASTENER

The input parameters for both hardening models are obtained from the cyclic experimental data to model the response of the single fastener. The simulation results for a typical load cycle with the displacement amplitude v_A = 1.2 mm are illustrated in Figure 9 along with the hysteresis curve from the experiment at that amplitude. The amplitude $v_A = 8 \cdot v_y$ is selected from the 5th series of the loading protocol, see Figure 3. The time displacement graph for the model is illustrated in the subfigure where the solid lines represent the load cycle that are extracted for the hysteresis curve. The isotropic hardening model simulated higher force values whereas the kinematic hardening simulated the force values closer to the experimental values at the selected cycle. The shape of the experimental hysteresis curve is similar to the load cycle of the kinematic hardening, provided the simplifications that the pinching effect achieved in the test is not included and only the linear elastic stiffness k_E is considered during the modelling.

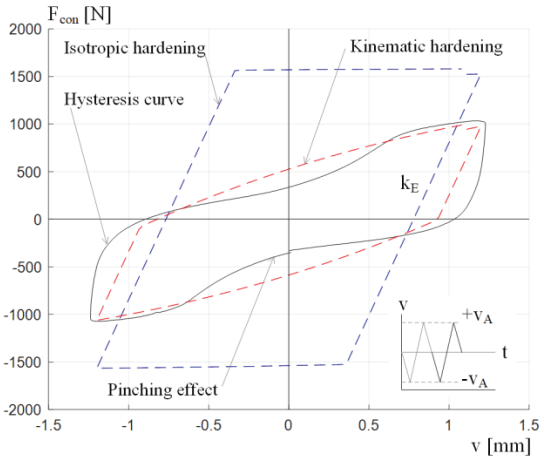

Figure 9: *A typical load cycle at a displacement amplitude of v_A = 1.2 mm from the single fastener cyclic test and models simulating isotropic and kinematic hardening.*

3.3 MODELLING OF A SHEAR WALL

The FEM model of the shear wall is used for both the monotonic and the cyclic loading. The monotonic loading for a prescribed displacement, u_{pres}, is illustrated in Figure 10 that shows the global behaviour of the wall for both hardening models of the fasteners. The blue curves illustrate the response while isotropic hardening is used in the fasteners and the red curves show the results if kinematic hardening is used for the monotonic loading of the wall. Two curves show the global response of the wall without defining the damage response in the connector model. The load in the wall increases asymptotically for both the hardening models, which is unrealistic from an experiment point of view. The two other loading curves show the global response with the damage initiation limit equal to the maximum load carrying capacity of the fastener from the test, $F_{con,max}$ = 1500 N and the relative displacement u_{dam1} = 1 mm. The damage response on the fasteners resulted in numerical instability in the model at the wall displacement around u_w = 24 mm. The reason for the instability is the significant drop in load carrying capacity of the fasteners (because of the steep gradient) after reaching the peak load, which is also an indication of the brittleness in the fasteners.

https://doi.org/10.52202/069179-0354

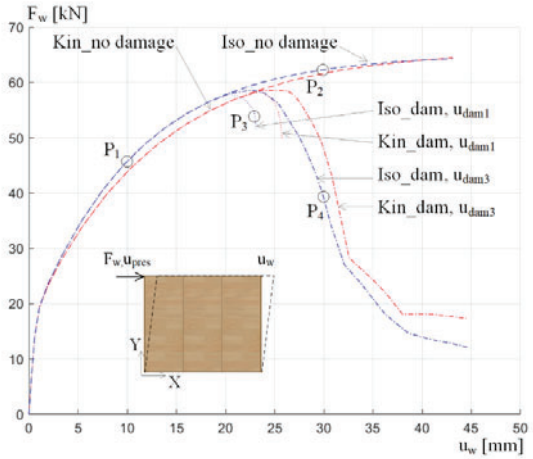

Figure 10: *Load displacement diagram of a shear wall model with damage response u_{dam1}, u_{dam3} and without damage response for both hardening models.*

To model the connector with an increased ductility, the damage response of the fasteners is redefined with u_{dam3} = 3 mm, and a third loading is performed. With the increase in the relative displacement, u_{dam3}, after the peak load in the connectors, the gradient is not so steep and the response of the wall is added in the load-displacement diagram, see Figure 10.

To comprehend the local phenomenon experienced by the fasteners, vector plots of the connector forces in the wall are plotted at different stages and for different assumptions regarding damage response, as positions marked by circles and denoted as P_1-P_4 in Figure 10. Since both hardening models showed similar global behaviour in monotonic loading, the force vector plots are presented only for the kinematic hardening model.

Figure 11 (a) and (b) show the vector plots at the position P_1 (u_w = 10 mm) and P_2 (u_w = 30 mm) respectively for the connector response with no damage defined. The green arrows show scaled vector plot of the forces in the connector at loads lower than the yield load F_y = 490 N and the pink arrows illustrate the vector plot of the forces between F_y and the maximum load carrying capacity of the connector, $F_{con,max}$ = 1500 N. Similarly the red arrows show the vector plot of the connector forces that are greater than $F_{con,max}$. It is observed that the fasteners at the corners of the wall panels reach their peak load first, followed by other fasteners placed close to them. As the displacement in the wall increases, the forces in the connectors also increase and at position P_2, most of the connectors have surpassed the defined peak load of the connectors.

Since the experimental results reveal that fasteners fail at $F_{con,max}$ = 1500 N, the wall model is analysed with the damage response on the connector model. Figure 11(c) illustrates the vector plot of the forces on the connectors at the position P_3 (u_w = 24 mm), which has the damage response definition by the force limit $F_{con,max}$ and the relative displacement u_{dam1} = 1 mm. The connectors at the

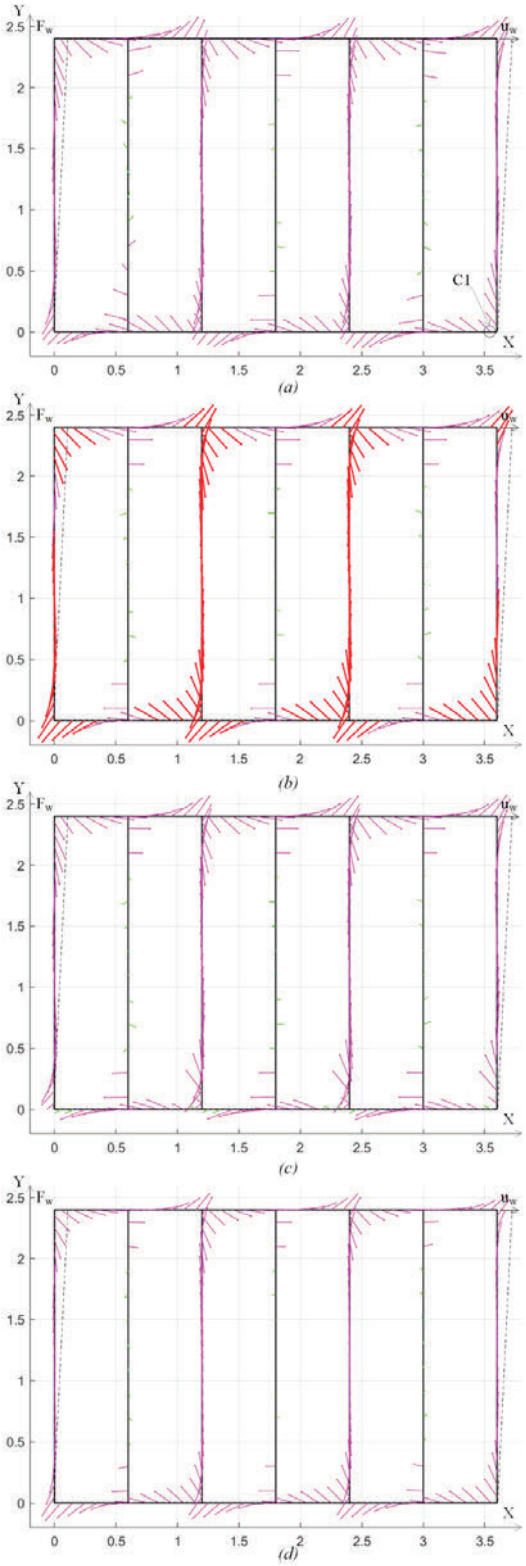

Figure 11: *Force distribution on fasteners of the shear wall model for monotonic displacements at positions (a) P_1, (b) P_2, (c) P_3 and (d) P_4 indicated in the Figure 10.*

https://doi.org/10.52202/069179-0354

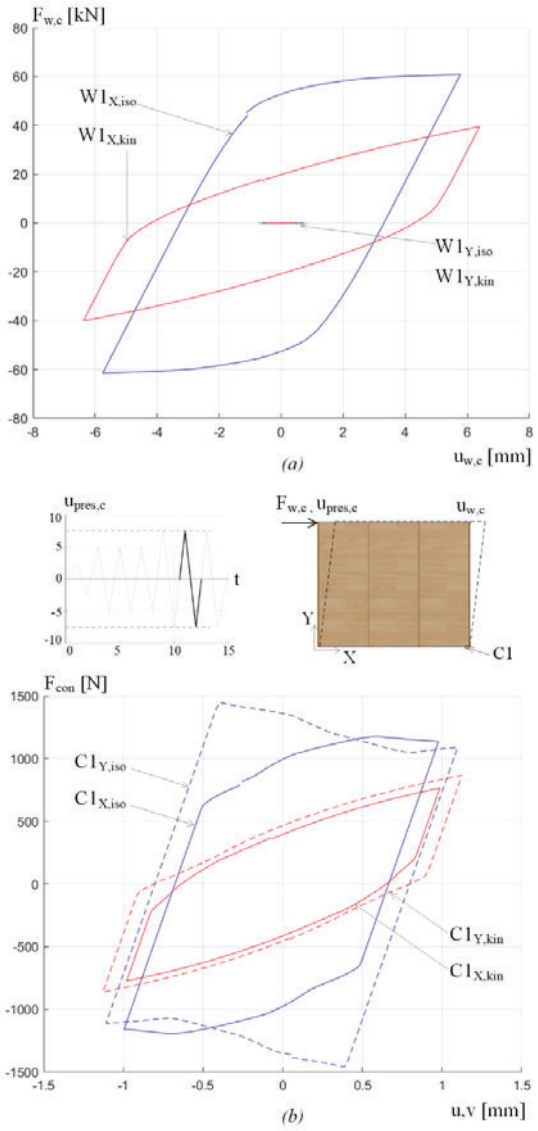

Figure 12: *Load displacement diagram for both hardening models in two orthogonal directions for the displacement amplitude $u_{pres,c}$ = 7.5 mm for (a) shear wall model and (b) for the most loaded fastener denoted C1.*

bottom corners of the three sheathing panels have drastically lower force values, which indicate that they have suffered the damage response the most, thus resulting to the numerical instability.

A comparison of the local connector behaviour is performed for the wall without damage response and with the damage response defined by the force limit $F_{con,max}$ and the relative displacement u_{dam3} = 3 mm. The vector plots for the former is discussed earlier in Figure 11(b) and the latter, at the position *P4* (u_w = 30 mm), is illustrated Figure 11(d). With the damage response u_{dam3}, the forces in the connectors don't exceed the maximum load carrying capacity, $F_{con,max}$. Moreover, the most loaded fasteners at the bottom corners of the sheathing panels have surpassed the $F_{con,max}$ and are in the state of decreasing load bearing capacity at that displacement.

The cyclic loading of the wall model is also simulated and the hysteresis curve for the prescribed displacement amplitude $u_{pres,c}$ = ± 7.5 mm is illustrated Figure 12(a) for the isotropic and the kinematic hardening models of the connector in both horizontal and vertical direction. The damage response for the connector models are not defined for the cyclic loading of the wall model. The displacement amplitude is increased from 2.5 mm with scale factors similar to those used for the single connector model, see subfigure. Since the load was applied along the horizontal (*X*) direction, the sum of the reaction force for the wall along the vertical (*Y*) direction is null. The load-displacement response of the wall exhibits similar shape as the connector model for both hardening models. Moreover, the maximum load applied for the wall with isotropic hardening model is higher compared to the maximum load with the kinematic hardening model, which correlates well with the results for the single connector model.

In order to compare the global wall behaviour with the local fastener behaviour, the force-displacement diagram for the most loaded connector *C1*, indicated in Figure 11(a) at the right end of the bottom rail without the damage response, is illustrated in Figure 12(b). Both the connector forces, defined as F_{con} in the *X*- direction and the *Y*- direction, are illustrated in the figure for both hardening models with respect to the connector displacement u and v in the *X* and *Y*- directions respectively. The connector properties are expressed in orthogonal directions, therefore the resultant of the connector force components in orthogonal directions is the total connector force in action. The kinematic hardening of the fastener for the load amplitude used has similar shape in the force-displacement diagram as the wall. The exception is that for the connector with isotropic hardening model, the vertical component $C1_{Y,iso}$ has higher force than at the horizontal component $C1_{X,iso}$.

4 CONCLUSIONS

The single fastener experimental tests were used to fit two types of elasto-plastic, zero-length coupled elements to the test results, one using isotropic hardening and the other using kinematic hardening. Both models used for the single fastener simulation and the wall simulation are appealing due to their wide availability, their degree of establishment and their simplicity. The comparison between results from simulation using the two models for plasticity and the experimental results indicate the considerable advantage of using a kinematic hardening model compared to the isotropic one for the current application. A benefit with both models is that different properties may be assigned in the two orthogonal directions so that orthotropy in the timber and in some of the sheathing panels may be included in the simulations. These properties influence results from analysis of shear

https://doi.org/10.52202/069179-0354

walls, in particular when the load directions in the fasteners vary during the loading of the wall.
Furthermore, the shear wall models were simulated with the connector models for monotonic and cyclic loading and it was observed that the shape of the load-displacement curve for the global behaviour of the wall was similar to that of the local behaviour of the connector for the most loaded fastener in the wall.
Moreover, the damage response for the connector model was defined to simulate the decreasing load carrying capacity of the fastener after the peak load and until the failure of the fastener. The suggested method for simulating the damage is efficient and the distinct effect of failure in fasteners on the load carrying capacity in the shear wall is shown.

5 FURTHER STUDY

In the current paper, the properties parallel and perpendicular to the fibers are assumed similar. To increase the accuracy of the model, orthotropic properties should be used for the fastener. A series of single fastener experiment for the loading perpendicular to the fibre direction can be performed in order to verify the orthotropic behaviour of the fastener. An experiment on cyclic loading for a simple wall can also be performed to validate the wall model with the zero-length element connector model. Moreover, the effects of large deformation in the connector and the pinching effect of the fasteners can also be included in the further studies.

ACKNOWLEDGEMENT

The research is financially supported by several wood construction companies in Sweden and by the strategic innovation programme Smart Built Environment and Formas. The authors acknowledge that support with great gratitude.

COLLAPSE FRAGILITY OF A 5-STORY CLT STRUCTURE UNDER CHILEAN SUBDUCTION EARTHQUAKE RECORDS

Alberto Aravena[1], Alan Hellman[2], Joaquín Miranda[3], Franco Silva[4], Diego Valdivieso[5]

ABSTRACT: Mass timber structures have been utilized in North America, Europe, and Oceania, and are being evaluated in Latin America to decrease the housing shortage and the construction industry's contribution to greenhouse gas emissions. In Chile, where seismic activity is common, it is crucial to provide resilient timber structures that safeguard life safety and reduce earthquake-induced damage and repair costs. The Performance-Based Earthquake Engineering (PBEE) framework offers a practical alternative for designing more efficient timber buildings and assessing the risks related to seismic hazards, potential damage, and economic losses. In this paper, the PBEE framework is employed to assess the likelihood of a government-subsidized 5-story cross-laminated timber building collapsing under seismic stress in Chile. The probabilistic seismic hazard analysis (PSHA) was used for hazard site characterization, and the collapse probability analysis indicated a probability of less than 0.1% for a building with the mentioned characteristic, making it suitable for construction in Chile. Further research is required to achieve loss estimation under the PBEE framework, such as quantifying damage fragility curves of representative engineering details for Chilean construction.

KEYWORDS: PBEE, CLT, PSHA, Conditional Mean Spectrum, Record Selection, Collapse

1 INTRODUCTION

Cross-laminated timber (CLT) is a mass timber product increasingly used in the construction of mid-rise and high-rise buildings, as an alternative to the traditional materials like concrete, steel, and masonry [2]. The usual constructive system in CLT buildings is the platform type, it consists of walls and slabs composed of solid timber panels with high stiffness and strength in their plane, attached through metal brackets and fasteners [3]. In these constructions, the floor panels are supported by the walls of the lower story, therefore the walls are interrupted at each level [4] and the main source of energy dissipation comes from the wall-to-wall parallel connections and overturning restraint system (i.e. hold-downs) as it is illustrated in Figure 1 [5].

In Chile, cross-laminated timber is a scarcely used product, unlike Europe and North America, where midrise and high-rise buildings have been built using CLT panels as the main material for walls and floor diaphragms [6-8]. However, recent studies [9-12] seek to promote the use of the CLT platform system using radiata pine grown in Chile as raw material by proposing design recommendations such as seismic performance factors (i.e., seismic response modification factor R = 2.0 and inter-story drift limit of 0.2%) and design procedures that are waiting for its incorporation in national design codes. Considering the high seismicity of the country and the lack of formal code-based recommendations, it is essential to provide resilient timber structures where structural and non-structural components adequately protect life safety and reduce earthquake-induced damage and repair costs. In this context, Performance-Based Earthquake Engineering (PBEE) becomes a convenient alternative when the structure's critical elements (CLT-to-CLT connections) exhibit non-linear behaviour, allowing for the design of more efficient buildings and assessing the risk associated with the seismic hazards, potential damage, and economical losses according to the location where they are built. In this paper, the PBEE framework will be employed to assess the probability of collapse of a government-subsidized 5-story cross-laminated timber building designed under the Chilean seismic design code considering the proposed seismic performance factors developed in [11].

2 BUILDING DESCRIPTION

It is important to clarify that the building being studied is still in the project stage. It was defined based on the criteria for government-subsidized housing in Chile, taking into consideration the specific needs and requirements of the target population. The projected building has five floors with a height of 2.6 m each. The length, width, and height of the building are 20.55 m, 7.05 m, and 10.4 m, respectively, with floors and walls made of 3-ply CLT (i.e., 120mm of thickness), using Chilean radiata pine as raw material, with two apartments in each level (55 m^2 per apartment). The building structure has been designed with monolithic wall as a lateral system with hold-downs and shear keys as overturning and sliding restraint systems, respectively. The staircase that provides access to the apartments is located in the middle. It was assumed that the building will be built on a typical soil type in the city of Santiago (i.e., Vs30 > 350 m/sec). The archetype of the building is illustrated in Figure 2. Figure 3 shows corresponding panels in a red box on the floor plan (a) to indicate the panel distribution on the elevations (b).

3 NUMERICAL MODELING

In order to evaluate the response of the building, two modeling variants were considered to illustrate the impact of considering a simplified 2D approach and the possible system effect on the response of the 3D structure. These are (i) a representative 2D planar elevation of the structure (i.e., A-A axis), and (ii) a full 3D representation of the building structure. Both numerical models were developed on OpenSeesPy [13]. Shell elements (i.e. shellMITC4 element) with isotropic material were used for the CLT walls panels and nonlinear springs (i.e. zeroLength element) were used for the hold-downs and shear keys (see Figure 4) as according to [5] both connection are responsible for the energy dissipation in the monolithic wall system. The wall-to-wall perpendicular connection was considered non-dissipative and perfectly rigid. The test data reported in [10] on full-scale CLT shear walls and in [14] on hold-downs and shear keys were considered for the calibration of the numerical model. The modeling and calibration procedure described in [12] was used as a base for the development of the input parameters (i.e., elastic parameters for shell elements and SAWS constitutive parameters for the zeroLength elements) models. Based on previous numerical studies [15], the floor and the roof were modelled as rigid diaphragms with mass lumped at each story.

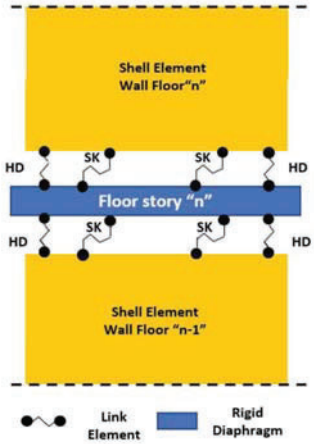

Figure 5: *Schematic of FE model for CLT shear walls at the story "n"*

For the 2D structure, the first fundamental period of the nonlinear structural model was determined as 0.515 sec. For the 3D building model, the first fundamental periods of the nonlinear building model at both translational directions were determined as 0.292 sec and 0.257 sec. The first mode is predominately in the X direction and the second mode is in the Y direction.

4 SEISMIC HAZARD

Chile is located in a highly seismic-prone area. Megathrust earthquakes are mainly attributable to the subduction of the Nazca plate beneath the continental South American plate. This subductive interaction is considered the only source of earthquake hazard to perform nonlinear time history analysis (NLTHA) and Multiple Stripe Analysis (MSA).

A probabilistic seismic hazard analysis (PSHA) was conducted to compute the seismic hazard associated with the site location of the building. For the development of the PSHA, the recurrence model developed in [16] and the Ground-motion prediction equation (GMPE) for the Chilean subduction zone developed in [17] were used. An example of the seismic deaggregation for the site of the building is presented in Figure 4 considering a return period of 4975 years (a 1% probability of exceedance in 50 years) at the spectral acceleration of the building period.

Table 1: *Deaggregation results.*

Mean Scenario	*Period (sec)*		
	0.515	*0.292*	*0.257*
Magnitude	*7.80*	*7.83*	*7.83*
Distance (km)	*135.2*	*147.3*	*145.8*

Ground motion (GM) records from the SIBER-RISK database were selected to match the target Conditional Mean Spectrum (CMS) on the period of interest considering the procedure developed in [18] and a maximum scale factor (SF) of 2.0. Figure 5 shows the response spectra of all selected motions adjusted to the CMS. Some of the selected records are summarized in Table 2.

https://doi.org/10.52202/069179-0355

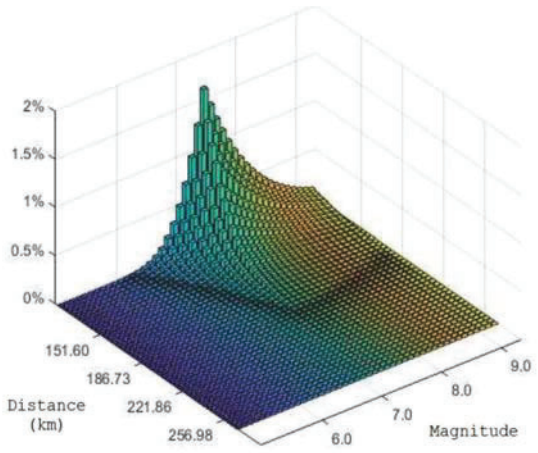

Figure 4: *Deaggregation for the considered site associated with the first mode of the 3D structure.*

In Figure 5, the conditioned spectra for both the 2D and 3D models are shown. Although these are different due to obvious reasons, such as the bidirectional quality for the 3D model, the records that fit these spectra turn out to be virtually the same. This is mainly due to the unique characteristics of the building, such as its stiffness and the parameters established, such as the selected return period.

5 RESULTS AND DISCUSSION

The Multiple Stripe Analysis (MSA) method was used for evaluate the structure fragility as is illustrated in Figure 6 and 7. As expected from any structure that is subjected to earthquake loads, major forces are found at the base of the structure. In this model case, base shear keys are the ones that present the biggest internal forces and displacements due to assuming spring-like supports instead of fixed or pinned supports, making these elements the ones that dissipate more energy during a seismic event. For the model developed in this study, an improvement proposal could be to consider different connections at the base than on higher floors or tension rods to prevent the exceeding of the collapse drift limit.

In Figure 8 and 9, the collapse fragility curves for the 2D simplified model and the 3D model shows that the 2D model collapses for lower IM levels in comparison to the 3D full scale model. The collapse fragility function is computed assuming that collapse observations are independent and fit into a binomial distribution, given that a record can either cause collapse of the structure or not.

The collapse margin ratio (CMR) is an important output from the MSA, defined as the ratio between median collapse capacity and the maximum considered earthquake intensity in the Chilean code (i.e., 2% in 50 years) SMT:

$$CMR = \frac{S_{CT}}{S_{MT}} \quad (1)$$

For the 2D simplified case SMT = 0.92g whereas for the 3D building model SMT = 1.35g. Then, the computed CMR is 3.8 and 2.45 for the 2D simplified case and 3D building model case, respectively. Shahnewaz et al. (2020) estimated the CMR for a 4-story CLT building as 2.78-3.55 at collapse drift ranging from 5% to 10% considering a 2% in 50 years scenario for Vancouver. Based on the results, the simplified 2D numerical model tends to underestimate the CMR making it a not good

representation of the response of the building. Having said that, this approximation could be a good estimation for buildings with a symmetric distribution of the structural components.

For the analysed structure and hazard scenario, the collapse probability is 0.5% and less than 0.1% for the 2D and 3D numerical models of the structure, respectively. This is mainly attributable to the strict design requirements of the Chilean seismic design code (i.e., mainly the inter-story drift limit of 0.2% for reduced seismic forces in an elastic design approach.

6 CONCLUSIONS

In summary, the Performance-Based Earthquake Engineering (PBEE) framework can offer a practical approach to designing resilient mass timber structures capable of withstanding seismic activity in highly prone areas such as Chile. The analysis of the collapse probability of a 5-story cross-laminated timber (CLT) building designed under Chilean seismic design code indicated a low probability of less than 0.1%, which suggests that CLT structures could be safely constructed in Chile. The simplified 2D axis has a different structural behaviour in relation to the same axis from the 3D model. From this, it can be concluded that the 2D model may not be a good representation of the behaviour of a full CLT structure given that it collapses to lower IM levels in comparison to the 3D full scale model.

Further research is necessary to improve the PBEE analysis and to obtain damage fragility curves associated with demand parameters such as inter-story drift (IDR) for structural and non-structural elements associated with CLT building design. To add depth and achieve a full

https://doi.org/10.52202/069179-0355

representation of the energy dissipated by the model, it can also be considered the perpendicular wall-to-wall connection in possible iterations of the analysis. To better estimate the effects from damage and the economic loss produced, it is necessary to develop fragility curves for typical structural connections used in timber buildings.

Non-structural components, such as MEP and fire protection installations should also be considered in a more complete risk assessment analysis, which adds more variables to the damage and economic loss estimation for a type of building that requires to manage the uncertainty of using technologies that have not been mass used before in the region, in the scale that it is proposed for future development of the timber industry in Chile. Thus, opening more opportunities for research through public-private partnership in design stages and building specifications for tall timber structures, making it possible to define the pros and cons of building in CLT and other timber engineered products and innovative construction materials.

It is also important to remember that in this present study, only the maximum values of IDR independent of its direction and location have been presented. Therefore, it would eventually be of interest to establish a more detailed description of these variables to better understand the behaviour of mid-rise buildings constructed using CLT. This is necessary for estimating economic losses and providing a full probabilistic risk assessment, which would enhance decision-making support for designers, investors, and stakeholders. Regardless, the use of mass timber structures in construction presents a promising method to reduce the housing deficit and greenhouse gas emissions while ensuring building safety and resilience in earthquake-prone regions.

ACKNOWLEDGEMENT

The research presented in this paper was made possible using SIBER-RISK, a ground-motion database for earthquakes in Chile. We express our gratitude to the creators and contributors of this research project for providing us the necessary information to get the results shown.

We would also like to extend our appreciation to the professor Jack Baker, who generously made all his knowledge available through his webpage, documents and code. The resources provided by Professor Baker played a crucial role in our research and we are grateful for his support and contributions.

FINITE ELEMENT ANALYSIS OF GLULAM BEAMS WITH TRANSVERSE AND LONGITUDINAL NOTCHES

Sardar Malek [1], Azadeh Goodarzi[2], Roger Parra[3], Parham Khoshkbari[4]

ABSTRACT: Laminated wood composites, such as glued-laminated timber (Glulam) and cross-laminated Timber (CLT), are increasingly being used in the design of mass timber buildings. In solid timber (sawn lumber) and engineered wood products (EWPs), transverse notches are generally used at connections or at supports to reduce the height of beams. Small longitudinal notches may also be cut along beams and columns for aesthetic purposes. It is known that abrupt cross-section changes create stress concentrations, which can cause the structural member to fail at lower loads compared to an unnotched member. European (Eurocode 5), Canadian (CSA O86-19), and American (NDS 2018) codes provide guidance on designing solid timber and Glulam beams with transverse notches. However, no recommendation has been provided for longitudinal notches along Glulam beams. To address this gap, a 3D Finite Element (FE) model is developed in ANSYS© software to assess the stress field of Glulam beams with the transverse end notches. The developed model is validated with experiments from the literature. The predicted load-bearing capacities are compared with those of notched beams based on the design equations provided in the codes and existing test data. The validated model is then used to comprehensively assess the effect of rounded notched corners and longitudinal notches on the stress fields of Glulam beams.

KEYWORDS: Glulam, Notch, CSA O86, Eurocode 5, NDS, Finite Element Analysis (FEA)

1 INTRODUCTION

Transverse notches are commonly used in solid timber and engineered wood products (EWPs) for various purposes. These notches are typically placed at connections like mortise and tenon or dovetail joints or at supports. In order to achieve a desired visual effect, it is also possible to create small longitudinal notches on structural members. It is well known that tension side transverse notches significantly reduce the load-bearing capacity of Glulam beams. This capacity reduction is mainly due to stress concentration near notched corners and the low tensile strength of timber perpendicular to the grain direction. The structural behavior of Glulam beams with transverse end notches has been studied experimentally and numerically in the literature [1-4].

European (Eurocode 5 [5]), Canadian (CSA O86-19 [6]), and U.S. codes (NDS 2018 [7]) provide design provisions for Glulam beams with the tension side transverse notches. However, currently, there are no guidelines or recommendations regarding longitudinal notches in Glulam beams.

In this paper, first, the design provisions for Glulam beams with transverse notches in their tension sides are reviewed and compared. A detailed review of the design equations, the considered notch geometry parameters, and limitations on maximum notch depth is provided. Then, the stress fields in a Glulam beam with the tension side transverse end notches are analyzed based on a 3D FE model developed in ANSYS software. The material and geometric parameters are selected based on the four-point bending test reported in [2]. The shear resistance of the end-notched Glulam beam based on provisions in various standards is compared with available test data [2] and the predictions of the developed FE model. The validated model is then used to numerically assess the effect of a rounded notch corner on the stress components. Finally, two longitudinal notches are added in the model, and the effects of these notches on the stress fields are investigated.

2 DESIGN APPROACHES FOR NOTCHED GLULAM BEAMS

A typical notched Glulam beam with a rectangular cross-section with a width of b and a depth of d, has been shown in Figure 1. In this figure, the d_n and i are the notch depth and notch inclination, respectively. The notch length, e, is defined as the horizontal distance from the support to the notched corner. The effective depth of the notched beam, d_{ef}, is obtained by:

$$d_{ef} = d - d_n \quad (1)$$

[1] Sardar Malek, University of Victoria, Canada, smalek@uvic.ca

[4] Parham Khoshkbari, Google LLC, California, USA

https://doi.org/10.52202/069179-0356

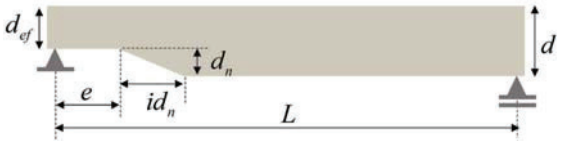

Figure 1: *Schematic of a typical notched beam.*

Based on the design provision provided in Eurocode 5 [5], the shear force at the notched support of the beam should be verified using:

$$V \leq \frac{2}{3} bd_{ef} k_v f_{v,d} \tag{2}$$

where $f_{v,d}$ is the design shear strength and k_v is a reduction factor calculated by the following equation for the Glulam beam:

$$k_v = \min\left\{ \frac{6.5\left(1 + \frac{1.1\, i^{1.5}}{\sqrt{d}}\right)}{\sqrt{d}\left(\sqrt{\alpha(1-\alpha)} + 0.8\, \frac{e}{d}\sqrt{\frac{1}{\alpha} - \alpha^2}\right)}, 1 \right\} \tag{3}$$

here, α is the notch ratio defined by $\alpha = d_{ef}/d$.
According to the design provisions in CSA O86-19 [6], the shear force at the notched support of a Glulam beam with less than 2.0 m^3 in volume should be verified by:

$$V \leq F_r \tag{4}$$

and

$$V \leq V_r \tag{5}$$

where F_r is the factored fracture shear resistance at a notch on the tension side at support obtained by:

$$F_r = 0.9 F_f d b K_N \tag{6}$$

In Equation (6), $F_f = f_f(K_D K_H K_{Sf} K_T)$. It should be noted that f_f is the specified fracture shear strength at a notch and obtained by $2.5(b)^{-0.2}$ or 0.9 MPa (whichever is greater). Other factors, K_D, K_H, K_{Sf}, and K_T are the load-duration factor, system factor, service-condition factor for fracture shear, and treatment factor, respectively. K_N is the notch factor calculated as follows:

$$K_N = \left[0.006d\left(1.6\left(\frac{1}{\alpha} - 1\right) + \left(\frac{e}{d}\right)^2\left(\frac{1}{\alpha^3} - 1\right)\right)\right]^{\frac{-1}{2}} \tag{7}$$

In Equation (5), V_r is the factored shear resistance obtained by:

$$V_r = 0.9 F_v \frac{2bd}{3} \tag{8}$$

for $e < d$, and

$$V_r = 0.9 F_v \frac{2bd_{ef}}{3} \tag{9}$$

for $e > d$. In the above equations $F_v = f_v(K_D K_H K_{SV} K_T)$. f_v is the specified strength in shear and K_{SV} is the service-condition factor for shear.
According to the design approach provided in NDS 2018 [7], the shear force at support should satisfy the following equation:

$$V \leq 0.48 F_v' b d_{ef} \left(\frac{d_{ef}}{d}\right)^2 \tag{10}$$

in which, F_v' is the adjusted shear design value parallel to the grain. A general comparison of the limitations stated for notched Glulam members in Canadian, European, and U.S. codes has been provided in Table 1.

Table 1: *Comparison of design approaches for notched Glulam beams in Eurocode 5, CSA O86-19, and NDS 2018 Standards, considering taper notches, notch length, and allowable notch depth.*

Standards	Taper Notch	Notch Length	Limitation on Maximum Notch Depth
CSA O86-19	-	✓	0.25 d
Eurocode 5	✓	✓	-
NDS 2018	-	-	0.1 d or 3"

Table 1 shows that CSA O86-19 and Eurocode 5 account for notch length, while taper notches are only considered in Eurocode 5. On the other hand, NDS 2018 and CSA O86-19 impose strict limitations on notch depth, while Eurocode 5 is comparatively more flexible.

3 FE MODELLING

3.1 TRANSVERSE NOTCH

A 3D finite element (FE) model corresponding to a notched Glulam beam with reported performance in the literature [2] is developed in ANSYS software. The Glulam beam has seven layers with uniform thickness (see Figure 2). The beam has a rectangular cross-section with a width of 100 mm, a total height of 220 mm, and an overall length of 4000 mm. The beam is notched at both ends, the depth of each notch is 110 mm (half of the depth of the beam), and the notch length is 250 mm. The beam is simply supported at two ends. Two-point loads of 5 kN (F=10 kN) are applied to the beam at a 1200 mm distance from the supports. Four steel plates with a width of 100 mm, length of 140 mm, and thickness of 10 mm are placed at the load application and support positions to reduce the effect of local indentations. All the above-mentioned geometric parameters of the beam are illustrated in Figure 2.
All of the geometric parameters, loads, and boundary conditions are symmetric in this problem. Therefore, the symmetric constraint is considered in the middle of the span of the beam, and just half of the beam (Figure 3) has been modelled.

https://doi.org/10.52202/069179-0356

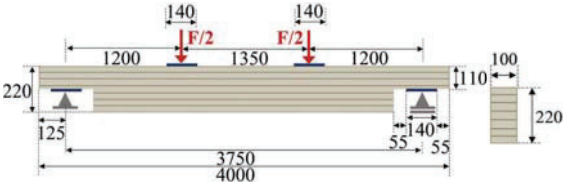

Figure 2: *Schematic of the notched glulam beam considered in [2] and the selected geometric parameters for model validation. All dimensions are in mm.*

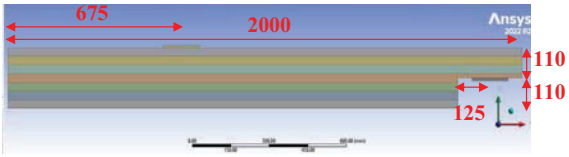

Figure 3: *Developed FE model corresponding to the beam in Figure 2. All dimensions are in mm. Half of the beam has been considered due to symmetry.*

3.2 ROUNDED NOTCH EFFECT

To investigate the effect of a rounded notch, two Glulam beams with rounded notched corners with a radius of 10 mm and 16 mm (see Figure 4) are analyzed in ANSYS Workbench. The stress fields in these models are compared with those of the Glulam beam with sharp notches in Section 4.3.

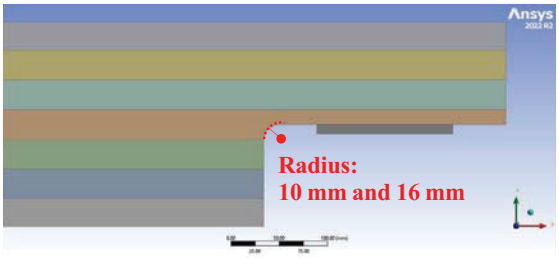

Figure 4: *Rounded notched corner.*

3.3 LONGITUDINAL AND TRANSVERSE NOTCH

In addition to the transverse end notches, two longitudinal notches are also included along the beam to investigate the effect of longitudinal notches on the stress fields (see Figure 5). The longitudinal notches have a square cross-section (20 mm × 20 mm) and are located under the sixth layer on both face sides of the Glulam beam.

4 RESULTS

4.1 VALIDATION OF THE MODEL

To validate the developed model, the predicted load-deflection curve of the selected Glulam beam with transverse notches is compared with experimental data as well as other reported models in the literature [2,3].
In experiments reported in [2], a linear elastic behaviour has been observed for the notched Glulam beam up to failure. In the FE model developed in [3], a linear elastic behaviour has also been predicted for the notched Glulam beam. Therefore, the comparisons are made based on the slope of the linear region of the load-deflection curves. The values of loads, deflections, and slopes of load-deflection lines are listed in Table 2. Preliminary results show a very good agreement between the models and experimental data (see Figure 6). The differences between the predicted slope of the load-deflection line in the current FE model and those obtained experimentally in [2] and those predicted in [3] are approximately 10% and 2%, respectively.

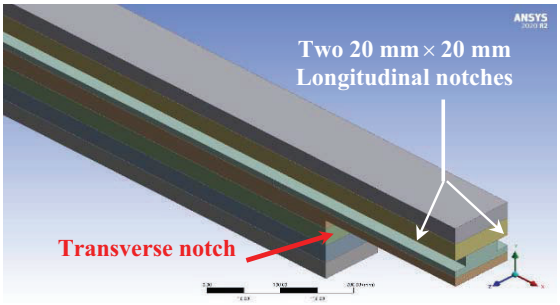

Figure 5: *3D FEM of the Glulam beam with the transverse and longitudinal notches.*

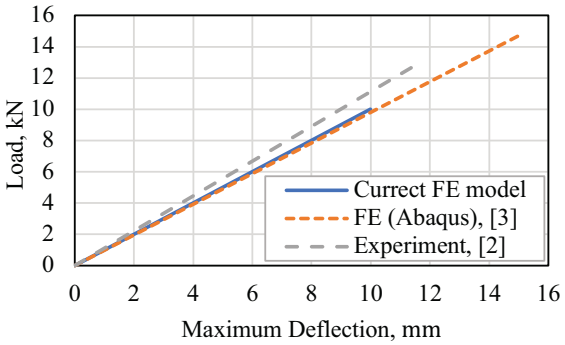

Figure 6: *Comparison between the elastic region of the load-deflection curves of the notched Glulam beam of the current FEM in ANSYS©, experiment [2], and FEM in ABAQUS© [3].*

Table 2: *Loads, deflections, and initial slopes of load-deflection curves of the notched Glulam beam of the current FE model in ANSYS©, experiment [2], and FEM in ABAQUS© [3].*

	Load (kN)	Deflection (mm)	Slope $10^6 \frac{N}{m}$
Experiment, [2]	12.8	11.5	1.113
FE Model in ABAQUS, [3]	14.8	15.1	0.980
Current FE Model (ANSYS)	10.0	9.98	1.001

4.2 EFFECT OF THE TRANSVERSE NOTCH ON INDUCED STRESSES

The distribution of perpendicular to the grain stress is shown in Figure 7. It is noted that the maximum value of this normal stress, σ_y, is 3.7 MPa and occurs at the notched corner.

The stress stress distribution is shown in Figure 8. The maximum value of the shear stress, σ_{xy}, (3.0 MPa) is highlighted at the notched corner.

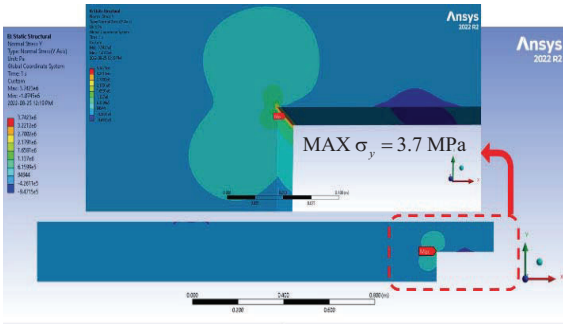

Figure 7: *Distribution of normal stress σ_y (Pa) under the applied load of 10 kN.*

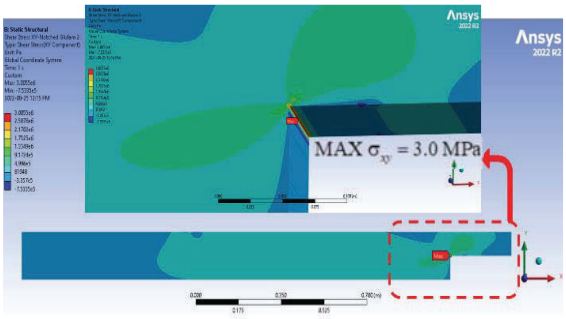

Figure 8: *Distribution of shear stress σ_{xy} (Pa) under the applied load of 10 kN.*

To study the state of stress at the notch vicinity, a path is defined in the model from the notched corner to the other end of the beam parallel to the beam direction. The yy and xy components of the stress components along this path are shown in Figures 9 and 10, respectively. An abrupt increase of the tensile stress perpendicular to the grain and shear stress at the notched corner has been noted.

It is noted that the values of shear stress and tensile stress perpendicular to the grain are increased significantly near the notch. These stress concentrations are the main cause for Mode I and II crack initiation at the notched corner and the reported brittle failure of notched Glulam beams in the literature [2].

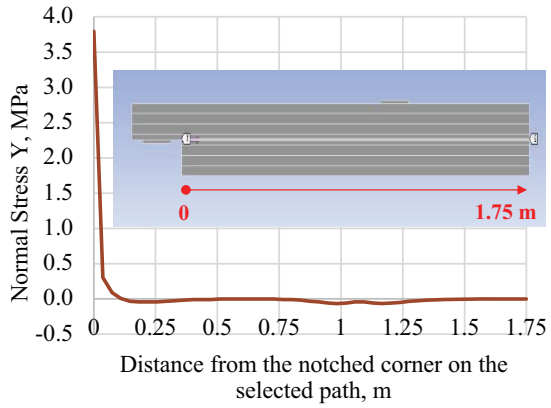

Figure 9: *Normal stress σ_y (MPa) along the selected path.*

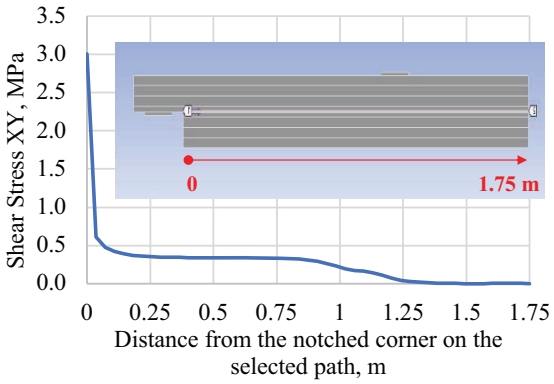

Figure 10: *Shear stress σ_{xy} (MPa) along the selected path.*

To define the input material properties in ANSYS, similar to [2], we have used the mechanical properties of spruce timber that is classified under strength class C22 in accordance with EN 338 [8]. The shear strength of the material is 3.8 MPa as highlighted in [2] and [8].

For verification purposes, a comparison was made between the measured capacity of the Glulam beam with deep, transverse notches reported in the literature [2] and the expected capacity of the end-notched Glulam beam using design equations provided in Eurocode 5, CSA O86-19, and NDS 2018 (see Figure 11). It should be noted similar strength values have been considered in Equations (2), (6) and (10) for this comparison (dry condition). Considering various adjustment factors and clauses highlighted in different standards (see Section 2), slight differences are expected for the beam capacity.

Figure 11 shows that Eurocode 5 and CSA O86-19 overestimate the capacity of the notched Glulam beam, while NDS 2018 underestimates it. Considering the differences between the definitions of adjustment factors in various standards, such discrepancies may be justifiable. Also, it is noted that the predicted load-bearing capacity using the current FE model (12.66 kN) is in good agreement with the measured capacity (12.80 kN). The beam capacity (12.66 kN) has been estimated numerically assuming the material behaviour is linear followed by a brittle failure when the shear stress at the notch corner

https://doi.org/10.52202/069179-0356

reaches the the shear strength of the selected spruce grade (3.8 MPa).

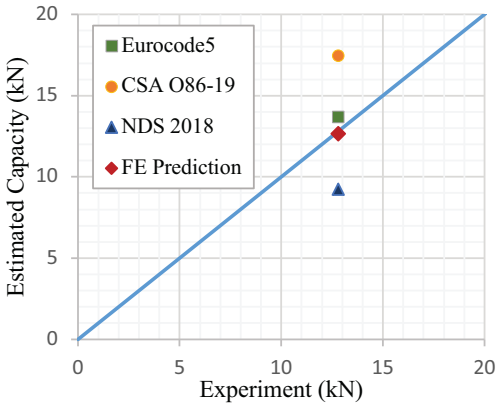

Figure 11: *Comparison between the estimated capacity based on Eurocode 5 [5], CSA O86-19 [6], NDS 2018 [7], FE model prediction and the measured capacity [2].*

4.3 EFFECT OF THE ROUNDED NOTCHED CORNER ON THE STRESS FIELD

4.3.1 Rounded notched corner with a radius of 10 mm

The validated model is used to conduct a range of parametric studies on the notch geometry. The yy component of the stress (perpendicular to the grain stress) in Glulam beam with a rounded notched corner with a radius of 10 mm is shown in Figure 12. The xy component of the stress tensor is also shown in Figure 13.

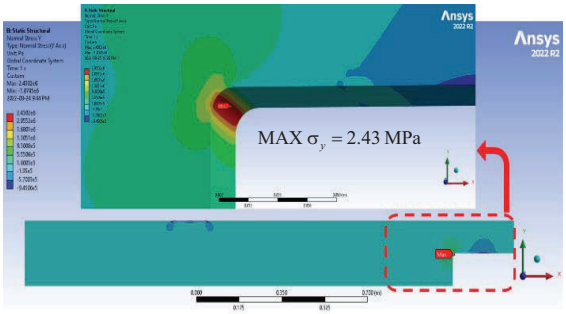

Figure 12: *Distribution of normal stress σ_{yy} (Pa) for the case of the rounded notched corner with a radius of 10 mm, under the applied load of 10 kN.*

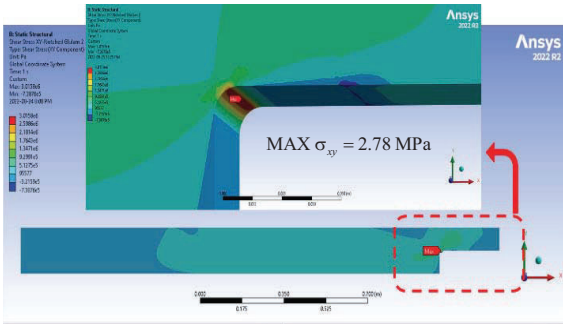

Figure 13: *Distribution of shear stress σ_{xy} (Pa) for the case of the rounded notched corner with a radius of 10 mm, under the applied load of 10 kN.*

4.3.2 Rounded notched corner with a radius of 16 mm

The yy component of the stress tensor of the Glulam beam with a rounded notched corner with a radius of 16 mm is shown in Figure 14. It can be seen that the maximum normal stress, σ_y, occurs at the rounded notched corner, reaching a value of 1.89 MPa under the applied load of 10 kN. The xy component of the stress tensor is also shown in Figure 15. Under the same applied load, the maximum shear stress, σ_{xy}, is 2.39 MPa which occurs at the notched corner.

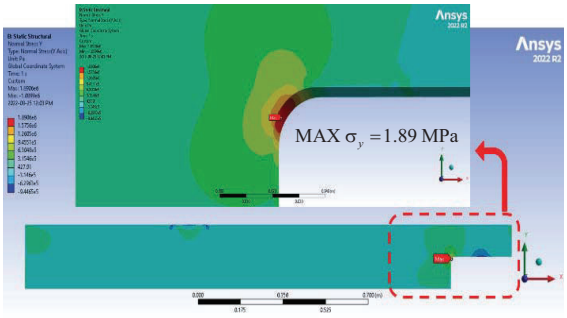

Figure 14: *Distribution of normal stress σ_{yy} (Pa) for the case of the rounded notched corner with a radius of 16 mm, under the applied load of 10 kN.*

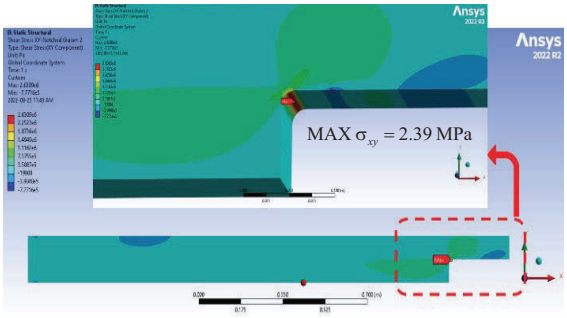

Figure 15: *Distribution of normal stress σ_{xy} (Pa) for the case of the rounded notched corner with a radius of 16 mm, under the applied load of 10 kN.*

4.3.3 Stress Field Comparison between Glulam Beams with Sharp Notch and Rounded Corners

A path is defined parallel to the beam axis starting from the location of the maximum stress component at the notched corner. The normal stress, σ_y, and shear stress, σ_{xy}, along the beam with the sharp notch, the beam with the rounded notched corner with a radius of 10 mm, and the beam with the rounded notched corner with a radius of 16 mm are shown in Figures 16 and 17, respectively.
According to Figure 16, it can be seen that the rounded notched corners with a radius of 10 mm and 16 mm reduce the maximum value of the normal stress, σ_y, by 34% and 49%, respectively. Based on Figure 17, using rounded notched corners with a radius of 10 mm or 16 mm can decrease the maximum shear stress, σ_{xy}, by 7% and 20%, respectively.

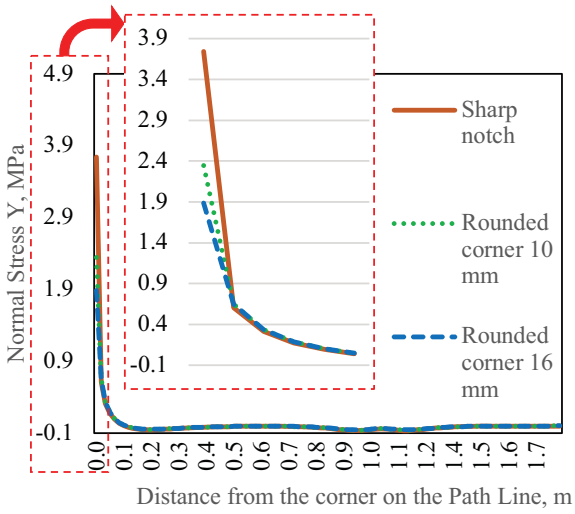

Figure 16: *Normal stress, σ_y, along the selected path.*

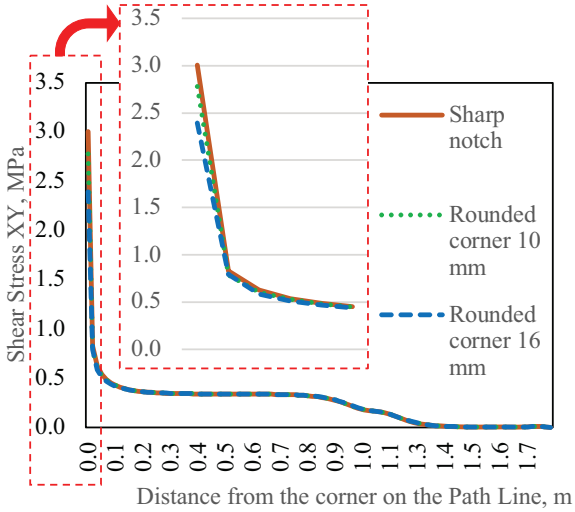

Figure 17: *Shear stress, σ_{xy}, along the selected path.*

4.4 EFFECT OF THE LONGITUDINAL NOTCH

For the case when the Glulam beam has two longitudinal notches in addition to the transverse end notches, the distribution of normal stress, σ_y, and shear stress, σ_{xy}, are shown in Figures 18 and 19, respectively.
The maximum values of normal stress, σ_y, and shear stress, σ_{xy}, for the Glulam beam with the longitudinal notches are 4.17 MPa and 3.33 MPa, respectively, occurring at the notched corner. It can be seen that the maximum values of normal stress, σ_y, and shear stress, σ_{xy}, for this beam are increased by 13% and 11%, respectively, compared to those values in the beam without the longitudinal notch.

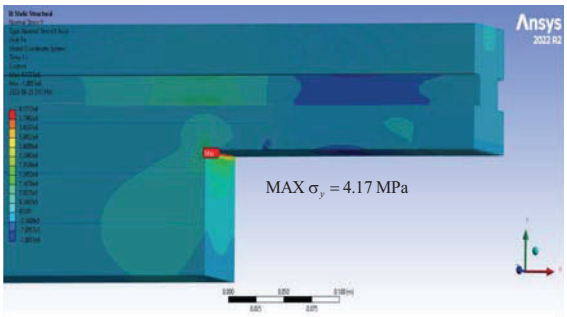

Figure 18: *Normal stress σ_y (Pa) distribution in the Glulam beam with the longitudinal and transverse notches, under the applied load of 10 kN.*

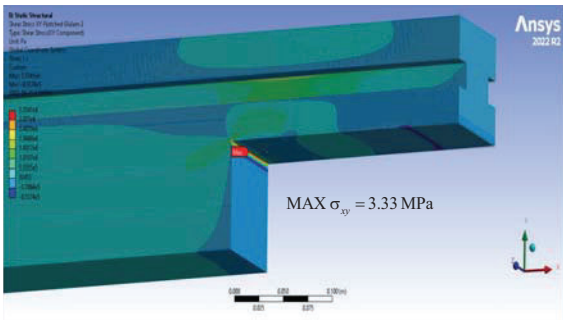

Figure 19: *Shear stress σ_{xy} distribution in the Glulam beam with the longitudinal and transverse notches, under the applied load of 10 kN.*

The stress distributions of σ_y and σ_{xy} for the layer of the Glulam beam in which the longitudinal notches are located are shown in Figures 20 and 21.
It is noted that at the longitudinal notch above the notched corner, the normal stress perpendicular to the grain, σ_y, has a maximum value of 1 MPa (see Figure 20). The maximum shear stress, σ_{xy}, also reaches 1.78 MPa (occurring at a location between the support and the notched corner) which is significant for the longitudinal notch (see Figure 21).

https://doi.org/10.52202/069179-0356

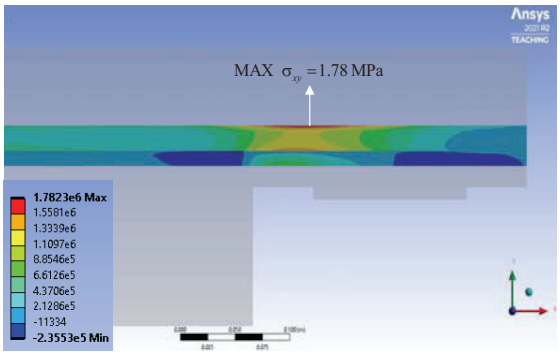

Figure 21: *Shear stress σ_{xy} (Pa) distribution in the layer of the Glulam beam in which the longitudinal notches are cut.*

5 CONCLUSIONS

A comprehensive review of design equations given in different standards for calculating the capacity of Glulam beams with transverse notches was conducted. Slight discrepancies were noted, which was expected due to various adjustment and safety factors. It was found that the Canadian standard (CSA O86-19) and Eurocode 5 consider the length of notches, while only Eurocode 5 accounts for taper notches. The maximum allowable notch depth is restricted by NDS 2018 and CSA O86-19, whereas Eurocode 5 is comparatively more flexible. There is currently a lack of provisions for notched columns subjected to combined axial and bending loads, which necessitates further investigation in the future.

To understand the effect of notch geometry and the interaction of notches cut in different directions, a FE model was developed and validated using experimental data. It was shown that the model predictions and experimental data in the literature are in agreement in terms of stiffness and strength. The difference between the predicted slope of the load-deflection line in the current FE model and the experimental value in the literature was approximately 10%. The current FE model also predicted a load-bearing capacity that is approximately 1.1% less from the test data reported in the literature [2].

The developed model in this paper was used to assess the notch effect on the stress distribution (normal and shear) in the tested Glulam beam for various notches and notched corners. It was shown that the longitudinal notches could interact with transverse notches and increase the stress levels. In the beam with both longitudinal and transverse notches, the maximum normal stress, σ_{yy}, and shear stress, σ_{xy}, at the notched corner were increased by 13% and 11%, respectively, compared to the values in the notched beam without a longitudinal notch. An increase in shear stress and normal stress perpendicular to the grain was also noted at the longitudinal notch near the transverse notch. It was shown that rounded notched corners with a radius of 10 mm or 16 mm could reduce the maximum normal stress, σ_{yy}, by 34% and 49%, respectively, and decrease the maximum shear stress, σ_{xy}, by 7% and 20%, respectively.

A STUDY ON THE SEISMIC PERFORMANCE OF SHEAR WALLS UNDER A DYNAMIC LOAD

Tomoki Furuta[1] and Masato Nakao[2]

KEYWORDS: Post-and-beam construction system, Plywood shear wall, Braced shear wall, Shake table test

1 INTRODUCTION

In recent years, the number of Japanese buildings that have suffered damage due to multiple large earthquakes has increased. As timber buildings do not have an obvious yield point, the shear stiffness of these buildings decreases gradually during the occurrence of multiple earthquakes. Consequently, there is concern about a decrease in seismic performance, which may result in the collapse of timber houses even during relatively small earthquakes.

Regarding timber shear walls, to investigate the dynamic performance and to build an analysis model in order to predict earthquake response, several experimental and numerical studies have been conducted, e.g. [1-5]. Nowadays, It has become possible to predict the earthquake response of timber houses.

Nevertheless, it remains difficult to predict the earthquake response of timber houses when there are multiple earthquake motions. For this reason, a shake table test of the shear walls of the Japanese post-and-beam construction system was conducted to understand the dynamic characteristics of shear walls during multiple earthquakes. Hysteresis models of the shear walls for earthquake response analysis are proposed using the shake table test results. Moreover, an equivalent linearization method as a simple prediction method for a maximum response displacement was tried.

2 SHAKE TABLE TEST

2.1 OUTLINE

Specimens for the shake table test were constructed using the Japanese post-and-beam construction system. The wall length of each specimen was 2730 mm, and the specimens contained four columns as shown in Figure 1. Two kinds of shear walls were tested. The first, a plywood shear wall, was 910 mm × 2730 mm in size. A sheet of plywood was nailed to the frame using N50 nails spaced at 150 mm. The second was a braced shear wall, two 45 mm × 90 mm timber braces were attached crosswise to the frame. Conventional brace connectors (C-brace) were used to connect the ends of the braces and the columns. Newly-developed ductile brace connectors (D-brace) were also used as a variation of the braced shear wall.

The new brace connector, as shown in Figure 2, includes a damping mechanism. The thickness of the steel for the connector is 3.2mm. As the lateral displacement of the braced shear wall increases, the bridges deform to absorb a displacement between a column and a brace. Damping force is produced by the plastic deformation of the bridges. The steel core is covered with high-damping rubber to use as a brace connector.

A 15.8 kN weight was applied to the beam (Figure 1). Rollers were arranged along the longitudinal direction of the weight. 25 kN hold-down connectors were installed to reinforce the joint between the ends of the columns and the horizontal members.

https://doi.org/10.52202/069179-0357

The seismic waves of the 1995 JMA Kobe NS earthquake (as observed at the Kobe branch of the Japan Meteorological Agency on January 17th, 1995) were applied to the specimen. The time history of acceleration and the response acceleration are shown in Figures 3 and 4, respectively.

The input level was stepped up to 80% for the plywood shear wall and up to 100% for the braced shear wall. Before each input step level, 50% of the previous level was applied in order to evaluate the earthquake response characteristics after the stiffness degradation of the shear walls, as shown in Figure 5. In this paper, the step-up input is referred to as "1st", whereas 50% of the previous level input is referred to as "2nd."

Accelerometers were attached to the shake table, the sill, and the beam of the specimens. The story displacement was measured between the beam and the sill.

2.2 SHEAR FORCE-DISPLACEMENT RELATIONSHIP AND FAILURE MODE

The shear force-displacement relationship of the plywood shear walls is shown in Figure 6. The shear force Q was calculated using Equation (1).

$$Q = m \cdot a \tag{1}$$

where m is mass(16kN/9800mm/sec^2), a is acceleration(mm/sec^2).

A remarkable degradation of shear stiffness was seen under the 40% input load. During the 80% input load, the shear stiffness significantly decreased. Pull-out, punch-out, and fracture of nails were observed as shown in Figure 7.

For the conventional brace connector, a remarkable decrease in the shear stiffness was observed during the 80% input load as shown in Figure 8. After the application of the 100% input load, as shown in Figure 9, the pull-out of the screws on the column and buckling of the stud were observed.

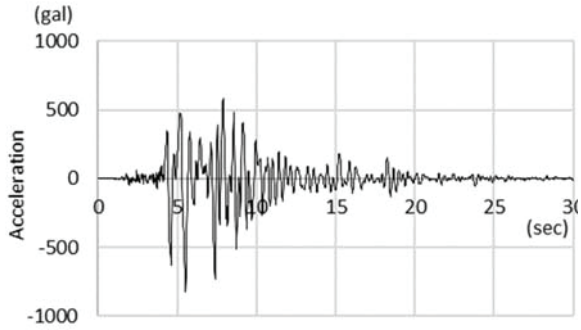

Figure 3: *Time history of JMA Kobe NS wave*

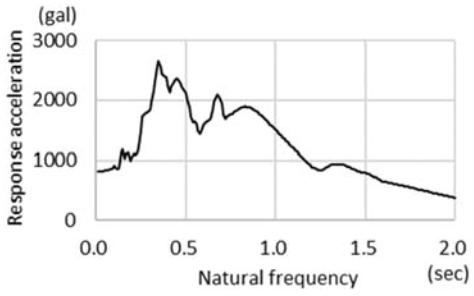

Figure 4: *Acceleration response spectrum of JMA Kobe wave (h=5%)*

Figure 5: *Input level of the JMA Kobe wave*

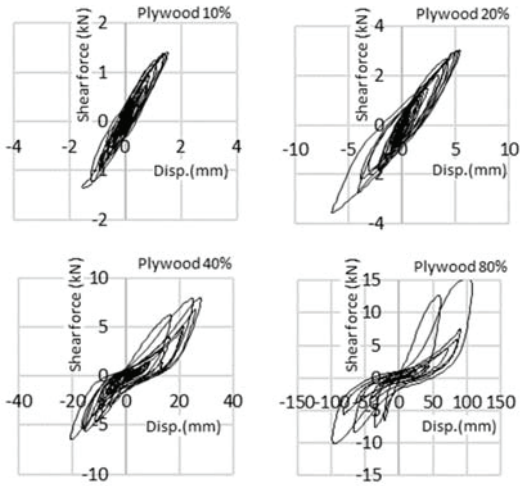

Figure 6: *Shear force-displacement relationships of plywood shear wall specimen on each input*

Figure 7: *Plywood shear wall specimen and nails after the test*

No shear stiffness reduction was seen in the shear force-displacement relationship of the braced shear wall with ductile brace connectors during the series of inputs as shown in Figure 10. There was no visible damage to the connectors even after the 100% input load, as shown in Figure 11.

The degradation of the shear stiffness can be found easily from the combined shear force-displacement relationships as shown in Figures 12 to 14. Skeleton curves of the shear force-displacement relationships are shown in Figure 15. The ratio of the shear forces at 1/120 rad for plywood shear wall: braced shear wall with conventional brace connectors: braced shear wall with ductile brace

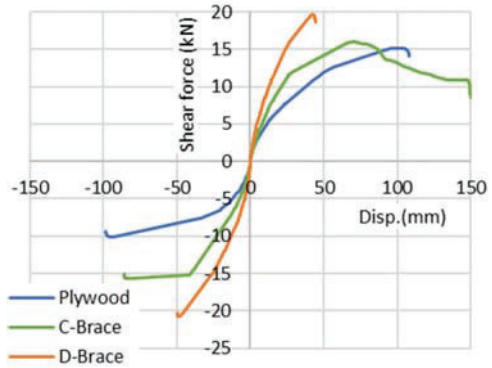

Figure 15: *Skeleton curves of shear force-displacement relationships of shear wall specimens*

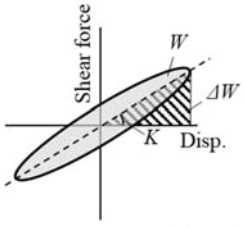

Figure 16: *Notations in Equation (2) for calculation of H_{eq}*

connectors was 1.0:1.4:2.0. It is obvious that the shear stiffness of the ductile brace connector is superior to the plywood shear wall and the braced shear wall with conventional brace connectors.

2.3 TRANSITION OF STRUCTURAL PERFORMANCE OF SPECIMEN

To grasp the structural performance transition of the specimens during a series of loading, the equivalent damping factor(H_{eq}) was calculated using Equation (2) on each input load. The notations refer to Figure 16.

$$H_{eq} = \frac{W}{4\pi\Delta W} \tag{2}$$

In addition to that, the shear stiffness of one shear force-displacement loop (K) that involves a maximum displacement was calculated. For a comparison, initial stiffness (K_0) was also calculated on each input load. The amplitude of one loop picked out for the calculation was approximately 0.5mm to 1.0mm.

Figure 17 shows the structural performance transition of the plywood shear wall. It is found that the H_{eq} is about 15% regardless of input level. It is also found that the

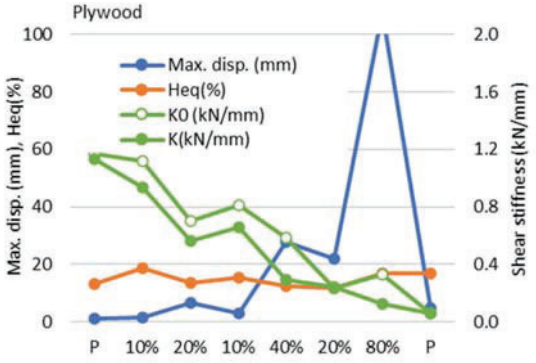

Figure 17: *Maximum displacement, equivalent damping factor(H_{eq}), shear stiffness K_0 and shear stiffness K of plywood shear wall specimen*

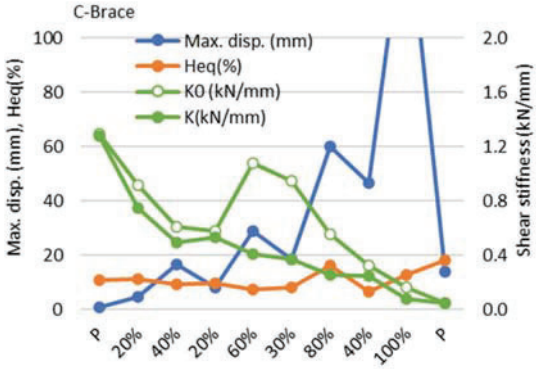

Figure 18: *Maximum displacement, equivalent damping factor(H_{eq}), shear stiffness K_0 and shear stiffness K of braced shear wall specimen with conventional brace connectors*

https://doi.org/10.52202/069179-0357

shear stiffness decreases as the maximum displacement increases. In terms of K_0, it is larger than K during a series of input loads.

Figure 18 shows the ones of the braced shear wall with convention brace connectors. H_{eq} is about 10 to 15% through the series of input loads. It is also found that the shear stiffness decreases as the maximum displacement increases same as the plywood shear wall. Unlike the plywood shear wall, the difference between K and K_0 is relatively large. It implies that the degradation of shear stiffness of the braced shear wall with convention brace fasteners is remarkable.

Figure 19 shows the ones of the braced shear wall with ductile brace connectors. H_{eq} is about 10%, it is lower than the plywood shear wall and the braced shear wall with conventional brace connectors. As in the previous Figure 14, the braced shear wall with the ductile brace connectors was almost elastic during the series of input loads, it is considered that damping due to plasticity is not contained in H_{eq}. Moreover, K_0 is close to K, and degradation of shear stiffness is considered to be little.

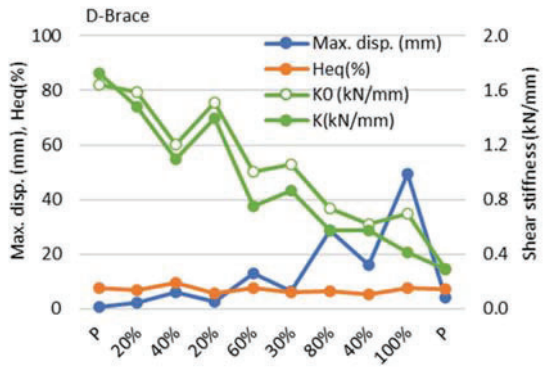

Figure 19: *Maximum displacement, equivalent damping factor(H_{eq}), shear stiffness K_0 and shear stiffness K of braced shear wall specimen with ductile brace connectors*

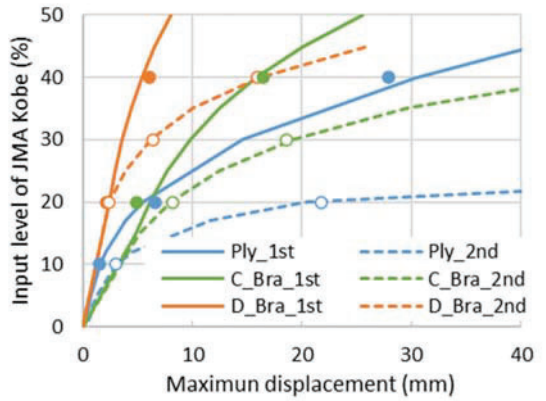

Figure 20: *Maximum displacement for different input levels*

2.4 EFFECT OF MULTIPLE INPUTS

Figure 20 shows the relationship between the input level of the JMA Kobe NS wave and the maximum response displacement of the shear walls. The regression curves for the 1st and 2nd inputs are also indicated in the figure. For the plywood shear wall, the 2nd displacement at 10% input was twice that of the 1st displacement. The 2nd displacement of the braced shear wall with ductile brace connectors exceeded that of the 1st displacement at an input over 20%, whereas the 2nd displacement of the braced shear wall with conventional brace connectors exceeded that of the 1st displacement at an input over 15%. From the regression curves, it can be seen that the response displacement of the 2nd input increases rapidly with the input level.

Figure 21 shows the relationship between the maximum displacement and the natural period of the three shear walls, where the maximum displacements were divided by the input level to convert to the one under 100% wave. The displacement response spectrums of the JMA Kobe NS 100% wave with 10%, 15%, and 20% damping ratio is also displayed in the figure. The natural period T was calculated using the mass, m=16kN/g (g=9800mm/sec^2), and shear stiffness, K(kN/mm).

$$T = 2\pi\sqrt{\frac{m}{K}} \tag{3}$$

Most of the maximum displacements are located between the displacement response spectrums of damping ratios of 15% and 20%. There is no remarkable difference between 1st and 2nd inputs. From the figure, it is found that a maximum response displacement can be estimated using the natural period based on K and the displacement response spectrum. Suppose the displacement response spectrum of a 15% damping ratio is used, predicted

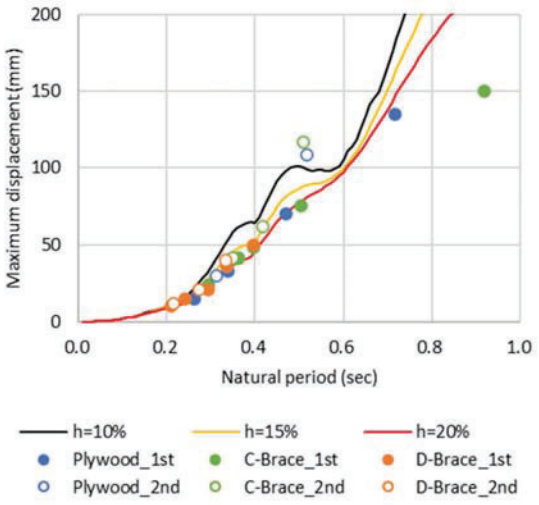

Figure 21: *Relationship between maximum displacement and natural period based on shear stiffness K*

https://doi.org/10.52202/069179-0357

response displacement would be the safe side for the three shear walls.
However, there is an issue that for predicting a maximum response displacement using a displacement response spectrum, it is impossible to grasp K beforehand because K is let from a maximum response displacement.

3 RESPONSE DISPLACEMENT PREDICTION

3.1 EARTHQUAKE RESPONSE ANALYSIS

On the basis of the shake table test results, hysteresis models of the plywood shear wall and the braced shear wall were set as shown in Figures 22 to 24. Earthquake response analysis was conducted using input waves on the shake table test. 16kN of weight and 10% of viscous damping were applied to single degree of freedom analysis model.
Figures 25 to 27 show maximum response displacements. A comparison of the earthquake response analysis using the hysteresis models and the shake table test results shows that the maximum response displacements of the analysis and the shake table test showed a good degree of correspondence in a small displacement range. In a large displacement range, there is a relatively large difference, which implies that more parameters of the hysteresis model are needed to predict maximum response displacements accurately in a wide displacement range.

3.2 EQUIVALENT LINEARIZATION METHOD

There was an issue that K derived from the maximum response displacement is needed to calculate the natural period for the prediction of maximum response displacement using a displacement response spectrum. As one solution for the above-expressed issue, in place of K, there is a possibility that K_0 is rather useful for the prediction of a maximum response displacement because K_0 can be calculated based on approximately 0.5mm to 1mm of amplitude. If time history data of displacement and acceleration could be recorded even under relatively small input, K_0 can be calculated.
Figure 28 shows the relationship between the natural period calculated using K_0 and the maximum displacement of the shear walls, where the maximum displacements were converted to the one under 100% wave. The displacement response spectrum of the JMA Kobe NS 100% wave with a 5% damping ratio is added to the figure as well as 10%, 15%, and 20%. Most of the maximum displacements of the shear walls are located near the displacement response spectrum of a 5% damping ratio, which implies that the response displacement can be predicted using the natural period based on K_0 regardless of the 1st or 2nd input.
Comparing the experimental maximum displacements and the displacement response spectrum, most of the maximum displacement was lower than the displacement response spectrum. Therefore, safe side prediction regarding maximum displacements is expected.
In case displacement and acceleration data can't be obtained, to grasp K_0 for the prediction of a maximum response displacement, it is valid to make use of the largest displacement in experienced displacements so far because there is a close relationship between the largest displacement in the past and K_0.
Figure 29 shows the relationship between the shear stiffness degradation ratio and the maximum displacement. The x value of each point is the largest

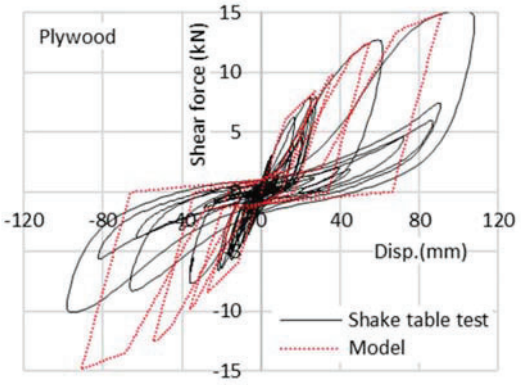

Figure 22: *Shear force-displacement relationship model of plywood shear wall*

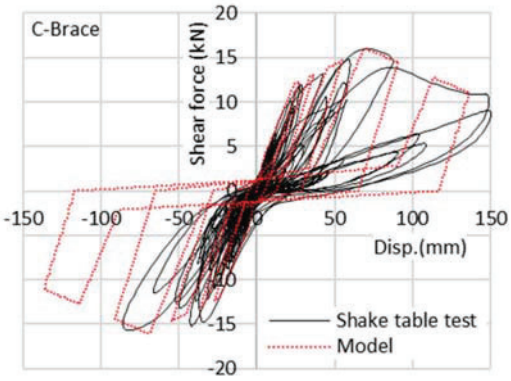

Figure 23: *Shear force-displacement relationship model of braced shear wall with conventional brace connectors*

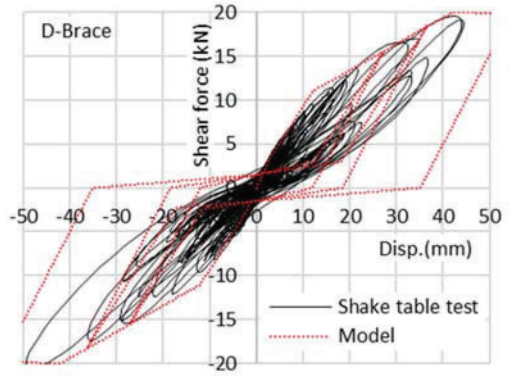

Figure 24: *Shear force-displacement relationship model of braced shear wall with ductile brace connectors*

https://doi.org/10.52202/069179-0357

displacement up to the time, and the y value, shear stiffness degradation ratio, is a ratio of the shear stiffness(K_0) after the input load where the largest displacement is recorded to the initial shear stiffness.
Ignoring the difference of 1st and 2nd inputs, regression lines according to the points belonging to each shear wall are also indicated in the figure. Equations (4), (5), and (6) represent regression lines of the plywood shear wall, the braced shear wall with conventional brace connectors, and the braced shear wall with ductile brace connectors, respectively.

$$y = x^{-0.4} - x/1000 \quad (4)$$
$$y = x^{-0.25} - x/500 \quad (5)$$
$$y = x^{-0.22} - x/500 \quad (6)$$

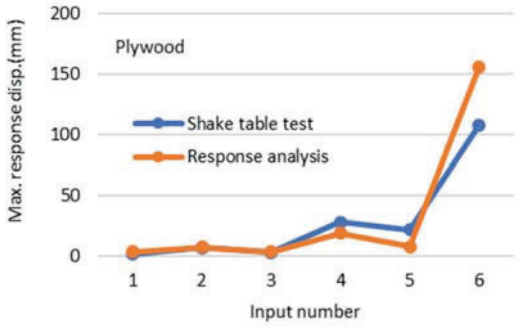

Figure 25: *Maximum response displacement of plywood shear wall*

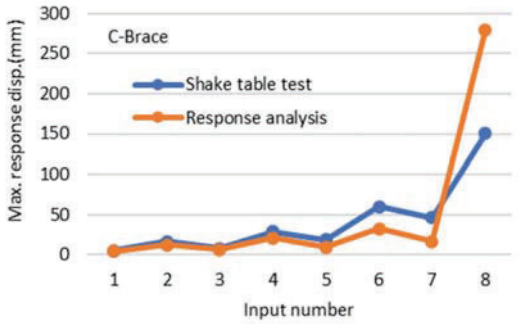

Figure 26: *Maximum response displacement of braced shear wall with conventional brace connectors*

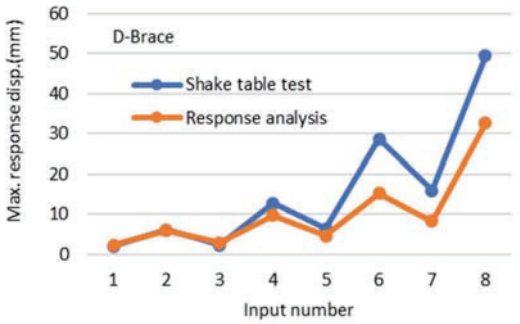

Figure 27: *Maximum response displacement of braced shear wall with ductile brace connectors*

In the case that the experienced largest displacement is known, the ratio of stiffness can be found using the equations, and K_0 can be calculated by multiplying the initial stiffness of the shear wall and the ratio of stiffness. Furthermore, using the displacement response spectrum of a 5% damping ratio, a maximum response displacement under the next input wave can be predicted. Figures 30 to 32 show maximum response displacements. Though the equivalent linearization method is simple, predicted response displacements are close to the maximum displacements obtained by the shake table test. With the derived regression curves from the shake table test results, the equivalent linearization method is

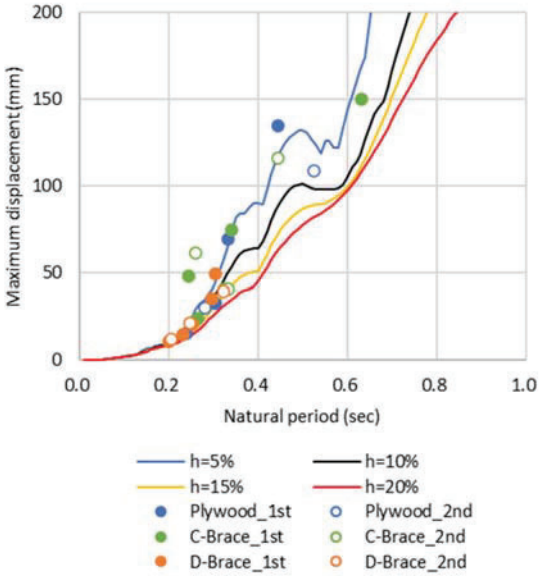

Figure 28: *Relationship between maximum displacement and natural period based on shear stiffness K_0*

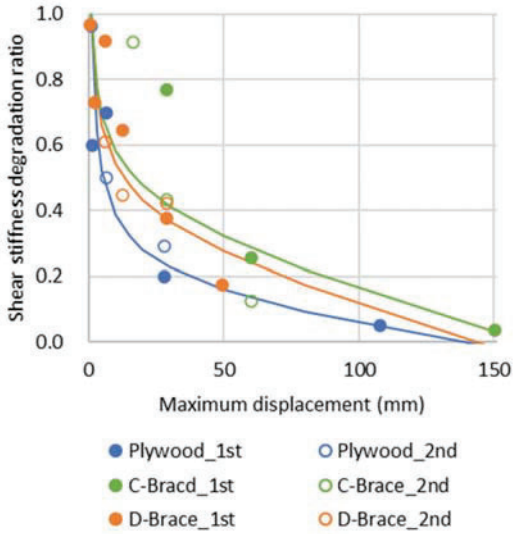

Figure 29: *Relationship between shear stiffness degradation ratio to initial shear stiffness and maximum displacement*

https://doi.org/10.52202/069179-0357

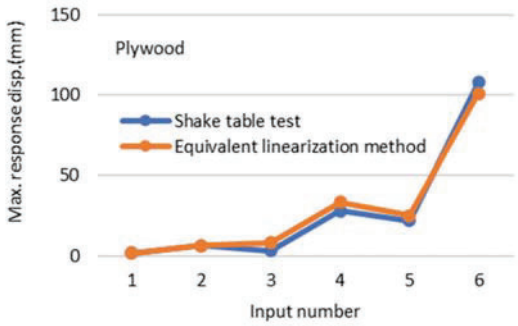

Figure 30: *Maximum response displacement of plywood shear wall*

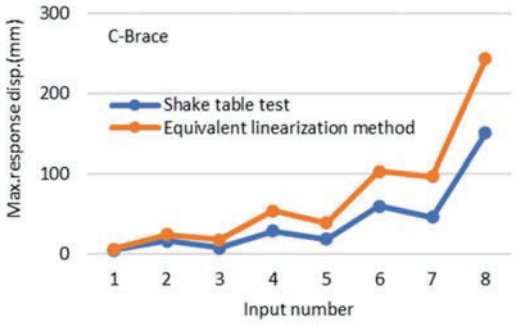

Figure 31: *Maximum response displacement of braced shear wall with conventional brace connectors*

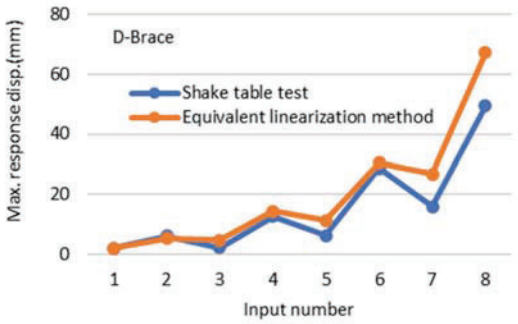

Figure 32: *Maximum response displacement of braced shear wall with ductile brace connectors*

considered to be a useful method to predict maximum response displacements even under multiple input waves.

4 CONCLUSIONS

Shake table tests of a plywood shear wall and braced shear walls were conducted to understand their dynamic characteristics under multiple earthquake inputs. Moreover, hysteresis models of the shear walls were proposed based on the shake table test results, and earthquake response analysis was conducted. The maximum response displacements from the analysis results were relatively close to the shake table test results in a small displacement range. Additionally, an equivalent linearization method as a simple prediction method for a maximum response displacement was tried. Using the initial shear stiffness and the shear stiffness degradation ratio derived from the shake table test results, the prediction results showed good correspondence with the shake table test results.

ACKNOWLEDGEMENT

Authors express our gratitude for the great support on the shake table test by Dr. Hideo Fujitani and Dr. Yoichi Mukai of Kobe university.

STRUCTURAL PERFORMANCE EVALUATION OF A TIMBER HOUSE USING NEW CONSTRUCTION SYSTEM WITH CLT HORIZONTAL DIAPHRAGM

Masato Nakao[1] and Tomoki Furuta[2]

KEYWORDS: Post-and-beam construction system, CLT, Horizontal diaphragm, Braced shear wall

1 INTRODUCTION

Japanese forest resources have been abandoned and accumulated for a long time. Making much use of CLT(Cross Laminated Timber) leads to consuming the forest resources effectively, it is necessary to develop various ways to use CLT.

As one of the ways to use CLT, authors have developed a new post-and-beam construction system with a CLT horizontal diaphragm. In the developed construction system, CLTs are used as a horizontal diaphragm, whereas beams are omitted. It may realize a short construction period, high structural performance, and high sound insulation.

This paper presents the structural performance evaluation of the newly developed construction system through the static incremental analysis of a prototype timber house.

2 OUTLINE OF PROTOTYPE HOUSE

Figure 1 shows the conventional post-and-beam construction system and the new construction system with a CLT horizontal diaphragm. In the new construction system, the floor system of the conventional post-and-beam construction system is replaced by CLTs. Because CLT has mortises, tenons of the end of columns can be joined to CLTs directly.

Figures 2 to 4 show a prototype house with the new construction system. Thanks to the rigidity of CLT, a large balcony can be placed on the southern part of the house, and it is tolerated that the external wall of the second story is not arranged just above the one on the first story. The CLT grade of the horizontal diaphragm at the floor level on the second story is Mx60-5-5[1]. The species of the CLTs is Japanese cedar.

Braces are used as the shear wall in the prototype house while the plywood shear wall is not used. The ends of the braces are connected by newly developed ductile brace connectors. 15kN hold-down connectors are installed on the ends of columns. CLTs as the second story floor are arranged as shown in Figure 5.

A half-lapped joint was adopted as the joint between CLTs of the horizontal diaphragm. Screws, 7 mm in diameter and 200 mm long, are driven at an angle of 45 degrees on the joint for reinforcement.

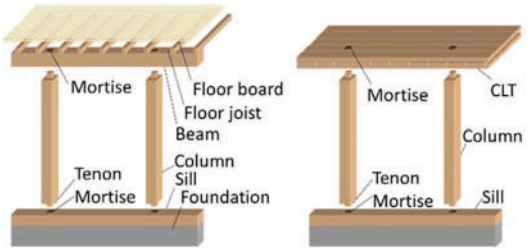

Figure 1: *Conventional post-and-beam construction system(left) and new construction system with CLT horizontal diaphragm(right)*

The weight of the first story of the prototype house is estimated as 191.1 kN, while the one of the second story is 120.7 kN, where the live load was assumed as 600 N/m^2[2].

Trans. comp. mem.	590	637

3 PROTOTYPE HOUSE MODELING AND INCREMENTAL ANALYSIS

To evaluate the structural performance of the prototype house, a 3D structural model for static incremental analysis was built.

3.1 CLT AS HORIZONTAL DIAPHRAGM

Because an evaluation method of the out-plane two-way bending stiffness of CLT is not established, the CLT model that consists of laminas as shown in Figure 6 was adopted. The section of the lamina was 227.5mm x 30mm, and the laminas were connected by the post members. On the top layer, the side of the lamina is expected to touch the next lamina under a bending moment of minor direction. Therefore, transverse compression members were arranged between laminas on the top layer. Young's modulus and shear modulus of the members that compose the CLT are listed in Table 1, where every member is assumed as elastic.

3.2 CLT-CLT JOINT

3.2.1 Tensile direction

To evaluate the tensile force-displacement relationship of a CLT-CLT joint of the second-story floor diaphragm, a tensile loading test was conducted. The joint type is a half-lapped joint with long screws that is 7mm in diameter and 200mm long. Figure 7 shows the specimen. There were major axis specimens and minor axis specimens regarding the lamina direction as shown in Figure 8, and three specimens were prepared for each axis. Two screws were driven to the specimen. Figure 9 shows a specimen set in the test apparatus. One directional tensile load was applied to the specimen.

Figure 10 shows the tensile force-displacement relationships of all specimens. The variation of minor axis specimens is relatively large, while the average curve of major axis specimens and of minor axis specimens are about the same level. The average maximum tensile force per screw was approximately 12.5kN. For major axis specimens, failure around the screw occurred, while split along the edge occurred in minor axis specimens as shown in Figure 11. Large plastic deformation of the screws was not found in both major axis or minor axis specimens.

The spring which represents the screw on the joint between CLTs was set to 4 kN/mm of stiffness for tensile direction considering the experimental data. Because a large axial force is not expected to be produced through the incremental analysis, the spring was elastic. Regarding the compression side, the stiffness was set to 4kN/mm same as the tensile direction.

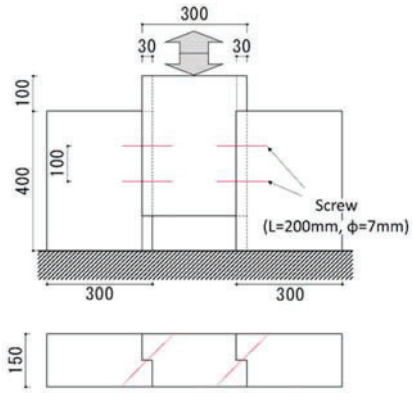

Figure 12: *Specimen of shear loading test*

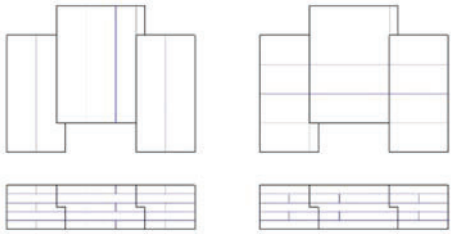

(a) Major axis specimen *(b) Minor axis specimen*

Figure 13: *Direction of lamina*

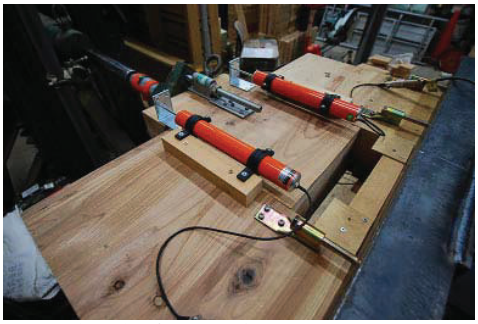

Figure 14: *Shear loading test of CLT-CLT joint*

3.2.2 Shear direction

To evaluate the shear force-displace relationship of a CLT-CLT joint of the second story floor diaphragm, a shear loading test was conducted. The joint type is also a half-lapped joint with long screws.

Figure 12 shows the specimen. There were major axis specimens and minor axis specimens regarding the lamina direction as shown in Figure. 13, and three specimens were prepared for each axis. Four screws were driven to Major axis 1 and Minor axis 1 specimens, while two screws were driven in the other specimens. Figure 14 shows a specimen set in the test apparatus. The repeated load was applied to the center peace of the specimen.

The results of the tests are shown in Figure 15. The maximum shear force per screw was approximately 10kN, and the screw was bent largely or fractured as shown in Figure 16. Figure 17 shows the skeleton curves of all specimens. The variation of major axis specimens is relatively large, while the average curve of the major axis specimens and the one of the minor axis specimens are about the same level.

https://doi.org/10.52202/069179-0358

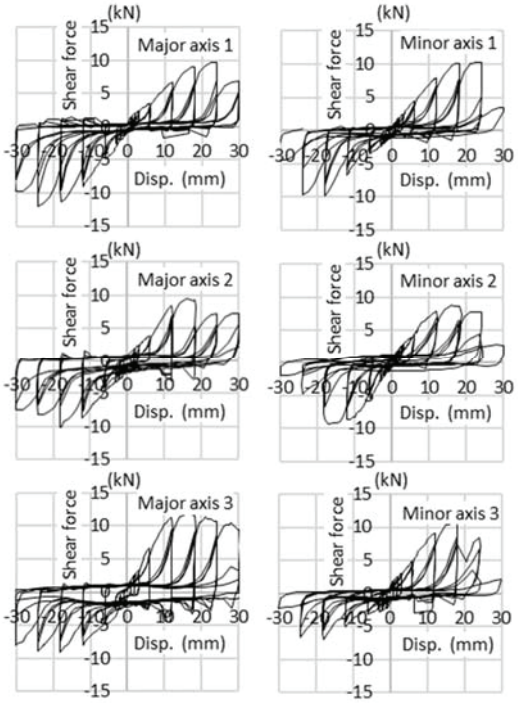

Figure 15: *Shear force-disp. relationship of CLT-CLT joint*

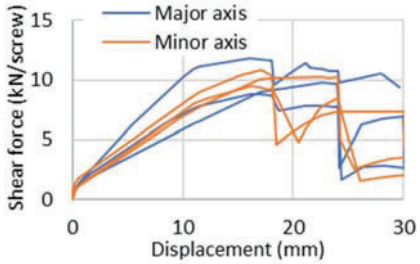

Figure 17: *Skeleton curves of shear force-disp. relationship*

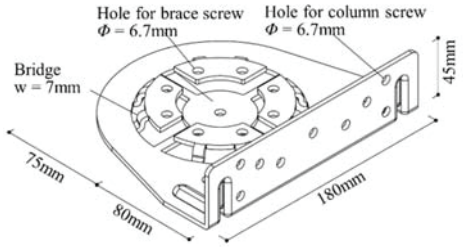

Figure 18: *Steel core of ductile brace connector*
(To use as a brace connector, this steel core is covered with high damping rubber.)

The spring which represents the screw on the joint between CLTs had 0.8 kN/mm of stiffness for in-plane shear direction. The spring was elastic, and the stiffness was derived from the experimental data.

3.3 BRACE

Regarding shear walls, braced shear walls are arranged in the prototype house. For reinforcing the joint between the end of a brace and a column, the ductile brace connector was used.

The ductile brace connector, as shown in Figure 18, includes a damping mechanism. The thickness of the steel for the connector is 3.2mm. As the lateral displacement of the braced shear wall increases, the bridges deform to absorb a displacement between a brace and a column. Damping force is produced by the plastic deformation of the bridges. To use as a brace connector, the steel core is covered with high-damping rubber.

Figure 19 shows a shear force-drift angle relationship of a single braced shear wall specimen as shown in Figure 20. Repeated lateral shear load was applied to the beam up to 0.02rad. After that, a one-directional shear force that causes tensile failure at the joint between the end of a brace and a column was applied.

The axial force-displacement relationship model of the brace with the ductile brace connectors is shown in Figure 21, where the compressive yield force of the model is the buckling strength of the brace.

3.4 COLUMN-CLT JOINT

To evaluate the tensile force-displace relationship of a joint between the end of the column and the CLT of the floor diaphragm on the second story, a tensile loading test was conducted.

Figure 22 shows the specimen, which has a tenon on the end of the column and a mortise on the CLT. A connector to prevent pull-out of the column was installed at the joint. Three specimens were prepared for the test, and a repeated load was applied to the column.

Figure 23 shows the axial force-displacement relationship of the joint between the end of the column and the CLT. Screws driven to the CLT were pulled out as shown in Figure 24, and the applied load decreased.

After the tensile loading test, a compressive loading test was conducted with the same specimen as the tensile loading test. The compressive load was applied to the specimen up to 50kN due to a limitation of the test apparatus, and relationships between compressive force and relative displacement between the end of the column and the CLT were derived as shown in Figure 25.

From the test results, an axial force-displacement relationship model at the end of the column, as shown in Figure 26, was set, and applied to the 3D prototype house model.

3.5 BUILDING UP OF 3D PROTOTYPE HOUSE MODEL

The 3D structural model of the prototype house is shown in Figure 27, which contains 8944 nodes and 16747 members, where the out-plane shear stiffness of the CLT-CLT joint was set as 10 kN/mm.

4 RESULT OF INCREMENTAL ANALYSIS

Figure 28 shows the story shear force-story displacement relationship from the static incremental analysis. Though the shear force along the Y-direction is slightly low compared to the one along the X-direction.

Regarding C_0=0.2 and C_0=0.3, where C_0 is the value of the story shear force divided by the weight the story carries, the maximum stress of the laminas and the maximum force of the screws on the CLT-CLT joint are listed in Table 2. The maximum bending stress of all laminas is 77% of the lower limit strength under C_0=0.3 shear force. For the maximum tensile stress, it is 21% of the lower limit strength, therefore CLTs are not considered to have damage even under relatively large earthquakes.

Regarding the tensile and shear forces carried by the spring at the CLT-CLT joint, they are considered to be in the elastic range compared to the test results such as Figures 10 and 17. As for the out-plane shear force, because no experimental data exist, an out-plane shear loading test will be planned to be conducted.

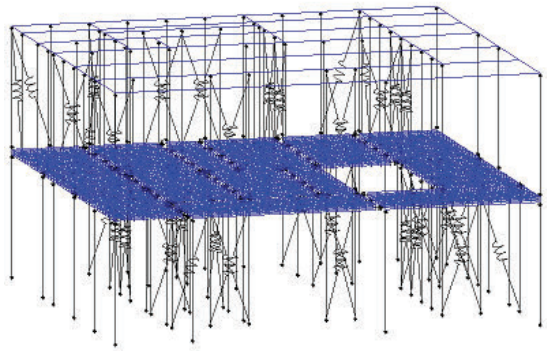

Figure 27: *3D structural model of the prototype house*

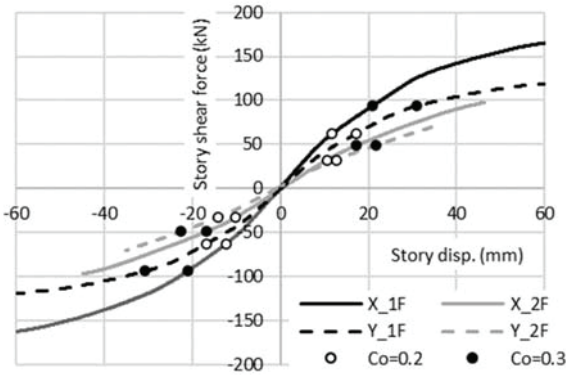

Figure 28: *Story shear force-story displacement relationship*

Table 2: *Maximum stress and force*

	Lamina (N/mm^2)		Spring between CLTs (kN)		
	Bending	Tension	Tension	In-plane shear	Out-plane shear
C_0=0.2	10.89	1.57	5.19	2.16	5.30
C_0=0.3	15.49	2.56	7.80	3.33	7.24

5 CONCLUSIONS

Static incremental analysis of the prototype timber house which is designed with the new post-and-beam construction system with a CLT horizontal diaphragm was conducted. From the experimental and numerical test results, it was confirmed that no damage to the CLT horizontal diaphragm was expected even under relatively large earthquakes.

NUMERICAL ANALYSIS ON SEISMIC BEHAVIOUR OF TIMBER FRAME STRUCTURE WITH HYBRID SCREWED-IN ROD CONNECTIONS

Jiwei Liu[1], Benkai Shi[2], Huifeng Yang[3]

ABSTRACT: A hybrid connection with steel bracket and screwed-in rods was developed for timber structures or hybrid steel-timber structures. Cyclic tests have been conducted upon the proposed connection and then compared it with the traditional bolted connections. Test results showed that the hybrid connection had better stiffness, energy dissipating capacity, and moment resisting capacity, compared with the bolted connection. The numerical models for the two types of connections were established. Bayesian parameter identification method was used to calibrate the parameters of the model. These two connection models were applied to a three-story frame numerical model in Open System for Earthquake Engineering Simulation (Opensees), and the seismic performances of the three-story frame with hybrid connection or bolted connections were evaluated, which can provide guidance for the application of the innovative connection hybrid connection. The results show that the hybrid connection can reduce the displacement response of the structure and improve the seismic performance of the structure, especially under rare earthquakes.

KEYWORDS: Steel bracket, Screwed rods, Bolted connection with steel plate, Three layers frame

1 INTRODUCTION

The bolted connections with steel plate are widely used in modern timber structures for convenient fabrication. However, bolted suffered lots of problems. Low initial stiffness may be caused by the space reserved for installation. Insufficient tensile and shear strength of timber results in low moment resisting capacity. Brittle failure mode of wood in tension and shear direction leads to brittle failure of joints [1-4]. In order to solve the above problems, screwed rods has been proposed to connect the beam and column. The joints connected by screwed rods have satisfactory initial stiffness and moment resisting capacity.

But the limitation in energy dissipating capacity restricts the ability of structures to reduce seismic response [5-7]. In this paper, screwed rods and steel bracket are used in beam-column connections. Cyclic loading test are implemented on bolted connection and hybrid connection to evaluate the initial stiffness, moment resisting capacity, and energy dissipating capacity. The connection numerical models are established in the OpenSees environment. Model parameters are identified by Bayesian method. The numerical models for bolted connection and hybrid connections are applied to a three-story structure model for nonlinear time history analysis. The interlayer displacement angles of the two structures are compared.

2 NUMERICAL ANLYSIS OF BEAM-TO-COLUMN CONNECTION

2.1 NUMERICAL MODEL

Figure 1 show the specimen design of the hybrid connection. The specimen had a timber beam member (135 mm × 420 mm in cross section, 1500 mm in length), a steel column member (350mm × 160mm × 20mm in cross section, 1500 mm in length). The steel bracket was a replaceable ductile energy dissipation element. Steel bracket was connected by bolts to the steel column. Steel bracket was connected to the screwed rods at the end of the timber beam. The test data of bolted connection with steel plate were compared with the hybrid connection.

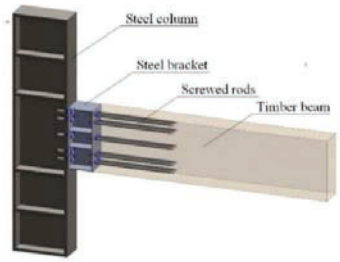

Figure 1: *Details of Hybrid connection*

https://doi.org/10.52202/069179-0359

In order to meet the need of nonlinear time history analysis of the structure, fiber model is used for finite calculation of the structure. Figure 2 shows the model of the connection. The steel column was modelled by dispBeamColumn element with steel02 material. The model has high precision and high numerical stability, and can effectively simulate the Bauschinger effect of rebar. The glulam beam was modelled by dispBeamColumn element with Concrete02 material. The model parameters were determined according to results of the mechanical tests of glulam. The steel bracket was simplified to a rotational spring. Compared with the experimental data of the connection, the multi-parameter Pinching4 material model could better simulate the degradation and damage of the steel bracket, as shown in Figure 3. The model parameters are calibrated by Bayesian method. The method of parameter identification is referred to the literature [8]. Parameter identification results are shown in Table 1.

2.2 CALIBRATION

In order to verify the accuracy of the numerical model, the simulation hysteresis curve of the connection model is compared with the experimental hysteresis curve. The hybrid connection test results are provided by the literatures [9]. Figure 4 and Figure 5 show the simulated result. The loading stiffness, bearing capacity and unloading stiffness obtained by numerical model are consistent with the experimental results, which proves that the model is effective and the parameter selection is reasonable.

3 NUMERICAL ANLYSIS OF FRAME STRUCTURE

3.1 NUMERICAL MODEL

According to Chinese code for seismic design of buildings (GB50011-2010) [10], a three-storey frame structure is designed. The structure is located in the 8 degree fortified area, the second group, the second site classification. As the structure is regular, the torsion effect can be ignored. Therefore, a longitudinal frame is proposed to reflect the longitudinal seismic performance of the whole structure. The frame consists of 3 spans of 5 meters each. Each layer of the frame is 4 meters in height, and the whole frame is 12 meters in height. Figure 6 shows the model of a three-story structure. A two dimensional three-storey frame was simulated. The model of beam, column and connection is established by the modelling method of Section 2. Spring elements using elastic materials with high stiffness were arranged at column base.

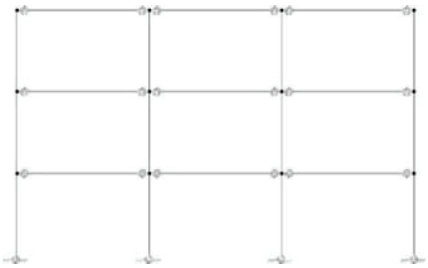

Figure 6: 3.1 *Numerical model for a three-story structure*

The modal analysis of the two frames is carried out respectively. The periods of the first two modes of the two frames are shown in the Table 2.

Table 2 Structural natural period of vibration

Specimen ID	First mode period /s	Second mode period /s
BC[a]	1.170	0.226
HC[b]	1.026	0.216

[a]BC (Bolted connection)
[b]HC (Hybrid connection)

Four natural ground motions were selected according to the site category of the structure, the design seismic grouping, the spectral characteristics of the standardized response spectrum and the first two natural vibration periods of the structure. The characteristics of each ground motion are shown in Table 3. The acceleration spectrum of each ground motion, the mean acceleration spectrum diagram and the target response spectrum are compared under the action of 8-degree frequent and 8-degree rare earthquakes as shown in Figure 7 and Figure 8.

3.2 RESULT AND DISCUSSION

According to different fortification standards, the time history analysis after amplitude modulation is carried out on the four ground motions before time history analysis. The top-level displacement-time history curves of the two frames under different seismic waves are shown in the Figure 9-Figure 12 (Rare earthquake) and Figure 13-Figure 16 (Frequent earthquake). The maximum displacement response and maximum interlayer displacement Angle are shown in the Under rare

https://doi.org/10.52202/069179-0359

earthquakes, hybrid connections can reduce the maximum displacement response by 19.62%, while under frequent earthquakes, hybrid connections can reduce the maximum displacement response by 9.38%. According to the simulation results, the hybrid connection can reduce the seismic response of the structure and improve the seismic performance of the structure. In rare earthquakes, the effect of lifting is more obvious.

Table ***4*** and Table 5.

By comparing the simulation results, it can be found that under rare earthquakes, the maximum displacement of the frame with hybrid connection is smaller than that with bolted connection. Under frequent earthquakes, the average maximum displacement of the frame with hybrid connection is smaller than that of the frame with bolted connection. However, the maximum displacement response of the frame with bolted connection is larger than that of the frame with hybrid connection under GM2.

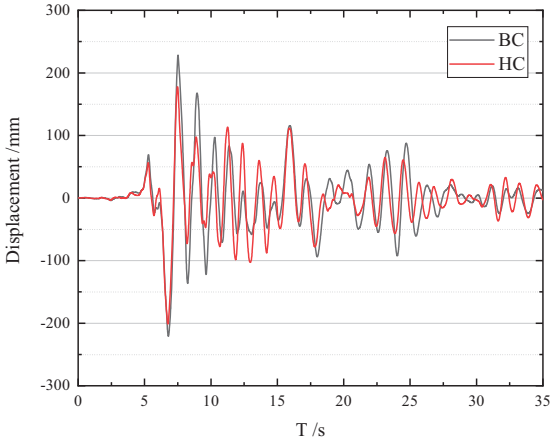

Figure 9: *Comparison of displacement time histories of the top layer of two frames under GM1 (Rare earthquake).*

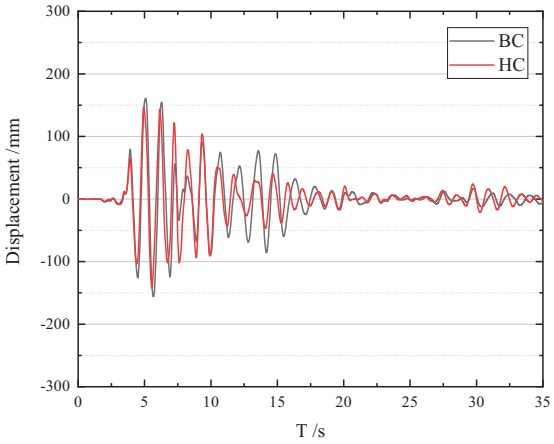

Figure 10: *Comparison of displacement time histories of the top layer of two frames under GM2 (Rare earthquake).*

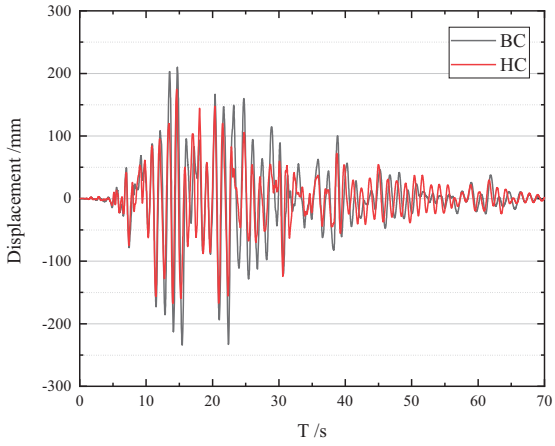

Figure 11: *Comparison of displacement time histories of the top layer of two frames under GM3 (Rare earthquake).*

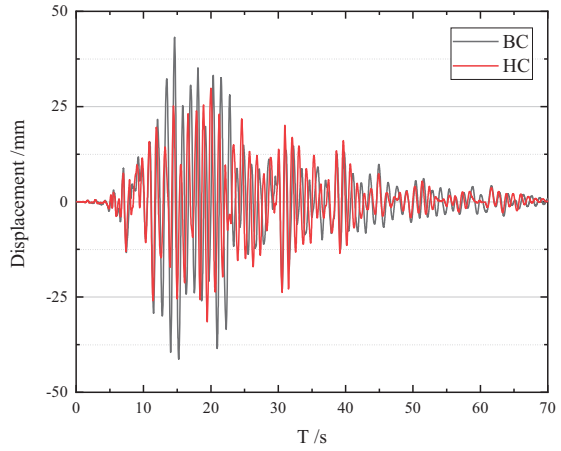

Figure 15: *Comparison of displacement time histories of the top layer of two frames under GM3 (Frequent earthquake).*

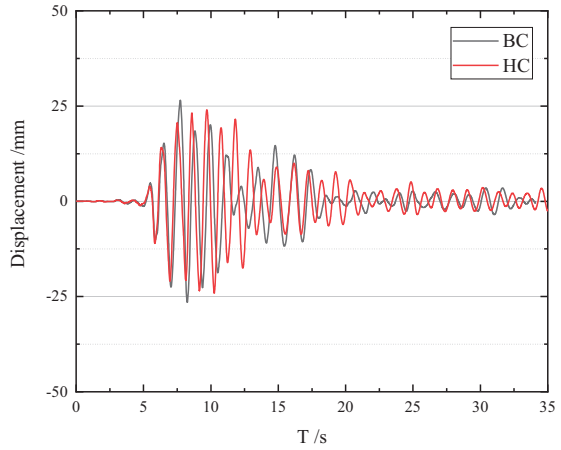

Figure 16: *Comparison of displacement time histories of the top layer of two frames under GM4 (Frequent earthquake).*

Under rare earthquakes, hybrid connections can reduce the maximum displacement response by 19.62%, while under frequent earthquakes, hybrid connections can reduce the maximum displacement response by 9.38%. According to the simulation results, the hybrid connection can reduce the seismic response of the structure and improve the seismic performance of the structure. In rare earthquakes, the effect of lifting is more obvious.

4 CONCLUSIONS

In this paper, a ductile beam-column connection, named as hybrid connection, was proposed and investigated. Compared with the traditional bolted connection, hybrid connection has higher stiffness, moment resisting capacity, and energy dissipating capacity. The joint models are established and compared with the experimental results to verify the accuracy of the model. Also, these two kinds of connections are applied to a three-story structure model. The interlayer displacement angles and interlayer displacement are compared. The following conclusions can be drawn:

1. The connection modelling method has been verified by experimental data with accuracy and can be used for connection modelling.
2. The frame with hybrid connection can reduce the displacement response of each layer of the structure and improve the seismic performance of the structure under the ground motions according to different fortification standards.
3. It is more obvious that the frame with hybrid connection can improve the seismic performance of the structure under rare earthquakes.

ACKNOWLEDGEMENT

This work was supported by National Natural Science Foundation of China (Grant No. 51878344, 51578284), which are highly appreciated.

EXPERIMENTAL AND NUMERICAL ANALYSIS OF HIGH-CAPACITY SHEAR WALLS WITH MULTIPLE ROWS OF NAILS

Ruite Qiang[1], Lina Zhou[2], Chun Ni[3]

ABSTRACT: With the increase of building height in light wood-frame construction and seismic design spectra in the 2015 edition of National Building Code of Canada, stronger shear wall systems have been facing higher demands, especially for mid-rise wood-frame buildings located in high seismic zones. In collaboration with FPInnovations, a new high-capacity shear wall system with two and three rows of nails was developed. A total of 30 shear walls had been tested under reversed cyclic loading. Results showed that the lateral resistance of shear walls with multiple rows of nails is roughly proportional to the number of rows compared to a standard shear wall with the same sheathing thickness, nail diameter and nail spacing. However, new failure modes, such as splitting of bottom plates, out-of-plane separation of end studs from bottom plates, rupture of sheathing panels, etc. have limited the post-peak deformation of the high-capacity shear wall and its ductility. A better understanding on the stress-strain development of wood material and connections is needed to develop design details to prevent these failure modes and increase the ductility and design resistance of wood shear walls with multiple rows of nails. A preliminary 3D numerical model of high-capacity shear walls with multiple rows of nails were developed using ABAQUS to simulate the lateral performance and failure modes of high-capacity shear walls. Testing data from previous research by the authors was used to verify the modeling techniques developed in this study. Results show that the detailed 3D shear wall model can reasonably simulate the lateral resistance of high-capacity shear walls and the failure modes that are not common in regular shear walls.

KEYWORDS: high-capacity shear wall, multiple rows of nails, lateral load, numerical modelling

1 INTRODUCTION

Light wood frame shear wall systems have been widely used in the construction of multi-story residential and commercial wood buildings in North America. Consisting of wood framing members, wood-based sheathing panels and fasteners, wood frame shear walls are the main vertical component in resisting lateral loads caused by wind or seismic actions.

The height limit of wood frame buildings has been firstly increased from 4 to 6 stories since 2009 in BC, and the seismic design spectra have also been increased substantially for all site classes in the provincial and national building codes of Canada (NBCC) [1,2]. Therefore, the demand for higher lateral load resisting systems for mid-rise wood frame buildings has increased, especially in high seismic zones. To respond to this demand, a high-capacity shear wall system with multiple rows of nails along sheathing edges has been jointly developed by FPInnovations and University of Victoria. There were 30 high-capacity shear walls with two and three rows of nails along sheathing edges tested over a three-year period [3,4]. Results showed that the lateral resistance of shear wall with multiple rows of nails is almost proportional to the number of rows. However, new failure modes that are not common in standard shear walls were observed in high-capacity shear walls, such as splitting of bottom plates, out-of-plane separation of end studs from bottom plates, rupture of sheathing panels, etc. Present of these new failure modes limited the post-peak deformation of the high-capacity shear wall system and its ductility. Additional design details had been tried in the past few years to prevent these new failure modes. For example, double bottom plates were used to avoid splitting of bottom plates. However, reinforcing one element of the wall system may shift the weakest point to another location. A better understanding on the stress-stain development of sheathing panels, framing members and connections is needed to develop design details to prevent these undesirable brittle failures and increase the ductility and design resistance of wood shear walls with multiple rows of nails.

Numerical models of light wood frame shear walls have been developed with different methods in the past [4].

Different approaches were used to describe the monotonic and reversed-cyclic behavior of nail joints and shear walls in light wood frame buildings [5–8]. For shear wall models, framing members and sheathing panels are usually defined as elastic beam-type and shell-type element, respectively, while the sheathing-to-framing nail joints are represented by nonlinear link elements [9–12]. In a standard shear wall, the wall performance is mainly governed by sheathing-to-framing nail joints. The assumption of elastic behavior of framing members and sheathing panels, and pin connections between studs and plates, is usually acceptable. However, for high-capacity shear walls, in order to simulate the framing septation, wood splitting, sheathing rupture, etc. more realistic framing member connection performance and wood material damage should be considered in the model.

The objective of this study is to develop a detailed 3D shear wall model to predict the structural performance of high-capacity shear walls and simulate the failure modes including those that are not common in regular shear walls. The numerical models of high-capacity shear walls with three rows of nails were verified with the test results obtained in previous research by the authors [4]. Detailed wall components and boundary conditions were included in the model to regenerate the lateral behavior and failure modes of high-capacity shear walls tested in the lab. The modelling will provide insights for design and future testing of high-capacity shear walls.

2 EXPERIMENTAL STUDY

2.1 SHEAR WALL SPECIMEN AND TEST SETUP

There have been 30 high-capacity shear walls with two or three rows of nails along sheathing edges and reference walls tested in the past three years. Table 1 summarizes the details of the 22 shear walls tested in the first two years [3,4]. The wall details cover a combination of different sheathing panel thicknesses, nail sizes and nail spacings. For each configuration except the 9.5 mm panel thickness walls, a standard shear wall with one row of nails was also tested as reference. The shear wall specimens are 2.4 m × 2.4 m in dimension, constructed with 2 × 4 or 2 × 6 Douglas Fir dimension lumber, and vertically sheathed with 1.2 m × 2.4 m OSB panels on one side. Figure 1 shows the configuration of a shear wall specimen with three rows of nails.

Construction details and test set up of shear walls with three rows of nails are presented in this section as the numerical modelling described in this paper was based on shear walls with three rows of nails which are more prone to fail in the new failure modes.

The framing members were connected using F1667 NLCMMS69 (76.2 mm × 3.05 mm) power driven common nails. There were two rows of nails spaced at 200 mm on center for built-up end studs, built-up interior end studs, and top and bottom plates. For built-up center studs, three rows of nails (76.2 mm × 3.05 mm) spaced at 100 mm were used to prevent separation of center studs [4].

The shear wall specimens were fabricated and installed according to ASTM E2126 [13]. Figure 2 shows the schematic test set up. For all shear wall specimens, continuous 28.6 mm (1-1/8 in.) diameter tie-rods were used to resist overturning moment. 6 Hex A325 anchor bolts (22.2 mm in diameter) with steel bearing plates (127 mm in length × 127 mm in width × 6 mm in thickness) were used to connect both top and bottom plates to load spreader beam (C180 × 18) and foundation steel beam, respectively. Steel bearing plates (165 mm in length × 114 mm in width × 25 mm in thickness) were used to hold the tie-rod against the top plates (Fig. 2 B-B). The lateral load was applied through the steel load spreader beam to the top of the shear wall, as shown in Figure 2a. There was no vertical load applied on the wall specimens. Reversed cyclic loading was applied on tested specimens, following the CUREE protocol (method C) in ASTM E2126 [13].

Table 1: *Shear wall test configurations*

Wall #	OSB thickness (mm)	Nail size (mm)	Row of nails	Nail spacing along panel edges (mm)
1	9.5	63.5 × 3.33	2	100
2	9.5	63.5 × 3.33	2	75
3	11	63.5 × 3.33	3	100
4	11	63.5 × 3.33	3	75
4r	11	63.5 × 3.33	1	75
5	15	76 × 3.76	2	100
6	15	76 × 3.76	2	75
6r	15	76 × 3.76	1	75
7	15	76 × 3.76	3	100
8	15	76 × 3.76	3	75
8r	15	76 × 3.76	1	75

Note: "r" refers to regular shear walls with one row of nails along sheathing edges.

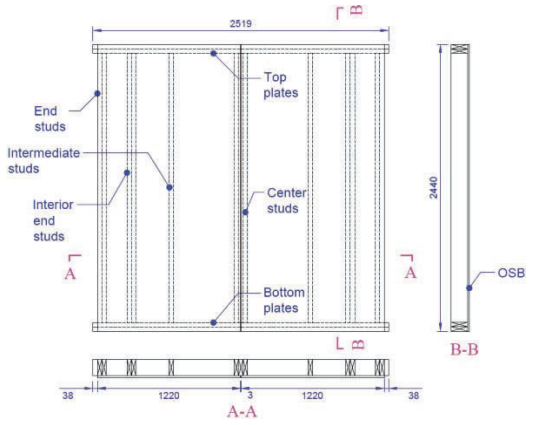

Figure 1*: Shear wall with three rows of nails [4] (Unit: mm)*

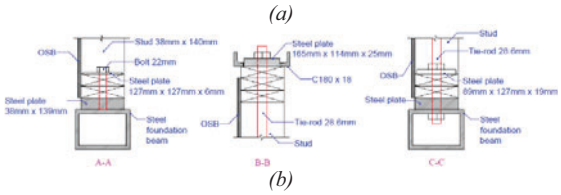

Figure 2: *Schematic of shear wall test set up: (a) front view, (b) cross section view [4]*

2.2 TEST RESULTS

Test results showed that shear walls with two rows of nails have approximately 2 times the lateral load resistance and energy dissipation capacity of a standard shear wall with the same sheathing thickness, nail diameter and nail spacing. According to seismic equivalency requirement in ASTMD7989 [14], a design value of 1.8 times standard shear walls can be assigned to shear walls with two rows of nails [3].

In general, shear walls with three rows of nails achieved approximately 3 times the lateral load resistance and energy dissipation capacity of a standard shear wall with the same sheathing thickness, nail diameter and nail spacing. However, a design value much less than three times of standard shear walls must be used to meet the ductility requirements. This is due to the undesirable failure modes which caused shear walls to lose resistance rapidly after the peak point [4].

Figure 3 shows the load-displacement response of walls with three rows of nails compared to a standard shear wall with one row of nails.

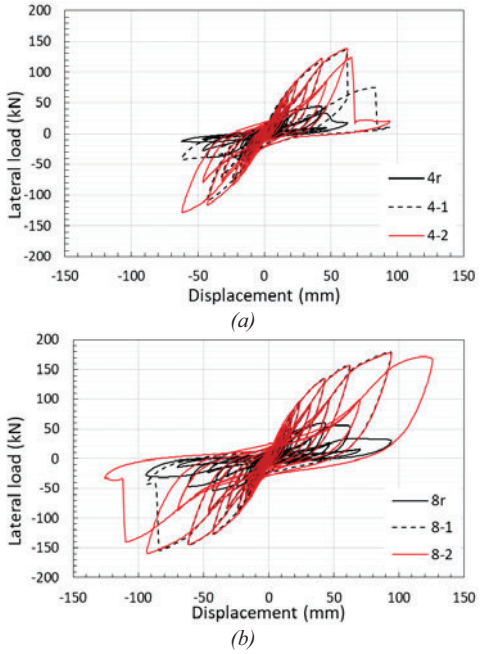

Figure 3: *Comparison of hysteresis loops of (a) Wall 4r, Wall 4-1, Wall 4-2, (b) Wall 8r, Wall 8-1, Wall 8-2*

2.3 FAILURE MODES

Besides common failure modes such as nail head pull through sheathing, nail chip-out from sheathing edge, nail withdrawal and fracture, other failure modes were also observed in the testing of high-capacity shear walls, including bottom plate splitting, end stud pull-out from bottom plates, center stud separation, and sheathing rupture.

In Wall 3 and Wall 4 (Table 1), bottom plates split due to a combination of factors (Figure 4 a), such as increased uplift force from three rows of nails, while the end of bottom plates was not restrained from uplifting. The splitting of bottom plates is brittle and undesired. This failure mode was prevented after installing bearing plates on bottom plates where tie-rods were located.

For most of the shear wall specimens with three rows of nails, end studs were separated from bottom plates (Figure 4 b), which led to the rupture of the sheathing panels in some cases (Figure 4 c). This is because the shear walls were only sheathed on one side which caused an out-of-plane moment on the end studs. This moment was amplified with increase of the number of rows of nails and using of 2 × 6 lumber compared to a 2 × 4 standard wall. The nails that connect bottom plates to end studs were not able to hold end studs and bottom plates together. The failure mode of end stud separation is brittle and need to be prevented.

Sheathing rupture was also observed in one of the shear walls (Figure 4 d). To prevent such failure, sheathing panels with higher thickness should be used.

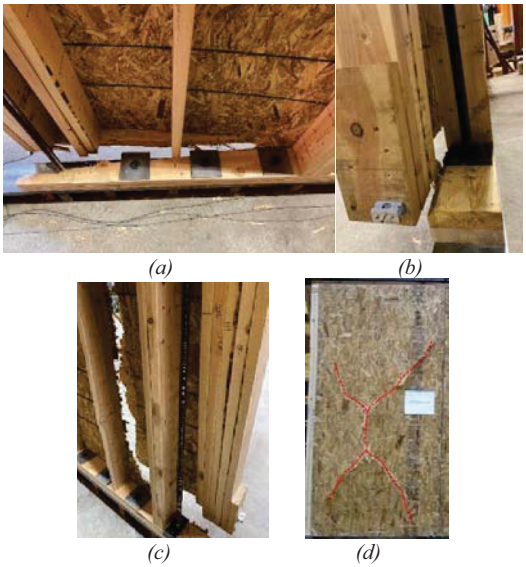

Figure 4: *Failure modes: (a) Splitting of bottom plates, (b) Separation of end studs, (c) Sheathing rupture due to end stud separation, (d) Sheathing rupture due to buckling and tension [4]*

2.4 NAIL JOINT TESTS

Nail joints made from the same materials (dimension lumber, OSB panels, and nails) as shear walls with two rows of nails were tested [3]. The test results were used in

https://doi.org/10.52202/069179-0360

the modelling of shear walls. Nail size of 63.5 mm × 3.33 mm and 76 mm × 3.76 mm were combined with sheathing thickness of 15 mm (Table 2). Figure 5 shows the test setup and configurations of the nail joint. The reversed cyclic loading protocol (CUREE) used for shear wall testing were adopted for nail joint testing, with half the displacement amplitude.

Table 2 shows the details of nail joint configurations and the average peak resistance of all replicates. It was found that the tested peak resistance of nail joints for both nail sizes is approximately 1.7 times the design value based on CSA O86 [15].

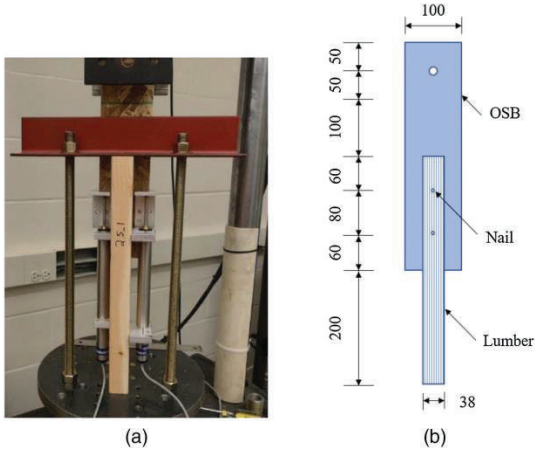

Figure 5: *Nail joint test: (a) Test set up, (b) Specimen dimension (mm) [3]*

Table 2: *Configuration and test results of the nail joints[3]*

Nail joint #	OSB thickness (mm)	Nail size (mm)	Peak resistance[1] (N)	Design resistance (N)
N2.5	15	63.5 × 3.33	1619	954
N3	15	76 × 3.76	1835	1105

1. The peak resistance is based on nail joint with one nail.

3 NUMERICAL MODELLING

Numerical models of the shear walls with three rows of nails were developed in ABAQUS. The sheathing-to-framing and framing-to-framing nail joints were simulated by a nonlinear fastener (link) element. The nail joint test data was used to derive the properties of fastener elements through fitting the load-displacement curve to the test curve. These properties of fasteners were then implemented in the shear wall models.

3.1 NAIL JOINT ELEMENT PROPERTIES

The tested nail joints with 15 mm sheathing thickness and 63.5 mm × 3.33 mm and 76.2 mm × 3.76 mm nails were modeled. The two nails connecting OSB panel and lumber were modelled using mesh independent fasteners. The fastener properties were derived from the average backbone curves and its corresponding EEEP parameters [13].

The fastener elements in ABAQUS were used to define a point-to-point connection between surfaces of OSB panel and lumber. An influence radius equal to the diameter of nail shank was used for each type of nails. A connector section was assigned to the fastener element, which allows behavior in three local directions. Elastic, plastic and damage behavior were assigned in the connector section. For elastic behavior, spring stiffness was assigned for each local direction. The average secant stiffness, *D*, derived from the tested nail joints was used, as shown in Table 3. Coupled plastic behavior with nonlinear isotropic hardening was defined using exponential law as shown in the following Equation (1):

$$F_0 = F|_0 + Q_{inf}\left(1 - e^{-b\bar{u}^{pl}}\right) \quad (1)$$

where F_0 is the yield surface size defined as the equivalent force in the connector, $F|_0$ is the yield force at zero plastic motion, Q_{inf} is the maximum change of yield surface, $\bar{u}^{pl}$ is the relative plastic motion, b is the rate of the change of the yield surface. The relative motion components are coupled in a quadratic form by defining the potential function [16]. Coupled damage behavior was also defined based on relative plastic motion, where linear softening was assumed.

The parameters for plastic and damage behavior were derived from the average backbone curve of the tests, as shown in Figure 6. Table 4 summarizes the properties of the fasteners, in which b is modified after back calculated from test data using Equation (1), plastic motion at failure was modified based on actual failure displacement to fit the test curve.

Monotonic push-over displacement was applied in the modeled nail joint. Load-displacement relationship of the models is compared with the average backbone curve of the tested nail joints, as shown in Figure 7. Overall, the parameters listed in Table 4 give a good fitting of the performance of the nail joints to the test data and can capture the post peak load-displacement behavior.

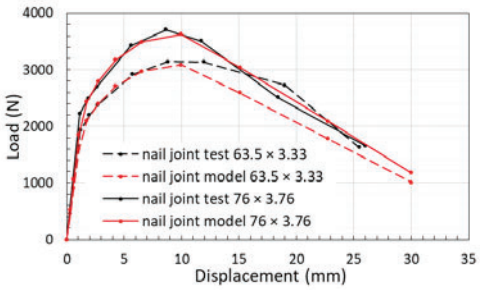

***Figure 7:**. Comparison of load displacement curves between nail joint tests and models*

3.2 SHEAR WALL MODEL

In the shear wall model, more details of the shear wall are included to simulate both the overall load displacement behavior and the possible new failure modes.

The framing members were represented with solid elements (C3D8R), and sheathings panels were modelled with continuum shell elements (CS8R). The framing members and sheathing were both assumed to be elastic. Table 3 summarizes the elastic properties of Douglas fir lumber and OSB panel. Sheathing-to-framing nails, nails for built-up studs and plates, nails connecting studs to plates were all represented by the fastener elements, in which both shear and withdrawal components were included. For sheathing-to-framing nails, properties are derived from nail joint fitting process (Table 3). Since properties in Table 3 refers to 15 mm sheathing thickness, a factor of 0.89 was used to adjust the resistance for 11 mm sheathing panel with combination of 63.5 mm × 3.33 mm nails based on the ratio of design resistance of these two different nail joints in O86-19 [15]. For nail joints in built-up studs and plates (76.2 mm × 3.05 mm), a factor of 0.98 was applied to the properties of 63.5 mm × 3.33 mm nail joint in Table 3. For nails connecting studs to top and bottom plates, an end grain factor of 0.67 was applied to the nail joints for built-up members to further reduce the resistance [15]. Table 5 and Table 6 shows the modified connector properties used for sheathing panels and framing nails.

***Table 4:** Material properties of nail joint model*

Material property	Douglas-Fir[1] (Mpa)	OSB[2] (Mpa)
E_1	11000	5323
E_2	748	3231
E_3	550	-
G_{12}	704	1574
G_{13}	758	1574
G_{23}	77	1574
μ_{12}	0.29	0.31
μ_{13}	0.45	-
μ_{23}	0.39	-

1. Properties of Douglas-Fir are obtained from O86 and Wood Handbook [15,17].
2. Properties of OSB are obtained from studies of Islam et al. [18].

***Table 5:** Properties of fastener elements used for sheathing-to-framing nails*

Connector property	Nail size (mm)	
	63.5 × 3.33	76 × 3.76
D_{11} (N/mm)	734.3	980.6
D_{22} (N/mm)	734.3	980.6
D_{33}[1] (N/mm)	9.6	10.6
$F\|_0$ (N)	856.1	1100.1
Q_{inf} (N)	539.4	743.1
b	0.4	0.4
Plastic motion at damage initiation (mm)	7.6	7.5
Plastic motion at failure (mm)	30	30

1. D_{33} is the nail withdrawal stiffness of sheathing-to-framing nails based on the local coordinate, which was assumed to be a small percentage of the lateral stiffness in this preliminary modeling with the assumption that the withdrawal resistance is limited after yielding of nails in shear and losing of friction from the surrounding wood when the nail is pulling out from studs.

***Table 6:** Properties of fastener element used in framing members*

Connector property	Nail type	
	Built-up member	Stud to plate
D_{11} (N/mm)	811.5	543.7
D_{22}[1] (N/mm)	811.5	543.7
D_{33} (N/mm)	811.5	543.7
$F\|_0$ (N)	946.0	633.8
Q_{inf} (N)	596.1	399.4
b	0.4	0.4
Plastic motion at damage initiation (mm)	7.6	7.6
Plastic motion at failure (mm)	30	30

1. D_{22} is the nail withdrawal stiffness of built-up members and stud-to-plate connections based on the local coordinates. No reduction of the lateral stiffness was used in this preliminary model.

Figure 8 shows a shear wall model. The assembly includes the shear wall panel, steel loading beam and foundation beam. The fastener elements were assigned for all built-up studs, top and bottom plates, stud-to-plates connections, and sheathing-to-framing connections. The top and bottom plates have pre-dill holes representing locations of anchor bolts and hold-downs (tie-rods). The hold-downs were represented by axial connector elements with a stiffness of 42.34 kN/mm [19], where the top of the hold-down element was coupled with the top plates over a surface area of the same size of the bearing plates. The bottom of the hold-down element was fixed at the foundation. The bottom plates were anchored to the foundation beam at the surfaces of the same size of bearing plates. The top plates and loading beam are simplified as tie constrained to eliminate slip between top plates and loading beam. A monotonic lateral displacement is applied through the loading beam. There's no out-of-plane degree of freedom allowed on the loading beam.

Overall, the model can predict the nonlinear behavior of

https://doi.org/10.52202/069179-0360

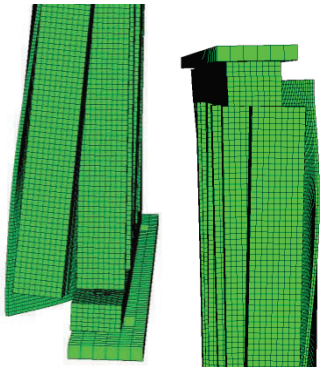
the shear wall including the post-peak load drop. The peak resistance of models and test results are compared in Table 7. It can be seen that the discrepancy of peak load is with 10% for most cases. In all shear walls with three rows of nails, namely Wall 3, Wall 4, Wall 7 and Wall 8, the stiffness of the models appears to be higher than the tested shear walls (Figure 9 a, b, d, e). In the reference shear walls, namely Wall 4r and Wall 8r, the models reach their peak load at a larger displacement than the tested walls, and the models do not have a significant load drop after peak load (Figure 9 c, f).

Table 7: *Comparison of the tested peak resistance and model peak resistance*

Wall #	Test P_{peak} (kN)	Model P_{peak} (kN)	Model peak/Test peak
3	91.5	103.5	1.1
4-1	114.1	125.5	1.1
4-2	133.7	125.5	0.9
4r	41.7	50.7	1.2
7-1	132.1	148.6	1.1
7-2	137.6	148.6	1.1
7-3	131.2	148.6	1.1
8-1	166.7	155.7	0.9
8-2	168.4	155.7	0.9
8r	57.2	65.7	1.1

In the shear wall models with three rows of nails, end stud separation from bottom plates was observed, as shown in Figure 10 a, which caused the load drop at the end of the load-displacement curves in Wall 4, Wall 7 and Wall 8. The end studs on the opposite side of the wall have also separated slightly from the top plates (Figure 10 b). The separation of end studs is due to the eccentric moment on end studs caused by sheathing only on one side of the wall and the relatively low resistance of fasteners connecting the end studs to the bottom and top plates, which are not strong enough to counteract the out-of-plane moment. The failure modes were also observed in shear wall tests. Separation of end stud from bottom and top plate can be prevented through reinforcing the stud-to-plate connections.

As framing members and sheathing panels were assumed to be linear elastic in this preliminary model to reduce convergence difficulty, the failure modes such as bottom plate splitting and sheathing rupture was not captured. Figure 11 shows the axil stress on framing elements. It can be seen that the compression stress was concentrated on end studs which indicates that the compression force due to over-turning moment is mainly resisted by the end studs. The contribution from the interior end studs (Figure 1) is limited. Therefore, when tie-rods are used in shear walls as hold-downs, the interior studs should neither be counted for resisting the compression force due to over-turning, nor the bearing area of the bottom plates. Figure 12 shows the principal stress distributed on the sheathing panels before end stud separation. It can be seen that the principal tensile and compressive stress developed on the sheathing panels are diagonal, which explains the failure in one of the Wall 4 replicates tested, in which 'X' shape fracture occurred in one of the sheathing panels (Figure 4 d).



(a) (b)

Figure 10: *Failure of the shear wall model (Wall 4): (a) End stud separation from bottom plates, (b) End stud separation from top plates*

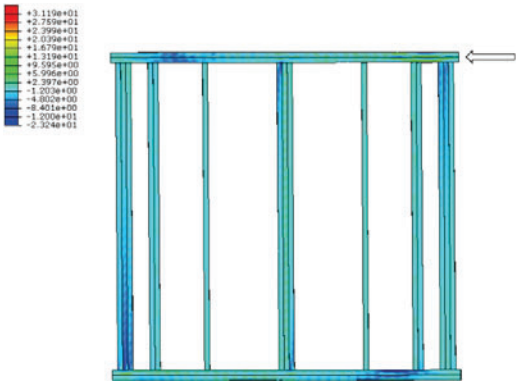


Figure 11: *Stress S11 along grain direction of framing members in Wall 4 model(MPa)*

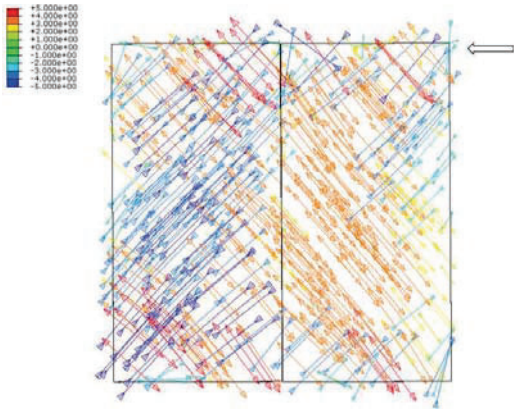

Figure 12: *Principal Tensile and compressive stress in sheathing panels of shear wall model (Wall 4) before end stud separation (MPa)*

Overall, the models can generally predict the load-displacement behavior and the end stud separation in walls with three rows of nails. With only fastener behavior assumed to be non-linear, the models are not able to predict material failure in sheathing panels and framing members. Although the stress distribution in sheathings showed potential cause for sheathing rupture, additional

wood damage definition is needed to simulate those failure modes.

3.3 ON-GOING WORKS

To better understand the split of bottom plate of shear walls with multiple rows of nails, a more detailed 3D sub-model of the shear wall is being developed only including the bottom plates and foundation beam. Steel anchor bolts and bearing plates are installed in the bottom plates. Nails and initial imperfections (cracks, checking) on wood will be added (Figure 13). The objective of this modeling is to capture the crack propagation parallel to grain under the one-sided shear force on the bottom plate. Moreover, more detailed material definition will be included in the shear wall model to capture the fracture of sheathing panel due to buckling or tension.

Figure 13: *Detailed sub-model of bottom plates*

4 CONCLUSIONS

In this study, high-capacity shear walls with multiple rows of nails were introduced and numerically simulated using ABAQUS. Test results of shear walls with two and three rows of nails were presented. The lateral load resistance is proportional to number of rows of nails. Failure modes that are not commonly observed in regular shear walls were found in shear walls with multiple rows of nails. To study the behavior of high-capacity shear walls, a preliminary 3D shear wall model with three rows of nails was developed. Fastener elements were used to simulate the non-linear behavior of nails, firstly, the properties for fastener elements were derived from the nail joint tests and through a fitting process. The fastener properties were then implemented in the shear wall models. In the shear wall model, all the framing-to-framing and framing-to-sheathing nails were represented by the non-linear fastener elements, while framing members and sheathing panels were assumed to be linear elastic. Components such as anchors, hold-downs, foundation beam and loading beam were also included. The main findings of the numerical modeling analysis are summarized as follows:

- The preliminary 3D model developed in this study can well capture the load-displacement performance of the high-capacity shear walls with multiple rows of nails, and predict the end-stud separation from the bottom plate.
- Failure on sheathing and framing members cannot be captured by the current preliminary model due to linear elastic material assumption.
- The principal stress developed on sheathing panels is diagonal, which explains the “X” shape fracture observed in one of the wall panels in the test.
- Compression force due to over-turning moment is mainly resisted by the end studs. The interior end studs should neither be counted for resisting this compression force in design, nor the bearing area of the bottom plates in a shear wall when tie-rods are used as hold-downs.

More detailed modelling and material damage definition need to be added to the current model to study the splitting of bottom plates, sheathing panel fracture, and other failure modes of high-capacity shear walls.

ACKNOWLEDGEMENT

This project is funded by Canadian Forest Service of Natural Resources Canada and Forestry Innovation Investment Ltd. in BC – Wood First Program. Donation of continuous threaded steel rods, coupler nuts and nuts by Simpson-Strong Tie, which have been used for tie-downs of the shear wall specimens, is greatly appreciated.

BUCKLING ANALYSES OF CROSS LAMINATED TIMBER PANELS

Martina Sciomenta[1], Yuri De Santis[2], Chiara Bedon[3], Massimo Fragiacomo[4]

ABSTRACT: This paper investigates the column buckling behaviour of three-layer Cross Laminated Timber (CLT) panels under compression, from both the experimental and numerical point of view. The main aim of present study is hence to define the expected load-bearing capacity for these composite CLT solutions, and to assess the typical fracture mechanism for two different series of specimens of possible technical interest for construction applications. To this aim, a total of 14 column buckling experiments is carried out. First, a set of 7 homogeneous specimens ("HO" series), which are entirely made of beech, are investigated. Their load-bearing capacity is compared with the column buckling performance of 7 hybrid specimens ("HB" series), whose inner layers are made of Corsican pine. Overall, the experimental analysis gives evidence of a rather stable column buckling capacity for CLT panels, with evidence of major failure mode due to out-of-plane bending phenomena, but also rolling shear and delamination. Finally, further assessment of experimental evidence is provided by extended analytical calculations (based on existing formulations, including the Eurocode 5 approach). Comparative results are discussed in terms of structural performance, capacity, weakness of analytical models for CLT solutions.

KEYWORDS: Cross-Laminated Timber (CLT), beech wood (Fagus sylvatica L.), Buckling, Experimental tests, Load-bearing capacity, Standards

1 INTRODUCTION

In the last years the Cross Laminated Timber (CLT) has become a widespread construction material in the framework of panel mid- and high-rise buildings [1]. The high prefabrication and the well-known advantages [2], such as the high dimensional stability, the elevated in-plane isotropic strength and stiffness with respect to sawn timber and the high speed of installation [3] contributed to spread their applicability, in addition with the great environmental benefits, in terms ot carbon absprtion and sustainability.

Several researches have been carried on to assess how and which parameters mainly influence the load-bearing capacity of this engineered wood product.

The results confirmed that the response of CLT is influenced by the lamellas' material and geometry, and in particular by: *i)* the layer thickness [4,5] ; *ii)* the wood species [6,7], and *iii)* the type of adhesive [8,9].

The choice of wood species is so relevant that different studies focused on this point even to emphasize the potential use of wood species other than fir and spruce [10,11,12] which are the most widespread used for commercial applications.

In this framework, native hardwoods species such as beech which is extensively available in European forests [13] proved to have relevant mechanical features for CLT structural applications [14]. Many researches have been also conducted to better understand the CLT behavior under different load conditions as bending [15], compression [16,17], and shear [18,19], nevertheless the CLT in-plane behavior under compressive loads, leading to column buckling is currently poorly investigated as for softwood [20,21] as for hardwood species.

For timber structural components and systems, stability issues have a critical role in design procedures, due to the challenging trend of modern applications towards the construction of high-rise timber buildings as well for the intrinsic material's nature.

In particular, due to the low modulus of elasticity parallel to the grain of timber in general and of the even lower shear modulus which affects the ortogonal layers, CLT is more prone to undergo instability phenomena.

CLT members, depending on the boundary conditions, can be addressed as: *i)* one-way elements if they are restrained on two opposite sides; or as *ii)* two-way elements if them are constrained on three or all sides.

Few studies that have addressed the buckling behavior of CLT members considered them as one-way elements [22]. Some researchers have been carried by performing experimental tests; [23] investigated the axial compression behavior of both cross-laminated timber columns (CLTCs) and control glued-laminated timber columns (GLTCs). It was discovered that CLT column specimens had better ductility and energy absorption. [24] carried on tests on Chilean radiata pine CLT panel, focalizing on the variation of the number of layers while keeping the panel thickness constant. At last, the test

evidences were compared with the numerical predictions and successfully validated.

Kudo *et al*. [25] conducted a series of buckling tests on full-size Japanese Cedar or Japanese Cypress CLT members. The buckling loads were compared with those calculated following the formulas of the Japanese Building Code; it was found that the formulas given in the national standard provided conservative results.

The worldwide standards (i.e. Eurocode 5 [26]) and national codes available for the calculation methods of the buckling capacity (or the stability coefficient) of axially loaded CLT members are only applicable to one-way CLT members.

The currend handbook/standards provide two methods for the calculation of the load-bearing capacity of axially compressed columns with and without eccentricity; the most simple one is based on the Effective Length Method (ELM), while, the other accounts for a 2nd order analysis of the structure. This latter, by the way, considers timber as an elastic material so, is not able to take into account its material non-linearity. The ELM assumes a simple equivalent column hinged at both ends. The simplicity of the approach is that the P-delta effect is taken implicitly into account through a buckling factor, k_c. The buckling factor has the role to reduce the compressive strength of the timber column, in the direction parallel to the grain, and strictly depends on the effective length of the structural element, which is conventionally expressed in terms of slenderness ratio λ.

2 EXPERIMENTAL TESTS

The herein reported buckling tests are part of a wider experimental campaign [27,28] performed at the Laboratory of Structures, Tests and Materials of the University of L'Aquila (Italy), aiming to investigate the possible structural applications of two of the most interesting Italian broad-leaved and conifer timber species, namely beech and Corsican pine [14].

The raw material for both species came from Calabrian forests – South Italy. A list of different preliminary steps was carried out to obtaining the final composition of investigated CLT specimens. Boards were at first strength graded according to EN 14081-2:2018 rules [29] by the grading machine ViSCAN-Portable (Mi-CROTEC). The machine settings used for the strength grading of the boards of both beech and pine were developed in previous studies [30,31,32]. The strength class combinations used to qualify the raw material were D40 and rejects for beech and C20 and rejects for pine (EN 338:2016 [33]). The outcomes are summarized in Table 1. Boards were planed to a thickness of 18 mm to guarantee the adequate planar surface necessary for the face gluing. Two different series of three-layer CLT panels, made respectively of beech and Corsican pine and only beech, were realized by bonding the boards and gluing them with a Melamine Urea Formaldehyde (MUF) adhesive (GripProTM Design – AkzoNobel). The narrow board edges were not bonded. The average of glue grammage was 190 g/m^2. The adhesive was applied in a factory condition of 17° C, with an environmental moisture of 50%. Formed panels were then cold-pressed for two hours, with a pressure of 1.4 N/mm^2.

Table 1: *Mean properties of timber species, as derived from the non-destructive measurements [14].*

Timber species	ρ (kg/m^3)	MOE_{dyn} (N/mm^2)	MoR (N/mm^2)	MOE_{global} (N/mm^2)
Beech	756	16077	80.1	16154
Corsican Pine	512	9650	38.2	9748

Seven specimens for each series were tested under central axial compression loading conditions.

The specimens' geometrical features are characterized by nominal dimensions equal to b=144 mm, t=54 mm and l=800 mm. The three constituent layers had identical nominal thickness t_i = 18 mm.

The buckling tests were carried out by applying a central axial compression on the top surface of the CLT specimens for an average duration of 30 minutes. This condition was pledged by a setup able to provide the desired loading and boundary conditions to the tested CLT beams (Fig. 1).

Each specimen was positioned between a couple of one-way knife hinges whose shape has been designed to ensure the right positioning in the underlying and overlying wedges. The distance between the axes of end hinges was set equal to L=1064 mm.

The horizontal displacements in the loading stage were measured by using four laser displacement transducers, which were placed perpendicularly to the lateral surfaces of each specimen (Fig. 1). In particular, two transducers were located at the midpoint and two near the corners, to account for possible torsional phenomena (Fig.1). Displacement-control tests with a limit of 15 mm to the vertical lowering of the machine crossbeam were carried out by means of an Instron-Schenck machine system. Load vs. mid-span deflections of each beam specimen was monitored and plotted with a sampling rate of 0.5 Hz. Two different speed rates were taken into account during each experiment. At first, until the critical load was reached for each sample, was set equal to 0.44 mm/s. Once the critical load was reached, the speed rate was then reduced to 0.33 mm/s.

Figure 1: *Experimental tests setup*

The experimental evidences related to buckling test are summarized in Table 2 and Table 3. For most of tested HO and HB samples, the typical failure mode was characterized by out-of-plane bending deflection due to buckling (all the HO specimens except for the HO-6 and HB-1). Nevertheless, rolling shear (HB-2, HB-3 and HB-5) and delamination phenomena (HB-6 and HB-7) occurred in a certain stage of the tests, especially for HB specimens. Typical failure mode outcomes are summarized in Fig. 2.

3 BUCKLING FORMULATIONS

In a typical column buckling analysis, two key aspects should be considered, namely: *i)* a geometric effect called P-delta, which describes the non-linear increasing of deformations due to the increasing eccentricity of the axial load, and *ii)* the non-linear behaviour of timber material under compression actions parallel to the grain. A large investigation on the P-Delta effect on axial compressed timber elements was carried on by Tetmajer *et al* [34] and confirmed by test campaign by Larsen and Pedersen [35], the influence of non-linearity of timber on the interaction between moment and axial force was numerically defined by Buchanan [36].

In this section, a comparison of commonly used analytical formulas for the critical buckling load evaluation was provided. At first, the Euler formulation for column buckling is defined; at a second stage, it is extended in order to account for a possible initial geometric curvature. Thereafter, the existing Eurocode 5 formulation for timber columns subjected to combined bending and axial compression parallel to the grain is discussed.

The buckling strength of CLT specimens under in-plane vertical compression could be provided by classical analytical formulations of axially compressed, monolithic columns [37]. The corresponding Eulerian critical load could be reasonably estimated as:

$$P_e = \frac{\pi^2 E I_{\text{ef}}}{l_0^2} \tag{1}$$

with:

https://doi.org/10.52202/069179-0361

$$I_{\text{ef}} = \frac{bt_i^2}{12} + (bt_i) \cdot \left(\frac{t_i}{2}\right)^2 \quad (2)$$

The flexural moment of inertia, for outer layers and for the inner layer; and

$$l_0 = \beta L \quad (3)$$

with l_0 the effective buckling length.
In Eq.(3), L is the maximum distance between the hinges center, while β is the buckling coefficient accounting for the actual restraint conditions, in this study it was set equal to 1 for pinned-pinned specimens.
The latter Eq. (1) describes the behaviour of an ideal compressed beam (Eulerian instability), without taking into account the material non-linearity as well the possible geometrical clearances caused by production tolerances that lead to an inevitable rectilinear imperfection, which must be taken into account when calculating the buckling load. To take into account this phenomenon, the initial specimen deflection must be considered. A stability analysis of the beam in its deformed configuration was carried out.
The initial deformation is schematized as in Fig. 4, by imposing a sinusoidal deformation where represents its maximum amplitude:

$$\tilde{v}(x) = e_0 \, sin\left(\frac{\pi \cdot x}{L}\right) \quad (4)$$

The elastic displacement behaviour can be hence modelled as:

$$Pv(x) = -EI_{\text{ef}}\left(v''(x) - \tilde{v}''(x)\right) \quad (5)$$

which can be rewritten as:

$$v''(x) + \alpha^2 v(x) - \tilde{v}''(x) = 0 \quad (6)$$

Where
Replacing Eq. (4) and (1) in Eq. (6) and solving, the solution of differential equilibrium equation is:

$$v(x) = e_0 \frac{1}{1 - \frac{PL^2}{\pi^2 EI_{\text{ef}}}} sin\left(\frac{\pi x}{L}\right) = e_0 \frac{1}{1 - \frac{P}{P_e}} sin\left(\frac{\pi x}{L}\right) \quad (7)$$

Its maximum displacement is reached in the middle point of the beam:

$$v\left(\frac{L}{2}\right) = e_0 \frac{1}{1 - \frac{P}{P_e}} \quad (8)$$

The limit load can be written as

$$P = \left(\frac{\alpha L}{\pi}\right)^2 P_e \quad (9)$$

3.1 EUROCODE 5

Based on the Eurocode 5 [26] approach, the buckling verification of timber columns subjected to combined bending and axial compression parallel to the grain is performed by taking into account its minimum relative slenderness ratio:

$$\lambda_{\text{rel}} = \frac{\lambda}{\pi} \sqrt{\frac{f_{c,0,k}}{E_{0,05}}} \quad (10)$$

with

$$\lambda = \frac{l_0}{\rho_{min} \sqrt{\frac{A}{I_{\text{min}}}}} \quad (11)$$

with A the cross-sectional area, $f_{c,0,k}$ is the characteristic compressive strength parallel to the grain, $E_{0.05}$ represents the fifth percentile value of the MOE parallel to the grain, β=1 is the factor for buckling depending on the support conditions and the load, L is the element length. The stability check of the member in pure compression requires that the design compressive stress $\sigma_{c,0,d}$ along the member would satisfy the condition:

$$\sigma_{\text{c,0,d}} \leq k_c \cdot f_{\text{c,0,d}} \quad (12)$$

where $f_{c,0,d}$ represents the design compressive strength in the direction parallel to the grain and k_c is a buckling reduction factor given by:

$$k_c = \frac{1}{k + \sqrt{k^2 - \lambda_{\text{rel}}}} \quad (13)$$

With:

$$k = 0.5(1 + \beta_c(\lambda_{\text{rel}} - 0.3) + \lambda_{\text{rel}}^2) \quad (14)$$

βc an imperfection factor equals to 0.2 or 0.1 for solid timber or glued laminated timber and LVL, respectively, while the coefficient $\beta_0 = 0.3$ in Eq. (14) finally, represents the minimum relative slenderness ratio λ_{rel} beyond which flexural buckling phenomena may occur in the column.

3.2 CANADIAN CLT HANDBOOK

According to the Canadian standard [38], when CLT panels are loaded under in-plane axial loads, only the layers with laminations oriented parallel to the applied axial load should be assumed to carry that load.
The compressive resistance is calculated as:

$$F_{\text{b}} = 0.8K_C K_{Zc} f_{c,0,d} A_{eff} \quad (15)$$

Where A_{eff} is the effective cross-sectional area of the panel accounting only for the layers with laminations oriented parallel to the axial load, K_C is the slenderness factor for compression members:

$$K_C = \left(1 + \frac{f_{c,0,d} K_{Zc} C_c^3}{35E}\right)^{-1} \quad (16)$$

Where E is the modulus of elasticity of the laminations oriented parallel to the axial load, K_{Zc} is the size factor for compression:

$$K_{Z,c} = \min(6.3\left(2\sqrt{3} r_{eff} l\right)^{-0.13}; 1.3) \quad (17)$$

Where r_{eff} is the radius of gyration accounting only for the layers with laminations oriented parallel to the axial load. C_c is the slenderness ratio:

$$C_c = \min(\frac{l}{\sqrt{12} r_{eff}}; 43) \quad (18)$$

3.3 CLT HANDBOOK U.S. EDITION

According to the U.S Edition of CLT handbook [39], for wall design, the failure load is given by the product of the adjusted compression strength for buckling times the area of the laminations where the grain is running parallel to the load.

$$F_{\text{b}} = C_p f_{c,0,d} A_{eff} \quad (19)$$

Where the column stability reduction factor is:

$$C_p = \frac{1 + \text{P}_{\text{cE}}/\text{P}_{\text{c}}^*}{1.8} - \sqrt{\left(\frac{1 + \text{P}_{\text{cE}}/\text{P}_{\text{c}}^*}{1.8}\right)^2 - \frac{\text{P}_{\text{cE}}/\text{P}_{\text{c}}^*}{1.8}} \quad (20)$$

Where P_{c}^* is the composite compression capacity and:

$$\text{P}_{\text{cE}} = \frac{\pi^2 E I_{app-min}}{l^2} \quad (21)$$

The minimum value of the apparent stiffness is to be determined as:

$$EI_{app-min} = 0.5184 EI_{app} \quad (22)$$

EI_{app} is a reduced effective bending stiffness to account for shear deformation.

4 COMPARISON WITH EXPERIMENTAL RESULTS

Table 2 summarize the average experimental loads and the predicted loads by means of standards formulations. The closest prediction is given by the Eurocode 5 formulation. It is worth noting that Canadian standard predict the same failure load for both homogenous and hybrid configurations. The Canadian standard completely neglect the mechanical properties of the layers perpendicular to the load. In the American standard the influence of the mid-layer is accounted only in the apparent stiffness calculation, while the effective area refers only to layers parallel to the load. The American standard predictions for the two cases are close together.

Table 2: *Comparison between experimental failure loads and predicted loads via standards formulations (HO= homogeneous; HB= hybrid).*

		F_b (kN)	F_b/N_c	Scatter (%)

	Eurocode 5	194	0.93	1.0
	Canad.Handb	176	0.88	-8.5
	U.S. Handb.	157	0.78	-18.5

5 CONCLUSIONS

Among others, stability issues are particularly critical in timber load-bearing components, due to their intrinsic anisotropy and to the increasing trend towards challenging high-rise timber buildings. As such, this possible vulnerability is even more pronounced for Cross Laminated Timber (CLT) components, due to their intrinsic composition and layout.
In this paper, a major attention was given to the column buckling behaviour of three-layer CLT panels. Technical advantage for the assessment of load-bearing capacity, failure mode and potentials was based on a set of experimental tests and also analytical models. Two different configurations were considered, the first (HO) composed of three layers made with the same timber specie, whereas the second was assembled with the inner layer made of a different timber specie (HB). Overall, the tested panels (14 in total) showed different failure mechanisms but little scattered results in terms of load-bearing capacity. Specifically, the hybrid (HB) specimens resulted in standard deviation.
In terms of analytical estimation of actual CLT capacities in column buckling setup, the attention was given to existing analytical models of literature, including the existing Eurocode and Handbook formulations.

https://doi.org/10.52202/069179-0361

Most importantly, the results provided by the analytical formulation, even though very close to the experimental ones, resulted always in favour of safety, since the analytical limit loads were found smaller than those obtained experimentally.

CONNECTIONS TESTING AND RELIABILITY ASSESSMENT OF TIMBER CONNECTIONS WITH DOWEL-TYPE FASTENERS.

E. Moreno-Zapata[1], B. Iraola[2], R. Quinteros-Mayne[3], I. de Arteaga[4], P. Tanner[5], C. Lara[6], J.M. Cabrero[7]

ABSTRACT: The accurate description of the structural behaviour of structural timber connections is still an open issue, which poses many unresolved challenges. The REACT research project engages in developing a reliable framework for the design of structural timber connections. Based on an extensive experimental campaign and novel multi-scale models, it will provide a sound reliability assessment of timber connections. This knowledge will stem from a multilevel analysis, ranging from the material up to the connection level, with a special focus on the interaction of timber with dowel-type fasteners.

As a major contribution, the project will deliver information for design practice, allowing to make use of the obtained knowledge in a simple yet efficient way.

KEYWORDS: Timber structures, Structural connections, Experimental tests, FEM, Multi-scale modelling, Computational mechanics, MonteCarlo Analysis

1 INTRODUCTION

Although timber is one of the oldest construction materials known to man, the scientific knowledge about its material behaviour is often surprisingly poor. Due to its orthotropic material structure, growth irregularities, and hundreds of different species, wood, as a natural material, is one of the most complex building materials.

The required development of appropriate design rules for current tall buildings poses a challenge to satisfy the required design criteria (e.g., vibrations, creep, avoidance of brittle failure modes, robustness) [1]. Furthermore, many unresolved challenges hinder the designer from obtaining a realistic prediction of the actual performance and reliability of structural timber connections.

Though Finite Element Models are the main technique to simulate timber structural behaviour, the required material models for comprehensive modelling of timber response are not yet fully developed, and moreover, offer high accuracy at the expense of high computational costs. Many different approaches have been developed by several researchers [8,12-14,19,20,33,34]. Among others, the main challenging points in timber structures simulation are high variability in material properties, presence of random singularities such as knots, complex microscopical structure with fibres and layers, surface finish and influence on contact behaviour, different behaviour in tension and compression; different failure mechanisms (brittle and ductile) for different orientations and loadings.

There are strong economic and safety reasons for developing a reliability assessment of the design framework of structural timber connections, which explicitly takes into account the interaction between components, and predicts the associated failure mechanism [2].

The REACT project, *Towards a Reliable and Efficient Analysis of Connections in Timber: material and interaction testing, and numerical modelling*, financed by the Spanish Ministry of Science and Innovation, and conducted in collaboration between the Onesta Wood Chair at the University of Navarra and researchers from the Institute for Construction Science Eduardo Torroja, aims at providing a new insight into the response and modelling of structural timber connection with dowel type fasteners. The following sections describe the proposed multiscale approach, which is explained in Figure 1 as well.

2 PROJECT TOPICS

The research project has the following objectives:

- Provide a multi-scale understanding of timber connections, from the material (micro-level) to the connection level (macro-level), with a

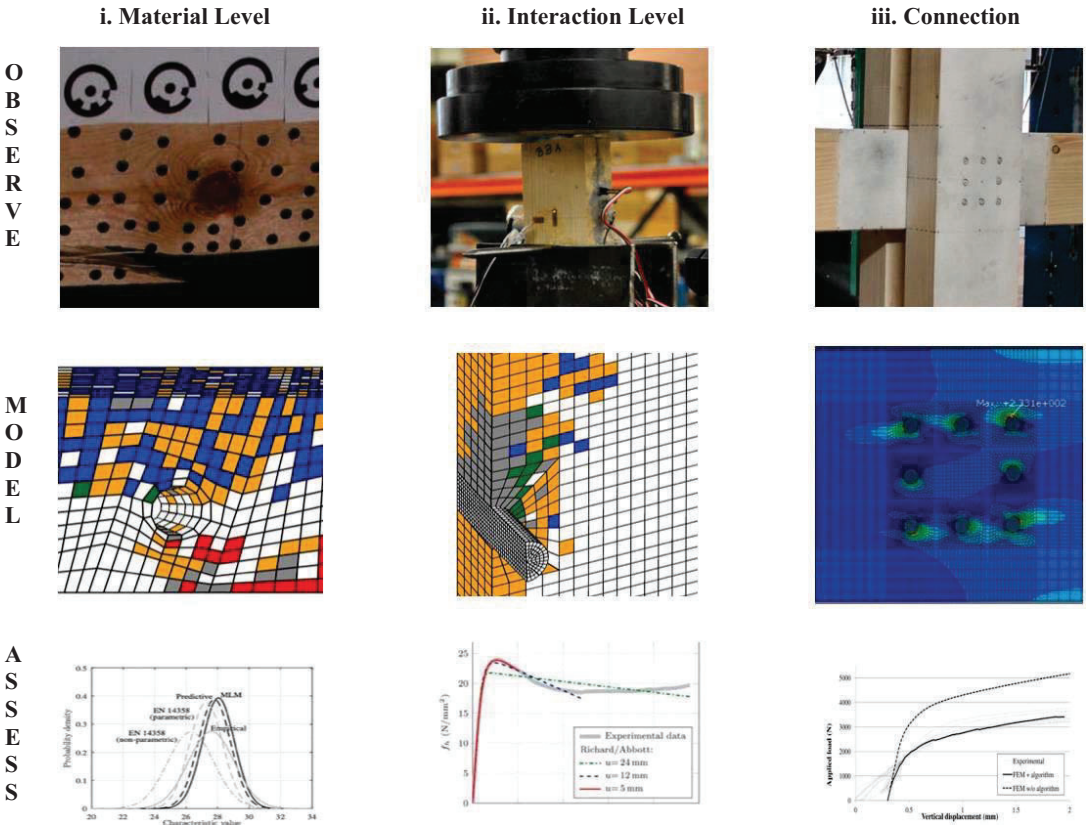

Figure 1: *Levels of analysis and related activities and results for each aim: tests, models and obtained results from the assessment. [10,17-20,31]*

particular focus on the interaction with the fasteners.

- Characterize more comprehensively the structural response of timber connections (stiffness, capacity and ductility) when submitted to realistic loads (i.e., different levels of interaction of forces, bending moment and shear and axial interaction…), with an emphasis of the capacity and type of failure.
- Develop three-dimensional models of structural timber connections based on a multi-scale modelling approach based on FEM, incorporating timber fracture.
- Assess the reliability of design models for timber connections.
- Deliver practical developments for the structural analysis and design of timber connections: verify and propose design models and criteria (i.e., overstrength) to ensure the ductile failure of the connection, an interaction criteria for the different types of loads and directions, an adequate design concept of the connection.

To accomplish these objectives, the project focuses on three different levels: material, interaction, and connection as a whole, and makes use of experimental tests, numerical finite elements modelling, and analytical models. The following sections describe the different topics.

2.1 OBSERVE THE BEHAVIOUR

A solid experimental foundation on which further theoretical and numerical developments can be built and validated is of course a preliminary and strong requirement. The experimental work plan is structured in the different levels to progressively apprehend the involved parameters and the complexity of the system. It is focus on products (solid wood and glulam) made of a representative species for softwood (spruce, Picea Abies), and two types of fasteners (dowels and self-taping screws). For each configuration, several replicates are testing to get statistically relevant distributions and properties. Such detailed results will be later used for different aims within the project, i.e., to validate the models for each level in detail, to provide material properties and their statistical distribution.

Additionally, to the traditional parallel and perpendicular loading testing, testing in intermediate angles (off-axis tests) are performed. Since parallel and perpendicular failure modes are different (i.e., plug-shear failure for the parallel tension loading and splitting for the perpendicular tension), the interaction at different angles and different connectors configurations needs to be studied. Figure 2 shows a depiction of the type connections to be tested. The

https://doi.org/10.52202/069179-0362

project challenges the current test setups by developing a new test philosophy, based on the available DIC techniques [21, 22] and off-axis tests to get new knowledge into timber response.

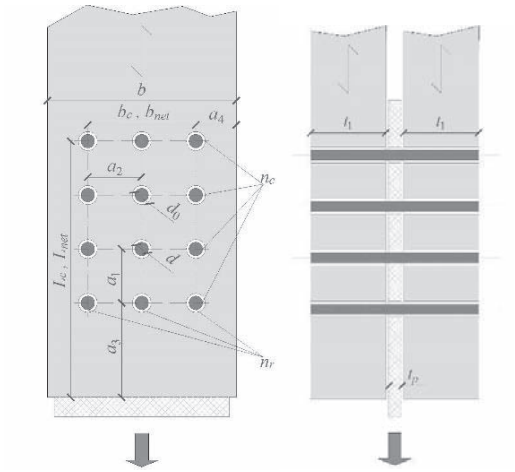

Figure 2: *Representative depiction of the types of connections to be tested with slotted-in-plates and dowel-type fasteners [9]: front (left) and side (right) views.*

2.1.1 Material tests

The experimental campaign at this comprehension level focuses on the mechanical response of timber. Samples with different anatomical features (with defects, i.e., knots, finger-joints) are tested instead of the classical approach of testing clear wood specimens (with no defects).

Material properties will be obtained using the current standard procedures [23], and by a novel experimental procedure, based on off-axis tests (as those depicted in Figure 3) and the use of DIC techniques [21,22]. The tests will provide the characterization of the different required material parameters (classical tests provide strength parameters and not actual material properties [3]), their variance, and correlation, as required for the reliability analysis. Non-destructive techniques (i.e., ultrasound) will be additionally used at each piece, to have an additional source of information, and a way to assess how to indirectly obtain material properties.

This level will give us a comprehensive description of the behaviour of the material, its fracture behaviour, the coupling among the different material orientations, their statistical properties, as well as the influence of the different anatomical defects.

2.1.2 Interaction test

This level will deal with the interaction of timber with a single dowel-type fastener, conceived as a system property [24]. Existing test standards will be again challenged. Two main configuration types, at different load and fastener angles to the grain, related to the distinct roles of the fasteners are developed: load transfer through contact between fasteners and timber by the standard [25] and novel off-axis [26] embedment tests; and the application of reinforcement by performing off-axis tests of reinforced timber. The versatility of the novel approach and the detailed description obtained employing the DIC will provide an improved understanding of the occurring phenomena.

The following phenomena are expected to be understood in more detail: rope effect, friction, clamping, residual stress around the fastener, the influence of load-to-grain angle, predrilling, and possible execution tolerances. The different required properties of the fasteners (i.e., withdrawal strength, head pull-through capacity) will be tested employing standard procedures [25,27-32].

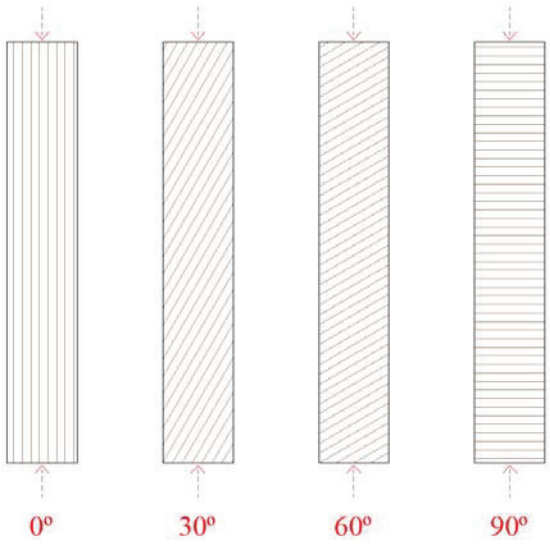

Figure 3: *Off-axis tests for the material level. Depicted, the concept for compression tests.*

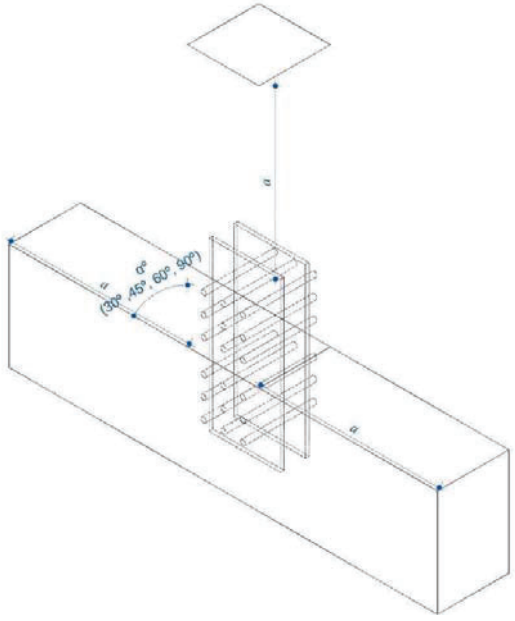

Figure 4: *Main concept and scheme for the tests of the structural connections, with a varying angle between members.*

This study will give us a new comprehension of the complexity of the stress field around dowel-type fasteners, the resulting stress field, and the related failure process.

2.1.3 Connection tests

Reinforced and unreinforced connections with different geometrical parameters and load orientation will be tested. While most available experimental studies focus on parallel tension loading [31,32], we will pursue load application setups to achieve complex and realistic load patterns, in which bending, shear, and axial interaction are present, to provide an understanding of the existing interaction, related to those observed in the previous levels. Figure 4 shows a depiction of the proposed test specimens.

A detailed description of the actual geometry after assembling the specimen will be obtained, which will provide a reliable source to quantify the execution defects before testing (i.e., misalignment, straightness of fasteners, actual positioning). These measurements will provide a database for its additional use for the uncertainty of execution in the reliability analysis.

The actual material properties of both timber and fasteners employed in the connections tests will be obtained after the tests, to reduce the uncertainties in the performed tests. To that purpose, pieces of the undamaged material will be extracted after testing and will be performed the corresponding material tests.

This study will give us a new perspective on the behaviour of connections. Based on the previous levels, which provide the influence of anatomical features and the interaction with the fasteners, here an understanding of the interaction of these different mechanisms altogether and their influence on the global response will be reached.

2.2 MODEL THE RESPONSE

This topic will develop an efficient FEM modelling framework of the connection, aiming at two different types of Finite Element Models. Within this work package, first, a usual (in research practice) three-dimensional FEM models for comprehensive modelling of the full response of the connections will be developed. ABAQUS will be used as the main platform [11,16,18,19], which will serve as the basis of the developments within this aim.

Subroutines for the material and the interaction levels within the FEM platform will be developed in two iterative steps: the first-generation models will serve as a validation of the techniques applied at each level and will be based on usual 3D models with solid (hexahedral) elements, in which the material and interaction levels will be implemented within user-defined routines into the commercial FEM code Abaqus via the different available interfaces, i.e. UMAT, UINT.

However, these 3D models are cost-intensive, not appropriate for practice. Carrying out reliability analysis based on them would be unfeasible. Therefore, to reduce the computational time, second-generation multi-scale models will be developed. These models, though simple, will be able to incorporate the material fracture, so they provide comprehensive modelling of the behaviour of timber connections at a reduced computational cost. These models will be used for the development of the required dataset for the subsequent reliability analysis. To that extent, realistic properties, mostly based on the obtained dataset from the experimental set and analysed in the following Aim, will be fed into the model. Moreover, these models, may provide a simple and reliable way to model connections in future practice.

To obtain the interaction and linking between the different models and ABAQUS, and the required parameterization for the stochastic models, a framework with the additional use of MatLab, Python, and C++ will be developed.

2.2.1 Material model

The main focus of this level is the modelling of the timber failure response, defined by the onset of failure, based on appropriate failure criteria for timber [33,34], and the following behaviour, either ductile or brittle, for the different stress combinations, and the different anatomical features.

Three-dimensional models reproducing the tests at this level consisting of simple geometries will be used to validate the developed material model. It will allow to develop appropriate modelling techniques for the material, and to incorporate in a realistic way timber defects, such as knots and grain deviation.

An appropriate homogenization technique will be developed, i.e., by adequate mixture rules to assign anatomical features and their corresponding properties to each element or representative volume element [15] to derive a product model for its use at higher levels. The developed script will provide realistic modelling of the material behaviour of timber products.

2.2.2 Interaction model

This level aims at developing an efficient technique for the modelling of load transfer through direct contact and reinforcement by embedment of fasteners into the timber. This model's developments will already take advantage of the previous material model since it is needed to reproduce the timber response. These models will be validated against the experimental tests.

2.2.3 Connection model

In the FEM it is crucial to appropriately define the coupling conditions for the different components. A full and detailed description of the connections' response (i.e., full non-linear load-slip behaviour, ultimate displacement, failure type…), and the resulting stress fields and interactions among the constitutive components will be obtained. These models will be validated against the existing tests.

https://doi.org/10.52202/069179-0362

2.2.4 Multiscale model

A multiscale model will be developed based on previous achievements. The proposal will be based on previous developments. Mainly based on the Beam on Elastic Foundation [8,37-39]. Such models, which make use of connector, beam and shell elements, reduce the computational cost to a fraction (results in the order of minutes), in comparison to the 3D models used in the previous parts. The multiscale model will incorporate fracture behaviour of timber, allowing for the first time for a full multiscale model of timber connections incorporating all the required parameters.

2.3 ASSESS THE RELIABILITY

This topic will develop a framework for the reliability assessment of timber connections, based on the dataset derived from the previously developed multiscale FEM models and the connection tests. The performed analyses will include material, execution, and geometric parameters as stochastic variables, based on the probabilistic properties derived in Section 2.1 and databases from the literature [40]. The developed framework in Section 2.2 will serve to calibrate existing and newly proposed design models to achieve the required level of calibration required for the relevant design situations. For this purpose, the uncertainties associated with such models must be quantified, which constitutes a crucial step to provide safe and efficient use of timber structures.

Load carrying capacity models should be calibrated to achieve the level of reliability required for the relevant design situations. For this purpose, the uncertainties associated with such models must be quantified, which is typically done by adjusting the model based on a best-fit criterion and by comparing the model outcome to the results of measurements and experimental tests. The degree of uncertainty of the model may be described in terms of the bias and the coefficient of variation that result from such comparisons. Additional conditions, such as measurement errors and statistical uncertainties due to a limited data set, real structure-specific conditions and scale effects should also be taken into account if required. Moreover, uncertainties describing random effects that are neglected in a resistance model and simplifications in the mathematical relationships on which it is based should be additionally incorporated.

For the calculation of the design value of the resistance, the Eurocode [41] makes a distinction between a partial factor associated with the uncertainty of the resistance model, γ_{Rd}, and a partial factor for material properties, γ_m. Depending on the type of structure considered, the partial factor γ_{Rd} may cover uncertainties in the resistance model; the bias in the resistance model, when relevant; and geometric deviations, if these are not modelled explicitly.

For certain types of structure, γ_{Rd} and γ_m may be combined into a single partial material factor, γ_M, and applied to material properties. Similarly, when applying partial factors to resistance for certain types of structure, γ_{Rd} and γ_m may be combined into a single partial resistance factor, γ_R.

The statistical determination and calibration of resistance models based on tests must consider the statistical uncertainty due to a limited number of results. To overcome such problems, the research project will involve the use of numerical models to complement the available test results. The model uncertainty should be treated as a random variable, and this research proposal will do so. In this context, it should be noted that if advanced models are used to calibrate simplified engineering models, then model and statistical uncertainties are present on both levels and should be taken into account simultaneously.

2.3.1 Dataset description

A detailed analysis of the test results from the experimental tests (see Section 2.1) will be performed, adequate for the assessment procedure to obtain the adequate statistical description, and analysis of the obtained results, assuming the appropriate distribution function for its uncertainty and variability. Probabilistic models for uncertain resistance characteristics may in principle be formulated at any level of approximation within the range of a purely scientific mathematical description of the physical phenomena governing the problem at hand (micro-level) and a purely empirical description based on observations and tests (macro-level).

In engineering analysis, the physical modelling is, however, normally performed at an intermediate level sometimes referred to as the meso-level. Reliability analysis will, therefore, in general, be based on a physical understanding of the problem but due to various simplifications and approximations, it will always to some extent be empirical. This essentially means that if experimental results are compared to predictions obtained through physical modelling, omitting some effect, then there will be a lack of fit. The lack of fit introduces a so-called model of uncertainty, which is associated with the level of approximation applied in the physical formulation of the problem.

It is important that the model uncertainty is fully appreciated and taken into account in the uncertainty modelling. This will be done in the project, following the principles established in the JCSS Probabilistic Model Code [40].

2.3.2 Montecarlo analysis

A Montecarlo analysis will be developed at the connections' level, including stochastic variables with values derived from the measurements within the experimental campaign. It is envisaged to also include the execution tolerances, taken from existing execution standards. The developed framework will provide a detailed insight into the response and reliability of timber connections, which is needed in current practice. It will provide an answer into problems such as overstrength, ductility, and type of failure, by giving special attention to estimating the proportion of different connection failure types within the considered design.

https://doi.org/10.52202/069179-0362

2.3.3 Model's uncertainty

This aim focuses on assessing the model uncertainty. The assessment of this variable is based on a comparison of model and test results and the determination of the associated partial factors include the following steps:

- Compilation of available test results.
- Calculation of the resistance for each of the tested specimens by using resistance models for relevant failure modes and measured values for dimensions and material properties.
- Determination of the theoretical load-bearing capacity and the associated failure mode.
- Comparison with experimental failure mode and capacity.
- Statistical evaluation of the results, in which the theoretical and the observed failure mode match.
- Suitable probabilistic description of the model uncertainty (lognormal distribution is commonly an appropriate distribution function).
- Determination of resistance model uncertainty partial factors depending on the partial factor format, parameters of the model uncertainty variable, target reliability and sensitivity factor.

When generalizing the model uncertainty beyond the scope of the database, trends with regard to mean and scatter should be carefully considered.

2.4 APPLY IN PRACTICE

Scientific knowledge, such as the herein proposed, must be made available for practice. Therefore, as a final step, all the developed scientific knowledge and strategies will be incorporated into tools for practice: design models for their consideration in design codes, such as the Eurocode.

Reports will be circulated and presented at the relevant Working Groups and Committees within the European standardization framework.

Such resistance design models are usually based on a combination of mechanical principles and empirical relationships. Newly developed models for inclusion in structural design codes should preferably be based on mechanical principles and meet the required level of reliability.

The expected outcome of the research plan will moreover allow developing improved design models for the capacity of the connections. It is expected to develop design models for the brittle failure of connections in the parallel and perpendicular direction and provide an interaction rule among these two capacities. The calibration procedure within Section 2.3 will allow providing a sound and consistent reliability background to the used fitting and safety coefficients in those models.

2.4.1 Design model

Based on the deep gained understanding of the behaviour of timber connections and their components, a design model will be developed to improve those existing (or still non-existing) within design codes. These models will be based on the existing design models from the literature (i.e., EYM) for the capacity of timber connections, for both failure types, ductile (EYM) and brittle, and will be calibrated, as described in Section 2.3. Additionally, it is expected to deliver a sound model for the brittle failure of timber connections for different load types and interactions. The developed design models will provide design principles and application rules for the design of timber connections in the future generations of timber design standards.

2.4.2 Reliability parameters

The statistical description of the uncertainty and the proposal of the developed reliability framework, which may be derived based on the JCSS Probabilistic Model Code [40], will be developed and presented at the appropriate standardization committees. The developed reliability assessment will allow proposing adequate safety concepts and calibration parameters for the design of timber structures and connections.

3 CONCLUSIONS

Tall timber buildings are becoming increasingly popular while challenging our surprisingly poor scientific knowledge of timber structures. However, current design approaches are still based on experience and tradition, and they are neither efficient nor reliable: while most members in timber structures are around 40-60% over-designed due to connection requirements [4,5], almost 25% of recent collapses of timber structures were related to connections. [2,6,7]

REACT engages in developing a reliable framework for the design of structural timber connections and structures. Based on the described extensive experimental campaign and the developed finite element models, both 3D-based and the novel multi-scale models, it will provide a sound reliability assessment of timber connections. This knowledge will stem from the described multilevel analysis, ranging from the material up to the connection level, with a special focus on the interaction of timber with dowel-type fasteners.

The experimental campaign focuses on three observation levels: material, timber-fastener interaction, based on standard and novel techniques; and connections. In this latter, the focus will be on realistic load patterns, in which bending, shear, and axial are present, to provide an understanding of the existing interaction among them. This challenges the current knowledge, mostly based on simple loading schemes.

This level-based experimental knowledge will inform the development of a multi-scale numerical model for timber connections which will be used to carry out the required stochastic models for the MonteCarlo Simulation and the subsequent reliability analysis of structural timber connections.

https://doi.org/10.52202/069179-0362

As a major contribution, the project will deliver information for design practice, allowing to make use of the obtained knowledge in a simple yet efficient way.

To exploit its extraordinary ecological potential and to enable its structural use, improved comprehension of the structural response of timber connections is required. REACT can make a significant difference towards more efficient, reliable, and safe timber constructions.

EFFECTS OF CONSTANT AND ELF STRENGTH PROFILES ON THE PERFORMANCE OF WOOD FRAME SHEAR WALL STRUCTURES

Francisco X. Flores[1] [2], Philip Line[3], Finley A. Charney[4]

ABSTRACT: Prior numerical studies to evaluate the sensitivity of modeled collapse performance of wood-frame wood structural panel shear wall structures have been limited to the 1- to 5-story index building models used in the FEMA P695 study. Investigated parameters included inherent damping, hysteretic behavior, P-delta effects, and strength profiles. Results showed that greater overstrength and a tapered strength profile from small at the roof level to large at the 1st story level had better collapse performance (i.e., lower collapse risk) and helped to support changes to design requirements in AWC SDPWS-2021. Sensitivity studies performed on 3-, 4- and 5-story building models reported herein expand on the prior evaluation of overstrength and strength profile effects. In addition, results from the study of a 6-story building model are also reported. Structural performance was evaluated using the probability of collapse per the FEMA P-695 methodology, and additional performance metrics such as energy dissipation and maximum story drift were investigated. The results of this investigation show the importance of the strength profile in Light Frame Shear Walls where a Constant strength profile along the building's heights displays the worst performance.

KEYWORDS Wood-frame shear wall, seismic analysis, collapse performance, FEMA P-695

1 INTRODUCTION

The collapse performance of wood-frame wood structural panel (WF/WSP) shear wall structures has been numerically investigated in the past [1-6]. Different parameters, such as inherent damping, hysteretic behavior, P-delta effects, and vertical strength profile, have been modified to evaluate the collapse performance using the FEMA P-695 methodology [7]. This study was conducted to expand previous studies on 3-, 4- and 5-story building models [1] and, for the first time by the authors, to evaluate a 6-story WF/WSP shear wall building model. Vertical strength profile is studied more in-depth by looking at different results, such as the sequence of yielding during a pushover analysis, energy dissipation at different intensity levels, earthquakes, and collapse performance. In addition, the influence of Rayleigh damping was quantified in terms of the probability of collapse and energy dissipation. Counterintuitively it was found that a constant strength profile along the building's height worsens the performance instead of being a conservative design.

2 NUMERICAL MODELS

The 1- to 5-story building models were taken from the FEMA P-695 wood-frame models. These systems were designed using ASCE/SEI 7-22 [8] and AWC Special Design Provisions for Wind and Seismic (SDPWS-2021) [9] requirements. The 6-story building model was developed assuming the same basic principles used for the 1- to 5-story building models.

Numerical WF/WSP shear models were created by modeling the load-deformation response at each level as a shear spring. The shear spring at each level was made using the CUREE-SAWS [10] model, which represents the nonlinear hysteretic behavior that accounts for pinching, stiffness, and strength degradation and is governed by ten different parameters [10-11].

Since diaphragms were idealized as flexible, torsion was not considered, and 2D numerical models developed in OpenSees were deemed sufficient to represent the buildings [12]. The shear wall response was modeled

https://doi.org/10.52202/069179-0363

using the SAWS 10-parameter hysteresis model with the backbone used in this study shown in Figure 1 as "Reference Backbone." The reference backbone, representing low-aspect ratio shear wall behavior, was used at all stories except with different scaling employed that varied peak strength to assess strength profile effects while preserving the backbone load-deformation shape.

In addition to the material nonlinearities incorporated in the numerical models, geometric nonlinearities (P-delta effects) were included explicitly. P-delta effects were modeled using a leaning column with no flexural capacity and significant axial stiffness carrying the gravity load.

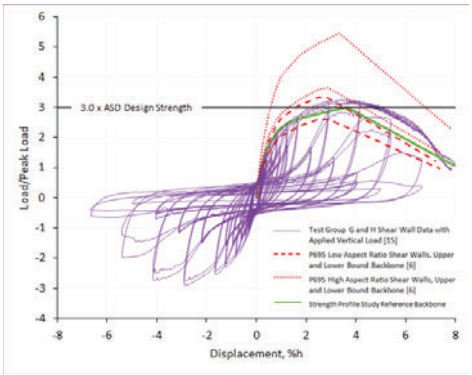

Figure 1 Reference Backbone Curve (green) vs. Test Data (purple) and FEMA P695 Wood Example (red) [1]

The strength profiles to be investigated herein are two for each structure. A "Constant" strength profile where the first story lateral force computed using the equivalent lateral force procedure is assigned as the strength along the building's height. The second strength profile ("ELF") is considered to be the same as the lateral forces computed using the equivalent lateral force procedure.

The shear walls were designed using allowable stress design (ASD) in accordance with SDPWS-2021 [9] and the seismic demands in accordance with ASCE 7-22. Based on test data, each shear wall's overstrength per story (Fu/VASD) was considered equal to 3. F_u is the maximum lateral strength shear wall capacity modeled using the ten parameter material within OpenSees. V_{ASD} is the allowable stress design story shear. In the case of the Constant profile, the maximum lateral strength capacity F_u was constant along the building's height. On the other hand, the F_u in the ELF profile follows the seismic demands at each story in accordance with ASCE 7-22 (Figure 2).

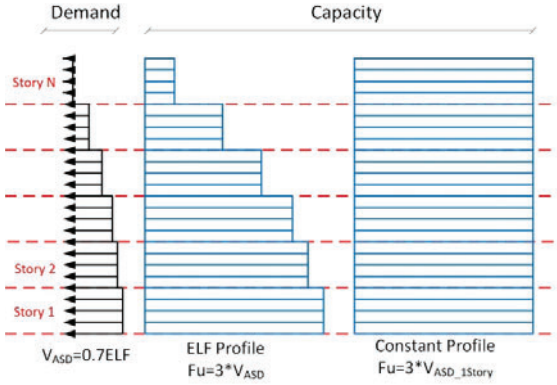

Figure 2 ELF vs. Constant Profile

Finally, Rayleigh damping was incorporated using three different percentages 1%, 2%, and 5% of critical damping. Damping was considered proportional to the building's mass and initial stiffness.

3 METHODOLOGY

The FEMA P695 methodology was used for this parametric study. The numerical models were subjected to static pushover and incremental dynamic analyses to evaluate their collapse performance. Static pushover analyses were performed to quantify overstrength and period-based ductility (μT) parameters. Before assessing the collapse performance of both strength profiles, the dynamic performance at MCE level was quantified using displacement time history and energy dissipation per story.

Incremental dynamic analyses were performed using 44 Far Field ground motions where spectral accelerations were increased until collapse was determined, defined as when the structure could no longer resist lateral loads (dynamic instability) such as from side-sway collapse or exceedance of a specified story drift of 8%. From these results, the probability of collapse for the maximum considered earthquake (MCE) was computed and compared among models.

4 NONLINEAR STATIC PUSHOVER ANALYSES

Nonlinear static pushover analysis was performed using the load pattern proposed in FEMA P695, based on the building's fundamental mode shape. All the structures using both strength profiles, Constant and ELF, were subjected to a lateral load until failure. The pushover curves, in conjunction with analyzing the sequence of yielding along the building's height, provide important insight into the structure's behavior under lateral loads.

Figure 3 displays the pushover curves, including P-Delta obtained for the 4-story model using both strength profiles, Constant and ELF. These curves show how both profiles have the same lateral strength with an overstrength (**Ω**) equal to 1.86. However, the

https://doi.org/10.52202/069179-0363

displacement capacity is significantly more significant for the ELF profile reaching a roof drift of 0.029 compared to 0.012. While the Constant profile has a ductility of 5.75, the ELF profile has a ductility of 8.66. This difference is important, and the reason behind the better performance is that yielding is concentrated in the first story in the Constant profile. On the other hand, yielding for the ELF profile when subjected to the same lateral load used for the Constant strength case is better distributed along the building's height.

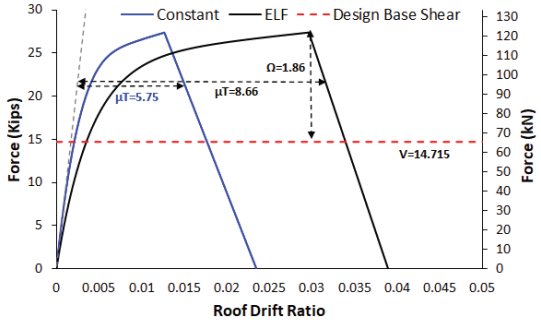

Figure 3 4-Story Pushover Curves

Figure 4 illustrates the performance of the 6-story models when subjected to the increasing lateral load. It can be seen once again that the maximum strength is the same for both strength profiles. However, the displacement capacity of the ELF profile is significantly larger (roof drift=0.011) than the Constant profile (roof drift=0.029). The ductility for the Constant profile is 5.06, while the ELF has a ductility equal to 8.40.

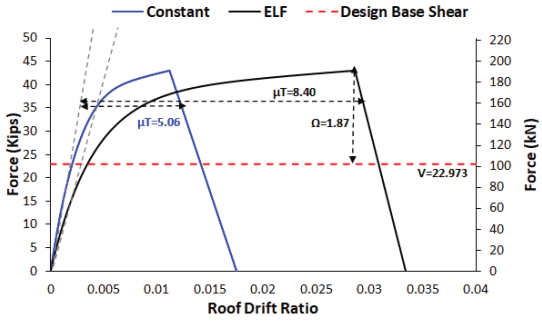

Figure 4 6-Story Pushover Curves

Even though pushover curves for the 4- and 6- story models are presented, the same trends were seen for the 3- and 5-story models.

5 GROUND MOTIONS

The ground motions used in this study were taken from the Far-Field set provided by the FEMA P-695 methodology. The Far-Field record set is twenty-two horizontal component pairs of records (44 in total) from sites located at a distance equal to or greater than 10 km from the fault rupture.

The methodology used to scale the ground motions was also taken from the FEMA P695 methodology and involved two steps: normalizing the individual ground motions with respect to the peak ground velocity and scaling the median acceleration spectrum to the MCE acceleration spectrum at the structure's natural period of vibration. The ground motions were also normalized by the 5-percent damping spectral acceleration at the building's period (S_{MT}). In this way, a scale factor of 2/3 and 1.0 represents the Design Basis Earthquake and Maximum Considered Earthquake (MCE), respectively.

6 DYNAMIC TIME HISTORY RESPONSE AT MCE

Before performing an Incremental Dynamic Analysis where the ground motions are amplitude scaled until the structure collapses, the seismic performance of the models is evaluated at the MCE level earthquake (Scale factor equal to 1). The performance quantification compares the roof drift ratio for both strength profiles. To further understand the complete behavior of the building model with a different strength profile when subjected to a ground motion, the hysteretic energy dissipated per shear wall at each story is computed. The hysteretic energy is calculated integrating the area under the Force (kN) vs. deformation (mm) curve. The results presented herein are for the 2% damping case.

Figure 5 illustrates the roof drift ratio for the 4-story model caused by one of the ground motions scaled at the MCE level. While results for only one ground motion are shown, the trend was the same for other ground motions that caused large displacements. It can be seen that the Constant profile has a residual roof drift ratio of around 0.0159 (roof drift = 7.65in, 194.36mm), while the ELF strength profile shows a residual roof drift equal to 0.048 (roof drift = 2.31in, 58.75mm). The larger residual deformation in the Constant strength profile case is from concentrated yielding in the first story.

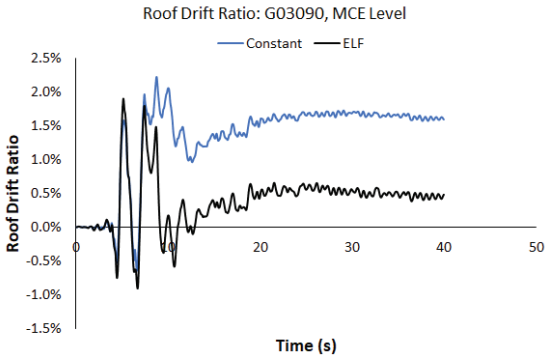

Figure 5 4-Story Roof Displacement Time History Analysis (G03090 MCE, 2% Damping)

Figure 6 and Figure 7 display the hysteretic energy dissipated by the Constant and ELF strength profile when the structure is subjected to the same ground motion (G03090) that caused the roof drift response shown in Figure 5. The dissipation is computed in time as the integral between the story force and story drift [13]. From

Figure 6 for the Constant profile, it can be seen how the first story shear wall is the one that dissipates energy the most (87.2%), meaning that this wall yields the most. This is a straightforward consequence of having first story drift concentrations. This figure also indicates that the last two stories remained elastic because they barely dissipated energy.

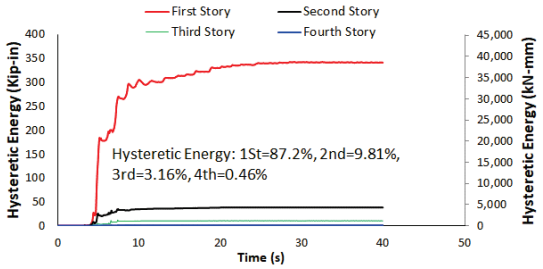

Figure 6 4-Story Energy Dissipation Per Story (Constant Profile, G03090 MCE, 2% Damping)

On the other hand, Figure 7 illustrates the hysteretic energy dissipated by each shear wall per story when the 4-story model has an ELF strength profile. The percentage of the energy dissipated by the first story is 69%, meaning yielding was distributed better along the building's height. Even though yielding distributes more uniformly in comparison to the Constant strength profile, more investigation is required to evaluate the effect of strength profiles that are intermediate between ELF and Constant as well as strength profiles based on targeted strengthening of lower stories to distribute better yielding in the first 2 or 3 stories.

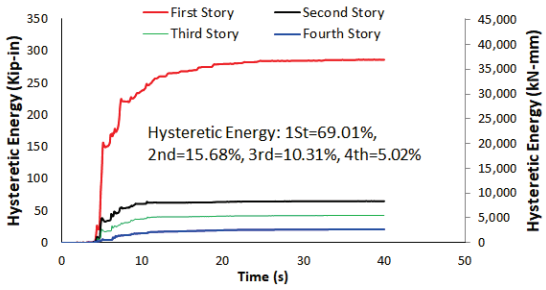

Figure 7 4-Story Energy Dissipation Per Story (ELF Profile, G03090 MCE, 2% Damping)

Figure 8 presents one of the results obtained from the 44 ground motions scaled at the MCE level to which the 6-story model was subjected. This figure shows that the Constant profile strength presents a residual roof ratio of around 0.79% (roof drift = 5.69in, 144.62mm). On the other hand, the ELF strength profile shows a residual roof drift ratio equal to 0.064% (roof drift = 0.46in, 11.68mm). The residual drift ratio is typically dominated by first story deformations, which could be confirmed by looking at the hysteretic energy dissipated by the shear walls.

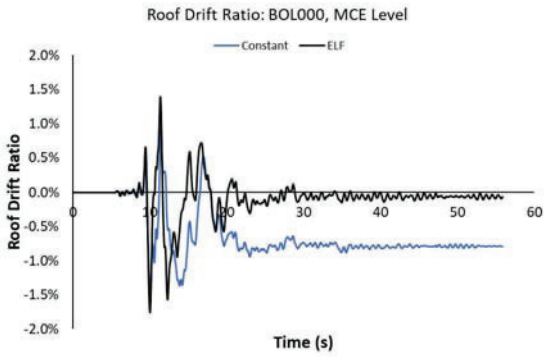

Figure 8 6-Story Roof Displacement Time History Analysis (MCE, Zi=0.02 Ko)

Figure 9 and Figure 10 show the hysteretic energy dissipated by the shear walls along the building's height when subjected to the same ground motion (BOL000) that caused the roof drift response shown in Figure 8. It can be seen how 89% of the dissipated energy, when the Constant profile is used, concentrates in the first two stories. On the other hand, around 71% of the dissipated energy, when the ELF profile is used, focuses on the first two stories. The reduction of the energy dissipated in the first story is around 18% when the ELF profile is used. As a result of having a more uniform distribution of yielding along the building's height, residual deformations decrease when the ELF strength profile is used, and the seismic performance is improved.

7 INHERENT DAMPING ENERGY DISSIPATION

Inherent damping in structures considers energy dissipation from components not explicitly modeled using nonlinear inelastic hysteretic models. It would be challenging to account for all the energy dissipated by all the elements in a structure during an earthquake and the energy dissipated by the lateral resisting system. Therefore, the percentage of the total energy dissipated during an earthquake is typically assigned to inherent damping using either modal damping or Rayleigh damping. Inherent damping evaluated in this study uses Rayleigh damping.

Inherent damping is assigned as an imaginary linear viscous damper within the building using a damping value that is a percentage of the critical damping. The commonly used values assumed vary from 1% to 5%. For instance, FEMA P-695 proposes that the value of inherent damping should be between 2% and 5%.

When Rayleigh damping is used, the damping matrix is formed by considering this matrix proportional to the stiffness and mass matrix. However, the stiffness matrix could change during a seismic analysis when the material and geometric nonlinearities are included in the model. Therefore, there are mainly two options when proportional stiffness damping is considered: initial and tangent stiffness.

In this investigation, 1%, 2%, and 5% proportional to the initial stiffness were considered, leaving the same analyses to be performed using tangent stiffness for future research. However, less energy is expected to dissipate when the tangent stiffness is used because the model's stiffness reduces when yielding occurs. Therefore, this section of the paper shows the amount of energy compared to the total energy taken by the inherent damping. Even though there is nothing proposed for how much energy inherent damping should dissipate as a percent of the total energy dissipated, this type of result could help inform future recommendations.

It was found that the percentage of energy dissipated by inherent damping compared to total energy dissipated for the 44 ground motions scaled to the MCE level depended mainly on the amount of damping assigned and not on the number of stories or the strength profile. The amount of energy dissipated by the inherent damping varies between 10% and 12% for 1% damping, 16% and 20 % for 2 % damping, and 30% and 38% for 5% damping. As previously mentioned, there is no proposed value on how much energy should be dissipated by inherent damping. In the case of wood-frame shear wall structure, this energy represents non-modeled components which, for this study, could potentially represent stucco and gypsum wallboard finish materials, partition walls, and diaphragms that will dissipate energy during an earthquake.

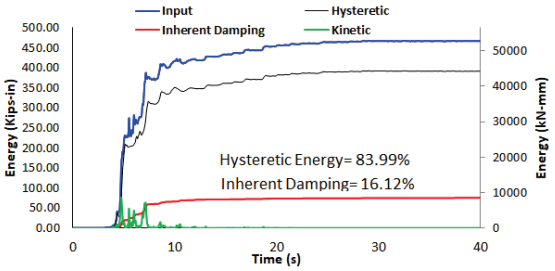

Figure 11 4 Story Energy Balance (Constant profile, 2% Damping)

Figure 11 and Figure 12 show the energy balance using 2% and 5% inherent damping for the 4-story Constant profile. The analyzed ground motion is again the G03090. It can be seen how energy dissipated by the inherent damping increases from 17% to 30.9%. Note that the hysteretic energy shown herein is taken by all the shear walls along the building's height. However, as previously described, the way it distributes depends on the strength capacity profile.

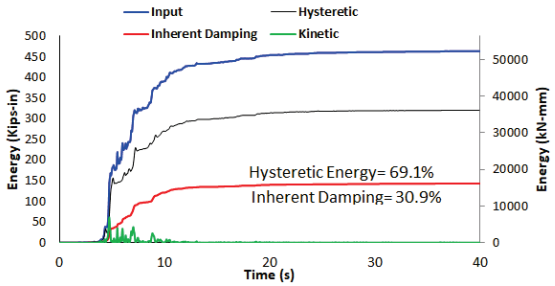

Figure 12 4 Story Energy Balance (Constant profile, 5% Damping)

8 COLLAPSE EVALUATION

The collapse performance of the models is evaluated following the FEMA P-695 procedure. Each building model is subjected to 44 Far-Field ground motions where Incremental Dynamic Analysis [13] is used to assess the model's collapse. Based on previous studies, the collapse is assumed to occur when story drift reaches a value of 8%, or dynamic instability occurs [1]. Once the scale factor that causes the collapse per ground motion is computed, the collapse margin ratio (CMR) is calculated.

https://doi.org/10.52202/069179-0363

The CMR is the ratio between the spectral acceleration that causes the median collapse (22 out of the 44 ground motions) to the spectral acceleration at the MCE level.

The probability of collapse is used as the metric to compare the performance among the building models and strength profiles. The ACMR is a ratio, as described by P-695, that adjusts the CMR with the Spectral Shape Factor (SSF), This accounts for the differences between the spectral shape of rare ground motions in California with the design spectrum or a uniform hazard spectrum. The probability of collapse is computed at the MCE level using as mean the lognormal of ACMR and as standard deviation the uncertainties (β=0.5) [15].

Figure 13 shows the probability of collapse for all the building models using both strength profiles and for different damping ratios. The Constant profile performs in all cases worse than the ELF profile. This could be counterintuitive if one thinks that constant strength at each story along the building's height would be beneficial. The performance worsens with the Constant strength profile because it is prone to drift concentrations in the first story. On the other hand, the ELF profile distributes yielding along the building's height, improving the performance by delaying the first story yielding, contributing to the modeled collapse.

Another important property is inherent damping and how it influences performance. For instance, the 4-story ELF profile modeled probability of collapse varies from 13.1% with 1% damping to 3.6% with 5% damping and is related to the amount of dissipated energy by the inherent damping compared to the total energy dissipated considering both inherent damping and structural system yielding.

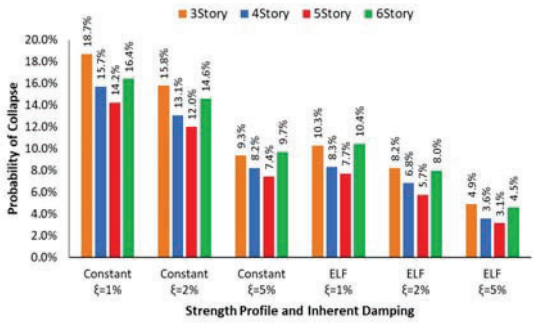

Figure 13 Probability of Collapse Evaluation

9 CONCLUSIONS

This study analyzed different building models ranging in height from 3 to 6 stories. Two different ways these buildings could be designed were considered: a Constant profile where the strength remains constant along the building's height and an ELF profile where a tapered strength from small at the roof to large at the 1st story level is used. In addition, three different values of inherent damping were considered, 1%, 2%, and 5%, proportional to the initial stiffness.

Findings from studies presented herein are summarized as follows:

- The pushover curves showed how the ELF profile improves the displacement capacity and ductility compared to the Constant profile.
- The analyses performed at MCE level earthquakes illustrate the difference in the residual deformations when both profiles are used. Furthermore, evaluating energy dissipated helps explain the extent of concentrated yielding on the first story in the Constant profile.
- A Constant strength profile is more prone to have drift concentrations in the first story resulting in a higher probability of collapse when compared to the ELF strength profile.
- Even though the ELF profile delays drift concentrations in the first story to higher scaling factors compared to the Constant profile, the failure mechanism is still the first story.
- The amount of inherent damping used in analysis directly affects the modeled performance. Therefore, this paper includes data on the amount of energy dissipated based on the damping assigned in the analysis.
- Inherent damping is related to the amount of unknown energy dissipated during an earthquake. However, there is no consensus regarding the amount of energy that should be dissipated by inherent damping. In the case of wood structures, there is likely a wide range given that there is a varied make-up of buildings and multiple components that dissipate energy that is not included in the mathematical model.

10 RECOMMENDATIONS

This study shows the importance of the strength profile on the seismic performance of Light Frame Shear Walls. The trends were the same for all building models from 2- to 6 stories, where the Constant profile performed worse than the ELF profile. In addition, damping was studied using an energy perspective that could help establish a recommended damping ratio value in the future. Even though important conclusions were obtained from this study, the following are recommendations for future research:

- Study profiles vary from the Constant to the ELF profile.
- Investigate profiles that strengthen only the first two stories to move yielding to the upper stories.
- Expand this type of study to other lateral resisting systems.
- Study more in-depth the energy dissipated when tangent stiffness is used instead of initial stiffness.

AN ANALYTICAL MODEL TO INVESTIGATE THE EFFECT OF DIAPHRAGMS ON THE ELASTIC BEHAVIOUR OF MULTI-STOREY COUPLED-PANEL CLT SHEARWALLS

Damian Oliveira[1], Ali Mikael[2], Daniele Casagrande[3], Ghasan Doudak[4]

ABSTRACT: This study develops an analytical model to describe the behaviour of multi-storey multi-panel CLT shearwalls, specifically accounting for cumulative loads between storeys and the effect of the diaphragm. The analysis considers the contribution of hold-downs, wall-to-floor connections, and panel-to-panel joints, as well as loads transferred from storeys above. The analysis has been developed for shearwalls acting as a series of coupled panels (CP) each individually rotating about a corner. Force transfer between storeys is implemented by distributing reactions through the upper floor diaphragm and a direct force from the upper storey's hold-down. Structuring the equations this way allows for a simplified formulation while including several components of the system's complex behaviour. Two-dimensional finite element modelling is used to verify the accuracy of the developed model.

KEYWORDS: CLT, Lateral Design, Modelling, Earthquake, Mid-rise, Derivation, Diaphragm Effect

1 INTRODUCTION

Lateral Load Resisting Systems (LLRS) in Cross Laminated Timber (CLT) used in platform-type buildings typically consist of two types of shearwalls; namely monolithic shearwalls made with a single panel or multi-panel shearwalls comprised of segments connected with vertical joints. The behaviour of multi-panel CLT shearwalls is primarily related to the properties of the vertical joints and mechanical anchors (e.g., hold-down and angle brackets), while the CLT panels generally behave as rigid bodies [1]. Depending on the relative stiffness between vertical joints and hold-down as well as the magnitude of vertical loads, three kinematic modes may be developed in single-storey multi-panel shearwalls, namely a mode consisting of individual panel rotation (coupled panel, or CP), a mode consisting of a global wall rotation (single wall, or SW) and an intermediate mode (IN) comprised of both CP and SW modes [2,3]. Several analytical methods have been developed to predict the elastic behaviour of single-storey multi-panel CLT shearwalls. Flatscher and Schickhofer [4] developed analytical expressions through displacement-based methods while Masroor et al. [5] proposed an analytical methodology taking into account the bi-directional behaviour of angle-brackets [6,7]. Studies on the mechanical behaviour of multi-storey multi-panel CLT shearwalls, including the structural interaction between floor and wall panels have been limited. D'Arenzo et al. [8] developed an analytical model to investigate the interaction between a two-panel shearwall and the upper floor but such model was limited to single-storey shearwall.

This paper seeks to expand the existing single-storey approach by developing analytical expressions to account for the behaviour of multi-storey multi-panel CLT shearwalls, focusing on the CP kinematic mode. In order to replicate the effects of multi-storey behaviour in a single-storey analysis, the resulting reactions of a storey are used to modify the loads applied to the lower storey. Accordingly, the storeys are analyzed sequentially, beginning from the uppermost storey and transferring reaction forces to the next, lower storey. Due to this transfer of forces between stories, the effect of floor diaphragms between the CLT walls is also investigated and incorporated into the method.

The analytical method incorporates the cumulative effects of force transfer from one storey to another, as well as more flexible formulations to describe the connections between the wall panels and the upper and lower floor diaphragms. The proposed equations are verified against the results of two-dimensional finite element modelling using the Dlubal RFEM software.

2 ANALYTICAL METHODOLOGY

Following the methods developed in [2], analytical equations are developed using the method of virtual work and static equilibrium. Due to the rigid nature of CLT panels, the lateral resistance of the wall is assumed to be

https://doi.org/10.52202/069179-0364

governed by the properties of the hold-downs, floor to wall connections and vertical joints used to connect the individual panels [5], as illustrated in Figure 1. The connection to the lower floor diaphragm is most commonly provided by angle brackets, while the connection to the upper floor diaphragm is often provided by self-tapping screws or angle brackets.

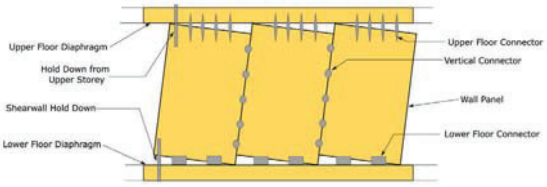

***Figure 1**: Displaced CLT shearwall and connection types*

The local stiffness of the connections between the CLT wall panels and the upper or lower floor diaphragms is distributed linearly along the panel edge, in order to broaden the applicability of the analytical method to various connection locations. The distribution of connection stiffness along the edge of CLT panels has been previously investigated in literature as a method to develop elastic analysis and modelling guidelines suitable for practicing engineers, and the method has achieved good agreement with experimental seismic responses [9].

The distributed stiffness of the wall-to-diaphragm connections, k_a when considering the connection to the lower floor or k_t when considering the connection to the upper floor, was calculated for several potential layouts. The equivalent stiffness was determined by equating the sum of work for a layout of connections with an integration of continuous forces representing the distributed stiffness. Illustration of the methodology with an arbitrary connector stiffness k_{br} is presented in Figure 2, with example stiffnesses presented in Table 1.

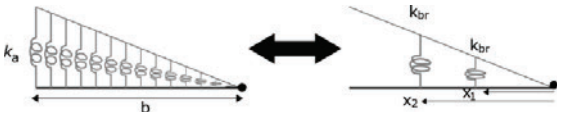

***Figure 2:** Equivalency illustration for two point-stiffnesses*

***Table 1:** Example distributed stiffness equations*

Bracket or Connector Layout	k_a or k_t
	$\frac{3}{2}k_{br}\frac{b^2+a^2}{b^3}$
	$\frac{n}{4}k_{br}\frac{3b^2+(n^2-1)a^2}{b^3}$

The analytical equations for the CP kinematic mode were determined using the principles of virtual work. The external work acting on the system was contributed to by the applied loads: lateral force F, uplift tension force T and downward vertical loads P_j from the upper floor (Figure 3). The internal work of the system includes contributions from the hold-down, vertical joints, and distributed connections to the upper and lower floor diaphragms. The expressions of external and internal work are presented in Equation (1) and Equation (2), respectively.

$$\sum W_{ex} = Fh\theta + Tb\theta - \sum \mathrm{P_i} b\theta \quad (1)$$

$$\sum W_{int} = \tfrac{1}{2}k_h b^2\theta^2 + \tfrac{1}{2}(m-1)(nk_c)b^2\theta^2 + \tfrac{1}{6}m(k_a+k_t)b^3\theta^2 \quad (2)$$

where m= number of panels, n= number of connectors in the vertical joints, k_h= hold-down stiffness, k_a= distributed lower floor-to-wall stiffness, k_t= distributed upper floor-to-wall stiffness and k_c= vertical connector stiffness.

The CP kinematic mode is defined by the behaviour during lateral displacement, where each panel within the shearwall rotates about a local corner as shown in Figure 3. Due to the equalized rotation across the panels, it is assumed the upper floor remains horizontal, as does the lower floor. The hold-down tensile force, T, and the vertical point loads P_j provide a different representation of the inter-storey load transfer compared to previous work [2].

https://doi.org/10.52202/069179-0364

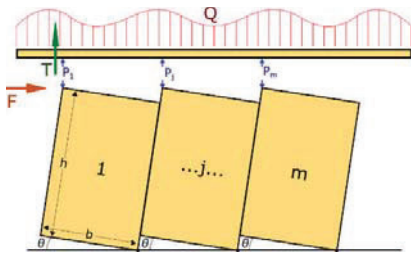

Figure 3: *Illustration of the coupled panel kinematic mode and applied load distribution*

The displacement of the wall causes tension in the hold down of the first panel (j=1), which is transferred as a vertical point load to the storey below. The load is applied upward at the corner of the first panel in the lower storey, as the walls are assumed to be vertically aligned for the transfer of force. The downward vertical load is transferred to the wall through the upper floor diaphragm and applied on the panel corners as point loads P_j. The method utilizes a beam analogy (Figure 4), which includes gravity loads and the net reactions of the storey above in the equivalent vertical load Q. While any pattern of loading can be applied to the beam analogy, the vertical loads and reactions for the panel corners and floor connections above are uniformly distributed along the length of the wall. This distribution of bearing reactions and connection forces is performed according to Equation (3) for storey under consideration (labelled s in the equation), where q_s is the gravity load applied on the floor in kN/m and $R_{cj,(s+1)}$ is the reaction force from the j-th panel of the upper ($s+1$) storey.

$$Q_s \cong q_s + \frac{\sum_1^m R_{cj,(s+1)} - m \times \left(\frac{k_a b^2 \theta}{2}\right)_{(s+1)}}{m \times b} \tag{3}$$

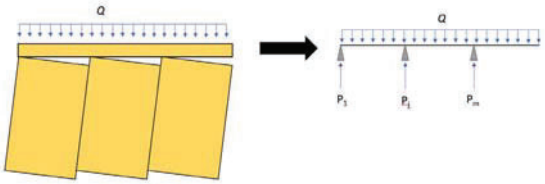

Figure 4: *Illustrated beam analogy for an example isolated shearwall acting in the CP kinematic mode*

Numerical models have shown that distributing the loads uniformly achieves equivalent P_j results as the individually applied reactions for CP analysis, and therefore uniform Q loads are used to simplify the analysis.

Within the analogous system, the contacting point of a panel with the upper floor is treated as a pinned support for a continuous simply-supported beam. This continuous beam represents the upper floor diaphragm above the wall, including an extra length cantilevering over the last supporting panel.

The extent of deflection in a CLT shearwall acting in the CP mode can be described using the angle of rotation θ, as defined in Equation (4), which is also critical in deriving expressions for the connection forces. The connection stiffness to the lower floor k_a, connection stiffness to the upper floor k_t, hold-down stiffness k_h, and the total stiffness of n fasteners in vertical joints nk_c are presented in Equation (5) to describe the combined stiffness k^*.

$$\theta = \frac{1}{k^*}\left(\frac{Fh}{b^2} + \frac{T}{b} - \frac{\sum_1^m P_j}{b}\right) \tag{4}$$

$$k^* = k_h + (m-1) * n * k_c + \frac{mb}{3}(k_a + k_t) \tag{5}$$

The displacement of any point along the wall can be calculated using the angle of rotation. The key displacements to describe the position of the wall panels can generally be defined as the displacement of the panel corners. These displacements include the lateral deflection Δ_h (equal to θ x h) and hold-down elongation v_0 (equal to θ x b).

The elastic resistance of the shearwall is governed by the resistance of the vertical joints and hold-downs, due to the high in-plane rigidity of CLT panels. The equations for the forces in the hold-down and individual vertical connectors, respectively, are presented in Equation (6) and Equation (7). While the stiffness of the connections to the floor diaphragms contributes to the behaviour of the system, they are assumed to not govern the elastic resistance of the wall. The angle of rotation and the location of the wall-to-floor connections can be used with methods of mechanics to calculate the forces in the discrete connectors and ensure adequate capacity.

$$R_h = \frac{k_h}{k^*}\left(\frac{Fh}{b} + T - \sum_1^m P_j\right) \tag{6}$$

$$F_{cy} = \frac{k_c}{k^*}\left(\frac{Fh}{b} + T - \sum_1^m P_j\right) \tag{7}$$

The equations for elastic resistance of the shearwall are derived from Equations (6) and (7), resulting in the set of expressions presented in Equations (8)-(10). Equation (9) provides the wall resistance in the scenario where the hold-down reaches its elastic limit before the connectors in the vertical joint, while Equation (10) provides the resistance where the vertical connectors yield before the hold-down. Due to the nature of the CP kinematic mode, all vertical joints in the wall are exposed to the same magnitude of force.

$$R_w = \min\{R_{wc}, R_{wh}\} \tag{8}$$

https://doi.org/10.52202/069179-0364

$$R_{wh} = r_h \frac{k^* b}{k_h h} + \frac{\sum_1^m P_i \times b}{h} - \frac{Tb}{h} \quad (9)$$

$$R_{wc} = r_c \frac{k^* b}{k_c h} + \frac{\sum_1^m P_i \times b}{h} - \frac{Tb}{h} \quad (10)$$

The defining boundary for the CP kinematic mode is that all panels remain in contact with the floor surface. As such, the boundary for the validity of the analysis can be defined as when the first panel's reaction force (R_{c1}, as calculated in Equation (11)) is greater than or equal to 0. This results in the condition presented in Equation (12), in terms of the applied uplift tension force T at that storey.

$$R_{c1} = R_h + \frac{b^2\theta}{2}(k_a - k_t) - nF_{cy} + P_1 - T \geq 0 \quad (11)$$

$$T < \frac{k_h - nk_c - \frac{b}{2}(k_a - k_t)}{mnk_c + \frac{mb}{3}(k_a + k_t) - \frac{b}{2}(k_a - k_t)} \left(\frac{Fh}{b} - \sum_1^m P_i\right) + \frac{P_1 k^*}{mnk_c + \frac{mb}{3}(k_a + k_t) - \frac{b}{2}(k_a - k_t)} \quad (12)$$

Equation (12) provides the maximum uplift tension force T a given wall can resist while maintaining CP behaviour, which indicates that the effect of hold-down forces from upper storeys on CP kinematic behaviour is significant. Figure 5 presents the limiting condition for CP behaviour, above which the wall is expected to act in the CP kinematic mode and below which it trends towards the SW kinematic mode. As the ratio of overturning moments changes, which includes uplift tension force T and lateral forces F, the boundary line raises such that a shearwall requires increased hold-down stiffness (or higher counteracting gravity load) to maintain CP behaviour. This is a considerable change from the case without uplift forces from upper storeys, represented by the solid line, where a stiffness ratio of 1 or greater is sufficient to ensure CP behaviour regardless of loading.

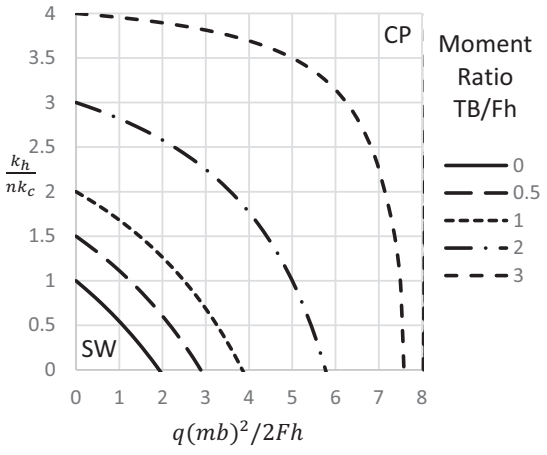

Figure 5: *Effect of uplift tension on behavioural boundary*

3 MODELLING METHODOLODY

Finite element models of both single-storey and stacked multi-storey shearwalls were developed and used to verify the proposed mathematical approaches. The single storey models were used to investigate the assumptions made within the analytical method, as well as verify the accuracy of the final equations. The single-storey models were analyzed sequentially, representing isolated storeys transferring forces to the wall below similarly to the analytical method. The stacked shearwall model is constructed to verify the accuracy of the analyses, as the multi-storey effects would inherently occur during the solution of the model.

The models consist of two-dimensional (i.e. area) rigid elements representing the CLT panels, connected with distributed springs (referred to as linear releases in the software) representing the connections between adjacent CLT panels and between the wall and the upper and lower floors. The floor diaphragms are modelled using properties representing a CLT floor system over an interior wall. Hold-downs are represented by spring elements between the first panels of adjacent storeys (Figure 6), and between the bottom of the lowest first panel and foundation. Dlubal RFEM is used to construct the models and analyze the results.

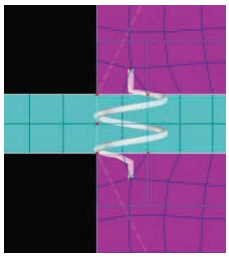

Figure 6: *Modelled hold-down element, in white, between shearwall panels, in purple*

Panel dimensions of 3 m in height and 1.5 m in width are used throughout the modelled walls for consistency. The four-storey model also includes an extended diaphragm, to better represent a shearwall as part of a larger structural system (Figure 7).

https://doi.org/10.52202/069179-0364

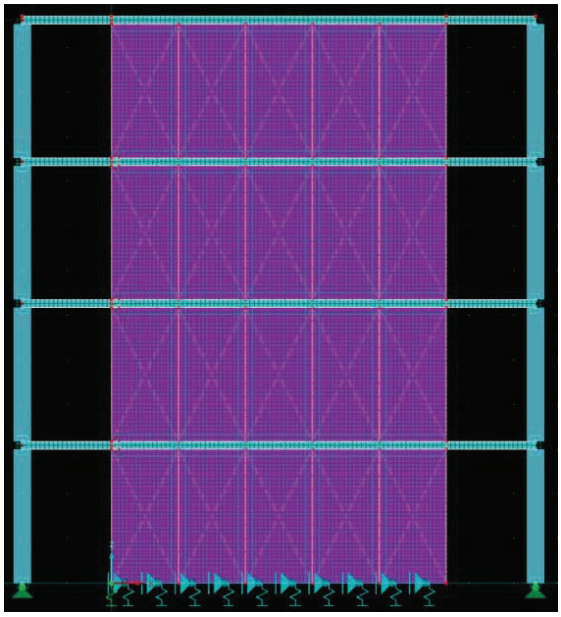

Figure 7: *Four-storey stacked CP model*

The finite element model considers a four-storey stacked five-panel shearwall loaded according to high seismic demands in Victoria (Canada). The load and connection properties are summarized in Table 2. The connection properties are based on manufacturer data for commercial products, and the same stiffnesses are used to connect the wall to both floors.

Table 2: *Coupled Panel modelling properties*

Storey	1	2	3	4
Applied Lateral Load (kN)	42.9	85.7	128.6	96.1
Distributed Gravity Load (kN/m)	20	20	20	10
Number of Vertical Connectors	24	24	15	15
Vertical Connector Stiffness (kN/m)	700	700	700	700
Hold-Down Stiffness (kN/m)	13136	13136	9973	9973
Distributed Floor Connection Stiffness (kN/m/m)	5147	5147	3823	1323

The modelled diaphragm for all cases is 175 mm thick, with an elastic modulus of 9348 MPa and width of 5 m.

4 MODELING RESULTS AND DISCUSSION

The results of the finite element models, as well as the analytical equations, are presented and compared in the following sections. The results of the stacked shearwall model are presented primarily as a target response for the other analyses. The single-storey models are used to investigate the assumptions used in the development of the analytical equations, and the results are compared between assumptions and against the stacked model. The calculated results from the analytical equations are compared against the stacked model result, to evaluate accuracy, as well as the single-storey model results to evaluate consistency.

A sensitivity analysis varying the properties of the floor diaphragm, both within the beam analogy and the finite element modelling, is also presented to investigate the sensitivity of the method.

4.1 STACKED MODEL RESULTS

The stacked shear wall model serves as the target values for verifying the analytical equations and benchmark for the behaviour of the single-storey models used to evaluate the analytical assumptions. The critical results for comparison between the analyses are lateral displacement, panel rotation, and hold-down tension.

The results for the four-storey stacked model indicated a decreasing level of rotation in lower storeys, due to the accumulated gravity load counteracting the lateral forces (Figure 8). While the floor diaphragms between storeys developed curved shapes, the overall surfaces generally remained level between the shearwalls. The results of the analysis are presented in Table 3, indicating inter-storey drift (Δ_h) as well as the total lateral displacement at each floor.

Table 3: *Four-storey stacked model results*

Storey	Δ_h (mm)	Total Lateral Displacement (mm)	θ (mrad)	R_h (kN)
4	3.75	10.37	1.25	15.4
3	3.88	6.56	1.29	19.2
2	1.62	2.64	0.550	16.5
1	0.98	0.98	0.330	6.85

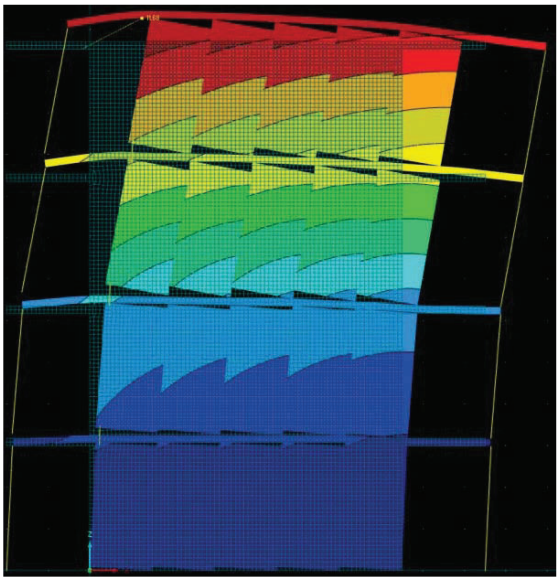

Figure 8: *Displaced shape of four-storey model, 140x deformation*

https://doi.org/10.52202/069179-0364

4.2 SINGLE-STOREY RESULTS

The single storey-models were analyzed sequentially, as in the approach used in the mathematical analysis. A model of the uppermost storey was analyzed first, and the reaction and hold-down results were used to modify the loads applied to the model of the lower storey.

The properties of the connections to the upper floor will influence the behaviour of the CLT shearwall, similarly to the connections between the wall and the lower floor. However, the inclusion of am upper floor diaphragm into the shearwall analysis does not only alter the system response through the connection to the wall panels. The addition of an upper diaphragm alone will modify how the vertical loads are distributed to the wall panels.

Two sets of single-storey models investigated the load distribution effect of floor diaphragms during CP behaviour. One set applies the vertical loads directly to the wall panels (Figure 9) (i.e. without considering a diaphragm), while the other model includes a modelled upper floor diaphragm which will distribute the applied vertical load to the wall panels (Figure 10).

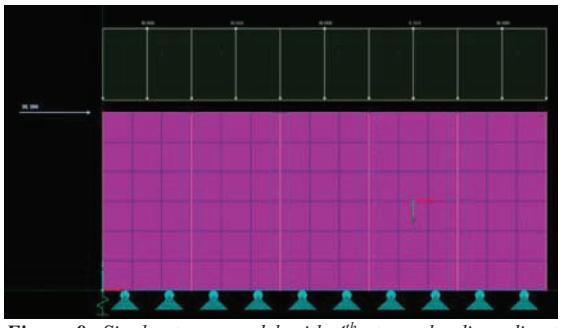

Figure 9: *Single storey model with 4th storey loading, direct panel loading*

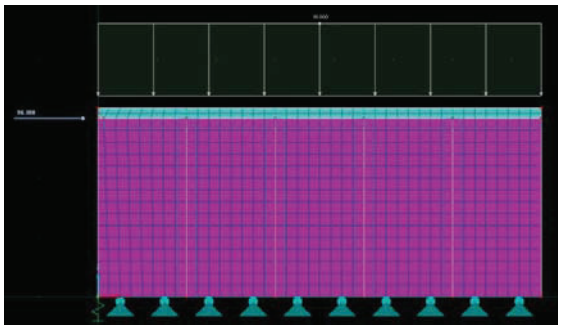

Figure 10: *Single storey model for 4th storey, with diaphragm*

Both models consist of five-panel shearwalls, and as indicated in Table 4, no floor connections were implemented in either model to maintain a valid comparison. Furthermore, the loading was identical between the models, despite differences in reaction values between the analyses which would cause cumulative differences as the forces are transferred to the analysis of the lower storeys. This overall harmonization between the models allows for a direct comparison between the single-storey models and isolates the effect of the floor's distributive properties.

Table 4: *Single storey model information for floor diaphragm comparison*

Storey	1	2	3	4
Lateral Load (kN)	353.3	310.4	224.7	96.1
Gravity Load (kN/m)	95	65	35	10
Uplift Force (kN)	40	35	20	0
Number of Vertical Connectors	24	24	15	15
Vertical Connector Stiffness (kN/m)	700	700	700	700
Hold-Down Stiffness (kN/m)	13136	13136	9973	9973

The model results are presented in Table 5, where it can be observed that the inclusion of the modelled floor diaphragm drastically reduces the lateral deflection for a given loading. This difference can be attributed to the increased moment arm that more directly counteracts the rotation of the panel when the gravity load is applied via a point load on the panel corner rather than distributed over the top edge.

Table 5: *Modelling results for single storey comparison of floor effect*

Storey	Q Loading			Diaphragm Loading		
	Δ_h [1]	θ [2]	R_h [3]	Δ_h [1]	θ [2]	R_h [3]
4	5.96	1.98	29.7	4.52	1.47	22.4
3	13.04	4.33	64.9	7.93	2.58	42.2
2	10.29	3.41	67.4	4.35	1.40	29.4
1	9.76	3.23	63.8	1.64	0.51	10.6

1: mm 2: mrad 3: kN

In order to compare against the four-storey stacked model, and therefore provide storey-be-storey equivalent analysis for comparison with the analytical equations, two additional models were analyzed using the same properties as listed in Table 2. The first set included a floor only above the wall panels, while the second model set extended the upper floor diaphragm to match the construction of the stacked model more closely (Figure 11).

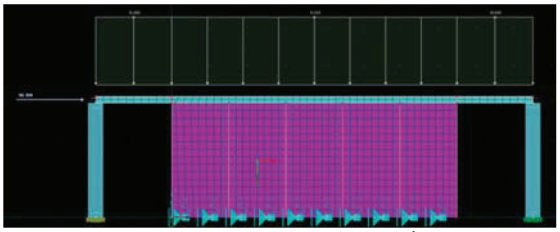

Figure 11: *Extended single storey model for 4th storey*

The accumulated gravity load applied to each single storey model is adjusted by distributing the net reactions from the storey above, using the same methodology presented in Equation (3). The resulting loads applied to

each non-extended single storey model are presented in Table 6, and the results of the analysis are shown in Table 7.

Table 6: *Loading cases for non-extended single storey model*

Storey	1	2	3	4
Lateral Load (kN)	353.3	310.4	224.7	96.1
Gravity Load (kN/m)	74.7	54.3	32.3	10
Uplift Force (kN)	33.7	32.3	17.2	0

Table 7: *Non-extended single storey modelling results*

Storey	Δ_h (mm)	θ (mrad)	R_h (kN)
4	3.45	1.12	17.2
3*	6.36	2.05	32.3
2*	4.71	1.51	33.7
1*	3.46	0.99	25.0

*: Uplift observed in first panel

While the single-storey results in Table 7 follow the same general pattern of diminishing rotation in lower storeys as those in the stacked model results (Table 3), several cases of the single storey analysis exit CP mode by exhibiting uplift in the first panel.

The extension of the floor increases the gravity load on each storey, as shown in Table 8. As a result, all extended single storey models remain in the CP kinematic mode. However, the extended model for the lowest storey does not meaningfully display rocking behaviour due to the accumulated gravity load, as shown in Table 9.

Table 8: *Loading cases for extended single storey model*

Storey	1	2	3	4
Lateral Load (kN)	353.3	310.4	224.7	96.1
Gravity Load (kN/m)	108.5	68.4	29.2	10
Uplift Force (kN)	9.23	20.7	16.4	0

Table 9: *Extended single storey modelling results*

Storey	Δ_h (mm)	θ (mrad)	R_h (kN)
4	3.30	1.07	16.4
3	4.18	1.35	20.7
2	1.44	0.44	9.23
1	0	0	0

Comparing the displacement results of both extended and non-extended models to those of the stacked four-storey model, it can be observed that the addition of the extended floor generally improves accuracy to within 10% of the stacked model results (represented by the solid line in Figure 12). As such, the specific distribution of forces from the floor diaphragm has significant influence on the overall behaviour of the shearwall. The tendency for the non-extended model to overestimate displacement is also noteworthy for the purposes of design conservatism and simplicity of implementation. The two primary factors contributing to this are the lesser amount of gravity load within the system as well as an altered load distribution associated with limiting the upper diaphragm length to only remain above the wall panels.

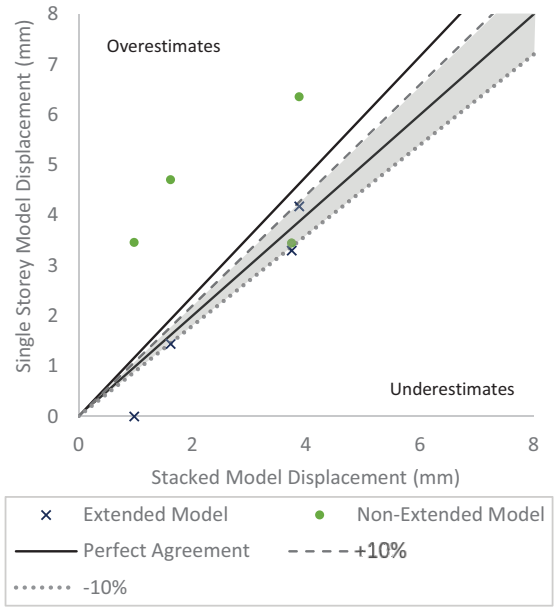

Figure 12: *Lateral displacement comparison between single storey models, against stacked CP models*

4.3 COMPARISON WITH ANALYTICAL RESULTS

The four-storey stacked shearwall was also analyzed using the analytical equations presented section 2. Given the observations regarding the importance of the extended floor diaphragm to the single storey CP models, a beam analogy including extensions equivalent to the stacked model was applied to better reflect the conditions within the stacked model (Figure 13).

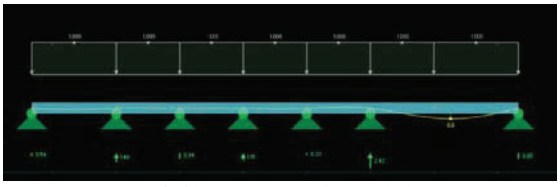

Figure 13: *Extended beam analogy for CP behaviour*

The elastic modulus used within the beam analogy is as presented in Table 2. Table 10 presents the equivalent vertical loads used in combination with the beam analogy, which includes adjustments based on the net reactions from the upper storey (Equation (3)).

https://doi.org/10.52202/069179-0364

Table 10: *Analytical vertical distributed loads*

Storey	Q (kN/m)
4	10
3	33.5
2	57.9
1	87.8

The results of the analysis of the four-storey shearwall acting in the CP kinematic mode are presented in Table 11, where similarly to the extended single storey model no rotation was obtained for the bottom storey. The analytical equations performed similarly to the extended single storey model, with overall good agreement with the four-storey stacked model (Figure 14).

Table 11: *Analytical results for four-storey CP shearwall*

Storey	Δ_h (mm)	θ (mrad)	R_h (kN)	Total Lateral Displacement (mm)
4	3.40	1.13	16.9	9.78
3	4.38	1.46	21.9	6.38
2	2.00	0.67	13.2	2.00
1	0	0	0	0

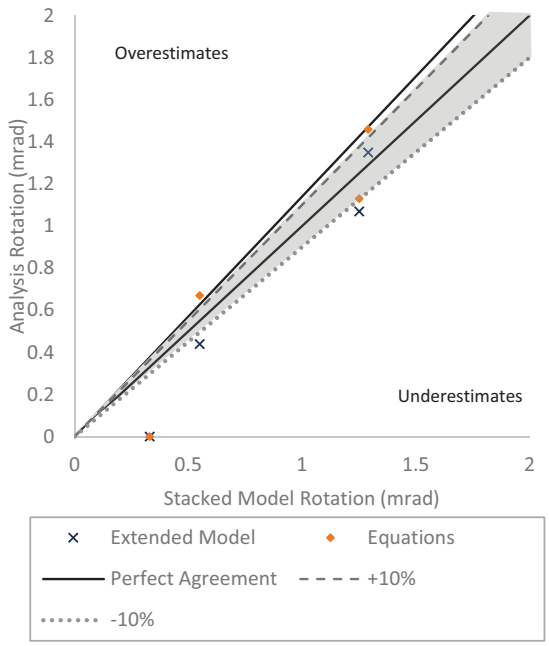

Figure 14: *Rotation angle comparison of proposed analytical expressions and extended model (single-storey), against stacked model*

4.4 FLOOR DIAPHRAGM EFFECT

In order to investigate the sensitivity of the analytical assumptions and finite element model, properties of the diaphragm were varied in both the beam analogy and the finite element model to evaluate the consistency of the results.

The beam analogy, evaluated via one-dimensional modelling, showed no variations in load distribution as elastic modulus of the diaphragm changed. Small variations were observed when changing the depth of diaphragm section, but as shown in Table 12 the discrepancies were minimal within the range of common CLT panel thicknesses. In this analysis, the beam analogy was applied to an isolated five-panel shearwall assumed to have a rotationally fixed boundary condition beyond the last panel, to simulate the effect of continuity on the modelled part (Figure 15).

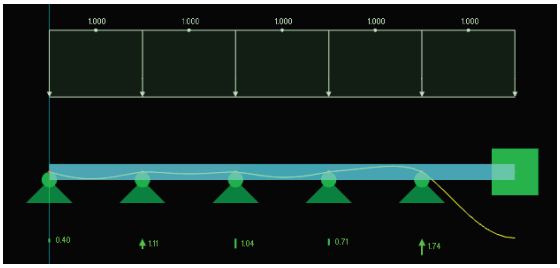

Figure 15: *Beam analogy used in section depth study*

Table 12: *Variation in load factor with diaphragm depth*

Section Depth (mm)	P_1 Factor	P_2 Factor	P_3 Factor	P_4 Factor	P_5 Factor
105	0.40	1.11	1.04	0.70	1.74
175	0.40	1.11	1.04	0.71	1.74
245	0.40	1.11	1.04	0.72	1.73

The sensitivity to floor diaphragm properties was further investigated by varying the effective bending modulus of the modelled floor within the finite element model. As presented in Figure 16, the model results remain consistent until the upper floor bending stiffness is significantly lowered, with only a 3% difference in displacement observed at an 89% reduction. At this point, the diaphragm remains in significant contact with the top surface of the wall panel during displacement and the transfer of forces extends beyond the corner of the modelled panel. As a result, the rotational resistance due to gravity load is reduced by shortening the moment arm and the system displacement begins to increase.

https://doi.org/10.52202/069179-0364

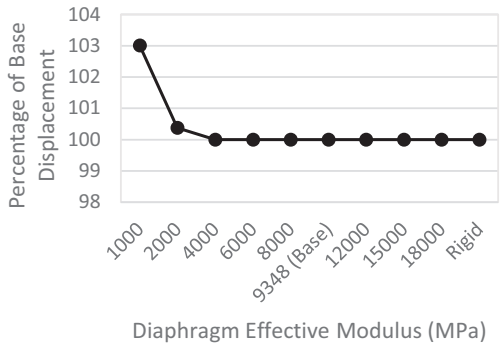

Figure 16: *Variation in model displacement with upper diaphragm stiffness*

While this behaviour contradicts the assumptions of the analytical equations, a floor diaphragm of reasonable stiffness for a CLT panel acting out of plane is expected to be sufficient for the assumed behaviour to remain valid.

These results indicate that the beam analogy for load distribution is reliably applicable to diaphragms in multi-storey platform-type CLT construction, and strengthens the assumptions used in the analytical method for wall behaving in the CP kinematic mode.

5 CONCLUSIONS AND FUTURE WORK

The analytical equations developed in this paper expand upon previous work and provides an approach to calculate displacements and forces in multi-storey CLT shearwall systems while including the effect of floor diaphragms. The results have shown reasonable accuracy when compared against finite element modelling, and the underlying assumptions simplify the individual contributions of the resisting elements while maintaining the complexity of the response. The assumptions regarding the distributive effect of the floor have been shown to be reliable at practical stiffnesses.

Future developments on the topic include expanding the analytical method to include SW kinematic behaviour. Additional modelling analysis can also be used to study and verify equations for more complex systems of shearwalls.

DEFLECTION OF CANTILEVER CROSS-LAMINATED TIMBER DIAPHRAGMS UNDER IN-PLANE LOAD

Bibek Bhardwaj[1], Weichiang Pang[2], Michael Stoner[3], Douglas Rammer[4], Steve Pryor[5]

ABSTRACT: Diaphragms are used to transmit lateral loads to the vertical elements (e.g., shear walls) of the lateral force resisting system of a structure. The extent of deflection in diaphragms can determine what mechanism needs to be considered during design for transfer of forces to the vertical elements. Current design specifications do not provide equations that engineers can use to determine the deflections in cantilever Cross-Laminated Timber (CLT) diaphragms. In this paper, the CLT shear wall equation prescribed by 2021 Special Design Provisions for Wind and Seismic (SDPWS) was adapted to get an equivalent analytical equation for cantilever CLT diaphragm deflection. A full scale 6.1 m x 6.1 m (20 ft. × 20 ft.) cantilever CLT diaphragm was tested using displacement controlled cyclic protocol and the deformations at various regions of the diaphragms were measured. Analysis of test results suggests that the modified shear wall deflection equation for a cantilever CLT diaphragm based on SDPWS overpredicts the contribution due to bending and shear deformations.

KEYWORDS: CLT Diaphragm, Diaphragm Deflection, Cantilever, Deflection equation

1 INTRODUCTION

Deflection in diaphragms is an essential consideration for structural design. Excessive deflection in diaphragms is often undesirable as the stiffness of diaphragms can affect storey drifts [1]. The U.S. standard for Minimum Design Loads and Associated Criteria for Buildings and Other Structures (ASCE 7-22) [2] section 12.12.1 sets criteria for allowable design story drift limits. To quantify the distribution of shear forces to the vertical elements, diaphragms are often idealized to be completely flexible or rigid. Section 12.3.1.3 of ASCE 7-22 permits diaphragms to be idealized as flexible if the maximum in-plane diaphragm deflection is greater than twice the average deflection of adjoining elements of the vertical lateral force resisting system (VLFRS). For flexible diaphragms, shear forces are distributed to the VLFRS based on tributary area while for rigid diaphragms, shear forces are distributed based on the relative lateral stiffness of the elements of VLFRS. For light frame diaphragms, section 4.2.4 of the 2021 Special Design Provisions for Wind and Seismic (SDPWS) [3] provides three-term equations for determining in-plane deflections of cantilever diaphragms of cases of uniformly distributed load and concentrated load at the end of the diaphragm. Cross Laminated Timber (CLT) was introduced in the 2015 version of the National Design Specification for Wood Construction (NDS) [4] but such provisions are not yet available for cantilever CLT diaphragms. In this research, the equation for CLT shear walls provided by SDPWS was utilized to get an equivalent expression for deflections in a cantilever CLT diaphragm. The analytical equation was evaluated by comparing its predictions to the observations made during a full-scale test of a 6.1 m x 6.1 m (20 ft. × 20 ft.) cantilever CLT diaphragm.

2 BACKGROUND

In case of light frame diaphragms, the SDPWS provides a three and four-term equation for determining the end deflection of a simply supported diaphragm (equations C4.2.3-2 and C4.2.3-1 respectively) for uniformly distributed load case. For cantilever diaphragms, SDPWS provides three-term equations for determining in-plane deflections for both uniformly distributed and concentrated load at the end cases (equations 4.2-2 and 4.2-3 respectively).

The equation provided by SDPWS for deflection at the free end of a cantilever light frame diaphragm under concentrated point load (4.2-3) is as follows:

$$\delta_{dia} = \frac{8vL'^3}{EAW'} + \frac{vL'}{1000G_a} + \frac{\sum x'\Delta_c}{W'} \qquad (1)$$

Where,

δ_{dia} = deflection at free end of the diaphragm, in.
v = unit induced shear, plf
L' = length of diaphragm, ft.
E = modulus of elasticity of diaphragm chords

[1] Bibek Bhardwaj, Clemson University, USA, bibekb@clemson.edu
[2] Weichiang Pang, Clemson University, USA, wpang@clemson.edu
[3] Michael Stoner, Clemson University, USA, mwstone@clemson.edu

[5] Steve Pryor, Simpson Strong-Tie, USA spryor@strongtie.com

https://doi.org/10.52202/069179-0365

G_a = apparent diaphragm shear stiffness from nail slip and panel shear deformation, kip/in.
x' = distance from chord splice to free end of diaphragm
Δ_c = diaphragm chord splice slip, in.
W' = total width of the diaphragm, ft.

The principal modes of deflection for equation 1 are assumed to be deflection due to bending (of the chords, excluding slip), shear deformation (of the panels, excluding slip), shear deformation due to nail slip in the panels and deformation due to anchorage slip. In case of CLT diaphragms, one of the early attempts at quantifying deflections was carried out by Spickler et al. [5] in a horizontal CLT diaphragm deflection design example. The equation presented in the design example was expanded from the four-term diaphragm deflection equation for light frame diaphragms. Unlike light frame diaphragms, where the flexural and shear members are distinct (the flexural deformation is considered only for the chord members while shear deformation is considered only for the sheathing material), for CLT diaphragms, the CLT panels themselves were designed as chord and shear members, capable of withstanding both bending and shear.

In the 2021 version of the SDPWS, section 4.5.2 suggests determining the deflection in a CLT diaphragm using principles of engineering mechanics without explicitly providing an equation. To help engineers and design practitioners come up with an estimate for diaphragm deflection for different layouts and configurations, Lawson et al. [6] have provided recommendations to estimating the various components of deflections in a CLT diaphragm.

Section 4.6.2 of SDPWS suggests determining deflection in CLT shear walls using principles of engineering mechanics as well but provides an equation for calculating the deflection in appendix B.4. Commentary on appendix B.4 provides further insights to the equation and its assumptions. Due to the similarity in layout between a CLT shear wall and a cantilever CLT diaphragm, an equivalent expression for CLT diaphragms can be determined based on the equations for CLT shear walls in the SDPWS.

The equivalent expression for free end deflection in a CLT diaphragm under concentrated point load at the end, generalized for different fastener types (not just nailed spline connection) is given as follows:

$$\delta_{dia} = \frac{576 v P_w L^3}{EI_{eff(in-plane)}} + \frac{vL}{GA_{eff(in-plane)}} + n_0 e_0 + e_{90}\frac{L}{P_W} + \frac{\Delta_a}{W} L \qquad (2)$$

Where,

δ_{dia} = deflection at free end of the diaphragm, in.
v = unit induced shear, plf
P_W = individual panel width, ft.
L = length of diaphragm, ft.
$EI_{eff\ (in\text{-}plane)}$ = effective in-plane bending stiffness of CLT panel, lbs-in^2
$GA_{eff\ (in\text{-}plane)}$ = effective in-plane shear stiffness of the CLT panel, lbs/in. of panel length
n_0 = number of locations for longitudinal (parallel to load) shear fasteners
e_0 = deflection at each fastener location in., (= 0 for single panel diaphragm)
e_{90} = transverse fastener slip, in.
Δ_a = slip at the anchorage, in.
W = total width of the diaphragm, ft.

It should be noted that equation 2 uses customary units used in the US and includes an implicit unit conversion factor in the first term for calculating the deformation due to in-plane panel bending. Modification of equation 2 for SI units would require a modification to that factor.

Figure 1 shows all the deformation modes considered for the equation 2.

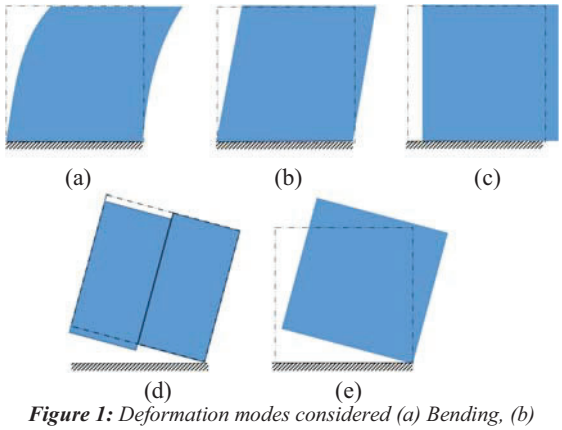

Figure 1: *Deformation modes considered (a) Bending, (b) Shear, (c) Longitudinal shear fastener slip (d) Transverse shear fastener slip, and (e) Anchorage slip.*

This paper takes results from an experimental test conducted on a cantilever CLT diaphragm and compares the deflections observed to the predictions made by the SDPWS based equation (equation 2).

3.1 LAYOUT

A 6.1 m × 6.1 m (20 ft. × 20 ft.) CLT diaphragm was tested destructively using displacement-controlled loading based on CUREE (Consortium of Universities for Research in Earthquake Engineering) [7] cyclic protocol [8]. The diaphragm was composed of four 1.5 m × 6.1 m (5 ft. × 20 ft.) panels resting on three 6.1 m (20 ft.) long 17.1 cm (6.75 in.) wide and 34.9 cm (13.75 in.) deep glulam beams along the short edges of the panels as shown in Figure 2. The long edges of the panels were connected using a 2.5 cm (1 in.) thick plywood surface spline using 16d common nails at 7.6 cm (3 in.) c/c as shown in Figure 2. The detailing for the surface spline

https://doi.org/10.52202/069179-0365

connection is shown in Figure 3. The CLT panels were connected to the glulam beams underneath using Simpson strong Tie's SDWS22800DB screws at 15.2 cm (6 in.) c/c on the two outside glulam beams and 20.3 cm (8 in.) c/c on the middle glulam beam (Figure 2). Custom made Simpson Strong Tie hold-downs were installed 25.4 cm (10 in.) from the edges on both sides (Figure 2).

The load was applied using a hydraulic actuator attached to the free end glulam beam.

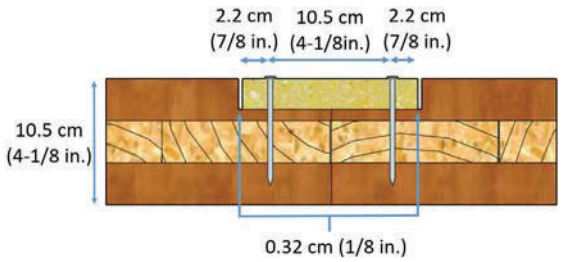

Figure 3: *Surface spline detail*

3.2 DESIGN OF CLT DIAPHRAGM

The diaphragm was designed (for seismic considerations) using recommendations from a design example [5] and SDPWS 2021. The diaphragm had a Load and Resistance Factor Design (LRFD) in-plane shear capacity of 98.3 kN (22.1 kip) based on the strength of the surface spline nailed connection. The Allowable Stress Design (ASD) capacity of the diaphragm was 70.2 kN (15.8 kip). The CLT-glulam screws were designed to have an additional 61% capacity over the design forces expected at the CLT glulam interface. All other components of the diaphragm were design to have at least two times the capacity compared to the design level forces at the respective component per the requirements of SDPWS 2021. The LRFD capacity summary for the diaphragm components is given in Table 1 [8].

Table 1: *LRFD capacities of Diaphragm Components (seismic design)*

Component	Required Capacity*	Design Capacity	Strength Ratio**
	kN (kip)	kN (kip)	
Panel-Panel nailed surface spline	98.3 (22.1)	98.3 (22.1)	1:1
Panel-Glulam screws	98.3 (22.1)	158.4 (35.6)	1.6:1
Tension Chord	222.4 (50)	323.8 (72.8)	2.9:1
Compression Chord	222.4 (50)	327.4 (73.6)	2.9:1
Hold-downs	222.4 (50)	560.5 (126)	5:1

*required capacity for non-shear elements is twice the capacity obtained using design shear forces

**ratio of design capacity to capacity obtained using design shear forces

3.3 INSTRUMENTATION SETUP

Figure 4 and Figure 5 show the location of the various string potentiometers used in the diaphragm test to track component deformations [8]. The load deformation response on the free end glulam beam was captured by the sensors in the hydraulic actuator. Figure 4 also shows the two load cells (LC1 and LC2) used to capture the uplift force experienced by the diaphragm at the hold-down location.

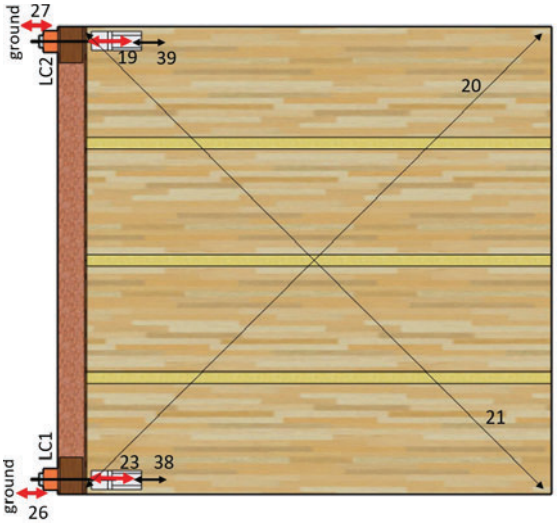

Figure 4: *String pot and hold-down layout on the top of the diaphragm*

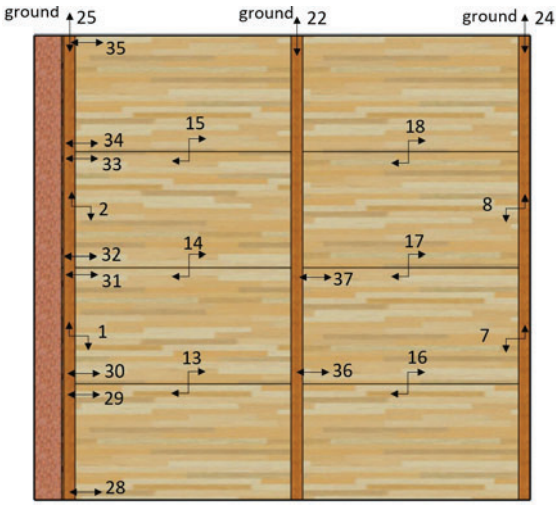

Figure 5: *String pot layout on the bottom of the diaphragm*

It should be noted that the instrumentation was not setup to capture the bending and shear deformations (described in Figure 1a and Figure 1b).

4 RESULTS AND OBSERVATIONS

4.1 OVERALL BEHAVIOUR OF DIAPHRAGM SETUP

Figure 6 shows the hysteresis for the applied displacement vs force observed for the diaphragm test setup [8]. The summary of the test results is shown in Table 1 [8]. The diaphragm setup displayed a relatively symmetrical behaviour for positive and negative cycles. The average initial stiffness of the setup was 24.1 kN/cm (13.8 kip/in.). The peak capacity of the diaphragm exceeded its LRFD capacity by a factor of 1.7. Through the observation of deformations during the test, it was inferred that the peak capacity of the diaphragm was primarily governed by the capacity of its surface spline nailed connection which was consistent with the design detail. Deformations could be visually observed on the surface spline nailed connection, the CLT-glulam screw connection and in the hold-down connection. No significant bending and shear deformation of the panels could be visually observed during the test. Thus, the primary energy dissipation mechanism was concluded to be governed by the various mechanical fasteners utilized in the diaphragm setup, with the CLT panels acting as rigid members. The mechanical fasteners also induced ductility to the diaphragm.

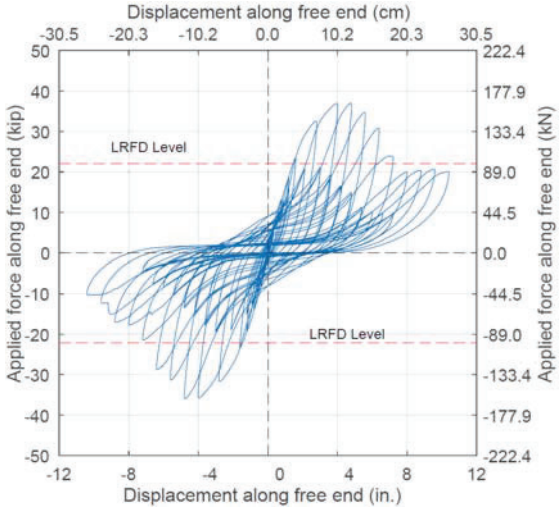

Figure 6: *Force vs displacement hysteresis for the diaphragm test*

Table 2: *Summary of the Diaphragm test*

Design LRFD load	98.3 kN (22.1 kip)
Peak positive load	164.5 kN (37 kip)
Peak positive displacement	11.4 cm (4.47 in.)
Initial stiffness (positive)	22.4 kN/cm (12.8 kip/in.)
Peak negative load	160 kN (36 kip.)
Peak negative displacement	11.2 cm (4.41 in.)
Initial stiffness (negative)	25.6 kN/cm (14.6 kip/in.)
Average peak/LRFD strength	1.7

4.2 DEFLECTIONS AT VARIOUS FORCE LEVELS

Figure 7 and Figure 8 show the contribution of fastener deformation to total diaphragm deflection at various force levels for positive and negative cycles respectively. The force level values in the figures indicate the first time those values were reached during the diaphragm test. The diaphragm level deformations were calculated from the fastener level deformations for nailed surface spline slip (transverse shear fastener), screw slip (longitudinal shear fastener) and slip in the hold-down assembly (anchorage) using the equation 2. The bending and shear deformations which were back calculated by subtracting all other deformations from observed diaphragm deflection. This was done because the test setup did not have sufficient instrumentation to properly isolate contribution due to bending and shear deformations.

Figure 7 and Figure 8 also show the SDPWS based (theoretical) estimates for total bending and shear deformations while Table 3 shows the numerical values.

Table 3: *SDPWS based estimates for bending and shear deformations at various force levels.*

Force level kN (kip)	Bending Def. cm (in.)	Shear Def. cm (in.)
22.2 (5)	0.208 (0.082)	0.107 (0.042)
44.5 (10)	0.417 (0.164)	0.213 (0.084)
70.3 (15.8) - ASD	0.658 (0.259)	0.337 (0.133)
98.3 (22.1) - LRFD	0.921 (0.362)	0.472 (0.186)

https://doi.org/10.52202/069179-0365

The plots suggest that SDPWS based calculation overpredicts the contributions due to bending and shear deformations in a cantilever CLT diaphragm.

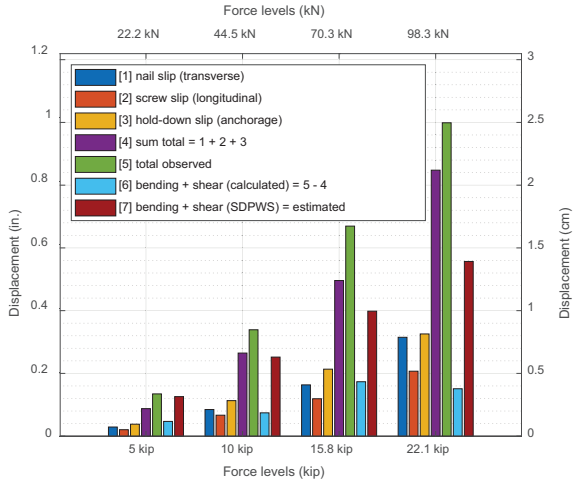

Figure 7: *Contribution of fastener deformation to total diaphragm deformation for positive cycle, ASD = 70.3 kN (15.8 kip), LRFD = 98.3 kN (22.1 kip)*

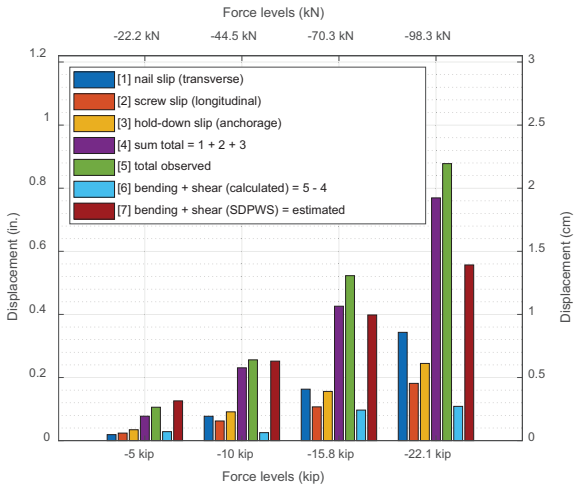

Figure 8: *Contribution of fastener deformation to total diaphragm deformation for negative cycle, ASD = 70.3 kN (15.8 kip), LRFD = 98.3 kN (22.1 kip)*

The back calculated values for bending and shear deformations were 34.8% and 26.8% of the total diaphragm deflections at force level of 22.2 kN (5 kip) for positive and negative cycles respectively. At LRFD level of 98.3 kN (22.1 kip), the back calculated values for bending and shear deformations were 15.1% and 12.4% of the total diaphragm deflection for positive and negative cycles respectively. The bending and shear deformation predicted by SDPWS would have been 93.6% and 119% (i.e., exceed observed diaphragm deflection value) at 22.2 kN (5 kip) for positive and negative cycles respectively. Similarly, bending and shear deformations predicted by SDPWS would have been 55.8% and 63.4% of the total predicted deflection at LRFD level for positive and negative cycles respectively.

The deformations also suggest that the bending and shear deformations were more significant at smaller load levels. It is speculated that as the load levels increased, the bending and shear deformation increased linearly while the other deformations increased non-linearly (at a higher rate), thus leading to lower contribution of bending and shear deformation at higher load levels as the fasteners which have started to deform and yield begin to experience more deflection relative to the CLT panels in bending and shear.

5 CONCLUSIONS

During design, the ratio of deflection in diaphragm to the adjoining components of the VLFRS can be utilized to idealize flexible, rigid or semi rigid diaphragm behaviour which governs the mechanism for force transfer to the vertical elements. The various mechanisms contributing to deflections in cantilever CLT diaphragms were investigated. Observation of deflection data from the test suggested that the equation derived using the in SDPWS equation for CLT shear wall over predicts the contribution of bending and shear deformations. Further experimental testing with instrumentation setup for capturing bending and shear deformations seems necessary to develop equations capable of providing a more accurate prediction for those terms.

EXPERIMENTAL ANALYSIS OF THE INFLUENCE OF OPENINGS IN THE DEFLECTION OF CROSS-LAMINATED TIMBER PLATES LOADED OUT OF PLANE

Pablo González-Serna[1], Miguel Yurrita[2], José Manuel Cabrero[3]

ABSTRACT:

This paper presents a series of experimental tests that were conducted to investigate the effect of openings on the deformation of cross laminated timber (CLT) floor panels. A comparison is made between the tests results and different FE shell models and simplified beam models developed for prediction. The research aims to provide new design criteria and user-friendly models to enhance the predictability of CLT structures and increase its versatility as a building material.

KEYWORDS: CLT, cross-laminated timber, mass timber, floors, openings, experimental investigation, modelling

1 INTRODUCTION

Cross Laminated Timber (CLT) is increasingly gaining recognition and popularity in the construction industry. This technological timber product combines crosswise oriented layers of timber bonded together by adhesives, resulting in large panels (of maximum sizes around 3m wide and 15 m long) that allow to develop mass prefabricated structures based on timber wall and floor panels. The combination of prefabricated walls and floors enables to a fast erection of many types of constructions, from small structures such as dwellings to very tall buildings. Full size wall and floor panels can be manufactured on demand, and easily installed on site. This includes the possibility to include cut-outs in the panels, such as windows or doors in wall elements. In the case of floors, these openings can be part of staircases, service conduit shafts or skylights.

Knowing the influence of such openings in the mechanical behavior and distribution of forces within the panels is key to seize the capabilities of the material, and design rules and verification methods are in demand among practitioners [1].

1.1 MODELS

Different studies have investigated the influence of openings on CLT shear walls, such as Shanewaz et al. [2], Casagrande et al. [3] and Awad et al. [4]. Stress concentrations around openings on CLT column-slab connections have been studied by Muster [5]. However, there is limited research on the influence of openings on CLT slabs under bending, which is the most usual demand/case.

A simplified approach to predict the behaviour of and verify openings on CLT slabs are grillage models. In this method, the slab geometry is divided into a system of longitudinal and transversal beams that can be analysed independently to determine forces and displacements around holes in the two main directions of the panel. Wallner-Novak et al. [7] describe the application of this method to centered openings in simply-supported longitudinal slabs with uniform distributed load. In this model, a beam width equal to one tenth of the span length is assumed.

Hast and Fatemi [6] compared the results of the grillage model from [7] with finite element models and found that the grillage model provided very conservative results in all cases, and required further adjustments. The possible influence of stress concentrations around the perimeter of the holes was not addressed in the study.

In practice, the most common approach to model CLT are finite element models (FEM) with two-dimensional shell components. This type of model combines Mindlin-Reissner thick plate theory and membrane theory [8], allowing to render axial, bending and shear stiffness, as well as the in-plane and twisting stiffness of panels. All these stiffness components are described by the material stiffness matrix, which can be derived from the orthotropic properties of the different timber layers, through the application of the laminate theory.

1.2 AIM AND OBJECTIVES

The presented research aims at bringing new insights into the influence of openings in CLT slabs on both ultimate limit state (ULS) and serviceability limit state (SLS), with the goal of making the use of CLT more efficient and user-friendly [9].

This paper, presented in companion with [10], describes a portion of the results obtained from the conducted test campaign, along with a description of the various analytical models utilized to predict the elastic behaviour of the panels. The experimental outcomes are presented and compared with the predictions made by the different models.

2 EXPERIMENTAL TESTS

2.1 TEST CONFIGURATION AND MATERIAL

To study the influence of openings in the behaviour of the panels, two series of panels were tested, one for analyzing the behaviour of the opening under bending and the second under shear, as depicted in Figure 1.

All specimens were made with a similar layup, a 5-layer composition with outers and mid layer in the parallel direction and odd layers crosswise bonded (0º-90º-0º-90º-0º) and a total panel height of 100 mm. Lamellas were made of European spruce (*Picea Abies*) graded as C24 (strength grade according to EN 338 [11], which corresponds to a bending strength of 24 MPa). Lamellas were 20mm thick, 230mm width, and non-edge glued. Individual lamellas with finger joints were fabricated according to EN 14080 [12].

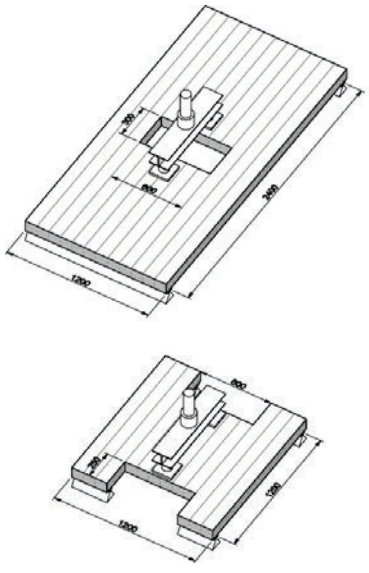

Figure 1: *Bending and shear test series.*

Test configurations were designed based on EN 16351 and EN 408 normalized tests [13]. Panel length, distance between supports and load application distance were set as a proportion of the panel height. Panel width was set to 1200 mm, so that openings of different widths could be tested, and bending in the secondary direction could be activated. Load was applied on two points, to induce bending in the two main directions. Square-shaped pinned pressure plates of 200 mm width were used.

The conducted experimental campaign involved testing full panels (without holes) within the elastic range, followed by testing the same panels with a 300 mm wide opening, also within the elastic range, and finally testing the panels with a 600 mm wide opening until failure. This paper presents the result of the non-destructive tests, which were conducted to evaluate the displacement predictions of different models.

2.1.1 Preliminary tests and material properties

Different material properties were evaluated experimentally before doing the cut-outs on the panels. Density of the panels was measured following the standard EN 408 [13]. The density was corrected to a reference moisture content of 12%, following the procedure of EN 384 [14]. Modulus of elasticity was determined on bending tests on panels without openings, following the test configuration from EN 16351 Annex C [15]. For these tests, a panel width of 1200mm was used. After testing all panels, rolling shear tests were conducted, according to EN 16351 [15] and EN 789 [16]. Rolling shear test specimens, as the one shown in Figure 2, were obtained from the opening cut-outs. Table 1 presents a summary of the obtained results.

Table 1: *Material properties obtained during the preliminary tests.*

Preliminary tests		
Property	Mean value	COV [%]
Density ρ [kg/m^3]	438,40	1,78
Full Cross-Section MOE $E_{CL,net}$ [N/mm^2]	13.578,59	5,53
Effective Shear Modulus G_{eff} [N/mm^2]	554,00	22,62
Longitudinal Shear Modulus G_0 [N/mm^2]	895	-
Rolling Shear Modulus G_R [N/mm^2]	41	19

https://doi.org/10.52202/069179-0366

Figure 2: *Rolling shear test.*

2.1.2 Bending series

Bending series was designed according to the configuration described in the bending test with load perpendicular to the plane from EN 16351 [15]. Distance between supports was set to 2400 mm, and the load application points were separated 600 mm. The overall size of the panels was 2500 x 1200 mm.

Figure 3: *Bending test.*

Openings were cut in the centre of the panel, following a symmetric configuration in the two main directions. Panels were tested within the elastic range. First, without any opening, then with an opening of 300 x 300 mm and lastly with an opening of 300 x 600 mm. Table 2 presents the various opening geometries that were tested on each specimen.

Table 2: *Test iterations on bending series.*

Bending series		
Test iteration	Opening width w_h (mm)	Opening length l_h (mm)
1	0	0
2	300	300
3	600	300

During the three tests, vertical displacement was measured around the opening, under the load application point and at the center of the panel edges, following the pattern illustrated in Figure 4.

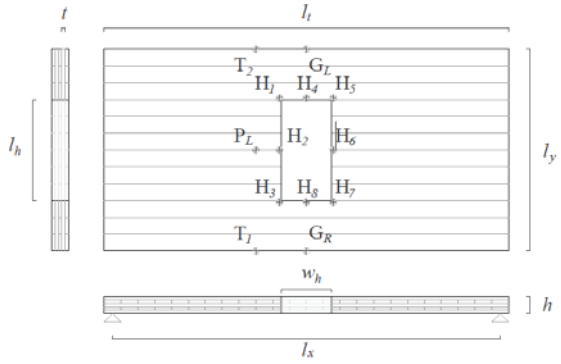

Figure 4: *Measuring points for vertical displacement in bending test series.*

2.1.3 Shear series

Shear series was designed according to the configuration of the bending test for determination of shear strength and stiffness from EN 16351 [15]. The overall size of the panels was 1300 mm long and 1200 mm wide. The distance between supports was set to 1200 mm, and the two load application points were separated 600 mm, the same as in the bending series.

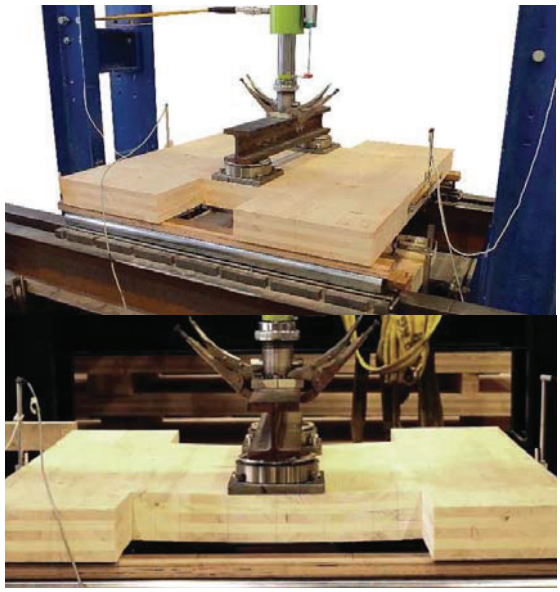

Figure 5: *Shear tests.*

Openings were cut at the supported edges of the panels, following a symmetric configuration in the two main directions. Panels were tested without any opening, then with two openings of 250 x 300 mm and lastly with an opening of 300 x 600 mm.

Table 3: *Test iterations on shear series.*

Shear series		
Test iteration	Opening width w_h (mm)	Opening length l_h (mm)
1	0	0
2	300	250
3	600	250

Vertical displacements were measured around one of the openings, in the central point of the panel, and at the center of the panel edges.

3 MODELS

3.1 ANALYTICAL MODELS

Beam grillage models [7] simplify the analysis by decomposing the floor slab with an opening into a grillage system composed of six beams. Each beam can be analysed independently and later combined with the rest to determine the deflection of the slab. Wallner-Novak et al. [7] describe this system for a rectangular slab with supports in two sides with a central rectangular opening. This method assumes a minimum strip width between the opening and the slab edge of one tenth of the span length l_x must remain.

Since the beam model proposed by Wallner-Novak [7] is for distributed load, a direct comparison with the test results, where point loads were applied, is not possible. Thus, two alternative assumptions have been considered for the validation.

In the first beam model (BM 1) the force is applied as a point load on both transverse beams 3 and 4. The second beam model (BM 2) considers an equivalent uniform distributed load obtained by redistributing the force around the panel surface. The equivalent distributed load is obtained by dividing the reference force F by the surface area of the slab A, as follows:

$$q = \frac{F}{A} = \frac{F}{(l_x l_y) - (l_h w_h)}$$

In both cases, an extra load equal to the self-weight of the panel is considered, obtained from the thickness of the slab h and the density of the panel ρ. The bending stiffness of the beams was assessed with the Modified Gamma Method [17], an adaptation to CLT of the method for composite structural elements included in the Eurocode 5 Annex B [18], originally proposed by Blass and Görlacher [19]. In the herein case of a CLT panel, the rolling shear stiffness of the transverse layers is considered, instead of the stiffness of the connectors. By including the shear influence, the corresponding deformation is increased.

$$(EI)_{ef} = E_{0,mean} \cdot I_{ef,net}$$

$$I_{ef,net} = \sum_{i=1}^{n} (I_i + \gamma_i \cdot A_i \cdot a_i^2)$$

The scheme of the load application and distribution in the two models is given in Figure 6.

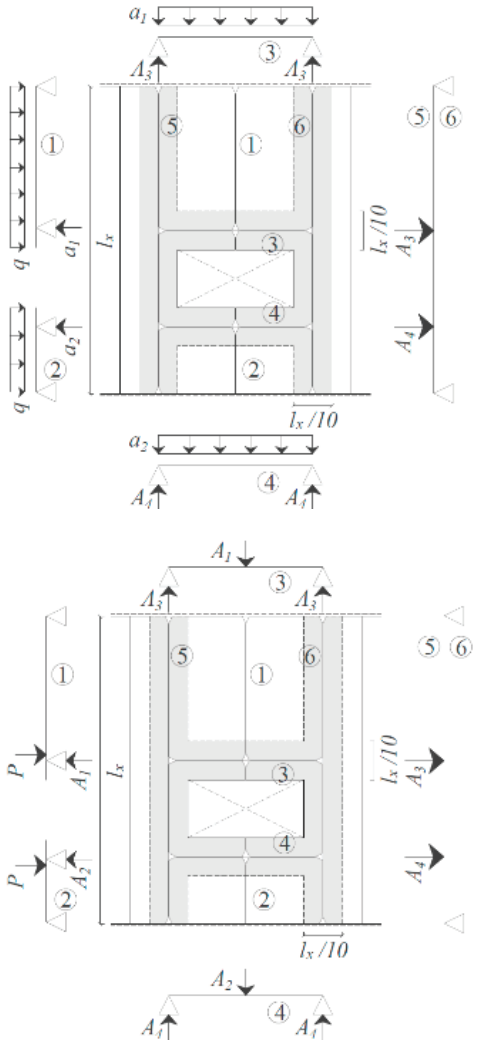

Figure 6: *Load application in beam model with distributed load (top) and beam model with punctual load (bottom).*

In the beam models with distributed load (BM 2), the force was applied to the transverse beams 3 and 4 as a distributed load equal to the reaction force of beams 1 and 2. Longitudinal beams 5 and 6 included both a distributed load and the reaction forces of the transverse beams. In the models with punctual load (BM 1), beams 1 and 2 were neglected, and the load was directly applied to the transverse beams 3 and 4 as punctual forces at their centers, and transferred to beams 5 and 6 as reaction forces. Both models assumed pinned beams. Additionally, to adapt the model with distributed load to the shear series, beams 1 and 2 were replaced by a single loaded beam connecting the center of beams 3 and 4.

https://doi.org/10.52202/069179-0366

3.2 FINITE ELEMENT MODELS

Linear finite element (FE) analyses have been performed using the software RFEM DLUBAL [20]. A parametric study has been carried, analyzing configurations with different opening widths, from 0 to 900 mm with steps of 100 mm.

The FE models were made with 2D shell elements, with stiffness matrix components derived from the individual layer properties according to the lamination theory [8]. Layers were modelled as non-edge glued by neglecting the stiffness in the transverse direction (E_y=0). Correction factors were applied to the torsional and membrane stiffness of the shell elements, according to Austrian National Annex of the Eurocode 5 [21]. The reduction factors for torsional stiffness D_{33} and membrane stiffness D_{88} were set to 0,59 and 0,68 respectively.

A quadrangular mesh with a density of 50 mm was implemented, so that there were always at least 4 elements within the width of the edge of the opening. Displacements were measured at the same points as the recorded displacement in the experimental tests and correspond also to the calculated points in the beam grillage model .

A first set of models (FE 1) was created using the mechanical properties declared in the ETA-06/0138 [22]. In the second set (FE 2) the material model was defined from the properties obtained experimentally in the peliminary tests. The FE models are shown in Figure 7.

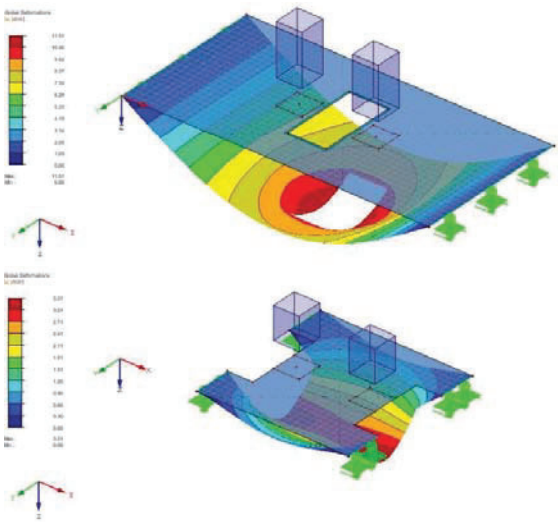

Figure 7: *FE models: bending series (top) and shear series (bottom).*

4 RESULTS AND DISCUSSION

The following graphs show a comparison of displacements from the tests, the FE models and the beam models. The displacement of three representative points is studied, whose location is based on those easily obtained from the beam models. These points are (A) the center of Beam 3, (B) center of Beam 5, and (C) the point where Beam 3 is supported by Beam 5. Points are shown in the diagrams in Figure 6. These points were directly studied on the FE models. However, in the case of the test results, some adjustments were required to do the comparison, since the measuring points were fixed for the three openings studied.

The comparison of the test results and the four cases derived from the analytical models is plotted for bending and shear specimens, respectively. The displacements for the three already described points are plotted separately: the center of Beam 3 (A) is presented in Figure 8 and Figure 11, the center of Beam 5 (B) is studied in Figure 9 and Figure 12, and the support of Beam 3 (C) is given in Figure 10 and Figure 13.

In all the graphs, the abscissas axis accounts for the width of the hole(s) of the slab, while the ordinates axis displays the displacement of the corresponding point. The results of the tests, which consider three cases of holes of widths 0, 300 and 600 mm, are plotted as single values. The behaviour of each of the four models is plotted with curves that consider an opening width range between 0 and 900 mm (when possible), and therefore allow to observe the trend in the response of each case.

The performance of the models clearly differs when considering bending or shear tests. The accuracy of the models is much higher in the bending series, while the displacements predicted for the shear cases are generally lower than the experimental results. It can also be clearly seen that, in all the graphs, the influence of the hole's width is not linear. This trend is reflected in the test results, the FE curves, and the beam models with distributed loads (BM 2). However, the beam model with point loads (BM 1) sometimes exhibits a linear behavior, as noticed for the case of support of beam 3, and in beam 5, for both bending and shear tests. This is due to the assumption of pinned beams, resulting in consistent reaction forces from beams 3 and 4 to beams 5 and 6 being in all hole width scenarios. Despite that, this model tends to predict higher deformations, leading to a more conservative model. No big difference is found between the FE models when considering different material properties.

PHENOMENOLOGICAL MODEL FOR SEISMIC DESIGN OF MULTI-STOREY CLT BUILDINGS: CALIBRATION OF INPUT PARAMETERS

Luca Pozza[1], Stefano Pacchioli[2], Andrea Polastri[3] , Valentino Nicolussi[4], Diego A. Talledo[5], Ian Smith[6]

ABSTRACT: A numerical modelling approach for the prediction of the seismic response of multi-storey CLT buildings is proposed. The approach is based on a simplified phenomenological model where the behaviour of the CLT system is reproduced by means of an equivalent elastic modulus assigned to the CLT wall in order to account for both the connections and panel deformability. Phenomenological modelling aims to reproduce faithfully the global response of the structural system in terms of principal elastic period, internal forces in the connection elements and inter-storey drifts. Results of a multy-parametric analyses carried out on different CLT walls, deigned considering increasing level of seismic intensity, are presented and discussed. A design abacus that allows designers for a direct implementation of the proposed phenomenological model and therefore an easy and efficient seismic analysis of a CLT building is finally proposed.

KEYWORDS: Cross-Laminated Timber, CLT building, numerical model, phenomenological modelling approach, seismic design, Timber structures

1 INTRODUCTION

Cross-laminated timber (CLT) is a material suitable to realize multi-storey earthquake-resistant buildings, characterized by timber lightness and by high in-plane strength and stiffness of the massive cross-laminated panel. For these reasons and due to simplicity and rapid execution, CLT buildings have become increasingly common over the last few years [1-2]. However, how to model the CLT buildings, especially under seismic actions, is still an open issue. Several researches study CLT panels mechanical behaviour under cyclic and seismic actions [3-4]; another important discussed topic is related to the panels assembling [5-9] and the presence of openings [10-11]. Connection characterization is a crucial aspect in order to obtain proper input data for the numerical models [12-13]. Results of the different modelling approaches available in literature demonstrate to be quite heterogeneous and do not allow to draw reliable outcomes especially for the case of linear analyses of buildings. Two main modelling approaches are typically adopted in literature for linear analyses of CLT buildings: the first one is a *component model* (*CM*), which adopts elastic springs for connections and elastic elements for the CLT panel generally represented as a lattice grid or as a 2D continuum, while the second one is a simplified *phenomenological model* (*PM*), where the behaviour of the system is reproduced by means of a conventional equivalent elastic stiffness assigned to the CLT wall and capable of accounting for the deformability of the CLT panel and connections assembly [14]. *CM* is typically adopted in the research field and involves a high computational effort since each component of the CLT system must be modelled and properly calibrated. After proper calibration, CM allows to account for the tension-shear behaviour of the connection elements [15-16]. Differently, the *PM* is easier and faster to use respect to the *CM* and is typically adopted by practitioners since commercial software permits to implement the letter straightforward. The aim of the present work is to suitably calibrate the equivalent stiffness that has to be assigned to CLT panels in a *PM* in order to reproduce the seismic behaviour of the entire CLT building. To provide reliable estimation of the equivalent stiffness for the *PM*, different case study configurations have been analysed varying the significant parameters controlling the building response such as number of storeys, connection pattern, geometry, wall slenderness. Results of the performed analyses are used to propose a design abacus that permits an easy implementation of a phenomenological models of a real CLT building by practitioners.

2 CALIBRATION PROCEDURE

Numerical response spectrum analyses have been conducted, comparing results of *CM* and *PM* in order to calibrate the correct equivalent stiffness (E_{eq}) to be assigned to CLT panels in the simplified phenomenological approach (Figure 1). Component-level (CM) modelling approach requires the calibration of constitutive laws for each component (CLT and connections) [17]. In detail CLT panels are modelled as an isotropic material (modulus of elasticity given by the weighted mean values of modulus in the parallel and perpendicular direction to the grain [18]) while connections are implemented as elastic springs (stiffness obtained from experimental tests).The PM modelling approach, at the opposite, disregards the contribution to the structural response given by each component of the system. Connection elements are not directly included in FE model and CLT panels are modelled assigning an equivalent elastic stiffness (i.e. modulus of elasticity) able to account for the deformability contributions of the connections and the panel itself.
In this work the equivalent elastic stiffness to be assigned to different configuration of CLT panels of the *PM* has been calibrated with an iterative procedure. In particular it was minimized an objective function which accounts for the difference between the value of certain control parameters (e.g. principal vibration period T_1, top displacement, inter-storey drift etc..) obtained with the *CM* and those obtained with the correspondent *PM* for the different building configurations.

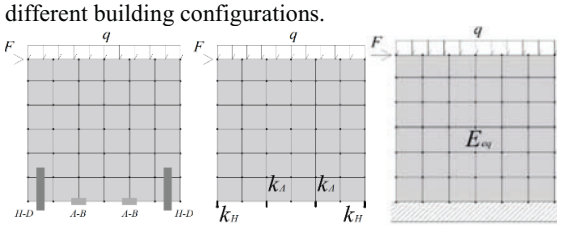

Figure 1: *Real configuration (left) component-level approach (centre) and phenomenological approach (right)*

A multi-parametric analysis was performed and an ad-hoc iterative procedure was implemented in order to provide a reliable definition of the equivalent modulus of elasticity (E_{eq}) to use in the modelling phase.
The iterative procedure starts selecting a certain shear-wall configuration characterized from a given geometry (length, height and thickness of the walls) and a given seismic mass and seismic intensity. The numerical-based approach consists in the iterative calibration procedure described below and schematized in Figure 2.

STEP 1 - definition of the connection pattern necessary to satisfying the different shear-walls configuration in terms of strength and deformability requirement;

STEP 2 - implementation of CM according to Polastri and Pozza [19]. Execution of the linear dynamic analysis to define the values of key parameters to be used for the subsequent calibration of the PM: principal vibration period (T_1^{CM}), base shear (V^{CM}), top displacement (δ^{CM}) and inter-storey drifts ($drift^{CM}$).

STEP 3 - consisted in the setting of the equivalent E_{eq} modulus of the CLT walls at each floor. It has been done thanks an implementation of PM performed with a linear dynamic analysis. The parameters taking into consideration in this analysis are: principal vibration period (T_1^{PM}), base shear (V^{PM}), top displacement (δ^{PM}) and nter-storey drifts ($drift^{PM}$).

ITERATIVE STEP - in the end the goal of this iterative calibration is the evaluating of equivalent modulus of elasticity (E_{eq}) in order to minimize the difference between the selected control parameters ($\Delta_j = Xj^{CM} - X_j^{PM}$). The iterative procedure ended when the comparison is acceptable ($\Delta_j < \Delta_{j_LIMIT}$) providing a reliable estimation of the equivalent elastic module E_{eq} to be used in the phenomenological approach.

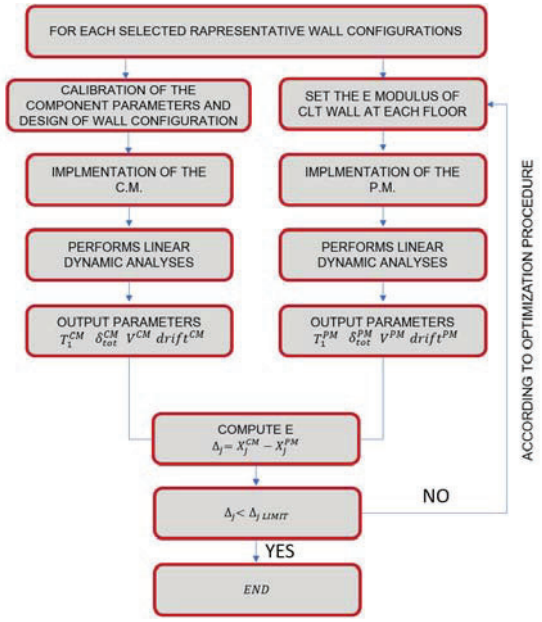

Figure 2: *Scheme of the conceptual iterative procedure for calibration of Eeq.*

The proposed methodology permit to overcome the inaccurate way of the behaviour evaluation of a simplified PM approach giving to a practitioner an extremely easier procedure of modelling thanks a calibration of a E_{eq} suitable for linear seismic analysis.

3 MULTI-PARAMETRIC FE ANALYSES

Numerical models of CLT walls were created using SAP2000 [20] Finite element code, Figure 3. A multi-parametric analysis was conducted considering the following variables: number of floors (3-5-7), base length of CLT panels (L=2,0m; 4,0m; 6,0 m), inter-storey height (assumed equal to 3m), seismic zone and seismic mass. All CLT wall configurations were modelled in 2-D

https://doi.org/10.52202/069179-0367

according to both a component-level approach and a phenomenological approach.

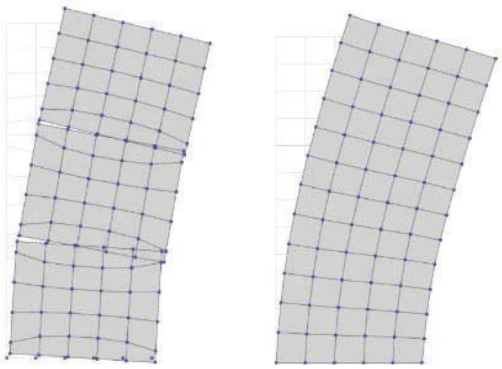

Figure 3: *Example of 3 storeys CLT wall implemented with CM (left) and PM (right)*

The earthquake action was calculated according to Eurocode 8 [9], using design spectra obtained with C soil type, a force modification factor q equal to 1.6. Two increasing levels of seismic intensity have been considered, respectively represented by PGA=0,25g (Low PGA) and 0,35g (High PGA).

Table 1 reports, for each considered configuration, the seismic mass on the wall at different floors.

Table 1: *Seismic mass at each level for each configuration.*

	L=2m		*L=4m*		*L=6m*	
Level	*High Mass* [t]	*Low Mass* [t]	*High Mass* [t]	*Low Mass* [t]	*High Mass* [t]	*Low Mass* [t]
Intermediate floors	3,8	5,6	7,6	11,3	11,4	16,9
Roof floor	1,9	2,8	3,8	5,65	5,7	8,45

Considering the two mass levels and the two seismic zones, a total of 32 different configurations were analysed.
Different pattern of connection specifically designed with regard to both resistance and deformability limit states characterized the different studied configurations. In the design the following connections were considered: WHT340-WHT620 and TTF200-TCF200, Hold-Down and Angle Bracket connection type, respectively. Table 2 reports the mechanical characteristics of the connections in terms of strength and stiffness. It is worth nothing that, for increasing number of storeys and for increasing level of seismic intensity it is necessary to use a larger the number of connectors in order to verify the structure.

Table 2*: Strength and stiffness of metal connection used in the analysis.*

Metal connector	WHT340	WHT620	TTF200	TCF200
Elastic siffness (kN/mm)	5,70	13,25	8,21	8,48
Design force (kN)	46,20	93,70	39,10	39,10

CLT panels were modelled with iso-parametric four-node quadrilateral membrane F.E. in both modelling approaches. In component-level approach (CM) the adopted values for elastic parameters, E=6600 MPa, v=0,35, were given by the weighted mean values of modulus in the parallel and perpendicular direction to the grain [8]. Connection elements (Hold-Down and Angle bracket) were modelled as linear elastic springs with stiffness derived from available experimental tests [ref]. In the *PM*, elastic stiffness of CLT walls was iteratively varied (i.e. reduced respect to the one used for the *CM*) in order to fit the global behaviour obtained with the *CM* by minimizing an objective function including the following control parameters: first vibration period T_1, top displacement, inter-storey drift and base shear force.

4 RESULTS AND DISCUSSION

Results obtained from the CM approach for all the considered configurations are presented in terms of fundamental elastic period (T_1), peak base shear forces at the Ultimate Limit State (ULS), maximum inter-story drift and top displacements at the Serviceability Limit State (SLS). These results are used as reference values for the calibration of the PM according to the proposed calibration procedure.

Figure 4 depicts the peak base shear forces on angle brackets at the ULS for each configuration. It is possible to observe how in several configurations, as the number of floors increases, the shear forces at the base varies slightly.

Figure 5 reports for all the examined shear-wall configurations the values of the principal elastic period. It is possible to observe how wall configurations with short walls and with a connections pattern related to low PGA, have high principal elastic periods T_1. Another parameter that greatly influences the period is represented by the slenderness of the wall. In fact, walls with high slenderness show greater periods of vibration than walls with less slenderness.

Figure 6 shows how an increase in the height of the building leads to high top displacements. For this reason the design requires the use of multiple Hold-Downs (more than two Hold Downs placed one-near-to the other at a corner of a CLT panel)in order to stiffen the structure and to reduce lateral displacements and inter-storey drifts (Figure 7).

Results assessed using the CM approach, on parametric wall configurations (results reported from Figure 4 to Figure 7), have been used in order to calibrate a set of E_{eq} following the optimization procedure previously described. The maximum errors on the significant control parameters ($\Delta_j=X_j^{CM}-X_j^{PM}$), obtained from the iterative procedure, are always lower than 5% confirming the effectiveness of the obtained equivalent modules E_{eq}.

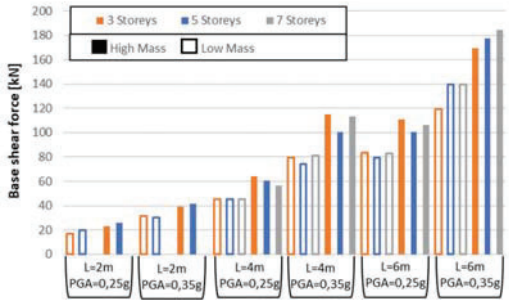

Figure 4: *Base shear force for each configuration*

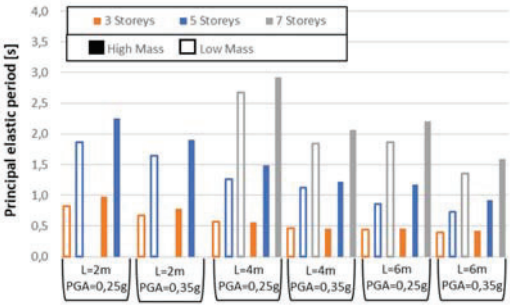

Figure 5: *Principal elastic period T1 for each configuration*

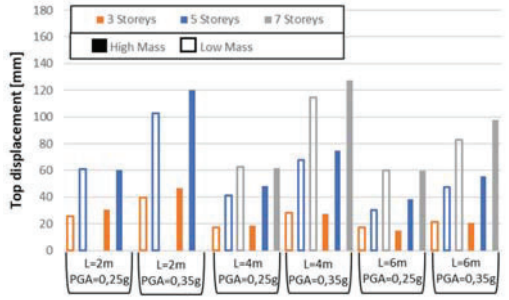

Figure 6: *Top displacement for each configuration*

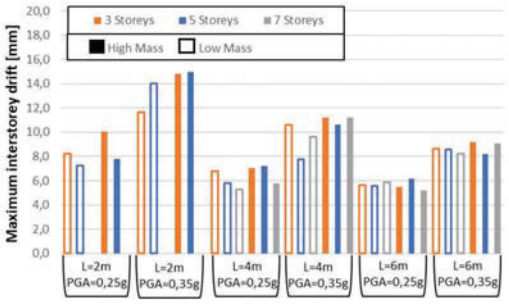

Figure 7: *Maximum inter-storey drift for each configuration*

Results were processed to define the suitable equivalent E modulus (E_{eq}) of the CLT wall as a function of: building geometry, seismic mass and seismic intensity. Obtained equivalent E modulus values (times the wall thickness), to be assigned to the wall of first floor (E_1) in case of a 3-storey building, are reported in Figure 8.

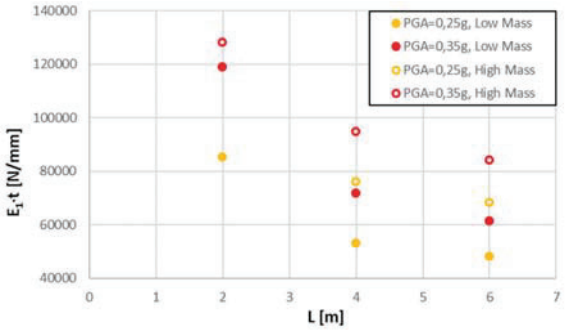

Figure 8: *Example of equivalent module to be assigned to the wall of first floor (E_1) for 3 storeys CLT structure*

A preliminary analysis of the results demonstrates the possibility to adopt a linear correlation between the equivalent stiffness of the wall at the level zero ($E_{eq,0}$) and the geometric proprieties of the shear-wall in terms of slenderness (λ) that is defined as the ratio between the height (H) and the base length (L) of the wall λ=H/L. The aforementioned linear correlation, for the two previously defined level of mass and level of seismic intensity considered in the parametric study, is shown in Figure 9.

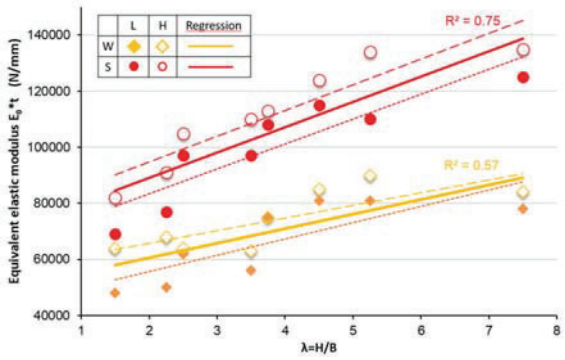

Figure 9*: Correlation between equivalent elastic modulus E_0 and slenderness of wall for different PGA, for different level of mass (Low: dotted lines and High: dashed lines) and level of seismic intensity (Weak: orange lines and Strong: red lines)*

The equivalent stiffness E_{eq0} assign to the wall of the level zero increases as the slenderness increases and is define as:

$$E_{eq0} \cdot t = a \cdot \lambda + b \quad (1)$$

Where: a=9044 and b=70987 for strong seismicity (continuous red line of Figure 8) while a=5184 and b=50325 for weak seismicity (continuous orange line of Figure 8). Based on the obtained results, the following function is proposed to correlate the Elastic module at the base level E_{eq0} and the elastic module at the i-th level $E_{eq,i}$.:

$$E_{eq,i} = E_{eq0}(1 - 0{,}31 \cdot n^{0.12}) \quad (2)$$

Where: n represent the floor number.

https://doi.org/10.52202/069179-0367

Figure 10 reports the mean and predicted values of equivalent stiffness of the upper floors ($E_{eq,i}$) scaled with respect to those of the ground floor ($E_{eq,0}$), at each level in case of a 3-storey building. It is possible to notice a knee adjustment in the stiffness values that can precisely predicted thanks to Equation 2.

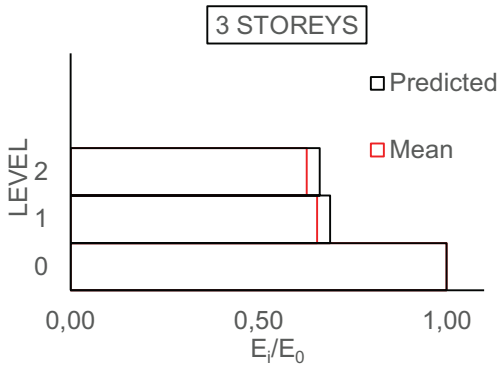

Figure 10*: Equivalent stiffness trend and prediction for 3 storey's structures.*

5 CONCLUSIONS

This study proposes a design-oriented numerical modelling approach for the prediction of the seismic response of multi-storey CLT buildings. It was proposed with the aim of faithfully reproduce the seismic behaviour of multi-storey CLT wall systems. The originality of the proposed phenomenological approach was the adoption of a properly calibrated wall equivalent stiffness accounting for both connections and panel deformability resulting in a real alternative to the more complex component modelling approach.
Results of the multi-parametric analyses and of the calibration procedure allowed the definition of a design abacus useful for a direct implementation of the phenomenological model in the analyses and design of a CLT building.

6 ACKNOWLEDGEMENTS

The Authors would like also to thank the company STP Srl for the support. A special thank goes to Lucia Bettelli for her help in the running of numerical analyses.

AN ACCURATE FINITE ELEMENT MODEL TO STUDY THE PROGRESSIVE COLLAPSE OF POST-AND-BEAM MASS TIMBER BUILDINGS

Chunhao Lyu[1], Benoit P. Gilbert[2], Hong Guan[3], Hassan Karampour[4], Shanmuganathan Gunalan[5], William Leggate[6]

ABSTRACT: The structural behaviour of mass timber buildings under the removal of a load bearing element is complex. To well understand this phenomenon and ultimately develop scientifically based design guidelines against progressive collapse for this type of buildings, there is a need to develop Finite Element models which accurately capture the non-linear structural responses of such buildings. This paper presents how mass timber post-and-beam systems can be accurately modelled using Finite Element under edge and corner column removal scenarios. The model was validated against published 3D experimental tests performed on scaled-down substructures. Results show that the model accurately replicated non-linear behaviour, load redistribution mechanisms, ultimate loads, failure modes, and strain developments. The use of the model was then illustrated by running parametric studies to quantify (i) the influence of the Cross Laminated Timber (CLT) floor panels layout and (ii) one alternative load path, typically ignored in design, on the progressive collapse resistance capacity.

KEYWORDS: Numerical simulations, Finite element, Mass timber post-and-beam buildings, Progressive collapse, Disproportionate collapse, Floor CLT panels layout

1 INTRODUCTION

Progressive collapses of buildings are triggered by abnormal loads, such as explosions, vehicle impacts, construction and design errors, fire and natural disasters [1]. These loads induce a local damage which may propagate throughout the building in a chain reaction, leading to its partial or entire collapse [2, 3]. While these events are rare, they result in significant economic losses, especially for tall buildings, and potential human casualties.

Mid-rise to tall mass timber buildings, i.e. buildings assembled from engineered wood products, such as Laminated Veneer Lumber (LVL), Glued laminated timber (Glulam) and Cross Laminated Timber (CLT) [4], are increasingly gaining international popularity. As these buildings become taller, commonly reaching six storeys and more, the consequences of a potential progressive collapse event also significantly increase. Studying the progressive collapse of mass timber buildings is still a relatively new research topic, and the structural response of various types of mass timber buildings to resist such events has been researched so far, through experimental [5-9], analytical [10, 11] or numerical [12-15] methods. However, the accuracy of the developed numerical models has not yet been verified against experimental tests, or only on component tests [15]. To improve design guidelines, such as the US Department of Defence (DoD) [16], the General Services Administration (GSA) [17], the Institution of Structural Engineers (IStructE) [18] and WoodSolutions technical guides [19, 20], there is a need to develop Finite Element (FE) models which are proven to accurately replicate the structural behaviour of mass timber buildings under a load bearing element removal scenario. Such FE models have been widely used in reinforced concrete and steel structural systems [21-28] to gain in-depth understanding on the structural behaviour through parametric studies and identify the key factors affecting the ability of the structures to resist progressive collapse. Mass timber buildings differ from their concrete [29-32], steel [33-35] and composite-steel [36, 37] counterparts, due to the lack of structural continuity (as built from prefabricated structural elements), the brittle failure mode of the material [38], and the typical lack of ductility of timber-to-timber connections [6, 39]. These characteristics result in mass timber buildings deemed to have fewer possibilities to redistribute the load after the loss of a load bearing elements [19], outlining the necessity to develop an accurate model specific to mass timber buildings.

Consequently, this paper presents how post-and-beam mass timber buildings can be accurately modelled using FE. The proposed numerical model was validated herein against quasi-static 3D experimental tests, performed by

the authors, on scaled-down substructures subjected to edge and corner column removal scenarios, totalling three different tests [7, 8]. As the layout of the CLT floor panels plays a critical role in redistributing the load through the building [7, 8], the influence of various CLT floor panels layouts on the progressive collapse resistance was numerically investigated through parametric study. The influence of the beam-to-column connections of the beams connected to the removed column on the ability of the building to redistribute the load was also studied.

2 FE MODEL OF 3D TESTS

2.1 GENERAL

The commercial finite element software package ABAQUS 6.14 [40] was used to simulate the 3D experimental tests. The beams and columns were modelled using beam elements B31. The 3-ply CLT panels were modelled using four-node general-purpose layered shell elements S4R. The *Composite Layup* tool was employed to define the material properties, thickness and orientation of each ply. Specifically, two types of *Lamina* materials were defined based on the properties provided by the manufacturer [41], namely 20 mm thick external (referred to as "*G8*") and 35 mm thick internal (referred to as "*G6*") laminae. A transversely isotropic material was used for each lamina, with the inputted longitudinal (*L* – parallel to the grain) and transverse (*T* – perpendicular to the grain) material properties summarised in Table 1. The two outer laminae were parallel to the face boards direction while the middle lamina was perpendicular to the two outer laminae. All connector properties were obtained from testing individual components and detailed in [42].

Table 1: *Material properties used in the numerical simulation*

Element	Moduli of Elasticity		Poison ratio	Shear moduli	
	E_L (MPa)	E_T (MPa)	μ_{LT} (-)	G_{LT} (MPa)	G_{TT} (MPa)
Beam/Column	14,100	-	-	800	-
CLT (outside layers)	9,000	450	0.3	700	90
CLT (inside layer)	6,000	300	0.3	400	60

Note: $_L$ – Longitudinal, parallel to the grain direction
$_T$ – Transverse, perpendicular to the grain direction (i.e., in both tangential and radial directions)

2.2 LOADING TREE

The two triangular steel plates and the six rectangular loading pads of the six-point loading tree (see [7] for more details) were simulated with four-node general-purpose shell elements S4R. The spreader beam linking the two plates was modelled with first-order beam elements B31. All these elements were assigned rigid material properties. Three-dimensional CONN3D2 connector elements were employed to connect the different elements together. The detailed model and the connector properties are shown in Figure 1. This model enabled the loading tree it to freely deform without resisting the applied load as in [7, 8]. The four corner nodes of each loading pad were connected to the CLT panels with only the translations restrained, the elements were therefore free to rotate relative to each other. Additionally, the contact between the six rectangular loading pads and the CLT panels was simulated using the "*hard contact* + *Rough*" surface-to-surface contact property, enabling pressure transmission without penetration in the normal direction and no sliding in the tangential directions.

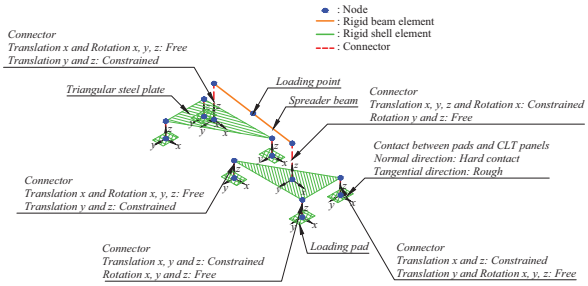

Figure 1: *Six-point loading tree details with local coordinate systems*
(Note: (i) connectors have a nil length in the model but are shown apart in the figure to clarify; (ii) the connector properties shown for the right triangular plate also apply to the left plate)

2.3 BOUNDARY CONDITIONS AND APPLIED LOADS

The overview of the FE model simulating Test EM-1 (and its repeat Test EM-2), with the boundary conditions, is shown in Figure 2. In reference to the global coordinate system *X*-*Y*-*Z*, the displacements of the bottom node of the eight permanent columns were restrained along all axes, while all rotations were released. To simulate the horizontal restraints provided to the substructure (See [7]): (i) the displacement along the *X*-axis of the six peripheral columns shown in Figure 2 was restrained at the elevation of the centreline of the beams and (ii) the edge nodes of the CLT panels shown in Figure 2 had their displacement along the *Z*-axis restrained. The same principles applied to Tests CM-1 and CM-2, but with the locations of the horizontal restraints given in [8].
In the analyses, the same loading sequence as in [7, 8] was simulated and consisted of:

- *Step 1:* Applying the self-weight of (i) the CLT panels of 0.37 kPa (average measured value on 27 panels) as an UDP, (ii) the weights, loaded on the bays not adjacent to the removed column, of 4.8 kPa as an UDP, and (iii) the loading tree (weighing 10.3 kN for Tests EM-1 and EM-2, and 9.4 kN for Tests CM-1 and CM-2) as a point load applied at mid-span of the spreader beam of the tree (see Figure 1). Note that the bottom node of the column stub of the removed column was constrained in displacement along the three degrees of freedom to simulate an undamaged structure during this step.
- *Step 2:* Removing the boundary conditions at the bottom node of the removed column.
- *Step 3:* Displacing along the negative *Y*-axis the node at mid-span of the spreader beam of the loading tree (see Figure 1) to simulate the applied load, maintaining the load applied in *Step 1*.

2.4 CONNECTIONS AND TIMBER FAILURE MODELLING

Connector elements CONN3D2, with the connector type *"Cartesian + Rotation"*, i.e., allowing all degrees of freedom to be entered by the user, were employed to connect the different components of the structure together, as described in [42].

Bending failure of the beams was observed experimentally in [7, 8] and while the beams were modelled elastically, bending failure of the beams was included in the model with connectors, used as fuses. The region of the maximum bending moment of the critical beams, i.e., the mid-span region of the middle row of beams, was modelled in 10 beam elements of 100 mm each. Adjacent segments were connected together by rigid connectors of zero length, therefore not affecting the elastic mechanical behaviour of the beams. The "*failure*" criteria option was used in the connectors to release the rotational stiffness when the bending moment reached the experimentally measured moment capacity of 13.7 kNm [7], therefore simulating the bending failure. The principle is illustrated in Figure 3 and was found (not shown herein) to correctly model the bending failure of the beams.

As the failure of the CLT panels was not explicitly observed experimentally, failure of the CLT panels was not modelled.

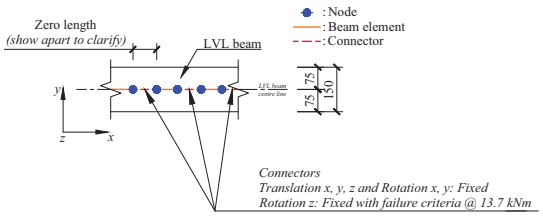

Figure 3: *Modelling bending failure of LVL beams (unit: mm)*

3 3D MODEL VALIDATION

3.1 LOAD-DISPLACEMENT CURVES AND FAILURE MODES

Figure 4 compares the experimental and numerical applied load in *Step 3* (see Section 2.3) versus the removed column displacement, under an edge column removal scenario. Note that the weight of the loading tree was included in the figure by offsetting the curves along the vertical axis as in [7]. Two numerical simulations were run with the shear capacity of the beam-to-column connections either inputted from the values obtained with or without the CLT panels, as discussed in [42]. Ignoring the contribution of the CLT panels in the shear capacity of the beam-to-column connections resulted in the FE analysis underestimating the ultimate load by 26% due to the premature failure of these connections in the second row of beams. It is therefore important to consider this contribution to accurately reproduce the overall structural behaviour and is now considered in this study.

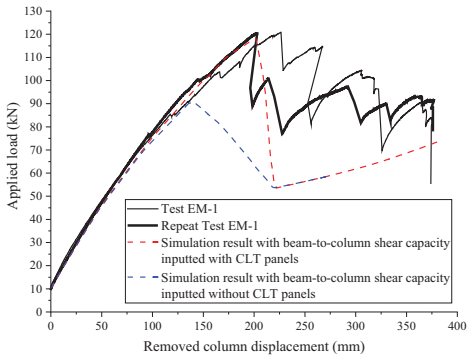

Figure 4: *Load – displacement curves from tests and numerical simulations (Edge column removal scenario only)*

Table 2 compares the experimental and numerical initial stiffness and ultimate loads for the edge column removal scenarios. The FE model accurately (within 3%) replicated both the initial stiffness and ultimate load.

Table 2: *3D FEA results comparison*

Specimen	Initial stiffness (kN/mm)			Ultimate load (kN)		
	Test	FE	Test/FE	Test	FE	Test/FE
EM-1	0.61	0.64	0.95	120.8	118.0	1.02
EM-2	0.66		1.03	120.4		1.02
CM-1	0.21	0.22	0.95	59.9	68.3	0.88
CM-2	0.75	0.63	1.19	97.3	105.7	0.92
		Average	1.03		Average	0.96
		COV	11%		COV	8%

In terms of failure modes, the FE model predicted shear failure to occur at the beam-to-column connectors linking both beams *B3* and *B4* to the interior column *C5* (see Figure 2 for element numbering). This failure mode corresponds well to the one experimentally observed for which shear failure occurred at beam *B3*-to-column *C5* connection. The difference of having two connections failing numerically, when compared to one connection failing experimentally, can be explained by the variability in the connection capacity. As the two connections are loaded similarly and have the same numerical capacity, they fail at the same time in the FE model. Experimentally, one connection will be statistically stronger that the other one, fail first and allow the load to redistribute before the second connection fails.

Note that the maximum load was reached due to bending failure of beam *B4* when repeating Test EM-1 (dotted line in Figure 4). This failure mode was also observed in Test EM-1 but after shear failure of the connection occurred. Bending failure was not observed numerically due to the

https://doi.org/10.52202/069179-0368

connections failing first in shear, and consequently unloading the beams due to the total applied force dropping.

Figure 5 plots the applied load versus the removed column displacement under the two different corner column removal scenarios. Regarding Test CM-1, the initial stiffness matched well with the experimental test, and the predicted ultimate load was 14.0% higher than the experimental test. The beam *B4* bending failure, which was predicted in the FE model was also observed in the experimental test. In the simulation, after the load dropped due to bending failure of beam *B4*, the load steadily increased, likely because the interaction between the bending moment and shear force in the behaviour of the beam-to-column connectors was not considered. Indeed, this allowed the applied load to be fully transferred to columns *C4* and *C8* in shear through the beam-to-column connectors, despite these connections completely failing in bending and likely having a reduced shear capacity. Also see Section 3.2 on the load transfer.

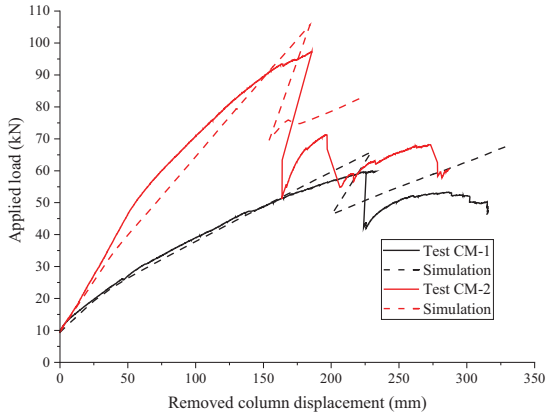

Figure 5: *Load – displacement curves from tests and numerical simulations (Corner column removal scenario only)*

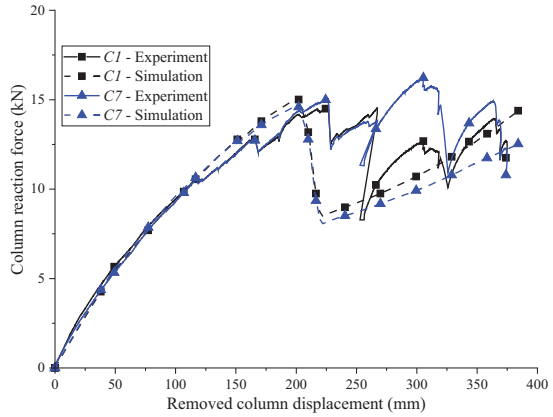
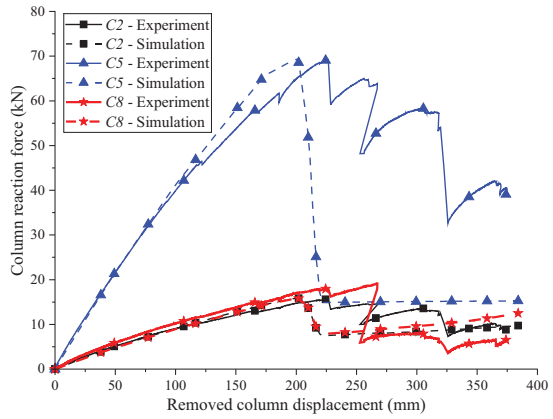
For Test CM-2, the initial stiffness was 20% different between the experimental test and the simulation results, but the overall trend of the load-displacement curve was well captured. Regarding the ultimate load, the experimental and numerical ratio was equal to 0.92. The FE model predicted failure to occur in bending at beam *B3*, matching well with the failure observed in Test CM-2. The numerical model stopped when the removed column displacement reached 220 mm, corresponding to the beam-to-column connector linking beam *B3* and column *C2* reaching its ultimate bending capacity.

3.2 LOAD REDISTRIBUTION

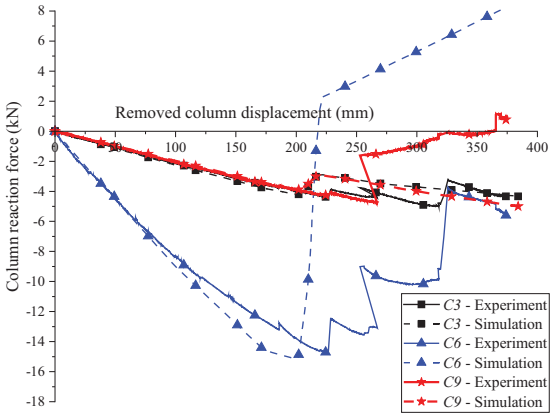
Figure 6 compares the experimental and numerical load redistribution through the system, taken as the column reaction forces, versus the removed column displacement. As the results for Test EM-1 and its repeat Test EM-2 were similar [7], only the results from Test EM-1 are plotted in the figure for clarity. The figure shows that up to reaching the ultimate load, corresponding to a removed column displacement of 122 mm, the numerical model accurately reproduced the load redistribution through the system. After failure, the numerical column reaction force for column *C5* dropped significantly more than the experimental tests due to the two beam-to-column connectors at column *C5* failing numerically against only one experimentally. The load redistribution after failure was however correctly captured for all other columns.



(a) Adjacent columns to removed column



(b) Interior and 2nd-row side columns



(c) 3rd-row column (back row)

Figure 6: *Load redistribution for edge column removal scenario (shown for Test EM-1)*

Figure 7 plots the experimental and numerical column reaction forces versus the removed column displacement for Test CM-1. Overall, the load redistribution was predicted well for all columns as outlined in the figure. The column reaction forces from Test CM-2 and simulation results are now compared in Figure 8. Similarly to the other two tests, the load redistribution was well captured by the numerical model for Test CM-2.

4 PARAMETRIC STUDIES

The validated 3D numerical models are used in this section to perform parametric studies by evaluating the influence of (i) the CLT floor panels layout and (ii) one alternative load path typically not considered in design, on the ability of the building to resisting progressive collapse. In total, eleven additional models were run as part of this section.

4.1 INFLUENCE OF VARIOUS CLT PANEL LAYOUTS

To cover different design practices than the staggered CLT panels from the validated model in Section 3, two additional layouts of the CLT floor panels were considered in this section. In the first and second additional layouts, all floor panels spanned one and two bays, respectively. Analyses were run for both edge and corner columns removal scenarios.

4.1.1 Edge Column Removal Scenario

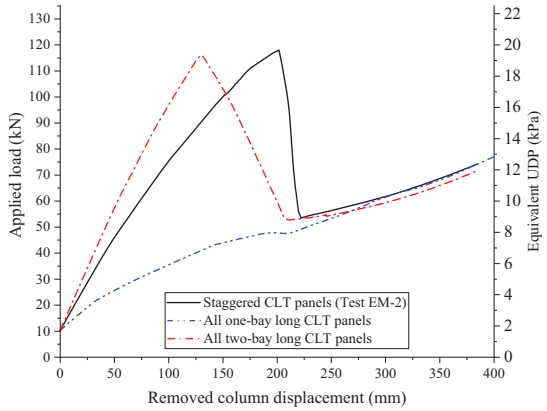
Figure 9 (a) compares the numerical applied loads in *Step 3* (see Section 2.3) versus the removed edge column displacement for the three different layouts of the CLT panels. Results showed that the initial stiffness was significantly influenced by the CLT panel layouts, with the stiffness when all panels spanned two bays being 4.6 times greater than when all panels spanned one bay. However, the capacity of the staggered and all two-bay long panels was within 3.5% of each other. The failure mode for these two configurations was the shear failure of the beam-to-column connectors on both side of interior column *C5*. For the all one-bay long panels, no specific failure mode was numerically observed. All configurations allowed to withstand an accidental design load of 8.95 kPa in the DoD [16], i.e. corresponding to an applied load of 53.7 kN.

4.1.2 Corner Column Removal Scenario

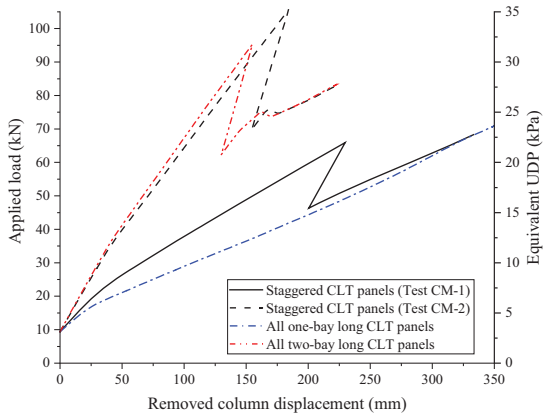
Figure 9 (b) compares the numerical applied load in *Step 3* versus the removed column displacement for the four

https://doi.org/10.52202/069179-0368

panel layouts, i.e., staggered (Tests CM-1 and CM-2), all two-bay long panels and all one-bay long panels. The initial stiffness of the all two-bay long panels was similar to the one of simulated Test CM-2. However, and while the same failure mode was encountered for these two layouts (i.e., bending failure of beam *B4*), due to different load distributions of the beam, the ultimate load of the all two-bay long panels was 10% lower. Similar to the edge column removal scenario, the model for all one-bay long panels showed the lowest initial stiffness and no specific failure mode was numerically observed. All configurations allowed to withstand an accidental design load of 8.95 kPa in the DoD [16], i.e. corresponding to an applied load of 26.9 kN.



(a) Edge column removal scenario



(b) Corner column removal scenario

Figure 9: *Numerical applied force versus removed column displacement for different CLT panel layouts*

4.2 INFLUENCE OF THE BEAM-TO-COLUMN CONNECTORS OF THE FRONT FRAME

During the experimental investigations [7, 8], and as captured by the previous numerical investigations, the beam-to-column connections of the beams connected to the removed column, but located at the opposite end of this column, provided a local support to the CLT panels above. This alternate load path allowed to transfer about 29% of the applied load to the columns directly connected to the removed one by these beams [7]. This local support can be seen in Figure 6 (a), Figure 7 (a) and Figure 8 (a), in which despite experiencing large rotation, the beam-to-column connections did not fail in shear and transferred load to the columns adjacent to the removed one. However, in a design situation and as no data would typically be available on the shear capacity of the beam-to-column connections experiencing large rotation, this alternative load path would be ignored. In other words, all beam-to-column connections of the beams attached to the removed column would be assumed to have failed and not carrying load.

To investigate the influence and the importance of the alternate load path mentioned above to the response of the building, another seven models were analysed with the same CLT layouts as in Section 4.1. In these models, (i) under the edge column removal scenario, the beam-to-column connectors of both beams *B1* and *B2* were ignored and removed from the models, and (ii) for the corner column removal scenario, the beam-to-column connectors of both beams *B2* and *BP3* were similarly removed from the models. The results, in terms of applied load versus removed column displacement, are plotted in Figure 10.

For the model with all one-bay long panels and edge column removal scenario, the structure was not able to carry its self-weight and loading tree when removing the column in *Step* 2 (see Section 2.3), so the response was not plotted in Figure 10 (a). This result shows the importance of the alternative load path offered by the beam-to-column connectors providing local support to the CLT panels above.

Still for the edge column removal scenario, the maximum load was reached for both staggered and two-bay long panels due to shear failure of the beam-to-column connectors linking beams *B3* and *B4* to column *C5*. The former and latter layouts reached a capacity 8.5 and 10.7 times higher, respectively, than the accidental design load of 8.95 kPa in the DoD [16]. In both scenarios, the models were not able to converge after the shear failure of the connectors, due to the sharp decrease of the load.

For the corner column removal scenario, the layout corresponding to one-bay long panels did not reached the accidental design load of 8.95 kPa in the DoD [16], while all other configurations reached a capacity at least 2.2 times greater than this accidental design load.

5 CONCLUSIONS

This paper presented and validated FE models of post-and-beam mass timber buildings under various column removal scenarios. Parametric studies using the validated numerical model were conducted. The main conclusions of this paper can be summarised as follow:

1. The FE model of the 3D substructures was found to accurately replicate the experimentally observed ultimate loads, initial stiffness, failure modes, load redistributions, deformed shapes and strain developments. The experimental-to-numerical initial stiffness and ultimate load were 1.03 and 0.96, respectively, with associated coefficients of variation less than 0.11.
2. When performing component tests, it was found that the CLT panels could significantly influence the shear capacity of the beam-to-column connections by delaying the failure. An increase in 30% in the shear capacity was attributed to the presence of the CLT panels. This behaviour needs to be considered to accurately capture the structural behaviour of post-and-beam mass timber buildings.
3. Parametric studies showed that if two-bay CLT panels are used: (i) for an edge column removal scenario, staggering or not does not influence the ultimate load, however, (ii) for a corner removal scenario, staggering the panels was found to influence the ultimate by up to 60.3%, when compared to non-staggered panels.
4. Parametric studies also showed that the alternative load path providing by the beam-to-column connectors of the frames connected to the removed column, and locally supporting the CLT panel above, is essential to achieve robustness when only one-bay long CLT panels are used. If this alternative load path cannot be relied on, post-and-beam mass timber buildings with one-bay long CLT panels are not able to resist the accidental design load under a column removal scenario.
5. The validated model can be used to eventually (i) quantify all parameters influencing the behaviour of post-and-beam mass timber buildings to resist progressive collapse, (ii) characterise the properties of timber-to-timber connections required to ensure robustness, (iii) evaluate the alternative load paths in an entire building and (iv) provide data to develop design guidelines.

ACKNOWLEDGEMENT

This study was funded by the School of Engineering and Built Environment, the Griffith University Sciences group and the Australian Research Council (ARC) Industrial Transformation Research Hub IH150100030 on tall timber buildings.

TIMBER STRUCTURES IN SUBTROPICAL CLIMATE ON DESIGN: BOIS DURAMHEN programs for Guadeloupe, Martinique and Guyane

Paul Quistin[1], Eric Fournely[2], Joseph Gril[3], Gael Godi[4], Luc Cador[5], Thierry Lamadon[6], Laurence Romana[7], Jacques Beauchêne[8], Rostand Moutou Pitti[9],

ABSTRACT: Mainly due to a lack of information on the local climate and its consequences on timber buildings, and regarding Eurocode standard, French West Indies islands and French Guiana remain considered as a service class 3 (SC3). Based on Meteo France (MF) data and moisture content measurements on more than 300 sites in the three departments, on local surrounding air humidity and temperature, the three programs Bois Duramhen 971 (European Synergîle), 972 and 973 (PACTE) are devoted to give answers on the impact of this climate on soft and tropical woods integrated in traditional or new timber structures. Data acquisition and analysis are described. Measurements are performed during more than one year, they are compared and completed by Meteo France data. The analysis is divided in two phases: equilibrium moisture content (EMC) calculated from HR(%) - T(°C) with NFEN1995-1.1/NA moisture diagram and direct measurement of instantaneous MC. Monitoring approaches are performed on, at least few members of two real buildings. In Guiana, drying element are also monitored in order to analyse this natural drying phase. Results obtained by the different approaches, comparison of measurements, calibration of measurement equipment, led to a wide data base and proposals of mapping have been deduced.

KEYWORDS: Service class, Moisture content, Equilibrium moisture content, durability

1 INTRODUCTION

Regarding Eurocode standard dedicated to timber structures, French West Indies islands and French Guiana are often considered as a service class 3 area (the most severe environmental conditions). This decision is partly based on the “severe” climate of these departments, but also mainly on a lack of information on the real local climate and its consequences on timber elements of buildings. A European project, *Synergîle-Bois Duramhen971:BD971*, is devoted to the study of environmental effects on timber structures in Guadeloupe island and two French national projects, *PACTE-Bois Duramhen972: BD972, and Bois Duramhen973: BD973,* propose the same approach for Martinique and French Guiana. The aim of these three programs is to produce a reliable data base and to build a map of service class zones (*SC2 & SC3)* whenever possible. The present work is the results of these studies related to Guadeloupe, Martinique and French Guiana. The chosen strategy is for each [1-3]:

- identification of available meteorological data;
- choice of different buildings or "sites" (≈ 100 for each department);
- 18-months measurement period: temperature (*T*) and relative humidity (*RH*) of surrounding air on the sites, and moisture content (*MC*) on timber elements;
- continuous analysis of the exploitation of data and measurements.

In order widen the data set, different axes of information were investigated (Figure 1). Data provided by Meteo France (MF), the National weather forecast agency, covered large period such as few decades but are limited to available MF stations. Project data covered narrow periods (12 months for the different sites) but a wide area with a large number of sites and buildings. They integrated environmental data but also *MC*.

To complete these measurements, two other main actions were conducted for each department:

- two sites were equipped with 3 monitoring sensors (*HR*%, *T*°C, *MC*%) for 10 months;
- specimens of wood were collected on site and studied for species identification and physical parameters determination on the one hand, tested in environmental chamber to obtain adsorption-desorption characteristics and validate (or not) the equilibrium moisture content (*EMC*) diagram, on the other hand.

Figure 1 illustrates the complementarity of these investigations.

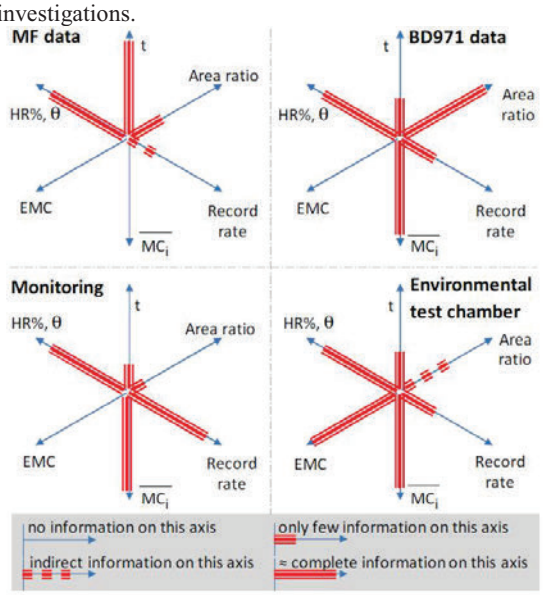

Figure 1: *Complementarity of investigations of projects BOISDURAMHEN [1-3]*

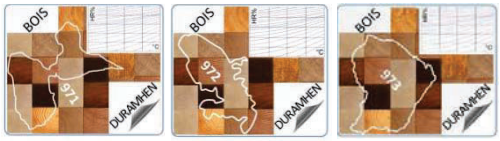
This paper will present successively the specificity of the tropical situation of French departments, the chosen strategy, experimentation on natural drying in Guiana and some results for BD971 (Guadeloupe), BD972 (Martinique) and BD 973 (French Guiana) regarding the sorption behaviour of local species typically used in construction.



2 SPECIFIC SITUATION OF FRENCH CARIBBEAN ISLANDS AND GUIANA

Guadeloupe (16-17°N, 61-62°W) is composed of a main island with two parts and few smallest islands; Martinique (14-15°N, 60-61°W) is one island [4], French Guiana is included in the South American continent.

The climate is a tropical marine one with a wet hot period and a slightly dryer one for the Caribbean islands [4]. French Guiana is located in the Eastern part of the Guiana Plateau, North of the Amazon basin. More than 90% of its territory is covered by humid equatorial forest [5]. The relief is a vast plateau of average altitude between 100 and 200 meters, with some massifs culminating at 800 meters. It is close to the equator (3-5° North latitude). For the study of the BOIS DURAMHEN projects, MF data (*T*, *RH*) were collected over 10 years for 10 to 16 MF stations per department [4-5]; they are positioned on the maps of Figures 2 and 3. The average *RH* history measured in French Guiana is shown in Figure 4.

3 DATA ACQUISITION

3.1 MONITORING OF CLIMATE AND MOISTURE CONTENT

For the 3 projects, the acquistion of data was based on two sources:

- data sets provided by Meteo France stations, principaly *HR* (%) and *T* (°C) of the surrounding air,
- on-site measurements of the same parameters and also *MC* (%), twice à month during 13 months with a manual measurement equipement (wood moisture meter with digital display, hand-held, non-destructive).

Some of the sites were chosen to be very close to MF station (less than 800 m) in order to compare *HR* and *T* coming from MF measurements records. In French Guiana, to complete the acquisition data and validate the measurements, 2 sites in different towns (Cayenne and Kourou) were equipped with monitoring sensors (3 per site) recording continuously *HR* and *T*, as well as *MC* of

https://doi.org/10.52202/069179-0369

the wood element (outdoor location). This equipment and its set up are presented on Fig. 5.

Figure 5: *Monitoring 3 wood elements (softwood and hardwood) equipped with sensors in Cayenne.*

3.2 MONITORING OF NATURAL DRYING

To study the natural drying of hardwood under the humidity conditions of French Guiana, the moisture loss down to below fibre saturation point (*FSP*) was monitored for two Guyanese wood species, Angelique (*Dicorynia guianensis*) and Gonfolo (*Qualea rosea*) (Figure 6).

Figure 6: *Natural drying tests: left,* D. guianensis*; right, 8 wood elements (*D. guianensis *and* Q. rosea*) equipped with sensors.*

3.3 MEASUREMENT OF SORPTION ISOTHERMS

The expected *EMC* of wood in a given climate defined by *HR*% and *T*°C, used to define the service class of a zone, is commonly based on the abacus provided by the National Appendix to Eurocode 5- part 1.1 [12-13]. In order to check its applicability to the local context, specimens from 5 typical tropical species used for construction in French Guyana were prepared in Kourou and sent to Clermont-Ferrand, France. Table 1 shows the species designation and the measured specific gravity of the samples.

Table 1 *Species used for sorption isotherm tests*

Species	ID	Specific gravity
Handroanthus serratifolius	EBE	1.071 +/- 0.014
Goupia galbra	GOU	0.883 +/- 0.007
Dicorynia guianensis	ANG	0.816 +/- 0.036
Qualea rosea	GON	0.657 +/- 0.008
Sextonia rubra	GRI	0.590 +/- 0.016

Wood plates 20x20x5mm3 were tested at 28°C in a MKF 240 climatic chamber, with mass measurement at each change of set point. Two samples per species were measured, one oriented TL, one RT. The sequence of *RH* steps, desorption followed by adsorption, is given in Table 2. The *RH* value was previously checked by means of a mirror hygrometer and the set values adapted accordingly [14].

Table 2 *Conditions of sorption isotherms*

Date	*HR* %	*T*°C	Date	*HR* %	*T*°C
01/4/21	93,8	Desorption, 28°C	19/4/21	10,0	Adsorption, 28°C
02/4/21	90,0		20/4/21	20,0	
06/4/21	80,0		21/4/21	30,0	
07/4/21	70,0		22/4/21	40,0	
08/4/21	60,0		23/4/21	50,0	
09/4/21	50,0		26/4/21	60,0	
12/4/21	40,0		27/4/21	70,0	
13/4/21	30,0		28/4/21	80,0	
14/4/21	20,0		29/4/21	90,0	
15/4/21	10,0		30/4/21	93,8	
16/4/21	7,7		03/5/21	0	103°

As the starting state of the wood was unknown, the first point could not be located between the adsorption and desorption isotherms. To clarify this point, a complementary campaign was carried out for the maximum RH level, imposing beforehand a saturation of the same samples by immersion in water for 72h. On this occasion, the hygrometer was recalibrated.

4 RESULTS AND DISCUSSION

4.1 SORPTION ISOTHERMS

The measured sorption isotherms at 28°C are shown in Fig. 7. For each species, the initial desorption is shown in blue and the subsequent adsorption in red. The prediction of the National Appendix [13] for this temperature is shown is dashed line, and the point measured a second time at high humidity, after resaturation, is indicated by the + sign.

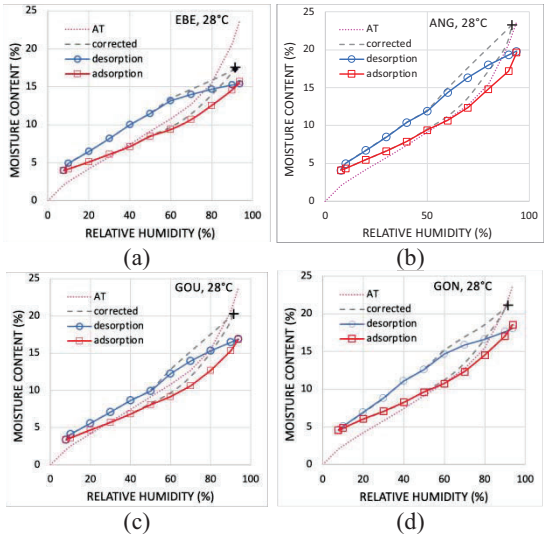

Figure 7: *Sorption isotherms at 28°C: (a)* H. serratifolius*; (b)* G. Galbra*; (c)* D guianensis*; (d)* Q. rosea*; (e)* S. rubra*. Dotted line: abacus from the National Appendix (AT). Dashed line: correction from new measurements after re-saturation.*

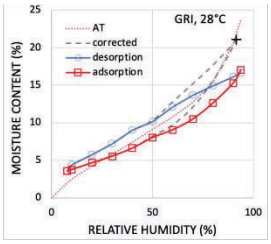
https://doi.org/10.52202/069179-0369



(e)

In the curves of the first campaign, a strong hysteresis between adsorption and desorption can be observed, which can be explained in part by the fact that the duration of the humidity steps is too short to reach a true equilibrium. In view of these results [14], a good agreement with the predictions of the Appendix appears for 40<*HR*<75%, these being placed in an intermediate position between the adsorption and desorption curves. At low humidities, the values are systematically slightly higher. This can also be explained by the slow diffusion process at low humidities. On the other hand, at high humidities the measured values were much lower, suggesting that these tropical woods are less hygroscopic than the temperate woods on which the Appendix charts are based. The measurements of the second campaign led us to question this analysis, as the points obtained, indicated by a cross on the graphs, were, on the contrary, very close. In addition to the correction on the mass allowed by the prior saturation, the more precise measurement of the hygrometry suggests that it had been slightly overestimated during the first campaign. The lower value observed for *H. serratifolius* could be explained by the high density (higher than 1) of this wood, which might have resulted in incomplete saturation. Independent observations [15] (J. Beauchêne, personal communication) suggest, however, that this species is really less hygroscopic than normal; it could be, especially for this species, that the bias on the slow diffusion applies to the whole isotherm, which would be globally overestimated. This reservation could also apply, to a lesser extent, to *G. galbra* which comes behind *H. serratifolius* in density and reputation for lower hygroscopicity [8, 10, 11, 14].

4.2 EQUILIBRIUM MOISTURE CONTENT EMC%

For each country, *EMC* was derived from climatic data, and *MC* was measured. A monthly average value is firstly considered to define service classes; an example of results is shown in Figure 8 for French Guaina.

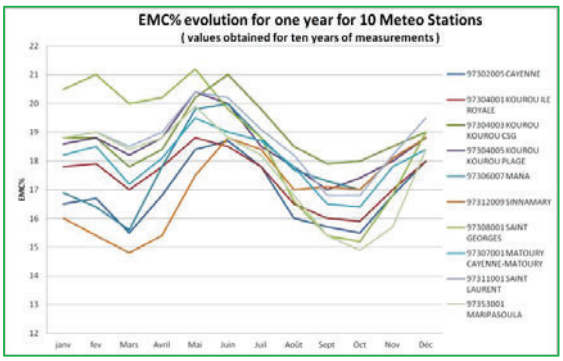


Figure 8: *French Guiana: calculated wood equilibrium moisture content (*EMC*, %) over 12 months [10]*

The average values of EMC and the difference between the minimum and the maximum during one year are taken into account. The results for 12 months can be illustrated in maps for each department (Figures 9-11).

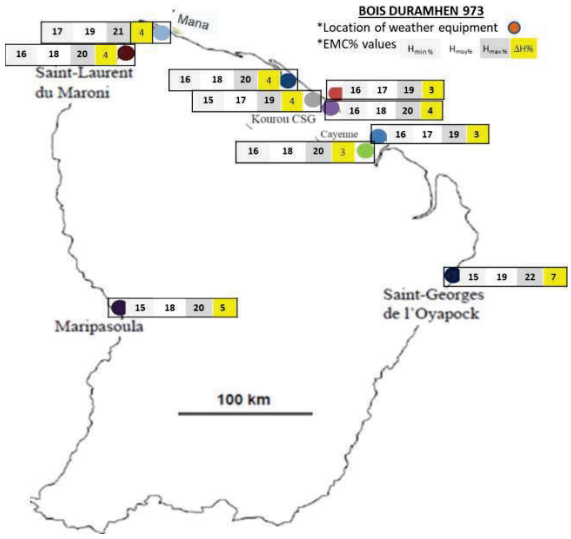

Figure 9: *12-months maps in French Guiana: extreme values of wood equilibrium moisture content (*EMC*, %) obtained for 10 weather stations [10]*

https://doi.org/10.52202/069179-0369

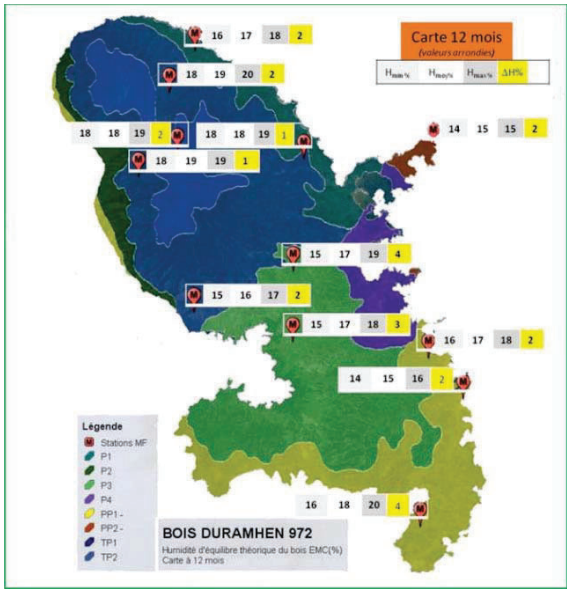

Figure 10: *12-months maps in Martinique: extreme values of wood equilibrium moisture content (*EMC*, %) obtained for 11 weather stations [9]*

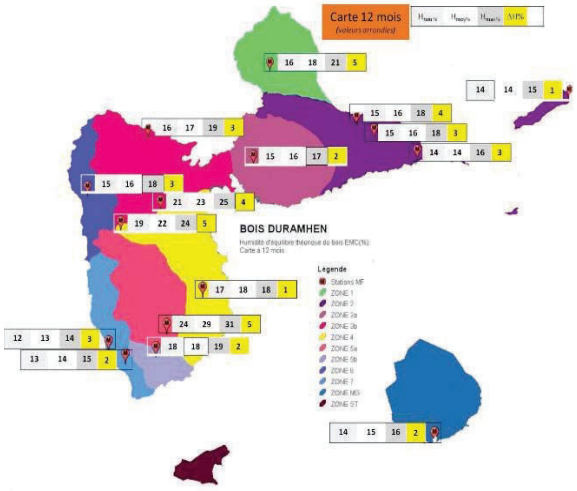

Figure 11: *12-months maps in Guadeloupe: extreme values of wood equilibrium moisture content (*EMC*, %) obtained for 16 weather stations [8]*

On most of the MF stations and different sites, the calculated and measured moisture content values fitted well within the MF Zone. In this case, service class zone could be clearly defined. In other zone(s), the service class determination had to be more detailed in order to propose a more precise mapping. The altitude is an important parameter, as well as the forest environment.

4.3 NATURAL DRYING WOOD AND MONITORING

Variations in *MC* below *FSP* are shown in Figure 12 for natural drying.

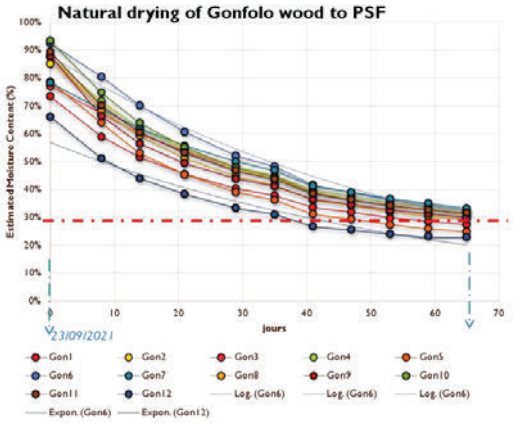

Figure 12: *Moisture loss tracking curves of Gonfolo (Q. rosea) wood (Cayenne) [10]*

Monitoring the humidity at different depths of the samples give information that can be used to monitor the drying of the wood below *FSP* (Figures 13, 14).

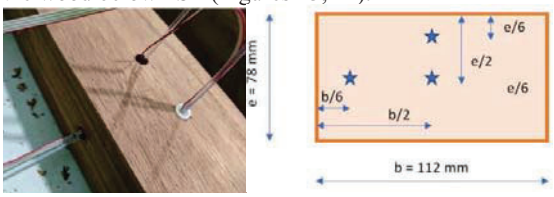

Figure 13: *Natural drying - Geometry, sensor position*

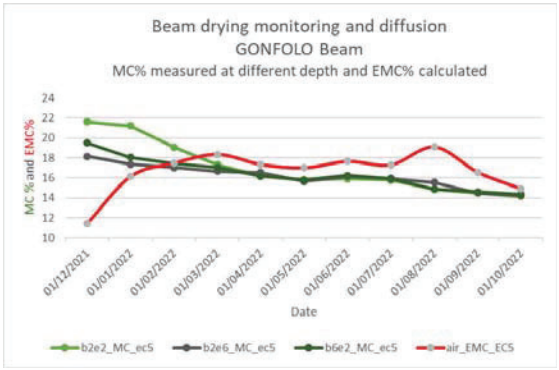

Figure 14: *Moisture content (*MC*, %) tracking curves of Gonfolo (Q. rosea) wood drying – equilibrium moisture content (*EMC*, %) calculated from local air sensor data.*

5 CONCLUSIONS

Results obtained by the different approaches, comparison of measurements, calibration of equipment led to a wide data base and gave interesting projections.

The work carried out confirmed the relevance of the abacus provided by the national appendix to Eurocode 5-part 1.1, to estimate the equilibrium water content of the woods most likely to be used for structural uses in the Guyanese context. However, a reservation must be made for the Ipe (*H. serratifolius*): because of its very high

density this wood had probably not reached the hygroscopic balance: the reputation it has of being less hygroscopic than the usual species could not be invalidated by our tests. Independent observations at CIRAD Kourou nevertheless suggest a lower hygroscopicity of Ipe, as well as Goupi (*Goupia galbra*) but to a lesser extent, whose high density is likely to slow down the achievement of hygroscopic balance. Measurements by dynamic sorption method, with analysis of the kinetics of mass change to extrapolate equilibrium values, could be carried out in order to verify the results obtained.

For the 3 French departments thanks to the results obtained by the BOIS DUR-AMHEN projects, maps were built allowing wood builders to know the humidity conditions of their construction, Figures 9-11.

Professional rules will allow these results to be used and disseminated. Especially for French Guiana, the calculated and measured moisture content values show that certain areas can be considered with conditions of a class of service 2 (SC2), but some towns present conditions of a class of service 3 (SC3).

ACKNOWLEDGEMENT

These works were supported for Martinique island and French Guiana by PACTE and for Guadeloupe island by FEDER Guadeloupe certified by the competitivity cluster Synergîle. Part of this work is based on Meteo France data base.

FRACTURE ANALYSIS OF CROSS LAMINATED TIMBER SHEAR-WALLS WITH OPENINGS

Martina Sciomenta[1]

ABSTRACT:

Strength capacity and deformation contributions of Cross Laminated Timber shearwalls with no openings are primarily governed by the behaviour of the connections. However, a considerably different behaviour and failure mechanism can be expected when openings are cut out of the shearwall panels – i.e. Monolithic Shear Walls. This paper aims to investigate the contribution of lintels and parapets on the mechanical behaviour of monolithic CLT shearwall assemblies with openings. The Abaqus software package was used to numerically investigate the racking resistance by using the extended finite element method (XFEM). A parametric study was performed on different configurations of two-storey CLT shearwalls with openings. The failure conditions related to either the CLT panels or mechanical anchors were taken into account in the analyses. The results showed that the strength and stiffness of shearwalls where openings are cut off the panel are significantly greater than those obtained for shearwalls assembled with separated elements – i.e. Segmented Shear Walls. The increase in strength and stiffness is particularly pronounced in the case of window openings.

KEYWORDS: Walls with Openings, Monolithic Shear Wall, Lintels, XFEM

1 INTRODUCTION

Connections strongly influence the strength capacity and strains of Cross Laminated Timber (CLT) shear-walls without openings but their behaviour and failure mechanism drastically change when openings are cut-out of Monolithic Shear Wall (MSW) panels (Figure 1a).
The opening could cause a significant increase in the shear deformation contribution of the CLT panel. This condition could led to high stress concentration around the corners of the opening, with a consequent possible premature and undesired brittle failure mode.
Openings can alternatively be realized by joining lintel and parapet elements to wall segments, denoted as Segmented Shear Walls (SSW) (Figure 1b). Following this construction method, no moment continuity is ensured between the timber members, so the wall segments could be assumed to behave as cantilevered beams.
Research on the mechanical behaviour of CLT shear-walls with openings has been quite limited, with some studies focussing on the determination of reduction factors on the stiffness of the CLT [1-2] or simplified modelling strategies [3-4]. Available literature on experimental tests indicates potential for brittle failure modes in the CLT panels [5-6], emphasizing the need to better quantify the conditions in which such failure mechanisms occur.
Investigating brittle failures in CLT shear-walls is quite challenging due to three main different aspects: the first one concerns the large scale and the complexity of the problem. In fact, shear-walls are characterized by the presence of both mechanical anchors (variable in number, type and position) and different geometrical properties of timber lintels and parapets

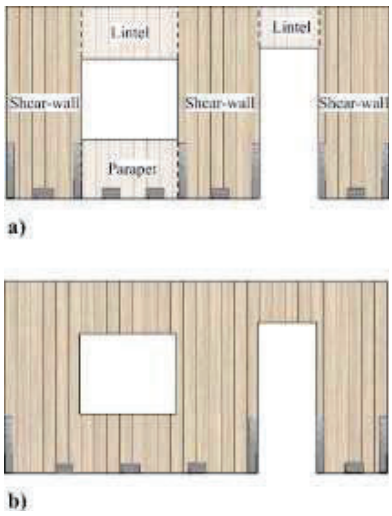

***Figure 1**. a) Monolithic (MSW) shear wall, b) Segmented (SSW) shear wall Fracture modes*

Up to now, instead, most studies involving the crack formation in timber were mainly performed at beam scale (such as LVL beams [7] and notched beams [8-9]), and to resolve detail issues (i.e joint bonding [10-11] and connection [12]).
The second aspect concerns the choice of either 2D or 3D analysis. Most of the FE timber fracture analyses have been carried out via 3D modelling; this latter is a powerful

[1] Martina Sciomenta, University of L'Aquila (DICEAA), Italy, martina.sciomenta@univaq.it

https://doi.org/10.52202/069179-0370

strategy to perform accurate fracture analyses on small scale components but, on the other way, makes the analysis time-consuming for large scale problems.
Finally, the modelling of structural elements with an existing sharp crack/notch allowed, in fracture analysis, the application of the classic finite element (FE) as well as the linear elastic fracture mechanics (LEFM) methods such as the Virtual Crack-Closure Technique (VCCT) or the Cohesive Zone Models (CZM).
However, the crack initiation and its propagation path is unknown a-priori in analysis of full scale walls due to the complex shear-walls mechanical behaviour.
The extended finite element method (XFEM) does not require to know a-priori the crack location and to re-mesh the crack surfaces (typical of the aforementioned classic FE, LEFM-based methods). The XFEM assesses the presence of discontinuities in a material by using special enriched functions in conjunction with additional degrees of freedom. It was first introduced by Belytschko and Black [13] and represents an extension of the conventional finite element method based on the concept of partition of unity introduced by Melenk et Babuska [14], which allows local enrichment functions to be easily incorporated into a finite element approximation.
The XFEM is a well-established method that does not require to know a priori crack path. This method, which is available with both 2D and 3D models, was used to model fracture mechanics problem on different structural materials such as steel [15], concrete [16] and composites [17], however just little was done in the field of timber and wood-based composites.
In this paper, the possibility to apply the XFEM procedure for the crack detection on CLT walls with opening is investigated. The aforementioned benefits of XFEM combined with a 2D analysis will be exploited to provide a novel CLT shear-walls modelling which furthermore allows the crack detection.
The two main aims of this paper are: *i)* to validate the proposed procedure for the cracks initiation and propagation in CLT shear-walls with openings and *ii)* to investigate the contribution of lintels and parapets on the mechanical behaviour of multi-storey CLT shear-wall assemblies.

2 STATE OF THE ART

2.1 FRACTURE MECHANICS

The solution to crack and defect problems can be achieved in the framework of the linear elastic fracture mechanics (LFEM), which is the basic theory of fracture that dealing with the initiation and propagation of cracks in elastic bodies. It was originally developed by Griffith [18] and completed in its essential form by Irwin [19] and Rice [20].
The fracture resistance is the ability of materials to withstand flaws that initiate failure, and usually these properties could be assessed by estimating the fracture toughness (based on Griffith's approach) or the critical value of energy release rate (based on Irwin's approach). These parameters measure the severity of the stress field around crack tips and determine the fracture criteria [21].
A material fracture resistance value varies depending on the loading mode. There are three fracture modes depending on the loading conditions for a crack, Mode I, II and III, representing fracture induced by pure tensile stress perpendicular to the crack plane and that induced by shear stresses, respectively. A mixed mode of Mode I and Mode II is the most common combination in structural applications [22].
The study of brittle failures in timber elements is challenging due to both to the nature of the material and the geometric complexity of some problems. In fact, being timber an orthotropic material, it is far more complicated than for isotropic materials due to the relevance of crack orientation, material stiffness and strength properties, which can all have an impact on the direction and load level at which cracks propagate [23].
However, the fast development of the finite element methods (FEM) allow the user to extended the LEFM concepts and crack criteria to problems with complex geometries and loading conditions [24].
For this purpose, the most common methods used are the Virtual Crack Closure Technique (VCCT) and the Cohesive Zone Model (CZM). VCCT theory assumes that when a crack is extended, the energy required to open the crack is the same required to close it. In the CZM, the equations needed to analyse the fracture process are simplified and focused only on the tip region of the crack, which considers the characteristics of this region with a traction-separation law. In the FEM, the traction-separation law is assigned to cohesive elements defined in the crack path [25].
Modelling stationary discontinuities, such as a crack, with the conventional finite element method requires that the mesh conforms to the geometric discontinuities. Therefore, considerable mesh refinement is needed in the neighbourhood of the crack tip to properly capture the singular asymptotic stress and the strain fields.
It is also required to establish a priori the path crack.
The extended finite element method (XFEM) alleviates these shortcomings as it assess the presence of discontinuities in a material by introducing specially enriched functions in conjunction with additional degrees of freedom.
To simulate crack propagation in wood by FEM, a crack initiation and a crack propagation criterion needs to be specified.
The damage initiation refers to the beginning of degradation of the material response in a certain point. Several damage initiation criteria are available: maximum nominal stress/strain, quadratic nominal stress or maximum principal stress/strain. In each case, damage is assumed to initiate when the stress/strain satisfy the input damage criteria.
The damage propagation specifies how the response (cohesive stiffness) of the material changes (degrade) once the initiation criterion is reached. The overall damage could be accounted by a scalar parameter D which ranges from 0 (no damage) to 1 (complete failure).

https://doi.org/10.52202/069179-0370

The stress that would be measured without damage is multiplied by (1-D) to calculate the stress after damage has occurred. Without damage (D=0), this leads to the undamaged response; with complete failure (D=1), the stress is 0; and in between a fraction of the stress will remain (Figure 3).

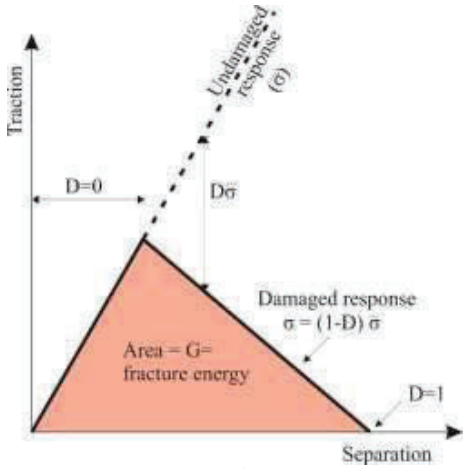

***Figure 3**. Damage initiation and evolution*

3 NUMERICAL ANALYSES

At first, the proposed XFEM procedure was validated for the crack detection on CLT walls with opening. The numerical results from FEM analyses were compared with the experimental ones obtained from a full-scale test performed by Casagrande et al [26] on a single-storey CLT shearwalls with single opening.

3.1 MODELLING STRATEGY

Abaqus software package [25] was used to carry out the numerical analysis.

In this work, 2D planar element were used to model the CLT panel and non-linear link elements were adopted to represent the behaviour of mechanical anchors (Figure 4). By using partitions, the shear-walls lintels and parapets were properly identified in the model. This procedure was particularly useful for our purposes since it allows the user to attribute different material features and enrichments (damage) to portions of mesh which can either experience damage (lintels and parapets) or not.

The elastic orthotropic material behaviour is accounted by considering the effective modulus of elasticity along the vertical, $E_{eff,v}$ (Eq. 1) and horizontal, $E_{eff,h}$ (Eq. 2) directions, as and the shear modulus, G_{eff} (Eq. 3) in accordance with Bogensperger et al. [27] and Brandner et al. [28].

$$E_{eff,v} = \frac{E \cdot t_v}{t_{tot}} \tag{1}$$

$$E_{eff,h} = \frac{E \cdot t_h}{t_{tot}} \tag{2}$$

$$G_{eff} = \frac{G}{1 + 6 \cdot \alpha_T \cdot \left(\frac{t_{mean}}{w_b}\right)^2} \tag{3}$$

being E the elastic modulus parallel to the grain, t_{tot} the total thickness of the CLT panel, t_v and t_h are the sum of thethicknesses of the vertical and horizontal layers, respectively, G is the board'sshear modulus, t_{mean} is the average thickness of boards, w_b is the width of boards and α_T is reported in Eq.4.

$$\alpha_T = p_B \cdot \left(\frac{t_{mean}}{w_b}\right)^{q_B} \tag{4}$$

where q_B is equal to -0.79 and p_B and is equal to 0.53 and 0.43 for 3 and 5 layers CLT panel, respectively, as reported in Brandner et al. [28].

For members not involved in the damage detection (i.e. wall segments), timber was defined as an elasto-plastic orthotropic material to take into account the local plasticization of wood in compression (Figure 4).

The Hill anisotropic yield criterion was adopted and based on the panel orientation, the reference resistance value was assumed equal to the CLT compressive strength parallel to grain: $f_{c,0}$. The corresponding anisotropic stress ratios (R_{ii} with i=1..3; j=1..3) for the other principal directions of interest were properly calculated (Equations 5 and 6).

$$R_{ii} = \frac{\bar{\sigma}_{ii}}{\sigma^0} \tag{5}$$

$$R_{ij} = \frac{\bar{\tau}_{ij}}{\sigma^0 / \sqrt{3}} \tag{6}$$

where $\bar{\sigma}_{11} = f_{c,0}$, $\bar{\sigma}_{22} = \bar{\sigma}_{33} = f_{c,90}$ and $\bar{\tau}_{12} = \bar{\tau}_{13} = \bar{\tau}_{23} = f_v$ are the measured yield stress value and $\sigma_0 = f_{c,0}$ is the reference yield stress specified for the plasticity definition;

The failure conditions related to either the CLT lintels and parapets or mechanical anchors were taken into account in the model analyses.

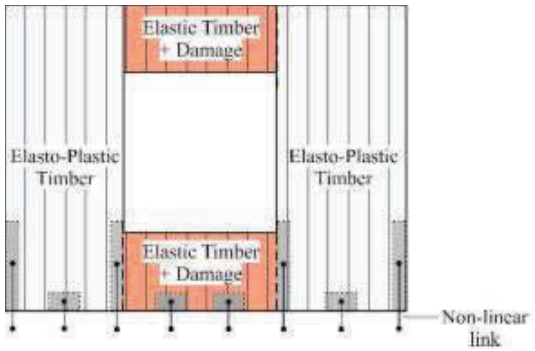

***Figure 4:** Schematic partitions, materials and mechanical anchors definition in Abaqus models*

https://doi.org/10.52202/069179-0370

Damage initiation is defined in the material properties by using a traction-separation law with the maximum nominal stress criterion – (MAXS). With this option, damage will initiate when the maximum stress ratio exceeds the unit (Eq. 7).

$$\max\left\{\frac{\sigma_n}{\sigma_n^0}, \frac{\sigma_s}{\sigma_s^0}\right\} = 1 \quad (7)$$

Being the CLT shear-walls lintels subjected primarily to bending and shear, the peak values of the nominal stresses, σ_n^0 and σ_s^0, are set equal to the effective bending strength in the horizontal direction $f_{m,h,eff} = \frac{f_m \cdot t_h}{t_{tot}}$ and the effective shear strength $f_{v,eff} = \frac{f_v \cdot min(t_h; t_v)}{t_{tot}}$, respectively.

The Wu crack propagation criterion was defined to compute the equivalent fracture energy release rate. It can be expressed in terms of energy release rate as in the following:

$$\left(\frac{G_I}{G_{IC}}\right)^{a_m} + \left(\frac{G_{II}}{G_{IIC}}\right)^{a_n} \geq 1 \quad (8)$$

where G_{IC} and G_{IIC} are the critical fracture energies required to cause failure in the normal and the shear directions, respectively, and G_I and G_{II} are the strain energy release rates which refer to the work done by the traction and its conjugate relative displacement in the normal and shear directions, respectively.

3.2 VALIDATION

A validation of the proposed FE model was carried out by comparing the model results with those obtained from experimental tests conducted by Casagrande et al [26] on single-storey CLT shear-walls with single opening (i.e. Wall 1).

The wall was made with a 3-layered 90 mm thick (30v-30h-30v) CLT panel .

The mechanical properties of the CLT panels are assumed from [26] and are E_0=13411 MPa, G=690 MPa, f_m=48.5 MPa, and f_v= 9.1 MPa. The wall height was equal to 2380 mm and the length was equal to 3300 mm. The geometrical dimensions of the door opening were (b x h / 600 mm x 2040 mm), while the lintel height was equal to 340 mm.

The test was carried out by using a commercially available hold-down anchors (WHT620) to connect the wall to the foundation. Each hold-down was connected to the wall panel using fifty-five 4x60 mm ring shanked nails, while the connection to the steel base beam was achieved using an M20 bolt. Additional blocking systems were adopted [26]. The mechanical anchor was modelled as a non-linear link accounting for its load-displacement curves obtained from Casagrande et al [26]. The blocking systems were modelled by applying a displacement boundary conditions with the component u_1=0 (Figure 5).

The critical values of the energy release needed for describing the fracture criterion were selected to be equal to $G_{IC} = 176\ N/m$ and $G_{IIC} = 734\ N/m$, according to the experimental evidences presented by Haller and Putzger [28], achieved by performing double cantilever beam (DBC) fracture tests and assumed by Kováčiková et al. [29] to study studies related to C24-graded elements fracture.

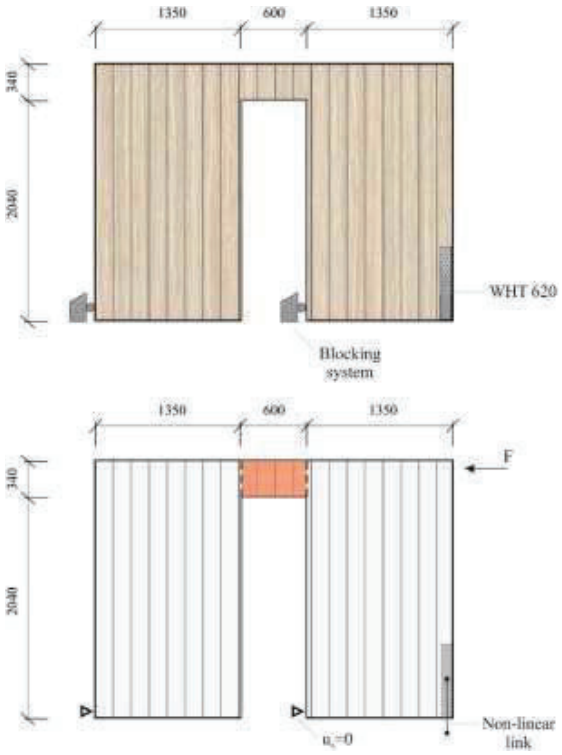

Figure 5: *Wall 1: Test setup (top) and schematic plan of partitions and mechanical anchors definition in Abaqus models (bottom) (measures in mm)*

The empirical parameters a_n and a_m are assumed as 0,5 and 1 respectively, according to [30].

A push-over analysis was carried out by increasing the lateral load applied at the top of the shear-wall.

In Figure 6 the comparison between the experimental and the FEM model curves proved a reasanable match, while in Figure 6 the position and the path of the crack reveal the same propagation observed in the test.

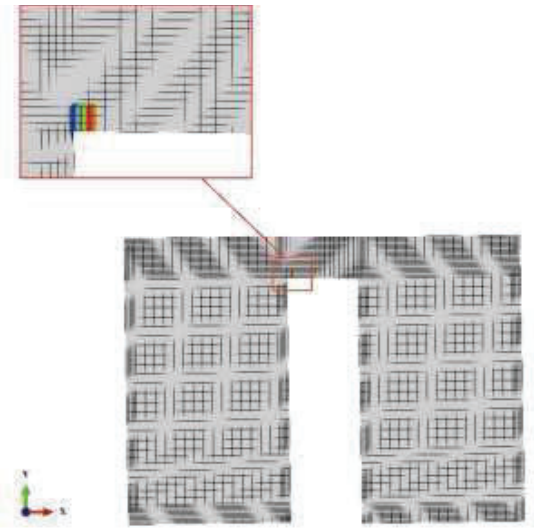

Figure 7. *Model validation with crack opening*

4 MULTI-STORY SHEAR-WALL CONFIGURATIONS

The validated model strategy was applied to two configurations of two-storey and multi-openings shear-walls.

Push-over analyses are carried out by applying a triangular distribution of horizontal forces on the top of the shear-wall.

For these configurations, the lateral stiffness, strength capacity and failure modes were documented and compared for shear-walls with openings either cut of out of the panels (MSW) or constructed with separate elements (SSW) (Figure 8).

The geometrical dimensions as well as the layout of mechanical anchors are reported in Figure 9 for Configuration #1 and in Figure 10 for Configuration #2, respectively.

For Configuration #1, the CLT panels have the same geometrical and mechanical properties of those of the wall described in the previous section. A vertical load equal to 15 kN/m was applied at each storey. The shear walls are anchored using ABR105 angle brackets spaced at 300mm and WHT620 hold-downs at each end of wall segments. The angle brackets are connected to the CLT panel using ten 4,2x89mm spiral nails and the hold-down are attached to the panels using fifty-five 4x60mm ring shanked nails.

For Configuration #2, the CLT panel is a 5-layered 100mm thick boards (20v-20h-20v-20h-20v) CLT shear-wall made of Spruce boards of C24 grade.

The mechanical properties of the CLT panels are assumed from [28] and are E_0=13878 MPa, G=690 MPa, f_m=50,2 MPa, and f_v= 11.0MPa.

The WHT 620 hold-downs and the angle bracket BMF 90x116x48x3 with 11 nails [31] were accounted. No vertical load was applied on Configuration #2 shear-walls

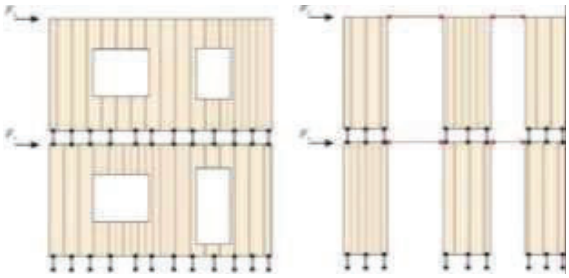

Figure 8: *left) MSW model; right) SSW model*

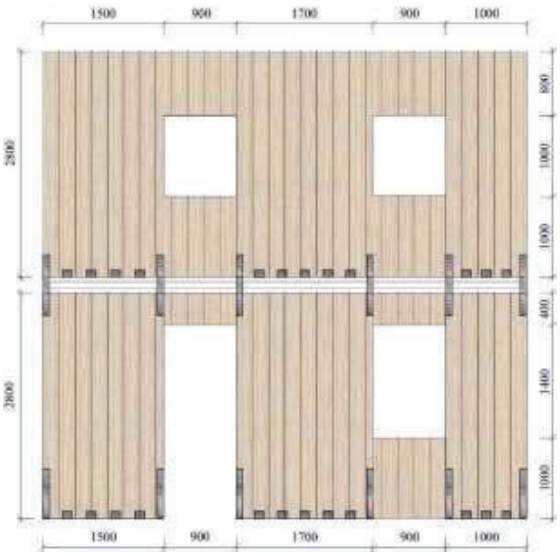

Figure 9: *Shear-wall Configuration #1 (measures in mm)*

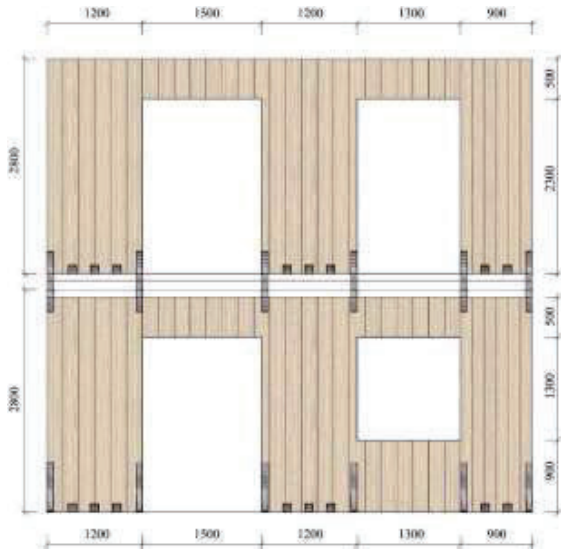

Figure 10: *Shear-wall Configuration #2 (measures in mm)*

The results from the two Configurations are significantly different both for in terms of strength and stiffness. In particular, the evidences from MSW are greater than those obtained for SSW, as displayed in Figure 11 and 12. The increase in strength and stiffness is particularly pronounced in the cases of window openings. The fracture analysis confirmed an high concentration of stress around opening leads to brittle failure modes in CLT lintels, which cannot be ignored in the design of such structural systems.

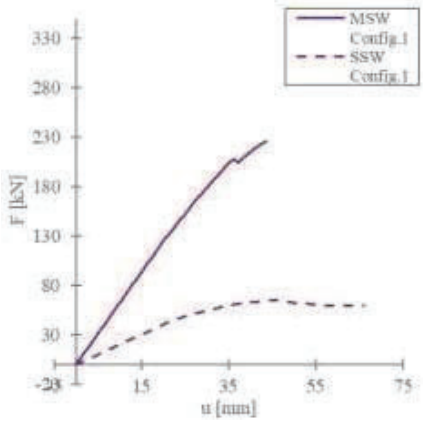

Figure 11: *MSW vs SSW models of cases shown in Figure 9 (Configuration #1)*

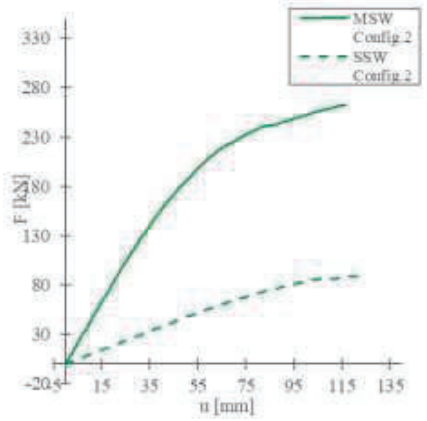

Figure 12: *MSW vs SSW models of cases shown in Figure 10 (Configuration #2)*

Moreover, the fracture mechanisms are also clearly highlighted for Configuration #2 (Figure 13).

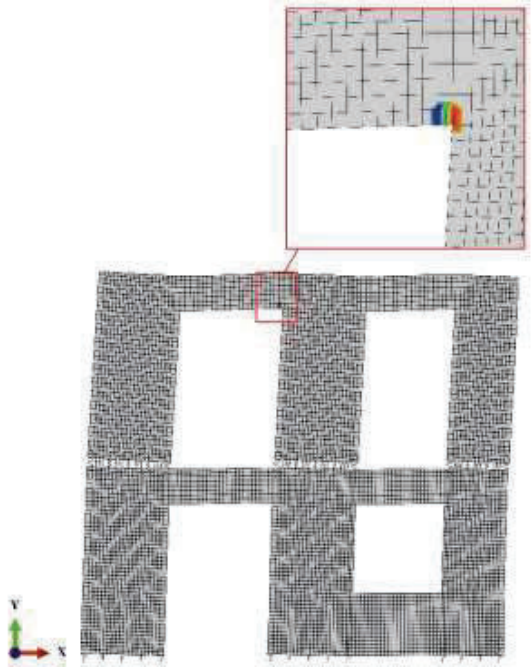

Figure 13: *Fracture mechanisms for Configuration #2.*

5 CONCLUSIONS

In this work a proposal for the crack detection in CLT shear-walls with openings is provided. The Abaqus software package was used to numerically investigate both the crack propagation by using the extended finite element method (XFEM) as well as the contribution of lintels and parapets on the mechanical behaviour of multi-storey CLT shear-wall assemblies.

https://doi.org/10.52202/069179-0370

The proposal was validated on shear-walls experimental evidences and highlighted an excellent matching both in terms of load-displacement curve as for position and path of the crack. Later, two different configurations of two-storey and multi-openings shear-walls were carried on. In addition, in this case the proposal was effective for the crack detection; it was also highlighted the great influence of lintel and parapets in terms of shear-walls global mechanical behaviour.

EMBEDMENT STRENGTH AND STIFFNESS FOR LARGE DIAMETER MECHANICAL FASTENER

Krunoslav Pavković[1], Dean Čizmar[2], Mislav Stepinac[3], Nina Pospiš[4]

ABSTRACT: The paper presents a parametric numerical analysis of the mechanical fastener developed for large span truss girder. The joint has already been presented in previous papers as well as the experimental tests made on the prototype of the truss girder with this type of joint. In this paper previously obtained experimental tests were used to calibrate the numerical model for parametric analysis. Numerical models are made in the Abaqus / CAE software package. Hill's and Tsai-Wu yield criteria, defined by UMAT subroutine, were used to model the wood yield criteria. Fasteners 49 mm, 59 mm, 69 mm and 79 mm in diameter and the angle between applied load and the grain 30°, 45°, and 60° were researched and results were carried out. From the results obtained by numerical models, expressions for stiffness and embedment strength were carried out and presented in the paper.

KEYWORDS: truss girder, large diameter, mechanical fastener, parametric analysis, UMAT, stiffness, embedment strength

1 INTRODUCTION

The growing presence of timber structures in the construction of large facilities, such as bridges and multi-storey buildings, requires development of the new joints with improved and increased strength and ductility. Since 80% of all timber structure damage has been noticed in the connections [1], it is necessary to develop new generation of joints that will ensure greater durability and ductility of the structure.

Joints in timber structures are commonly made with screws, dowels, and nails or dowel-type fasteners. Extensive research has been conducted on embedment strength parallel to the grain, with several proposed expressions for embedment strength [2–4]; however, most of these are limited to small diameter fasteners. One of the well-known design criteria is defined by Johansen [2], which includes the embedment strength and the appearance of a plastic joint in the fastener. Mentioned criteria are part of the Eurocode 5 (EC5) design fastener protocol and will be only satisfied if the minimum distances between the fastener and the loaded edge of the timber element are respected to ensure ductile behaviour of the joints.

Ensuring the ductility of the large diameter fasteners, often requires increasing the timber element dimensions to unrealistic proportions, which is not economically justified. Another solution is to determine the resistance of the joint to brittle failure mode [5,6] or to locally reinforce the zone around the fastener [7–10] in order to ensure ductile behaviour.

1.1 JOINT DESIGN AND FAILURE MODES

The design of a joint made with fasteners can be divided into two criteria: the first criterion involves the local design of each individual fastener, and the second criterion involves the design of the entire joint.

The first criterion involves using the limit state method and equations based on K.W. Johansen's work [6] which are already mentioned. According to this theory, joint failure occurs when the pressure in the timber around the fastener reaches the embedment strength or if the plastic moment resistance in the fastener is reached. The mode of failure that will be critical in each joint depends on the thickness of the timber elements, the diameter and material quality of the fastener, the number of share planes, and the boundary conditions of the connection. Figure 1. shows three characteristic failure modes of wood-wood joints with two share planes, and each failure mode can be expressed by the following equation for joint design resistance (R_d):

Mode failure I

$$R_d = f_{h,\alpha,d} \cdot t \cdot d \tag{1}$$

Mode failure II

[1] Krunoslav Pavković, Department for Civil Engineering, University of Applied Sciences, Zagreb, Croatia, e-mail: kpavkovi1@tvz.hr
[2] Dean Čizmar, Department for Civil Engineering, University of Applied Sciences, Zagreb, Croatia, e-mail: dcizmar@tvz.hr
[3] Mislav Stepinac, Faculty of Civil Engineering, University of Zagreb, Croatia, e-mail: mstepinac@grad.hr
[4] Nina Pospiš, Department for Civil Engineering, University of Applied Sciences, Zagreb, Croatia, student, e-mail: nina.pospis@tvz.hr

https://doi.org/10.52202/069179-0371

$$R_d = f_{h,\alpha,d} \cdot t \cdot d \left[\sqrt{2 + \frac{4M_{y,d}}{f_{h,\alpha,d} \cdot d \cdot t^2}} - 1 \right] \quad (2)$$

Mode failure III

$$R_d = \sqrt{4 \cdot M_{y,d} \cdot f_{h,\alpha,d} \cdot d} \quad (3)$$

Where d is the fastener diameter, t is the thickness of the timber element, $f_{h,\alpha,d}$ is design embedment strength for the load at the angle α regarding to the grain and $M_{y,d}$ is a fastener design plastic moment resistance.

Results obtained using equations (1, 2, and 3) are presented by graphs in Figure 2. and Figure 3. for a joint with one embedded steel plate in the middle of the timber element. Graphs are displayed as a relation between the width of the timber element and the diameter of the fastener. Two graphs are obtained, one for fasteners up to 30 mm in diameter (Figure 4.) and other for fastener larger than 30mm (Figure 5.) on which above mentioned equation according to Eurocode 5 (EC 5) [11], does not apply. Reason for diameter restriction for which formulas can be used, is shown on diagrams where can be seen that 49 mm diameter fastener has a larger design resistance than 79 mm diameter fastener.

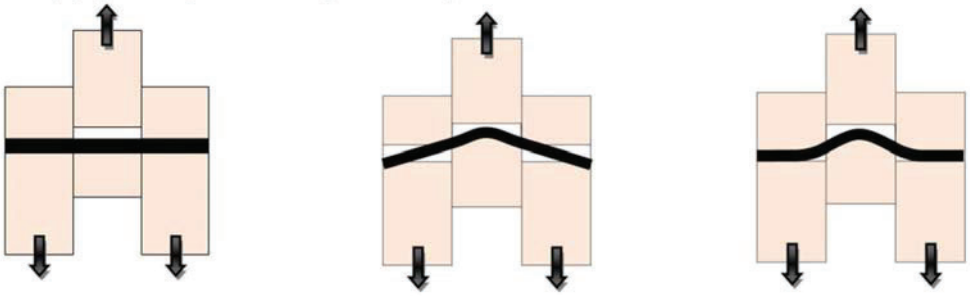

Figure 1. *Connection failure modes, from left to right: Mode I, Mode II and Mode III*

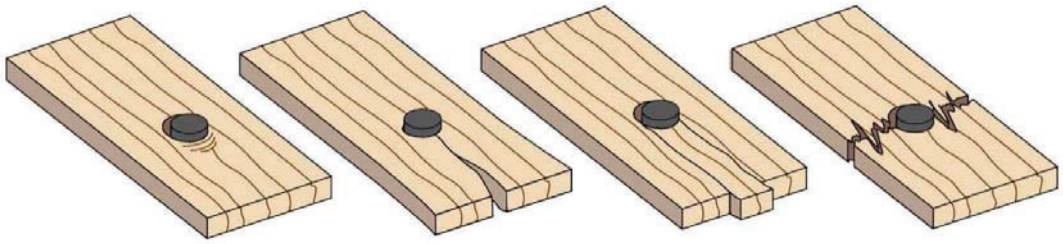

Figure 2. *Failure modes in timber joints* [9]

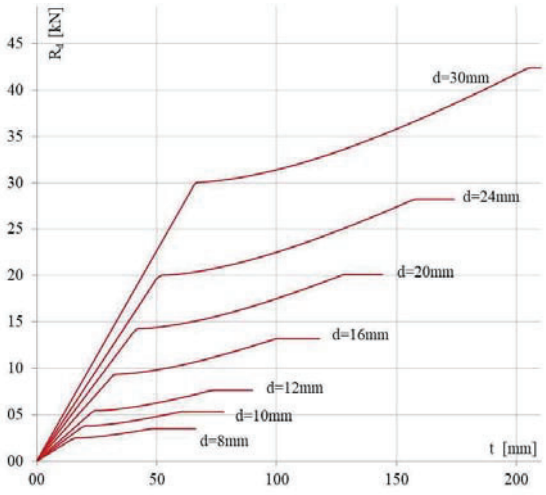

Figure 4. *Fastener resistance in relation to the timber width and fastener diameter up to 30mm*

The second criterion for the joint design is guidelines for the minimum distances between fasteners and the minimum distance between fasteners and the element edge. These given minimum distances prevent the timber element brittle failure modes and enable the ductile behaviour of the joint. In Figure 2. are presented failure modes including the first ductile mode (left picture) which are mentioned above and can be expressed with Johansen equations and followed by three pictures of brittle failure modes occurred due to: splitting, row shear, block, and plug shear or net tension.

The low deformation capacity of the brittle failure modes does not allow any redistribution of forces and causes an immediate failure of the entire connection and at the end of the entire structure [12].

Minimum distances between connectors that fall within the range of 3d to 7d usually require a large surface area for the connection. If the minimum distances are applied to dowels type fasteners with a diameter of 30 mm or more, then the problem arises on how to ensure the

https://doi.org/10.52202/069179-0371

minimum distance between the fastener and the element edge which becomes unsolvable without increasing the timber element's dimensions and increasing the wood consumption in the entire structure.
The connection analyzed in this study by using parametric finite element (FE) analysis does not have any problems with brittle failure modes due to its geometry. Since the joint concept within the truss structure ensures ductility and the large diameter tube (fastener) prevents bending of the fastener itself, the only failure mode that needs to be considered and researched is the embedment strength which is expressed by Equation 1.

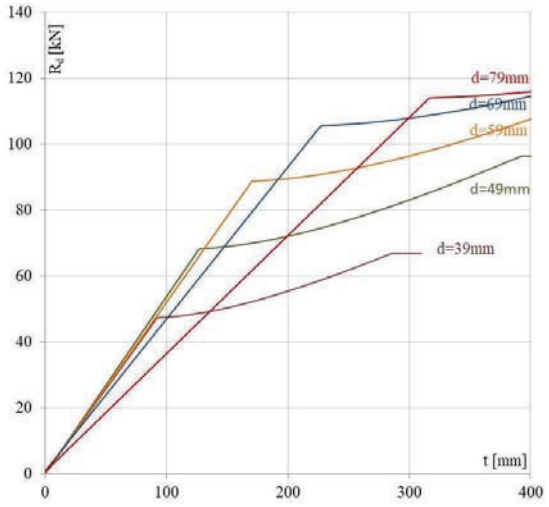

Figure 5. *Fastener resistance in relation to the timber width and fastener diameter above 30 mm*

2 EXPERIMENTAL REASERCH

Previous experimental studies on the joint with a large diameter mechanical fastener were conducted on 12 small samples, in which the load was applied perpendicular, parallel, and at the 45° angle to the grain. In small samples, failure modes were complex and were mostly caused due to cracking under tensile force perpendicular to the grain which was presented in previous papers [8,9,13].
On four large truss girders experimental research was conducted and presented in paper [14].
The truss girder joint consists of the fastener which is a large diameter pipe mounted in the cord of the truss girder and threaded rods glued in the web elements.
Load transfer from the cord to the web is carried out through high-grade bolts that connects the pipe and the connection nut mounted at the end of the threaded glued-in rod. This type of joint design for truss girders provided very ductile behaviour, unlike small samples where failure modes were mostly brittle due to cracking and block tearing. Measurements conducted during experimental research provided a good basis for calibrating finite element models (FEM) and conducting parametric FE analysis to determine a more suitable expression for large diameter fastener embedding strength.
The results obtained from experimental testing on the truss girder are shown in the graph in Figure 7 (grey lines) together with the results obtained from the FEM (black line).

Figure 6. *Joint monitoring during experimental research on a prototype of truss girder*

From the processed experimental results, mechanical characteristic values were determined: maximum force F_{max} = 333 kN, yielding force $F_{y,A}$ = 240.87 kN, $F_{y,B}$ = 191.09 kN, stiffness K_s = 52, and ductility D = 7.02.

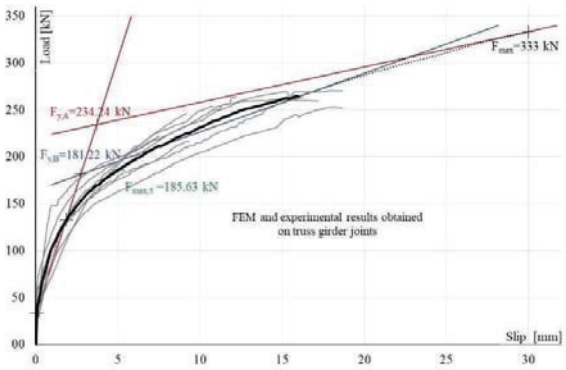

Figure 7. *Results obtained from experimental and FEM results*

3 PARAMETRIC FINITE ELEMENT MODEL ANALYSIS OF THE JOINT

FEM of the truss girder joint were modelled in Abaqus/CAE software package. C3D4 FE were used for modelling timber and steel elements. Considering that only the local behaviour of the joint is researched, a small part of the timber element (500 mm) around the fastener is modelled. Furthermore, for extra CPU time save, one half of the connection was modelled, as shown in Figure 9.
Within the parametric analysis, a total of 12 FEM were made to obtain results for joint stiffness and embedment strength in relation to the fastener diameter. Parametric numerical analysis was made for fasteners 49 mm, 59 mm,

https://doi.org/10.52202/069179-0371

69 mm, and 79 mm in diameter. Also, for each fastener diameter, three models were made with applied load at the angle of 30°, 45°, and 60° to the grain.
The mechanical properties and yield criteria of the wood were defined in the UMAT subroutine, i.e., Tsai-Wu for the connection zone and Hill for the rest of the timber element, as shown in Figure 8. The UMAT subroutine was described in detail in previous research [8].

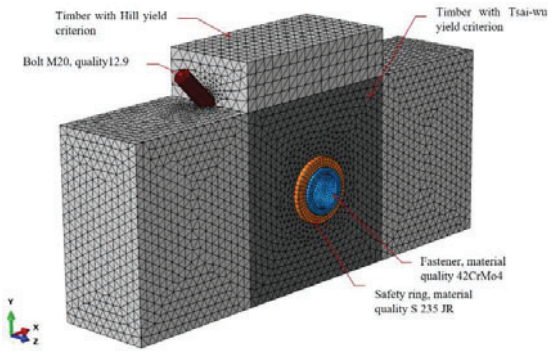

Figure 8. *Assigned yield criteria to joint FEM*

Absolute stiffness for normal stresses was used to model the contact surfaces, as well as the ability of two surfaces to experience tangential sliding with a friction coefficient. The friction coefficient applied for steel-steel contact was adopted as 0.2, and for wood-steel contact, 0.25.
FEM analyses were carried out using nonlinear analysis with included geometric and material nonlinearity. As in previous research papers [8,14], the Newton method with automatic step control was adopted for force control. The maximum load increment step was limited to 0.25t, with an initial setting of 0.1t, and the load increment was linearly set to 1.0 kN per unit time t.
The loading was modeled as a pressure on the bolt cross section in direction parallel with the axes. The given pressure on the surface was 4.40567 N/mm^2, which corresponds to the force of 1000 N on a surface of 226.98 mm^2. The force increment was linearly guided by the amplitude ratio as a function of time.

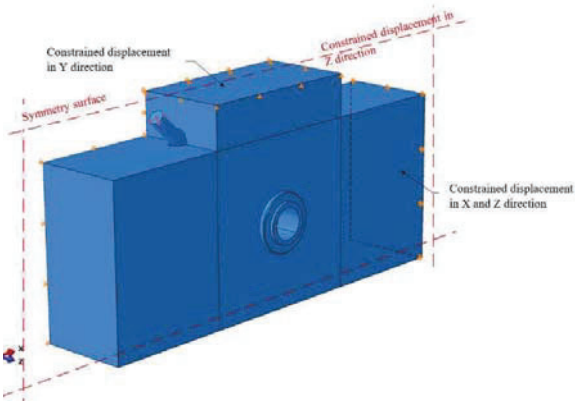

Figure 9. *FEM boundary conditions*

4 RESULTS AND DISCUSSION

As previously mentioned, a total of 12 FEM were analysed. Results of the joint load-slip behaviour were obtained for each model, and some of the results are shown in Figure 10.
The obtained results were processed according to EN 12512 standard [15], using both recommended methods (Method A and B) for determination of yield force and maximal force of the joint.
According to this standard, the maximum force is determined as the smaller value of the following three conditions: the force at the point of joint failure, 80% of the maximum force reached within a displacement of 30 mm if there is a descending branch in the load-slip curve, and the maximum force at a displacement of 30 mm.

Table 1. Joint characteristic values obtained from load-slip graphs

d [mm]	α [°]	$F_{y,A}$ [kN]	$F_{y,B}$ [kN]	K_s [kN/mm]	D	$F_{max,5}$ [kN]	$f_{h,0}$ [N/mm^2]
49	60	224.41	174.03	38.88	5.64	166	31.37

https://doi.org/10.52202/069179-0371

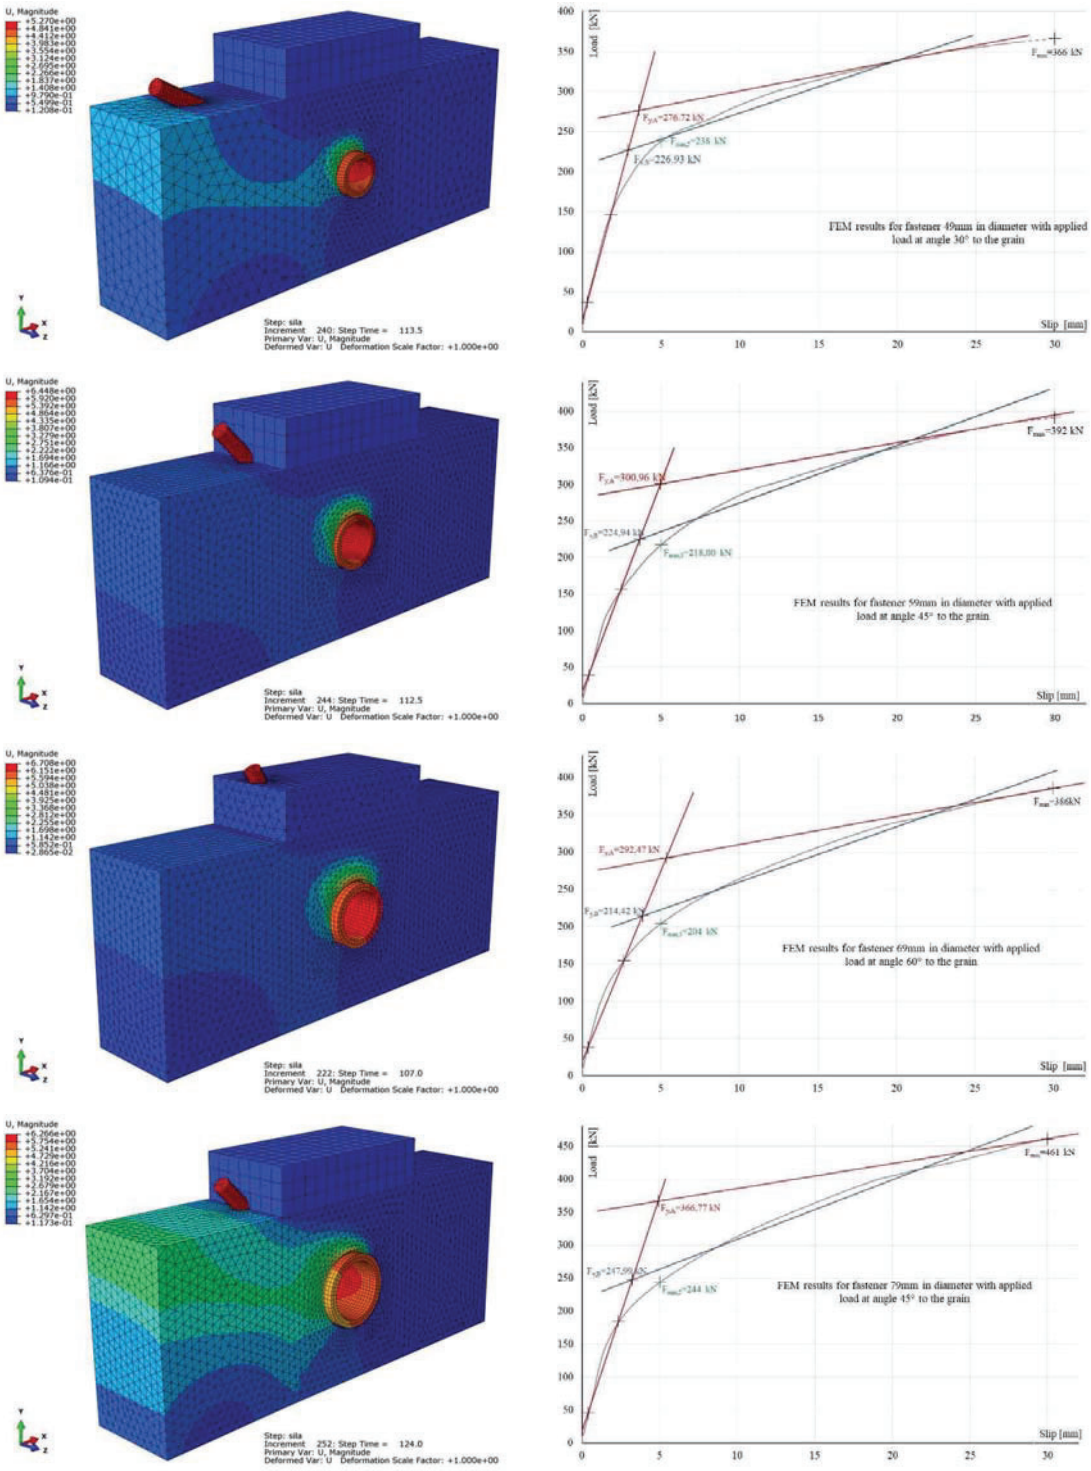

Figure 10. *Representation of joint displacement and load-slip graphs obtained by FEM*

Yield force according to the method A is determined by the intersection of the two lines; the first line is defined by the values of 10% and 40% of maximal load and the second line is defined by 1/6 inclination of the first line and maximal load. Method B is carried out by replacing the plastic region of the load-slip diagram from the yield force obtained from method A to the maximum force with a line defined by the least-squares method. The obtained

values from both methods are presented in Table 1. Also, the obtained results are analysed according to EN 12512 for determining the stiffness of the joint, according to the expression:

$$k_s = \frac{0.4F_{max} - 0.1F_{max}}{\delta_{0.4} - \delta_{0.1}} \quad (4)$$

For each FEM fastener embedment strength is determined according to EN 383 [16]. According to this standard, the characteristic embedment strength is obtained by dividing the force which corresponds to a 5 mm slip values ($F_{max,5}$) by the fastener diameter and thickness of the timber element in which the fastener was mounted. These embedment strengths were converted to embedment strength parallel to the grain, and the obtained values are presented in Table 1.

The obtained stiffness results of all 12 FEM were presented in the graph in Figure 11. Using the least-squares method, formulas for the joint stiffness were obtained for each applied load angle separately. Since the graph shows that all three angles of applied load have similar slopes, the main slope was adopted as the unique stiffness equation:

$$K_S = 0{,}673 \cdot d + 66{,}71\cos\alpha - 24{,}59 \quad (5)$$

The described procedure yielded a unique Equation (5) for determining the stiffness of the researched joint. Since the interception of the results with the y-axis depends on the applied load angle to the grain, and generally on the elastic modulus parallel and perpendicular to the grain, it is necessary to introduce the elastic modulus into the equation. According to the literature [17], the dependence of the three elastic modulus in softwood can be put in a relationship as E_L:E_R:$E_T \approx 20$:1.6:1.

$$K_S = 0{,}718 \cdot d + (2{,}713\cos\alpha - 1) \cdot 2{,}173 \cdot E_L \quad (6)$$

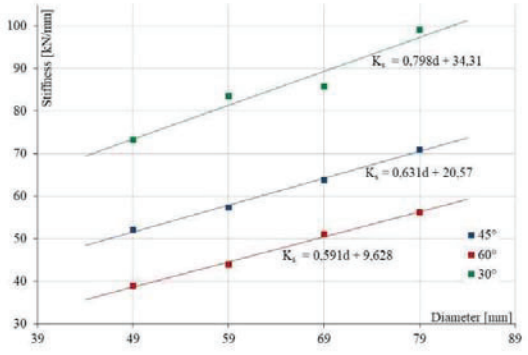

Figure 11. *Joint stiffness in relation to the fastener diameter*

Taking this into consideration, it can be concluded that introducing one elastic modulus is sufficient for defining unique Equation (6) which covers the type of timber, the fastener diameter, and the applied load according to the grain.

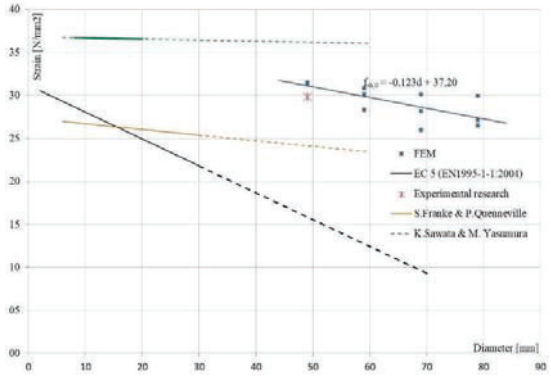

Figure 12. *Embedment strength in relation to fastener diameter*

The embedment strength for the load parallel to the grain is graphically shown in Figure 12. The results were approximated by a straight line obtained by the method of least squares and the equation of the obtained straight line is given by:

$$f_{h,0} = -0{,}123 \cdot d + 37{,}20 \quad (6)$$

From this equation, an expression for the characteristic embedment strength depending on the characteristic density of timber and fastener diameter can be derived as follows:

$$f_{h,0.k} = 0{,}084(1 - 0{,}0033d)\rho_k \quad (7)$$

This equation in comparison to the equation for embedment strength in the EC 5 norm gives a more precise embedment strength for large diameter fasteners loaded parallel to the grain.

5 CONCLUSIONS

The connection designed for large span truss girders with large diameter fastener, as presented in this paper, has shown great ductility and resistance. The geometry of the connection ensures failure due to exceeding the embedment strength. Such a designed joint with a large diameter fastener has served as a good basis for determining the expression for the embedment strength. From the parametric analysis, expressions for the embedment strength for fastener larger than 30 mm in diameter were derived. A comparison of the results showed that the proposed expression falls within the limits of previously obtained expressions and has good overlap with the results obtained from experimental research.

The experimental tests and parametric analysis showed that the expression for the embedment strength found in

https://doi.org/10.52202/069179-0371

Eurocode 5 loses accuracy with increasing diameter of the fastener and requires further adjustment through extensive research. Additionally, it is necessary to consider incorporating an expression for embedment strength for fasteners larger than 30 mm in diameter; because this paper, along with several others, has shown that large-diameter fasteners can ensure joints with ductile behavior, high resistance, and stiffness.

NUMERICAL MODELLING OF MASS TIMBER BEAM-COLUMN CONNECTIONS

Labuwatte Manathum Milindu B Jayasekara[1], Robert M Foster[2]

ABSTRACT: Multi-storey timber buildings are becoming increasingly popular due to advancements in engineered timber technology. Sophisticated timber connections in such buildings play a critical role in both the performance and safety of the structure, particularly in accidental and earthquake situations. Therefore, a thorough understanding of timber connection behaviour is necessary for safe and efficient building design. However, few existing studies capture timber connection behaviours in a sufficiently comprehensive manner to be applied to the complex loading conditions that can occur in accidental situations. This study develops a computational modelling approach that can predict intricate pre- and post-failure behaviours of timber beam-column connections under various loading conditions. First, the commercially available Finite Element software package Abaqus was used to model a timber beam-column connection. Then, nonlinear quasi-static analyses were performed under shear and moment conditions. Finally, sensitivity analyses were conducted to ensure that the model produces consistent results. The computational results obtained agree well with experimental results available in the literature. The developed numerical modelling approach is thus shown to have potential for simulating the complicated behaviour of timber connections under loads and, hence, for the design of safe, efficient timber connections.

1 INTRODUCTION

Engineered timber is built up from mechanically or adhesively connected timber lamellae to form larger, more homogeneous structural sections suitable for the construction of larger timber structures. Engineered timber is increasingly seen as an alternative to conventional construction materials such as concrete and steel for reducing CO_2 emissions in the construction sector [1] - [2]. As a result, engineered timber is now being used extensively in multi-storey building construction [3].

Commonly used engineered timber products are glued laminated timber (glulam), laminated veneer lumber (LVL) and cross-laminated timber (CLT) [4]. These materials are predominantly used in three main building types [5]: Light-timber frame structures, composed of dimensional lumber and engineered timber that are regularly spaced and fastened together to create floor and wall cassettes: CLT buildings, composed of solid CLT floor and wall panels in a platform-type construction arrangement: and post-and-beam structures, consisting of continuous vertical posts and horizontal beams that are, usually, pin-connected to each other. Post-and-beam structures are thought to offer the greatest potential for realising timber buildings taller than 10 storeys [6] and the heights of such buildings are rapidly increasing [7].

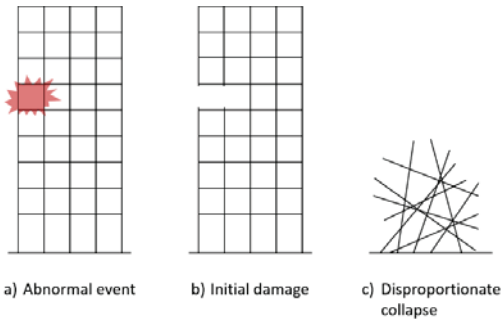

Figure 1: *Disproportionate collapse*

The greater the heights of timber buildings, the more acute the need for thoughtful consideration of abnormal conditions such as fire [8] or disproportionate collapse in design. Disproportionate collapse is a structural collapse in which there is a pronounced disproportion between the initial damage caused by an abnormal event and the extent of the ensuing collapse [9]. A graphical representation of

this concept is depicted in Figure 1. The key design strategy against this phenomenon is to ensure adequate resistance against failure propagation, i.e., robustness. By limiting the initial damage progression from (b) to (c) in Figure 1, a sufficiently robust structure can be obtained.

Timber beam-column connections, which are often made of steel or aluminium, play a vital role in ensuring reliable robustness of multi-storey timber buildings. These connections provide ductility and continuity to buildings, and with sufficient strength and deformation capacities, they can allow the formation of alternative load paths (ALPs) during initial damage [10] - [11]. These ALPs bridge or bypass a local failure zone; preventing failure propagation throughout the structure and hence averting disproportionate collapse. Examples of such ALPs are catenary, arching and membrane actions [12]. Understanding connection performance under load is thus crucial for achieving a robust building design. However, limited literature is available on timber post-beam connection behaviour [13] - [14].

Computational methods can be a cost-effective and efficient approach for capturing connection behaviours. With recent developments in computational mechanics and failure theories, it may be possible to simulate isotropic metals, anisotropic timber and their combined behaviour in timber connections beyond initial failure. The majority of existing studies are limited to linear elastic-plastic behaviour [15] or simple dowel-type connections [16] or one material/parameter performance [17]. Some studies employ pre-defined failure surfaces to initiate failure [18] - [19] but these may not be suitable for all types of loading because of the need to predefine failure. In addition, the numerical solving methods used in these studies may not be suitable to simulate complex pre- and post-failure material behaviour in timber connections [20]. Therefore, a comprehensive modelling technique is required to capture the behaviours of timber connections under any mechanical loading condition.

This research project aims to develop a computational modelling technique that can capture complex pre- and post-failure behaviour of timber beam-column connections under various loads. This paper presents the initial stages of building the complete computational model. First, material properties and connector details are outlined. Second, the modelling approach and results are discussed. Third, a parametric study is demonstrated. Finally, the conclusions of the study so far are presented.

2 TIMBER CONNECTION

A T-section connector tested by Masaeli et al. [21] and shown in Figure 2 was selected from the literature as an initial experimental benchmark for the development of the computational modelling technique. Full experimental details are provided by Masaeli et al [21] with key properties reproduced here. The tests used Douglas fir LVL timber column and beam sections of sizes 360 × 360 mm^2 and 600 × 252 mm^2 respectively. The T-section was made of AW 6005-A aluminium alloy, and the connection was composed of two rows of six 16 mm (M16 grade 8.8) bolts and ten 16 mm steel dowels (S355). The connector was tested experimentally under shear and moment quasi-statically [21], and the testing arrangements adopted are illustrated in Figure 3. These experimental results are used in this paper to evaluate the performance of the Finite Element (FE) model.

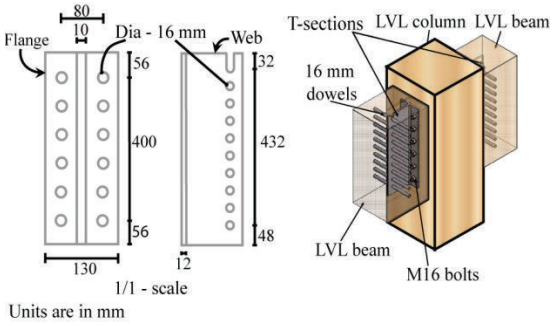

Figure 2: *T-connector details, redrawn after Masaeli et al. [21]*

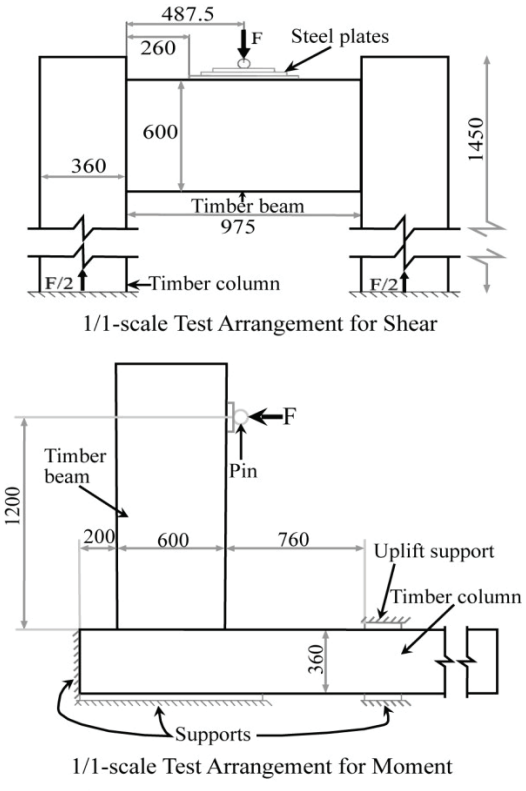

Figure 3: *Experimental testing setups, redrawn after Masaeli et al. [21]*

Material properties adopted in the FE analyses are given in Table 1 and Table 2 for timber and metals respectively.

The majority of these material properties including Young's modulus (E), Poisson's ratio (υ), shear modulus (G) and shear strengths (f_v) are those reported by Masaeli et al. [21]. Strains (ε) for metals are obtained from the wider literature [22]. Steel and aluminium are considered as isotropic materials whereas timber is modelled as an orthotropic material. Principal material directions for timber are depicted in Figure 4.

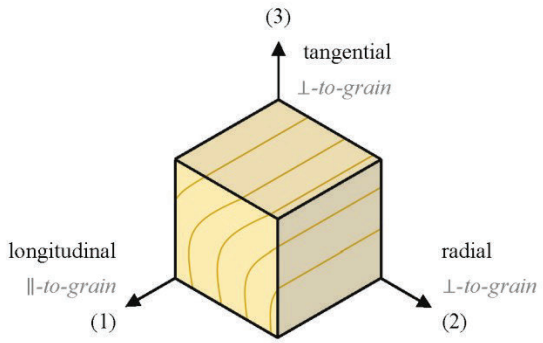

Figure 4: *Timber material directions*

Numerical subscripts for each timber material property represent these principal directions. Subscripts "c", "v", "y" and "m" denote compression, shear, yield and maximum respectively. "f", "σ", "ε_m" and "ε_{tf}" refer to strength, stress, engineering strain at maximum stress and true fracture strain respectively.

3 FINITE ELEMENT MODEL

All the parts of the connection were drawn separately and assembled as depicted in Figure 5 using the FE software package Abaqus [23].

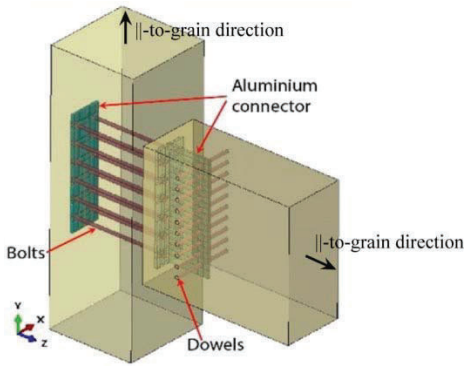

Figure 5: *FE model of the timber beam-column connection*

For the aluminium connector, small 8 mm chamfers were introduced at 90^0-degree corners to avoid numerical singularities. To define relationships between the components, 35 separate contact interactions were defined and constitutive models for metals and timber were specified to simulate their individual behaviour under loads. After performing a mesh sensitivity analysis for each component, boundary conditions and loadings were applied to simulate both shear and moment behaviour of the connector. These are discussed in detail in this section.

3.1 HILL CRITERION FOR TIMBER

The constitutive relationship for timber is defined in this study assuming orthotropic material properties. Only the ductile behaviour of timber under compression was considered in this paper. An elastic-perfectly plastic material model based on the Hill criterion with anisotropic yielding was employed using the properties given in Table 1. The Hill criterion has been successfully used in timber modelling to define plastic yielding [24]. Equation (1) shows the Hill criterion. Yielding occurs when the function reaches the value of 1.

$$f(\sigma) = [F(\sigma_{22} - \sigma_{33})^2 + G(\sigma_{33} - \sigma_{11})^2 + H(\sigma_{11} - \sigma_{22})^2 + 2L\sigma_{23}^2 + 2M\sigma_{31}^2 + 2N\sigma_{12}^2] \quad (1)$$

where:

$$F = \frac{1}{2}\left(\frac{1}{R_{22}^2} + \frac{1}{R_{33}^2} - \frac{1}{R_{11}^2}\right)$$

$$G = \frac{1}{2}\left(\frac{1}{R_{33}^2} + \frac{1}{R_{11}^2} - \frac{1}{R_{22}^2}\right)$$

$$H = \frac{1}{2}\left(\frac{1}{R_{11}^2} + \frac{1}{R_{22}^2} - \frac{1}{R_{33}^2}\right)$$

$$L = \left(\frac{3}{2R_{23}^2}\right), M = \left(\frac{3}{2R_{13}^2}\right), N = \left(\frac{3}{2R_{12}^2}\right)$$

$$R_{11}^2 = \frac{f_{c11}}{f^0}, R_{22}^2 = \frac{f_{c22}}{f^0}, R_{33}^2 = \frac{f_{c33}}{f^0}$$

$$R_{12}^2 = \frac{f_{v12}}{\tau^0}, R_{13}^2 = \frac{f_{v13}}{\tau^0}, R_{23}^2 = \frac{f_{v23}}{\tau^0}$$

https://doi.org/10.52202/069179-0372

where f^0 is the reference yield stress and $\tau^0 = f^0/\sqrt{3}$.

3.2 PLASTICITY MODEL FOR DUCTILE MATERIALS

An elastic-plastic material model was applied for ductile metals. Material properties given in Table 2 were utilised to obtain the engineering stress-strain curves for bolts, dowels and aluminium connector. Yielding was defined using the Von Mises yield surface with isotropic hardening. This criterion has shown promising results in the literature [22]. Von Mises yield criterion is given in Equation (2) and yielding occurs when $\sigma_v \geq \sigma_y$:

$$\sigma_v^2 = \frac{1}{2}[(\sigma_{aa} - \sigma_{bb})^2 + G(\sigma_{bb} - \sigma_{cc})^2 + (\sigma_{cc} - \sigma_{bb})^2 + 6(\sigma_{bc}^2 + \sigma_{ca}^2 + \sigma_{ab}^2)] \quad (2)$$

where σ_v is the Von Mises (equivalent) stress and a, b, c are the principal material directions.

Abaqus requires an equivalent stress-strain curve as input to simulate this yielding of metals. Therefore, engineering stress-strain curves were first converted to true stress-strain curves using Equation (3) and Equation (4):

$$\sigma_t = \sigma_e(1 + \varepsilon_e) \quad (3)$$

$$\epsilon_t = ln(1 + \varepsilon_e) \quad (4)$$

where σ_t is the true stress, σ_e is the engineering stress, ϵ_t is the true strain and $\varepsilon_e$is the engineering strain. As these equations are valid only up to necking, Hollomon's extrapolation method [25] was used to obtain the full curve. The true stress-strain curves were then converted to equivalent stress-strain curves, noting that the true stress-strain curve and equivalent stress-strain curve up to necking are the same. After necking, the Gromada correction factor was applied to account for the tri-axial stress state [25]. The resulting equivalent stress-strain curves are presented in Figure 6. Continuum damage modelling techniques were also employed after necking to simulate the ductile failure of materials [23].

3.3 MESH

Separate mesh sensitivity analyses were conducted for each component of the connection. From these, a suitable mesh arrangement was chosen for each component to maintain accuracy. A total of 268502 8-node linear hexahedral elements (C3D8R) are used in this model. Reduced integration and relax-stiffness hourglass options were included in these elements to minimise shear locking, computational effort and zero-energy deformation modes.

3.4 CONTACTS AND BOUNDARY CONDITIONS

The general contact algorithm in Abaqus was utilized with element-based surface definitions to define contacts in the connection model. These element-based contact surface pairs were specified individually to avoid numerical problems and unwanted energies. To simulate the sliding behaviour of these contacts, a friction coefficient of 0.3 was applied for the tangential direction. For the normal direction, a generalised Lame function proposed by Dorn [26] was employed to characterise pressure-overclosure (resistance to penetration) behaviour of surfaces. This accounts for the softening of timber near bolts and dowel holes.

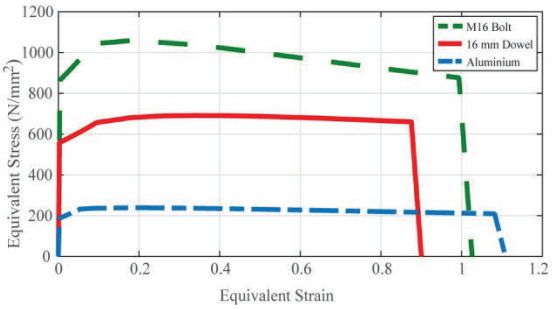

Figure 6: *Equivalent stress-strain curves of bolts, dowels and aluminium connector*

For numerical efficiency, finite sliding with balanced contact weighting was used. This is beneficial for simulating large deformations and for minimising unrealistic node penetrations in contact surfaces. Furthermore, a penalty constraint was also applied to allow these small penetrations in contacts and, therefore, to reduce artificial resisting forces that can cause numerical instabilities. This is particularly useful when circular shapes, such as bolts and dowels, are included in the model.

Boundary conditions were also employed to replicate both shear and moment loading conditions for the connection. The top and bottom surfaces of the column were fixed as shown in Figure 7. A distance of 250 mm between the connector and the fixed boundary conditions was kept to eliminate influence from the fixity to the connector. For the shear analysis, translational degrees of freedom (DOFs) in x- and y-directions at the end of the beam were restrained to resemble the shear behaviour.

3.5 LOADING

For all the numerical analyses conducted, only displacement-based loads were specified to capture moment and shear responses. First, a small displacement of 10 nm was applied to all the parts near contacts for initiating the contacts and eliminating numerical problems. This imposed displacement was then removed while enforcing new vertical displacements to simulate the required responses of the connector.

These vertical displacements were assigned to reference points using a fifth-order polynomial function until failure occurs [23]. The location of the reference point changes depending on the behaviour the numerical model tries to capture: moment or shear. In the case of the moment test, the end of the beam was constrained to a reference point

using coupling constraints with continuum distribution as illustrated in Figure 8. This constrains the DOFs of the nodes in the connecting surface to the DOFs of the reference point. By doing so, imposed displacement to the reference point is distributed in an average sense to the connecting nodes by producing realistic results. A similar procedure was followed for the shear test, but now the connecting surface is at the top of the beam as shown in Figure 8. Accordingly, from the results of numerical models tested in moment and shear, moment-rotation and load-displacement curves were extracted respectively.

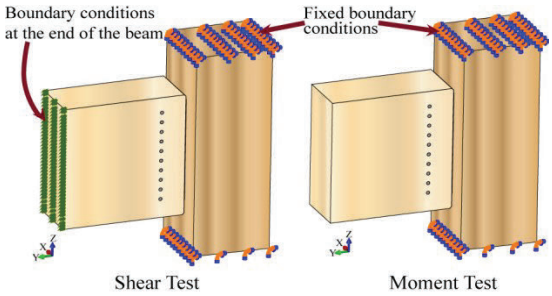

Figure 7: *Boundary conditions of FE models*

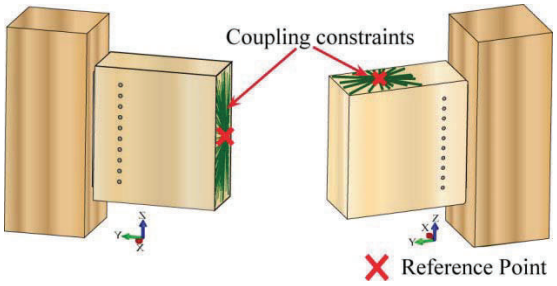

Figure 8: *Coupling constraints and reference points for the moment (left) and shear (right) simulations*

3.6 SOLVER

Owing to the complexities of the behaviour modelled, the commonly used Abaqus standard solver is not suitable for analysing such timber connections. The reason is that this solver solves for equilibrium [23], which means that problems become difficult to solve when a large number of contacts, failure mechanisms and non-linearities are involved. Abaqus explicit solver, on the other hand, solves equations of motion, which means that the calculation remains straightforward, and the overall analysis is efficient. However, this method is more commonly applied for dynamic analyses.

In order to perform a quasi-static analysis using the explicit solver, two sensitivity analyses have to be conducted to keep the kinetic energy acceptably low. One analysis is to identify a load rate that produces zero kinetic energy. It is impractical, even with high-power computing, to recreate the actual load rate used in the experimental tests due to the large number of time increments needed for the analysis. Therefore, a computationally less expensive load rate must be selected. However, increasing the load rate alone may not be sufficient to achieve a computationally efficient analysis.

Mass scaling is another parameter used to aid quasi-static analyses. This speeds up the analysis by increasing the time increment of the solver. However, by doing so, the kinetic energy of the system increases. Therefore, a sensitivity analysis must be performed to find a mass scaling factor. Both these sensitivity analyses are trial-and-error processes. Therefore, a separate dynamic analysis was performed to find the natural frequency of the model, and this was used to decide an initial trial value for the load rate. The resulting selected load rates are 0.25 m s^{-1}, 0.5 m s^{-1} and 1 m s^{-1} and the chosen mass scaling factors are 5, 10 and 20.

The model developed for the moment test was utilised in these two sensitivity analyses. Displacements were applied as described in Section 3.5 using the three different load rates and mass scaling factors. The moment vs rotation plots are shown in Figure 9.

Kinetic energies for each test were also compared to ensure that the kinetic energy is less than 5% of the internal energy. It can be seen that the results converge when the load rate and the mass scaling factor decrease, meaning that kinetic energy is low. Therefore, considering computational cost and kinetic energy, a load rate of 0.25 m s^{-1} and a mass scaling factor of 10 were chosen. The rest of the analyses were conducted using these selected parameters.

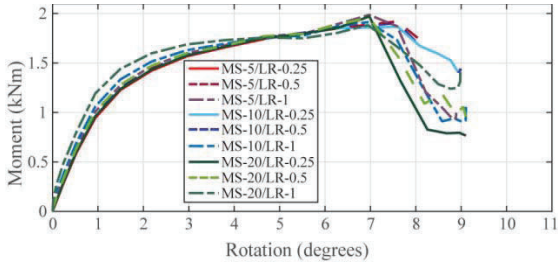

Figure 9: *Sensitivity analysis for mass scaling and load rate*

4 RESULTS AND DISCUSSION

The developed numerical connection model was analysed under shear and moment. Displacement-based loads were applied as described in Section 3.5 with the load rate and mass scaling factor obtained in Section 3.6.

Figure 10 illustrates the moment-rotation prediction in contrast to experimental results in [21]. The computational model captures the moment-rotation response of the connector including post-failure behaviour with good accuracy. The predicted initial stiffness, rotational capacity and maximum moment capacity agree well with the experimental results. It should be noted that, for the maximum moment capacity, there is a deviation of 1% from the average experimental

https://doi.org/10.52202/069179-0372

result. This distinction, however, lies within the experimental envelope and is due to the insignificant dynamic behaviour after elements start to fail. The predicted failure mechanism shown in Figure 11 matches well with the experimental observations of Masaeli et al. [21] – tearing near bolt holes and fracturing at the flange-web interface of the aluminium connector. However, in the FE model, the fracture at the interface is partial in contrast to the experimental fracture.

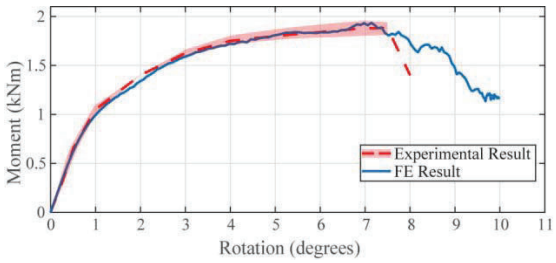

Figure 10: *Experimental [21] and numerical moment vs rotation response*

The shear response of the connector was also estimated and is presented in Figure 12. Overall, the load vs displacement behaviour is similar to the experimental behaviour. However, FE values over-predict the force response and under-predict the displacement response with a maximum variation of 28% and 65% from the average experimental result for the forces and displacements respectively. This may be primarily because of the exclusion of timber brittle failure under tension in these FE models.

As seen in Figure 13, experimentally observed tensile failure perpendicular to grain [21] was not captured in FE simulations. Instead, the applied loads primarily concentrated on the aluminium connector leading to higher resistance and lower displacement capacity. Hence failure occurred in the connector in simulations. Despite this, the numerical model captures the maximum strength capacity well, with a deviation of 2.4%.

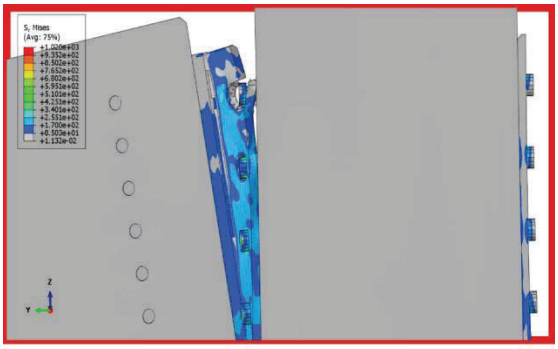
In all these analyses, energy outputs of the FE models such as artificial energy, kinetic energy, contact penalty energy, etc., were checked against the recommended limits to ensure that the results are accurate [23].

5 PARAMETRIC STUDY

Parametric studies were conducted to identify the effects of three different parameters. These are discussed in detail in this section.

5.1 BEAM-COLUMN GAP

In the computational models, a small gap between the column and the beam was kept, as displayed in Figure 14. The gap of 23 mm represents the weakened hollow portion of the beam due to machine cut – since this is a concealed connector – and was set to provide 4 mm initial clearance between the bolt nut and the timber. The inclusion of the gap is beneficial in avoiding complicated contacts and reducing computational effort. To explore the influence of this gap, another FE model was developed in which the beam touches the column by fully enclosing the connector. The moment-rotation and load-displacement responses are plotted in Figure 15 and Figure 16 for both models.



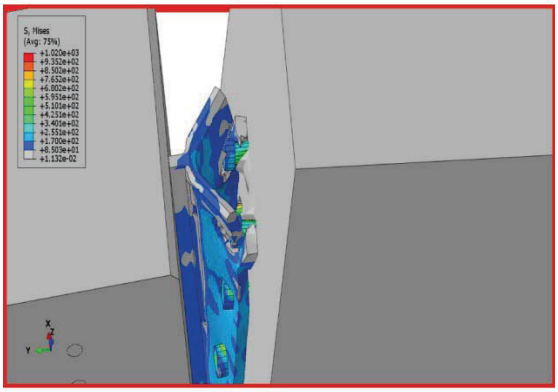


Figure 11: *Failure mode under moment test*

From Figure 15, it can be seen that the results of the FE model without the gap deviate significantly from the experimental results. The maximum moment capacity predicted has a variation of 14.3%. Furthermore, the rotational capacity is under-predicted by approximately 1°. This indicates that if the weakened hollow portion of the beam is not appropriately modelled artificially high resistance against rotation may be observed.

The shear response of the model without the gap shows similar peak resistance but less ductility than the FE model with the gap. For FE models without the gap, a 2.6% higher peak shear resistance and a 30% lower deformation capacity compared to the FE model with the gap were noted, and these may be a result of increased contact area between the connector and the timber beam. Failure modes of both moment and shear simulations are similar to the original FE models. These results suggest that a gap between the column and the beam can be employed to minimise the above-mentioned discrepancies in modelling these types of timber connections.

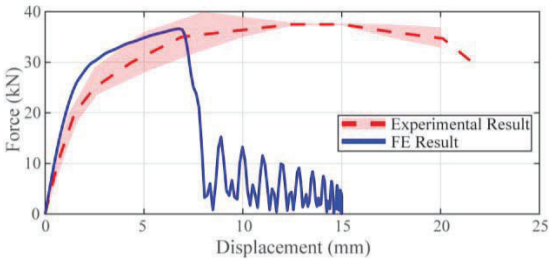

Figure 12: *Experimental [21] and numerical load vs displacement response*

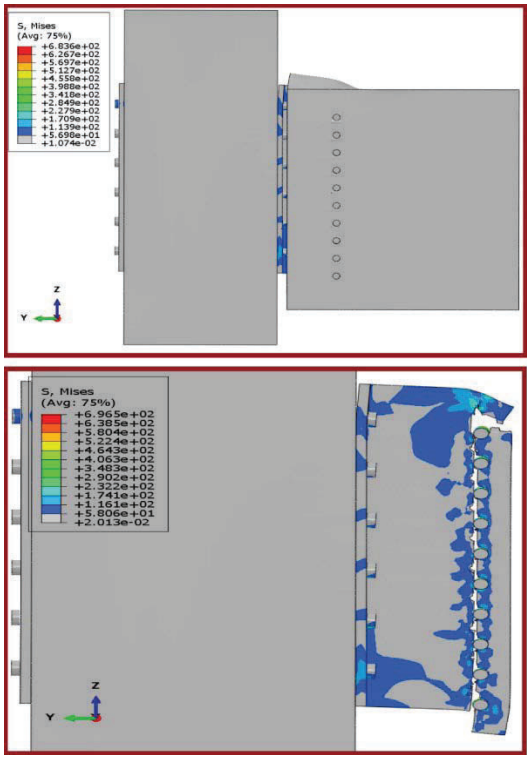

Figure 13: *Failure mode under shear test*

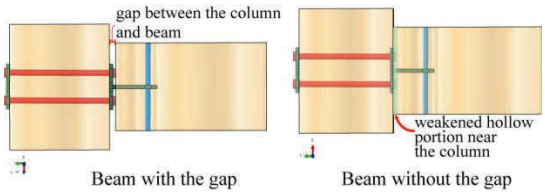

Figure 14: *Column-beam gap*

5.2 CHARACTERISTIC ELEMENT LENGTH

In continuum damage modelling, a total plastic deformation parameter is defined to simulate ductile damage of metals [23]. This parameter is constant for a particular material, and when an element reaches the specified total plastic deformation, element deletion occurs. Total plastic deformation (U^p) is given in Equation (5).

$$U^p = L_c\left(\varepsilon_{tf}^p - \varepsilon_{tn}^p\right) \tag{5}$$

where L_c is the characteristic element length, ε_{tf}^p is the true plastic strain at fracture and ε_{tn}^p is the true plastic strain at necking. ε_{tf}^p and ε_{tn}^p are material properties and are independent of element properties.

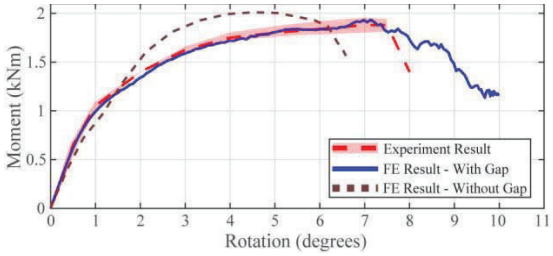

Figure 15: *Experimental [21] and numerical moment vs rotation response of models with and without the gap*

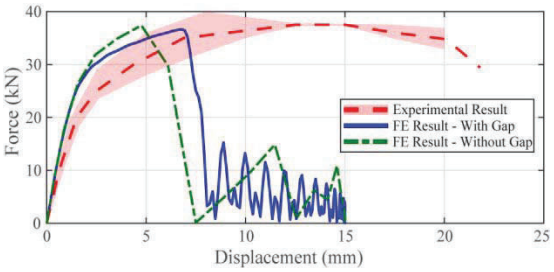

Figure 16: *Experimental [21] and numerical load vs displacement response of models with and without the gap*

Characteristic element length depends on the element geometry and formulation. Same-size elements with an aspect ratio of unity are usually recommended to achieve a uniform L_c in the mesh. If the L_c of elements in the mesh varies significantly from that specified in the damage model, damage behaviour can be different from that defined. As the mesh varies near the holes and the T-joint of the aluminium connector, a sensitivity analysis was conducted for the connector to investigate the impact of L_c on the analysis.

In the original FE model, a value of 2.34 mm was used as L_c for modelling damage in the connector. This value was determined based on the average dimensions of elements in the connector mesh. Another two L_c values were selected for U^p keeping the mesh constant; L_c = 2.10 mm and L_c = 2.60 mm. These two values adequately represent possible element sizes in the mesh. The moment-rotation curves obtained using each L_c value are illustrated in Figure 17.

All three plots follow the same experimental moment-rotation response until approximately 6° of rotation. However, considerable differences between the plots start to appear near the failure point. For L_c = 2.6 mm the analysis over-predicts the maximum moment capacity by 6%, whereas for L_c = 2.1 mm the analysis under-predicts

https://doi.org/10.52202/069179-0372

by 5%. In terms of rotational capacity, L_c = 2.6 mm shows good agreement with the experimental value while L_c = 2.1 mm shows about 1° lower rotational capacity.

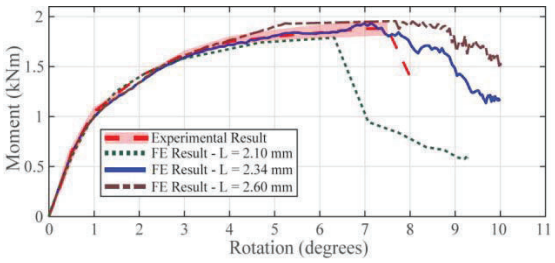

Figure 17: *Experimental [21] and numerical moment vs rotation response for characteristic element length analysis*

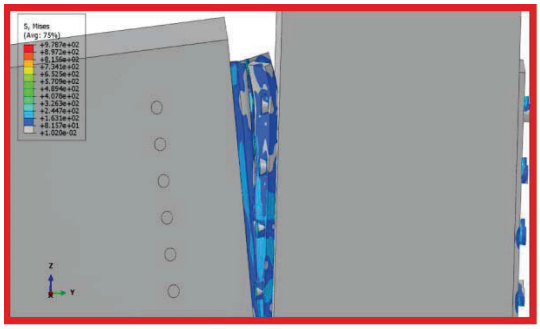
Failure modes for L_c = 2.1 mm, L_c = 2.34 mm and L_c = 2.6 mm are shown in Figure 18, Figure 11 and Figure 19 respectively. Three different failure modes were identified. FE models with L_c = 2.1 mm and L_c = 2.34 mm exhibit tearing of aluminium as was seen in experiments, and in the L_c = 2.1 mm model, even the complete fracture near the web-flange interface can be observed. When L_c = 2.6 mm, failure first occurs in the bolts near the column as presented in Figure 19. Failure modes for the shear tests were similar for all three cases as the actual failure occurred in the timber beam.



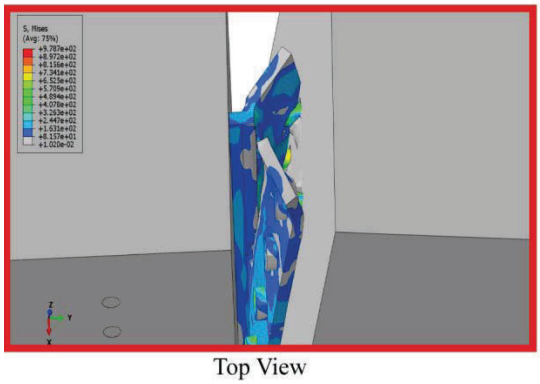


Figure 18: *Numerical failure mode of FE models with L_c = 2.1 mm*

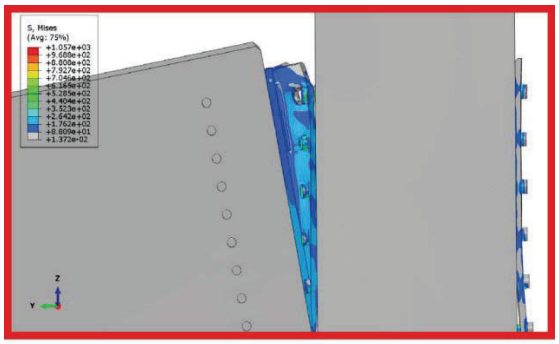
The three failure behaviours observed – tearing and partial fracture, tearing and complete fracture, and bolt failure – are possible alternatives for this connection under moment loading. Therefore, one should consider all such possible mechanisms in order to make predictions and designs if a mesh size of a part varies. In such cases, it is advisable to conduct a parametric study for L_c. This will also take into account the material property variability indirectly in the simulations. Nevertheless, the FE model with average element length may yield overall good results for moment and shear responses.



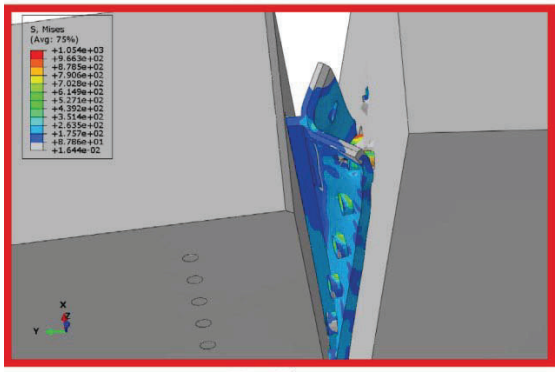


Figure 19: *Numerical failure mode of FE models with L_c = 2.6 mm*

5.3 SYMMETRY OF THE MODEL

To reduce the computational cost, the symmetry of the connection was considered. Based on that, half-models as shown in Figure 20 were created for both moment and shear simulations.

In addition to the boundary conditions and constraints discussed in Section 3.4, symmetric boundary conditions were employed as depicted in Figure 20. Note that, these are applied to the boundary surface excluding the nodes that are involved in contact definitions. This eliminates over-constraint issues. For symmetric boundary conditions, translational DOF in the x-direction and rotational DOFs in the y- and z-directions were restrained. Then, the models were analysed under shear and moment loading conditions to investigate the effectiveness of taking symmetry into account. Moment-rotation and load-displacement curves are shown in Figure 21 and Figure 22, respectively.

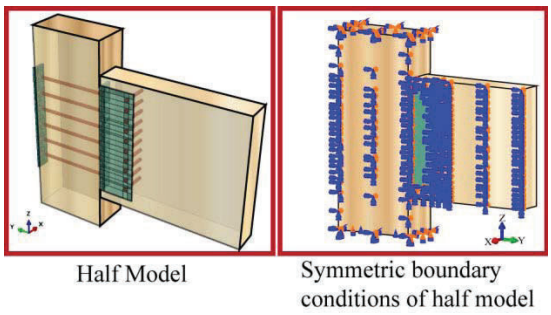

Figure 20: *Half-model and symmetric boundary conditions*

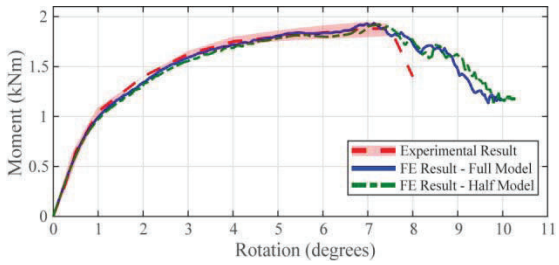

Figure 21: *Experimental [21] and numerical moment vs rotation response of full and half models*

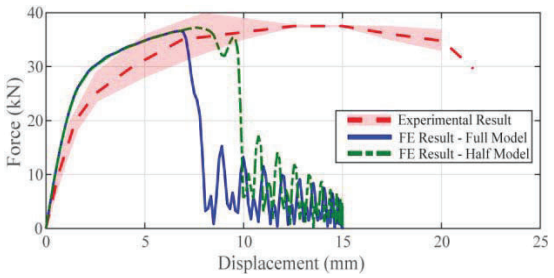

Figure 22: *Experimental [21] and numerical load vs displacement response of full and half models*

The results of the half-model for both moment and shear match closely with the full-model predictions. Therefore, symmetry can be utilised in simulating such timber connections, and this also reduces the computational cost.

6 CONCLUSIONS

This study aims to develop a computational modelling technique that can capture complex pre- and post-failure behaviour of timber beam-column connections under various loads. This paper presents the initial stages of building the complete computational model. A numerical modelling technique was developed using the FE package Abaqus. This technique was then used to analyse a T-section connector under shear and moment to demonstrate the performance of the method. A parametric study was also conducted to increase the accuracy of the model predictions and to evaluate the consistency of the modelling approach adopted. The following conclusions can be drawn:

1. The developed numerical model demonstrates potential in capturing complex pre- and post-failure behaviours of timber connections through large deformations and under different loading situations.
2. For concealed connections, introducing a suitable gap between the column and the beam in the FE models to account for weakening of the hollow portion may provide more realistic results.
3. A sensitivity analysis for the characteristic element length is needed if damage modelling for ductile metals is employed with non-uniform meshes. This is particularly important for FE predictions and designs. An average element length, however, was found to yield overall good results.
4. The symmetry of connections can be taken into account in numerical modelling of connections of this type to improve computational efficiency.

This technique has potential to support design and optimisation of timber connections, especially for robustness. Future works will develop this model to include tensile failure of timber.

ACKNOWLEDGEMENTS

A NEW MULTI-SPRING ELEMENT TO SIMULATE CLT CONNECTIONS UNDER COMBINED LOADINGS

Matías F. Chacón[1], Pablo Guindos[2], Jairo Montaño[3]

ABSTRACT: A new numerical model of five uncoupled spring elements is proposed to simulate the panel-to-panel Cross-Laminated Timber (CLT) connections made of discrete fasteners. The model accurately simulates the main phenomenological effects in the translational and rotational directions of connections: asymmetrical axial gap (open/closure), in-plane and out-of-plane sliding of panels, and radial/bending stiffness/strength of fasteners. Linear/non-linear spring elements with different constitutive material models for each phenomenological effect are considered. For instance, a modified Richard–Abbott model is used for the radial/bending hysteresis of fasteners. The model is implemented in the ANSYS software through user elements and material routines. An illustrative example under different loading conditions is elaborated to show the main capabilities of the proposed model. Finally, the model is validated with two experimental monotonic in-plane CLT slab tests, where the initial/hardening stiffness, strength capacity, and failure mechanism of both specimens are correctly predicted.

KEYWORDS: CLT connection models, non-linear finite elements, phenomenological-based models, hysteretic models.

1 INTRODUCTION

1.1 OVERVIEW

Nowadays, with the arrival of new mass timber products, such as glue-laminated timber and Cross-Laminated Timber (CLT), the incorporation of efficient and innovative high-ductile connectors, and elaboration of high-precision and faster-prefabricated components, provide a viable option to build mid- to high-rise residential/non-residential buildings under a severer seismic hazard [1]. Particularly, CLT panels can be used in either floor and wall elements or as the material for the entire building.

The most critical and vulnerable part of CLT buildings is their connections, which must be designed with extreme care. Moreover, connections' mechanic capabilities (strength, stiffness, ductility, and dissipated energy) typically govern the whole structure's behaviour, particularly under seismic loads [2]. Those connections can be strengthened with an adequate layout of special straight or inclined fasteners (e.g., nails, screws), special steel parts, or slot connectors, which, together with the connection panel type (e.g., butt, half-lap, single or double surface spline) define mainly their hysteretic behaviour [3]. Several tests have been performed to characterize most of these configurations [3,4].

Complex physical effects are present in the interaction of CLT connections, such as opening/closing of panels, friction, withdrawal extraction of fasteners, large deformation and buckling of fasteners, local compression of wood, and fracture and local separation of pieces of their panels [5]. Hence, it is necessary to consider an adequate numerical model to predict the complex response of these connections and provide a more robust design process for CLT buildings.

1.2 CLT CONNECTIONS MODELING

Generally, Finite Element (FE) macro-models are used to simulate CLT connections, where each component is modelled separately, i.e., timber panels with shell elements and discrete fasteners with a set of nonlinear uniaxial or muti-directional coupled/uncoupled springs based on a mechanical and/or phenomenological material approach (e.g., walls [6] or slabs [7]). Uniaxial elements with uncoupled directional springs consider a specific model for each direction [6,8], while multi-directional coupled several directions [9]. Generally, uniaxial FEs are the most controllable and can generate a combined effect that fits well with experimental tests [10].

Phenomenological-based hysteretic models used for spring elements of CLT connections can be divided into the type of constitutive equations (e.g., algebraic [11] or first-order ordinary differential equations [12]) or in their shape (i.e., smooth [12,13] or polygonal [11,14]). The unloading/reloading paths and pinching effect are simulated in all these models with different precision levels. Moreover, some models include stiffness/strength cyclic degradation [13,14].

1.3 GOAL AND SCOPE

This article summarizes the main results of another recent publication by authors, which provides a new robust non-linear FE model to simulate the CLT connections made of discrete fasteners under different loading conditions. More details can be obtained in the article of Chacón *et al*., 2023 [15]. Section 2 describes the numerical connection model, including its spring elements and material models. Moreover, an illustrative example is added to show the proposed model's capabilities. Also, Section 3 shows the results of two simulated experimental in-plane monotonic CLT slab tests with the considered FE model. Finally, the conclusions are listed in Section 4.

2 NUMERICAL CONNECTION MODEL

Five uncoupled spring elements were considered to simulate a generic discrete-fastener CLT connection. User-element and user-material FORTRAN77 subroutines of FEs and their materials were computationally implemented into the ANSYS software [16], respectively.

2.1 FINITE ELEMENTS

Two bar elements were implemented: (i) a uniaxial straight element of two nodes with one translational or rotational Degree Of Freedom (DOF) per node, called hereafter E1; and (ii) a radial 2D straight element of two nodes with two translational DOFs per node and a Lagrangean co-rotational formulation with radial strain, called hereafter RE2.

2.1.1 E1 element

This bar element has two nodes with one translational (U_x, U_y, or U_z) or one rotational DOF per node (Θ_x, Θ_y, or Θ_z), and one integration point at centroid of the element. It has a non-zero initial length l_o, and due to external forces/moments, the bar suffers a small displacement/rotation in each node $\aleph_i$ with $i \in [1,2]$. Considering a small engineering strain metric, the updated element tangent stiffness $\boldsymbol{K}_{n+1} \in \mathbb{R}^{2\times2}$ is given by

$$\boldsymbol{K}_{n+1} = v_o \frac{\partial \sigma_{n+1}}{\partial \varepsilon_{n+1}} (\boldsymbol{B} \otimes \boldsymbol{B}), \tag{1a}$$

$$\boldsymbol{B} = \frac{1}{l_o}[-1 \quad 1], \tag{1b}$$

where $v_o = Al_o$ is the initial element volume, with A being the cross-section element area, and $\frac{\partial \sigma_{n+1}}{\partial \varepsilon_{n+1}}$ is the consistent material tangent stiffness. Moreover, the updated internal force vector $\boldsymbol{F}_{\text{int}_{n+1}} \in \mathbb{R}^{2\times1}$ is expressed as

$$\boldsymbol{F}_{\text{int}_{n+1}} = v_o \boldsymbol{B}^T \sigma_{n+1}, \tag{2}$$

where σ_{n+1} is the updated material stress. Figure 1a shows two of the six cases that this element can adopt, where the U_x and Θ_y DOFs are shown. It cannot consider a zero-length element due to software restraints.

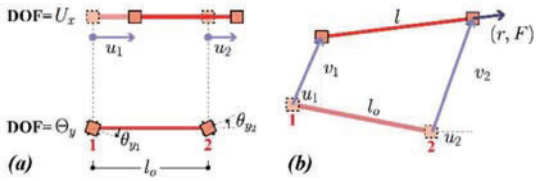

Figure 1: *Definition of the two bar finite elements implemented: (a) E1 (U_x and Θ_y DOFs cases); and (b) RE2.*

2.1.2 RE2 element

This bar element has two nodes, with two translational DOFs per node (U_x and U_y) and one integration point at the centroid of the element. Given some initial position of their nodes $\boldsymbol{x}_i = (x_i, y_i)$, with $i \in [1,2]$, due to external forces, the bar suffers a large arbitrary displacement in each node $\boldsymbol{u}_i = (u_i, v_i)$ (see Figure 1b), which elongates the bar from l_o to l length. Then, considering the Lagrangean co-rotational formulation with engineering strain metric (i.e., $\varepsilon = (l - l_o)/l_o$), the total updated tangent stiffness $\boldsymbol{K}_{n+1} \in \mathbb{R}^{4\times4}$ of this element is expressed as

$$\boldsymbol{K}_{n+1} = v_o \frac{\partial \sigma_{n+1}}{\partial \varepsilon_{n+1}} (\boldsymbol{B}_1 \otimes \boldsymbol{B}_1) + v\sigma_{n+1} (\boldsymbol{B}_2 \otimes \boldsymbol{B}_2), \tag{3}$$

where $v_o = Al_o$ and $v = Al$ are the initial/current element volume; and $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$ are vectors given by

$$\boldsymbol{B}_1 = \frac{1}{l_o}[-\Delta x/l \quad -\Delta y/l \quad \Delta x/l \quad \Delta y/l\,], \tag{4a}$$

$$\boldsymbol{B}_2 = \frac{1}{l}[\Delta y/l \quad -\Delta x/l \quad -\Delta y/l \quad \Delta x/l\,], \tag{4b}$$

with $\Delta x = \Delta x_o + u_2 - u_1$, $\Delta y = \Delta y_o + v_2 - v_1$, $\Delta x_o = x_2 - x_1$, and $\Delta y_o = y_2 - y_1$. The initial/current length l_o and l can be obtained, respectively, as

$$l_o = \sqrt{\Delta x_0^2 + \Delta y_0^2}, \tag{5a}$$

$$l = \sqrt{\Delta x^2 + \Delta y^2}. \tag{5b}$$

The first term of Equation 3 represents the material tangent stiffness, while the second one the geometric stiffness. Moreover, the updated internal force vector $\boldsymbol{F}_{\text{int}_{n+1}} \in \mathbb{R}^{4\times1}$ is given by

$$\boldsymbol{F}_{\text{int}_{n+1}} = v_o \boldsymbol{B}_1^T \sigma_{n+1}. \tag{6}$$

Their element response is studied with a displacement-controlled rotation loop $\theta \in [0, 2\pi]$ and a constant stretching Δl_0, i.e., the displacement load vector $\boldsymbol{u}$ is

$$\boldsymbol{u}(\theta) = (l_o + \Delta l_0) \begin{bmatrix} \cos(\theta) \\ \sin(\theta) \end{bmatrix} - l_o \begin{bmatrix} 1 \\ 0 \end{bmatrix}. \tag{7}$$

A J_2 von Mises material model with a bi-linear isotropic hardening law is assumed. Figure 2 compares their response with the well-known two-node bar element with two translational DOFs per node. Note that only the RE2 element predicts the overall angle's response well, where a constant force and radial to the element direction independent of rotation is observed.

https://doi.org/10.52202/069179-0373

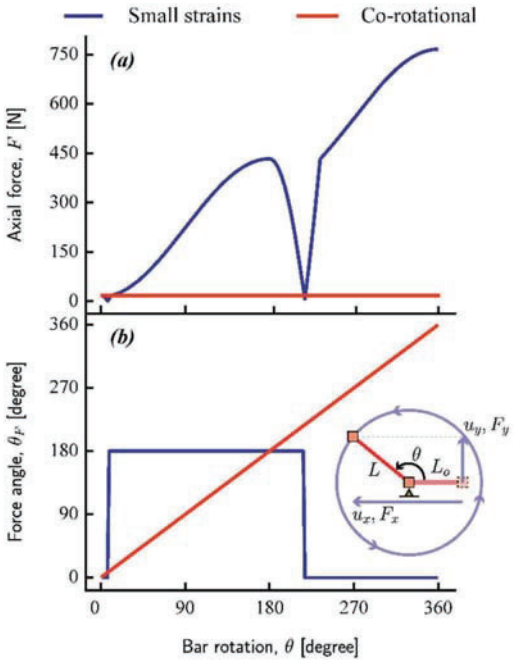

***Figure 2**: Comparison of the RE2 element response between small-strain and co-rotational formulations for a rotation loop $\theta \in [0,2\pi]$ with a constant stretching Δl_0: (a) force-rotation $F(\theta)$; and (b) angle force-rotation $\theta_F(\theta)$.*

2.1.3 Spring elements

To simulate the discrete CLT connections, five uncoupled springs are considered: (i) axial E1 element with asymmetric tensile/compressive model to include the gap of panels; (ii) in-plane shear E1 element with linear-elastic behavior to simulate the lateral slip between panels; (iii) out-of-plane shear E1 element with linear-elastic behavior to include the vertical slip between panels; (iv) radial RE2 element with the Richard–Abbott (RA) model [17] model to add the fastener capacity; and (v) bending E1 element with the RA model to represent the out-of-plane rotation of panels. Figure 3 and Table 1 summarize these elements' main properties and functions.

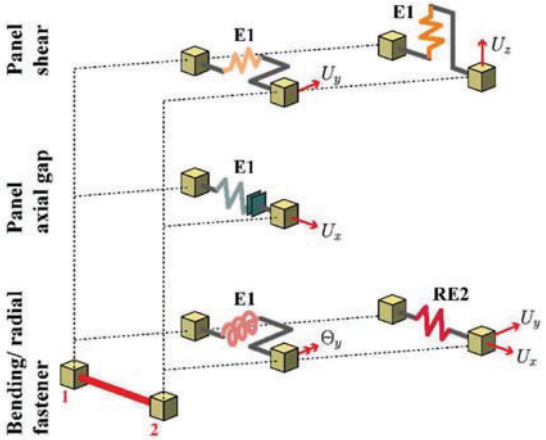

***Figure 3**: Spring elements to simulate a discrete CLT fastener connection. Figure extracted from Chacón et al., 2023 [15].*

***Table 1:** Springs elements for the CLT connection model.*

Id	Function	FE type	DOFs	Material
S1	Panel gap	E1	U_x	Gap
S2	In-plane shear panel	E1	U_y	Linear elastic
S3	Out-of-plane shear panel	E1	U_z	Linear elastic
S4	Radial fastener	RE2	U_x, U_y	Richard–Abbott
S5	Bending fastener	E1	Θ_y	Richard–Abbott

2.2 MATERIAL MODELS

2.2.1 Gap model

A simple and robust asymmetric model simulates the closure/opening gap of CLT panels. It is assumed the following gap force-displacement $F_g(u)$ relation

$$F_g(u) = \langle u \rangle^+ K_g^+ + \langle u \rangle^- K_g^-, \tag{8}$$

where $K_g^{\pm}$ are the Positive/Negative (P/N) (opening/closure) gap stiffness, and $\langle \blacksquare \rangle^{\pm}$ are the P/N Macauley functions (i.e., $\langle \blacksquare \rangle^{\pm} = (\blacksquare \pm |\blacksquare|)/2$). Note that this relation gives a discontinuous slope at zero displacement, which can generate some convergence problems at the FE level.

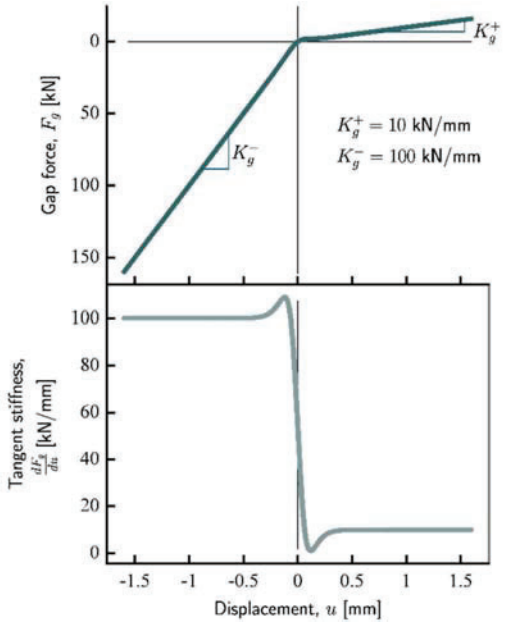

***Figure 4**: Response of gap model: (a) force-displacement $F_g(u)$; and (b) tangent stiffness-displacement $\frac{dF_g(u)}{du}$.*

Then, Equation 8 can be rewritten in terms of some approximated smoothed (C_1-class) P/N Heaviside functions $\widetilde{\mathrm{H}}^{\pm}(u)$ as

$$F_g(u) = \left(\widetilde{\mathrm{H}}^+(u) K_g^+ + \widetilde{\mathrm{H}}^-(u) K_g^-\right) u. \tag{9}$$

Hence, they derivative $\frac{dF_g(u)}{du}$ can be obtained as follows

https://doi.org/10.52202/069179-0373

$$\frac{dF_g(u)}{du} = \sum_{\aleph}\left(\frac{d\widetilde{\mathrm{H}}^{\aleph}(u)}{du}u + \widetilde{\mathrm{H}}^{\aleph}(u)\right)K_g^{\aleph}, \tag{10}$$

where symbol $\aleph$ denotes the '+' and '-' superscript, respectively. For the sake of simplicity, it is considered here the following approximated P/N Heaviside functions $\widetilde{\mathrm{H}}^{\pm}(u)$

$$\widetilde{\mathrm{H}}^{\pm}(u) = \frac{1}{2}[1 \pm \tanh(ku)], \tag{11}$$

where k is an arbitrary parameter such as $\lim_{k\to\infty}\widetilde{\mathrm{H}}^{\pm}(u) = \mathrm{H}^{\pm}(u)$, with $\mathrm{H}^{\pm}(\blacksquare)$ are the P/N stepped Heaviside functions. Figure 4 shows an illustrative example of the gap force-displacement $F_g(u)$ relation and their derivative $\frac{dF_g(u)}{du}$. Note that the slope continuity in both functions is satisfied in the overall displacement range.

2.2.2 Fastener model

A modified version by authors of the Richard–Abbott model [17] is considered to simulate the stiffness/strength fastener capacity. This model was first proposed to simulate the hysteresis of steel connections and can also adequately simulate the cyclic behaviour of timber connections. The model includes the pinching effect, symmetric/asymmetric behaviour, and low-cycle fatigue phenomena.

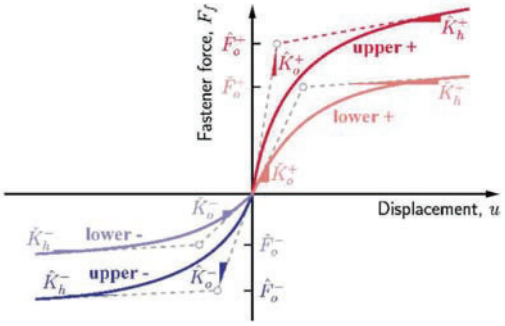

Figure 5: *Definition of parameters for the Richard-Abbott fastener model.*

First, the P/N generalized force-displacement $F_f^{\pm}(u)$ curves (e.g., force or moment and displacement or rotation, respectively) are stated as a combination of an upper $\hat{F}^{\pm}(u)$ and lower $\check{F}^{\pm}(u)$ P/N curves (see Figure 5), and are defined as

$$F_f^{\pm}(u) = f_r^{\pm} - \left(\frac{K_{et}^{\pm}}{\psi_t^{\pm}} + K_{ht}^{\pm}\right)z, \qquad \text{with} \tag{12a}$$

$$\psi_t^{\pm} = \left(1 + \left|\phi_t^{\pm}\right|^{n_t^{\pm}}\right)^{1/n_t^{\pm}}, \qquad \phi_t^{\pm} = \frac{K_{et}^{\pm}z}{f_{1t}^{\pm}} \tag{12b}$$

where $K_{et}^{\pm} = K_{ot}^{\pm} - K_{ht}^{\pm}$, $f_{1t}^{\pm} = f_{ot}^{\pm} + |f_r^{\pm}|$, $z = u_r^{\pm} - u$; $(u_r^{\pm}, f_r^{\pm})$ are the P/N reversal point of curves; $f_{ot}^{\pm}$ are the P/N initial force; $K_{ot}^{\pm}$ and $K_{ht}^{\pm}$ are the P/N initial/hardening stiffnesses, respectively; and $n_t^{\pm}$ are the P/N factor that control the shape of curves. The parameters $f_{ot}^{\pm}$, $K_{ot}^{\pm}$, $K_{ht}^{\pm}$, and $n_t^{\pm}$ are expressed as

$$K_{ot}^{\pm} = \hat{K}_o^{\pm} - (\hat{K}_o^{\pm} + \check{K}_o^{\pm})t, \tag{13a}$$
$$K_{ht}^{\pm} = \hat{K}_h^{\pm} - (\hat{K}_h^{\pm} + \check{K}_h^{\pm})t, \tag{13b}$$
$$f_{ot}^{\pm} = \hat{f}_o^{\pm} - (\hat{f}_o^{\pm} + \check{f}_o^{\pm})t, \tag{13c}$$
$$n_t^{\pm} = \hat{n}^{\pm} - (\hat{n}^{\pm} + \check{n}^{\pm})t, \tag{13d}$$

where $\hat{\blacksquare}$ and $\check{\blacksquare}$ are upper and lower parameters, respectively. The parameter $t \in [0,1]$ is a transition factor that combines the upper and lower parameters linearly and is given by

$$t = \left(\frac{v^{\pm}}{1+v^{\pm}}\right)^{t_2^{\pm}}, \qquad \text{with} \qquad v^{\pm} = \left|\frac{u-u_r^{\pm}}{t_3^{\pm}\left(u_{\max}-u_r^{\pm}\right)}\right|^{t_1^{\pm}} \tag{14}$$

where $t_3^{\pm} \in [0,1]$ are P/N displacement factors that control the shape of pinching curves. Note that the definition of P/N variables $v^{\pm}$ varies from the original RA model to give a symmetric response under symmetric displacement loads. The variable $u_{\max}$ is the maximum displacement at the loading direction, which is defined as

$$u_{\max} = \mathrm{H}^{+}(\zeta)r^{+} + \mathrm{H}^{-}(\zeta)r^{-}, \qquad \text{with} \tag{15a}$$
$$r^{+} = \max_{\tau\in[0,t]}(r^{+}(\tau), \langle u\rangle^{+}), \tag{15b}$$
$$r^{-} = \min_{\tau\in[0,t]}(r^{-}(\tau), \langle u\rangle^{-}), \tag{15c}$$

where $\zeta = \mathrm{sgn}(\dot{u})$ is the loading direction, and $r^{\pm}$ are the P/N displacement thresholds. Note that variables $r^{\pm}$ grow monotonically according to obtained displacements and are independent in both directions.

Second, the model also includes a strength/stiffness degradation phenomenon (fatigue effect), where the degraded generalized force $F_{\omega}^{\pm}$ and the degraded hardening stiffness $K_{h\omega}^{\pm}$ are evaluated according to respective relations

$$F_{\omega}^{\pm} = (1-\omega_f)F_f^{\pm}, \tag{16a}$$
$$K_{h\omega}^{\pm} = (1-\omega_k)K_h^{\pm}, \tag{16b}$$

where $\omega_f \in [0,1]$ and $\omega_k \in [0,1]$ are the strength/stiffness damage variables, respectively, given by

$$\omega_f = 1 - \exp(-J_f\Upsilon), \tag{17a}$$
$$\omega_k = 1 - \exp(-J_k\Upsilon), \tag{17b}$$

with J_f and J_k are the strength/stiffness degraded factor, respectively. Both variables are dependent on the hysteretic dissipated energy Υ (i.e., $\Upsilon(t) = \int F(t)du$). The damage variable ω_f and ω_k does not distinguish the P/N regime, taking the accumulation in both directions. Moreover, Equations 17a-b do not require the completion of cycles to increase the damage as occurs with other proposed models [13,14].

Additionally, the choice of P/N parameters and variables $\theta^{\pm}$ are determined according to loading direction ζ, i.e.,

$$\theta = \mathrm{H}^{+}(\zeta)\theta^{+} + \mathrm{H}^{-}(\zeta)\theta^{-}. \quad (18)$$

Finally, it is essential to note that this model considers a generalized force-displacement (or moment-rotation) relation, whereas the two material models inside of the user-implemented FEs work in the stress-strain space. Then, converting from the force-displacement to stress-strain relation is necessary to give the same FE response as the theoretical point level. Since this model has physical-based parameters, the conversion is explicit and only requires the conversion of three types of parameters: (i) P/N stiffnesses $K_o^{\pm}$ and $K_h^{\pm}$ (or $K_{\theta o}^{\pm}$ and $K_{\theta h}^{\pm}$) for the upper/lower cases; (ii) P/N strengths $F_o^{\pm}$ (or $M_o^{\pm}$) for the upper/lower cases; and (iii) energy-based strength degradation factor J_f. Then, for a force-displacement and moment-rotation relations, their respective above parameters require the following factors

$$\varphi_K = \frac{l_o}{A}, \quad \varphi_F = \frac{1}{A}, \quad \varphi_Y = l_o A, \quad (19a)$$

$$\varphi_K = \frac{l_o}{I_o}, \quad \varphi_F = \frac{1}{I_o}, \quad \varphi_Y = l_o I_o, \quad (19b)$$

where l_o is the element length, A is the cross-section element area, and I_o is the cross-section inertia of element with respect to their centroid. Note that the gap model also requires the conversion of their P/N stiffnesses $K_g^{\pm}$ from force-displacement to stress-strain space, which is used the factor φ_K of Equation 19a.

In summary, the model uses four quadruplets of parameters to define the upper and lower curve ($K_o^{\pm}$, $K_h^{\pm}$, $F_o^{\pm}$, and $n^{\pm}$), three pairs of parameters to state the transition parameter t ($t_2^{\pm}$, $t_2^{\pm}$, and $t_3^{\pm}$), and two parameters to control the fatigue (J_f and J_k). Hence, the model has a total of 24 parameters. An explicit numerical integration scheme for the updated force of this model is performed, where six state variables are considered $\boldsymbol{q} = \{\zeta, \Upsilon_d, r^{+}, r^{-}, u_r, f_r\}$.

Three illustrative examples are considered to show the capabilities of this model. The first two are illustrative examples, where it is used a set of symmetrical and asymmetrical P/N parameters, respectively. In contrast, the third example is a validation of the experimental in-plane cyclic CLT connection test of Gavric *et al.* [5]. Table 2 lists all parameters considered for the three cases. Figure 6 shows the first two cases, whereas Figure 7 the third one. Four increased amplitude loading displacement cycles are applied in the first two cases (see Figure 6). The same displacement pattern as the experimental test is considered for the third case.

***Table 2**: Parameters for the three examples of the RA fastener model.*

	Example		
Parameter	E1	E2	E3
K_o [kN/mm]	[2, 2, 2, 2][(a)]	[3, 2, 3, 2]	[1, 1, 3, 3]
K_h [N/mm]	[30, 30, 10, 10]	[70, 20, 10, 10]	[220, 200, 60, 60]
F_o [kN]	[10, 10, 1, 1]	[10, 5, 3, 1]	[7, 6, -1, 2]
n [-]	[1.5, 1.5, 1.5, 1.5]	[1.5, 1.5, 1.5, 1.5]	[4, 4, 4, 4]
t_1 [-]	[10, 10][(b)]	[15, 15]	[40, 40]
t_2 [-]	[0.9, 0.9]	[0.9, 0.9]	[0.1, 0.1]
t_3 [-]	[0.9, 0.9]	[0.9, 0.9]	[1, 1]
J_f [-]	0	9×10^{-4}	5×10^{-7}
J_k [-]	0	1×10^{-4}	1×10^{-8}

[(a)] P/N upper and P/N lower values, respectively; [(b)] P/N values, respectively.

First, Figure 6a shows the force-displacement hysteresis using symmetrical P/N parameters, where symmetry is preserved regarding the force/stiffness of the envelopes and pinching curves. Second, Figure 6b shows the response of the second case, where a notable strength asymmetry and stiffness/strength degradation is observed. Third, a good fit in terms of envelopes and pinching paths is kept for the third case (see Figure 7a), where an error less than 1% is measured for the peak strength and respective displacement in both directions, and a coefficient of determination η_{det} (R^2) for the force history of 93.25 is calculated. Moreover, the model reproduces with considerable precision the low-cycle fatigue phenomena.

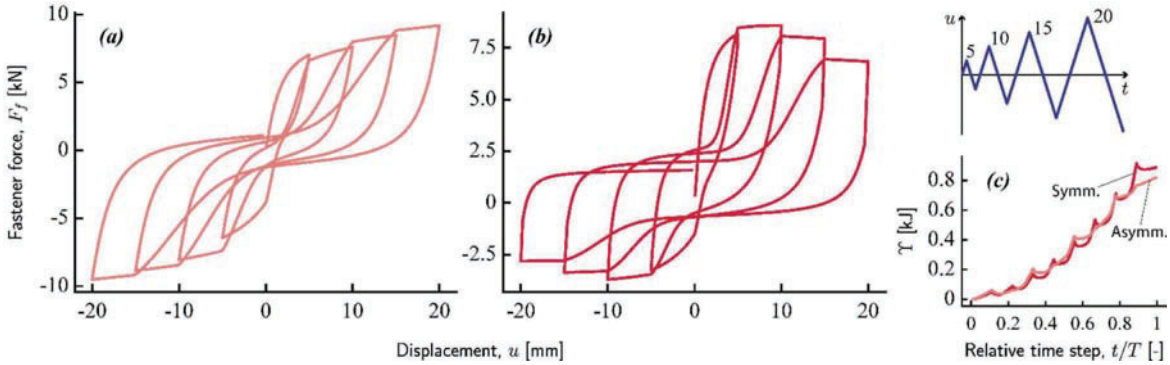

***Figure 6:** Force-displacement hysteresis $F_f(u)$ of the RA fastener model for two illustrative examples with different set of parameters: (a) symmetrical P/N parameters; (b) asymmetrical P/N parameters; and (c) hysteretic dissipated energy of both cases.*

https://doi.org/10.52202/069179-0373

Moreover, Figures 6c and 7b show the history of dissipated energy $\Upsilon(t)$ for all cases. A more significant amount of energy is dissipated in the second case than in the first one due to the incorporation of the stiffness/strength degradation factors in the model. For the third case, an excellent fit is observed concerning the experimental test, where a coefficient of determination η_{det} of 99.02 is estimated. Nevertheless, some minor differences exist, showing a moderate underestimation at 0 to 0.6, while an overestimation from 0.8 to the end is noted.

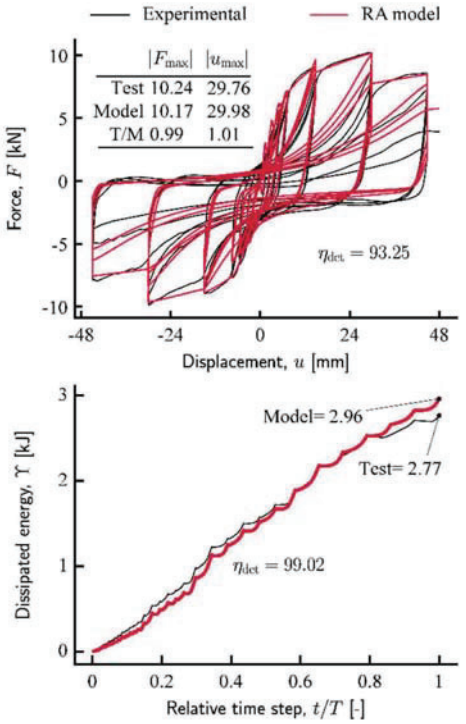

Figure 7: *Third example of the RA fastener model validated with the in-plane cyclic CLT connection test of Gavric et al. 2015 [5]: (a) force-displacement $F(u)$; and (b) dissipated energy-relative time step $\Upsilon(t/T)$.*

2.3 CONNECTION MODEL RESPONSE

To show the response of connection FE model under different loading conditions, an illustrative example is elaborated (see Figure 8a). Two generic square 3-layered CLT panels (t=100 mm) with a width of 1200 mm are joined with nine generic fasteners (ϕ=6 mm), equally spaced along the edge, and are loaded with different independent cyclic loads: axial, in-plane shear, and out-of-plane bending. Displacement-controlled load is applied at right edge of right panel, whereas a fixed support is considered at left edge of left panel. A gap separation of 5 mm between panels is imposed to get a more realistic response and to consider a non-zero length for the spring elements.

A Three-Dimensional (3D) FE model is generated in ANSYS, as shown in Figure 8b. On the one hand, the CLT panels are simulated with a four-node layered-shell element SHELL181 with a linear-orthotropic material model for each lamella, whose material X-axis is oriented parallel-to-grain direction of each lamella. This element accounts for the shear distribution using the Mindlin-Reissner first-order shear-deformation theory and can adequately represent the mechanical behaviour of orthotropic plates since their stiffness depends on the loading situation. On the other hand, each fastener is simulated with the proposed set of five two-node spring elements USER300 and their materials of Sections 2.1 and 2.2, respectively.

[(a)] $G_{xz} = 0.5E_x/(1+\upsilon_{xz})$ and $G_{yz} = G_{xz}$; [(b)] P/N upper and P/N lower values, respectively; and [(c)] P/N values, respectively.

Table 3 lists the material parameters for the CLT panels and three of the five spring elements (radial, bending, and

gap). Moreover, for the two shear springs (in-plane and out-of-plane), it is assumed a linear-elastic material, where Young's modulus equal to XZ-shear modulus of CLT panels G_{xz} is considered for both springs for simplicity. Also, for the in-plane shear spring, a shear area of $A_{vy} = 5/6A_{\text{fast}} \times 10^{-5}$, with A_{fast} is the fastener cross-section area, is assumed to simulate quasi-null in-plane friction and to avoid singularity (null pivot) at stiffness matrix. In contrast, for the out-of-plane shear spring, a shear area of $A_{vz} = 5/6A_{\text{fast}}$ is taken because no out-of-plane slip is assumed.

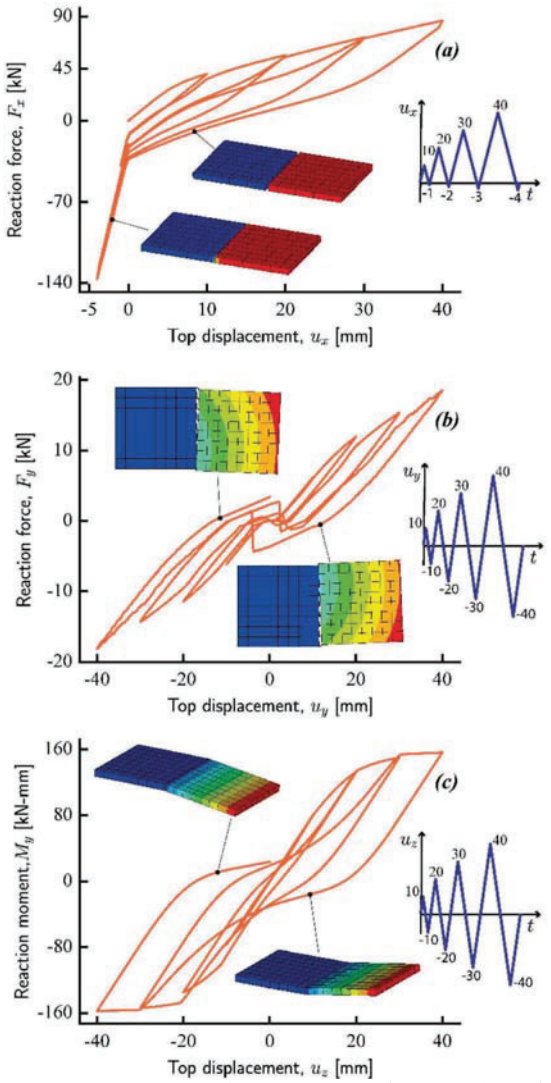

Figure 9: *Response of connection model example under different loadings conditions: (a) axial; (b) shear; and (c) bending. Figures include the displacement field of the FE model for a P/N loading condition at some unspecific time step.*

Figure 9a shows the axial reaction force-axial top displacement $F_x(u_x)$ curve of this FE model under a cyclic axial displacement load. An asymmetric displacement load pattern with four cycles of increased magnitude is considered, where positive (tensile) displacements values are larger than negative (compressive). The gap effect of panels is correctly simulated, where a cyclic behaviour with stiffness degradation and pinching is present in the tensile regime. In contrast, a marked linear-elastic behaviour is noted in the compressive one.

Figure 9b presents the in-plane reaction shear-lateral top displacement $F_y(u_y)$ relation of this FE model under a cyclic in-plane lateral displacement load. Conversely to the axial case, a symmetric P/N displacement load pattern with four cycles of increased magnitude is applied. A symmetric response is observed, with a larger amount of hardening in their envelopes, a significant pinching at the unloading/reloading paths, and an initial gap displacement of approx.—5 mm associated with the length of spring elements. Moreover, a snap-through behaviour is observed at relatively small displacements (around 5 to 10 mm), which is more pronounced at larger displacements. This phenomenon can be attributed to coupling gap/radial fastener springs. Note that this class of load test is scarce in literature (with free panel rotation) and that the shear capacity is lower than the axial one, contrary to several experimental CLT joint tests [4,5].

Figure 9c shows the bending reaction moment-vertical top displacement $M_y(u_z)$ curve of this FE model under a cyclic vertical displacement load. An identical symmetric displacement load pattern to the second case is applied vertically. A hysteretic response is observed, similar to the pure RA fastener response, like in Figure 6a, that no other coupling effects are present for this load case.

3 VALIDATION EXAMPLES

To experimentally validate the proposed numerical connection FE model, the two in-plane monotonic CLT slab test specimens of Veliz *et al*., 2023 [18] are simulated (see Figure 10a). The first specimen, called hereafter Slab1, is composed of three 5-layered CLT panels elaborated with C24-class Chilean radiate pine (t=165 mm) and two top surface spline connections, each made of plywood (t=18.5 mm) and 11 Simpson SDWS22600 (ϕ5.6x150 mm) screws [19] alternated placed. The second specimen, called hereafter Slab2, is composed of four 3-layer CLT panels of identical wood specimen and quality (t=99 mm) and three top butt joint connections, each made of stainless-steel plate (t=3 mm) and 18 Simpson SDS25312 (ϕ6.4x89 mm) screws [19] orthogonally placed. A gap separation of 5 mm between panels was imposed initially in both specimens to avoid an undesirable compression failure between panels and neglect friction forces into the response.

Figure 10b shows the 2D plan view of both specimens and their loading setup. First, a displacement-controlled load is applied in both specimens using two actuators positioned at the middle panels (see Figure 10b). Then, a monotonic load is applied up to reach the complete failure of each slab.

https://doi.org/10.52202/069179-0373

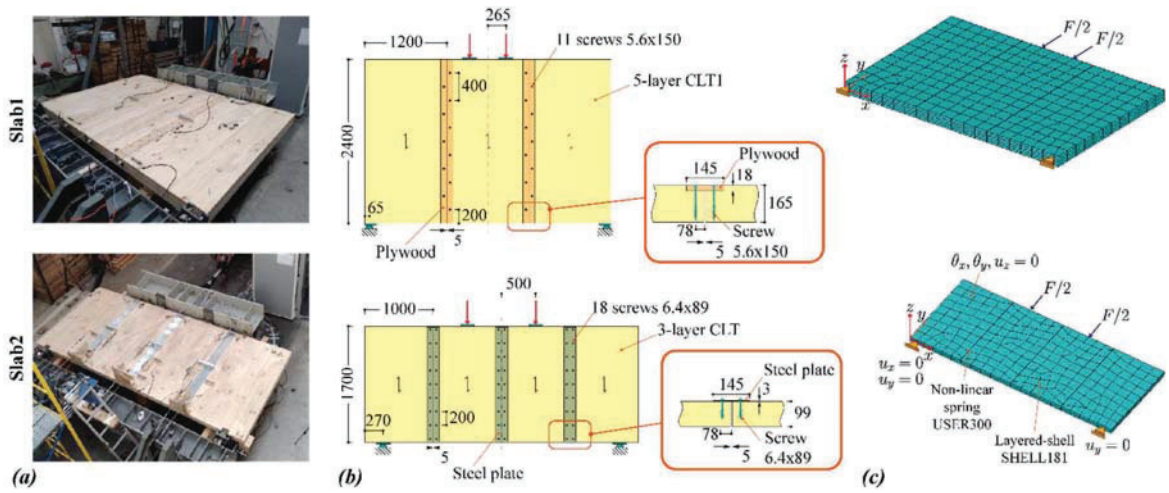

Figure 10: *In-plane monotonic CLT slabs tests of Veliz et al., 2023 [18]: (a) 3D view photograph; (b) 2D plan view of setup; and (c) 3D view of FE model. Figure extracted from Chacón et al., 2023 [15].*

Experimentally, both specimens showed a moderate ductile behaviour, with a ductility of approx. 3.5 and 2.5, respectively (see Figure 12). On the one hand, the failure mechanism of Slab1 was due to the damage of 10 screws (22 in total), which had a mixed failure mode (i.e., 4 ductile and 6 shear brittle). Moreover, fibre densification of CLT around all hole screws and penetration of almost head screws inside plywood were observed. Also, a rigid body motion of panels (without significant damage) with a moderate beam effect was observed, which generates an important shear slip of the central panel, a rotation of both lateral panels, and, consequently, a moderate lateral aperture of both connections. On the other hand, a similar failure mechanism occurred with the Slab2 due to the shear failure of 34 screws (54 in total) and tensile perpendicular-to-fibre failure at central edge panels. In addition to the fibre densification around all hole screws, the steel plates suffer a partial global buckling between each screw span and plastic deformation around screw holes. Furthermore, a more pronounced beam effect than Slab1 was viewed for this specimen due to a larger aspect ratio, where a considerable lateral aperture of connections and a less shear slip of the two central panels were noticed. Finally, note that all these observations explain why Slab2 is stiffer, stronger, and less ductile than Slab1.

Like example of Section 2.3, a 3D FE model is generated in ANSYS for each specimen, as shown in Figure 10c. On the one hand, the CLT panels are simulated with three/four-node layered-shell element SHELL181, where a linear-orthotropic material model is considered for each layer. On the other hand, each fastener is simulated with three of the five proposed spring elements and their respective materials (see Sections 2.1 and 2.2). The three springs considered are panel gap (S1), out-of-plane panel shear (S3), and radial fastener (S4). The other two springs were not required due to that was experimentally observed a significant gap separation between panels (in-plane spring S2) and a negligible out-of-plane rotations (bending fastener spring S5). Note that the out-of-plane spring S3 was included exclusively to avoid a null pivot in the vertical direction of the element stiffness matrix. Moreover, the panel gap springs (S1) were placed only at the nearest node at the top/bottom panel edges. Table 4 lists the material parameters for the panels and two spring elements (radial and gap). Also, same spring element S3 as the example of Section 2.3 is considered here because no significant out-of-plane slip was measured. A monotonic displacement-controlled load pattern is applied equally at the two nodes where the actuators were positioned and using 300-time steps for both specimens.

Table 4: *Material parameters for the two simulated CLT slabs.*

	CLT slab	
Parameter	Slab1	Slab2
CLT

G_{xy},G_{xz},G_{yz} [GPa]	0.69, 0.345[(a)], 0.345[(a)]	0.69, 0.345, 0.345
Radial spring (S4)		
K_o [kN/mm]	[0.5, 0.5, 0.5, 0.5][(b)]	[0.8, 0.8, 0.8, 0.8]
K_h [N/mm]	[50, 50, 20, 20]	[70, 70, 20, 20]
F_o [kN]	[2.3, 2.3, 1, 1]	[7, 7, 1, 1]
n [-]	[4, 4, 4, 4]	[4, 4, 4, 4]
t_1 [-]	[40, 40][(c)]	[40, 40]
t_2 [-]	[0.1, 0.1]	[0.1, 0.1]
t_3 [-]	[1, 1]	[1, 1]
J_f [-]	5×10^{-7}	1×10^{-7}
J_k [-]	3×10^{-8}	3×10^{-8}
Gap spring (S1)		
K_g^+ [kN/mm]	2.99	1.74
K_g^- [kN/mm]	74.80	43.56

[(a)] $G_{xz} = 0.5E_x/(1+\upsilon_{xz})$ and $G_{yz} = G_{xz}$; [(b)] P/N upper and P/N lower values, respectively; and [(c)] P/N values, respectively.

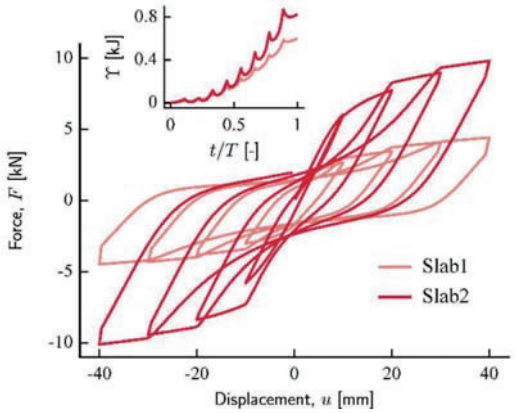

***Figure 11**: Force-displacement hysteresis $F(u)$ of the S4 radial fastener spring element for the two simulated CLT slabs. The figure includes the respective dissipated energy-relative time step $\Upsilon(t/T)$ relation.*

Figure 11 depicts the force-displacement hysteresis of the S4 spring element (radial fastener) with the RA model for the two simulated CLT slabs. Note that the fastener springs of Slab2 have more strength/stiffness than used in Slab1, which is according to the admissible strength capacity of each screw [19]. The traditional inverse iterative approach is considered to calibrate the parameters of springs S1 and S4 for both specimens, where the force-lateral displacement curve $F_y(u_y)$ of each entire FE model is used to minimize the error concerning the experimental test (see Figure 12). Additional experimental CLT connection tests under monotonic/cyclic axial and in-plane shear loads can be required to directly calibrate the spring elements (S1 and S4) to avoid this iterative process. During this process, it was observed that the tensile gap stiffness of spring S1 plays a key role in the failure mechanism of the entire model, especially at the hardening phase. Small values of this parameter give a more CLT panel rotation, whereas large values generate a quasi-pure panel translation.

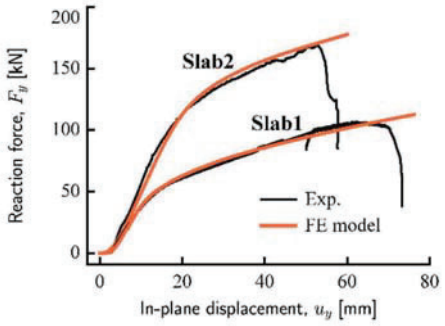

***Figure 12:** Comparison of reaction force-displacement $F_y(u_y)$ for the two tested and simulated CLT slabs.*

Figure 12 compares the experimental measurements concerning the reaction force-lateral in-plane displacement $F_y(u_y)$ curve of each simulated CLT slab. It should be noted that for Slab 1, it was necessary to add an offset displacement of 2.5 mm to the experimental data due to an initial gap separation of 5mm in the model. Nevertheless, it was observed in both slab models a good fit for the elastic and hardening phase concerning experimental results. Although the RA model includes strength degradation, the complete FE model cannot adequately simulate both tests' abrupt softening failure phase.

Figure 13 shows the equivalent von Mises stress (i.e., $\sigma_{eqv} = \sqrt{3/2\boldsymbol{s}:\boldsymbol{s}}$, with $\boldsymbol{s} = \boldsymbol{\sigma} - (\sigma_x + \sigma_y + \sigma_z)I/3$ is the deviatoric stress tensor and $\boldsymbol{\sigma}$ is the Cauchy stress tensor) of the two simulated CLT slabs at the final time step. The maximum value of this field in both specimens is observed to be lower than the allowable compressive strength parallel-to-fibre of panels obtained from the current timber code designs, i.e., $f_{c,0}$=8 MPa [20]. Moreover, the images also show the displacement field, which agrees with the failure mechanism of both experimental tests [18].

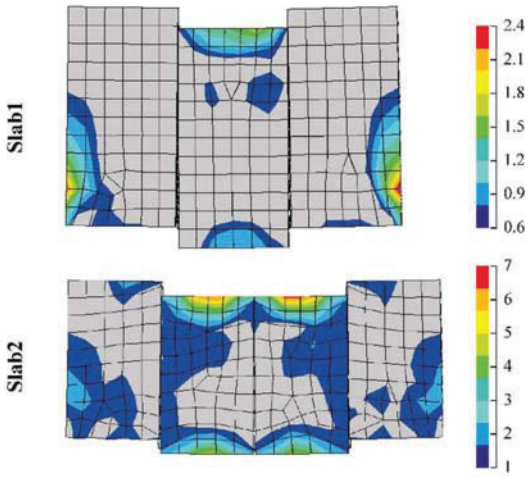

***Figure 13**: Equivalent von Mises stress field σ_{eqv} of the two simulated CLT slabs. Units in MPa. Note: the images also include the displacement field amplified by 3 times.*

4 CONCLUSIONS

A new Finite Element (FE) model is proposed to simulate the discrete-fastener panel-to-panel CLT connections. A set of five linear/non-linear uncoupled spring elements are considered, where each of them simulates the main phenomenological effect of connections under different loading conditions: (i) gap of panels with an axial element and asymmetrical tensile/compressive (gap) model; (ii) in-plane and out-of-plane slip of panels with two linear-elastic uniaxial elements; and (iii) radial and out-of-plane bending stiffness/strength capacity of fastener with a respective radial and uniaxial element using both the modified Richard-Abbott hysteretic model. The main conclusions are:

- On one hand, the gap model adequately simulates the axial behaviour (closure/opening) of CLT panels. On the other hand, the modified Richard-Abbott model

https://doi.org/10.52202/069179-0373

predicts well the contribution of discrete fasteners for the CLT connections. In addition, this model accurately simulates the hysteresis of a generic timber connection, including pinching, asymmetric positive/negative loading, and stiffness/strength degradation phenomena.

- The FE connection model simulates three satisfactory loading conditions: axial, in-plane shear, and out-of-plane bending. The gap effect (open/closure) is correctly simulated at axial loads, where a hysteretic tensile/linear compressive regime is stated. Moreover, at in-plane shear loads with a free panel rotation, a snap-trough behaviour at small displacements is observed due to the coupling of gap and radial fastener springs. Also, at bending loads, the pure bending fastener spring is represented in the overall response of the model.
- The FE model is correctly validated with the experimental results of two CLT slabs under in-plane monotonic loads. Furthermore, the 3D FE models generated agree with the experimental tests regarding initial/hardening stiffnesses, strength capacity, and failure mechanism. Also, it is observed that a critical role plays in the tensile stiffness of the gap spring in predicting the failure mechanism of the entire specimen, where smaller values give larger panel rotations.

EXPERIMENTAL AND NUMERICAL ASSESSMENTS OF A LONG-SPAN MASS TIMBER FLOOR SYSTEMS SUBJECTED TO FOOT-FALL INDUCED VIBRATION

Christian Slotboom[1], Carla Dickof[2], Tobias Fast[3]

ABSTRACT: The following paper presents a series of experimental and numerical vibration assessments completed on the long-span floor system of Fast+Epp's home office. Measurements were taken on the building throughout different stages of construction to understand the impact of non-structural elements on floor vibration. Factors considered are partitions, concrete toppings, and screws between the glulam beam and CLT topping. Finite element models are also created for the structure, and predictions from these numerical models are compared to experimental data. The model used simplified models, similar to those practicing designer would make, and several parameters in these are varied to understand their impact on vibration. It was found that non-structural elements had a significant effect on the vibration performance of the system, changing both the fundamental frequency and reducing the overall accelerations.

KEYWORDS: Vibration, Mass Timber, Long-span floor, Footfall loads.

1 INTRODUCTION

Long-span floor systems are preferred for many types of buildings such as office and commercial buildings because they allow for flexible open floor plans suitable to any tenant. However, long-span floors are generally more susceptible to serviceability constraints such as footfall vibration. Human-induced vibration on a floor is the result of periodic excitation (i.e. steps at a regular frequency); this periodic force will cause the floor to vibrate, and if that vibration is too large it may cause occupant discomfort.

Floor vibration is of particular concern to mass timber floor systems. Mass timber's high strength-to-weight ratio makes it an appealing material for use in long-span floor system. However, the lower mass means it is more susceptible to footfall excitation and vibration will more often govern the size of the floor structural elements. As mass timber continues to grow as a building material, it is important to have both accurate structural models and a body of research and in-situ data on vibration performance.

Guidance for designing structure for vibration and completing vibration assessments is established in many well-known documents such as the CCIP design guide for footfall vibration, or the US Mass Timber Floor Vibration Design Guide [1-4]. However, an area of uncertainty that often arises is how non-structural elements in a building, such as the partitions or concrete topping, impact vibration. Some physical testing has noted that non-structural elements have a large impact on floor behaviour [5]. However, the impact of non-structural elements has not been quantified for many in-situ mass timber floors, and few studies have been completed on long-span mass timber floor systems.

As Fast+Epp recently constructed a new home office, an opportunity arose to study some of the uncertainties affecting vibration during the construction of that office. A research program was developed to conduct vibration tests on a full-scale mock-up, and the Fast+Epp home office itself. Assessment of the floor system in Fast+Epp's home office was completed in two phases. In phase one, a physical mock-up of the floor plate used in the office was built and assessed for vibration. A summary of the first phase is provided in Slotboom et al. [6].

The second phase of testing would occur on the home office, and is presented in the following study. Of particular interest for the second phase was how the vibration performance of the structure would change throughout construction. Testing was therefore set up to understand:

- The overall vibration performance of the long span floor system in the building.
- The impact of various structural and non-structural components on the floor's vibration performance.
- How predictions from finite element models compare to actual measurements of the floor system, and how modelling of future floors can be improved.

The results are used to recommend some practical guidelines for modelling practices.

2 EXPERIMENTAL PROGRAM

2.1 BUILDING OVERVIEW

The Fast+Epp home office, as shown in Figure 1, is a four-story structure with a 35m long by 12m wide floor plate and 3mx12m structural grid. The office features a long span mass timber floor system, consisting of 3ply CLT panels supported on glulam beams that span up to 11.5m

[1] Christian Slotboom, Graduate Engineer, Fast+Epp, cslotboom@fastepp.com
[2] Carla Dickof, Associate Principle, Fast+Epp, cdickof@fastepp.com
[3] Tobias Fast, Partner, Fast+Epp, tfast@fastepp.com

https://doi.org/10.52202/069179-0374

between steel columns and a CLT wall. The floor panels are V2M1.1, 105mm SPF CLT, that span perpendicular to the beams and continuously across 2 or 3 bays. The beams used were made of grade 24f-E 608mm deep Douglas Fir Glulam, with width that varies between 265mm, 315mm, and 365mm depending on the floor and location. On the west side of the building, the glulam beams are connected to a series of steel HSS columns with a bolted knife plate connection. A similar detail is used to connect the beams to a CLT wall on the north side of the building. Figure 2 below summarizes floor grid building, while Figure 3 shows the knife plate connection used.

Figure 1: *The Vancouver home office of Fast+Epp.*

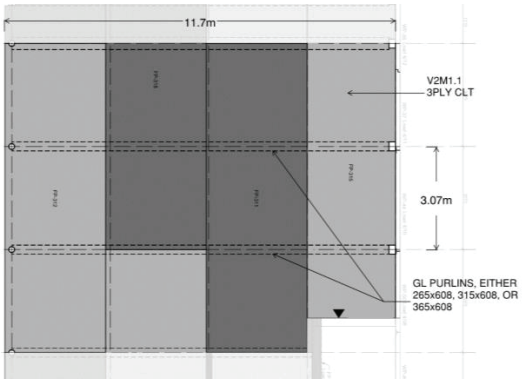

Figure 2:*Summary of the floor grid*

The CLT panels were connected at panel joints plywood splines. These consisted of a 140 mm x 25 mm thick D.Fir strip of plywood along the CLT panels full length. Splines were connected to the panel with 4x60 ring shank nails spaced at 64mm on centre. CLT panels were connected to beams using 6Øx220 partially threaded screws with counter sunk heads, spaced at 400mm. The screw spacing was informed using studies performed on the mock-up [6], where it was found adding additional screws had diminishing returns on stiffness. After the panel was installed, a 50mm concrete topping was applied over an acoustic layer on top of the CLT panel. The concrete had a compressive strength of 32Mpa, and no supplementary connectors were used to join the concrete floor with the CLT panel.

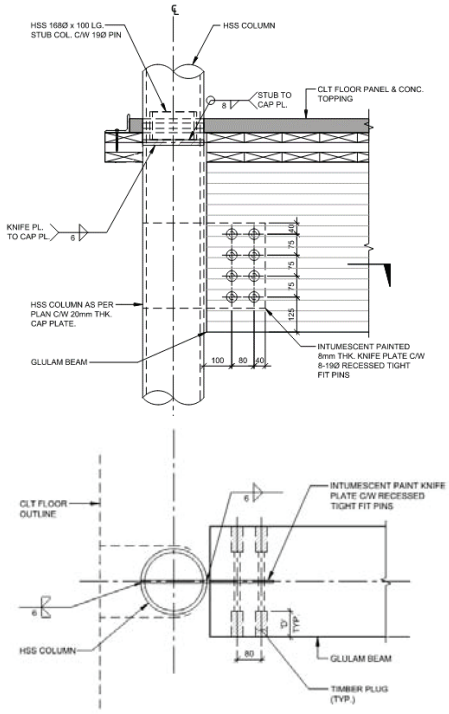

Figure 3: *Colum to beam connection detail.*

2.2 EXPERIMENTAL PROGRAM

Vibration testing on the office was completed at several points during construction to both gauge the performance of the building, and understand the effect of non-structural components on it. A total of four building states were measured:

1. B1: bare superstructure,
2. B2: post concrete topping,
3. B3: post partition installation, and
4. B4: with full building furniture fit-out.

For each building condition, three types of vibration tests were run: ambient vibration, heel-drop, and walking vibration. Vibration was measured with a Crystal Instruments Spyder Analyzer vibration sensor and two accelerometer sensors used to measure vertical accelerations. Most of the testing used a recording increment of 0.002s. Tests were run in a suite, where a receiving location was chosen, and a series of walking trials were completed. Note that because testing occurred during construction, it was not always possible to test all floors of the building, or use the exact same test locations between each test, due to material on site. In particular, testing on L4 was not completed in B1, because the level had not been constructed on the test day.

Walking tests were completed by recording the acceleration response of the floor while a single tester walked along specific walking paths at specific frequencies. Figure 4 provides an overview of the recorder location and typical paths used for the walking tests on the structure. For each receiver location chosen, a

https://doi.org/10.52202/069179-0374

total three walking paths were chosen, and four walking frequencies were tested for each path.

Table 1: *Walking test suite designations.*

Building State	Level	Receiver Locations
B1	L2	R1, R2, R5
	L2	R1, R2, R5
B2	L3	R1
	L4	R1, R2, R5
B3	L4	R1, R2, R5
B4	L3	R1
	L4	R1, R2, R3

Figure 4 also shows typical walking paths and heel drop locations taken for the structure. For each receiver location, several walking paths are walked. The walking paths were chosen and named as follows:

- W1: Walking transverse to the primary beam span, along the centre of the outermost panel.
- W2: Walking parallel to the primary beam span, at the mid-point of the panels.
- W3: Walking parallel to the primary beam span, directly over the beam.

For each walking path, walking tests were completed using four walking frequencies. These were named as follows:

- F1: 1.25 Hz (75 Steps per min).
- F2: Hz (95 Steps per min).
- F3: Hz (110 Steps per min).
- F4: Hz (125 Steps per min).

In heel-drop tests, one vibration sensor was placed at the location of the heel-drop, and another was placed far from them. A tester performed a heel-drop near the accelerometers and the floors acceleration response to that impact was recorded. The heel-drop tests were completed in a grid of points across the floor, where the main sensor location remained in the same place, and second sensor moved with the heel drop location. These tests were used to get a more accurate measurement on the frequencies floor modes were responding at, as walking vibration tests do not have a clear signal decay. Table 2 overviews the heel drop grids that were completed on the floor.

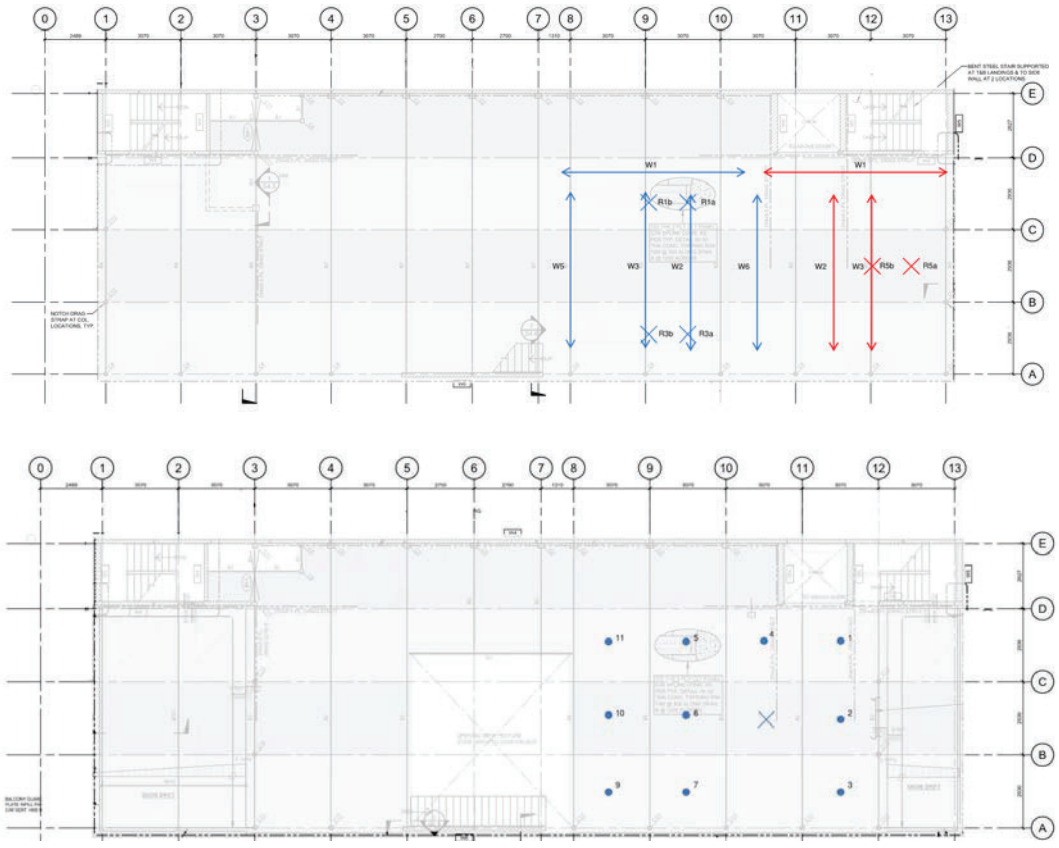

Figure 4: *Summary of walking paths (Wi) and receiving locations (Rj) for testing on 3rd floor, and the heel drop locations on the fourth floor.*

https://doi.org/10.52202/069179-0374

Table 2: *Heel Test Suite Designations.*

Building State	Level	Receiver Location	Heel drop Locations
B2	L3	R6	H1-H9
B3	L4	R6	H1-H11
B4	L3	R6	H1-H11
	L4	R6	H1-H8

Combined, the above naming convention can be used to give each test a designation, based on a test's building state and location. Each walking suite is given a representation based on where it was completed, Ba-Lb-Rc-Wd-Fe, where:

- "a" represents the building state,
- "b" represents the level testing occurred at,
- "c" represents the receiver location chosen,
- "d" represents the walking path taken,
- "e" represents the walking speed used.

Similarly, heel drop experiments were given a designation Ba-Lb-Rc-Hd, where parameters "a", "b", "c" are as described above, and "d" is the number of the heel drop test used.

2.3 EVALUATION METHODOLOGY

There are two significant outputs from each vibration measurement: a signal of the raw acceleration over time, and a frequency spectrum of the Fourier transform that shows which frequencies are dominant in the vibration. The time-acceleration response is used to measure the magnitude of vibration that occurs in the floor, as well as qualitative gauge the response of the floor. Qualitative measurements were completed by visual inspection of vibration signals, to determine if the floor has resonate response to loads and can be characterized as a low frequency floor. The magnitude of vibration is measured by calculating the Root mean Square (RMS) of the vibration signal. Recommendations from CCIP-016 [2] were used to calculate the RMS, including using an averaging time of 1s, and applying a band pass filter to the raw data.

The results frequency domain data were largely used to predict the fundamental frequency of the floor, and estimate changes in system stiffness. The fundamental frequency of the floor was estimated using the frequency of the lowest local peak in the frequency response spectrum. Changes in frequency between building states estimated using first principles, as frequency (ω) is known to be proportional to system stiffness (k) and mass (m) per equation (1).

$$\omega \sim \sqrt{\frac{k}{m}} \qquad (1)$$

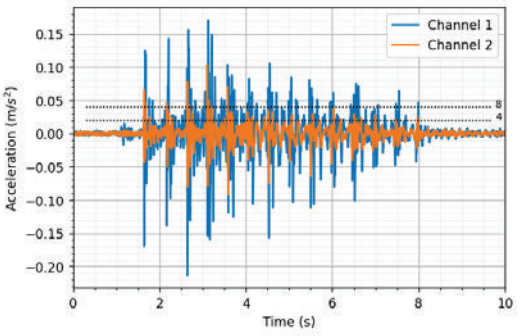
Damping measurements for the floor were also measured using the results of heel-drop tests. A logarithmic decrement method was used to measure damping, where peaks from the damped signal were extracted and then an exponential function was fit to those peaks. The resulting function was used to estimate damping in the system.

3 EXPERIMENTAL PROGRAM RESULTS

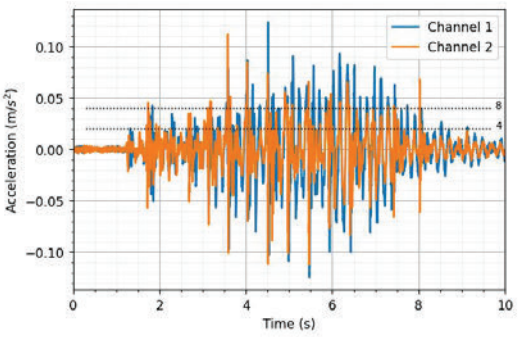
Testing was completed. Due to issues accessing the site during construction, different testing locations were used between the L3 test on B1, and L3 tests on B2/B4. The effect of this change in location is discussed in Section 4.3.

3.1 ACCELERATION RESULTS

Raw acceleration signals were examined qualitative assess if the floor behaved like a low frequency floor, where response is governed by a resonant build-up of vibration, or a high frequency floor, where response is governed by impulse. Based on the data collected, the floor had a mixed response but mostly behaved as a high frequency floor. However, for many tests it was also observed that the vibration did not fully decline between footfalls. This indicates that there was some resonant response, and the floor did not behave purely as a high frequency floor. Figure 5 shows summarize typical vibration signals seen at walking speed F4. Some resonant behaviour is observed in the second signal, while the first signal is governed by transient response.



B2-L4-R1-W2-F4



B2-L4-R2-W3-F4

Figure 5: *Acceleration observed in for different walking paths in B2-L4.*

To gauge the comfort of the floor for vibration, the RMS for each acceleration signal was calculated, and the peak value was extracted from the RMS plot. Figure 6 overview the peak RMS and R value recorded by each

channel for mock-up one and two, respectively. R values were determined by dividing the RMS acceleration by a baseline value of 0.005m/s^2. Also included in each figure is a line of the median data observed in the experiment. There is generally an upward trend in response factors as walking speeds increase, and the median RMS acceleration generally decreased as the building became more complete. The median R value in each suite of tests is recorded experiment in Table 3. The same trend from Figure 6 is observed, with decreasing RMS accelerations as the structure progresses through construction.

For office occupancy, a response factor in the range of 4-8 is a typical acceptable limit. The observed response factors were generally within the range of 5-20, showing the floor was on the edge of what would be considered commercially acceptable.

3.2 FREQUENCY RESULTS

The frequency response of the structure was characterized by an initial peak in the range of 5-10Hz, followed by various local peaks between 15Hz and 30Hz. Based on experience from phase one of testing on the full-scale mock-up, it's expected that the lower peak corresponds to vibration modes from exciting the beams, and the higher frequency peaks come from modes where the panel between beams is excited. To allow for easy comparison, the frequency response plots have been normalized by dividing each graph by its peak response. Figure 7 show typical frequency responses observed for a walking test, and a heel drop test.

Like RMS acceleration, the frequency where the peak occurs is extracted in each test, with a sample plot shown in Figure 8. Table 4 summarize the predicted fundamental frequency of the floor observed in each test, based on figures similar to Figure 8. Here the fundamental frequency of the system is estimated as approximately the lowest frequency peak observed during testing for all channels.

https://doi.org/10.52202/069179-0374

Comparing results between B1 and B2 for L3, a smaller decrease in frequency was noted than expected. When the topping was added to the building, the weight of the system increases from approximately 0.75kPa to 1.95kPa – more than doubling. Based on equation (1), the additional weight of concrete should have decreased the fundamental frequency approximately 40% however, a drop in frequency of about 15% was observed. This effect is discussed further in section 4.3.

3.3 EQUIVALENT VISCOUS DAMPING

The equivalent viscous damping of the floor was also estimated using the heel drop test data. It was generally found that there was a high variance in the predicted damping. This is likely due to vibration not decaying in a cleanly exponential decay, with instead a large drop occurring in the signal after the initial peak. While there is a large spread in the observed values, the damping generally increase in the building through construction.

Table 5: *Damping measurement in the floor system.*

Floor	Condition	Mean (%)	S.D. (%)
L3	B2	3.0	1.0
	B4	4.7	1.3
L4	B2	1.6	0.5
	B3	2.2	1.2
	B4	3.6	1.8

3.4 COMPARISON WITH MOCK-UP

Comparisons were also made between the frequency of the mock-up observed in phase one of testing [6] and the building in condition B1 on L3. Results were used for the mock-up model in condition M1c, which used 6Øx220 screws between the CLT panel and glulam column spaced at 300mm. Table 6 summarizes median frequency observed in both experiments. A higher fundamental frequency was observed in the building compared to the mock-up, indicating that the building was stiffer. The mock-up rested directly on supports in bearing, so an explanation for this increase in stiffness is that the knife plate connectors used have more stiffness than a simple bearing connector.

Table 6: *Observed frequency in Mock-up vs. in the building.*

Test Location	Test Designation	Median Frequency (Hz)
Mock-up	M1c	7.5
Building	B1-L3	8.5

4 NUMERICAL STUDIES

To understand how well Finite Element Model (FEM) predictions compared to observations in experimental data, a set of simplified numerical models were created of the floor in the software package RFEM [9]. The goal of this analysis was not to create highly detailed FEM models; it's known that a sufficiently detailed finite element model can closely match experiment. Instead, the numerical models were built to understand how typical models used by a designer might compare to experimental data. Therefore, only information that designers are likely to have during design was considered, for example, the stiffness from partitions was neglected as this is not typically known. First, baseline models are made and compared to experimental results, then parameters in those models are varied to assess the impact on the dynamic properties of the floor.

4.1 MODEL OVERVIEW

The models considered the whole floor plate for L3, and the right portion of the floor plate on L4. The structural elements considered were as described in section 2.1, and material properties of the elements were estimated from CSA 086.6 [8] for timber and CSA A23.3 [9] for concrete. Figure 9 provides an overview of the baseline models for the first and fourth floor respectively. The CLT using 2D shell elements and RFEM's RF-laminate module [10] while beams were simple beam elements.

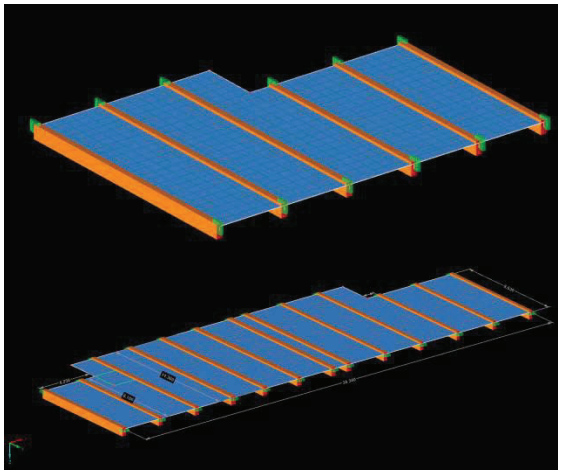

Figure 9: *The FEM model for L4 (top) an L3 (bottom).*

The mass in the model is estimated based on the site conditions observed for each test. Table 7 summarizes the total loads considered, broken down by load source for dead load (DL), superimposed dead load (SDL), and live load (LL). Loads are reported in kPa and converted by RFEM into an appropriate mass. Note that DL has been reported as an equivalent uniform load, however, in the model it assigned to elements as a self-weight. To account for moisture uptake of the members, a self-weight of 4.6kN/m3 is used for the CLT, while 5.3 kN/m3 is used for glulam. In B1, only the self-weight of the structure is considered, while in B2 a 50mm concrete topping is also included in the analysis. For B2, B3 and B4, the weight of the mechanical systems and furnishings are estimated based on the state of the building when tested. No change in mass was noted between B2 and B3 because a similar amount of construction material was on site for each study.

Table 7: *Vibration loads applied to model.*

Condition	DL (kPa)	SDL (kPa)	LL (kPa)
B1	0.7	-	-
B2	0.7	1.2	-
B3	0.7	1.2	-
B4	0.7	1.5	.2

How connections and boundary conditions are modelled will generally have a big impact on system stiffness and the fundamental frequency. For the Yukon office floor there are three main connection fixities to consider: fixity of the panel-to-panel spline connection, fixity of the beam-to-panel, and fixity of the beam to column/wall connection. In the base model a fixed connection was used between the beams, which is also the boundary condition for the model. Because the fixity of beam to column connection has a large impact on system stiffness, both a fixed and pinned connector were studied.

The beam to panel connection will affect composite action of the system. Findings from the mock-up were used to estimate the degree of composite action, with a predicted increase in system stiffness of 40%. Composite included in the model using an offset between the slab and the beam that would increase the system's EI by the appropriate amount. The effect of spline connections is not considered in the assessment, and it is assumed that the concrete toping transfers vibration between with an unobstructed load path.

4.2 COMPARISON ON OF MODELS

Once the base model was finished, several parametric studies were run on typical model assumptions. These studies are used to understand what parameters are most important to include in the model. The parameters considered include: beam stiffness, CLT stiffness, degree of composite action, stiffness from concrete topping, and boundary connection.

Variations of beam and CLT stiffness were completed by applying a stiffness modifier of 0.75 or 1.25 to the system. increasing and decreasing stiffness by 25%. These studies were run to understand how the uncertainty in timber

https://doi.org/10.52202/069179-0374

material might change observed results, and only run on L3. Degree of composite action was measured by running models that had no offset between the CLT and glulam beam, and thus no composite action. The effect of boundary condition and composite action assumptions were also examined. In the pin-connected model, the moment restraint was released at each column to beam connection.

Stiffness from concrete topping was included by adding the concrete stiffness to the CLT stiffness. Including the stiffness this way assumes no composite action between the two layers. Table 8 summarizes the change in stiffness of the CLT in each direction, where EI_x and GA_x are in the strong axis, and EI_y and GA_y are the weak axis. It can be observed that the concrete topping significantly increases the weak axis bending and shear stiffness.

Table 8: *Stiffness per unit meter of bare CLT and topped CLT.*

Condition	EI_x	EI_y	GA_x	GA_y
	($Nmm^2/m \times 10^9$)		($N/m \times 10^6$)	
CLT	883	34	7.5	7.5
CLT & Topping	1230	386	682.5	682.5

Table 9 and Table 10 summarizes the changes made to the base model, as well as the resulting changes to fundamental frequency. These can be compared to the in-situ experimental data to understand how accurate the trends are. For each model and test, the mode shape is extracted from the FEM models at the input location of vibration testing. The effect of concrete topping was examined in the base model, the model using no composite action, and the model using a pin connection. It was found that including the concrete topping increased system stiffness in the range of 5-10%. For variations in stiffness, it was found that variations in CLT stiffness had a low impact on the total stiffness of the system, while variations in beam stiffness affected the frequency on the order of 10-15%. Changes to the composite action also had a moderate effect on the system, on the order of 5-10%. Finally, it was noted that boundary condition had a large influence on the systems stiffness, where the fundamental frequency decreased in the range of 30-40% for models with a pin connection.

Table 9: *Measurements of on L3.*

Model	Condition	Level 3		
		B1 (Hz)	B2 (Hz)	B4 (Hz)
In-situ Experimental Data	-	8.5	7	8

	Topping	14.1	8.7	7.7
Pin Connection	No topping	8.9	5.5	4.9
	Topping	9.2	5.7	5.1

4.3 IMPACT OF NON-STRUCTUAL ELEMENTS

Results from FEM data can be used to predict the effect of non-structural elements on the system. In all numerical models considered, a downward trend in fundamental frequency is observed. Figure 10 provides an overview of the FEM base and pinned model predictions, compared to the experimentally observed data in experiment B1 to B4 on the third floor. The experimental frequencies reported are approximately the lowest from all test groups in Table 4. FEM results are taken from Table 9, and the mode used corresponds to the lowest mode active at the testing location. Results for the experimental data were closer to the pinned model in the bare floor condition, and closer to the fixed model in the final building condition.

A different trend in the observed frequencies was also noted between the FEM data and experimental response. The FEM models had their fundamental frequency decrease by approximately 30% from B1 to B2, and B2 to B4. This contrasts with the experimental model that decreased by only 10% from B1 to B2, and increased marginally between B2 to B3.

Based on Table 9, it's expected that the FEM would predict frequencies approximately 5% higher if the concrete topping is included in the model in a non-composite way. This difference is not enough to explain the differences observed between FEM predictions and experimental data, indicating that some other factor increased the system stiffness between both building

conditions. This suggests that the non-structural concrete topping and other elements had a larger impact on stiffness than expected.

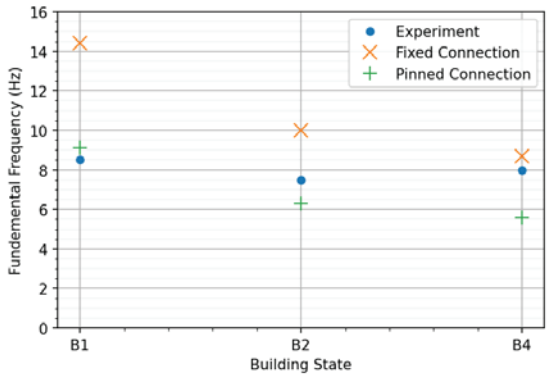

Figure 10: *Comparison of FEM and experimentally observed frequencies.*

The FEM data can also be used to assess the effect changing locations had on the experimental fundamental frequency. As noted prior, different testing locations were used between B1 and B2/B3. A prediction of the frequency at the original testing location can be made based on FEM data. In the models, it was noted that a different mode was active at L3 for the test location used in B2 and B4. This mode had a frequency approximately 20% higher than the base mode shape used in L1. The frequency can therefore be adjusted to approximately 6Hz at B3, and 6.5 Hz at B4.

The fundamental frequency decrease of 25% between B1 and B2 is more closely in line with the expected 40% reported in section 3.2, but still less than expected. This suggests that the concrete topping, or another factor had a larger than expected impact on the stiffness of the system. Some possible reasons for the increases in stiffness in B2 include: additional composite action occurring in the CLT to beam system due to clamping from the concrete weight; or contribution of the concrete slab to the floor stiffness, in either composite or non-composite action.

Similarly, the increase in frequency between B2 and B4 observed in experiment suggests that the non-structural elements such as partitions had a significant effect on the stiffness of the system for vibration.

5 CONCLUSIONS

A series of vibration tests were performed on Fast+Epp's new home office during its construction. In the final state of the building, it was found that the long-span floor system of Fast+Epp's home office was within vibration tolerances for office building. Most observed acceleration signals during walking tests had a response value less than 8. It was also found that non-structural elements had a large impact on the vibration performance of the floor. Based on experimental data normalized with FEM results, on the third floor, the fundamental frequency changed from to 8.5Hz to a 6Hz going from bare floors to floors with topping. This was less than the decrease of approximately 40% that would have been expected with no additional stiffness. The fundamental frequency increased as partitions and furnishings were added, to the building, indicating that these elements added enough stiffness to the floor to overcome the additional mass added.

Finally, during numerical modelling of the floor it was found that the parameter with the largest effect on the floor system was the boundary condition used. It was found that the floor in its final built condition was most accurately described using a fixed connection. It was also found that the trend of frequencies observed during construction in FEM modelling did not match the trend of data from experiments. The inclusion of non-composite stiffness from the concrete topping was not enough to account for the change in stiffness expected. Both trends suggest that non-structural components added more stiffness to the system than expected.

STRUCTURAL PERFORMANCE OF TWO-PANEL CLT SHEAR WALL WITH BOLTED CONNECTION

Daiki Hinata[1], Jun Kubota[2], Takashi Shima[3], Shinji Takatani[4], Masanori Hisada[5], Naohiro Haneda[6]

ABSTRACT: The increasing demand for using timber structures as building structures has led to the development of many cross-laminated timber (CLT) shear wall systems including details on connecting the walls. However, these details are still not sufficient for quick and easy installation purposes. Therefore, ways of improving the installation productivity on site are required. In this study, we propose installing a pair of CLT panels as a single shear wall, i.e., a two-panel CLT shear wall, with bolted connections as a solution. The heavier CLT panels are, the more difficult on-site installation work becomes. If the panels are divided into two, they would be easier to handle as each panel is lighter. Furthermore, a bolted connection is one of the easiest on-site installation connections. This paper presents the structural performances of a two-panel integrated CLT shear wall with bolted connection, which was investigated in element tests on bolted connections and full-scale wall tests. An FE analysis was also conducted to investigate the stresses on the CLT panels and the ultimate behaviors. The results indicated that this system has a high lateral resisting strength and ductility.

KEYWORDS: CLT shear wall, Two-panel CLT wall, Structural test and FE analysis, High productivity

1 INTRODUCTION

The demand for timber components for building structures has been increasing around the world, leading to the development of many cross-laminated timber (CLT) shear wall systems which include connection details [1-3]. However, the connections for CLT shear walls are difficult to install quickly and efficiently. When installing CLT shear wall panels in a steel moment-resisting frame, steel plates are typically inserted into the CLT panel with a slit at the top and bottom, integrating it by driving in drift pins, and bolting the inserted steel plate to a gusset plate pre-installed on a column or beam [3]. This method has two connections between the CLT panel and steel frame, CLT panel-to-steel plate and steel plate-to-gusset plate, which causes low productivity of construction due to the work for installing both connections. Moreover, drift pin connections must be fabricated extremely precisely because the bores for drift pins need to match that on the steel plates, due to the minimum tolerance requirement. It is crucial to find ways of improving installation efficiency on site. Thus, we propose installing a pair of CLT panels as a single shear wall, i.e., a two-panel CLT shear wall, with a bolted connection as a solution. Figure 1 shows sketches of this system in which two sheets of CLT panels are installed on both sides of the gusset plates. The heavier CLT panels are, the more difficult on-site installation work becomes. If the CLT panels are divided into two panels, they can be easier to handle because each panel is lighter. In addition, a bolted connection is one of the easiest to install on site. This paper presents the structural performance of the two-panel integrated CLT shear wall with the bolted connection, which is investigated through element tests for the bolted connections and full-scale wall tests. We also conduct an FE analysis to investigate the stresses in the CLT panels and ultimate behaviors.

determine an appropriate bolt configuration on the CLT shear wall, we conducted element tests for the bolted connections. The tested connections consist of steel plates, assumed to be gusset plates, a pair of CLT panel pieces, and bolts. The bolted connections are shown in Table 1 and Figure 2. In this study, seven types of bolted connections were tested. The parameters were the grade and lamina composition of the CLT, the loading direction of the CLT, and the bolt diameter and arrangement. We used S60 grade 3-ply 3-layer CLTs with a lamina width of 120 mm and thickness of 90 mm, without edge bonding, and S60 grade 5-ply 5-layer CLTs with a lamina width of 122 mm and thickness of 150 mm, with edge bonding. We also conducted tests on M20 series connections with two rows of bolts in the major direction.

It was previously found that the placement of the bending connections, such as drift pins and bolts, between the laminae on the CLT panel can degrade shear strength [4]. Therefore, to eliminate these effects, bolted connections were placed at the center of the lamina width for the CLT shear wall in our study. Accordingly, the CLT panel width of the test area on the element tests is the same as that of the single lamina. Although the structural performance of the bolted joints has been shown to be sufficient in previous experimental results [5], in our study, the CLT panel includes counterbores to prevent the bolt heads from protruding from the face of the CLT panels, for the sake of visibility.

The tests were carried out by applying a tensile force to the upper and lower steel plates attached to the connection, using a universal testing machine. The relative displacements between the steel plate at the position of bolted connections and CLT panels at the same level were measured by LVDTs. We used average relative displacements of the right and left for the following evaluations.

2.2 TEST RESULTS

The relationship between force and displacement is shown in Figure 3, the representative failure mode in Figure 4, and the ultimate strength and initial stiffness derived based on perfect elasto-plastic modeling [6] in Table 2. The bolted connection is not expected to deform more than 40 mm in the CLT shear wall connections because this only occurs when the CLT shear wall drift angle is over 1/20 radians. Therefore, only element test data up to a displacement of 40 mm were used for the evaluation. In Figure 3, the force-displacement curves were shifted to eliminate the influence of the initial slip, which is within approximately 1.5 mm, due to the bolt-hole clearance according to the perfect elasto-plastic modeling rule [6] so that the straight lines between 0.1 Pmax and 0.4 Pmax match zero force / zero displacement point.

At the beginning of all tests, the strength increased almost linearly; however, the slope of the force-displacement curve decreased due to the pop-out failure at the inner lamina (the side in contact with the steel plate) with the width of the bolt diameter in the major direction loading tests, as well as split failure of the inner orthogonal lamina in the minor direction loading tests. The strength was still maintained, mainly due to the resistance of the outer lamina. As the deformation increased, the bolt heads and washers appeared to be significantly embedded in the CLT. After the tests, we observed that all bolts were bent at the center.

The M12 series demonstrated stable structural behavior, regardless of the loading direction, and no significant decrease in strength was observed. Because the M20 series contained thicker CLT panels (5-layer and 5-ply), the major direction tests showed stable structural performance up to a displacement of 40 mm even in the connection with two rows of bolts. However, in the minor

direction tests, damage to the laminae led to ultimate failure when the deformation was approximately 5 mm. For the six specimens in all tests, the behaviors were approximately similar.

The ultimate strength and initial stiffness tend to be larger for larger bolt diameters and connections arranged in the major direction. Although the strength of the two rows of bolts connection was expected to be less than twice the strength of a single bolt connection due to the group effect, within the scope of this test, the connections with two rows of bolts had approximately the same failure mode as that of the single bolt type, and its strength was slightly higher than that of the single bolt ones.

Thus, we verified that this bolted connection with CLT placed in the major direction is sufficiently ductile with little decrease in strength even after exceeding the elastic limit. Meanwhile, the minor direction connections demonstrated fewer deformation capacities compared with the major direction specimens, indicating that providing a sufficient margin for the bolt connection strength in the CLT minor direction of the shear wall is important for the structural design.

3 FULL-SCALE CLT SHEAR WALL TEST AND ANALYSIS

3.1 STRUCTURAL TEST OUTLINE

A list of full-scale two-panel CLT shear walls is shown in Table 3, the diagrams are shown in Figure 5, and photos of the test setup are shown in Figure 6. The CLT test walls consist of a gusset plate attached to a steel stub, a pair of CLT panels, and bolts. The parameters were the vertical and horizontal dimensions, CLT composition, and bolt configuration. The combination of bolt diameter and CLT compositions in the CLT wall are the same as the element test detail, and as with the element specimens, bolts were arranged at the center of each CLT lamina width. A clearance of 40 mm was provided between the CLT edge and the upper and lower steel stubs to avoid generating friction forces and compression struts when deformation increased. During the tests, lateral forces were applied to the top of the specimens, and the vertical jacks kept the steel stubs horizontal while allowing them to move vertically. The loading protocol was as follows: ±1/600, ±1/450, ±1/300, ±1/200, ±1/150, ±1/100, ±1/75, and ±1/50 radians for three cycles and ±1/30 and ±1/20 radians for two cycles.

In the S-M12 and S-M16 tests, no damage to the CLT panels was observed while the loading. In the S-M20, a failure of the inner lamina near the outermost bolt was observed at the -1/20 radians peak, as in the element tests. M-M20, with two rows of bolts, also showed no strength reduction, although there were two pop-out failures at the edge of the CLT panels at 1/50 radians and three at 1/20 radians due to bolt deformation. The reason the CLT panels were not damaged was that the average shear stress of the CLT panels at ultimate strength was about 0.66 N/mm^2, which was less than the standard shear failure stress of CLT panels. The strength and initial stiffness of

M-M20 with two rows of M20 bolts tended to be slightly higher than twice the strength of S-M20.

After the test, the CLT walls were decomposed to determine the internal damage on the CLT panels. The inside of the CLT panel of S-M16 is shown in Figure 7. We observed bolt tracks in the diagonal direction with a length of 40 mm in total in the outermost position, as well as bent bolts.

3.2 SIMULATION ANALYSIS OUTLINE

To establish an analysis method for this two-panel CLT shear wall, we compared the test results with the simulation results obtained from an FE analysis. In addition, we also investigate the stress states of the CLT shear walls. The analysis was performed using the MSC Nastran 2019.0 software with monotonic loading. In the analytical model, the gusset plates and CLT panels were modeled with elastic shell elements, and the bolted connection was modeled with nonlinear spring elements in two directions (vertical and horizontal) connecting the gusset plates and CLT panels. Elastic orthogonal anisotropy was applied to the shell elements of the CLT panels as material properties, and the elastic moduli in the major direction, minor direction, and shear were determined by the values of standard [7]. The nonlinear characteristics of the spring elements were assumed to be perfect elasto-plastic. The yielding point and initial stiffness were calculated from the element test results of the major and minor CLT panel directions by using Hankinson's equation shown in equation (1). An outline of the calculation methods is shown in Figure 8. The ultimate strength (P0, P90) and initial stiffness (K0, K90) from the CLT element tests on the major and minor directions are inserted into Hankinson's equation, and the characteristic values (Pθ, Kθ) in the θ direction are then separated into vertical and horizontal components (Pθ_0, Pθ_90, Kθ_0, Kθ_90) by applying a trigonometric function. However, it is necessary to determine the deformation angles of each connection, as observed in the tested CLT wall, because the structural properties depend on the loading direction in practice. Thus, a convergence calculation was used to obtain the deformation angle θ. As shown in the procedure in Figure 9, the deformation angle θ was calculated so that all CLT panel elements and the

https://doi.org/10.52202/069179-0375

springs of bolted connections are satisfied with equilibrium of the deformation and stress.

$$P_\theta = \frac{P_0 \cdot P_{90}}{P_0 \cdot \sin^2\theta + P_{90} \cdot \cos^2\theta} \quad (1)$$

Where P_θ=strength in the θ direction, θ=deformation angle. This equation can be used for stiffness K instead of strength P.

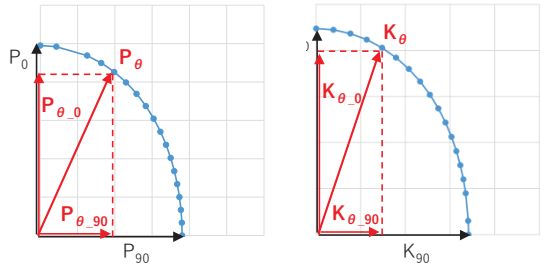

Figure 8: *Calculation method for spring properties at a specific angle*

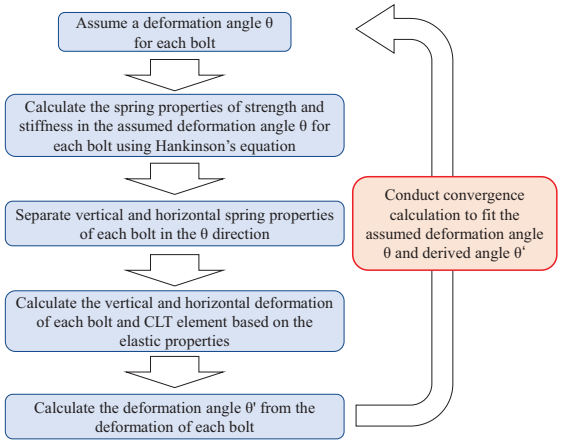

Figure 9*: Convergence calculation process*

3.3 DISCUSSION OF TEST AND ANALYSIS RESULTS

The ultimate strength and initial stiffness calculated by perfect elasto-plastic modeling are listed in Table 4, and Figure 10 shows the relationship between shear force and drift, and its skeleton curves from the full-scale CLT wall tests and simulation. The drift angle on hysteresis curves was calculated by dividing the horizontal displacement between the top and bottom steel stubs by the height between them.

In all specimens, the strength continued to increase up to 1/20 radians, and no significant reduction in strength was observed, indicating that the CLT shear wall exhibited a substantially high deformation capacity. Furthermore, a clearance of +1 mm at the bores on the CLT panel and gusset plates for the bolted connection did not cause slip behavior throughout the tests.

The shear force-drift relationship from the simulation for each CLT shear wall is largely consistent with the test skeleton curves. Because the yielding point of the outermost bolts in the analysis coincides with the elastic limit on the tests, we conclude that the specimens reached the maximum strength through a gradual reduction in stiffness due to the yielding of the bolts. Moreover, from the above, it can be said that the bolt strengths in the analysis were set at a reasonable value. In the S-M16, S-M20, and M-M20 tests, the initial stiffness in the test and the analysis were almost identical. However, in the S-M12 test, the initial stiffness of the analysis was lower than in the test results. One reason for this may be that the initial stiffness obtained by the perfect elasto-plastic modeling of the element tests for the M12 series was evaluated to be lower than the actual values. In the modeling, the initial stiffness is calculated based on the slope connecting the points at 0.1 Pmax and 0.4 Pmax. The evaluation of the test result with the M12 bolt seemed to be affected when the stiffness had already decreased at the 0.4 Pmax point because the maximum strength is much higher than the elastic limit. As a result, it is possible to estimate the initial stiffness of this CLT shear wall from the element test results, but it also illustrates the importance of using the appropriate initial stiffness for the connection.

Hankinson's equation used to calculate the stiffness and strength at an angle was originally devised for materials with a constant wood grain direction, such as lumber and glued laminated wood, and is not intended to be applied to composite materials with orthogonal wood grain directions in each layer, such as CLT. However, we found that the bolted connection showed similar behavior to that of glued laminated timber as the laminae located close to the gusset plate mainly resisted the bolt deformation. This suggests that Hankinson's equation can be used to estimate the spring properties at a specific angle in the bolted connection.

Figure 11 shows the vertical and shear strain contour and the maximum and minimum strain at +1/20 radians for the S-M16 and M-M20 FE analyses, which contain larger values in the same dimension of the CLT shear wall. The shear strain contour indicates that the strain is concentrated at the center of the CLT panel, and the maximum strain in M-M20 at a large deformation is over 3500 μ, which is beyond an allowable value. However, the strain in the surrounding area was kept small, which is consistent with the full-scale test results that showed no damage to the CLT panels.

In conclusion, although there are some issues in the evaluation of stiffness, this simulation method can be used to evaluate the structural performance of the CLT shear wall with sufficient practical accuracy.

Table 4: *Ultimate strength and initial stiffness of CLT shear walls*

ID	Ultimate Strength [kN]		Stress		Initial Stiffness [kN/×10^{-3}rad]

4 CONCLUSION

To improve on-site productivity, we have developed a two-panel CLT shear wall system with a novel bolted connection in which a steel plate is sandwiched between a pair of CLT panels. In the study, we conducted element tests on the bolted connection, a full-scale shear wall test, and an FE analysis. The results showed that this system has a high lateral resisting strength and ductility. Our findings are summarized as follows.

The bolted connections showed high deformation capacities even beyond the elastic limit when the force was subjected to the CLT major direction within the range of the tests.

The full-scale CLT shear wall tests showed that the CLT panels were not damaged up to a large deformation of 1/20 radians in all specimens and the CLT panels had high deformation capacity with no reduction in strength.

For the FE analysis, Hankinson's equation was applied to the element test results to estimate the spring properties of the bolted connection. The simulation results showed that the analytical results were highly consistent with the test results, except for some initial stiffness. Thus, we can conclude that the analytical method is feasible for simulating the structural behaviors of the two-panel CLT shear wall.

FORCED RESPONSE MEASUREMENTS ON A SEVEN STOREY TIMBER BUILDING IN SWEDEN

Andreas Linderholt[1], Pierre Landel[1,2], Marie Johansson[2]

ABSTRACT: Forced vibration tests have been conducted on the seven-storey timber building Eken in Mariestad in Sweden. The main objective is to estimate the building's dynamic properties from test data. The eigenfrequencies, mode shapes and their scaling are useful to calibrate numerical models. However, the most important outcomes are the estimates of the modal damping values. The reason is that the damping impacts the acceleration, and thus the serviceability of the building, and at the same time, it is very hard to model damping. So, during the design phase, one must rely on previous test data (of which very few exist for taller timber buildings) or rule of thumbs. It is therefore important to gain knowledge about the damping for timber buildings in order to enable good designs of future and taller timber buildings. The test data shows that the modal damping is roughly equal to 2% of the critical viscous ones for the eigenmodes extracted. The test campaign on Eken is made as a part of the project Dyna-TTB in which vibrational tests have been performed on eight high-rise timber buildings, in Europe, of which Eken is one.

KEYWORDS: Forced vibration, timber building, damping, eigenmodes, experimental modal analysis, Dyna-TTB

1 INTRODUCTION

Within the project Dyna-TTB, measurements on eight multi-storey timber buildings around Europe have been conducted to gain more knowledge on their dynamic performance at serviceability level. The dynamic response of a structure is governed by four quantities: the mass, the damping, the stiffness, and the dynamic load. The damping is the one that is hardest to predict; reliable models are rare and most often the damping is taken from tests or as one value of modal viscous damping taken from rule of thumbs. One of the primary objectives of the Dyna-TTB project is to broaden the knowledge base regarding damping in timber buildings. Such a data base is useful during the development of future, possibly even taller than the tallest today, high rise timber buildings. For modelling purposes, it is also important to have information regarding resonance frequencies, mode shapes and modal masses. The Swedish case study in the DynaTTB project was the seven-storey building Eken (the Oak in English), see Figure 1. For more information on the DynaTTB project see [1]. Examples of other measured buildings in the DynaTTB project can be found in [2]–[5].

The purpose of vibration tests is to get measures of resonance frequencies, to estimate damping, mode shapes and modal masses. The test set-up answers the questions how to excite a structure as well as how and where to measure responses.

The models used to calculate accelerations due to wind loads, in the serviceability limit states, vary between different codes [6]. However, all of them are based on the same concept; only the first bending mode is included. If one assumes the shape of the first bending mode to be known and that the first resonance frequency is associated with the first bending mode, one accelerometer is sufficient to get the desired information. More sensors are beneficial but not necessary. However, to get data for model calibration, several spatially resolved mode shapes are needed or at least most desired. Furthermore, there are many ways of exciting a structure. Forced response measurements have the advantage that they enable scaling of the mode shapes. Shaker excitations are commonly used in forced vibration measurements. It is important that all the excitations stem from the shaker or shakers in the intended directions and that the stimuli are measured. Among different signals that can be used for the shaker excitations, stepped sine testing has the advantage of focusing all the energy in one frequency at the time, which is beneficial when large structures are excited by limited forces.

When creating an FE-model, here representing a multi-storey timber building, important input parameters are the

stiffnesses and masses of the different parts of the building system. One example of important parameters is the stiffnesses of connections. This has also been studied in the DynaTTB project [5], [7], [8].

This paper describes the forced vibration test campaign on the building Eken in Sweden. The measurement campaign was performed in the spring of 2022. The paper also presents some of the test results in the form of frequency response functions (FRFs) and modal properties for some of the extracted modes.

2 THE BUILDING EKEN

The building Eken was finished in 2019 and contains 31 rental apartments. It is in the city of Mariestad in the south part of Sweden, see Figure 1. The height, width and depth of the building are 24, 27 and 19 m respectively. The building was built by the company Stenmarks Bygg and it is owned by Mariehus.

2.1 THE BUILDING SYSTEM

Half of the bottom floor is made of concrete whereas the other half, the other storeys and the elevator shaft are made of timber. The building is built using the Moelven Trä 8 system [9]. The load bearing system consists of glued laminated timber (glulam) beams and columns whereas glulam trusses form the stabilizing elements, see Figure 1. In total the structure consists of 12 glulam trusses, four in the weak direction of the building and eight in the strong direction of the building. The glulam trusses are, in principle, symmetrically located in the building and the trusses in the middle go through all seven storeys of the building.

The floor system is made of strengthened LVL sheets acting as a diaphragm system. The connections in the glulam trusses are slotted-in-steel-plates fastened with steel dowels. The other glulam beams are fastened using steel hangers screwed to the gluelam members. These glulam building components are manufactured and assembled by the company Moelven Töreboda.

The apartments are vibrationally isolated from each using a thin concrete screed resting on sound insulation on top of the LVL floors. The floors are separated in all apartment separating walls. The internal walls and ceilings consist of gypsum wall boards on acoustic studs.

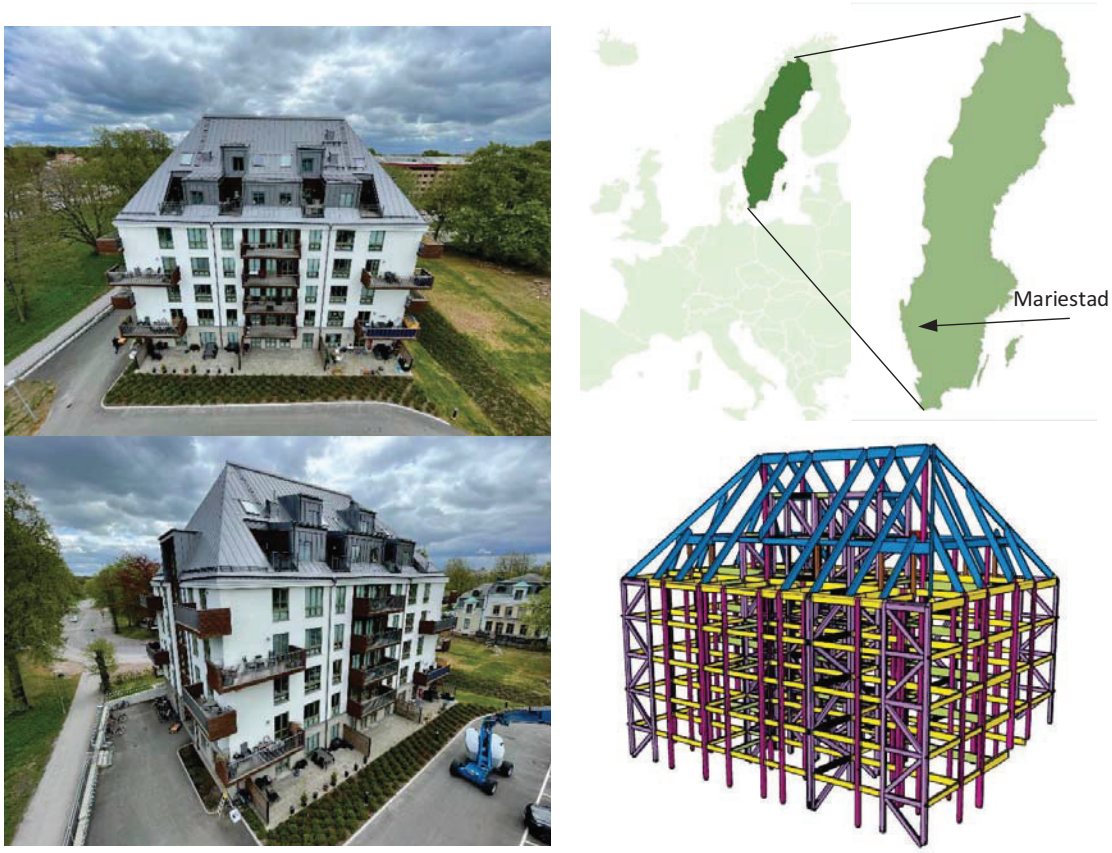

Figure 1. *The Eken building in Mariestad with images of the finished building, its location in Sweden and the glulam parts of its structural system.*

https://doi.org/10.52202/069179-0376

2.2 The test set-up

The dynamic performance of the building Eken has been studied during the measurement campaign using a forced vibration set-up. Forced vibration tests have the benefit of enabling more precise damping estimates than ambient vibration tests. It also renders in e.g., scaled accelerances. Mass inertia forces can be used to excite buildings in forced vibration tests. For that purpose, an APS 420 shaker was used in the Eken measurement campaign, see Figure 2. The shaker was placed in the ventilation room on the top (seventh) floor. Due to the heavy weight (140 kg) of the shaker, it had to be lifted using a crane through a roof window, see Figure 6. To properly excite the building structure, the shaker was bolted to a specially produced steel plate, that was screwed through the floor to one of the main glulam beams and clamped around one of the main glulam columns that runs vertically through the whole building, see Figure 2. The steel plate was prepared to allow for three positions of the shakers to excite the building along its main axis, perpendicular to its main axis and at 45º.

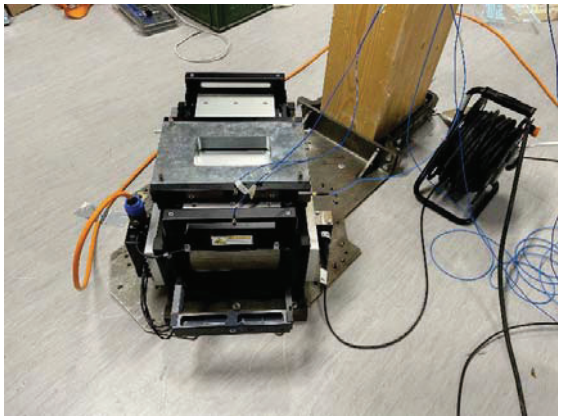

Figure 2. *Excitation by mass inertia, using an APS 420 shaker, used for stepped sine excitation, fastened to a steel plate fastened to the main glulam structure using screws. In this set-up the shaker is placed in a 45° angle to the buildings main axis.*

In total 45 accelerometers: PCB 393B12 and PCB 393M62, with the sensitivity 10V/g, were used to measure the response of the building at different places and different directions. The main configuration of the accelerometers was two accelerometers, mounted on small steel cubes, placed on the building to measure the responses in two orthogonal directions, see Figure 3. The steel cubes with the accelerometers were screwed directly on the structure of the building at four different levels at each of the four corners of the building, under the balconies, see Figure 4, and two positions under the main roof beam at the top of the building. There were also accelerometers placed on the top floor close to the shaker and in the staircase.

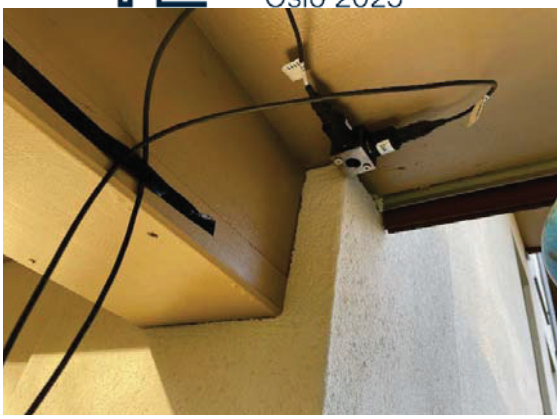

Figure 3. *Two PCB-39 accelerometers positioned under a balcony at one of the corners of the building.*

Three Siemens Scadas data acquisition (DAQ) units, connected via fiber-optic cables, were used to control the excitation and to collect measurement data. One of the boxes was placed in the room where the shaker was located, and it controlled the other two boxes located at the ground outside the building. Each DAQ was put into a plastic box for weather protection and the boxes communicated with the accelerometers via cables, see Figure 5. The accelerometers, cables and the Siemens Scadas data acquisition cables were installed using a 25 m tall skylift, see Figure 7.

Figure 5. *One of three Siemens Scadas Acquisition boxes.*

https://doi.org/10.52202/069179-0376

2.3 The forced vibration test of the building

The forced vibration test was performed using a stepped sine test set-up. Stepped sine testing has the advantage of focusing all the energy in one frequency at the time. Here, an APS 420 (APS Dynamics) inertia shaker was used for stepped sine testing from 2 Hz to 20 Hz. The excitations were made in 0, 45 and 90 degrees in relation to the axis along the width of the building. The steel plate, under the shaker, was used to connect the shaker directly to the load-bearing structure. The accelerometers were also placed directly to the main glulam structure. Thus, the force was made likely to excite the global modes of the building.

The total recording time for a stepped sine test, going from 2Hz to 20 Hz with a step size of 0.01 Hz took about four hours. Thereafter the direction of the shaker was changed to another angle and the test was repeated. This was made to make sure that all modes in the frequency range were captured.

Figure 6. *Lift off the 140 kg shaker from the ground to the top floor position through a small attic window.*

3 RESULTS

The test data were evaluated using the software Siemens Test Lab. The evaluated parameters in this first basic evaluation were:

- resonance frequencies,
- modal damping,
- mode shapes and
- modal masses.

The data evaluated were in the form of FRFs from which the modal properties were estimated. The quality of the estimates was examined by a comparison between the measured FRFs and the synthesized counterparts. The part of the direct point receptance for excitation in the Y-direction (the flexible direction) that includes the first three resonance frequencies, is shown in Figure 8.

The first bending mode in the weak direction was found to have a frequency of 2.4 Hz. The next mode is a torsional mode at 2.7 Hz.

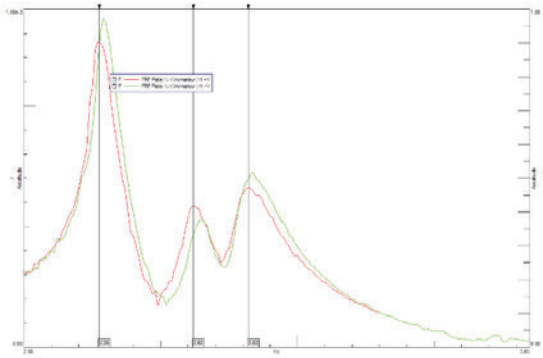

Figure 8. *An FRF stemming from excitation in the Y-direction (the flexible direction). The first three resonances are shown, x-axis scale 2-3 Hz.*

To verify that a sufficient frequency resolution is used, a Nyquist plot is useful, see Figure 9. The plot shows the frequency range including the first three resonance frequencies.

The damping could be evaluated for these modes. A preliminary estimation showed that the relative viscous damping was 1.6% for the first bending mode in the weak direction (at 2.4 Hz). The first torsional mode was found to have a relative viscous damping of 1.9% (at 2.7 Hz). The second bending in the flexible direction had 1.6% damping at 7.0 Hz.

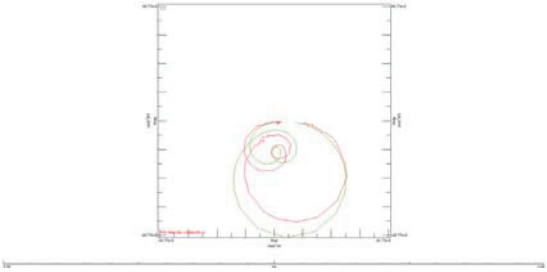

Figure 9. *Nyquist plot for an FRF stemming from excitation in the Y-direction (the flexible direction). The first three resonances are shown.*

Scaled mode shapes were also extracted from test data. An AutoMAC was calculated, and it shows that the mode shapes extracted from the test data are very close to orthogonal. The modal parameters will be used to calibrate an FE-model representing the building. It was possible to find fifteen distinguishable modes in the frequency range 2-20 Hz when exciting the building in the Y-direction (the flexible direction), see Figure 10.

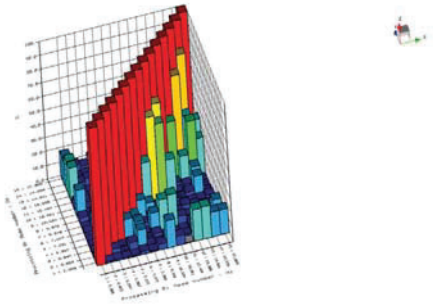

Figure 10. *AutoMAC for modes stemming from excitation in the Y-direction (the flexible direction). There are fifteen distinguishable modes in the frequency range 2-20 Hz.*

When exciting the building in the X-direction (the stiff direction), there were ten distinguishable modes in the frequency range 2-20 Hz, see Figure 11. Some of the

https://doi.org/10.52202/069179-0376

modes are the same in the sets stemming from excitation in the X- and Y-directions. In total around twenty separate modes could be seen in the data.

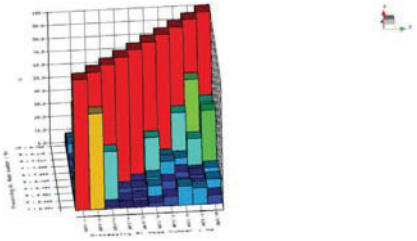

Figure 11. *AutoMAc for modes stemming from excitation in the X-direction (the stiff direction). There are ten distinguishable modes in the frequency range 2-20 Hz.*

The plots of mode shapes, see Figure 12, Figure 13 and Figure 14, show the first bending mode in the Y-direction, the first torsion mode and the second bending mod in the Y-direction. The first bending mode is very symmetric and shows an almost pure bending of the building.

The torsion mode shows a mode shape that is almost symmetric but with the rotation center moved slightly from the center of the building. This is due to that the trusses are not placed perfectly double symmetrical.

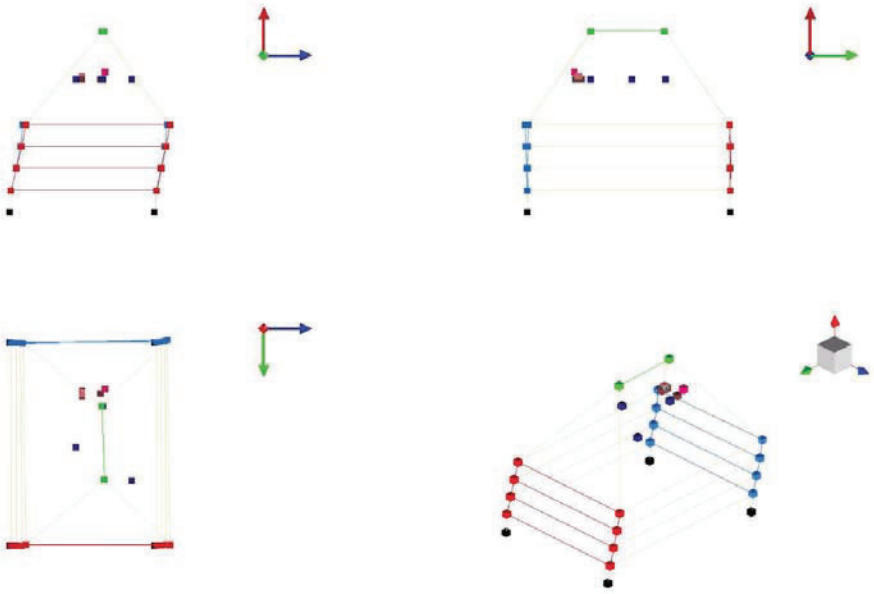

Figure 12. *The first bending mode in the Y-direction (the flexible direction).*

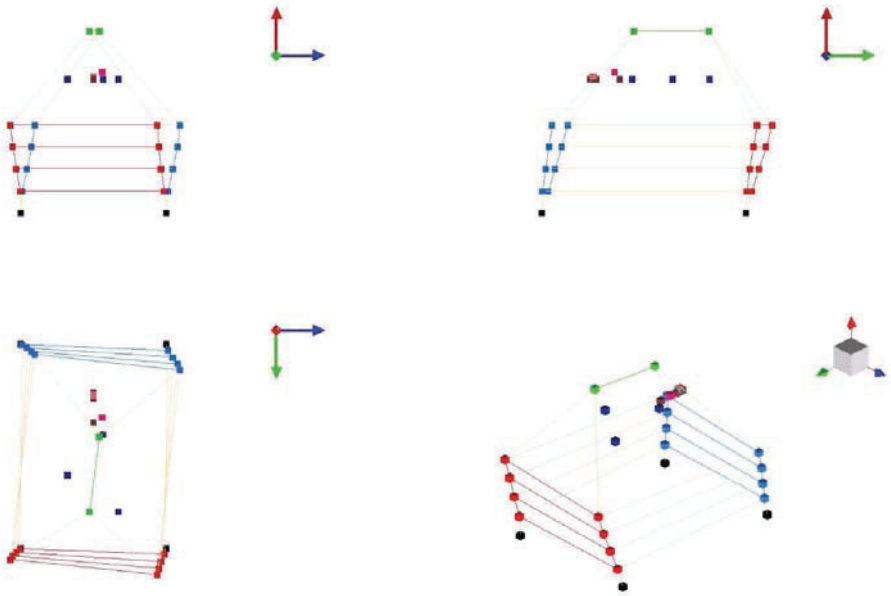

Figure 13. *The first torsion mode.*

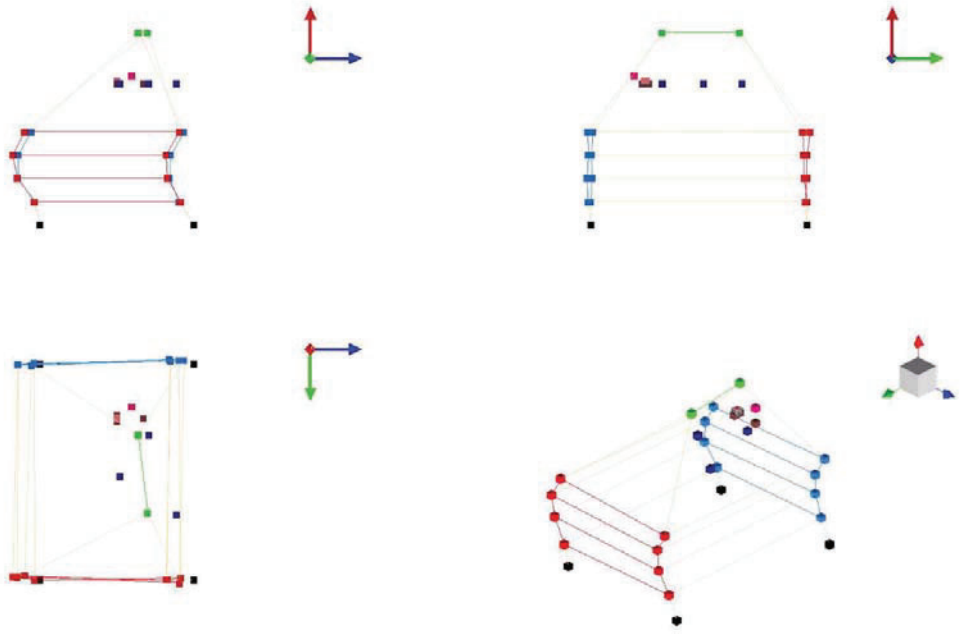

Figure 14. *The second bending mode in the Y-direction (the flexible direction).*

https://doi.org/10.52202/069179-0376

The most important outcome is the contribution to the knowledge base regarding damping in high-rise timber buildings. The damping values are roughly 2% for the modes extracted, see examples in Table 1. That knowledge is valuable in the design work of future and taller timber buildings.

Table 1. *Resonance frequency and relative viscous damping for three vibration modes.*

Mode	Resonance frequency	Damping relative viscous
1st bending, flexible direction	2.4 Hz	1.6%
1st torsion	2.7 Hz	1.9 %
2nd bending, flexible direction	7.0 Hz	1.6 %

4 CONCLUSIONS

In this paper, the vibrational test campaign made on the seven-story timber building Eken in Mariestad in Sweden is presented. By using mass inertia forces generated by an APS 420 shaker in combination with sensitive accelerometers, 10 mV/g, the fundamental and global modes were successfully extracted from test data even when the excitation force amplitude was low. The estimated damping values agree with estimated damping values from other test campaigns within the project Dyna-TTB. The results contribute to the knowledge base regarding damping in high-rise timber buildings and are thus useful for future design of tall timber buildings.

SYSTEM IDENTIFICATION OF TALL MASS TIMBER STRUCTURES EMPLOYING AMBIENT VIBRATION TEST AND FE MODELLING

Samira Mohammadyzadeh[1], Jianhui Zhou[2], Lin Hu[3], Fei Tong[4]

ABSTRACT: Despite the recent rapid development in dynamic characteristics identification of structures, lack of knowledge in dynamic properties of tall mass timber buildings is still an open issue for researchers and designers. There are ongoing international efforts to develop a comprehensive database for predicting the vibration performance of timber structures for serviceability and seismic design. This paper discusses an ambient vibration test (AVT) that was conducted on a six-storey mass timber building known as Wood Innovation and Design Centre (WIDC) located in Prince George, Canada. The test results including the experimental natural frequencies and damping ratios were compared with a three-phase test program undertaken in 2014, 2015, and 2017 by FPInnovations. In addition, a numerical modal analysis was conducted on the same building, using both simplified and complex finite element (FE) models. A sensitivity analysis was carried out considering various assumptions of connection types to investigate its effect on the natural frequencies of the structure. The results of current AVT showed minor changes in frequencies over the service time in comparison to previous tests. According to the numerical results, the simplified FE model poorly matched with the results from AVT, while the complex model showed a better agreement with the measured fundamental frequency; however, significant discrepancies were observed in the second and third modes. The sensitivity analysis indicated low impact of different connection type assumptions on the natural frequencies of the case building obtained from the FE models.

KEYWORDS: System identification, Timber buildings, Dynamic properties, Ambient vibration test, Numerical modelling

1 INTRODUCTION

With the use of mass timber products, interest in constructing more high-rise timber buildings has increased recently. However, due to the lightweight and high flexibility of tall timber buildings, they are susceptible to dynamic lateral loads that are induced by wind and earthquakes [1]. To understand their structural behaviour under lateral loads, prediction of the building dynamic properties is of great importance in the design stage. The National Building Code of Canada (NBCC) allows designers to estimate the fundamental period of timber buildings by an empirical formula which was not developed specifically for timber buildings [2].

To address the lack of data, there is an ongoing research campaign on vibration testing of timber buildings to extract the dynamic properties of these structures to form a database [3-6]. Feldmann et.al studied nine timber towers and three tall timber buildings by ambient vibration testing. The results verified the efficiency of this type of experiments and contributed test data on low-amplitude wind vibration of tall timber structures [1]. Reynolds et al. investigated the difference in dynamic properties between two similar 5-storey timber buildings with the same layout and a concrete core. The difference was in walls and floors, the first was made of a light wood frame and the second was made of cross laminate timber (CLT). The results showed high similarity between the dynamic properties of these two buildings [7]. Hafeez et al. studied dynamic properties of 32 light wood frame buildings and concluded that it was inaccurate to take the height of structures as the sole variable in determining the fundamental period of timber structures [8]. Recently, more mass timber buildings in Canada [3-5] and Europe [9] have been tested under dynamic loads at the serviceability level.

Having an experimental database of modal parameters, FE models with increased accuracy can be developed by engineers in practical design [10]. However, certain details of modelling such as connection types and material properties are still open issues in frequency calculations

and overall dynamic behaviour of timber building. Reynolds et al. reported, for the two 5-storey buildings, that the FE modelling of just concrete core provided lower fundamental natural frequencies than the measured values [7]. Larsson et al. investigated a nine-storey concrete-timber hybrid building and found that dynamic properties were highly sensitive to the selected elastic properties of CLT walls, but insensitive to the connection properties [10]. Aloisio et al. modelled eight-storey CLT student apartments building located in Norway. The calibration of their model based on AVT results indicated that the impact of connectors under serviceability conditions is negligible [11]. In this regard, Tulebekova et al. had different findings that the stiffness of connections of the glulam frame in modelling the Mjosa tower were a governing parameter [12]. Kurent et al. updated FE model of a seven-storey CLT building based on an input-output vibration test result. Good agreement was observed between the numerical and experimental frequencies in the first six modes. However, the results showed that frequencies matched better in lower modes than in higher modes. [13].

In this study, an AVT was conducted on Wood Innovation and Design Centre (WIDC) building located in Prince George, Canada, to determine its experimental natural frequencies, damping ratios, and mode shapes. The test results were compared with the existed three-phase test program undertaken in 2014, 2015, and 2017 by FPInnovations [5]. The present study contributes to the assessment of dynamic properties change of a mass timber building during different time of its service life. Furthermore, to investigate the efficacy of commercial structural analysis FE software for modal analysis of tall mass timber buildings, two simplified and complex FE models were developed respectively for sensitivity analysis of different connection properties assumptions, and the results were compared with the experimental data. The test results were compared with predicted fundamental frequency from the NBCC equation.

2 MATERIALS AND METHODS

2.1 BUILDING DESCRIPTION

WIDC is a 29.5-meter tall, six-storey (with a mezzanine and a penthouse) mass timber building located in Prince George, British Colombia, Canada (Figure 1). The main structure consists of an innovative combination of post-and-beam construction and built-up cross-laminated timber floor panels. A balloon-type CLT core around the staircase and elevator shaft serves as the lateral load resisting system. WIDC was built in 2014 and was the tallest modern timber structure in Canada at the time of its construction.

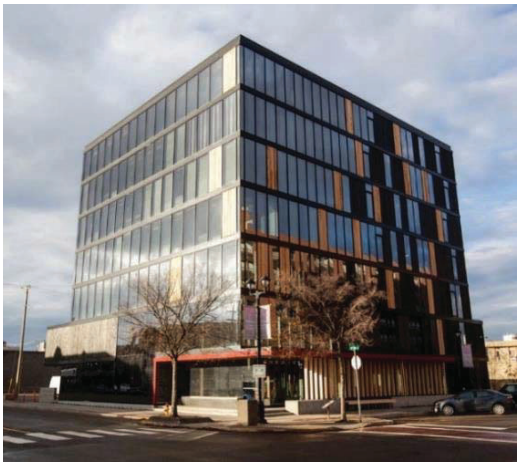

Figure 1: *Wood Innovation and Design Centre [14].*

2.2 AMBIENT VIBRATION TESTS

In 2014, while the building was about to complete with only the structural components and no enclosures, an AVT was conducted to determine its natural frequencies and damping ratios. After the building was completed with all non-structure components and fully occupied in 2015, Phase-II AVT was carried out.

Phase-III AVT was conducted in 2017, to check if the natural frequencies and damping ratios changed from the values measured in 2015. In these three phases, two reference sensors were fixed in the 5th floor level (Phases I and II) and the 6th floor level (in Phase-III). Six sensors with 500 mV/g sensitivity were roved between stories 2-6, 4-6, and 5 to 6 in the three tests, respectively. The location of the sensors is shown in Figure 2.

The results of these previous tests are listed in Table 1 [5]. The first and second vibration modes of the building are the first translational modes along the principal directions, X and Y, respectively, as shown in Figure 2, while the third mode is the first torsional mode.

Table 1: *Frequency and damping ratios of previous phases [5]*

Modes	Natural Frequency (Hz)			Modal Damping Ratio (%)		
	Phase I	Phase II	Phase III	Phase I	Phase II	Phase III
Translation in X	1.1	1.4	1.4	3.0	3.0	2.0
Translation in Y	1.3	1.6	1.6	2.0	2.0	2.0
Torsion	1.5	1.9	1.9	2.0	2.0	3.0

https://doi.org/10.52202/069179-0377

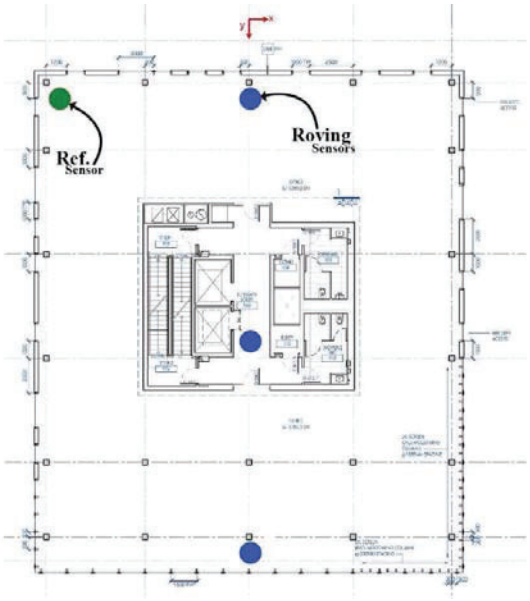

***Figure 2**: Location of the sensors (privious study [5])*

Aiming to monitor the dynamic properties of WIDC at the 9th year of its service life, Phase-IV tests were conducted in January 2023, as discussed subsequently. For the current AVT protocol, a 24-channel SEIMENS SCADAS dynamic data analyser with 10 uniaxial PCB accelerometers of 100 mV/g sensitivity and a sampling frequency of 200 Hz is used for data collection. The time duration for each setup was considered 240 sec. Two accelerometers were mounted on the roof level as the reference accelerometers in X and Y directions of the building and 8 accelerometers were roved between storeys 2-6 for measuring natural frequencies, mode shapes, and damping ratios. The second-floor plan is different from the above floors. However, the sensors were installed at all the floor levels at the same location in plan. No measurements were conducted at the mezzanine floor, which was anticipated not to affect the expected first three mode shapes. Figures 3 and 4 illustrate the locations of the sensors in the building and the overall view of test setup, respectively.

Post-processing of the operational modal analysis (OMA) was carried out using Simcenter Testlab using the OMA add-in. After correlation of time domain measurements, PolyMAX option, which is a curve fitter or modal parameter analyser, was used for producing cross power spectra to estimate the dynamic parameters of the desired system. In this process, all the cross powers functions were visualized along with their sum. Using the sum which is a complex average of all the included cross powers allows the identification of amplitude peaks [15].

2.3 NUMERICALL MODELLING

The experimental results were used to verify the FE model that was developed for modal analysis. For this purpose, the structure was modelled using RFEM 5.25 software in two stages. In the first stage, only the CLT core walls were modelled with lumped seismic inertia assigned at floor levels. The lumped mass was determined based on the actual mass of the materials and effective floor loads of the building. In the second stage, a complex model was developed including glulam beams and columns, CLT shear walls, and CLT floors. The details of modelling (the used material, structural element size, and layout of the elements) is according to the existing technical drawing of the building.

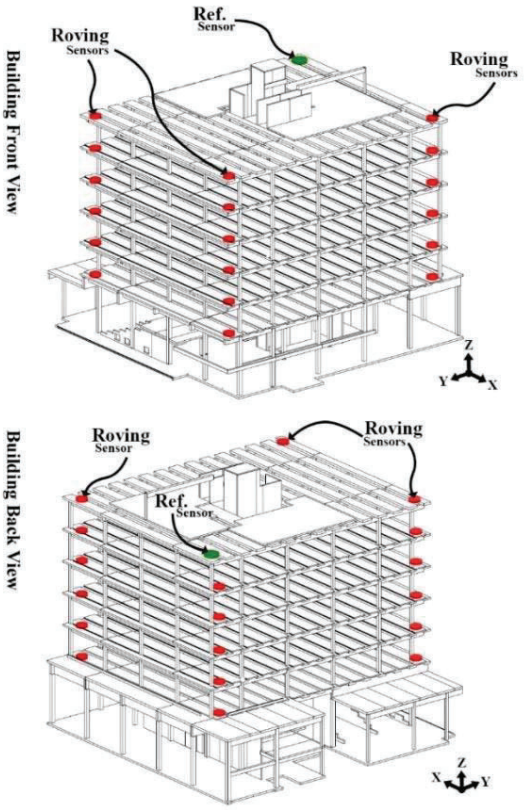

***Figure 3**: Locations of the sensors (phase IV)*

According to available information, the CLT panels used in wall construction are E1 grade 5-ply (175mm) sprue-pine-fir (SPF), and the staggered CLT floors were constructed with E1 grade 5-ply (175mm) and 7-ply (245mm) SFP CLT panels. These floors were modelled as an equivalent 6-ply CLT panel in the complex model. The 24f-EX Douglas Fir glulam beams and 16c-E Douglas Fir glulam columns were used throughout the building. Non-structural elements such as partition walls, façade, claddings, etc were not included in the complex model. The CLT walls and floors were modelled using the RF-Laminate add-on module in RFEM.

A pinned condition was assumed at the base of the columns and walls. As the post and beam were not designed to carry moments, beam-to-post connections were assumed as being pinned. The connections of floor-to-wall and wall-to-wall panels were considered as being fixed. Figures 5 and 6 show the simplified and complex FE models, respectively.

https://doi.org/10.52202/069179-0377

For the sensitivity analysis, floor-to-walls and wall-to-wall panels connection type assumptions were changed to pinned condition while columns and walls connections to the foundation were switched to fixed. This was to investigate the impact of various joint conditions on natural frequencies of the building.

***Figure 4**: Overall view of test setup*

2.4 NBCC PERIOD EQUATION

NBCC (2020) provides empirical equations to estimate the fundamental period of buildings. These equations are applicable to structures with various lateral resistance systems such as reinforced concrete moment resisting frames, steel moment resisting frames, for shear walls, etc.

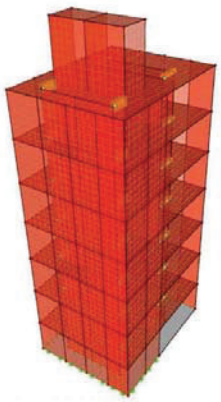

***Figure 5**: Simplified FE model*

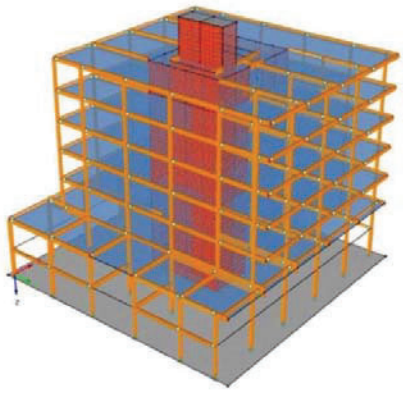

***Figure 6**: Complex FE model*

However, no equation is provided specifically for timber structures. In this paper, the equation for 'shear wall buildings and other structures' was adopted, as follows:

$$T_S = 0.05(h_n)^{3/4} \quad (1)$$

where, T_S and h_n are the fundamental period and the height of structure, respectively [2].

3 RESULTS AND DISCUSSION

3.1 EXPERIMENTAL TEST RESULTS

As listed in Table 2, the results indicate minor changes in the fundamental frequencies of the building over time. Figure 7 shows the cross-power function obtained from OMA. Comparing the test results of Phase III and IV, only 7.1% and 5.2% increase can be seen in the first and third natural frequencies, respectively, while the natural frequency of the second mode remains nearly the same. The relatively small discrepancy in the first and third mode frequencies may result from the differences in test setups used in Phase III and IV. Though accelerometers with different sensitivity (500 mV/g and 100 mV/g respectively) were used in the previous and present study tests, respectively, the sensors' sensitivity in both tests are adequate enough for capturing low frequencies required for this case study.

The consistency of natural frequencies during the time indicates no stiffness degradation in both connections and elements of the building. It should be mentioned that the occupancy of the building is still the same as the previous test, meaning negligible changes of the total mass of WDIC. Damping ratios of the first three modes of the structure at serviceability load level are listed in Table 2. It is well known that the measurement of damping ratios could have high degree uncertainty. Although, some changes can be seen between the values of damping ratios in this study and phase III of the previous study, rounding of the measured damping ratios in phase IV to the integer leads to the same results as previous phase test.

Table 2: *Comparison of natural frequencies (Hz) and damping ratios (%) of the first three modes*

Index	Modes	Values		
		Phase III [5]	Phase IV	Change (%)
Natural Frequencies (Hz)	Translation in X	1.4	1.5	7.1
	Translation in Y	1.6	1.6	0.0
	Torsion	1.9	2.0	5.2
Damping Ratios (%)	Translation in X	2.0	1.5	-25.0
	Translation in Y	2.0	2.0	0.0
	Torsion	3.0	1.5	-50.0

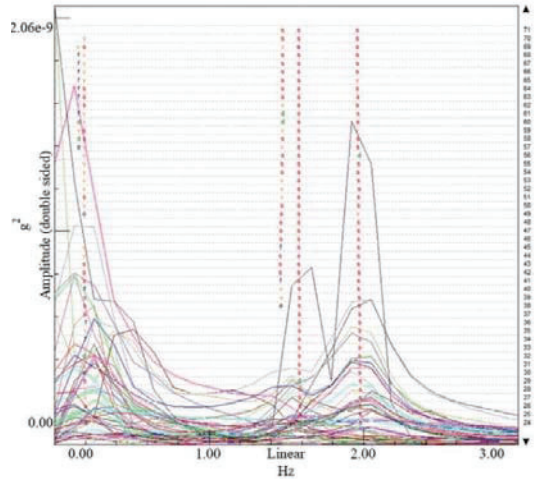

Figure 7*: Typical cross-power function obtianed from phase-IV test*

3.2 FE Modelling Results

The other dynamic property investigated in this study is the mode shapes. As mentioned before, in AVT's the first three mode shapes are the first bending in X direction, the first bending in Y direction, and the torsional mode, respectively. The results of the FE models show good agreement with the finding from AVT. Three first mode shapes of the simplified FE model are shown in Figure 8. Furthermore, the results of the structures mode shapes for phase-IV test and complex numerical FE model are shown in Figure 9.

The comparison between frequency of the first mode in the phase-III AVT, phase-IV AVT, the simplified model, and the complex FE model of the building along with NBCC formulation is shown in Figure 10. As it is clear in Figure 10, there is a significant discrepancy of about 47% between the first natural frequency of the simplified model and the result of Phase-IV AVT. Modelling only CLT core of the building could not predict the building frequencies accurately in this case study, as the first frequency of this model is not well-matched with the measurement. It is worth noting that difference between fundamental natural frequency of the complex model and phase-IVAVT is about 10.8%.

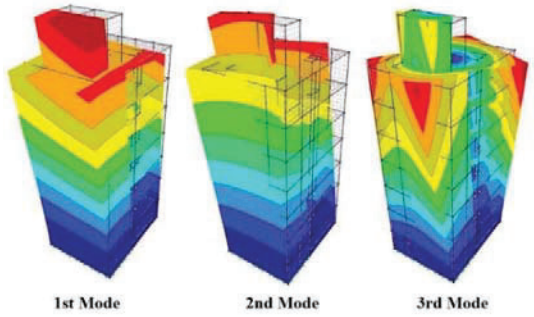

Figure 8*: First three mode shapes of the simlified model*

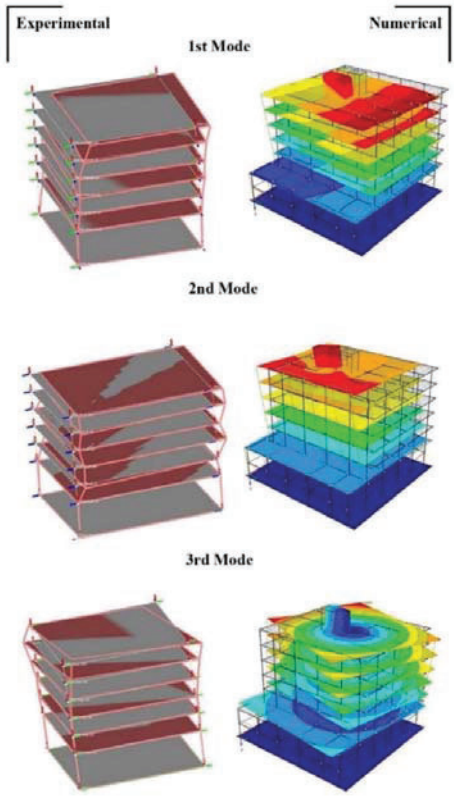

Figure 9*: First three mode shapes of the complex model both numerically and experimentally*

Because the first three measured frequencies of the building are close to each other, the discrepancy of 10.8% between first frequency of the FE model and experiment data cannot be considered as a good match between FE model and test data, though, this discrepancy is lower in comparison with the simplified model. Besides, it is interesting to find that first natural frequency of the

https://doi.org/10.52202/069179-0377

building estimated using the NBCC equation matched the measured value reasonably well from designer's point of view based on the data measured on 19 buildings [16] and close the predicted by the complex model. The results of the first three natural frequencies of the simplified and complex model are listed in Table 3. It is clear that the simplified model provided overestimated frequencies for all the three modes. Moreover, the differences between the measured and FE modelled frequencies are larger in higher modes. This finding agrees with the results found in [13] that matching higher modes of the FE modelling with the test results is more difficult than the lower modes.

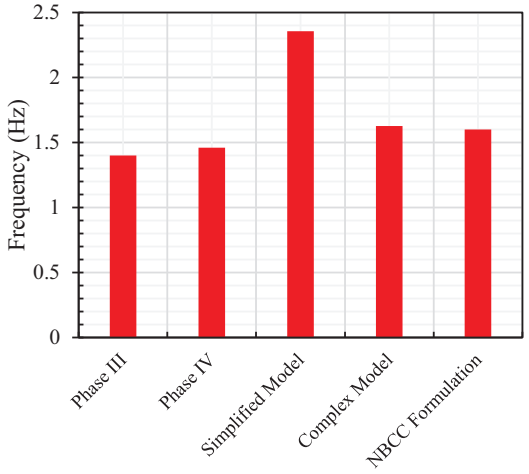

***Figure 10**: Comparision between avt, FE modelling, and nbcc equation for prediction of the first natural frequency*

***Table 3:** Frequencies of the simplified and complex model*

Modes	Simplified model (Hz)	Complex model (Hz)	Discrepancy (%)
Translation in X	2.3	1.6	35.9
Translation in Y	4.3	2.6	49.3
Torsion	6.0	5.0	18.2

3.3 SENSITIVITY ANALYSIS

A sensitivity analysis was carried on both the simplified and complex numerical models to investigate the sensitivity of the frequencies to different assumptions of connection types. The initial models are based on the assumptions mentioned in section 2.3. As shown in Figure 11, by changing wall and columns base connections from pinned to fixed in simplified model, less than 0.3% soar in all three frequencies is observed. Altering wall-to-wall connections from fixed to hinged leads to a reduction of less than 0.6% in all frequencies. Considering wall-to-floor connections hinged as an alternative for fixed assumption, caused 2.6% decrease in the frequencies.

The sensitivity analysis of the complex model yields similar results to the simplified model. By changing floor-to-wall and panel-to-panel wall connections from fixed to hinged, less than 0.7% reduction is observed. Considering fixed connections instead of pinned in the base supports leads to less than 0.5% increase in all frequencies. Details of the sensitivity analysis of the complex model is shown in Figure 12 for the complex model. The results agree well with the findings in [10,11] that indicates low sensitivity of the FE model developed in RFEM to the different assumptions of connection types in structural elements (fixed, pinned or hinged).

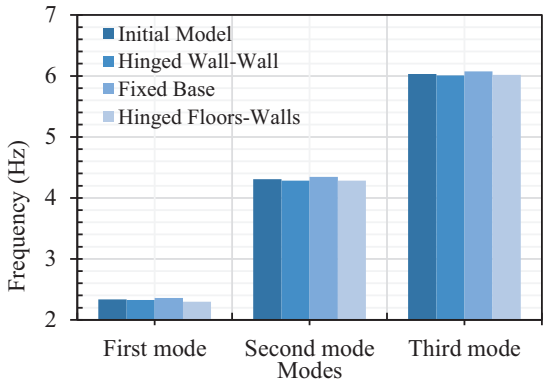

***Figure 11**: Details of the sensitivity analysis of the simpified model.*

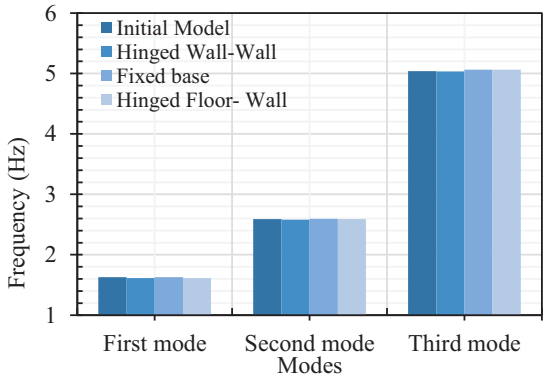

***Figure 12**: Details of the sensitivity analysis of the complex model.*

4 CONCLUSIONS

The dynamic properties of a 29.5-m mass timber building was investigated through both AVT and FE modelling. An ambient vibration test was carried out on the building to assess the differences of the dynamic properties after 9 years of its srvice time, as the result of three-phase AVT is already available from the building construction time. Then, two types of FE modelling were developed in RFEM software and the results of both numerical models were compared with the measured frequencies. Finally, a sensitivity analysis was performed to see the effect of different connection type assumptions on the building frequencies.

https://doi.org/10.52202/069179-0377

A summary of the results and recommendations limited to the current case study can be concluded as follows:

1. According to the experimental test, the first natural frequencies of the structure did not have a significant change in comparison to the last performed AVT in 2017. Frequency change between the first three phase is due to the fact that phase-I testing was performed on the building under construction with only frame and structural components without enclosure. The second phase testing was performed on the finished building with all components that added stiffness and mass, which increased the building frequencies.
2. The results of simplified FE model poorly matched with results of AVT and the complex FE model. Though, the complex model shows a better agreement in the first frequency with the measured frequency values. However, a significant discrepancy can be observed in higher modes. The modal parameters in FE model shows a low sensitivity to the type of connection assumptions (fixed, pinned or hinged), and requires experimental verifications.
3. It is recommended that in the absence of a reasonable reliable FE model, for the design purpose, the NBCC simple equation can be considered to estimate the first natural frequency of mass timber buildings with only shear walls. It is also recommended that for design purpose, for such type of wood construction, 2-3% damping for the occupied building may be used. Besides, if FE modelling is used for design, caution, verification, and calibration is needed.

ON FINITE ELEMENT MODELLING AND MODEL UPDATING OF MULTI-STOREY TIMBER BUILDINGS

Blaž Kurent[1], Boštjan Brank[2], Wai Kei Ao[3], Aleksandar Pavic[4], Manuel Manthey[5]

ABSTRACT: The results of three case studies of timber and hybrid timber buildings have been reviewed. For each case study, experimentally obtained modal data was available. A detailed numerical finite element (FE) model of each building has been developed and used to carry out sensitivity analysis on the uncertain FE modelling parameters and model updating of the most influential input parameters. The importance of several modelling parameters and assumptions is discussed: perpendicular to the grain deformations of floor slabs, connections between cross-laminated timber panels, floor slab deformability, vertical foundation stiffness, and stiffness effect of the façade.

KEYWORDS: tall timber buildings, case studies, finite element model, model updating, modal properties

1 INTRODUCTION

In the last decades, there has been a large increase in the use of timber for multi-story buildings. One of the reasons is that it shows a potential for being a sustainable alternative to mineral-based materials [1]. This has been found through LCA studies showing significant reductions in embodied emissions when substituting timber for concrete [2] [3] [4]. Due to its light weight, timber might play an important role in sustainably densifying the cities [5], mainly by refurbishing existing buildings by adding new storeys or building new and taller buildings onto the existing foundation.

The structural design of a building is often governed by serviceability criteria [6]. For tall timber buildings, a key limitation regarding the serviceability is wind-induced vibrations [7] [8]. To satisfy current comfort criteria (e.g. ISO 10137 [9]) for wind-induced vibration an estimate of the fundamental frequency is needed. A simplistic estimation of the first natural frequency as $46/h$, where h is the height of the building in meters, is offered by Annex F of Eurocode 1 [10]. However, if wind-induced vibrations are governing design criterium, a more accurate estimation method might be desired. Often a finite element (FE) model is built, but there are some uncertainties when it comes to decisions about modelling assumptions.

Connections between CLT panels have been found to govern the behaviour of CLT buildings under seismic loads [11], however, there is no evidence to support similar claims for wind loads. Another uncertainty is connected to the contribution of non-structural elements to the global stiffness of the building. It was often found that for standard steel and concrete multi-storey buildings such non-structural elements increase the first natural frequency of the building [12] [13] [14] [15]. Additionally, for 3-storey OSB sheathed light-frame timber building it was found that non-structural elements increase the natural frequency of the building. It was also found that with increasing amplitude of excitation of the building contribution of the non-structural elements is smaller. Another study on laboratory-based 6-storey light timber-framed building [16] showed that both plasterboards and masonry façade significantly increase the natural frequency of the building. However, how to take them into account in the modelling of timber building is not clear. A large uncertainty is also attributed to the material properties of timber. For the shear modulus of CLT panels mean values of 450 MPa and 650 MPa have been proposed, based on whether narrow sides of boards are glued or not and whether cracks are present [17]. Besides the high variance of material properties of wood by itself, there is a large dependency of material properties on moisture content [18] which initially decreases after construction but then also changes seasonally [19].

2 CASE STUDIES

Three case studies were conducted to learn about the as-built stiffness characteristics of the buildings. They followed a similar procedure.

In each, forced vibration tests were carried out, identifying modal properties (natural frequencies, mode shapes and damping ratios). For each of the three buildings, a numerical FE model was built to calculate the modal properties of the building. The FE natural frequencies and mode shapes were compared against the experimental. As a measure of mode shape correlation modal assurance criterion (MAC) was used. The model was then changed by adopting different modelling assumptions to see how the model can be improved. The influence of different modelling parameters was tested with the sensitivity analysis. The more influential parameters were then chosen to be updated in order to find the best match with the experiments. The objective function consisted of measures for comparing natural frequencies and mode shapes. After the model updating the updated parameter values were informative about the modelling error of the initial model. Individual findings and implications will be presented in the next section.

The first case study is Yoker (see Figure 1a) – a seven-storey timber building located in Glasgow, UK [20] [21]. It is fully constructed out of CLT in platform frame type. It has a distinct irregular shape of the building that strongly determines the dynamic properties of the building. The modal testing resulted in eight identified modes of vibration [22], though only the first six were successfully connected with the FE model.

The second observed building is Trinity College student residential five-storey building (see Figure 1b), located in Cambridge, UK [23]. It is a timber-concrete hybrid building with the basement and ground floor constructed out of reinforced concrete and the remaining four floors of the superstructure out of CLT. The building is cladded with a 100 mm self-supporting masonry wall, which is connected with the CLT load-bearing structure with steel horizontal ties. The building is located in a tight urban environment and is being in contact with the abutting building on one end. Modal testing identified three modes of vibration.

The third one is the Hyperion tower in Bordeaux (see Figure 1c), France, with a height of 56 m and 16 storeys. The first three levels are made of concrete and the 13 upper ones are composed of a concrete core, steel peripheral columns with infilled pre-manufactured timber-frame façade, CLT floors, and glue-laminated beams. Three modes of vibration have been identified with forced vibration tests.

3 FINDINGS FROM CASE STUDIES

The three buildings are substantially different in regard to their structural systems, heights and shapes. Each case study was a very unique investigation work to find a model that matches the experiments well. The most difficult was to obtain good MAC values and in each building, a different set of effects were identified that were crucial to obtaining good results. However, two effects had repeated:

1. Vertical stiffness is lower than what is anticipated when the foundation is modelled as rigid and the load-bearing structure is modelled with mean material properties. Not only compliance of the foundation is a possible cause for that, but also perpendicular to the grain deformations of floor slabs in platform frame type buildings could be a reason.

2. The shear stiffness of the CLT walls is higher than what is anticipated when only load-bearing structure is modelled and mean stiffness material properties are adopted. The most probable reason for that is a significant contribution of non-structural elements (such as façade, partition walls, plasterboards etc.), but also the uncertainty of material properties could play an important role. This effect was not found in the hybrid building with concrete core - Hyperion.

In regard to those two effects, several modelling assumptions are discussed below.

Figure 1 Three studied buildings: (a) Yoker, (b) Trinity, and (c) Hyperion.

https://doi.org/10.52202/069179-0378

3.1 PERPENDICULAR TO THE GRAIN DEFORMATION

The two main types of framing for timber buildings are balloon and platform frame type. A well-known limitation of a platform frame are perpendicular to the grain deformations. Due to orthotropic material properties, with elastic modulus perpendicular to the grain being much lower than along the grain elastic modulus, floor slabs are being squeezed between the walls, as illustrated in Figure 2. The large weight of the building acting on a small area under the walls causes local deformations that might result in a damaged façade or plasterboards if the vertical differential movement is not allowed for in the design of those elements.

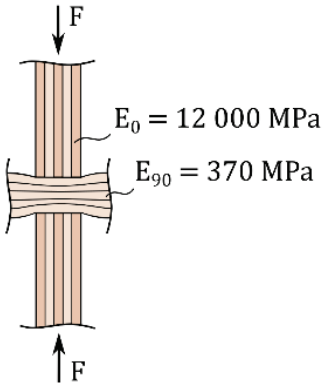

Figure 2 Perpendicular to the grain deformations of CLT floor slabs.

The same effect is observed when the global stiffness of the building is considered. Despite the almost negligible thickness of floor slabs, their vertical deformations are of comparable magnitude to those of the walls. The effect is explained more in detail in [20]. Calculations estimated that a reduction of up to 50 % in overall stiffness in the vertical direction is possible.

These local softening effects are difficult to model accurately when using shell elements. In Yoker and Trinity, this effect was modelled as a reduction of the elastic modulus of vertical layers of CLT walls (while horizontal layers remain unchanged).

Model updating of Yoker resulted in a 40-50% reduction of elastic modulus in the vertical direction, which parallels well with the simplified estimates of this effect's influence. However, reducing the stiffness of the foundation in the vertical direction causes a similar change in the model and, therefore, it is not certain which effect plays a more important role or how their influences are distributed.

This effect was also modelled for Trinity, but no conclusive results were obtained. The reason for that is the low influence of this parameter on the modal properties of the building as was shown with sensitivity analysis. Trinity is not as slender building and its fundamental modes are characterized more by shear rather than bending of the structure.

This effect was not present in Hyperion as loads of columns are not transferred over CLT floor slabs. The columns are stacked directly on top of each other.

Further research in a controlled environment is needed to more clearly understand the effect of perpendicular to the grain deformations on the overall stiffness of the building.

3.2 CONNECTIONS BETWEEN CLT PANELS

Connections between CLT panels pose a large uncertainty when it comes to their contribution of the dynamic properties of the building. In seismic design, connections seem to be the weakest link, however, when exposed to small amplitude excitation they might not contribute as much to the stiffness of the structure. The distinction here should be made between the connections that conjoin CLT walls and floors (in platform frame building), where large friction forces are to be exceeded before the connections are engaged and connections where no large axial forces help join CLT panels (e.g. in-plane connections between floor slab panels).

The stiffness of the connections between CLT walls (in Yoker and Trinity) was not directly modelled, rather a rigid bond was assumed. The contribution of the connections to the modal properties of the building is expected to be found indirectly from model updating. If the in-plane shear modulus of the CLT walls results in a lower value than what is proposed by its producers, connections might be responsible for such a reduction of stiffness. However, both case studies (Yoker and Trinity) concluded that the in-plane shear stiffness of the walls is higher than what was anticipated based on the mean material properties. In Yoker, the in-plane shear modulus was found to be around 60% higher than anticipated. In Trinity, shear stiffness was found to be at least 25% higher. This suggests that connections do not significantly reduce the overall stiffness of the building for small amplitude vibration.

In Hyperion, CLT panel are only used for floor slabs. They will be discussed in the following section.

3.3 FLOOR SLAB IN-PLANE DEFORMABILITY

Floor slabs being modelled as rigid diaphragms is a common assumption, but it may not always be suitable. For all three case studies, it was tested on the models and compared with the assumption of deformable CLT panels. The latter is considered as a more accurate model.

In Yoker, the assumption of a rigid diaphragm gives sufficiently good results for the first three modes (bending and torsion modes), however, to obtain higher modes, modelling floor slabs as deformable was necessary. Namely, higher modes consisted of substantial in-plane deformations of floor slabs. The study of Yoker also suggested that the connections between CLT panels of floor slabs might reduce the stiffness of the floor slabs,

https://doi.org/10.52202/069179-0378

which differs from what has been discussed about the connections between walls and floor slabs in the previous section. Perhaps due to lower axial forces not offering strong friction between floor slab panels.
In Trinity, even the first modes needed floor slabs to be modelled as deformable. This was expected due to its low height.

In Hyperion, the assumption of rigid diaphragm doesn't change the first three natural frequencies significantly. It seems that the assumption is suitable for slender structures.

3.4 FOUNDATION MODELLING

Boundary condition that models soil structure interaction has a paramount influence on the dynamic properties of the building. Commonly, only a rigid foundation is assumed due to a lack of information and large uncertainty connected to the properties of the soil. For timber buildings, which are normally significantly lighter than reinforced concrete buildings, also significantly less material is used to form foundation. Its effect might be far from negligible. For the three observed buildings, the influence of the foundation was studied.

In Yoker, reducing the vertical stiffness of the building was necessary to improve the matching of the model to the experiments. Besides perpendicular to the grain deformations, which were discussed in Section 3.1, soil-structure interaction could be the reason behind the reduced stiffness of the building. In model updating, both vertical and horizontal stiffnesses of the foundation were included. Updated values suggested a rigid boundary condition for horizontal stiffness, but slightly compliant in the vertical direction.

In Trinity, modelling of foundation as flexible in the vertical direction was crucial to obtain a good match with the experimental modal properties. The updated value of the foundation stiffness reduced the stiffness of the building by at least 7% and 26% in the x and y directions, respectively.

Model updating of Hyperion also suggested that the foundation should be modelled as flexible in the vertical direction, whereas, constrained horizontal deflections do not worsen the accuracy of the model. If accurate modelling is desired, the stiffness of the foundations should not be neglected.

3.5 INFLUENCE OF FAÇADE

There is a variety of different façade solutions. Their stiffness properties and mounting to the load-bearing structure vary greatly, therefore, general conclusion for the façade are not possible. However, the three case studies may present an illustrative example.

In Yoker, the in-plane shear modulus of the walls was updated to a 60% higher value that the one proposed by the producers. Façade (together with other non-structural elements) could be the reason for this increase. Though the façade – acrylic brick slips – is quite thin and might not offer significant support.

In contrast, the façade of Trinity consists of 100 mm thick masonry cladding (self-supported masonry wall, connected to the load-bearing structure by horizontal steel ties). It was shown that the inclusion of the masonry cladding was needed and an important contribution to the modal properties of the building. Even when masonry cladding was modelled as an additional rigidly-bonded layer to the CLT, the in-plane shear modulus was updated to a value between 125 % and 210 % of the initial value (proposed by the producer). If the masonry façade was neglected almost a 400 % increase of CLT in-plane shear modulus was obtained from the model updating. This suggests a significant influence of masonry cladding on modal properties of the building.

Prefabricated elements are used for the façade of Hyperion. They are made of 10 mm cladding, 12 mm and 18 mm layers of OSB and 12 mm gypsum panels. The layers are connected with battens to make space for almost 0.5 m insulation and ventilation layers. Model updating of Hyperion did not provide definite conclusions on whether such a façade influences dynamic properties significantly. The governing structural system defining dynamic properties was a reinforced concrete core.

4 CONCLUSIONS

Three case studies of timber and hybrid timber buildings have been reviewed, and their findings are compared. In each, forced vibration testing has been performed to obtain at least 3 modes of vibration, finite element model has been constructed and updated based on the experimental results.

All three case studies showed that modelling foundation as slightly compliant in the vertical direction offers a more accurate prediction of modal properties. The updated stiffness of the foundation differed between the case studies. Two case studies of CLT buildings updated the shear stiffness of the walls higher than initially anticipated based on the assumption of mean material properties of the CLT (and neglecting non-structural elements such as plasterboards, façade, and partition walls). One of the case studies of a platform frame CLT building found a significantly reduced vertical stiffness due to perpendicular to the grain deformations of floor slabs. Case studies showed that the modelling assumption of the rigid diaphragm for floor slabs was suitable for tall and slender buildings in predicting the first three modes. The lower building was not successfully modelled with such an assumption.

The model updating of such complex systems can only be used to obtain such broad findings. For more precise conclusions (perhaps about the effect of connections between CLT panels), testing in a more controlled environment should be performed.

AMBIENT VIBRATION TESTS AND MODAL ANALYSIS OF A SIX-STORY LIGHTWEIGHT TIMBER FRAME BUILDING

Carmen Amaddeo[1], Michael Dorn[2]

ABSTRACT: This paper describes the in-situ ambient vibration tests of a lightweight timber frame building, performed in order to obtain its modal properties. Our case study is a six-story lightweight timber frame building in Varberg, Sweden. Five battery-driven wireless data acquisition units with a total of 14 uni-axial accelerometers were used to perform the in-situ measurements. Accelerations along the two horizontal directions were recorded with a duration of approximately 40 minutes. Two different only-output frequency and time domain Operational Modal Analysis (OMA) methods were used to evaluate the dynamic properties of the building. The modal parameters obtained from the in-situ measurements, such as natural frequencies and mode shapes, were compared with the parameters obtained from the Finite Element (FE) model of the structure. To perform a detailed numerical analysis of the light-frame timber building, all lateral-load resisting system components were modelled. The FE model was calibrated in function of the results obtained from the OMA of the building. Based on the obtained results from the calibrated FE model, it was possible to conclude that the non-structural elements have an influence on the global dynamic response of the building.

KEYWORDS: Timber, multi-story lightweight timber frame building, operational modal analysis, finite element modeling

1 INTRODUCTION

The realization of multi-story residential and commercial timber buildings is rapidly increasing all around the world. Timber structures are, in general, cost efficient, easy to transport, and quickly built on-site due to the high level of prefabrication. Light-frame timber systems have frequently been used to realize multi-story buildings. For this reason, it is important to understand their in-situ dynamic behavior to verify that such a typology of structures meets the design requirements in terms of structural safety as well as serviceability.

Ambient vibration tests are performed in order to obtain the in-situ modal parameters of the building. The results obtained from in-situ measurements can be used to validate and calibrate the Finite Element (FE) model of the building [1]. Calibrated FE models can be used to optimize the design of similar structures under ultimate and serviceability limit state load conditions.

Tests on lightweight timber frame multi-story buildings have not been extensively conducted with the exception of a few cases. The stiffness of a six-story timber frame building, during the construction stages, using dynamic testing has been evaluated by Ellis et al. [2]. Shake table tests on a full-scale two-story lightweight timber frame structure have been conducted by Filiatrault et al. [3, 4], in order to evaluate the dynamic parameters of the building and its seismic performance. In addition, shake table tests on a three-story lightweight timber frame building have been performed by Sartori et al. [5], focusing on the seismic performance of a prefabricated light-frame timber building and on the interaction of structural components.

In our study, to identify the dynamic parameters of the building, the Enhanced Frequency Domain Decomposition (EFDD) [6], and the Stochastic Subspace Identification (SSI) [7] methods have been used. Operational Modal Analysis (OMA) is considered an effective, non-destructive method to assess the actual operational condition of an existing structure.

This paper presents the in-situ dynamics tests carried out at the so-called, Hus 35 in Varberg, Sweden (Figure 1).

Figure 1: *East view of Hus 35 in Varberg, Sweden (picture by the author).*

[1] Carmen Amaddeo, Linnaeus University, Sweden, carmen.amaddeo@lnu.se
[2] Michael Dorn, Linnaeus University, Sweden, michael.dorn@lnu.se

https://doi.org/10.52202/069179-0379

The structure was subjected to small ambient vibrations induced by wind. The results obtained in this study will be used as a benchmark for a more extensive test campaign that will be conducted on this building as well as on a second neighboring light-frame timber building in Varberg, Sweden, realized with the exact same design.
The modal parameters obtained from the in-situ test were compared to the one obtained from the FE model of the building. Simplified FE models have been widely used because they are numerically efficient and they demand a low computational effort [8, 9, 10]. Recent studies have focused on developing non-linear FE models including a larger number of deformation mechanisms such as: the detailed modeling of each connection, the individual timber frame stud elements, and the sheathing boards [11]. A detailed modeling strategy was developed by Kuai et al. [12] in order to analyze the deformation behavior of light-frame walls. Due to the high computational demand in modeling all connections, this work will include only the spring connections between different panels in the calibration phase of the FE model of the building. A preliminary study of the same building was developed by Amaddeo and Dorn [13] using a simplified modeling approach.

1.1 BUILDING DESCRIPTION

The Pilgatan block in Varberg consists of four six-story buildings all realized with the same light-frame system and built consecutively from 2020 to 2022. Each building has four apartments at each floor with the staircase and elevator shaft in the middle of the building along the East side (see Figure 2).

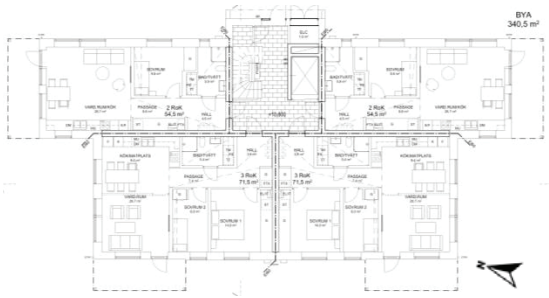

Figure 2: *Plan of a typical story.*

The load bearing system is composed of lightweight timber frames elements. The timber-framed wall panels of the external walls are made of timber studs, 45 mm x 170 mm, and a double layer of Oriented Strand Board (OSB) sheeting panel, 11 mm thick (see Figure 3.a and 3.b). The timber-frame internal walls are made of timber studs, 45 mm x 220 mm and 45 mm x 95 mm, and particle board sheeting panel 38 mm-thick. The elevator shaft and staircase are made with the same system. The load-bearing wall elements are prefabricated and assembled directly on-site. For horizontal stabilization, diagonal steel rods have been used.

This study will focus on the dynamic characterization of one of the buildings in the Pilgatan block, refer to as Hus 35, using ambient vibration tests.

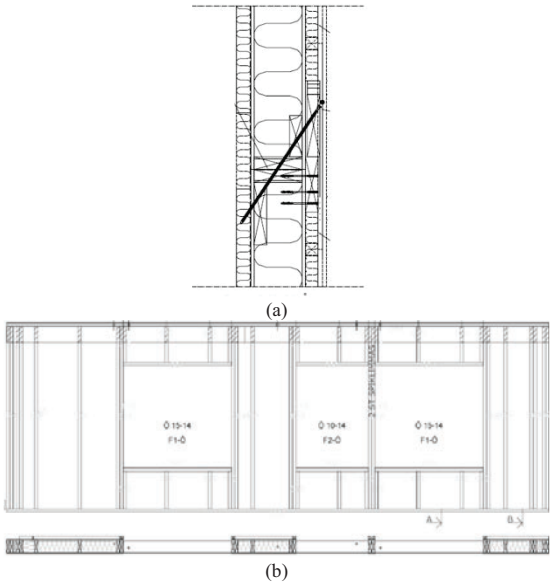

Figure 3: *External wall: (a) Detail of the load-bearing section of a timber-framed wall, (b) Front view of one of the lightweight timber frame panels.*

2 EXPERIMENTAL TESTING PROCEDURE

A first ambient vibration test was carried out in May 2021 [13], using only two data acquisition systems and four accelerometers. During this preliminary test a total of 9 measurements, with a duration of approximately 30 minutes each, were performed. During each measurement, the sensors at the first floor were used as a reference. The extracted natural frequencies of the building were used to validate the sensor layout for the presented study.

Figure 4: *Test setup: two of the total five portable data acquisition systems during the synchronization phase.*

https://doi.org/10.52202/069179-0379

A more extensive ambient vibration test campaign has been conducted starting in October 2022. During this second phase, five wireless data-acquisition systems (see Figure 4) with 14 uni-axial accelerometers, model PCB 393B12 with a sensitivity of 0.5 V/g, were used during the ambient vibration tests.

This type of accelerometers allows us to record low acceleration values also at a low frequency. The sensors were connected to a steel cube element to ensure the orthogonality of the recorded accelerations. The cubes with the accelerometers were connected to a steel plate which secured the placement against sliding, as shown in Figure 5.

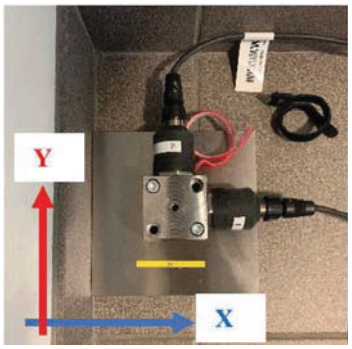

Figure 5: *Detail of the sensors at the first floor, location #1 with the direction of the recorded acceleration.*

Ambient vibration tests are sensitive to the presence of noise, so that both the sensors' location and duration of the test are important parameter during the testing campaign. A thorough placement and proper time synchronization reduces measurement noise and ensures the accuracy of the results.

Three accelerometers were placed on each floor as well as on the roof, except at the third floor where no accelerometers were placed, as shown in Figure 6.

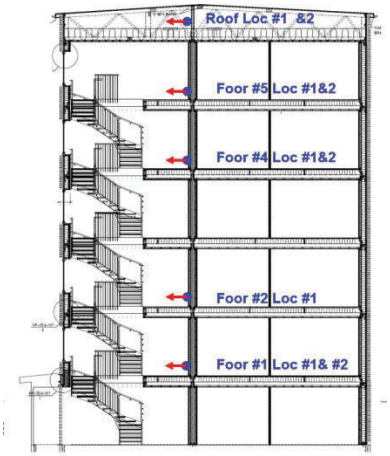

Figure 6: *Building section along the EW direction showing the sensor layout at each level.*

The accelerometers were used to measure the wind and traffic induced ambient vibrations. To minimize the interference with the occupants as well as the input from human induced vibration, the dynamic tests were conducted during the less crowded hours of the day during a work week.

The accelerometers were placed in the area next to the staircase and elevator shaft (see Figure 7). The layout of the sensors for the typical floor level is shown in Figure 7.a, and for the roof level is shown in Figure 7.b, where the sensors are placed farther apart from each other along the longitudinal direction (x-direction).

Measurements were conducted using three accelerometers per floor: one along the longitudinal (x-direction) and two along the transversal (y-direction) direction except at the second floor where only two accelerometers, one along the longitudinal and one along the transversal direction were used (see Figure 6).

The ambient vibration data were recorded for approximately 40 minutes, with a sampling frequency of 120 Hz. The five data-acquisition systems were cable synchronized at the beginning of each test in order to have the same time stamp (see Figure 4). Thereafter, each system was moved to its respective floor and the sensors were connected to each data acquisition system. Actual useable measurement time was reduced by approximately 5 minutes.

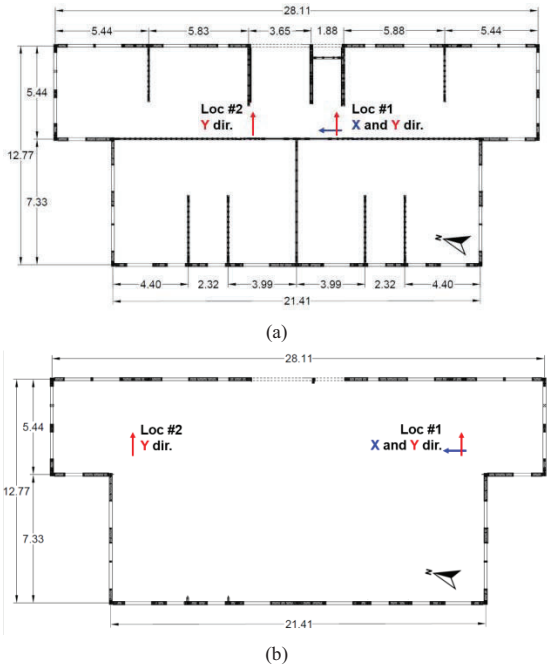

Figure 7: *Sensor layout with the location and direction of the accelerometers. (a) Typical floor level, and (b) Roof level.*

Three different tests were performed on the building in the period between October 2022 and January 2023, to see if any variation of the modal parameters had occurred under different environmental conditions.

https://doi.org/10.52202/069179-0379

The tests were performed respectively on: October 5th, 2021 (Test #1); November 23rd, 2022 (Test #2); and January 10th, 2023 (Test #3). Monthly tests will be performed for a full year in total.

3 EXPERIMENTAL RESULTS

Modal parameters of the building were identified using the EFDD, and SSI methods, respectively a frequency-domain, and a time-domain system identification method. These OMA techniques are available in the software ARTeMIS [14], that was used to analyze the recorded data.

The recorded data were post-processed in order to eliminate corrupted data from the analysis as well as the high-noise signals. A Butterworth filter between 0 and 6 Hz was used to better identify the natural frequencies of the building. This frequency range includes the first three mode shapes of the building in the two translational and torsional directions.

An example of the recorded acceleration at the roof level along the x-direction for a 20 second segment is shown in Figure 8, in which the periodicity of the response can be seen.

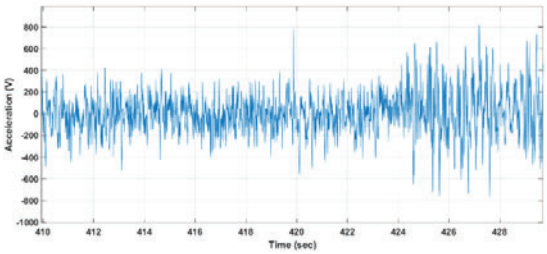

Figure 8: *Acceleration time-history for a 20 second fragment of the 40 minutes data recorded on January 10th, 2023.*

The auto Modal Assurance Criterion (autoMAC) values were calculated [15] and used to measure the degree of correlation and consistency between the mode shape pairs evaluated with one set of collected data. The autoMAC value is defined by Equation (1) as:

$$MAC_{rs} = \frac{|\{\varphi_r\}^T\{\varphi_s^*\}|^2}{\{\varphi_r\}^T\{\varphi_r^*\}\{\varphi_s\}^T\{\varphi_s^*\}} \quad (1)$$

where φ_r and φ_s are the modal vector for the frequency r and s respectively.

3.1 Enhanced Frequency Domain Decomposition (EFDD)

In the EFDD method, in order to evaluate the spectral matrix, the Power Spectral Density (PSD) of a single-degree-of-freedom systems is transformed into the time domain using an inverse discrete Fourier transform [6].

The Singular Value Decomposition (SVD) obtained for the three performed tests is shown in Figure 9. For all measurements, three well defined peaks can be observed at a frequency range between 2 - 4.0 Hz (see Table 1).

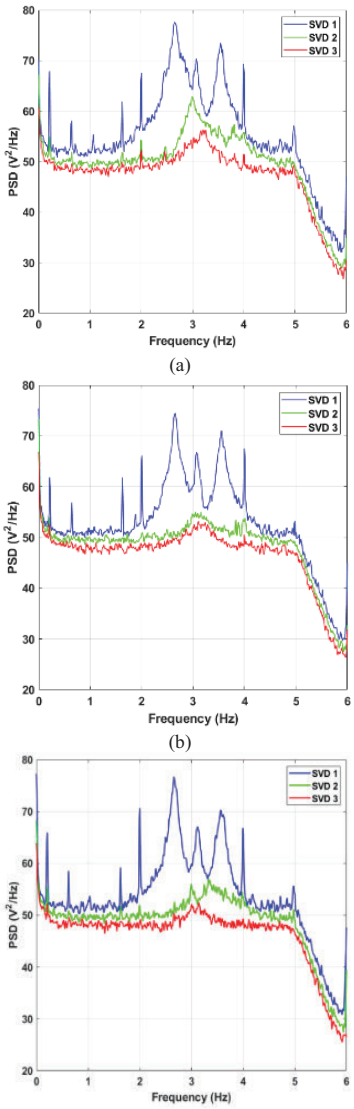

Figure 9: *Singular Value Decomposition (SVD) plot for the EFDD method: (a) Test #1, (b) Test #2, (c) Test #3.*

3.2 Stochastic Subspace Identification (SSI)

The second used system identification method is a time-domain approach. The SSI method is a parametric system identification method that allows the construction of stabilization diagrams. A stabilization diagram is a useful tool for evaluating stable modes and eliminating noise and unstable modes [7, 17].

The state space models' stabilization plots for the three performed tests are shown in Figure 10. The maximum model order is shown by a green horizontal line in Figure 10. In particular, for Test #1, the model order is equal to 23 (see Figure 10a), for Tests #2 and #3 it is equal to 18 (see Figure 10b and 10c).

https://doi.org/10.52202/069179-0379

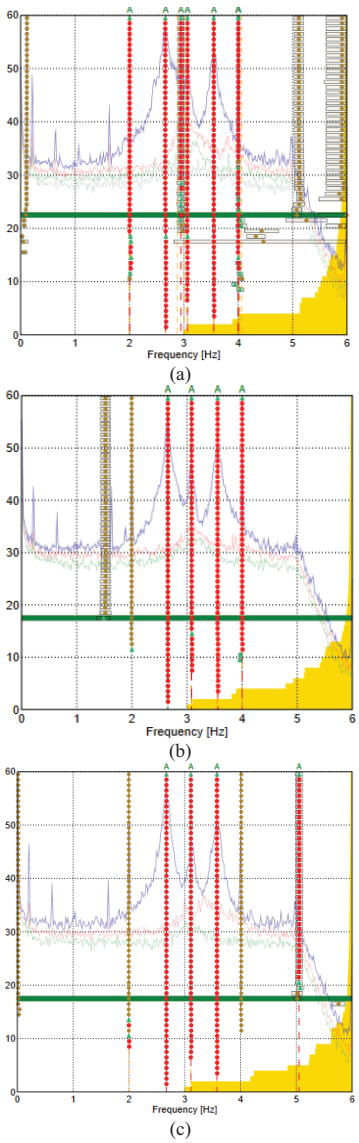

Figure 10: *State space models for the SSI method: (a) Test #1, (b) Test #2, (c) Test #3.*

The vertical red dots in Figure 10 indicate the stable modes within a frequency range between 0 and 6 Hz. The total number of stable modes is changing between the performed tests. Considering that some of the identified frequency values were very close, only the modes with a low value of complexity were considered as real structural modes (see Table 1).

3.3 Results comparison

Table 1 shows the results obtained from the three tests in terms of natural frequencies and damping ratios using the two OMA method, EFDD and SSI method respectively. Three modes of vibration were identified using both system identification methods.

Table 1: *Natural frequencies and damping ratios identified by the EFDD and SSI methods.*

EFDD Method			
	Test #1	Test #2	Test #3
Mode 1	$f_1 = 2.664$ Hz	$f_1 = 2.648$ Hz	$f_1 = 2.673$ Hz
	$\zeta_1 = 2.799$ %	$\zeta_1 = 1.344$ %	$\zeta_1 = 1.549$ %
Mode 2	$f_2 = 3.072$ Hz	$f_2 = 3.075$ Hz	$f_2 = 3.121$ Hz
	$\zeta_2 = 1.143$ %	$\zeta_2 = 0.821$ %	$\zeta_2 = 0.975$ %
Mode 3	$f_3 = 3.546$ Hz	$f_3 = 3.551$ Hz	$f_3 = 3.577$ Hz
	$\zeta_3 = 1.423$ %	$\zeta_3 = 1.707$ %	$\zeta_3 = 1.657$ %
SSI Method			
	Test #1	Test #2	Test #3
Mode 1	$f_1 = 2.658$ Hz	$f_1 = 2.652$ Hz	$f_1 = 2.671$ Hz
	$\zeta_1 = 2.399$ %	$\zeta_1 = 1.627$ %	$\zeta_1 = 1.375$ %
Mode 2	$f_2 = 3.064$ Hz	$f_2 = 3.084$ Hz	$f_2 = 3.110$ Hz
	$\zeta_2 = 1.754$ %	$\zeta_2 = 1.347$ %	$\zeta_2 = 1.449$ %
Mode 3	$f_3 = 3.550$ Hz	$f_3 = 3.557$ Hz	$f_3 = 3.577$ Hz
	$\zeta_3 = 1.452$ %	$\zeta_3 = 1.522$ %	$\zeta_3 = 1.547$ %

It is possible to observe a small variation in terms of natural frequencies identified during the three different tests with both methods. For the natural frequency evaluated with the EFDD method it can be seen a maximum variation equal to 1.5%, for the second identified mode. For the natural frequency evaluated with the SSI method, it can be seen a maximum variation equal to 1.47%, for the second identified mode. Only minor differences in the values of the natural frequencies between both methods are seen.

The SSI method, in general, gives more accurate results while evaluating the damping ratio also for highly complex data, and when there are closely spaced modes as in our case (see Figure 10).
The damping ratio variations between the performed tests are more significative. In particular, it is possible to observe a minimum variation equal to 16.6%, and a maximum variation of 51% for the evaluated damping ratios extracted using the EFDD method. For the SSI method, it can be seen a minimum variation equal to 6.1%, and a maximum variation of 43% for the evaluated damping ratios.
The identified mode shapes, using both OMA methods, for Test #3, performed on January 10th, 2023, are shown in Figure 11.

The first mode shape, shown in Figure 10.a and 10.b, is a translational mode along the transversal direction (y-direction). The second identified mode, shown in Figure 10.c and 10.d, is a torsional mode. The third mode, shown in Figure 10.e and 10.f, is a translational mode along the longitudinal direction (x-direction). Same results in terms of mode shape are visible also for the other performed tests.

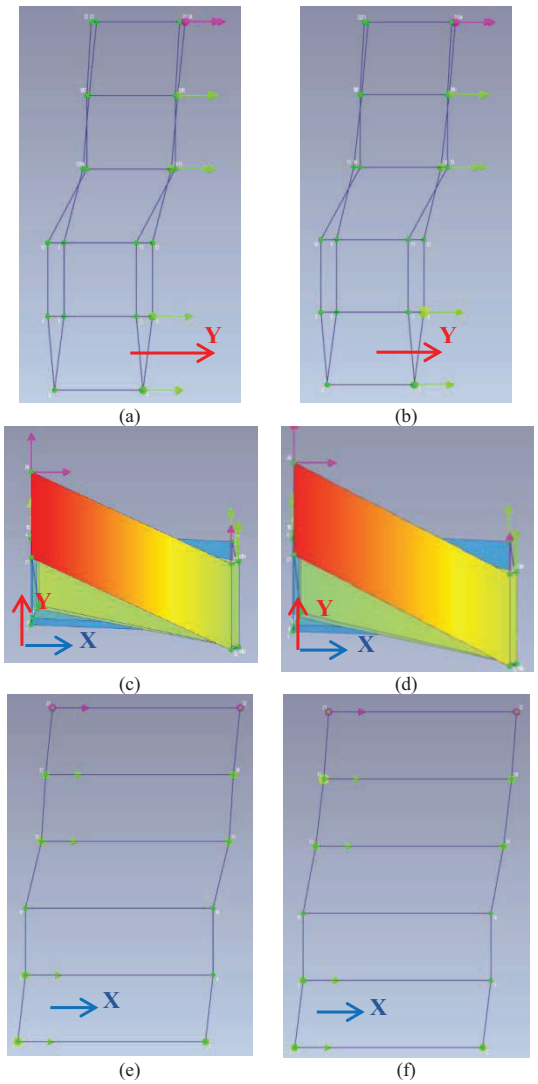

Figure 11: *Identified mode shapes for the Test #3: (a) Mode #1 - EFDD method; (b) Mode #1 - SSI method; (c) Mode #2 - EFDD method; (d) Mode #2 - SSI method; (e) Mode #3 -EFDD method; and (f) Mode #3 - SSI method.*

The autoMAC values for the three performed tests on Hus 35 are shown in Figure 12. Each bar represents the autoMAC value for a specific mode extracted with the SSI method, the values between 0 and 1.0 are proportional to the degree of correlation. The autoMAC value is equal to 1.0 if the mode shape pairs are exactly a match and equal to 0 if those pairs are completely independent or unrelated. Based on the values of the autoMAC, it can be seen that some of the modes are correlated. For this reason, the closed spaced modes with a low value of complexity were considered to be structural modes (see Table 1).

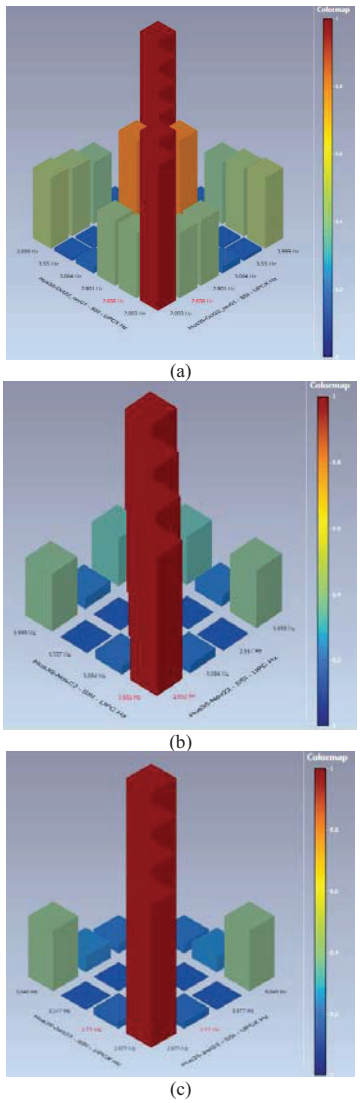

Figure 12: *AutoMAC values for the identified modal parameters with the SSI method: (a) Test #1; (b) Test #2; and (c) Test #3*

4 STRUCTURAL MODELLING

In this study, the FE model of the building was developed using SAP2000 [14]. The FE model was developed to validate the results obtained from the in-situ test in terms of modal parameters as well as to understand the role of non-structural elements in the changes of fundamental frequencies for lightweight timber frame structures.

Every component of each lightweight wall was included in the FE model. In particular, beam elements were used for the timber frame members (studs), shell elements were used for the sheeting boards (OBS panel for the external walls and particle boars panel for the internal walls) and two joint link connections were used for the panel's connections. The detail model for one of the wall panels is shown in Figure 13.

https://doi.org/10.52202/069179-0379

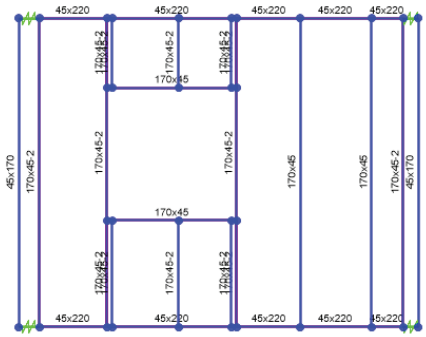

Figure 13: *Lightweight timber frame wall modeled components.*

Table 2 shows the material properties used for the FE model for each different element.

Table 2: *Modeling properties of the elements.*

Element	Characteristics	Properties
Studs (C24 timber)	45 x 170 mm 45 x 220 mm 45 x 95 mm	E = 10200 MPa G = 690 MPa
Sheeting boards	11 mm OSB	E = 6000 MPa G = 1574 MPa
Sheeting boards	38 mm particle board panel	E = 4480 MPa G = 1670 MPa

In order to reduce the computational effort, the floor and roof structural elements, such as joists and floorboards, are not modelled, but only their mass and gravitational loads are included. The FE model developed in SAP2000 is shown in Figure 14.

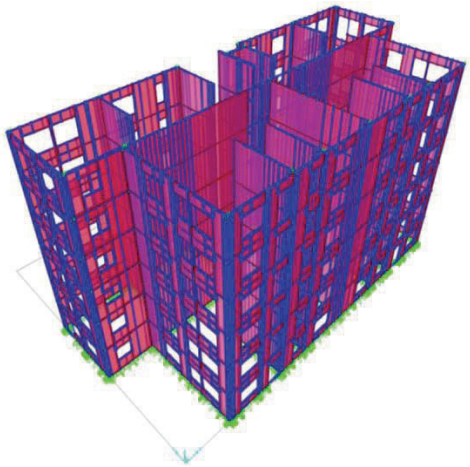

Figure 14: *View of the FE model of the building developed in SAP2000.*

In a first stage, the FE model was developed considering only the gravitational loads from the load bearing system and the slabs (Stage 1). After the ambient vibration tests were performed, in order to calibrate the modal parameters, the load of the non-structural wall components and the façade were added (Stage 2). The façade is a freestanding but horizontally connected to the structure.

The first three modes of the building obtained from the calibrated FE model are shown in Figure 15.

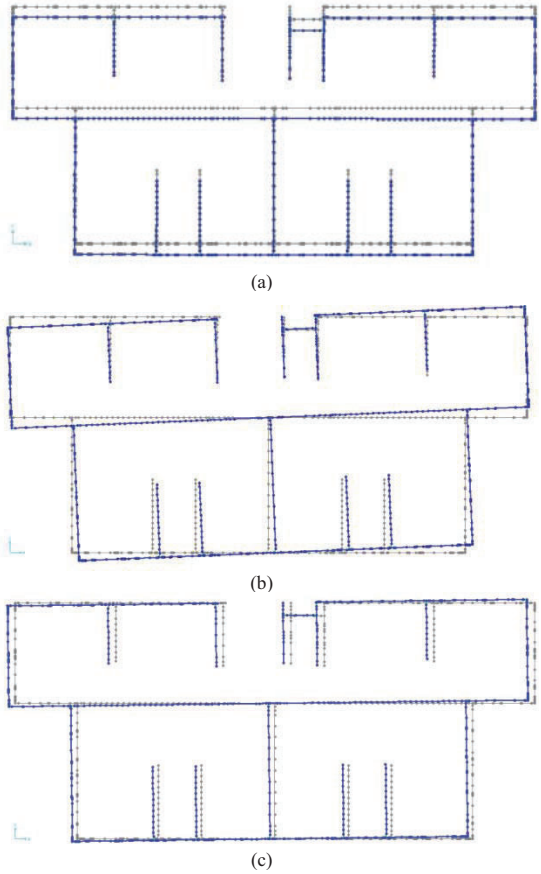

Figure 15: *Mode shapes obtained with the FE model of the building: (a) 1st Mode: f_1=2.80 Hz; (b) 2nd Mode: f_2=3.38 Hz; and (c) 3rd Mode: f_3=4.732 Hz.*

The frequencies identified in Stage 1 were lower than the ones obtained from the ambient vibration tests. The changes in the computed natural frequencies between Stage 1 and 2 are equal to 16% for the translational mode along y-direction, 13.5% for the rotational mode, and 15% for the translational mode along the x-direction.

Figure 16 shows that the frequencies identified in the first stage where higher than the frequencies identified with the updated FE model (Stage 2). These last ones are consistent with the frequencies identified with the OMA for the three performed tests.

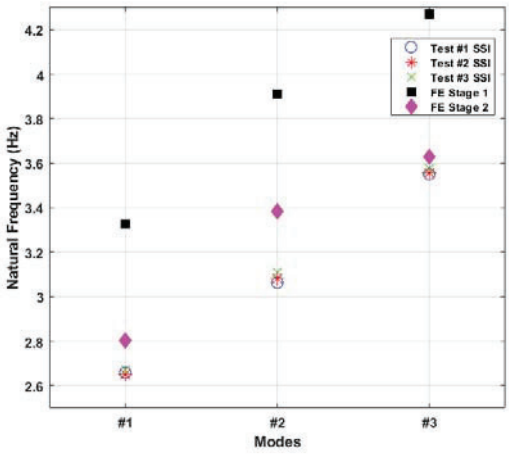

Figure 16: *Comparison between the natural frequencies obtained with the SSI method and the FE model at different stages.*

The higher values of natural frequencies in Stage 1 are compatible with what has been identified in previous studies on a similar building [18]. In particular, for low amplitude wind induced vibrations, ignoring the contributions of non-structural components will lead to an overestimation of the natural frequencies of the building.

5 CONCLUSIONS

The dynamic properties of building Hus 35, part of the Pilgatan block, were identified using frequency and time domain only-output OMA methods. Multiple ambient vibration tests were performed between October 2022 and January 2023. The aim of the testing campaign was to estimate the fundamental natural frequencies, damping ratios and mode shapes of the building and compare them with the one obtained from the FE model.

Three structural modes were identified using the two OMA methods: two translational and one rotational mode. The FE model of the building was developed using elastic beam elements for the studs, elastic isotropic shell elements for the sheeting boards of the external walls and internal walls, and joint link connections for the wall panels connections.

The FE model was calibrated in order to match the results from the in-situ tests in terms of natural frequencies. In particular, the weight on the non-structural elements was added during Stage 2. The mass of the building is a critical parameter while performing the modal analysis of a building. The weight of the exterior wall panels of the façade is an important aspect in calibrating the modal frequencies of the lightweight timber-frame analyzed building.

Further work is necessary in order to develop a more detailed model. In the next stage, the calibrated model should take into account the mechanical behavior of the connections. This will include the sheathing-to-framing connection and the friction and contact interaction between the slabs and the lightweight frame panels. Due to the high computational demand, the implementation and calibration of the mechanical behavior of the connections will be a challenging step.

For low vibrations amplitudes, compatible with the vibrations at the serviceability limit states, the non-structural elements, such as the façade, contribute to the global stiffness of the buildings. For this reason, neglecting the non-structural components in the FE model will overestimate the natural frequencies of the investigated building.

This study is part of a project plan to perform monthly measurements in two identically realized buildings like the one shown in this study. The aim of the project is to relate the possible changes in dynamic properties to the changes in the environmental conditions. Such variations will be implemented also in the FE model of the building to study how such changes can influence the lateral stiffness of the building and its global responce.

DYNAMIC RESPONSE OF TALL TIMBER BUILDINGS UNDER SERVICE LOAD – RESULTS FROM THE DYNATTB RESEARCH PROGRAM

Rune Abrahamsen[1], Magne A. Bjertnæs[2], Jacques Bouillot[3], Boštjan Brank[4], Roberto Crocetti[5], Olivier Flamand[6], Fabien Garains[7], Igor Gavrić[8], Ludwig Hahusseau[3], Alan Jalil[6], Marie Johansson[9], Thomas Johansson[5], Wai Kei Ao[10], Blaž Kurent[4], Pierre Landel[9, 11], Andreas Linderholt[11], Kjell Malo[12], Manuel Manthey[6], Petter Nåvik[2], Alex Pavic[10], Fernando Perez[13], Anders Rönnquist[12], Iztok Šušteršič[8], Saule Tulebekova[12]

ABSTRACT: Wind-induced dynamic excitation is a governing design action determining size and shape of modern Tall Timber Buildings (TTBs). The wind actions generate dynamic loading, causing discomfort or annoyance for occupants due to the perceived horizontal sway, i.e. vibration serviceability problem. Although some TTBs have been instrumented and measured to estimate their key dynamic properties (eigenfrequencies, mode shapes and damping), no systematic evaluation of dynamic performance pertinent to wind loading had been performed for the new and evolving construction technologies used in TTBs.

The DynaTTB project, funded by the ForestValue research program, mixed on site measurements on existing buildings excited by mass inertia shakers (forced vibration) and/or the wind loads (ambient vibration), for identification of the structural system, with laboratory identification of building elements mechanical features, coupled with numerical modelling of timber structures. The goal is to identify and quantify the causes of vibration energy dissipation in modern TTBs and provide key elements to finite element models. This paper presents an overview of the results of the project and the proposed Guidelines for design of TTBs in relation to their dynamic properties.

KEYWORDS: Timber building, wind load, forced vibration, discomfort, modelling, damping, full scale.

1 INTRODUCTION

1.1 Background

The complexity of the design and the construction of buildings increases with their height and the number of storeys. Tallness is relative to experience, situation, or context so the definition of a Tall Timber Building (TTB) cannot be universal. Complexity is found in the production on the construction site due to a high building's height but also in the need for extra technical systems and control. The increased height means higher vertical loads caused by higher weight but also significantly higher horizontal wind loads. For taller structures, the wind load can generate dynamic effects on the structure which must be included in the serviceability design.

1.2 Building system for TTBs

The studies in the Dynamic Response of Tall Timber Buildings Under Service Loads (DynaTTB www.dynattb.com) project show that TTBs, due to their low masses compared to steel and/or concrete buildings, are sensitive to wind loads in the serviceability limit state. The building height where sway is necessary to consider in the design of the structural system is lower than for other building materials such as steel or concrete. The number of storeys where wind-induced vibrations govern the design vary dependent on the building system, building shape and wind speed in the actual location. In zones with high wind velocity and buildings with a larger height to width ratio, it can be a good practice to check the acceleration levels at the highest floor for buildings as low as six storeys in order to check the serviceability limit state criteria [1], [2].

TTBs can be built with several different building systems introducing different difficulties during design and construction. The most common building systems for TTBs are planar elements, beam-column systems with trusses and hybrid systems utilising a combination of materials for the load bearing structure, see Figure 1.

1.3 Acceleration and code calculations

The limiting factor in serviceability limit state (SLS) design is in most codes the peak acceleration at the top floor of the building. Often the limit for the acceleration defined in ISO 10137 [1] as the maximum peak acceleration, caused by a wind velocity level with a one-year recurrence period is used. The recommended upper acceleration limits are higher for office buildings than for residential buildings. The maximum acceleration limit is an SLS requirement and is therefore an issue that should be agreed upon in the contract between the property owner and the engineers/contractor.

The codes provide recommendations for how to calculate the along-wind accelerations, as for example in annex B and annex C in Eurocode [2]. These calculation models are built on four types of parameters:

i) the wind velocity and terrain,
ii) the geometry of the building giving the force coefficient,
iii) the aerodynamic properties of the building, and
iv) the mechanical properties of the building.

Some of these parameters are related to the properties of the structure of the building. These parameters are necessary for the actual building and are estimated using a simulation model, often a finite element (FE) model. These structural parameters are:

- the natural frequencies for the bending modes in the two main directions of the building,
- their mode shapes and
- their related modal masses.

The last parameter necessary for the calculation of the along-wind accelerations is a value for the modal damping, which is difficult to model. Therefore, an estimated/measured value must be used. Within the DynaTTB project the modal damping values of eight timber buildings with different structural systems in several European countries have been measured and evaluated, see Table 1.

1.4 The DynaTTB project

The project DynaTTB; Dynamic Response of Tall Timber Buildings under Service Load, ran between 2019 and 2022 with partners from France, Norway, Slovenia, Sweden, and the UK. The main objective of the project was to experimentally identify a number of full-scale TTB structures (finished or currently being built) and, based on these, develop representative FE models for predicting the vibration response of TTBs exposed to wind-induced dynamic loading. The project represents the first systematic evaluation of dynamic performance pertinent to wind loading in the world for TTBs using, in addition to ambient vibration tests, also forced vibration tests. The main results have been included in a Guideline for practicing engineers on how to design TTBs subjected to wind loads in the Serviceability Limit State (SLS). Results have also been disseminated through scientific journals and seminars/conferences. This paper presents an overview of the results and the main structure of the guidelines. More detailed results can be found in [3]–[6] which will be presented at the WCTE 2023 conference. Other results can be found in for example [7]–[15].

2 DESCRIPTION OF BUILDINGS

In the project, a total of eight buildings, see Figure 1, have been tested using, in addition to preliminary ambient vibration tests, also forced vibrations to estimate their dynamic properties: eigenfrequencies, normalized modes shapes and damping. One more building has been tested using Ambient excitation and three of the buildings have also been equipped with long-term monitoring equipment.

The buildings vary in height from four to eighteen storeys with several building systems to represent TTBs in Europe today.

3 CASE STUDIES

This section shortly presents results from three case studies, built with different building systems and of different heights. The presented results include the first natural frequencies, an example of a captured mode shape and a damping value. The three buildings are:

- the seven storey, full CLT building Yoker in UK,
- the seven storey, glulam post and beam structure Eken in Sweden,
- the seventeen storey, hybrid building Hyperion in France.

3.1 Yoker building, UK (CLT structural system)

The building Yoker is located in Glasgow, UK. The building is designed by Smith and Wallwork Ltd and it is built using cross-laminated timber (CLT) from Stora Enso company. The characteristic dimensions of the building are: 31m by 28m in plan, 22m in height above the ground floor slab, 3745m^2 gross floor area, and 550m^2 footprint area. The building is T-shaped with three “wings” and a centrally located stair and elevator shaft. The building was designed using CLT panels in a platform building system, see Figure 3. Five different types of CLT panels were used, varying in thickness from 100mm to 140 mm (except for the stair half-landing with 200mm CLT

[2] The building consist of three wings and the measurement gives the maximum extreme points of the building.

https://doi.org/10.52202/069179-0380

panels), having either 3 or 5 layers were used. The external walls (as well as some internal walls) consist of large CLT panels which have the height of the storey and the length of the building edge, with pre-cut openings for windows. The CLT panels in the Yoker building are typically connected using a combination of angle brackets and wood screws. For more details of the buildings, see [14].

Figure 3. *The main structure of the Yoker building, showing the distribution of the CLT panels in the external walls.*

The dynamic testing of the building was performed using three synchronised APS Model 400 electrodynamic shakers with a total moving mass of 68.85 kg, which were installed on the 6th floor. Altogether 13 sensor locations were chosen with 2 sensor locations on each floor and an additional one on the 6th floor as a reference sensor near the shakers. Each sensor location measured accelerations in two horizontal directions. At the time of the measurements, the building was operational, so installation of the sensors was limited to the corridors in the core of the building. The measurements were performed by researchers from University of Exeter.

An FE-model was built for the structure using the following assumptions: (i) the foundation is rigid and fixed, (ii) the connections were not explicitly modelled, and (iii) the floors are flexible (i.e. the assumption of the rigid-diaphragm is not used). The initial shape for the first bending mode is shown in see Figure 4. The model was updated based on the measurement results in the next phase. The updating showed that shear stiffness of the CLT walls is higher than anticipated by the initial model. Furthermore, the analysis showed that vertical stiffness of the building is lower than initially estimated. The modelling was performed by researchers from University of Ljubljana, for more details of the modelling see [14].

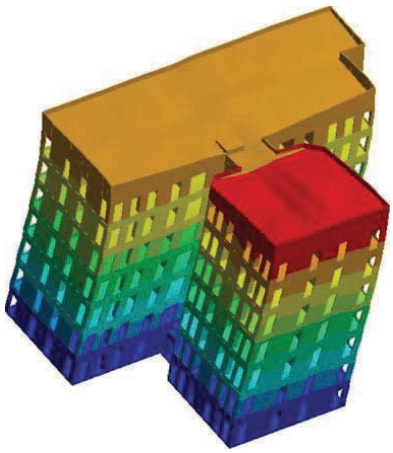

Figure 4. *First mode shape from the FE-analysis.*

The modal properties from the measurement on the Yoker building showed that the first bending mode (including some torsion) had a natural frequency of 2.85 Hz with a relative viscous damping of 1.4%, see [16]. The results also showed that the damping was frequency dependent.

3.2 Eken building, Sweden (Glulam truss structural system)

The building Eken was finished in 2019 and contains 31 rental apartments. The height, width and depth of the building are 24 m, 27 m and 19 m, respectively. The building was built by the company Stenmarks Bygg, and it is owned by Mariehus. The building is built using the Moelven Trä 8 system [17]. The load bearing system consists of glued laminated timber (glulam) beams and columns whereas trusses form the stabilizing elements, see Figure 5Figure 1. The total structure consists of 12 glulam trusses, four in the weak direction and eight in the strong direction of the building. The glulam trusses are in principle symmetrically located in the building and in the centre of the building they stretch from the concrete foundation through all seven storeys of the building. The floor system is made of strengthened LVL sheets acting as a diaphragm system. The connections in the glulam trusses are slotted-in-steel-plates fastened with steel dowels. The other glulam beams are fastened using steel hangers in the glulam beams. These glulam building components are manufactured and assembled by the company Moelven Töreboda.

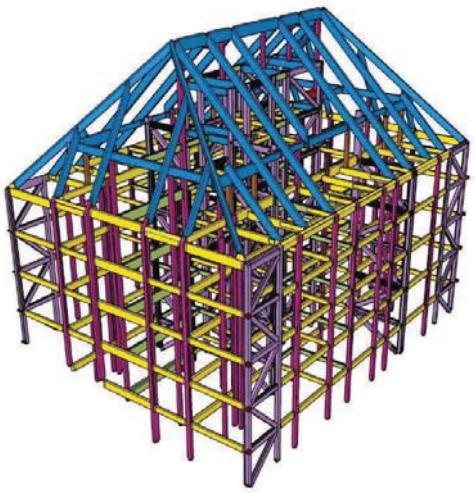

Figure 5. *Glulam structure of the building Eken.*

The dynamic performance of the building Eken has been studied during the measurement campaign using a forced vibration set-up. For that purpose, APS 420 shaker was used, and it was placed on the top (seventh) floor in the ventilation room. In total 45 accelerometers were used to measure the response of the building at different places and directions. The accelerometers were placed at four different levels at each of the four corners of the building, under the balconies, and two positions under the main roof beam at the top of the building. The first bending mode in the weak direction was found to have a frequency of 2.4 Hz. The measurements were performed by Linnaeus University.

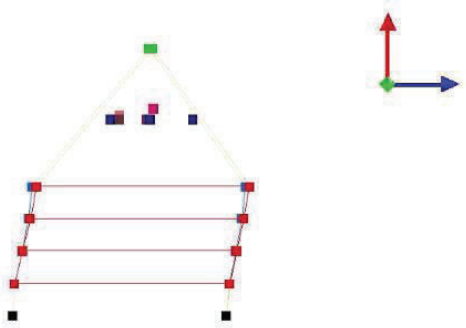

Figure 6. *Modes shape for the first bending mode.*

The first mode was a pure bending mode in the weak direction of the building, see Figure 6. The damping could be evaluated for each resonance frequency. A preliminary evaluation showed that the relative viscous damping was 1.6% for the first bending mode in the weak direction. More details of the measurements can be found in [3].

3.3 Hyperion, France (Hybrid structural system)

The Hyperion Tower, located in Bordeaux, is one of the tallest mass timber buildings in France with 57m height and 17 storeys. It was built by the Eiffage Construction company following a design by Jean-Paul Viguier architect and SETEC structural design office. It is a private housing which is distinguished by its 141 large balconies, made of steel. As for the majority of French buildings using timber it is a hybrid structure, i.e. a central concrete core gives the main resisting part to horizontal loads and satisfies the local fire safety requirements. In Hyperion Tower all floors and horizontal beams are made of CLT, the façade itself uses wood panels as stiffeners.

Mode shapes, frequencies and damping have been measured using excitation by a heavy mass shaker [11], [12] with a 550 kg moving mass allowing large amplitude displacements, used for the evaluation of damping at various stages of amplitude. The first natural frequency of the building was 0.91 Hz with a mode shape as shown in Figure 7.

An FE model was built with ANSYS [13] and used to prepare the testing session as well as checking that the shaker would not overload the structure.

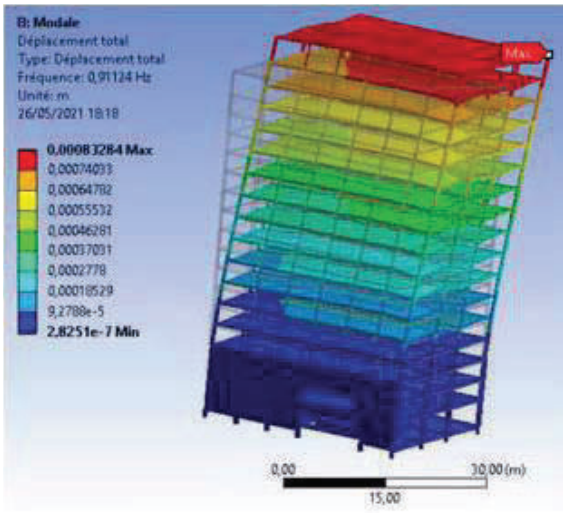

Figure 7. *Mode shape for the first bending mode from the FE-model.*

The FE-model was improved to match the results from the on-site testing, providing a reliable digital twin of the real building. The building was finally equipped with a long-term monitoring system including the measurement of wind 10 m above the roof, in order to check the dynamic behaviour under strong wind. The modelling and measurements were performed by CSTB.

4 GUIDELINES FOR SLS DESIGN OF TTBs

4.1 Overview of the Guidelines

The aim of the guideline is to give recommendations to structural engineers designing TTBs, but is also aimed at manufacturers of timber building systems, property developers interested in building taller with wood and researchers dealing with dynamic effects on TTBs. The focus is on the design for the serviceability limit state (SLS) of tall buildings with timber structures, their

https://doi.org/10.52202/069179-0380

dynamic properties and how wind-induced vibrations can be mitigated. There are several books that describe general design of TTBs, especially with focus on ultimate limit state [18], [19] as well as guides for modelling timber structures [20].

The results of the project will be collected into a written guideline with the tentative title: **Dynamic Properties of Multi-Storey Timber Structures for Wind-Induced Vibrations: Case Studies of Full-Scale Testing and Modelling.**

The general structure of the guidelines will be:

1. Guidelines on calculation of wind-induced vibrations
2. State-of-the-art
   - 2.1 Tall timber building systems
   - 2.2 Wind loads requirements in serviceability limit state
   - 2.3 Dynamic testing of tall timber buildings
   - 2.4 Modelling of tall timber buildings for dynamic response in SLS
3. Building case studies
   - 3.1 Building A
   - 3.2 Building B
   - 3.3 Building …
   - 3.N Building N

4.2 Recommendations for FE-modelling of TTBs

The FE-models established for evaluating the SLS response should provide as a minimum result at least the following parameters: the first natural frequency in bending in the two main lateral directions of the building, their associated mode shapes and the equivalent, or modal, masses.

Based on the project outcomes, the following recommendations can be given when creating an FE-model of a TTB for SLS design:

- Use mean values for density of materials and nominal dimensions of structural elements.
- Use mean values for stiffness of material.
- Masses of non-structural elements should be included in as accurate location as possible.
- Most probable value for live load should be included in the model. Actual live load can be significantly lower than the values recommended in building codes, such as Eurocode 1 [21].
- For structures using planar wood elements, walls and floors are recommended to be modelled including openings.
- For buildings designed using a platform structural system, perpendicular to the grain flexibility of floor slabs is recommended to be included in the model.
- Connections that exhibit semi-rigid behavior in SLS in both translational and rotational directions should be included in the model. As a starting point connection stiffnesses calculated according to Eurocode 5 [22] can be used.
- For hybrid buildings with concrete cores and/or timber concrete floors, average material values representative for the concrete elements are considered. Assumptions made for dynamic seismic models (cracked concrete, etc.) are not relevant.
- For composite timber-concrete floors, the rigid diaphragm assumption can be considered provided that the minimum concrete thickness required for this assumption is verified (see ETA document of considered floor system).
- The horizontal and vertical stiffnesses of the foundation can have a large impact on the results. Soil parameters such as stiffness, damping, etc. are strain rate dependent. Reference values from seismic analysis should be adjusted for SLS verifications.
- Contribution of stiffness of non-structural elements should be explored as their impact on the modal response of the building has been observed.

In general, it is on the safe side to assume conservative mass and stiffness values for the building when creating the model. There are large uncertainties in the FE-models, especially regarding the effect of stiffness of connections, foundation, and the contribution from non-load bearing elements. It is therefore advised to do a sensitivity study for the effect of these parameters on the results.
An FE-model can also be used to estimate the acceleration levels directly if the model can include a representative wind load model.

4.3 Recommendations for on-site measurements

The current number of TTBs completed in the world is still relatively low. Hence, there is still a lot of uncertainties in the modelling, design and construction of these kinds of structures. It is therefore important to measure and evaluate completed structures to investigate the accuracy of the models and update the recommendations and the best practice for modelling TTBs in SLS. The current codes and standards used today also have very limited information on how to model TTBs and on values to be used for example for modal damping in tall timber structures in SLS. To create a statistical basis for a recommended value for damping to be used in the codes, it is necessary to evaluate the modal damping in more completed TTBs. Natural frequencies and mode shapes give a good basis for checking the simulation models used in the design. Further development of the models to simulate the real behaviour of TTBs subjected to wind loads is needed.

For evaluating the dynamic properties of a structure, it is necessary to measure the response (for example accelerations) of the building to a varying force. The building response is normally measured using accelerometers. The force can be imparted to the structure using three principal approaches:

- Ambient vibration (AVT) – Excitation with unknown external force which is assumed to have a frequency spectrum which is broadly flat across the frequency range of interest.
- Free Vibration Test (FreeVT) – The structure is first set into motion by applying known initial conditions,

e.g., by a pull followed by a sudden release or by some unmeasured artificial excitation, such as synchronized swaying of one or more humans or shaker, and then left to vibrate freely on its own.

- Forced vibration test (FVT) – excitation with a known force, for example from a shaker imparting an excitation force to the structure that can be measured, or an impact hammer instrumented with a force sensor.

These methods have benefits and drawbacks for measuring different dynamic properties and are suitable for establishing different properties. Depending on the property of interest, different test methods are most suited, see Table 2.

Table 2: *Dynamic properties and recommended method to use for evaluation.*

	Suitable testing methods		
Property of interest	AVT	FreeVT	FVT
Natural frequency	X	X	X
Modes shapes	X	X	X
Modal damping		X	X
Modal mass			X
Frequency response function			X

For measuring mode shapes, it is necessary to use several sensors along the height of the building. Strong amplitude-dependent behaviour is to be expected for TTBs. To address this in detail, dynamic testing techniques that can cope with such structural features, such as FVT or FreeVT, are required. Accelerometers must follow the motion of the TTB structure they are attached to. Timber floors in TTBs are often covered by acoustic layers. If horizontal shakers are used, such layers can prevent direct transmission of the shaker force to the TTB structure by introducing unwanted flexibility.

5 SUMMARY

This paper presents an overview of the most important results from the DynaTTB project. The results are gathered in a Guideline for engineers and researchers interested in designing and evaluating TTBs.

The results show that it is possible to measure the dynamic properties of the buildings. The results also show that to make an FE model that is valid in its representation of a building's dynamic behaviour in SLS, in terms of eigenfrequency and modes shapes, it is important to take the effect of stiffness in the connections, the foundation and in some cases also non-loadbearing structures such as partition walls, screeds and curtain walls into account.

The results also show that in most cases TTBs exhibit non-linear damping behaviour, which in some cases might be important to consider. In general, the damping is in the range of 1.5-3% of the critical viscous damping depending on the amplitude of the vibrations.

6 ACKNOWLEDGEMENT

The research leading to these results has received funding from the ForestValue Research Programme which is a transnational research, development and innovation programme jointly funded by national funding organisations within the framework of the ERA-NET Cofund 'ForestValue – Innovating forest-based bioeconomy'".

QUANTIFYING ROBUSTNESS IN TALL (TIMBER) BUILDINGS: A CASE STUDY

Konstantinos Voulpiotis[1], Styfen Schär[2], Andrea Frangi[3]

ABSTRACT: Robustness research has become popular, however very little is known on its explicit quantification. This paper summarises a quantification method previously published by the main author and proceeds in demonstrating its step-by-step application with a case study tall timber building. A hypothetical 15-storey timber building is designed for normal loads and four improved options are designed to account for abnormal loads in order to increase the building's robustness. A detailed, nonlinear dynamic Finite Element model is set up in Abaqus® to model three ground floor column removal scenarios, and a Random Forest classifier is set up to propagate uncertainties and efficiently calculate the probability of certain collapse classes occurring and the importance of each input parameter. The results show how design improvements at the whole building scale (e.g., strong floors) have a higher impact on robustness performance than just improving the strength and ductility of some selected connections, although these results are exclusive to the building studied. The whole procedure is put in context of the practicing engineer, with a suggestion for a calculation-free, purely qualitative robustness framework. The case study reinforces the importance of a sound conceptual design for achieving robustness in tall timber buildings.

KEYWORDS: Disproportionate collapse, Finite Element Analysis, Random Forest classification, machine learning

1 INTRODUCTION

Our profession is seeing a paradigm shift towards buildings of lower carbon footprint: tall timber buildings are a fine example of this shift. Any departure from the "familiar waters" of the common structural typologies runs a higher risk of not having identified or anticipated certain structural behaviours: similar to the scaling issues that led to the partial collapse of the Ronan Point in London in 1968 [1], we must understand how timber buildings scale to the new heights constructed in the last 10 years, particularly regarding their disproportionate collapse behaviour.

Structural robustness, or disproportionate collapse resistance, is the ability of a structure to withstand damage without disproportionate further consequences, and it is an important and yet not so widely understood quality of our building stock. While a lot of work has been put into understanding structural robustness at a qualitative level and regarding concrete and steel buildings, little is known on the robustness of timber buildings and even less on how to specifically quantify how robust is a building, and whether this is enough or not.

In this paper, we build on the framework presented by Voulpiotis et al. [2] on robustness quantification followed by a case study tall timber building. How to connect this complex work to design in practice is presented in the end. Only essentials are discussed here – for more details and the literature review on the topic please refer to the doctoral thesis of Konstantinos Voulpiotis [3].

2 QUANTIFICATION FRAMEWORK

Since it belongs to the category of extreme (rare) events, disproportionate collapse is best studied in a probabilistic manner. Of the frameworks that have been proposed to quantify robustness in the last 30 years [4–7], the robustness index is a common measurement of the disproportionality of risk: the importance of secondary, or indirect consequences (C_{Ind}) compared to the direct ones (C_{Dir}) given the probability of them occurring following a damage scenario ($P(C|D)$):

$$I_{Rob} = \frac{C_{Dir}}{C_{Dir} + P(C|D) \times C_{Ind}} \quad (1)$$

According to Voulpiotis et al. (2021) [2,8], the consequence can be measured in terms of extent of collapse area ($C_{Dir/Ind} \rightarrow A_{Fail,Dir/Ind}$). Since a damaged building can fail in different ways (let us assume n different "collapse classes"), we calculate the robustness index for a given damage scenario by summing the indirect risk occurring from each collapse class i:

$$I_{Rob} = \frac{A_{Fail,Dir}}{A_{Fail,Dir} + \sum_{i=0}^{n}(P(C_i|D) \times A_{Fail,Ind,i})} \quad (2)$$

Given several damage scenarios, we can obtain a weighted robustness index which is unique to that building design. Assuming several building design

https://doi.org/10.52202/069179-0381

improvements, we can use the increase (or decrease) of the average robustness index to decide on the best design solution to increase robustness. This is demonstrated in the case study below.

3 CASE STUDY ANALYSIS

3.1 BUILDING DESIGN

A hypothetical 15-storey timber building skeleton structure for offices in Zürich, Switzerland, is designed to the Swiss standards to quantify its robustness using the method described in the previous section. The design is kept as simple as possible to focus on the collapse performance (Figures 2 & 3): post-and-beam construction with glulam timber beams and columns, and timber-concrete composite floors, all designed for category B loads (office) in service class 1 and also checking for fire, buckling, deflections, and creep. The loads are assumed to go back to a CLT core which functions are a vertical cantilever (not explicitly designed). The materials used are GL32h glulam timber (SIA 265:2012) [9], C25/30 concrete with B500B rebar (SIA 262:2013) [10], and 5.6 connector steel for screws and dowels (SIA 263:2013) [11]. The substructure has not been designed.

The main design focus has been put on the connections, as there is evidence that they play a significant role in increasing structural robustness [12]. We used dowelled connections with slotted-in steel plates for the beam-column connections, glued-in rods for the column-column connections and screwed steel angle brackets for the floor-floor connections. They are all assumed to be pinned for the design of the building, however, their actual stiffness and resistance on all degrees of freedom have been estimated using first principles. An idealized elastic-plastic curve has been assumed for each degree of freedom, defined by only four values: elastic stiffness (K_e), yield load (F_y), plastic deformation (δ_p), and ultimate load (F_u). Full details are in Voulpiotis [3].

Four improved versions of the building have also been designed for comparison: options 2 & 3 employ a diagonally-braced "strong floor" at the 15th or both 7th and 15th floor respectively with the columns designed to work in tension should a support be compromised. Options 4 & 5 employ an increase in the ductility of the beam-column and column-column connections respectively. This increased the size of the connections, which in turn also affected the size of the columns. The buildings have been parametrically defined in Abaqus® and studied in ground floor column removal scenarios using both implicit and explicit solver to consider dynamic and nonlinear effects.

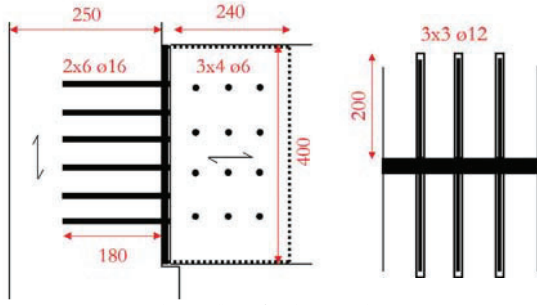

Figure 1: *Beam-column (l) and column-column (r) connections*

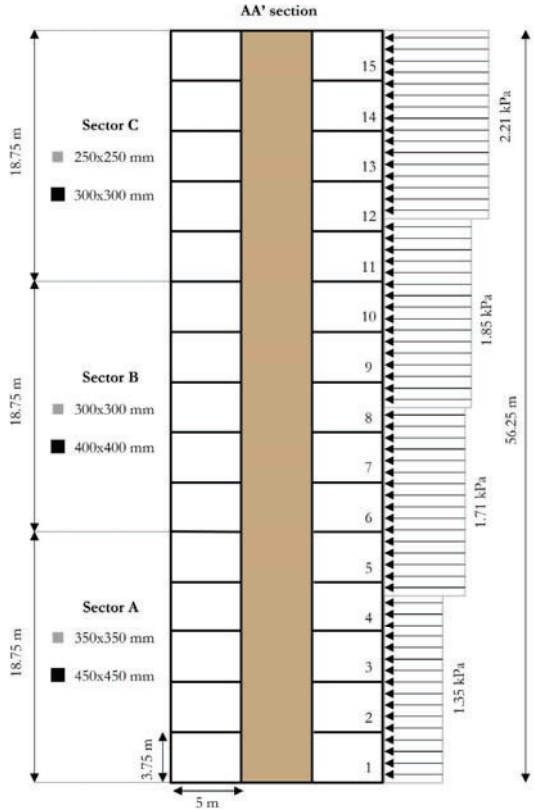

Figure 2*: Case study building section*

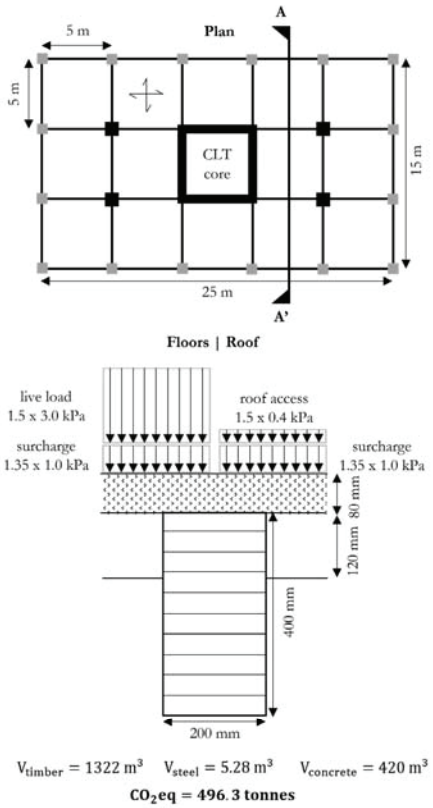

Figure 3: *Case study building plan and detail*

https://doi.org/10.52202/069179-0381

3.2 SURROGATE MODELLING

A surrogate model is a simplified, computationally cheap-to-evaluate mathematical representation of the complex finite element model, necessary to calculate the probabilities of each collapse class occurring in a reasonable amount of time.

Three independent damage scenarios were studied: the removal at the corner, edge, and internal ground floor columns with a removal time of 2 ms:

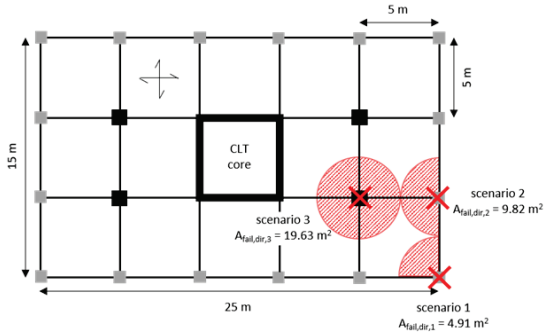

Figure 4: *The three damage scenarios studied*

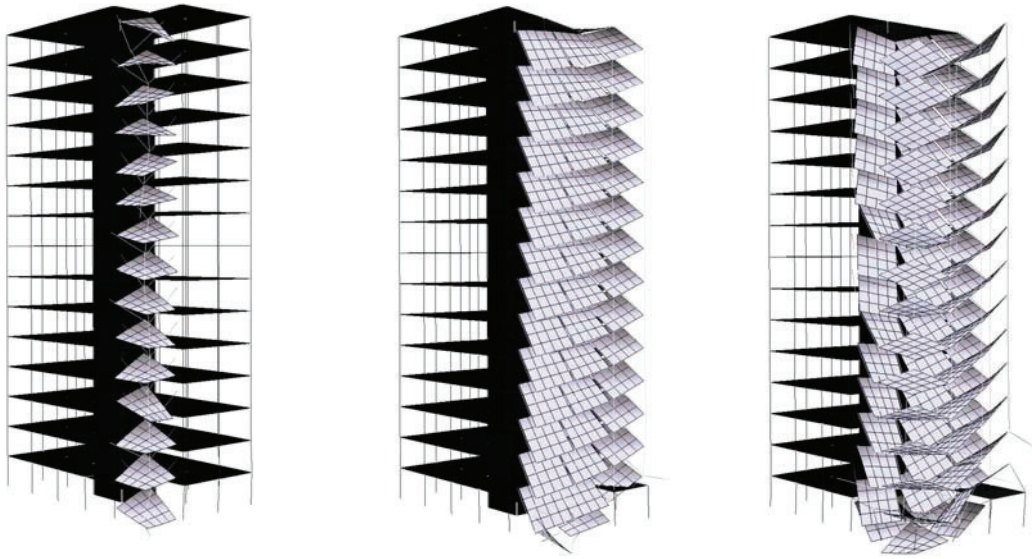
A probabilistic input vector was set up for each building design and used to train a Random Forest classifier [13], later enriched in the domains of the minority classes using synthetic sampling (SMOTE) [14]. This way the probability of each collapse class occurring (for a given damage scenario) could be calculated with only around 1,500 model runs for each building design. Performance scores (accuracy and macro F1 score) of the classifiers were obtained using k-fold cross-validation [15] and sensitivity analyses were carried out using the Impurity-Based Importance (IBI) [16]. Everything was set up in Python®, using the Scikit-learn [17] and Imbalanced-learn [18] modules. Full details of the algorithm setup and hyperparameter optimisation are provided in Voulpiotis [2]. This learning algorithm can efficiently find patterns in computationally expensive models with chaotic tendencies and is opening up new horizons in the numerical analysis of large, complex structures, such as highly nonlinear analyses of tall timber buildings.

3.3 RESULTS

All analyses were run on the "EULER" High Performance Computer Cluster of ETH Zürich [19]. Using master scripts in Python and a batching system, Abaqus input files and job submissions were performed in parallel by both Intel® and AMD® compute nodes. The model deformations were extracted at the 1.3 second timestamp before the results showed chaotic tendencies (a small change in the inputs led to large, inconsistent changes in the outputs). It is assumed that capturing the initial collapse stages using the method from section 2 suffices to explore cost-effective robustness solutions. Further collapse does occur beyond 1.3 seconds, however, modelling this is both unreliable and also unnecessary.

3.3.1 Design option 1

The code-compliant design option 1 partially collapses in all of the three damage scenarios shown in Figure 4. Additionally, a dominant collapse class is always present (375 m^2 for scenario 1; 1,100 m^2 for scenario 2; and 2,200 m^2 for scenario 3, see Figure 5). The extent of the collapse is increasingly worse by scenario: a corner column removal causes the entire corner of the building to collapse, an edge column removal causes the entire edge of the building to collapse, and an internal column removal causes half the building to collapse (until the assumed rigid core).



Scenario 1, severity = 375 m^2 Scenario 2, severity = 1,100 m^2 Scenario 3, severity = 2,200 m^2

Figure 5: *Abaqus® images and severity ($A_{Fail,Ind,i}$) values for the dominant collapse classes for design option 1*

The mechanics of the collapses in design option 1 are simple to explain by scenario:

Scenario 1: The load of the 14 unsupported floors is initially transferred towards the neighbouring columns via the beams in cantilever action, and via the floors in in-

https://doi.org/10.52202/069179-0381

plane shear action. The beam-column and floor-beam connections break very quickly, and the entire corner of the building, with the floor slabs detached, is accelerating towards the ground.

Scenario 2: The mechanism is similar to scenario 1, however this time the unsupported area is double in size and the forces are carried by three beams and two slabs per storey. The horizontal forces developing in the edge beams pull on the adjacent corner column, causing it to buckle and collapse too.

Scenario 3: With an even larger initial failure (four times that of scenario 1), a larger portion of the internal frame spreads loads to its surrounding beams and slabs in the same manner as scenarios 1 & 2. However, horizontal resistance is only provided from one side, the core, causing everything on the outer side of the building to buckle and collapse as well.

3.3.2 Design option 2

No collapse was observed for damage scenario 1 in design option 2, where the top floor is a trussed "strong floor". Although to a significantly lesser extent than in design option 1, the failure of an edge or an internal column again caused a progressive collapse. The truss structure is unable to carry the weight of the unsupported building when its area exceeds half a bay. It is therefore not surprising that scenario 3 leads to a collapse, albeit of lower initial extent than in the original design option. Upon removal of the column, the column-column connection breaks axially, and the membrane action that develops in the slabs is pulling the surrounding structure inward (Figure 6). Since stiffness is asymmetric (the core side is much stiffer), the edge of the building buckles and a substantial collapse initiates.

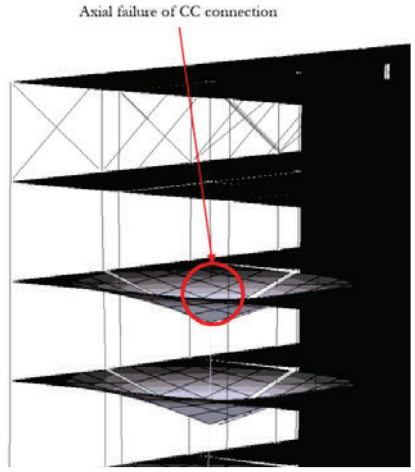


Figure 6: *Scenario 3 of design option 2 @0.5 s, column connection axial failure*

Scenario 2 is more marginal in that it could have supported the weight of the collapsing building had dynamic factors been included in the sizing of the stronger connections. However, the design of the strong floor was static, and the fast column removal speed is causing larger, dynamic force reactions. The failure that caused the collapse was the column-column connection in shear at the floor below the truss (Figure 7). This indicates that the strong floor is not stiff enough to prevent large deformations that will induce very large forces in the surrounding connections. Also, even the much stronger column-column connections are not particularly strong in shear: an alternative for this degree of freedom is an option worth exploring.

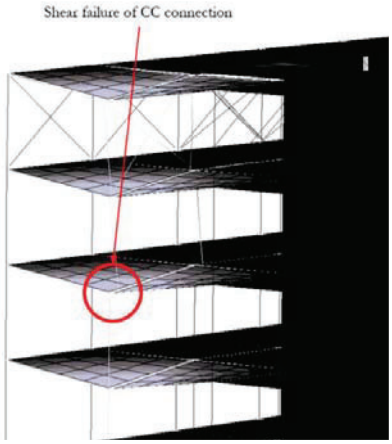

Figure 7: *Scenario 2 of design option 2 @0.4 s, column connection shear failure*

3.3.3 Design option 3

Design option 3 was similar to design option 2 in that scenario 1 was fully arrested. Scenario 2, however, showed a wider and more severe response spectrum (severities up to 1,300 m^2 compared to 950 m^2 for design option 2). The mechanics of the collapse in scenario 2 are similar to design option 2, with the difference that shear failure occurred both above and below the truss strong floor in the middle of the building and destabilised the edge of the building. Collapse very quickly spreads to the lower half. Scenario 3 showed mixed results: in most cases the building survived. No axial failure at the column connections was observed. There were, however, cases where again the shear failure of the column-column connection under the middle strong floor caused the initially contained collapse to spread downward. Unlike design option 1, the horizontal connectivity with the truss reduced the initial spread of the damage to the adjacent corner column in both design options 2 & 3.

3.3.4 Design option 4

No resistance improvement compared to design option 1 was observed for design option 4: although scenario 1 sometimes survived the damage, the spread of collapse classes was much wider with the majority collapse class still being the corner bay as with design option 1, with similar mechanics described earlier and shown in Figure 5. Damage scenarios 2 & 3 showed very consistent behaviour despite the variability of the probabilistic inputs. A possible explanation is that although alternative load paths changed with the improved connections, they could not find their way back to the core. A closer look at the simultaneous improvement of the floor slab design and connectivity, together with the beam and column connectivity, is a worthwhile investment.

3.3.5 Design option 5

Finally, in design option 5, the small change of the column-column connection to increase its ductility did not

improve the robustness performance at all. Collapse mechanics were also similar to option 1.

3.3.6 Robustness indices

The results show that the performance of the original design is disappointing ($I_{Rob,av}$ close to zero) and so is the performance of options 4 & 5 with an improved connection ductility. On the other hand, options 2 & 3 perform much better, although at a higher cost in terms of embodied carbon due to the substantially larger columns and connections to accommodate the strong floor forces. Option 4 performs equally well as option 1, but it also costs more, therefore it is not a cost-effective solution.

The summary of the results is clear in the following table which compares the robustness indices for each damage scenario in each design option, as well as their cost in terms of CO_2-equivalent based on the volume of the structural materials. Surrogate modelling performance scores are also provided below.

Table 1: *Robustness comparison between all design options, including accuracy and marco F1 scores*

	$I_{Rob,sc1}$	$I_{Rob,sc2}$	$I_{Rob,sc3}$	CO_2eq (t)
Concept 1 scores	0.0129 (0.94 / 0.75)	0.0088 (0.73 / 0.40)	0.0088 (0.90 / 0.63)	**496.3**
Concept 2 scores	1.00 (0.83 / 0.36)	0.0182 (0.58 / 0.46)	0.0144 (0.76 / 0.71)	**519.6 (+4.7%)**
Concept 3 scores	1.00 (1.00 / 1.00)	0.0133 (0.56 / 0.43)	0.0274 (0.70 / 0.49)	**520.8 (+5.0%)**
Concept 4 scores	0.0119 (0.68 / 0.49)	0.0091 (1.00 / 1.00)	0.0090 (1.00 / 1.00)	**505.4 (+2.4%)**
Concept 5 scores	0.0095 (0.69 / 0.63)	0.0059 (0.33 / 0.33)	0.0088 (1.00 / 1.00)	**496.27 (-0.002%)**
Average	0.4069	0.0110	0.0137	
$A_{Fail,Dir}$	4.91	9.82	19.63	

With a 34-fold increase in the average robustness index, design options 2 & 3 with structural improvements in the whole building scale ("strong floors") are much better solutions for this particular building. They owe this improvement due to the full arrest of collapse in scenario 1 ($I_{Rob,sc1} = 1.0$) and the marginal, but insufficient improvement of collapse in scenarios 2 and 3 ($I_{Rob,sc2/3} < 0.03$, which is practically not different from zero).

This result is in line with the observations of Mpidi Bita et al. (2019) [20], who also proved the benefit of designing a strong floor from which columns can hang the floors below in case of damage. The benefit of the conceptual design is evident despite their study being on a different structural typology (flat-plate CLT building). Design option 4, equally robust as option 1, requires more steel in the connections and thus becomes uneconomic in the given assumptions. This is not to say that an improvement in the connections cannot increase robustness; rather, the specific solution implemented does not provide sufficient alternative load paths. Design option 5 is marginally worse than the starting option in terms of performance. These results are in line with the alternative load paths and collapse mechanisms discussed in the previous paragraphs. They highlight once again the significance of understanding how alternative load paths are formed, and making sure they lead to the ground. Increasing the ductility of only two connections (e.g. beam-column and column-column in option 4) allows loads to better redistribute in these parts of the structure, however, collapse resistance is also dependent on the floor-beam and floor-floor connections, global stiffness symmetry, and the buckling of columns. One should have a clear understanding of the flow of loads in a structure at the global scale (conceptual design) in order to make the right decisions regarding connection and component detailing.

3.3.7 Sensitivity studies

The properties of the columns and the column-column connections dominate the importance for external damage (scenarios 1 & 2), while the properties of the beams and floors dominate the importance for internal damage (scenario 3). However, the spread of importance values throughout the Random Forest is high, and the importance values themselves are neither high, nor very different from each other. This indicates an absence of an overall dominant feature, which reflects the observations in the collapse mechanisms, and explains why design options 4 & 5 do not perform better in terms of robustness. Collapse is arrested by the structure functioning as a large, complex system and an improvement on many variables, rather than just a few, is necessary to achieve an overall better robustness performance. Full details of the sensitivity study with figures is provided in Voulpiotis [3].

4 FROM RESEARCH TO PRACTICE

4.1 QUALITATIVE DESIGN (SCALE APPROACH)

The procedure outlined so far and the example case study are fairly complex, time-consuming activities. We do not suggest that practicing engineers must go through all this to ensure robustness; rather, simplified, qualitative techniques shall be used for simple or well-established structural typologies, and the full quantification procedure shall only be used for new, unknown typologies (of any material) whose collapse would have very serious consequences to the society.

A reinforced concrete, cast in-situ midrise building is a simple, known structure where robustness can be implicitly assumed. A method to assess its robustness more rigorously without performing any calculations is detailed in Voulpiotis et al. (2021) [2] and is based on considering structural robustness on different levels of the scale (Figure 8): whole building, compartments, components, connections, connectors, and material microstructure. What is important to understand is that current robustness design methods are largely based on preventing collapse to propagate from the component to the whole building level. If we are able to prevent collapse propagation also from connections to components, and from components to building compartments, the disproportionate collapse probability dramatically decreases. This is demonstrated by an example "stacked compartment" structure in Figure 9.

The qualitative approach may of course be also used for complex, unknown structures such as midrise timber buildings like the one studied in this paper. In

https://doi.org/10.52202/069179-0381

combination with advanced quantitative techniques, collaborative work of researchers and practitioners can

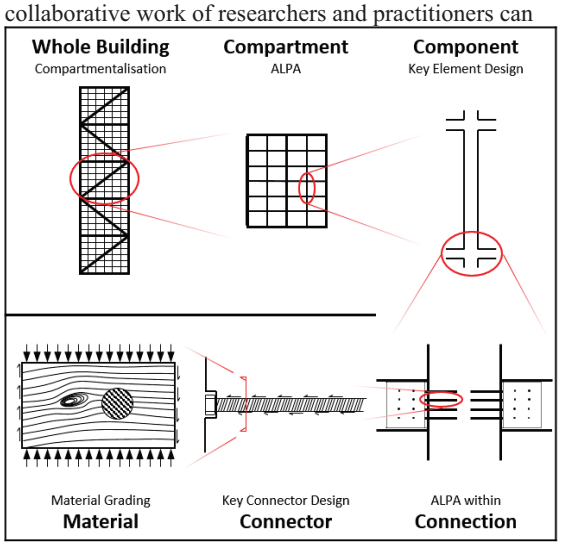

Figure 8: *Robustness can be qualitatively achieved by assessing the load redistributions at different levels of the scale*

lead to a much better understanding of the structural behaviour of new typologies in an implicit fashion, that is, the expert will be able to have a "gut feeling" of a sufficiently robust structure in the exact same way the experienced engineer knows if a beam or column cross section is sufficient in size to serve its purpose without performing any calculations. We may thus be able one day to decide on robustness design improvements based on tabulated design data or using simplified equations, like it is currently done with component design in the building codes.

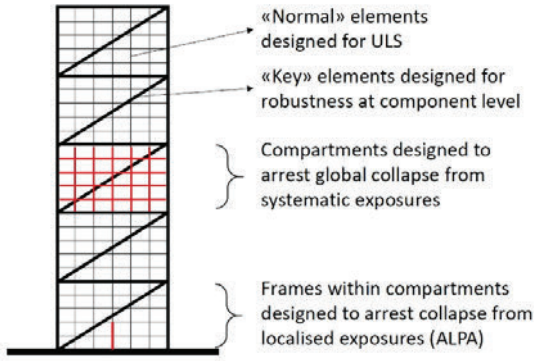

Figure 9: *Proposal of a theoretically "holistically robust" building according to Voulpiotis et al. (2021)* [2]

4.2 RELEVANCE OF BUILDING CODES

As we are aspiring for the building codes to be able to guide practitioners in more detail when it comes to robustness (whether a step-by-step guidance is truly feasible is a debate outside the scope of this paper), we hope to see a shift in the current approach, which offers little more than vague requirements without guidance. The work of Mpidi Bita, et al. (2019) [21] summarises the existing approaches of building codes in various regions (Canada, USA, Europe, Australia/New Zealand) and presents the results from a 171 participant survey. The survey asked practitioners whether they consider robustness in their design and to what extent this is affected by building codes. By looking at the different approaches in concrete, steel, and timber in each of the studied regions, the authors identify key improvements which can be made to existing codes and guidelines, such as the inclusion of specific recommendations for structural robustness, and a performance-based approach, rather than prescriptive requirements.

One of the most important findings of the survey is that robustness is practiced more consistently in regions or materials where the building codes provide more detailed help. With the case study in this paper, we hope to have started a necessary contribution of modelling data, such that timber-specific building codes can adapt and include more detailed guidance on designing robust tall timber buildings.

5 CONCLUSIONS

In this paper we presented an application of the quantification methodology originally presented by Voulpiotis et al. (2021) [2] in the previous world conference (WCTE 2021).

A case study, 15-storey timber building is designed to the Swiss building codes and is run through the quantification methodology using high-fidelity Finite Element Modelling and an adaptive surrogate modelling approach based on Random Forest Classifiers.

The results demonstrate how a sound conceptual design is more important to achieve robustness than localised strength or ductility improvements.

We finally paint a bigger picture of a qualitative-quantitative robustness approach, where the designer considers robustness on different levels of the structural scale, hoping that eventually we will be able to understand robustness intuitively for tall timber buildings as we currently do for simpler structures, such as cast-in-situ reinforced concrete midrise buildings.

The quantification framework and its application are valid for structures of any material and make an important step towards a better understanding of the collapse behaviour – and hence safety – of new structural typologies such as tall timber buildings.

ACKNOWLEDGEMENTS

The financial support of the Albert Lück Stiftung in Switzerland and the technical support of Prof. Dr. Jochen Köhler at the NTNU in Norway have been essential for the successful outcome of this research.

LONG-TERM MONITORING OF TALL MASS TIMBER BUILDINGS – EVALUATION OF DYNAMICS PROPERTIES

Samuel Cuerrier Auclair[1], Christian Dagenais[2], Girma Bitsuamlak[3]

ABSTRACT: Due to the lightweight nature of wood construction, wind excitation induces vibration with a larger amplitude when compared to buildings built with heavier materials, such as steel and concrete. The design method provided in the National Building Code of Canada requires buildings' natural frequencies and damping ratios as input. However, there is little data available for mid-to high-rise timber buildings. Therefore, FPInnovations launched a research project to measure mid-to high-rise timber buildings' natural frequencies and damping ratios in attempt to expand the database and validate or adapt the existing equations to estimate the natural frequencies. Two high-rise timber buildings were equipped with an anemometer and accelerometers and are constantly monitored to study how the wind excites high-rise timber buildings. The measurements suggest that the Arbora building and the Origine building have a modal damping ratio of about 2.5%.

KEYWORDS: Tall wood building, Wind-induced vibration, Damping ratio, Empirical mode decomposition (EMD), ambient-vibration test (AVT)

1 INTRODUCTION

Mass timber construction is known to be lightweight and has lower lateral stiffness in comparison to steel or concrete construction. These properties make the building more susceptible to wind-induced vibration in high-rise construction [1, 2]. Excessive vibration of buildings can cause occupants discomfort and damage to finish materials, services, and equipment in the building [3, 4]. These kinds of vibrations are not safety-related issues but may affect the market acceptance of mid- to high-rise timber buildings. Despite the challenge that comes with designing high-rise mass timber (MT) buildings, there is an international interest in building with wood, as it is more sustainable compared to concrete or steel [5]. However, there are still some unknowns regarding the dynamic properties of tall MT buildings under wind-induced vibration.

To evaluate the building response to wind loads, Davenport [3] has developed a process named wind load chain, illustrated in Figure 1, which laid the foundation of modern wind engineering and provides a theoretical basis for many building codes and standards.

Figure 1: *Wind loading chain of Davenport [3]*

As shown in Figure 1, the first step is to study the climate of the target site to define the design wind speed. This design wind speed could be directly taken from the climatic table in the National Building Code (NBC) in Canada [6], or it could be estimated from reliable anemometers. The wind flow around the building site is influenced by the terrain which is, in general, characterized by the roughness (e.g., vegetation, buildings, etc.) and the local topography. The third element of the wind load chain is the aerodynamic effect which is directly influenced by the building shape. This element is generally studied in boundary layers wind tunnels or with computational fluid dynamics (CFD). CFD can only be used for pre-design or for research since the NBC directly states that CFD cannot be used independently of boundary layers wind tunnel procedures. The fourth element of the wind load chain is the dynamic effect. This element is influenced by the dynamic characteristic of the wind and the dynamic properties of the structures. Since tall MT structures are a relatively new type of structure, there are several unknowns regarding its dynamic properties, especially the modal damping ratio [2]. The last element is the criteria which are generally defined by codes and standards.

The study of Bezabeh et al. [2] illustrated the impact of different modal damping ratios on the top floor acceleration caused by induced wind vibration. Several building heights from 10 to 40 storeys were studied with damping ratios from 1% to 10% in different exposure conditions, such as open country, suburban, and urban. The results of this study have shown the importance of the damping ratio on the evaluation of the top floor acceleration.

To fill the knowledge gap in the modal damping ratio of high-rise MT buildings, several European universities and

institutions launched the DynaTTB initiative in attempt to quantify these properties [7]. In Canada, FPInnovations started a similar research project aiming at quantifying the acceleration and damping ratio under different wind conditions of two existing high-rise MT buildings. As such, two high-rise MT buildings have been equipped with an anemometer and accelerometers to study how the wind excites the buildings. The first building is named Origine and is located in Québec City, and the second is named Arbora and is located in Montreal, both in the province of Québec.

2 BUILDING DESCRIPTION

2.1 ORIGINE BUILDING

Origine is a 13-storeys with a height of 40.0 metres completed in 2018 and designed by Nordic Structures. It is located in Quebec City in Canada and its near surroundings are a green park on the north side, a river on the west side, and low-rise buildings or no buildings on the south and east side, as shown in Figure 2.

The first level consists of a concrete podium, while the twelve other levels are made of MT elements (glulam and CLT). The gravity system consists of a post-and-beam glulam frame and 175 mm 5-ply CLT floor slabs. The typical clear span of the floor is 5.5 m. This type of floor can be considered as a semi-rigid diaphragm.

The lateral load resisting system (LLRS) consists of balloon framed CLT shear walls with vertical glulam elements at the ends of the shear wall. CLT and glulam extend from the concrete podium floor to the roof. The CLTs are either 9-ply 291 mm, 7-ply 244 mm, or 5-ply 175 mm panels, depending on the location and magnitude of the lateral force. For that type of LLRS, the lateral load is essentially taken by the CLT, and the uplift load is resisted by the glulam. The hold-down connectors consist of steel plates with dowels fastened into the wood. The horizontal joints between the CLT panels are connected with steel plates and dowels fastened into the wood. The vertical joints are connected with shear keys, as shown in Figure 3. These connectors are stiffer and stronger compared to traditional fasteners, such as nails, screws, or dowels. To ensure good contact between the two panels, self-tapping screws were inserted diagonally in addition to the shear keys. Several architectural and gravity CLT panels were also installed in the building which certainly contributes to stiffening the building laterally.

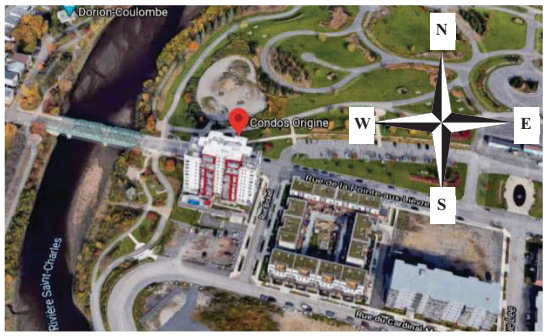

Figure 2: *Surrounding of the Origine building*

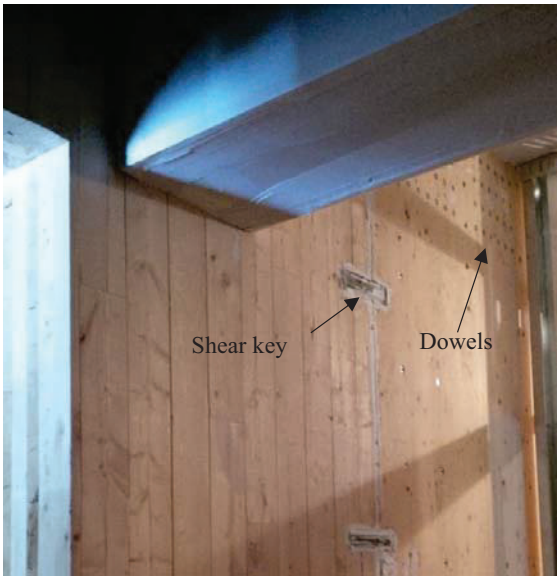

Figure 3: *Shear wall with shear keys and a hold-down with dowels*

2.2 ARBORA BUILDING

Completed in 2017, Arbora building is 8 storeys tall with a height of 24.5 metres and designed by Nordic Structures. It is located downtown Montreal in Canada and its near surroundings are buildings with a similar height except on its south side where it is a large one storey industrial building as shown in Figure 4.

The first level is a concrete podium, and the seven subsequent levels are made of MT (Glulam and CLT). The gravity system consists of a post-and-beam glulam frame and 175 mm CLT floor slabs. The typical floor clear span is 5.5 m. As with Origine, this type of floor creates a semi-rigid diaphragm effect. The LLRS are balloon framed CLT shear walls and elevators cores that extend from the concrete podium floor to the roof. The CLT shear walls are made of either 7-ply 244 mm or 5-ply 175 mm panels, depending on the location and magnitude of the lateral force. The uplift force is resisted by steel plates anchored to the CLT using ring shank nails, as shown in Figure 5. The vertical and horizontal joints between panels were designed with steel plates with ring shank nails. This kind of connection forms a flexible connection between CLT panels.

3 APPROACHES

3.1 Position and location of the devices

Both buildings are being constantly monitored with a set of accelerometers fixed on the ceiling of the top storey and an anemometer located on the roof of the building to roughly estimate the wind speed experienced by the buildings. The monitoring started in 2018 and is still ongoing.

The anemometer on both buildings is from Young Company, and the model used is 05103VK, which offer an output signal voltage output from 0 to 5V for wind speed from 0 km/h to 200 km/h (0 m/s to 55.5 m/s). The anemometer also has a mechanical range of 360° for the wind direction and an output signal of 0 V to 5 V. The location of the anemometer is shown on Figures 6 to 8. It must be understood that the wind flow around a building can be greatly influenced by the structure itself [8, 9]. This means the wind speed measurement cannot be taken as a precise value of the wind speed experienced by the building, namely if the anemometer is in a turbulent region. The analysis of the acceleration responses of the building with respect to the wind speed and direction needs to be made with precautions. Thus, the value measured by the anemometer only gives an indication of how much wind the building experiences. In attempt to limit the turbulence effect, the anemometers were positioned at about 2.5 m above the roof stair entrance (Figure 8).

Figure 6: *Location of the anemometer on the Origine building*

Figure 7: *Location of the anemometer on the Arbora building*

Figure 8: *Photo of the anemometer installed on the Origine building*

The accelerometers used to monitor the building acceleration are model 626B02 from PCB Piezotronics that uses the ICP® signal technology. The main benefit of an ICP® signal in this project is the low output impedance (<100 Ohms) which allows signals to be transmitted over long cables through harsh environments with minimum loss in signal quality [10]. The model 626B02 has a low frequency sensitivity ranging from 0.2 Hz to 6000 Hz and a measuring acceleration range of ± 10 g (± 98 m/s^2). The output signal of the accelerometer range is ± 5 V which gives a sensitivity of 500 mV/g (51 mVs^2/m).

Figures 9 and 10 show the plan locations where a pair of accelerometers have been fixed to measure the acceleration in the x and y directions. They have been fixed on the ceiling of the top floor. Ideally, these accelerometers should have been installed at the corners of the building, but this location would have been within a unit, and if for any reasons these accelerometers would have needed to be accessed, it would have been impossible. Therefore, the accelerometers were installed in a common area hidden in the ceiling.

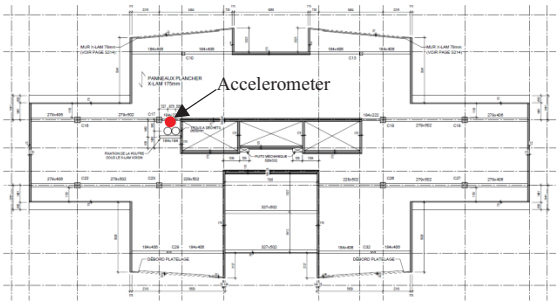

Figure 9: *Location of the accelerometers on the ceiling of the top floor for the Origine building*

https://doi.org/10.52202/069179-0382

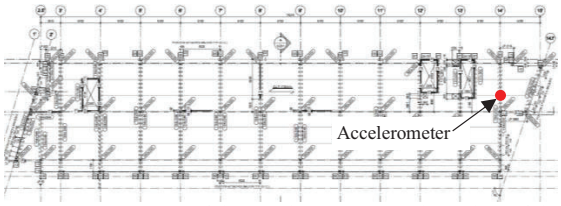

Figure 10: *Location of the accelerometers on the ceiling of the top floor for the Arbora building*

3.2 Data analysis

The data from the accelerometers and the anemometers are acquired at a frequency of 100 Hz permanently. The data are saved in a binary format in blocks of 6 hours. All the acquired data are then screened with a python script to extract meaningful 2-minute data. The trigger to extract the 2-minute window data is based on the 3 seconds average wind speed. The following rules are followed to extract the data for the Origine buildings:

1. If the maximum 3 seconds average wind speed of the 6 hours data block is below 10 m/s, no data are extracted;
2. If the maximum 3 seconds average wind speed of the 6-hour data block is between 10 and 15 m/s, one 2-minute data block is extracted;
3. If the maximum 3 seconds average wind speed of the 6-hour data block is between 15 and 20 m/s, three 2-minute data blocks are extracted unless if the maximum 3 seconds average wind speed of the subsequent data blocks is lower than 15 m/s for which no block is extracted;
4. If the maximum 3 seconds average wind speed of the 6-hour data block is higher than 20 m/s, five 2-minute data blocks are extracted unless if the maximum 3 seconds average wind speed of the subsequent data blocks is lower than 20 m/s for which only three blocks are extracted, or if the maximum 3 seconds average wind speed is lower than 15 m/s for which no data block is extracted.

For the Arbora building, the following rules are used:

1. If the maximum 3 seconds average wind speed of the 6-hour data block is below 10 m/s, no data are extracted;
2. If the maximum 3 seconds average wind speed of the 6-hour data block is between 10 and 15 m/s, two 2-minute data blocks are extracted;
3. If the maximum 3 seconds average wind speed of the 6-hour data block is between 15 and 20 m/s, ten 2-minute data blocks are extracted unless if the maximum 3 seconds average wind speed of the subsequent data blocks is lower than 15 m/s for which only two blocks are extracted;
4. If the maximum 3 seconds average wind speed of the 6-hour data block is higher than 20 m/s, 2-minute data blocks are extracted with no limit on the quantity until the maximum 3-seconds average wind speed of the subsequent data blocks is lower than 20 m/s for which the previous rule applies.

Two different extraction rules were used to have sufficient data for both buildings. The Arbora building is less exposed to wind compared to the Origine building. Therefore, less data during high wind speed events is available.

As described in the previous subsection, the sensitivity of the accelerometers used for the acquisition is 500 mV/g. These accelerometers are considered very sensitive but much more sensitive accelerometers exist at 10,000 mV/g. With the current accelerometers, if the maximum acceleration experienced by the building is the limit prescribed by the NBC for the residential building, 15 milli-g, the actual measurement over the measuring capacity will only be 0.15%. Therefore, noise in the measurement is almost inevitable in this case. In order to extract reliable dynamic properties of the building, the method to analyse the data needs to be carefully chosen.

The load experienced by the building is unknown, thus the modal identification technique used to process the signal of the accelerometer needs to be able to analyse output data only. Over the past decades, different time-frequency methods, including wavelet transform (WT) [11, 12], blind source separation (BSS) [13], and empirical mode decomposition (EMD) [14] have been used as modal identification techniques for large-scale civil infrastructure. Of all methods, EMD has the capability of using only a single channel of measurement.

There are different derivatives of the EMD method, such as the variational mode decomposition (VMD) [15], the multivariate empirical mode decomposition (MEMD) [16], and the time varying filtering-based EMD (TVF-EMD) [17]. This study utilizes the TVF-EMD method, since it can be used with only a single-channel measurement without causing mode-mixing or end effects under the presence of closely spaced modes or measurement noise. This is an important property of this technique, since the signal-to-noise ratio is small for the measurement performed in this study. Additionally, each channel is analysed independently, since the two accelerometers at the top of the building are placed orthogonally and the accelerometers at the ground are not considered during the analysis as the excitation from the ground is negligible in comparison to wind.

The EMD method decomposes the signal into a set of oscillatory waveforms known as intrinsic mode functions (IMFs). Then, the time varying filtering-based EMD (TVF-EMD) [17, 18] performs local cut-off filtering where the signal is successively filtered into local high-pass and low-pass components to decompose it into narrowband signal components (i.e., IMFs). Each IMF has a specific energy and frequency. To determine the modal damping ratio of the structure, an IMF with high energy (high RMS value) around the natural frequencies of the structure is chosen, which is represented by a red "x" and a red circle in Figures 11 and 12. This IMF is then analysed into the time domain by performing an autocorrelation to extract the damping ratio, as shown in Figure 13. The equation shown in Figure 13 is of the following form:

$$E(\tau) = Ae^{-\zeta f_n 2\pi\tau} \quad (1)$$

https://doi.org/10.52202/069179-0382

where ζ is the modal damping ratio, f_n the natural frequency of the IMF, τ is the time lag, A is the amplitude and $E(\tau)$ is the envelope of the autocorrelation.

This method is performed for every 2-minute extracted data. As such, a statistical analysis of the evaluated modal damping ratio for each extracted IMFs can be performed. When extracting modal damping ratio with ambient load, the level of confidence with the modal damping ratio is generally quite low since this is a parameter difficult to evaluate [19]. The level of confidence for every single data of modal damping ratio in this study is in the same order. However, one of the originalities of this study is to have performed that analysis more than 1000 times to obtain a statistical distribution of the modal damping ratio. Therefore, the modal damping ratio of the monitored structure could be based on the average, the median, or the mode in which we have a much better degree of confidence due to the quantity of data.

4 RESULTS AND DISCUSSION

This section presents the results from the statistical analysis of the extracted modal damping ratio. The monitored buildings are equipped with two uniaxial accelerometers fixed on the ceiling of the top floor. One accelerometer is measuring the acceleration along the short axis of the building, while the other is measuring the acceleration in the orthogonal direction, i.e., along the long axis.

From the monitored data, several 2-minute window data are analysed to extract the damping ratio with a TVF-EMD algorithm [17]. Figures 14 to 17 show the probability density of the extracted damping ratio. It should be noted that, since evaluating the modal damping ratio under ambient loading is very difficult, the reliability of a single measurement for the modal damping ratio is relatively low [19] and therefore, using this method in which there is a statistical distribution of the modal damping ratios is recommended. Analysing more data and then performing statistical analysis of these data is a way to increase the reliability of the damping ratio value assigned to the building, as long as there is no systematic error in the method employed to extract the damping ratio.

It can be observed from Figures 14 to 17 that the lognormal distribution fits the measured damping ratio distribution very well. As a property of lognormal distribution, the probability density below the mode, i.e., highest probability density, decreases rapidly. It means that a very low modal damping ratio is less probable than a high damping ratio. Therefore, the average and the median are always higher than the mode. Tables 1 and 2 provide these estimated values for all the data points and for high wind events. The threshold for high wind events has been chosen only to have enough 2-minute window data under relatively high wind events. Since Origine is more exposed to wind, there is more data available for this building under these wind events. Consequently, threshold value is 18 m/s for Origine and 15 m/s for Arbora. From those tables, it can be observed that the extracted modal damping ratio under high wind speed is similar to the damping ratio extracted under wind speed higher than 10 m/s. This is an important observation, since it indicates that the building is still experiencing a linear behaviour under different wind conditions. Buildings are designed to remain elastic under wind load, but the connections between panels generally exhibit non-linear behaviour even under low load. The non-linear behaviour

https://doi.org/10.52202/069179-0382

of these connections does not seem to influence the damping ratio of the structures under wind loads noticeably.

As mentioned in commentary A of the NBC when defining the stiffness of new material, such value should be based on a 50% exclusion, i.e., the median. Material stiffness is generally used for serviceability limit state verification. Top floor acceleration limitation is a serviceability limit state verification. Therefore, it is believed that the damping ratio of the Arbora and Origine building could be considered as 2.5% which is found to be slightly lower than the median under high wind speed for the fundamental frequency of both buildings. Table 1 and Table 2 present the statistical parameter of the modal damping ratio for both buildings.

Arbora and Origine have similar construction systems. The LLRS are made with balloon frame CLT, and the floors are made with CLT. However, the shape of the buildings is different. Origine has more a tower shape by being almost square, while Arbora is rectangular, and its length is much longer than its height. Since these two buildings have a similar construction material but different shapes, it seems that MT buildings with CLT balloon-framed shear walls have a damping ratio of about 2.5%.

Table 1: *Statistical parameter of the modal damping ratio for the two first natural fundamental frequency for the Origine building*

	Wind > 10 m/s		Wind > 18 m/s	
Statistical Parameter	f_1	f_2	f_1	f_2
Number of data	1883	1885	350	351
Average	3.26	3.56	3.05	3.44
Median	2.96	3.25	2.75	3.15
Mode	2.44	2.71	2.23	2.65

Table 2: *Statistical parameter of the modal damping ratio for the two first natural fundamental frequency for the Arbora building*

	Wind > 10 m/s		Wind > 15 m/s	
Statistical Parameter	f_1	f_2	f_1	f_2
Number of data	900	900	63	63
Average	2.80	3.15	2.88	3.34
Median	2.59	2.91	2.66	3.11
Mode	2.22	2.48	2.27	2.69

5 CONCLUSIONS

This study investigated the modal damping ratio value of the Origine and Arbora mass timber buildings under wind-induced vibration. The Origine building is 13 storeys with a roof height of 40.0 m, and the Arbora building is 8 storeys with a roof height of 24.5 m. These buildings were designed through the development of alternative solutions conforming to the National Building Code of Canada. Although the height of these buildings is not enough to raise serious concerns regarding the wind-induced vibration behaviour of the buildings, they can give relevant and critical data, such as modal damping ratio, that can only be evaluated on real-size buildings. This variable is critical when evaluating the dynamic behaviour of the building under wind-induced vibration.

To extract this dynamic property of the Origine and Arbora buildings, they were equipped with accelerometers fixed on the ceiling of the top floor and an anemometer fixed on the roof to almost permanently monitor the acceleration experienced by the buildings. These data were then screened to extract meaningful 2-minute data windows. These 2-minute data windows were then analysed with a time varying filtering-based empirical mode decomposition (TVF-EMD) algorithm to extract the modal damping ratio of the analysed data. A statistical analysis of the damping ratio was then performed to increase the reliability of the extracted damping ratio, since evaluating such parameters under ambient load with a single measurement has limited reliability. From these analyses it was found that the Origine and Arbora buildings have a damping ratio of about 2.5% for their fundamental natural frequencies. Therefore, for future high-rise mass-timber (MT) buildings with lateral load resisting systems (LLRS) made of cross-laminated timber (CLT), the damping ratio could be assumed around 2.5% or below. Currently, damping ratio for wind-induced vibration is usually assumed to be 1% for MT buildings. Such value is now believed to be overly conservative for high-rise MT buildings with CLT shear walls.

The next steps of this research project will be to estimate the top floor acceleration of different designs of high-rise MT buildings and then to iterate on different structural parameters to optimize the structure for reducing the wind-induced vibration. Usually, for very tall buildings such as skyscrapers, this optimization is made along with shape optimization. However, going through a shape optimization process for high-rise MT buildings may not be the most efficient and economical way, since the height in comparison to conventional steel or concrete skyscrapers is still small and only structural optimization may be sufficient. Such a study will allow defining the best strategies to reduce wind-induced vibration for MT buildings.

DIFFERENTIAL MATERIAL MOVEMENT IN TALL MASS TIMBER STRUCTURES

Richard McLain[1], Josephine Racine[2], Bryce Lumpkin[3]

ABSTRACT: As mass timber buildings reach unprecedented heights, not to be overlooked in the design and detailing of these structures is the effects of vertical movements, particularly due to their cumulative. Glulam column shrinkage, joint settlement, and creep can affect vertical mechanical systems, exterior enclosures, and interior partitions, as well as differential create challenges where timber framing systems move relative to other structural systems such as concrete core walls. This paper analyzes the reasons for vertical movement (both short and long term), provides methods of calculating anticipated movement, compares calculated movement to on-site verified movement, highlights detailing options, and discusses vertical movement strategies implemented on tall mass timber projects completed in North America.

KEYWORDS: Creep, Settlement, Shrinkage, Crushing, Movement, Deflection, Columns, Monitoring, High-Rise

1 INTRODUCTION

As the height of mass timber buildings continues to grow, a new set of design and detailing challenges arises, creating the need for new engineering solutions to achieve optimal building construction and performance. One necessary detailing consideration is vertical movement, which includes column shrinkage, joint settlement, and creep.

2 TALL MASS TIMBER

U.S. interest in tall timber buildings, i.e., buildings that exceed height and area limits prescribed in the 2018 and previous versions of the International Building Code (IBC), has steadily increased over the past several years. With the introduction of three new construction types in the 2021 IBC—Types IV-A, IV-B and IV-C, which allow up to 18, 12 and nine stories of mass timber construction respectively—these projects are also getting built. Currently, more than 10% of the mass timber buildings in design or built in this country exceed the 2018 prescriptive height limits. Tall projects such as Heartwood in Seattle, 1510 Webster in Oakland, Ascent in Milwaukee, INTRO in Cleveland, 11 E Lenox in Boston, and 80M in Washington DC are either under construction or completed and occupied. At the time of writing, several others are set to break ground.

As the height of mass timber buildings continues to grow, a new set of design and detailing challenges arises, creating the need for new engineering solutions to achieve optimal building construction and performance. One necessary detailing consideration is vertical movement, which includes column shrinkage, joint settlement, and creep. The main concerns are the impact of deformations on vertical mechanical systems, exterior enclosures, and interior partitions, as well as differential vertical movement of timber framing systems relative to other building features such as concrete core walls and exterior façades. This paper analyzes the reasons for vertical movement (both short and long term), provides methods of calculating anticipated movement, compares calculated movement to on-site verified movement, highlights detailing options, and discusses vertical movement strategies implemented on tall mass timber projects completed in North America.

3 SOURCES OF VERTICAL MOVEMENT

Vertical movement occurs in all buildings, regardless of height and structural materials used. The key to mitigation is to understand all potential sources of movement, calculate the sum of the ones predicted, and provide connection details that minimize movement and its effects while allowing for field adjustability. Most tall mass timber projects use a structural system of timber beams and columns supporting mass timber floor and roof panels. The columns and beams are usually glue-

https://doi.org/10.52202/069179-0383

laminated timber (glulam), though structural composite lumber (SCL) can also be used, and options for the panels include cross-laminated timber (CLT), nail-laminated timber (NLT) and dowel-laminated timber (DLT), among others. It is common for the vertical lateral force-resisting systems to be non-wood—e.g., concrete shear walls and steel braced frames. As the primary vertical elements in a tall mass timber building, the timber columns have a significant impact on the net vertical movement of the building. However, the connections of column to column, beam to column and floor panel to column can also play a significant role. Not only should the net vertical movement of the timber columns and connections be considered, so too should the movements of these elements relative to other building systems which may not be moving to the same degree or in the same direction (e.g., timber column movement relative to concrete core wall movement).

The main sources of vertical movement in tall mass timber structures, all of which are addressed in this paper, include:

- Column axial shortening
- Column creep
- Column, beam and panel shrinkage
- Beam and panel crushing perpendicular to grain
- Settlement at connections

4 BUILDING CODES AND STANDARDS

Applicable building codes and standards vary based on the project's location, the jurisdiction's adopted building code, and any relevant amendments. The following codes and standards commonly apply to tall mass timber buildings.

International Building Code (IBC)
The IBC is a model building code developed by the International Code Council (ICC). Adopted as a base code by most jurisdictions in the U.S., it addresses health and safety concerns for buildings based on prescriptive and performance requirements. This document refers to the 2021 IBC unless otherwise noted.

Chapter 35 of the IBC provides a list of referenced standards, which represent consensus on how a material, product or assembly is to be designed, manufactured, tested or installed to achieve a specified level of performance. Standards that address vertical movement topics are noted below. Additionally, IBC Section 2304.3.3 requires that wood-framed projects greater than three stories include an analysis of the effects of shrinkage. It stipulates that shrinkage in a wood building not have adverse effects on systems such as roof drainage, electrical, mechanical, or other equipment.

National Design Specification® (NDS®) for Wood Construction
Published by the American Wood Council (AWC), the NDS defines the methods to be used in the structural design of wood members and connections. It contains information related to the design of mass timber products including CLT, glulam and SCL. Topics in the NDS that can impact vertical movement include creep and wood crushing when loaded perpendicular to grain.

Product Standards such as ANSI/APA PRG 320 Standard for Performance-Rated Cross-Laminated Timber and ANSI 190.1 Standard for Wood Products – Structural Glued Laminated Timber
Standards for mass timber products typically include dimensional tolerances. For example, PRG 320 requires that the actual width of a CLT panel be within +/- 3.175 mm (1/8-in.) of the specified width, and actual panel length be within +/- 6.35 mm (1/4-in.) of the specified length. Glulam columns up to 6.1 m (20 ft) long must have an actual length within +/- 1.59 mm (1/16-in.) of the specified length. These tolerances can impact vertical movement, particularly at connections.

Note that the abovementioned codes and standards do not contain explicit information on some aspects of vertical movement in tall timber structures. For example, calculations for determining shrinkage in wood members are not detailed in codes and standards, nor is the creep factor for column axial shortening. As such, engineering judgement is necessary and other sources of information are relied on. As with any circumstance requiring the use of engineering judgement, it is the responsibility of the engineer to use the most current information, research, test results, etc. to inform or validate assumptions made. The following sections note several *possible* methods of quantifying vertical movement in tall timber buildings. This information is intended to demonstrate options for quantifying these movements; it is not intended to cover all the options or solutions.

5 QUANTIFYING VERTICAL MOVEMENT

5.1 COLUMN AXIAL SHORTENING

Axial forces on any structural column, be it timber, steel or concrete, cause shortening of the member. Using the

https://doi.org/10.52202/069179-0383

principles of mechanics of materials, the axial shortening of a column is calculated with the equation:
$\Delta_{as} = PL/(AE)$

Where:

- Δ_{as} = column axial shortening (mm or in.)
- not including creep effects
- P = axial load supported by the column (N or lbs)
- L = length of the column (mm or in.)
- A = cross-sectional area of the column (mm^2 or in^2)
- E = modulus of elasticity of the column (kPa or psi)

Following is an example axial column shortening calculation. Note that this is an arbitrary design example and is not related to the actual project examples in the on-site verification information contained in the full document.

- Axial load of 200.2 kN (45,000 lbs) of which 89 kN (20,000 lbs) are dead load, and 111.2 kN (25,000 lbs) are live load, duration of load factor = 1.0
- Assume a 222 mm x 229 mm (8-3/4-in. x 9-in.) Douglas-fir glulam column, layup combination 2
- Column length = 4.6 m (15 feet)
- F'c = 13,445 kPa (1,950 psi)
- E = 11,031,612 kPa (1,600,000 psi)

$\Delta_{as} = PL/AE = (200.2)(4600)/((222*229)(11,031,612/1000^2) = 1.6$ mm
Or $(45,000)(15*12)/((8.75*9)(1,600,000)) = 0.06$ in.

Section 3.5 of the NDS discusses creep effects of long-term loading on deflection of bending members. Although this section of the NDS is directly applicable to bending members, it is not uncommon to also apply creep calculations to axial column deformations (shortening). Equation 3.5-1 in the NDS provides a method of quantifying the deformation effects of long-term loading on bending members.
$\Delta_{as,T} = K_{CR}\,\Delta_{LT} + \Delta_{ST}$, where:

- $\Delta_{as,T}$ = column axial shortening including creep effects (mm or in.)
- K_{CR} = time-dependent deformation creep factor
  - If we assume the creep factor for axial compression is the same as for bending,
- K_{CR} = 1.5 for seasoned timbers, glulam or SCL used in dry service conditions.
- Δ_{LT} = immediate deformation due to long-term loading (mm or in.)
- Δ_{ST} = deformation due to short-term loading (mm or in.)

For the column in the above example, the 89kN (20,000 lbs) axial dead load on the column is the long-term load, and the 111.2 kN (25,000 lbs) axial live load is the short-term load. If one applies this creep deformation equation to axial column shortening, accounting for long-term creep effects, the total anticipated axial column shortening in this example would be:
$\Delta_{as,T} = (1.5)(1.6)(89/200.2) + (1.6)(111.2/200.2) = 1.9$ mm
Or $(1.5)(0.06)(20{,}000/45{,}000) + (0.06)(25{,}000/45{,}000) = 0.07$ in.

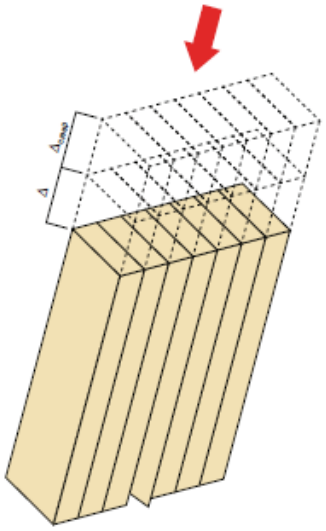

Figure 3: *Shortening of glulam columns*

5.2 SHRINKAGE

Simplistically, wood's cellular structure can be imagined as a bundle of drinking straws held together with a rubber band, with each straw representing a longitudinal cell in the wood. As noted, water can be free water stored in the straw (cell) cavity or bound water absorbed by the straw (cell) walls. At high moisture contents, water exists in both locations. As the wood dries, the free water is released from the cell cavities before the bound water is released from the cell walls. When wood has no free water and yet the cell wall is still saturated, it is said to be at its fiber saturation point (FSP).

The FSP of different species of wood varies but for most common softwoods is around 28-30%. The MC of lumber in service is typically 7-14%, much lower than the FSP. Wood remains dimensionally stable above the FSP, i.e., it doesn't change in dimension with an increase or decrease of moisture as long as it remains above the FSP at all times. This is because the water being absorbed or released is largely free water, not bound water. Once the moisture content drops below the FSP (i.e., bound water is being removed), the wood starts to change dimensionally.

Wood moisture content (MC) is the weight of water in wood as a percentage of the completely dry wood weight. During the life of a tree, its MC can exceed 200%, meaning the total water weight in a given volume of wood makes up two thirds or more of the total weight.

https://doi.org/10.52202/069179-0383

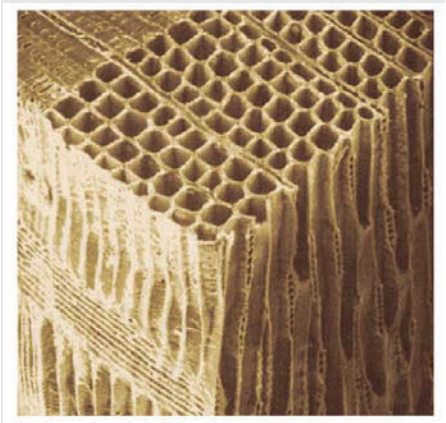

Figure 4: *Southern yellow pine cellular makeup*
Photo: USDA Forest Service Agricultural Handbook

Average shrinkage values from FSP to oven dry are approximately 5% and 7% (radial and tangential shrinkage, respectively), while longitudinal is approximately 0.1% to 0.2% for most species of wood. However, columns in mass timber construction are installed well below the FSP and maintain some residual moisture greater than oven dry. Since only a range of longitudinal shrinkage is provided, the engineer should use engineering judgement when determining the appropriate shrinkage coefficient to use. One method of calculating glulam column longitudinal shrinkage would be to assume an average shrinkage of 0.15% from fiber saturation point (FSP) to oven dry. Assuming that FSP is 28% MC, this allows one to calculate a coefficient of 0.15% / 28 = 0.000054, which equals the amount of longitudinal shrinkage per mm (or inch) of column length per % of MC change.

Using the column from the example earlier in this document, assume a 222 mm x 2229 mm (8-3/4-in. x 9-in.) column, 4.6 m (15 ft) long, with installed MC of 19% and EMC of 12%. Calculated longitudinal column shrinkage is:

$\Delta_{shrinkage}$ = (4600 mm)(0.000054)(19-12) = 1.7 mm
Or (15 ft)(12 in./ft)(0.000054)(19-12) = 0.07 in.

Detailing the column-to-beam connections should also include shrinkage consideration. Cross-grain shrinkage is much more significant than longitudinal shrinkage. A common coefficient used to calculate the cross-grain shrinkage of wood members is 0.0025 in. per inch of cross-sectional dimension for every 1% change in MC. Recall the common range of radial and tangential shrinkage discussed previously, 5% to 7% from FSP to oven dry, and we can see how this 0.0025 coefficient is derived. Assume a worst case of 7% shrinkage and an FSP of 28%, and the cross-grain shrinkage coefficient = 7% / 28 = 0.0025.

For example, a 222 mm x 610 mm (8-3/4-in. x 24-in.) glulam beam with an installed MC of 19% and EMC of 12% would have an anticipated shrinkage of:

Beam Depth: $\Delta_{shrinkage}$ = (610)(0.0025)(19-12) = 10.7 mm
Or (24 in.)(0.0025)(19-12) = 0.42 in.

Beam Width: $\Delta_{shrinkage}$ = (222)(0.0025)(19-12) = 3.9 mm
(8.75 in.)(0.0025)(19-12) = 0.15 in.

If this beam depth shrinkage occurs at each level, the overall effects on a 12- or 18-story mass timber building would be significant, resulting in multiple centimetres of building shrinkage. This is one reason why detailing the beam-to-column connections in multi-story mass timber structures such that beam shrinkage is isolated from impacting the overall building height is a key method of minimizing the impacts of vertical movement.

Consider the relative differences in the following column-to-beam configurations:

Option 1: An upper column bears directly on the mass timber floor panel, which bears directly on the support beam which bears on the lower column. This is essentially a platform-frame detail; because the shrinkage zone per floor is relatively deep (equaling the depth of the floor panel plus depth of the beam), shrinkage per floor is high. In the example above, the shrinkage in the depth of the beam would be approximately 10.7 mm (0.42 in.) per level, in addition to approximately 3 mm (0.12 in.) of panel thickness shrinkage, assuming a 175 mm (6-7/8-in.) deep panel. The total shrinkage per floor due only to beam and panel shrinkage is 13.7 mm (0.54-in.).

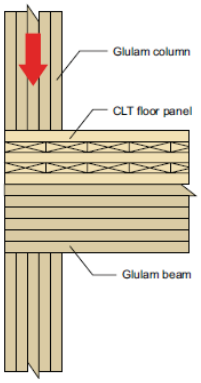

Figure 5: *Example column and beam connection; beam bears directly on column with beam shrinkage accumulation sub-optimal*

Option 2: beams and panels are isolated from the shrinkage zone by connections in which the beams do not bear directly on top of the columns below and similarly, the upper columns do not bear directly on top of the beams or panels. Detailing strategies involve either notching the column to allow the beam to bear on a shelf or creating a

https://doi.org/10.52202/069179-0383

vertical load path where columns above bear directly on columns below, in some cases involving beam hangers. These options essentially eliminate all cross-grain shrinkage zones.

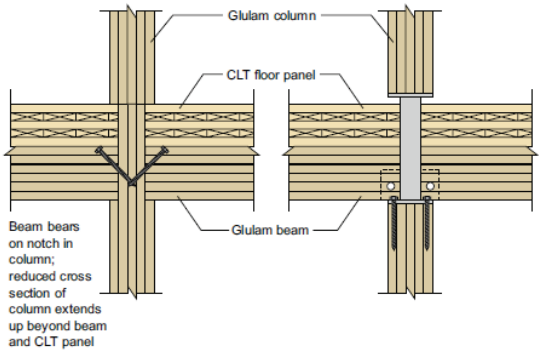

Figure 6: *Example column and beam connections, with beam shrinkage isolated from cumulative building shrinkage*

As the connections in Option 2 illustrate, it is possible (and preferable) to completely isolate beam depth shrinkage from impacting the overall building shrinkage. This is not to say that beam depth shrinkage will not occur—it will. However, keeping the beam depth shrinkage isolated from the continuous vertical load path of the columns minimizes the impacts, which are realized at each individual level without being transferred from one level to the next.

For additional connections and detailing options, browse the WoodWorks CAD/Revit tool and accompanying *Index of Mass Timber Connections* [4].

5.3 PERPENDICULAR-TO-GRAIN CRUSHING

Not only do column, beam and floor panel connection details impact vertical movement because of shrinkage potential, they can add to vertical movement due to crushing of the wood members. When loaded perpendicular to grain, wood members are prone to isolated crushing. NDS Section 3.10.2 provides general guidance on bearing perpendicular to grain, and the NDS Supplement provides allowable perpendicular-to-grain stresses. For softwood species commonly used in mass timber products, the typical range for allowable perpendicular-to-grain stresses is 2758 to 5516 kPa (400 to 800 psi.). Even when keeping actual perpendicular-to-grain stresses at or below allowable levels, some crushing does occur.

For steel-on-wood bearing conditions with the wood member loaded perpendicular to grain, the equations for calculating wood crushing are below. Note that crushing at 73% of allowable perpendicular-to-grain stress is 0.5 mm (0.02 in.) and crushing at 100% of allowable perpendicular-to-grain stress is 1 mm (0.04 in.).

Where: $f_{c\perp} \le F_{c\perp 0.02\ in}$

$$\Delta = 0.02 \times \left(\frac{f_{c\perp}}{F_{c\perp 0.02\ in.}} \right)$$

Where: $F_{c\perp 0.02\ in.} < f_{c\perp} < F_{c\perp 0.04\ in.}$

$$\Delta = 0.04 - 0.02 \times \frac{1 - \left(\frac{f_{c\perp}}{F_{c\perp 0.04\ in.}} \right)}{0.27\ in.}$$

Where: $f_{c\perp} > F_{c\perp 0.04\ in.}$

$$\Delta = 0.04 \times \left(\frac{f_{c\perp}}{F_{c\perp 0.04\ in.}} \right)^3$$

Assume the column in this design example bears on top of a 222 mm x 610 mm (8-3/4-in. wide x 24-in.) deep glulam beam. $F'_{c,perp}$ = 4482 kPa (650 psi.). The perpendicular-to-grain stress on top of the beam is:

$Fc_{,perp}$ = 200.2 kN/(222/1000)(229/1000) = 3940 kPa
Or 45,000 lbs/(8.75)(9) = 571 psi

And the resulting crushing is:
Stress ratio = 3940/4482 = 0.88
Or 571/650 = 0.88. Therefore, use equation 2.0 to calculate crushing:

$\Delta_{crushing}$ = (0.04 - (0.02)((1-(571/650))/0.27)) = 0.03 in. = 0.8 mm

Note that this is the crushing at one of the column-to-beam interfaces (top or bottom of beam surface). The same crushing occurs twice in this instance, essentially doubling the cumulative beam crushing (1.6 mm or 0.06 in total).

Similar to the discussion in the *Quantifying Wood Shrinkage* section above, where beam-to-column connections can be detailed in such a manner as to isolate beams from impacting cumulative building movement, the same is true for beam crushing. By utilizing details where upper columns do not bear directly on top of beams below, and beams do not bear directly on top of columns below, crushing of the wood members is isolated or eliminated and therefore does not contribute to overall building shrinkage. Additional discussion on effective detailing strategies for minimizing shrinkage and crushing effects at beam and column connections is included below.

One place where beams bearing on top of columns may be desired is at cantilevers. When columns are held back from the exterior wall, with the beams and floor panels cantilevering out to support the exterior wall, it might be assumed that the beams need to run directly over the column, which is undesirable from a beam crushing and shrinkage perspective. Rather, a double beam system with

each beam straddling the column, supported by partial bearing on a notch into the column, would allow the beam cantilever while avoiding cumulative effects of both. An example of this detail is shown in Figure 7.

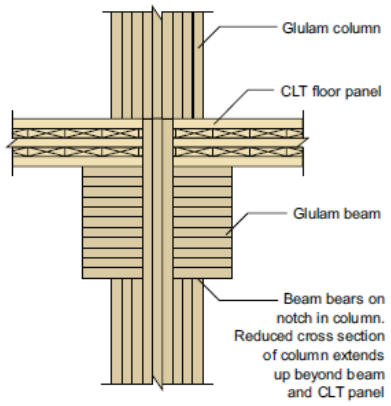

Figure 7: *Double beam system with each beam straddling the column, supported by partial bearing on a notch into the column*

5.4 JOINT SETTLEMENT AT CONNECTIONS

Small amounts of vertical settlement can occur at mass timber connections such as column base and column cap conditions. In addition to mass timber member tolerance allowances (i.e., the length of a column could be +/- 1.6 mm (1/16-in.) of its specified length) the steel hardware at these connections also has tolerance limits that may result in small amounts of settlement. Some engineers include this additional movement in total building shrinkage calculations (1.6 mm or 1/16-in. per floor could be an assumption for this settlement amount) while others choose to ignore it.

6 NET VERTICAL COLUMN MOVEMNT

Summing all of the vertical movements noted above, the net vertical column movement for the design example is calculated as:

$$\Delta_{column} = \Delta_{as,T} + \Delta_{shrinkage} + \Delta_{crushing} + \Delta_{settlement}$$

Using the detail shown in Figure 5 where the beam **is not** isolated from the shrinkage and crushing zone, the net vertical movement per level is:

Δ_{column} = 1.9 + 10.7 + 1.7 + 1.6 + 1.6 = 17.5 mm
Or 0.07 + 0.42 + 0.07 + 0.06 + 0.06 = 0.68 in.

Using the detail shown in Figure 6 where the beam is isolated from the shrinkage and crushing zone, the net vertical movement per level is:

Δ_{column} = 1.9 + 0 + 1.7 + 0 + 1.6 = 5.2 mm
Or 0.07 + 0 + 0.07 + 0 + 0.06 = 0.2 in.

The difference between the two detailing options is significant, further emphasizing the importance of providing details that isolate beam shrinkage and crushing from the overall building movement. Even when doing so, the net vertical column movement for this example, in a 12-story building, would be approximately 62 mm (2.4 in.). Some of this net vertical movement could be reduced with vertical adjustment in connections via shims or other elements placed during construction. This method is described below.

7 DIFFERENTIAL MOVEMENT

The above sections note the potential sources of vertical movement in mass timber framing systems, particularly columns and connections. In most instances, this vertical movement is a downward movement. It is also important to consider how mass timber framing systems interact with other building materials and building components. Other materials may exhibit significantly different vertical movement characteristics. For instance, some materials:

1. Expand due to moisture or thermal changes (brick veneer, masonry shaft walls)
2. Do not shrink due to moisture change but may move with thermal changes (steel framing, and steel/cast iron/PVC piping)
3. Shrink much less than mass timber (concrete core walls)

It is this differential movement that can create issues with the function and performance of finishes, openings, enclosures, mechanical/electrical/plumbing (MEP) systems, structural connections, and more. One of the primary ways to avoid negative impacts is to limit vertical movements of the timber structure as noted in the sections above, while also using detailing strategies discussed in the sections below. It is also important to monitor differential movement during construction, adjusting as necessary. Construction documents and details that provide guidance on how field adjustments should be made at material interfaces are important pieces of the long-term performance solution.

7.1 EFFECTIVE STRATEGIES AND DETAILING TO MINIMIZE AND ACCOMMODATE MOVEMENT

Several detailing options for beams to columns and columns to columns are shown in Figure 6. Particularly for tall mass timber buildings, where it might be desirable or necessary to make vertical adjustments at the column connections during construction based on real-time feedback (i.e., vertical elevation monitoring), using a detail like the ones in Figure 10 can be effective. In addition to isolating the panels and beams from the shrinkage and crushing zone, these steel connections, which often utilize tube or pipe sections fitted together, can be adjusted by inserting steel shims. For example, the 18-story Brock Commons Tallwood House project discussed later in this document utilized a series of 1.6 mm (1/16-in.)-thick steel shim plates at the column-to-column connections on three strategic levels (8, 12, and 16).

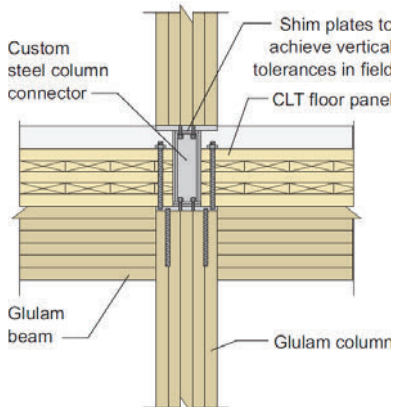

Figure 9: *Column-to-column connection details, with vertical load path isolated from beams and panels*

At connections between different materials, such as a mass timber beam or panel connecting to a concrete core wall, allowances for horizontal and vertical adjustability should be included. One example from the INTRO, Cleveland project is shown in Figure 10. A steel embed plate was cast with the concrete core wall, oversized relative to the steel ledger angle that was later attached to it. The connecting CLT panel was fabricated to allow a small gap between the end of the panel and face of the wall, sized as a function of the tolerance limits for the panel length and wall face location. Vertical adjustability was provided by the oversized embed plate, allowing the steel angle to be field welded to the plate once final elevations were determined (and ideally once some initial shrinkage and settlement had occurred). A similar condition can be used at a beam-to-core wall connection.

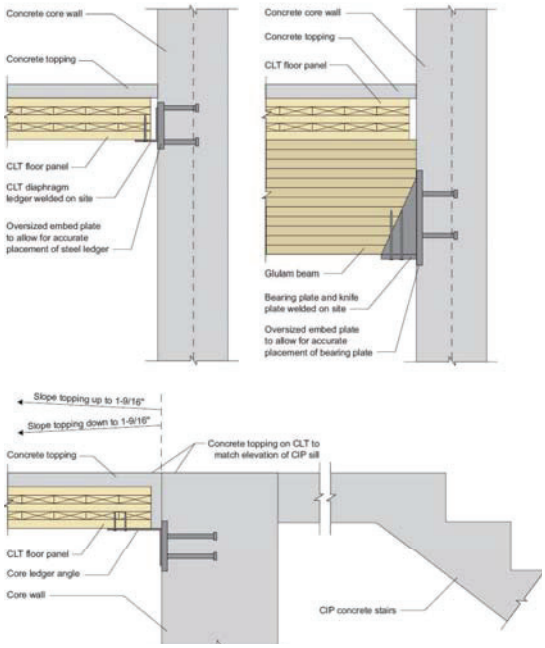

Figure 10: *Options for accommodating differential movement at timber to concrete walls*

Differential movements must also be accounted for in other elements of the building such as vertical MEP runs and exterior wall assemblies. Flex connections within MEP distribution lines (e.g., ductwork, drainage piping, conduit) at each level or every few floors may be prudent. Discussion with the mechanical and electrical engineer is recommended to determine the appropriate steps.

https://doi.org/10.52202/069179-0383

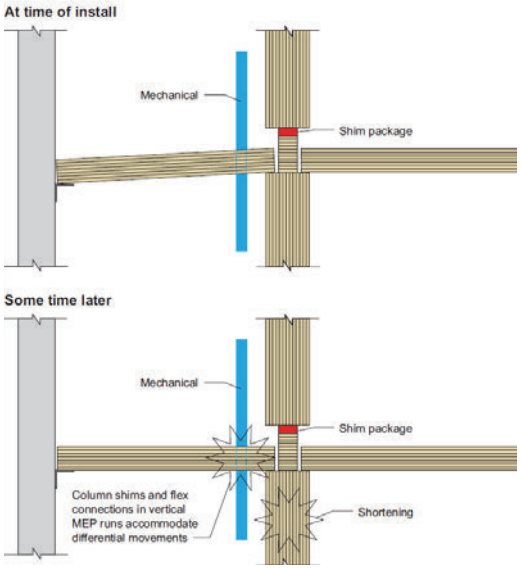

Figure 11: *Potential negative impacts of vertical movements on vertical MEP runs*

Since tall mass timber projects primarily use post-and-beam structural systems, the exterior walls are usually non-load bearing. As such, slip connection details at head of wall conditions not only allow the structure to deflect under gravity loads without loading the walls, but can also function as flex connections that account for vertical differential movements.

7.2 MOISTURE PROTECTION AS A MEANS TO MINIMIZE VERTICAL MOVEMENT

Moisture protection cannot be overemphasized for mass timber, and it is critical that all parties understand the potential effects of moisture on vertical movement potential. It is common on a mass timber project for the architect or engineer, through their specifications, to require a moisture management plan from the contractor. Although on-site material protection is usually considered a means and methods item for the contractor, mass timber is typically both structure and exposed finish. As a result, the design team may have more input on construction moisture management practices than on a non-mass timber project. The design team and owner may choose to require a preconstruction meeting with the contractor to review on-site moisture management techniques.

Key elements of effective construction-phase moisture control in mass timber buildings include:

- Coverings and other means of bulk water deflection/diversion
- Adequate ventilation to promote drying
- Removal of any standing water as soon as possible
- Coatings to protect the mass timber elements, particularly the end grain
- Installation of exterior enclosures in tandem with erection of the timber structure (off-site panelized exterior wall assemblies can aid in this regard)

For additional information on moisture control for mass timber projects, see the WoodWorks publication *U.S. Mass Timber Construction Manual*.

8 SITE VERIFICATION AND HEALTH MONITORING

Structural health monitoring involves the measurement, observation, and analysis of a structure to determine its status over time. These results can be used to determine necessary maintenance, and to ensure intended behaviour of the structure is reflected in the field. Measurements are taken by sensors at regular intervals to provide a numerical history of the structure. The data allows engineers to make observations about the loading and short-term behaviour, draw conclusions about the current state of fatigue, and forecast changes over time.

Once data has been acquired, it must be post-processed to remove noise, normalize variability from environmental effects, and reach meaningful results. Cleansing of data is also important to remove unreliable data, which can result from faulty installation or operation of a sensor.

To monitor short-term and long-term vertical movements in tall mass timber buildings, sensors can be installed throughout the structure to capture specific behaviours of interest. String potentiometers (string pots) can be used to determine vertical movements. These devices use a measuring cable and spring coupled to a spool and rotational sensor. The cable is attached to the point of interest, which will deform relative to the potentiometer. The spring works to maintain tension in the cable, while the sensor determines how much vertical movement has taken place based on the rotation of the spool. String pots can achieve accuracy ±0.0025% of the full scale of the string pot.
