An industrially manufactured wooden facade system here refers to a facade solution for buildings consisting of a set of components that are fully or partially ready-made and dimensioned regarding adjustment for specific dimensions of buildings. The components of the facade system are joined industrially to facade elements, corners, footboards, cornices, and connections at openings. On the construction site, the facade system is assembled and mounted on a building. The result is that the construction site becomes more of an assembly site, where finished elements of the facade system are assembled. This differs from the methods that are common procedure today; were wooden facades are assembled with a nail gun board by board on the construction site or in a factory on a prefabricated wall structure.

2.1 PROJECT VALUE CHAIN

The participating partners covered the whole value chain, including researchers, engineers, architects, constructors, raw material suppliers, manufacturers, builders, and property owners.

The engineer and architect were responsible for the architectural and constructive design, the raw material supplier for the manufacture of the components, the manufacturer for assembly of the parts, the paint supplier and the chemical industry for surface treatments and paint, the contractor and building company for mounting and the manager for care and maintenance.

2.2 PROCESS

Customer requirements, building regulations and the market for facade systems were initially investigated, analysed, and compiled. The aesthetic design was developed with the purpose of making the facade attractive and easy for architects and builders to use. Wood properties and surface treatments were studied and verified in scientific tests to achieve fire safety and long service life. Heartwood of pine and spruce were chosen because of its suitable material properties for facades.

Wood properties and surface treatments were studied and verified in tests to achieve fire safety and long service life. The facade system's functions were verified in lab tests and by small scale design prototypes. Full scale tests of the mounting of the facade system were executed on two buildings in Luleå, where mounting time and functions were evaluated. A full-scale fire test of the facade system was carried out with Teknos´ fire protection paint, which passed the SP Fire 105 test. Overall, the façade system was developed to be market-competitive and contribute to a sustainable bio-based economy. To assure this, durability and circularity have been considered both in the design and the choice of materials.

2.3 CO-DESIGN

In the project the term co-design refers to a process where the participants collaborated in a design process, including all the participants' knowledge and reasons for participating and enabling them to together create knowledge development, ideas, and concept generation when developing the product. It also meant creating a foundation of trust and understanding enabling participants who were not trained in design to be co-designers. Co-design methods can be used in all stages of the design process, though they are mostly used in the idea or concept phase. In the project several co-design methods have been used to facilitate participation and cooperative design, such as workshops, making prototypes, mock-ups, discussions of drawings and scenarios. To verify the prototypes aesthetically, discussions with partners in the

value chain including a reference group of architects were engaged.

3 RESULTS

The development of the façade followed an interactive development process with interaction between design, function, and production, figure1.

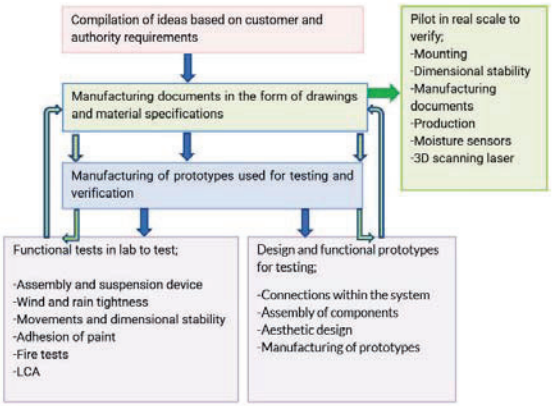

Figure 1: *Iterative development process in the project "Facade in the city Swift, Stylish, Smart", Development of the facades is based on requirements, laboratory tests and functional prototypes in an iterative process and thereafter verified as a pilot installation on two buildings [1]. (Image Karin Sandberg RISE).*

3.1 CO-DESIGN PROCESS IN THE FASADE PROJECT

The design was developed to make the facade attractive for architects and builders to use. The development process used in the project is described in full in a rapport [5].

3.1.1 Co-design in project managing, planning resources and anchoring decisions

Co-design enabled the partners to plan the project, asset manage, plan meetings and workshops alternating between including all participants and in smaller focus groups where specific tasks could be solved. The result of discussions, visualizations and prototypes were thoroughly documented in notes and the scientific tests, aesthetic tests, and functional verifications were described in rapports. The meetings with the partners were used to anchor decisions. The decisions were documented with meeting notes which were followed up by the project research leader who also distributed resources for implementation. Design choices and asset management were thus continuously updated leading to specification of the design criteria step by step.

3.1.2 Phases in the co-design process

The co-design process in the development of the facade system consisted of different phases,
-inventory phase
-analysis phase
-verification phase

The phases were developed in a semi parallel flow. The development took place iteratively where prototypes were tested and improved and adapted to production together with the partners in the project.

3.1.3 Inventory phase

Acknowledging the complexity and the nature of the scope at the very beginning of the project, the partners saw the benefit of establishing a common ground, thus creating engagement for the project. The common ground was the interest in the material, heartwood pine and spruce. The project established an interesting opportunity of understanding the material from different aspects, by reading it from the other partners perspectives, thus together creating more knowledge of its performance in a façade system including all aspects from design to manufacturing and mounting.

The design choices were based on an inventory that was carried out initially. It compiled customer requirements, building regulations and markets for facade systems and these were researched, analyzed, and compiled.
The engineers developed the scheme for verifying the performance through experimental design and appropriate test methods and technical equipment. The industrial partners gave input on production parameters important to consider.

Design criteria was summarized in a list of requirements on the product. The design criteria created a systematic and structured foundation for deciding on design, assessing criteria and discuss solutions. The design criteria enabled the partners to consider their own roles and connections with possible assets which was beneficial for the collective effort.

3.1.4 Analysis phase

In the analysis phase project drawings and visualizations were used, creating a foundation for testing the design decisions and further discussions. To verify the design decisions production feasibility and development of the manufacturing process design prototypes were built and tested. All prototypes were made of heartwood from Scots Pine (Pinus *Silvestris*) and Norway Spruce (*Picea abies* (L) Karts), figure 3.

Figure 3: *Prototype testing of different design of the façade boards. (photo Camilla Schlyter RISE).*

https://doi.org/10.52202/069179-0511

The cooperation in the value chain, from choice of material to production method resulted in, for example in a series of new expressions of the surface figure 4.

Figure 4. *Example of one of the protypes built in the façade project. The milling of the boards was tested together with assembly of the boards. (photo Camilla Schlyter RISE).*

3.1.5 Verification phase

In the production phase full scale prototypes were tested. A pilot test was executed on a building in Porsön, Luleå. Full scale tests of the mounting of the facade system were executed on two buildings in Luleå, where mounting time and functions were evaluated. A full-scale fire test of the facade system was carried out with Teknos´ fire protection paint and passed the SP Fire 105 test.
The raw material supplier manufactured the components and the components were thereafter assembled by the wood industry partner.

3.1.6 Co-design process

The requirement on the co-design methods was that communication should be enhanced and enable interactivity between the partners and thus promote innovation.

The co-design process was based on building trust and an understanding of the partners points of departure. It was from the start considered crucial to build a common ground, a common language and a willingness to share competence. The methods of arriving to a result at first differed amongst the partners for instance; concerning the design of the product, the engineer relied on scientific results and validation, the manufacturer on efficient production methods and the architect from synthesizing design decisions by developing aesthetic design solutions. The different points of departure sometimes resulted in conflict in the beginning of the project. Opinions, ideas and thoughts could be ventilated in the co-design process and knowledge was exchanged concerning how to pursue the project.

In figure 5 the co-design process in the façade project is shown.

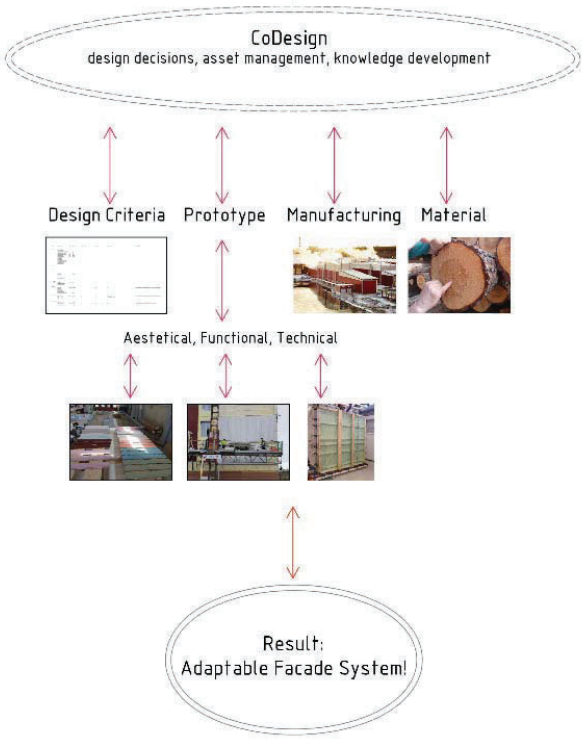

Figure 5: *Diagram over the co-design process. (Image Camilla Schlyter RISE).*

Attitudes, values, and expert knowledge was shared and communicated in the co-design process and conditions were created to enable tying together complex challenges in terms of design, materials, maintenance, and finances

https://doi.org/10.52202/069179-0511

and at the same time ensure that all voices were heard. By understanding the partners knowledge and starting points, consensus was created concerning the product idea and assessment of resources.

3.2 THE ARCHITECTS ROLE

The architect's role in the co-design process was to ensure that the products architectural values and design quality was upheld thru the process and result in an aesthetically pleasing and functional product. The architect used design knowledge to negotiate design criteria by translating and mediating diverging information and transform this knowledge into form by sketches, drawings, and visualizations and create drawings for the prototypes. The purpose was to ensure that all project partners were part of the design and that their knowledge, values and perspectives were lifted into the project and addressed. The role of the architect changed during the course of the project, from being considered the decision maker of aesthetic design to facilitating for others to participate in making the design decisions.

3.3 SUMMARY OF THE RESULTS

Alternatives in aesthetic design, manufacturing process and functional/technical design were formulated and tested in an iterative process between project partners, where everyone contributed with their knowledge and intent. A continuous dialogue and compilation of experiences from design choices took place against the background of design criteria. The design choices were verified through a series of aesthetic, functional and technical prototypes. The design was changed if it did not deliver the results the partners anticipated. New design and new prototypes were created until desired result was achieved.

The aim with the developed co-design process was to ensure that all the requirements were identified, met, and processed. A result with the process was that the participants became co-designers, and the architect acted as a facilitator concerning design methods leading, guiding, and listening to the participants aiding the process of creating knowledge and making design decisions. This resulted in that the partners gained knowledge concerning design and design methods.

The co-design method enabled a discussion in which the project partners could work with technical and aesthetic solutions in parallel. This was ensured by the architect and the research leader working closely together thus giving scientific methods and design methods equal value.

• Of importance was that the project management consisted of an engineer and an architect, which meant that functional and design aspects were discussed in parallel and guaranteed that they were of equal value. The architect and the research leader acted closely together and enabled conflicting issues to be resolved by facilitating and mediating the design process thru co-design methods. An interesting result of this collaboration was that parallels in working methods emerged scientifically on the part of the engineer and aesthetically on the part of the architect.

• Through frequent meetings with the partners, consensus and common starting points were created. Any conflicts, values and purpose of the project could be raised right from the start, which enabled creating a synthesized target goal with the project together, in collaboration. The initial discussions concerning the partners' driving forces and respective positions were crucial to create trust and commitment to the project. By understanding each other's knowledge and starting points, consensus was created around the product idea. Attitudes, values, and expert knowledge could be shared and communicated in the co-design process.

• Another important result of the project was allowing time in the initial phase to create understanding regarding function and design to be of equal value. Using design knowledge and methods from the start to the finished result was of importance for the result. The projects specific co-design process enabled complex criteria to be solved. This contributed to understanding the benefits of involving design knowledge. The architect became an "insider" engaged in the development of a new product.

• This method of collaborating throughout the project enabled criteria to be met, discussed, and communicated in a continuous dialogue between project partners. In the project several specialists' engineers but also industry partners were involved and they all co-operated leading to the common goal. Partners dared to be open to different hypothetical solutions and not decide on a solution too early. Although it took time to collaborate with many partners, the result generated that more aspects than expected were solved and discussed and more questions were raised. It also resulted in that important issues and ideas were not overlooked.

• Understanding of the value of creating knowledge together already in the formation of the consortium. This made it possible for criteria to be met, discussed, and communicated in a continuous dialogue between project parties. It resulted in a wooden façade system in which all parties in the consortium were involved.

The project has resulted in commercialization of one of the components in the façade system, the developed boards with different surfaces are now in production by one of the partners see figure 6. Discussions on commercializing the entire system are continuing.

https://doi.org/10.52202/069179-0511

Figure 6. *Image of one of the commercialized components in the façade system. (photo SCA).*

4 CONCLUSIONS

Demonstrated here are the possibilities of using co-design methods when developing a façade system. The aim with the prolonged design process developed in the project was making all parties involved in the design of the new product.

The project result shows that co-design methods profoundly influenced the product development and were valuable for promoting interdisciplinary communication and innovation concerning new product development.

The architect worked closely with the project research leader in mediating and facilitating the development process ensuring the quality of the design decisions. Coming from two different paradigms in research, essentially using scientific methods on the part of the research leader and design methods on the part of the architect the negotiations between them guaranteed that aesthetic and functional qualities were developed in parallel. The architect and research leader created a solid ground for design decisions by using co-design to create trust amongst the partners in the development process.

The identified gap between the actors in the value chain was considerably diminished by using co-design methods. This was verified in interviews with the partners in the project. As one of the partners commentated, he had never really understood how design knowledge could be used in new product development in the wood industry but after the project he understood the potential of co-design methods.

The co-design method used in the project can be applied to the development of other adaptive product families in the wood industry. The design method enables criteria to be met, discussed, and communicated in a continuous dialogue between project parties.

ACKNOWLEDGEMENT

Thanks to the strategic program Bioinnovation Construction & Design, IPOS – Innovations in wood-based building materials and products, subproject "The facade of the city Swift, Stylish, Smart". The project is founded equally by Vinnova Sweden's innovation agency, the Swedish Energy Agency, and Formas together with the industry partners. Thanks to E2B2 Swedish Energy Agency concerning the project Climate smart renovation with innovative façade system. A special thanks to SCA and Hedlunda for industrial input and KBAB.

MULTI-CRITERIA ASSESSMENT FOR FLEXIBILITY IN MODULAR TIMBER SCHOOL PROJECT BASED ON AHP-TOPSIS

Puxi Huang[1], Yiping Meng[2]

ABSTRACT: Sustainable development has been one important transition goal worldwide. The flexible design extends the frequency and lifespan of buildings by meeting the ever-changing needs of users to increase building sustainability. In this research, module coordination is selected to balance the modularity and flexibility of the modular timber school project. Functional flexibility is quantified by the AHP method based on a three-layer tree diagram assessment framework. The criteria and indicators are determined from the literature following the PRISMA systematic review process. According to the British Educational Building Design Code on area, the common module of school buildings is summarised by comparing the basic spatial dimensions of school buildings of different scales. Six modular grid sizes are selected as the scenarios for comparing the overall flexibility and flexibility in production, construction and service supported by the TOPSIS multi-criteria decision-making method. The ranking for the six sets of the modular grid for timber school classroom unit are summarized in different perspectives.

KEYWORDS: Flexibility, School project, Timber, Modular Construction, Quantification

1 INTRODUCTION

The UN document on sustainable development emphasizes the importance of building connections across economic, social, and environmental sustainability [1]. According to the report [2] and research studies [3], the construction industry consumes up to 35%-40% of the world's energy and generates 36% of greenhouse gas emissions [4], which can contribute to air pollution and material waste [5]. Decarbonization and achieving net-zero emissions have become new standards for the construction industry. The goals of sustainability and decarbonization are closely linked, both of which aim to reduce CO2 emissions for a sustainable future society and economic development.

To lower the impact of the construction industry on the environment, a variety of sustainable approaches have been proposed, e.g., industrial building system (IBS) andof industrialization and standardization in construction has proven to be an effective way of reducing time and waste [9]. Compared to traditional on-site construction methods, prefabrication and modular design/construction are more efficient in terms of time and materials [10,12].

To increase the sustainability of buildings and align with the UK's national strategies for Net Zero, Circular Economy, and Build Back Greener [13], one potential approach is to improve the flexibility of modular design to accommodate varying climates and conditions [14]. Architectural flexibility refers to a space's capacity to accommodate various customizations and layouts [15]. The degree of flexibility and adaptability in a building's design is crucial to meet its users' evolving social and environmental needs [16]. By repurposing existing structures, adaptive reuse can considerably minimize waste and help conserve the energy typically required for material manufacturing and construction [17].

The flexibility of the building can be achieved through design for adaptivity and modular construction [16,18].

The key challenge in designing a new construction project, particularly in the field of the school building, is to achieve flexibility at the design stage. This flexibility is essential in extending the lifespan of the building and meeting sustainability and Net Zero targets[19]. New design models and workflows must be developed to address the challenges posed by the new teaching, learning, and working patterns of a dynamic society in an ever-changing environment. In the post-pandemic era, it is crucial for new school buildings to be adaptable to their users' needs, with dynamic rather than static designs, taking into account the unique characteristics and requirements of the school community.

In the UK, the Department of Education (DfE) builds up to 200 new schools each year in order to fulfil the demand for student places and maintain its inventory. To optimize the learning and working environment, the DfE envisions better design methods, more efficient manufacturing

https://doi.org/10.52202/069179-0512

processes, increased productivity, and zero carbon emissions, enabling faster construction while promoting sustainability [20]. In the UK, the demands for mass construction and rebuilding of schools prioritize sustainability and addressing climate change [21]. Correspondingly, timber has been gradually applied in different types and different scale of projects worldwide because of its sustainable properties and reliable structural behaviours [22,24].

In modular construction of timber school buildings, the relationship between modularity and flexibility is a critical consideration. The principles of flexibility in construction, specifically the evolution for different users and usage rearrangement in the whole lifecycle [15, 25-26], provide a conceptual framework for understanding the meaning of "flexibility" in construction. his research aims to determine the quantified relationship between flexibility and the module of timber school buildings, enabling them to adapt to different functional requirements and meet sustainable construction needs. The study involves comparing module series of school-type buildings, beginning with the determination of an AHP tree to scope the criteria and impact factors of flexibility, followed by comparisons between different module sets using TOPSIS. Based on the simulated results, a numerical relationship between flexibility and module can be obtained, which can inform module coordination strategies.

2 METHODOLOGY

To quantify the flexibility, which is commonly defined qualitatively, the criteria and factors are retrieved from the literatures using PRISMA [27]. Based on the retrieved literatures, the assessment framework for flexibility of timber schools would be developed.

2.1 CRITERIAL AND INDICATORS RETRIEVAL

The identification for PRISMA is shown in Figure 1. Scopus and Web of Science (WoS) are selected as the database for searching. The Boolean syntax is applied for scoping the keywords, setting as follows: TITLE-ABS-KEY (‘Flexibility’ OR ‘ADAPTABILITY’ OR ‘REVERSABILITY’) AND TITLE-ABS-KEY (‘BUILIDNG’ AND ‘DESIGN’) AND TITLE-ABS-KEY (‘ASSESSMENT’). The range for the publication year is (2010,2022). The workflow for determining the final articles for reviewing is shown in Figure 2.

A total number of 617 literatures are selected after the first step of searching. 21 Literatures are selected for reviewing following main procedures of identification (536), screening (136), eligibility check (45) and final inclusion. The research area, title, keywords, and abstracts are checked throughout the whole workflow.

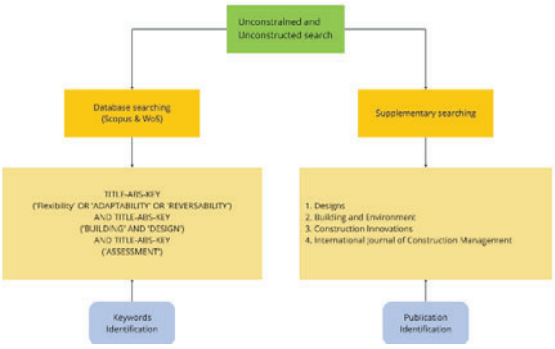

Figure 1: *Identification phase of PRISMA Method*

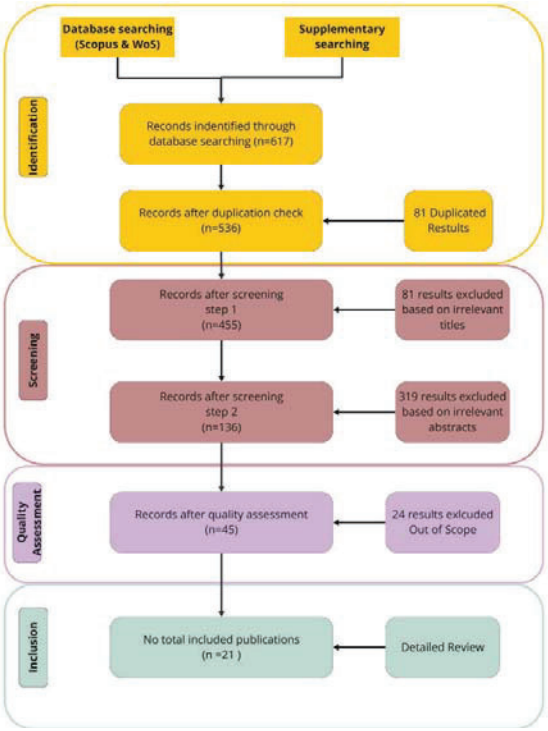

Figure 2: *Workflow for literatures retrieval*

2.2 FLEXIBILITY ASSESSMENT FRAMEWORK

The AHP-Tree Diagram assessment framework including the criteria and indicators are shown in Table 1. To cover the main stages of a cradle-to-cradle whole life cycle related to school building, three criteria have been established: Production, Construction, and Service [28]. The criteria and indicators identification follows the generic principles of flexibility [19, 29] the factors that influence the flexibility of school-type projects are selected from soft aspects [30]. For example, school buildings cater to a wide range of users with age-specific usage requirements, which is why multi-purpose spaces and components are highly demanded to meet their various needs. Under this consideration, the versatile

functionality and structural components are selected as the important indicators (Product types (C_2) and Potential for multifunctional use of space (C_{14})).

Following the AHP Tree Diagram, the weights are determined by collected 12 rating scale questionnaires. After the consistency check for the three factors in criterial level and the 16 factors in indicator level, the weights for the assessment framework ARE summarised in Figure 3.

Table 1: *Flexibility Assessment Framework for Timber School*

Target Level (A)	Criteria(B)	Indicators (C)	Reference
Flexibility	Production (B_1)	Pre-fabrication level (C_1)	[31]
		Product types (C_2)	[30]
		Specific connection (C_3)	[32]
		Structure layers (C_4)	[30]
		Geometry of plan (C_5)	[33]
	Construction (B_2)	Technological flexibility related to the easy installations (C_6)	[34]
		Installation Workflow (C_7)	[30]
		Modular Construction (C_8)	[35]
		System Interaction (C_9)	[36]
		System Zones(C_{10})	[37]
		Ease for deconstruction or disassembly (C_{11})	[38]
	Services(B_3)	Position of technical services (C_{12})	[33]
		Achieved degree of freedom of interior space(C_{13})	[33]
		Potential for multifunctional use of space (C_{14})	[33]
		Planning for future changes and service life (C_{15})	[30]
		Easy maintenance of installations (C_{16})	[34]

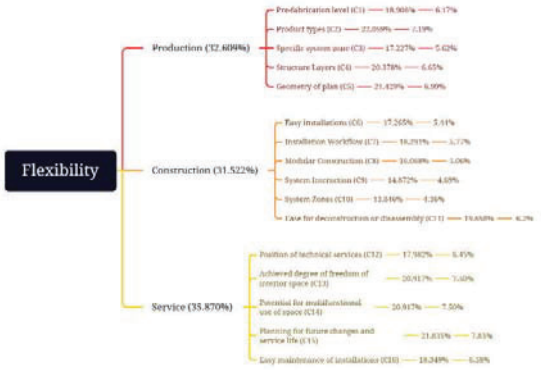

Figure 3: *Weights of the AHP Tree Diagram*

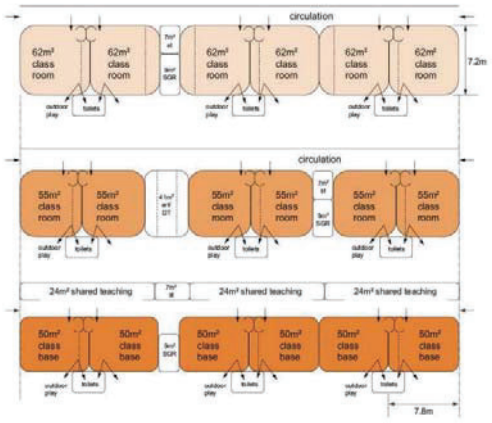
3 TOPSIS FLEXIBILITY ASSESSMENT

Based on the assessment framework, the multi-criteria assessment would be operated using TOPSIS based on the selected scenarios. The scenarios would follow the Net Capacity Guidance for the Mainstream School Design Guidelines from DfE [39]. In this research, the net area for teaching area is selected to determine the initial grid size scenarios. According to the net area guidance, the area for the same functions in primary school and secondary school are different, which are summarised in table 2 and table 3.



https://doi.org/10.52202/069179-0512

Figure 4: *Options for arranging basic teaching area, and associated storage, toilets and group rooms, in primary schools[39].*

The determination of grid size scenarios is based on the net area requirements for classrooms and group rooms in primary and secondary schools, listed in [39].

Table 2: *Teaching Space in Primary School*

Zone	Area Name	Size used in a SoA tool	Grid Size ($\boldsymbol{m} \times \boldsymbol{m}$)
B	Large group room	27m2 for 15	$\mathbf{7.2 \times 7.8}$
B	Classbase without/with sink	50 m2 for 30	$\mathbf{7.2 \times 7.2}$
C	Junior classroom	55m2 for 30	$\mathbf{7.2 \times 7.8}$
D	Reception classroom	62m2 for 30	$\mathbf{7.8 \times 7.8}$ $\mathbf{7.6 \times 8.4}$
D	ICT rich practical room	62m2 for 30	$\mathbf{7.8 \times 7.8}$ $\mathbf{7.6 \times 8.4}$
D	ICT-rich classroom	62m2 for 30	$\mathbf{7.8 \times 7.8}$ $\mathbf{7.6 \times 8.4}$
D	Music classroom	62m2 for 30	$\mathbf{7.8 \times 7.8}$ $\mathbf{7.6 \times 8.4}$
E	Science studio	69m2 for 30	$\mathbf{8.4 \times 8.4}$

The common grid size ranges from $\mathbf{7.2}\boldsymbol{m} \times \mathbf{7.2}\boldsymbol{m}$ to $\mathbf{8.4}\boldsymbol{m} \times \mathbf{8.4}\boldsymbol{m}$. According to normal module coordination set 300mm as the basic unit, then the modules for the timber floor could be $\mathbf{7.2}$, $\mathbf{7.2} + (\mathbf{2} \times \mathbf{0.3})$, $\mathbf{7.2} + (\mathbf{4} \times \mathbf{0.3})$. Timber manufacturing company would list the geometry size of their products. For example, the width of CLT floor panels from HESS timber is 2.2-3.2m with length up to 20m, which satisfies the module of gird size in this research. Based on the module range, six grid size scenarios for TOPSIS assessment are set. After the sum of squares normalization process, the TOPSIS assessment results for the six grid size scenarios are shown in Table 4-6. The positive ideal solution $\boldsymbol{A+}$ for construction criteria is: $[\mathbf{0.474}, \mathbf{0.557}, \mathbf{0.461}, \mathbf{0.522}, \mathbf{0.476}]$ and the negative ideal solution $\boldsymbol{A-}$ for construction criteria is $[\mathbf{0.355}, \mathbf{0.318}, \mathbf{0.329}, \mathbf{0.326}, \mathbf{0.317}]$. The positive ideal solutions $\boldsymbol{A+}$ for the other two criteria are $[\mathbf{0.522}, \mathbf{0.546}, \mathbf{0.551}, \mathbf{0.493}, \mathbf{0.486}, \mathbf{0.508}]$ and $[\mathbf{0.497}, \mathbf{0.497}, \mathbf{0.555}, \mathbf{0.547}, \mathbf{0.476}]$ respectively. The negative ideal solutions $\boldsymbol{A-}$ for construction and service criteria are $[\mathbf{0.326}, \mathbf{0.273}, \mathbf{0.344}, \mathbf{0.302}, \mathbf{0.324}, \mathbf{0.318}]$ and $[\mathbf{0.331}, \mathbf{0.311}, \mathbf{0.277}, \mathbf{0.328}, \mathbf{0.357}]$. The ranking for different grid size scenarios in different criteria are presented in Table 4-6.

4 MULTI-CRITERIA DECISION MAKING FOR FLEXIBILITY

Previous part operates the TOPSIS assessment for the six scenarios from production, construction and service criteria. When determining the module of grid size, for stakeholders from different fields, they would have different focuses on different criteria. Multi-criteria decision making (MCDM) could provide a comprehensive analysis for the flexibility of timber school.

Table 3: *Teaching Space in Primary School*

Zone	Area Name	Size used in a SoA tool	Grid Size ($\boldsymbol{m} \times \boldsymbol{m}$)
C	General classroom	55m2 for 30	$\mathbf{7.2 \times 7.8}$
D	Extensive classroom	62m2 for 30	$\mathbf{7.8 \times 7.8}$ $\mathbf{7.6 \times 8.4}$

Table 4: *TOPSIS Results for Production Criteria*

Module Scenario	Positive ideal distance $\boldsymbol{D+}$	Negative ideal distance $\boldsymbol{D-}$	Relative closeness $\boldsymbol{C}$	Ranking
$\mathbf{7.2 \times 7.2}$	0.284	0.266	0.484	2
$\mathbf{7.2 \times 7.6}$	0.272	0.180	0.398	4

$\mathbf{7.2 \times 7.6}$	0.358	0.116	0.245	5
$\mathbf{7.2 \times 7.8}$	0.328	0.129	0.282	4
$\mathbf{7.6 \times 7.8}$	0.243	0.230	0.486	3
$\mathbf{7.8 \times 8.4}$	0.213	0.259	0.549	2

8.4 × 8.4	0.119	0.432	0.784	1

Table 7: *Weights of Entropy Method*

Indicator	Information entropy value e	Weights
C_1	0.9975	6.15%
C_2	0.9982	4.49%
C_3	0.9980	4.96%
C_4	0.9977	5.68%
C_5	0.9960	9.76%
C_6	0.9984	3.98%
C_7	0.9977	5.74%
C_8	0.9960	9.78%
C_9	0.9947	12.93%
C_{10}	0.9992	2.08%
C_{11}	0.9980	4.93%
C_{12}	0.9965	8.59%
C_{13}	0.9990	2.32%
C_{14}	0.9976	5.88%
C_{15}	0.9988	2.88%
C_{16}	0.9960	9.84%

For the comprehensive assessment framework, entropy method is selected to determine the weights for all the 16 indicators, shown in Table 7. After the sum of squares normalization process for the values of six scenarios, the comprehensive positive ideal solution $A+$ and negative ideal solution $A-$ are: $[0.474, 0.557, 0.461, 0.522, 0.486, 0.522, 0.546, 0.551, 0.483, 0.486, 0.508, 0.497, 0.497, 0.555, 0.547, 0.476]$ and $[0.355, 0.318, 0.329, 0.326, 0.324, 0.326, , 0.273, 0.344, 0.302, 0.324, 0.318, 0.331, 0.311, 0.277, 0.328, 0.357]$. Based on the ideal solutions, the results for TOPSIS assessment for flexibility are shown in Table 8.

Table 8: *TOPSIS Results for Flexibility Assessment*

Module Scenario	Positive ideal distance $D+$	Negative ideal distance $D-$	Relative closeness C	Ranking
7.2 × 7.2	0.573	0.526	0.479	2
7.2 × 7.6	0.511	0.364	0.416	4
7.2 × 7.8	0.514	0.291	0.361	6
7.6 × 7.8	0.510	0.373	0.423	3
7.8 × 8.4	0.568	0.381	0.401	5
8.4 × 8.4	0.483	0.580	0.545	1

The relative closeness and ranking of three main criteria and comprehensive flexibility for the six scenarios are summarised in Table 9, where S means the scenarios, the same as Table 8; C means relative closeness; R means ranking; B_1 to B_3 means criteria following Table 1.

Table 9: *TOPSIS Results for Whole Assessment Framework*

S	B_1		B_2		B_3		Flexibility	
	C	R	C	R	C	R	C	R
S1	0.484	2	0.643	1	0.216	6	0.479	2
S2	0.398	4	0.549	2	0.245	5	0.416	4
S3	0.391	5	0.435	3	0.282	4	0.361	6
S4	0.438	3	0.360	5	0.486	3	0.423	3
S5	0.386	6	0.324	6	0.549	2	0.401	5
S6	0.541	1	0.388	4	0.784	1	0.545	1

The rankings are demonstrated in Figure 5. For production, the 7.2×7.2 and 8.4×8.4 grid sizes rank top whereases 7.2×7.8 and 7.8×8.4 have less flexibility in production. For construction, the smallest modular grid size has the biggest flexibility in construction. With the increase of grid size, construction flexibility gradually decreases, but it shows an increasing trend when it reaches the maximum size. The scores for services increase as the grid size enlarges, showing a positive correlation. The highest level of flexibility for both the minimum and maximum grid sizes is observed. However, as the grid size increases, the construction flexibility gradually decreases until it reaches a minimum value, after which it begins to increase. The overall trend of flexibility is similar to that of production. Specifically, flexibility exhibits a pattern of decreasing, increasing, decreasing, and then increasing again.

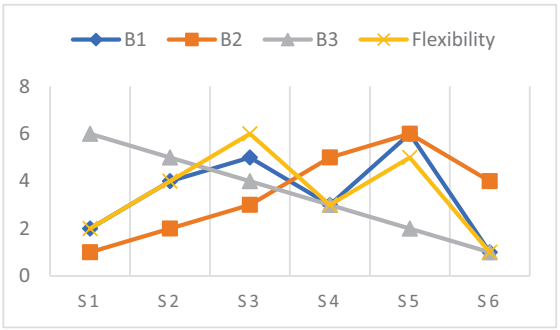

Figure 5: *Ranking for different Scenarios*

5 DISCUSSION AND CONCLUSIONS

This research develops a framework to quantify flexibility by identifying the criteria and indicators selected from the literatures aiming to cover cradle-to-cradle life cycle. Six modular grid sizes are set as the scenarios for comparisons following the net area design guidance of DfE of UK for primary and secondary schools. AHP is utilized to determine the weights of the tree diagram of the

https://doi.org/10.52202/069179-0512

assessment framework and TOPSIS is applied to finalise the value of different modular grid size scenarios. The MCDM results demonstrates that the biggest grid size 8.4×8.4 in this case has the biggest flexibly in production, services and comprehensive flexibility. The reason might be the bigger size provide more potential in layout changing for different functionalities. Modular grid size 7.2×7.2 ranks top in construction flexibility mainly because of the geometry size is easy to assemble. The comprehensive flexibility has the similar trend of production flexibility means the production pre-dominate the overall flexibility performance.

Based on the TOPSIS assessment results, for timber school projects, to achieve the maximum flexibility, module coordination [35] can be operated following the rules adjusted from the general rules :

- Delineation of hierarchy of the space;
- Define the zones for different functions;
- Select the area with demands/potential for flexibility as the reference system;
- Situated the components in different size according to the reference system;
- Choose one module series including the basic, multi- and sub module;
- Coordinate the module according to the function requirements.

Future work would be focusing on the specific workflow of module coordination for flexibility based on the TOPSIS assessment framework by setting 7.2-9m as a range to coordinate the module for maximum flexibility.

World Conference on Timber Engineering Oslo 2023

MONO-MATERIAL TIMBER CONSTRUCTION RE-INVENTION OF PRESS-FIT TIMBER CONSTRUCTIONS

Hans Drexler[1]

ABSTRACT: The paper presents the development of a building system made from solid timber that fulfils the requirements of modern buildings while expanding the design possibilities through re-inventing traditional timber techniques. Press-fit-timber connections, which were the basis of centuries-long building traditions all over the world, can be cost-efficiently used in contemporary buildings using modern manufacturing techniques.
The main goals of the research are:

- Develop a building system with mono-material timber structures (in contrast to hybridization with concrete and steel)
- Optimize the recyclability of building structures: Design to disassemble (on the level of the building and components)
- Improve cost-efficiency by industrial manufacturing methods for mono-material timber constructions.

KEYWORDS: Mono-material timber construction; building system; adaptability; recycling; design to dissemble;

1 INTRODUCTION

Before the advent of industrialization, timber was one of the essential construction materials due to its local availability, easy workability, good load bearing, and overall structural properties. For centuries, carpenters built impressive timber constructions without metal fasteners. Europe and Asia have a wealth of historical examples of timber joints for the widest variety of load cases and construction designs. Multi-story, large, and complex buildings were constructed with purely timber-based methods and only press-fit timber joints.

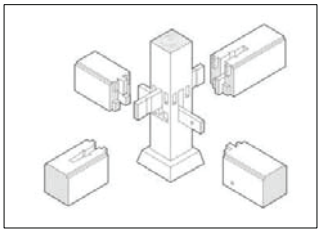

Figure 1: *Yatoi-Hozo-Sashi, three-dimensional joint of the Ashikatame post (main post), graphic: DGJ Architektur, based on Sato Hideo and colleagues [1].*

But this tradition fell into disuse in the wake of industrialization. Not only were such joints – made by highly skilled craftsmen in a time-consuming and thus wage-intensive manner – replaced by cheaper metal fasteners such as nails, screws, and bolts, but even timber itself was displaced as a primary construction material by new materials such as cast iron, steel, and concrete. To this day, these materials are sold at lower prices because they can be produced in higher volumes, and their external costs, especially environmental costs, are left out of the pricing equation. And even though solid timber has many advantages compared to other construction materials. Timber requires less energy than concrete or steel for its production. As a renewable resource, it stores atmospheric carbon during the lifespan of the building. Timber is central in the current discourse on carbon-neutral, energy- and resource-efficient construction [2]. The ecological and economic advantages make mono-material timber systems an interesting alternative for efficient and sustainable buildings.
In order to make the most efficient use of these opportunities, this research operates on two levels. On a first technological level, it offers transferable solutions for the local and the global structure of multistorey residential buildings, which are accompanied by an easy-to-use Excel tool for estimating the dimensions of the primary structural components. On a second architectural level, the research explores how the building system called '*Open Architecture'* [3] can be used to design a wide variety of flexible and adaptable residential buildings. It enables flexible, sustainable, and cost-effective construction with press-fit timber joints that can be easily recycled, and a design that adapts to the respective circumstances without sacrificing design quality and living comfort.

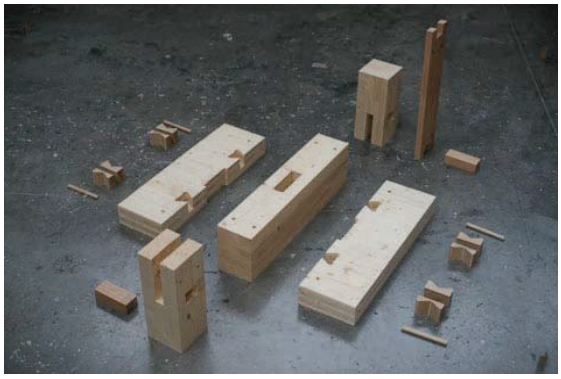
2 PRESS-FIT TIMBER CONSTRUCTION SYSTEM

Thanks to advancements in digital design and production technology, it is now possible with computer-controlled machines to produce perfectly fitting joints economically, regardless of the geometry's complexity.
New computational design and digital fabrication promise to enable different access to traditional construction materials. Digital timber fabrication (CNC-milling machines) allows for the precise and efficient milling of solid timber with very low tolerances. In addition, computational design strategies enable the development of adaptive and integrative design tools with a direct transfer of fabrication data, ultimately opening new potentials for design and production.

In two research projects, *DGJ Architektur* with *Pirmin Jung Ingenieure GmbH* has developed a timber construction system in which the entire load-bearing structure and all joints are press-fit without metal connectors [4]. Part of the research is a complete set of construction details so that the system fulfils today's regulatory requirements regarding fire protection, acoustic insulation, structural calculation, and industrial construction standards.



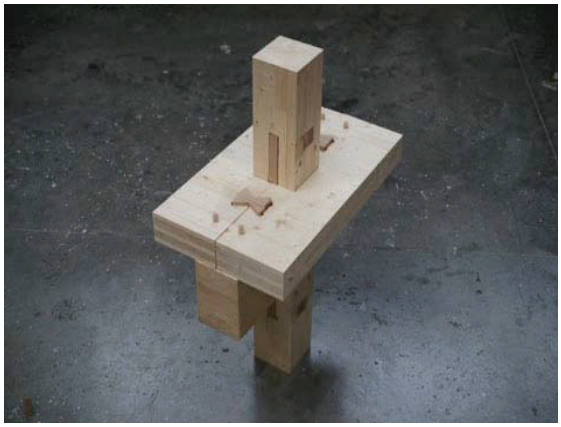


Figure 2 and 3: *Prototype of the construction detail: Intersection of column, beam, and ceiling, Photograph: Hans Drexler, DGJ Architektur, 2018.*

The construction system is based on readily available materials, technologies, and processes at all levels so that the system can be applied by all larger carpentry companies. Standardized materials, such as structural timber and CLT, can be used. The structural analysis of the load-bearing structure and the joints are based on the current Eurocode; in principle, any engineer can calculate and dimension them.
Thus, the innovative part is not newly developed materials or machines but the more intelligent and smart use of existing methods, technologies and materials and combining them into a system.
As part of our research project [4] an Excel-based design tool was developed that enables our system to be pre-dimensioned and costs and performance to be evaluated. It allows the designer to estimate the inputs (timber volume, costs) and performance (living space, efficiency (gross floor area/living space). The joints are designed using modern, three-dimensional CAD systems widely used by architects and engineers. Fabrication data can be generated in the design phase with little extra effort. The system, including press-fit joints, can be produced with widely available timber CNC milling machinery. In this way, traditional knowledge is translated into contemporary building technologies and materials.

3 STRUCTURAL SYSTEMS

Different structural systems for the building system were explored in developing the load-bearing structure: skeleton, hybrid, or solid timber. An essential part of the research is concerned with describing and evaluating the advantages and disadvantages of the various structural systems. A key parameter is the amount of timber required for the load-bearing systems. Other parameters that were examined included the usability and flexibility of the building, but also fire protection, acoustic insulation, and thermal construction physics as mentioned above.

3.1 SKELETON CONSTRUCTION

Timber – produced from tree trunks – is initially a linear, rod-shaped construction material, which lends itself to building skeletal constructions [5]. Given, for example, the high prices for timber and difficulties in the supply in 2022, the structure's efficiency is an important criterion, which was investigated by comparing different articulations of the building system. For non-load-bearing walls and facades, timber-panel and timber-frame constructions are used, which can be produced inexpensively, using less timber.

Another advantage of the skeleton system is flexibility. Taking Steven Groák's definition of flexible housing [6], i.e., a physically and structurally changeable structure, the skeleton construction offers the best opportunities to create flexible housing by separating space creation and load-bearing functions. As a result, the load-bearing skeleton allows both external and internal walls to be moved and altered. If one considers the rapid changes in lifestyles, resulting social structures and demographics (e.g., the declining number of families with the typical, traditional family structure and shrinking household

https://doi.org/10.52202/069179-0513

sizes), then inflexible housing layouts are not sustainable in the long term.

3.2 HYBRID SOLUTIONS: COMBINING SKELETON AND SOLID CONSTRUCTION

In the mid-1990s, a solid timber construction known as cross-laminated timber (CLT) came onto the market, which offered key advantages, especially for taller buildings, because solid wall panels perform better in terms of vertical load transfer and cross bracing of the global load-bearing structure. When developing this press-fit construction system, a combination of the advantages of the two construction methods was explored: parts of the skeleton structure are replaced by load bearing and bracing cross-laminated timber elements, which allow for an efficient transfer of the horizontal loads. Thus, a part of the walls enclosing the bathrooms, which are in the same vertical line on all floors, and a part of the party walls are designed to replace posts as load-bearing wall segments. The horizontal bracing is achieved by means of bracing walls of solid timber (cross-laminated timber) that are connected to the posts by means of tenons.

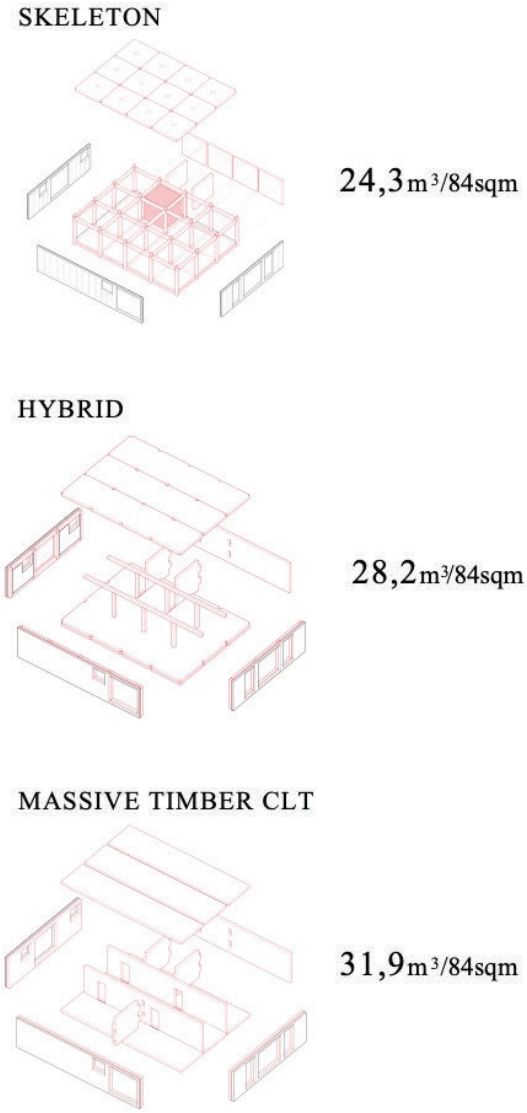

Figure 4: *Axonometric drawings of structure / Comparison of wood volume necessary in different construction methods for a typical apartment of 84 sqm. Designed by DGJ Architektur, Illustration: DGJ Architektur.*

Figure 4 shows a comparison of the consumption of wood in different construction methods. For the hybrid construction, consisting in part of solid walls, the amount of timber used in Case-Study 1 (*Collegium Academicum*), with a load-bearing timber skeleton, a bracing core, and ceilings of cross-laminated timber (CLT), totals 28,2 cubic-meter or 14% more timber than the skeleton construction.

3.3 SOLID TIMBER CONSTRUCTIONS

During the development of the system, it emerged that the introduction of cross-laminated timber resulted in a construction that combined aspects of a skeleton construction (i.e., only linear load-bearing elements) with aspects of a solid construction for ceilings and bracing walls. This led to redundancies at the intersections. The

https://doi.org/10.52202/069179-0513

bracing wall could take all loads vertically and thus replace not only the column but the beam as well. Thus, based on the grid, this system could be implemented as a solid timber construction. The disadvantage of solid interior walls is their low adjustability.
The solid construction for ceilings and bracing walls is more material-intensive, although the strength of the individual walls can be reduced by the uniform load transfer.

3.4 LOCAL STRUCTURES AND JOINTS

Given the wide variety of traditional timber joints such as tenon and mortise, lap joints, dovetails etc., the research examined which joints can easily be applied to modern production in real-life practice. Here two different approaches were examined and compared: integrated or differentiated joints.
The integrated joints are cut so that the elements fit into the geometric space of the adjacent elements and guarantee a press-fit joint via the interlocking of the elements' geometries. The initial idea of our construction approach was to produce geometrical locking and press-fit joints when cutting and sizing the elements, thus making fasteners unnecessary. Our reference point was a Japanese "Yatoi-Hozo-Sashi" joint, which fits two main beams into the geometric space of the post to form beam-to-post joints, but also forms a lapped end-to-end connection from beam to the beam by means of rod tenons, which are secured in place with wedges or cross tenons. The load of the beams is transferred not only via the rod tenons but, above all, via a parapet from beam to post, into which the beam is precisely fit. The principle of this joint is that the geometric spaces overlap, and the members are joined with comparably complex geometries.
Differentiated joints separate the geometric spaces of the components, which are then connected via secondary elements.

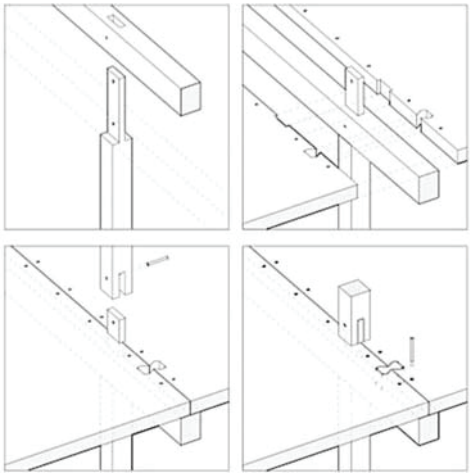

Figure 5: *DGJ Architektur, 3D model of the construction system's beam to post joints, DGJ, 2016.*

The combination of timber components is an advantage of the differentiated local system. The solid ceiling elements are joined to the post with dovetail joints made from hardwood. This type of joint is complicated to build on-site but allows for the transfer of shearing, compressive, and tensile forces. Beech dowels are used for the shearing forces between the ceilings and the beams. The final detail, the vertical connection between the two columns above and below the ceiling, is produced from hardwood (beech wood LVL), which allows for the transfer of the vertical forces through a smaller cross-section.
In this context, discussing the weakening of the supporting beams by such geometric joints is interesting. At first glance, the beams and columns sections increase the timber volume necessary for structural performance. But it became apparent during the development that there is a system synergy between fire protection and structural performance. When measuring the load-bearing capacity of the beams under fire conditions, the entire timber volume is not applied to the load transfer. Still, it is assumed in the case of fire that the outer layer of the beam burns away slowly, ensuring the remaining beam's stability for the required time. In the case of the press-fit joints, this layer is also part of the structural elements used for the joints, which serve as an integrated fire-resistant layer.
In the first case study (see Case Study 1: *Collegium Academicum*), the connections between posts and beams and beams and ceilings were increasingly simplified during the design process, i.e., separated into their own geometric spaces. Vertically, the forces are achieved by lapping the elements, which are secured in position with beech wood dowels. The stable plate effect of the ceiling elements is achieved by lap-joining ceiling elements with dovetail joints. This differentiated construction has two advantages: first, it makes the timber trimming process for the individual elements easier because the elements lie above and next to each other. The geometry of the components is more straightforward, and the production is cheaper. Second, the differentiated construction of the components allows the dimensional tolerance of the individual parts to be compensated across the load-bearing structure, as the horizontal accuracy of the fit is initially not decisive for the load transfer. The vertical inaccuracy can be compensated locally. The disadvantage of joining in this way is that the connections with beech wood dowels can only be released by drilling out the dowels, which makes dismantling more difficult.

3.5 DESIGN TO DISSASEMBLE

An essential aim of the research was to develop a mono-material construction system based on renewable materials. Since all parts of the structure are made from timber, the system is also easy to dismantle later. The disadvantage is that putting it together requires high precision and leaves little room for dimensional tolerance.

In the real-life buildings so far designed and studied, the idea of mono-material timber construction is only applied to the primary structure of the building. Therefore, secondary systems for facades and fit-outs would still use screws and other metal fasteners. Even though comparable automated methods for fixing panels using timber nails are readily available, the necessary

https://doi.org/10.52202/069179-0513

certificates are not. Also, timber nails do not offer the same performance as metal screws.

Figure 6: *Timber Prototype House, Photographs: Thomas Mueller, 2018.*

In a small-scale prototype building, the idea of mono-material timber construction was demonstrated comprehensively: The '*Timber Prototype House'*, which is part of the international building exhibition IBA Thüringen, is made from timber (and glass for the windows), joined by press-fit timber construction. The building still fulfils all technical requirements, including thermal insulation [5]. But the design and production processes are still too complicated and costly to allow for use in affordable buildings.

4 RESEARCH BY DESIGN

The development of *'Open Architecture'* [3] as a building system was as much about exploring the architectural potential as the technical solutions. A series of case studies were used to incrementally improve the building system, using a set of criteria for sustainability, efficiency, and usability. The system was developed in 2015 through several 15 case studies [3]. During the research, the development of the system (planning and design methodology) was combined with analysis (evaluation and optimization). This has brought to light an essential aspect of explorative applied construction research: Design has both creative and analytical aspects, which interact with each other in iterations and recursions. In the day-to-day designing and planning process, iterations, parameters, criteria, and decision paths are seldom explicit, and as such, they are not transparent. They take place in numerous sketches, drawings, models, and discussions. In the research and development project, the analytical parts are made explicit and operative, thus complementing the design. From these analyses, tools were developed with which the construction system can be adapted to different locations and functions. In developing this system, the levels of research and parameters for a given object are evaluated and optimized.

https://doi.org/10.52202/069179-0513

The case studies are vehicles and research objects at the same time. The transferability and usability of the construction system are identified. Through the systematic research of the application parameters, load cases and characteristics, an estimate of the dimensions of the structure can be calculated for each application. To study the possibilities in terms of building typology, we first defined a series of design parameters, the permutations, which can be expressed as a matrix. The matrix is a parametric design tool for the performance and dimensions of the system, depending on the building-typological characteristics of the respective permutation. In the matrix, all three analysis levels – design, structure, and performance – are interlinked and influence each other.

4.1 CASE STUDY 1: *COLLEGIUM ACADEMICUM*

Animation: https://vimeo.com/459124025

Figure 10: *Case Study 1: Collegium Academicum in Heidelberg, Germany, designed by DGJ Architektur, Photographs: Copyright Thilo Ross Urh. Nr. 4026999.*

One of the first case studies was the *Collegium Academicum, a* project of the International Building Exhibition (IBA Heidelberg). It is a student residence with 176 units. A new housing typology was developed, which enables residents to change and adapt their apartments to various spatial configurations.

Figure 11: *Construction detail, Collegium Academicum. DGJ Architektur, and photograph: Hans Drexler, DGJ Architektur, 2018.*

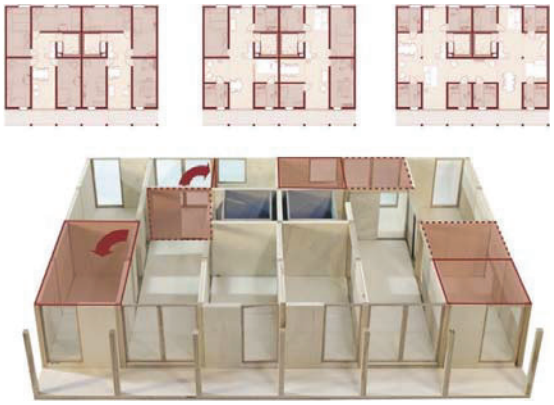

Figure 12: *Three possible floor plan configurations (top), physical model of the construction system, model scale 1:25, DGJ Architektur, and photograph: Hans Drexler, DGJ Architektur, 2018.*

The residents can quickly and easily reposition partition walls within the apartments, thereby changing the size of the rooms. The individual rooms consist of two sections: a core area of seven square meters and a flexible area of seven square meters, which can be used as personal space or be part of the apartment's shared space. Depending on individual preferences, the flexible area can remain completely open, partially separated by dividing elements (table, shelving), or partitioned off entirely by placing the wall between the core area and the flexible zone. Thus the building becomes an adaptable space where the individual inhabitants and housing communities can reconfigure and negotiate the space requirements.

The project is part of the program “Variowohnungen” of the German Federal Institute for Research on Building, Urban Affairs and Spatial Development (BBSR) in the Federal Office for Building and Regional Planning (BBR) and is additionally funded by the program “Holz Innovativ” of the state of Baden-Württemberg. “Holz Innovativ” is financed with the European Regional Development Fund (ERDF) funds.

Figure 13: *Model apartment, Collegium Academicum. DGJ Architektur, Photographs: Copyright Thilo Ross Urh. Nr. 4026999, Source: DGJ Architektur.*

https://doi.org/10.52202/069179-0513

4.2 CASE STUDY 2: *GEMEINSAM SUFFIZIENT LEBEN* (LIVING TOGETHER SUFFICIENTLY)

Figure 14: *'living together sufficiently', physical model of the construction system, model scale 1:50, DGJ Architektur, and photograph: Hans Drexler, DGJ Architektur, 2016.*

This building is designed for a small housing cooperative: a group of families and individuals who asked for a variety of apartment types and sizes within a comparatively small building. The design offers a wide range of different apartments that are suitable for families, senior citizens, couples, and individuals. However, due to the basic concept (*'living together sufficiently'*), the individual rooms are relatively small for the respective use and therefore offer little scope for other uses. The common areas and central facilities offer an advantage for long-term usability and the adaptability of the building. Different divisions and apartments on the floors can be realized, from a small two-room studio to a five-room family apartment. The building is planned as a skeleton structure with a stiffening core. The concentration of bracing around the access gives a high degree of freedom for the design of the floor plans. The flexible but clearly structured system has proven to be a suitable means of planning. The structure allows for individual requests and long-term customization without jeopardizing the integrity of the overall system.

Several types of apartments for different living needs were developed for dialogue with the living group. Ultimately, no variant is implemented similarly but redesigned in dialogue with future users. The large 4-room apartment was redesigned into a 5-room apartment, which was chosen together with the smaller 3-room apartment on almost all floors.

Figure 15: *Case Study 2: 'sufficiently living together', apartment layouts, graphics DGJ Architektur, 2016.*

The square grid permits different apartment layouts adapted to individual needs and wishes and flexibly combined. At the same time, the layouts of the apartments remain flexible/adjustable for future changes.

4.3 CASE STUDY 3: ARRIVAL CITY 4.0

Animation: https://vimeo.com/240369724/0d8d1520a6

Figure 16: *Case Study 3: Arrival City 4.0, model and photograph by DGJ Architektur, 2016.*

Arrival City 4.0 was designed to respond to the so-called refugee crisis at the end of 2015 in Europe. The project was intended to demonstrate how spatial and social structures can contribute to the creation of affordable housing and integration. The building system '*Open Architecture*' [3] was used to provide people not only a

place to live in the short term but also to give them a long-term perspective. *Arrival City 4.0* is an expandable design representing a general low-investment approach to housing shortages. The primary structure and a basic building envelope made from polycarbonate panels can be built with minimal investment in a short period of time. This basic shelter would gradually be transformed into a permanent building by the inhabitants by adding internal walls, technical systems, and more advanced façade panels.

Figure 17: *Case Study 1: Arrival City 4.0, model and photograph by DGJ Architektur, 2016.*

5 FINDINGS: CHALLENGES AND OPPORTUNITIES FOR PRESS-FIT TIMBER CONSTRUCTION

5.1 RE-USE AND RE-CYCLING

Due to the widespread use of non-renewable construction materials and given that most construction materials are rarely reused or recycled (only downcycled), the construction industry is responsible for a large share of waste that is generated today. This building practice also results in the high use of resources. Sustainable buildings must be built differently: The individual construction elements should be joined to be taken apart again. The shearing layers of construction should be joined to maintain, repair, or replace individually since they have different life spans.

For the primary structure, the developed mono-material timber constructions offer an alternative that can be reused and recycled into engineered wood products, such as OSB boards. The constructions' simplicity promotes sorting, an essential prerequisite for recycling materials.

The system is designed to allow components and materials to be dismantled and reused, but implementation is limited to the primary construction in the first use cases. Looking at the building, further potential for recycling needs to be raised. The ability to be dismantled, the reuse of components and the recycling of building materials are essential criteria for a holistically sustainable building design. Ideally, the buildings of the future will consist of components and materials that can either be reused as such elsewhere or that can be easily broken down into components suitable for reuse. The principles of circular construction should be applied systematically at all construction levels. Optimizing the construction system regarding a circular economy and closed material cycles is the most crucial technical optimization that must be addressed within the system. Even more, than in conventional construction, the system presented is suitable for meeting this requirement regarding flexibility and the construction hierarchy. These include in particular:

- Hierarchy of construction according to life expectancy and subsystems.
- Simple, removable, and self-explanatory constructions that favor dismantling.
- Use of renewable building materials.
- Use of materials that can be easily recycled.
- If possible, define parts and components that can be reused as a whole unit.

More precise planning and analysis of the assembly and disassembly processes and the subsequent recycling of the disassembled parts are required here. Analysis, evaluation, and optimization of all building materials installed in the system are necessary.

5.2 HIERARCHY OF CONSTRUCTION

The primary structure determines the basic structure of the building to a large extent. In today's construction, where a whole range of requirements and technology must be met, many other components and layers are added to this primary construction. The question of how these are structured and interconnected has received little attention from research. For example, no terms and definitions are introduced for the different hierarchies, which can be used to distinguish between different types of construction. In the following, such terms are developed to be able to categorize the other construction methods.

Within the construction, subsystems can be identified that are analogous to the 'Shearing Layers of Change' [7]:

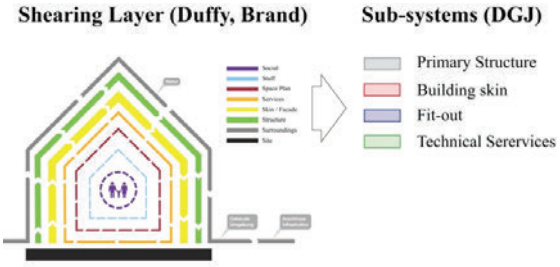

Figure 18: *Shearing Layers introduced by Frank Duffy, further elaborated by Stewart Brand [7], sub-systems for constructions graphics by DGJ Architektur, 2020.*

Structure: All primarily load-bearing and stiffening components of the skeleton structure fall into the subsystem of the supporting system.

Façade / building envelope: The subsystem of the building envelope includes all structural elements that form the primary external space closure. The corresponding components fulfil the basic functions of fire protection, heat, and weather protection.

https://doi.org/10.52202/069179-0513

Fit-out: Both fundamental components and individual component layers, which are necessary to meet the requirements for interior room closures, can be assigned to the subsystem of the interior design (e.g., for apartment partition walls and floor constructions).
Technical building equipment: Technical systems form a separate subsystem since interchangeability and flexibility should be guaranteed to an exceptionally high degree.

The definition of the subsystems was developed in the project to analyse buildings. The four subsystems can be viewed on three hierarchical levels because the interior and building services subsystems are arranged on the same hierarchical level [8]. Regarding the separability of materials, efficient assembly and the dismantling of components, a strategy for structuring the system should be selected that provides for a clear hierarchical structure in constructive-functional and temporal dimensions as well as the flexibility of the components. As part of the research, a series of constructions were developed and analysed, allowing the identification of categories of timber constructions. Depending on the degree of differentiation and/or overlap between the sub-systems, the constructions are more or less flexible and/or suitable for recycling.

The definition of the hierarchical levels is primarily linked to the expected life span of the individual materials and components. On the one hand, this should ensure flexibility in the assembly process since the components can be prefabricated together as larger modules or installed successively on-site. The system should, therefore, also be adaptable for project-specific circumstances and restrictions (transport, accessibility of the property, possibility of prefabrication, etc.). On the other hand, the service life is crucial, especially the ability to overhaul, exchange, convert, dismantle, and recycle the components. The clear separation of the hierarchical levels should, therefore, also be reflected physically, i.e., concretely in the components' constructive connection and geometric arrangement, to ensure that they can be separated according to type. For the assessment, the individual subsystems are assessed separately regarding accessibility and the possibility of adaptation.

5.3 SUSTAINABILITY

As a domestic, renewable resource, timber is the most sustainable construction material available since it is the only construction material that can be used for all construction tasks in large volumes and is not based on limited resources (fossil fuels, sand, iron ore …). Thanks to Germany's established, sustainable forestry industry, timber can serve indefinitely as a renewable raw material. Model computations indicate that the timber needed for the country's total construction activity can be covered by just one-third of its annual timber output [9]. Using timber as a renewable resource, our construction system has ecological advantages; improving the reusability of the construction elements can increase these advantages even further. The production and processing of timber require significantly less primary energy. Wood absorbs carbon dioxide from the atmosphere and thus stores it over the lifetime of the building. In the hybrid construction variant, the reduction of CO^2 emissions by wood is partially offset by high emissions related to secondary materials, like cement or steel.

5.4 COST EFFICIENCY

Regarding commercial viability, timber-only joints may have advantages over constructions using metal fasteners. The fasteners by themselves are high-quality and expensive construction elements, especially given the current high prices for metals and energy. Moreover, mounting the fasteners represents a considerable expenditure of time in the production and assembly at the construction site. When processing times are minimized, costs are also reduced. The high complexity of timber-trimming processes means longer processing times at the milling machine but reduced time for fasteners on site.
The building system's first real-life applications did not show a significantly lower price than conventional timber constructions. This could be because, in both buildings, the manufacturer used the press-fit structure for the first time and could not calculate prices more aggressively.

5.5 PRECISION

Press-fit joints require a high degree of precision in production and assembly. Especially in the case of larger buildings, where imprecision in construction elements and their fitting can add up, joining with press-fit elements is a challenge. In both real-life applications, the construction on site was faster than expected due to the higher precision achieved with the system. Within the press-fit construction, building components fit together as 3D puzzle, constantly eliminating impressions in the assembly process.

5.6 SOUND PROOFING

Timber constructions, in general, are comparatively lightweight and can, therefore, absorb sounds less efficiently than heavier materials such as concrete or bricks.
In press-fit timber constructions, an additional conflict of objectives is found: The press-fit connections should be as tight as possible for structural integrity. For soundproofing, decoupling of the elements would be preferable when building components continue through sound barriers, such as ceilings or walls between apartments. Two strategies can be used to minimize the problem: decoupling and stiffening. The sound transmission is minimal when the construction is decoupled using vibration isolation (high-density foam materials). For example, partition walls between apartments are designed as double walls and decoupled. The ceilings are equipped with sound insulation, which decouples them from the primary structure and the rooms below. Beams and load-bearing walls must be individually assessed as secondary noise transmission channels. Here the strategy was to stiffen the connection between the column and the beams, as well as between the walls and the ceilings, respectively, to a point where all components acted as a unified system. Due to the

increased mass, they absorb more sound energy, which will not be transmitted.

5.7 FIRE PROTECTION

Given the combustibility of the primary construction material, special care must be given to fire protection. In the simplest scenario, timber can protect itself from combustion. Timber forms a relatively stable charcoal coating in a fire, which in turn delays full destruction by fire. This effect is included in the dimensioning of the construction elements for fire conditions, in that the beams are sized larger than what they need to be to meet their load capacity requirements so that in case of fire, the remaining beams assure the stability of the building for the prescribed amount of time. Press-fit joints can, as a rule, be considered homogenous construction elements. In practice, however, care should be given that the joints are so tight that fire cannot penetrate them.

Supporting and bracing parts of the structure are generally not reached by a fire for five to ten minutes due to the low combustibility of a closed timber surface. In most cases, fires are fueled initially by furniture and fixtures so that houses have been evacuated by the time the fire reaches the supporting and bracing elements. This, in turn, means that the primary fire protection goal would be met. If added fire protection of the supporting and bracing elements is required, e.g. because it is prescribed by regulations and/or due to increased evacuation risks (higher buildings, more complex layout), the primary timber load-bearing structure can be additionally protected from fire by encasing it with cladding so that the combustible elements can be protected from the fire for a defined period of time (30 min., 60 min., 90 min.).

6 CONCLUSIONS AND OUTLOOK

6.1 CONCLUSIONS

The building system '*Open Architecture'* has so far been used for three residential buildings in Germany, which are constructed in Frankfurt, Heidelberg, and Mannheim. This indicates that the system fulfils all technical and legal requirements.

Given the technological advances in automated cutting and milling of timber, mono-material timber construction is a plausible solution for solving the problem of higher costs and carbon emissions caused by metal components and improving the recycling potential of timber buildings.

6.2 OUTLOOK: SIMPLICITY AS DESIGN PARAMETER

Mono-material timber construction's high ecological and economic potential needs a comprehensive approach. Most parts and all sub-systems of the building should be mono-material and/or designed to disassemble. Given the many requirements a contemporary building must fulfil, like structural performance, insulation against heat and cold, fire protection, soundproofing and many others, most building designs tend to translate each into discrete layers or components. This strategy adds to an enormous complexity in the construction, making the design and building process challenging and re-use or recycling almost impossible. To make extensive use of the simple and effective idea of press-fit timber construction, the complexity of the building construction must be dramatically reduced. At the same time, the hierarchy of the constructions, according to life span and functional sub-systems (or shearing layers), can be used as a design strategy.

World Conference on Timber Engineering Oslo 2023

A DESIGN FRAMEWORK FOR TIMBER BUILDING SYSTEMS

Marius Nygaard[1], Kjetil Nordby[2]

ABSTRACT: The paper proposes a design framework as a means to invigorate considerations of ecological, social and economic sustainability in the development of industrialized timber building. The framework describes principles, participants, processes and tools. Central requirements are (1) open innovation, (2) user / inhabitant participation and influence, (3) simplified quality control and production of code compliant design documentation, (4) adaptability, (5) integration of self-build, (6) preparedness for material hybridity, and finally (7) circularity of materials, components and buildings. To test the relevance and design implications of these imperatives, a diagrammatic study of a four storey block of flats was carried out. The example shows that a high degree of adaptability can be achieved while maintaining openness for integration of a wide variety of light-weight timber structures. In turn, this provides options for the size and weight of elements and components. They can be adapted to different strategies for off-site production and on-site assembly. The design framework will impact the patterns of information and influence in design and construction processes. Sharing of solutions and experience will speed up the innovation needed to meet the sustainability goals of the building industry.

KEYWORDS: Timber, building systems, circular building, industrialized building

1 BACKGROUND

A holistic understanding of future building systems is vital to meet the UN sustainability goals. Unfortunately, architect-designed building systems tend to be beautiful but with limited spread. [1], [2]. One reason is that they focus on detailed design of key components instead of defining the boundaries and rules of the building system itself.

Modern building systems face a series of new challenges. For instance (A) the sorting, evaluation, and reuse of parts from used (demolished) structures must be facilitated in the system. (B) The components and subsystems or "layers" [3] of future buildings must be designed for variable cycles of construction, maintenance, exchange, disassembly and reassembly. And (C) user participation and self-build options should be integregrated, as they may affect the durability, costs and availability of housing.

N. John Habraken´s work on inhabitant participation in the early 1960s, and Norwegian examples of studies of building systems in the 1970s [4] have gained new relevance reflected in recent open building initiatives [5].

Against this backdrop we propose a design framework for timber building systems supporting open innovation. We define key requirements common to all building systems, and test their impact through a diagrammatic exploration of a system for lightweight, wooden buildings.

As example we have chosen a four storey timber block of flats. The advantages of low production emissions and sustained carbon storage in timber buildings are well documented [6]. Low-rise buildings in high-density urban patterns represent the biggest potential for increased use of timber. Lenient codes, especially up to 4 stories, make this building category a low-hanging fruit for innovators. Challenges regarding the future availability and cost of sustainably harvested timber also favour the efficient, light-frame structures suited for low-rise buildings.

2 A DESIGN FRAMEWORK FOR TIMBER BUILDING SYSTEMS

A design framework for building systems is the overarching structure that definine the key properties of the subsystems and components constituting a finished building. This comprise of the cyclic processes of design, production, use, disassembly, reuse, and the organizational structure of maintaining the system itself through open innovation. We propose the following key properties as useful for defining an effective design framework for building systems.

2.1 OPEN INNOVATION

To make the design framework expand and evolve according to the needs of users and industries we propose applying an open innovation process. Ollila & Yström (2016) [7] outline how a focus on engaging the participants of a community is central in open innovation projects. Because of this we suggest a focus on development of open-source design resources shared

[1] Marius Nygaard, The Oslo School of Architecture and Design (AHO), marius.nygaard@aho.no

[2] Kjetil Nordby, The Oslo School of Architecture and Design (AHO), kjetil.nordby@aho.no

https://doi.org/10.52202/069179-0514

under open licences such as creative commons [8] Open-source development is an ongoing process dependent on a system that is both used and expanded through the contributions of a community. In the case of a building design framework, we will emphasize the need to simplify use through making the design resources available as easy too use tools, such as integrations in common CAD applications or in emerging web based systems. The latter is crucial since online systems can better enable participants to access, discuss and add contributions to the system.

2.2 USER / INHABITANT CENTERED

Recent research (Groba 2021) [9] shows that user involvement may clarify architectural strategies that increase the understanding and appreciation and thus the durability of timber buildings. This also applies to the programming of private and common areas. The building design framework must define roles, interaction and output for the design process. It also needs to provide design resources such as tools and guidelines that are adapted to the requirements both of the future inhabitants and the participating architects, engineers and builders. All aspects can be supported by applying human centered desing processes such as ISO 9241-210:2019 [10]. The upper part of Figure 1, shows the outline of the design framework and its development through user-centered and interdisciplinary design processes.

2.3 SIMPLIFIED QUALITY CONTROL AND CLASSIFICATION

The design framework must give immediate access to qualified competence and certified products and solutions. Environmental, planning and building legislation, together with building codes, standards, and certifications constitute a regulatory control and information system for the building industry. It aims to secure democratic processes and reduce risk of damage to people, property or environment. However, its complexity has grown into an obstacle for overview and participation by users of buildings. In Figure 1, the control and information system is visualized as a table of information that has to be filled in to initiate and finalize each step in a building process. At the end of a building´s lifecycle, the system should enable tracing of all subsystem and component properties that are relevant for reuse. This is presently far from being implemented.

The design framework must contribute to information systems that support cicularity. It will harvest information from each production step for relevant materials, products and buildings, and integrate it in user / inhabitant - centered design processes. The overview in Figure 1 both of the regulatory system and the production of materials and construction of buildings must inform the processes and tools of the design framework.

In Norway, SINTEF / Byggforsk´s Building Research Design Guides [11] provide comprehensive and updated input to a design framwork for timber building systems. They are supplemented by SINTEF Technical Approval (TG) of building systems, modules and components, which is coordinated with European standards, marks and certification systems. Other product databases together with Environmental Product Declarations (EPDs) and building classification systems (e.g. BREEAM-NOR) offer important additional information. For Technical Approvals, not all data are open source, and several databases require subscription and payment for access. A systematic overview is required to optimize data access and exchange between the design framework and other sources. Sharing of information is essential. Open catalogues of design solutions may be an integrated part of the design framework, or maintained by the associated architects, consultants and builders. Combinations may also be developed.

Norwegian and EU codes and directives for qualification of architects and other design and construction professionals must be integrated in the recruitment of participants in the design framework.

2.4 ADAPTABILITY

The building system must be adaptable to local conditions. In Norway, this means a variety of climate zones and prospects of a warmer, wetter and wilder future. Topography and biodiversity, together with building heritage and urban patterns, also demand adaptabilty of building systems. A potential for density is necessary to limit land use and emissons related to transport. Many of these properties are embedded in timber building traditions, but they must be rediscovered and reinterpreted.

User needs will change according to the inhabitants´ life situation and with changes of residents. Adaptability of the dwellings is therefore essential. The spaces should be general, and the internal walls easily movable to facilitate refurbishment. During a buildings´s lifecycle, integration and separation of dwellings may vary, and this must be part of the system design. Expandability of dwellings is associated with detached, semidetached and terraced housing, but should also be considered in low-rise, multistory buildings.

Adaptability impacts the choice of structural systems, their span widths and the solutions for noise and fire protection. Moving or exchanging parts requires easy access to structurally and functionally independent subsystems and components. This affects the design of joints and details. In turn, these choices have implications for the readability of the building system and its architectural character and qualities. Clarification of these implications must be integrated in the design framework.

2.5 INTEGRATION OF SELF-BUILD

A user-centered design process based on open innovation will strengthen the inhabitants´ knowledge about the

https://doi.org/10.52202/069179-0514

buildings. It will prepare active participation in changes and maintenance. It will counteract the present loss of contact with construction, and also of mastering and appreciation of practical skills. Low-cost laser-based and magnetic instruments for measurement and detection improve precision in traditional do-it-yourself work. Better screws and multifunctional, loadable electric tools also push the limits for self-build. By integrating builders and craftsmen in the design processs, new divisions of labour and responsibility may be developed without sacrificing quality.

The adaption described above is not only dependent on access to and exchangeability of parts, but also on the size and weight of the components. When it comes to prefabrication of light-weight, multistory timber buildings in Norway, there is presently (spring 2023) a trend towards larger floor and façade elements (8 meters long and 3 storeys high), which means speedier montage [12]. At the same time, robots are being developed for operations within the heights and spatial constraints typical of multistory timber housing (Tekna 2018) [13]. This may represent an area of innovation where manual construction assisted by lifting tables and hoists gradually may include robots (Figure.1). It will also be a robust production environment which may backtrack to traditional methods if scarcity of money or high-tech components should occur. Small structural members and building elements expand the possibilities of self-build also of multistory buildings. They may be supplied by a large number of diverse producers. Small components reduce the dependency on transport by ship, train or heavy trucks, and montage by tower cranes. This also contributes to economic and logistic robustness. Division into small (demountable) components does not exclude larger assemblies to rationalize the initial on-site construction.

2.6 PREPARED FOR MATERIAL HYBRIDITY

We have recently experienced that pandemics, wars and blocking of shipping routes may disrupt supply chains. Wood-based building systems must therefore be prepared to include other materials. For timber, beetle attacks and climate-induced droughts, storms and wildfires may be more acute threats. They remind us that optimal use of timber in many buildings should be the aim, rather than maximized use of the same resources in fewer projects.

The distribution of emissions among the different building subsystems is important when combinations of materials are considered. Column and beam structures account for a small part of material-related emissions compared to floors and external walls. Thus converting to a steel skeleton will have minor effects. The slimmer steel columns and beams are easier to integrate in wall and floor constructions. Steel joints and details may be better suited for future disassembly and reuse than screws or wood-only connections (Vandkunsten Open source 2021) [14]. To limit the emissions from weight-increasing tiles in the large floor areas, using clay instead of concrete may be beneficial.

2.7 DESIGNED FOR CIRCULARITY

The adaption of dwellings to the inhabitants should be facilitated by reusable components and materials. Circularity starts inside a dwelling and continues at the end of the building´s service life. For each component, the size, geometry, robustness and integrity of form and function must be balanced against adaptability to new needs and preferences, both of the existing habitants and and future constructors and users of the next building. The next building should be designed to utilize a variety of materials inherited from donors in good shape.

In an environmental perspective, the slowing down of material cycles in buildings contribute to increased carbon storage. At the same time, climate change may impose threats to the long-term safety of building sites. Design for circularity also means preparedness for moving buildings instead of deserting or demolishing them.

3 EXPLORATION OF A SYSTEM EXAMPLE

To test the relevance and design implications of the design framework, we have applied it on a project example. A four storey block of flats was chosen as a case. As emphasized above, this is a large building category where timber is well suited. Low emissions related to production of sustainably harvested timber materials is a framework condition for the study. Figure 2 and 3 give an overview of the system example explored below.

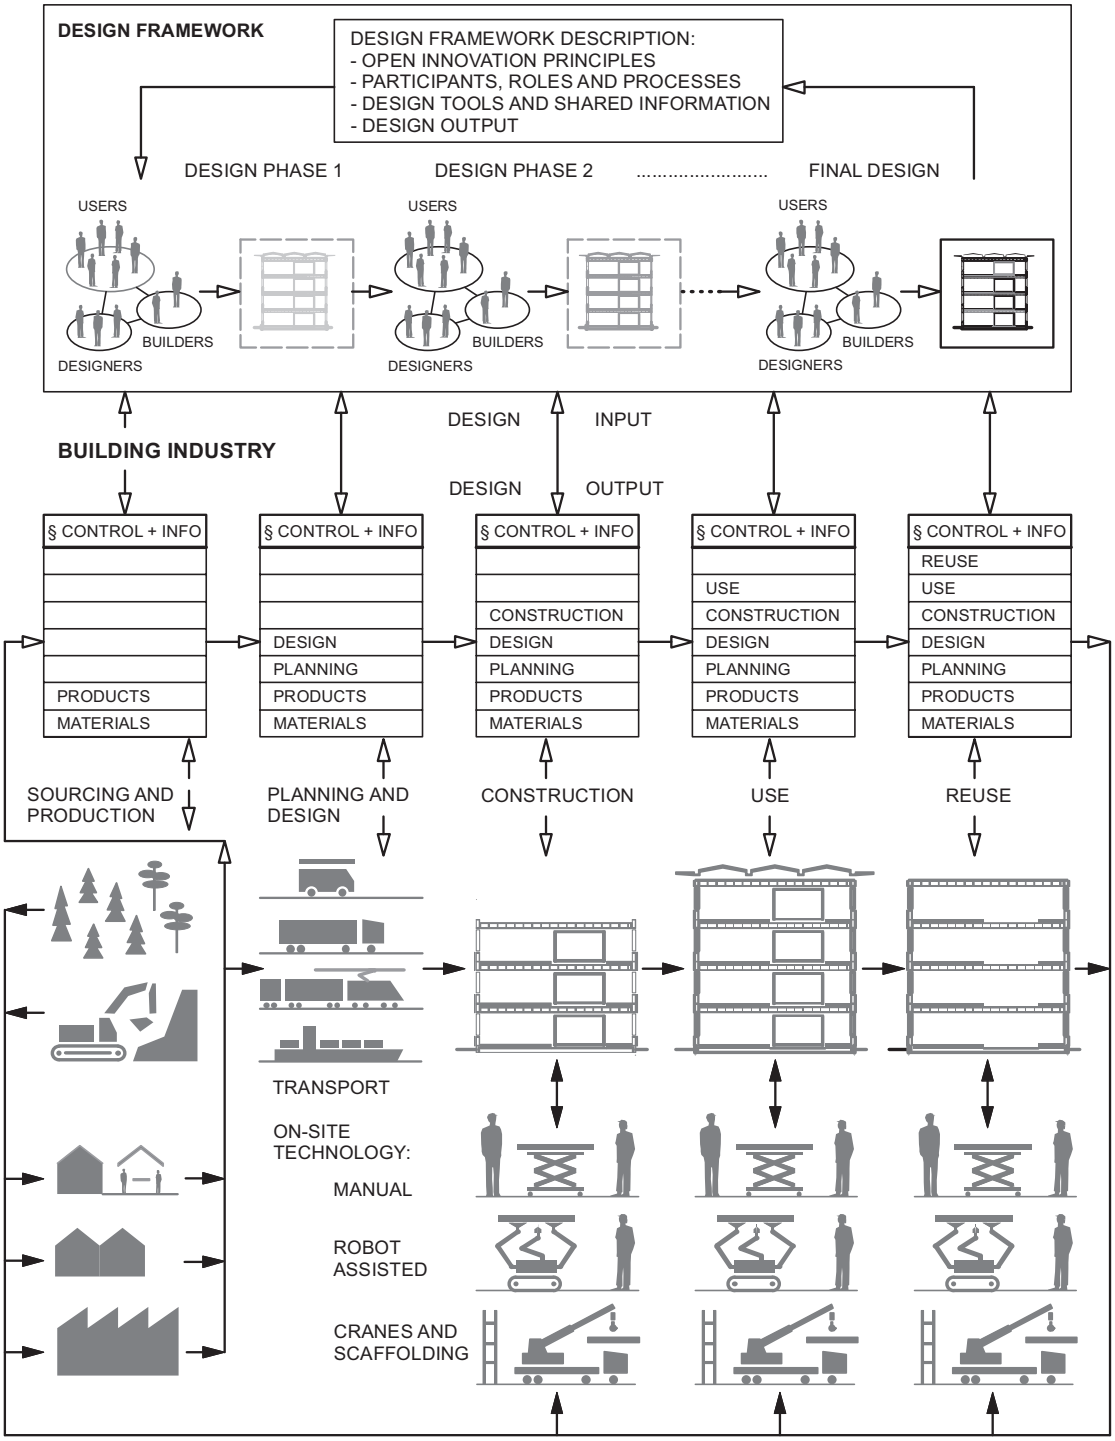
3.1 PROCESS AND PARTICIPATION

The purpose of a diagrammatic study is to facilitate an immediate and active user or inhabitant participation in the design of buildings. In Figure 1 it would be carried out in the first phase of design within the design framework. It focuses on the main functional and architectural properties while maintaining openness for a variety of choices regarding materials, structures and details. Simplified quality control and classification should be embedded in the components that are introduced and then repositioned and transformed during this initial design phase. As emphasized above, qualified architectural and technical advice must be defined as a part of the design framework.

3.2 ADAPTABILITY TO CLIMATE, SITE AND URBAN PATTERNS

To ease the overview of the example, The authors have chosen to focus on a limited number of environmentally significant features that are shown in the upper diagrams in Figure 2.

https://doi.org/10.52202/069179-0514



TOP: The design framework and the processes it defines
MIDDLE: The regulatory control and information system
BOTTOM: The cycles of materials and components, and the associated transport systems and construction technologies.
Black arrowheads mark material and mechanical flows, systems and interactions.
White arrows mark interaction and influence based on flows of information.

Figure 1: *Overview of design framework and building industry.*

Figure 3: *Solutions developed in the diagrammatic study applied in the "Block" and "Line" examples. Bottom: Geometric adaptions of the "Cube" example*

https://doi.org/10.52202/069179-0514

- A well insulated envelope that encloses a compact building volume. This limits heat loss to the exterior.

- A flat, ventilated (cold) roof with easily accessible gutters leading to external downpipes.

Ventilated roofs reduce melting and icing in near-zero temperatures, and also heating of the interior during summer. In a four storey building, a flat roof may serve as platform for solar cells with a signifcant area per apartment. It will be an important step towards lower energy demands. In Norway, 10 degree slope towards East and West is optimal on flat roofs. An elevated, lightweight roof structure will facilitate future maintenance or exchange of the photovoltaic panels. Significant roof overhangs will allow variation in the direction of the "solar waves" without affecting the overall character of the building. The overhangs will accentuate the separate roof. The folded geometry will improve ventilation and drainage. External downpipes eases local use of rainwater in landscaping, combined with measures for delayed stormwater runoff. There are also caveats linked to flat, ventilated roofs in arctic climate, but this is an opportunity for rethinking.

- The basic components can be applied in buildings with varying depth and orientation, adaptable to different topographies and urban patterns.

Figure 2 shows the starting point of the diagrammatic system study - called "Cube". As higher user involvement and lower costs are intended, the initial floor plan is dimensioned for four two-bedroom flats. They are adequate entry-level dwellings of 65 m2, served by a compact, central stair and elevator core. The total building however, is about 17,5 x 17,5 m, which demands a relatively level site. The four-sided orientation, which is optimal for views and daylight, puts limits to the arrangement of groups of such buildings. The "Cube" siteplan in Fig. 2 shows rows of separate, low-rise apartment buildings sharing a common, inner green belt.

In Figure 3, the upper diagrams show the "Block" alternative where the four combined apartments are rearranged within a slimmer (13,1 m) and two-sided building. This can be adapted to slightly steeper slopes (12%), and to a traditional urban block pattern, which is shown in the "Block" section and siteplan.

The middle diagrams of Fig.3 show the "Line" alternative, which is a still slimmer solution (11,0 m), adaptable to slopes of 20% or more. Such topographies demand a linear urban pattern, which should also be able to follow varying contours of hillsides. This is accommodated by introducing linking volumes with a flexible geometry.

A common requirement for all building types and urban patterns should be a capacity for high density. The site plans of "Cube", "Block and "Line" vary between 11,4 and 14,5 dwellings per 1000 m2 of the rectangular net sites shown in Figures 2 and 3. These are urban levels in a Norwegian context. The similarities in density indicate that the tree building alternatives can be combined in a diverse urban "vocabulary" without losing density.

3.3 ADAPTABILITY TO INHABITANTS´ FUTURE NEEDS

The primary structural system of the diagrammatic study is a regular and modular skeleton system, which allows for large spaces free of columns and loadbearing walls. The stair and elevator shafts, together with the floors provide lateral stiffness. The free spans are limited to 4,8 m, which is sufficient for housing (Drexler 2020) [15]. It opens for use of a variety of materials and timber technologies. The small and light structural members will be managable in manual building, and transportable by small vehicles. They may also be supplied by a large number of producers.

The sizes and weights of the infilling floor and external wall elements are also limited to be adaptable to different assembly procedures. As shown in Figure 2, the typical wall elements are 1.2 m wide, and typically ca. 2.5 m tall, which allows inclusion of doors and windows with free openings demanded for universal access and secure escape routes. The floor elements have a maximum free span of 3,6 m, A spatial zone of 50 cm height is assigned to the floor construction. This is a conservative starting point, may be controversially so. It allows for a variety of sound-insulating layers above and ceilings below beams, that also may vary in design, size and stiffness. (Required airborne sound insulation between dwellings in Norway is $R'_w \geq 55$ dB, and impact sound insulation $L'_{n,w} \leq 53$ dB.) The gross storey height is initially set to 3.0 m, which represents an incentive for slimmer floors that will increase spaciousness and daylight in the dwellings. The secondary, infilling systems are placed between, and not on top of, or overlapping the structural members of the primary, loadbearing skeleton. This limits construction heights and depths. The components are easily accessible and demountable to facilitate maintenance, modification and reuse. The section and façade diagram in Figure 2 show horizontal and overlapping bands of façade cladding which create depth and shadows, while opening for use and reuse of many types of materials. They also ease inclusion of different kinds of solar shading. The horizontal cladding and protruding eaves contrast the vertical modules of the external walls, forming a basis for further architectural development.

The possibility of expanding the size of spaces or dwellings is referred to as elasticity in buildings systems. In the plan drawing in Figure 2, bordering zones of adjacent flats are prepared for connections horisontally or vertically. The idea of allowing expansion, also outside the initial envelope of multistory buildings, is more radical. It is however, a natural next step in building adaptable, first dwellings. The plan diagram in Figure 1 shows a series of expansion zones of 3,6 x 3,6 m, offering substantial, functional additions to the dwellings. They

https://doi.org/10.52202/069179-0514

are based on the same structure and materials as the main volume, and will maintain views and daylight in the original spaces. Similar additions are prepared in the diagrams of "Block" and "Line" in Figure 3. Agreeing on the time and sequence of additions to different floors is a complex, but solvable issue. The initial building volumes of all alternatives are regular, which means that they will grow into complexity and hopefully, richness of expression. If such variety is carefully balanced in the intitial situation, expansions may be regarded as unwanted, or they may fill in gaps, resulting in bland regularity.

Rectangular structural grids are advantageous in accomodating varied floor plans and furnishing. They also ease alternative reuse of the infilling, secondary components. The design framework should however, not have inherent, geometric constraints, which have proven to be damaging to many building systems. Adaptability to different geometries is exemplified in the bottom diagram in Figure 3.

3.4 BATHROOM MODULES AS TECH CENTRALS IN APARTMENTS

The bathrooms contain the dwellings´most complex subsystems and components. Their design and production are subject to detailed, interdisciplinary coordination, regulation and control. Water damage is very expensive, and may induce health risks in the form of fungi. It is natural to expand the "technical core" to include ventilation and power supply. Service systems stand for a growing part of the emissions related to production of materials and components. Simplification and concentration may reduce emissions and at the same time free larger parts of the buildings of interference with the technical systems. Incorporating partially natural ventilation may play a role here.

The sound insulating layers that are required on top of timber floors (normally 100 mm or more) solve the problem of step-free access to bathrooms. The bathroom floors may substitute sound and fire insulation functions of the layers on top of timber floors. Bathrooms are typically produced as whole "plug-in" modules. This means that they are difficult to move, exchange or modify. An element-based design, both of bathrooms, technical niches and ventilation systems would ease the adaptability to changes in flat layout and available technology.

The bathroom unit shown in the "Cube" floor plan in Figure 2 is also used in the "Block" and "Line" alternatives. In the large, two-sided apartments in the "Block" solution, a separate toilet is added, linked to the technical core (also shown in Figure 2).

4 DISCUSSION AND CONCLUSION

Some architects regard building codes, standards, design guides and pre-accepted solutions as the place where innovative architecture goes to die. For the authors, this made it a good place to start. The search for a safe acoustic point of entry resulted in 50 cm thick floors, including a continous, double layered ceiling of gypsum boards. Fire concerns pointet towards columns and beams integrated in walls and floors, again hidden behind two layers of gypsum (fire resistance rating REI 60 in walls and floors between dwellings). Standard tables for structural capacity confirmed that with spans of 4,8 and 3,6 meters, timber could do the job alone, but slimmer steel profiles would ease the integration and protection of a skeleton structure in walls and floors.

Hiding the timber was not a wanted or final solution, but a choice of postponing its return to visibility until the implications for a detailed design (succeding the diagrammatic study) could be mapped. When structural timber enters interior spaces, it is usually upscaled to allow burning and charring while maintaining its loadbearing capacity until sprinkler systems or firefighters interfere. It may also need vibration damping in the form of elastomer pads or strips to prevent sound transfer between dwellings. Unlike concrete, appreciation of exposed timber does not get smaller when the the dimensions get bigger. Visible structures communicate how the building is constructed and how it can be used. They also frame the spaces and add interplay of materialities to the atmosphere of the interiors [9].

The principle of adding high quality timber to be sacrificed in the case of fire, could be substituted by a slimmer, hybrid solution that still conveyed the position and character of the structural system. For many inhabitants wood everywhere may be too much. Visibility is not the only way. A complete documentation will include 3D models of the different subsystems. They will enable Lidar-scanning smartphones to visualize the exact positions of columns and beams in a room.

With timber, sound and fire out of sight (until further notice), focus could be put on processes and principal solutions.

The systems overview (Figure.1) made clear some features and constraints that would support use of local resources and expertise and facilitate user involvement in adaption, and potentially in construction. Together with environmental parameters they were included in the design framework for the diagrammatic study.

The diagrammatic study was an exercise in modular stringency and extraction of a small number of standard parts. Having completed the initial "Cube" solution (Figure 1), developing the "Block" and "Line" variants proved to be surprisingly simple. Interestingly, the limited kit of parts forced compromises that (to the

https://doi.org/10.52202/069179-0514

authors) appreared new and appealing. The "too big" but multifunctional and generously daylit corridor in the flanking aparments in the "Line" alternative (Figure 3) may not have appeared in a more fine grained system.

The diagrammatic study may form the basis for a pilot system that can be easily visualized in open source and web-based 3D software. The digital model will then be integrated in quick cycles of user-centered design development. As a process example this may respond to the call for speeding up the adaption of the building industry to environmental demands. Cheaper and better housing is a central aspect of the UN goal for sustainable cities and communities. By maintaining compliance with industry standards, the process may also ease the production of documentation required for agreements and construction.

This combination of new design organization and new digital tools may affect several industrial patterns. First and foremost, the presence and influence of the user / inhabitant will be stronger. It will affect when and how the architect communicate with the users and other members of the design team. The dependency on dominating CAD systems may be reduced. Instead, they will be expected to communicate with high frequency output from open innovation processes. Open source publication of architectural details may demand more and speedier technical approvals, which will also be expected to be competitively priced and openly documented. Complete and tracable building data is vital for circular flows of materials and products. The vision of open and accellerated innovation challenges the knowledge gaps that are part of the economic foundation of many businesses within the building industry. Their skill and strength are vital to take on the inherent responsibilities and risks of large projects. On the other hand, tendencies of dominance by acquisitions rather than competitive innovation may postpone vital transitions beyond critical points. This paper argues that processes of real participation in designing buildings with real adaptability and real reuse, are necessary to limit the environmental risks embedded in present industrial trends.

TAMANGO BUILDING: TYPOLOGICAL EXPLORATION FOR A 12-STOREY WOODEN APARTMENT BUILDING IN A SEISMIC AREA.

Gerardo Armanet[1] Juan José Ugarte G.[2], Sebastián Cárcamo[3], Andrés Sierra[4], Diego Valdivieso[5], Juan José Ugarte Á.[6]

ABSTRACT: In 2020, Tallwood was commissioned to build a 12-story building with a mixed commercial and residential program in Coyhaique, the gateway to Chilean Patagonia and one of the most virgin territories in the world, but also a city that has one of the worst pollution rates in Latin America and is part of one of the countries with the highest seismicity in the world.

This article explains the process and methodology behind the architectural and structural solution for the "Tamango" building, which today has a construction permit and is in the final phase of economic studies to start the construction of its 12-story tower and 21,112m2, which includes 2,806m2 for offices and commerce on a reinforced concrete plate and 9,528m2 for 68 apartments distributed in a hybrid structure of LVL columns and beams, CLT and reinforced concrete composite slabs, and vertical cores of reinforced concrete.

KEYWORDS: Wooden High-rise Buildings, Wooden Architecture, Hybrid Concrete and Wood Structures, Structures in Seismic Zones.

1 INTRODUCTION

1.1 THE PLACE

Coyhaique is one of the southernmost cities in the world. According to the 2017 census [1], it has approximately 57,818 inhabitants within the Aysén Region, where 103,158 people live in 109,024km2, resulting in a density of less than one inhabit/km2, being one of the least populated and most pristine areas on the planet.

However, Coyhaique is also among the most polluted cities in America [2]. In June 2018, the city reached an index of 166.8 PM2.5, considered a very unhealthy category, mainly due to the burning of wet firewood for heating.

Figure 1: *Aerial view of Coyhaique without air pollution. Source: Rakela.*

1.2 THE CLIENT

Considering the context described above, Tallwood was contacted by two families from the area interested in leaving a legacy in the area and doing it through a sustainable real estate project and efficient construction, also considering the problematic access to materials and skilled labor in the area.

Thus, the building takes the name of "Tamango," a traditional boot worn by Patagonian gauchos, as a symbol of the mixture between simplicity and comfort sought after the inclement Patagonian climate.

This is how it was decided to develop a structure in which the latest technologies for high-rise timber construction were put into practice, with mechanized elements of CLT, GLULAM or MLE, LVL engineered timber, and certified sawn timber with different structural grades. All of the construction systems, proven in other parts of the world, meet the requirements of the clients by coming from renewable sources and having, at the same time, advantages of prefabrication, such as shorter assembly times, dry and silent works, low emissions of particulate matter, and greater quality control in construction.

The characteristics of these materials also greatly facilitate reaching efficient energy solutions for heating, and their hygroscopic quality of retaining and releasing moisture gives that feeling of comfort that has long been studied as beneficial for living.

Figure 2: *Landscape of "Cerro Castillo" in Aysen region, Chile and a original "Tamango" (traditional boot worn by Patagonian gauchos). Source: Corsilver and Guillermo Helo..*

1.3 THE LAND

The land where the project will be located is challenging since it is central -it is located three blocks from the main square of the city -will become an urban landmark- but it is also a boundary condition looking towards the nature of the "pampas" and the Coyhaique River.

Planning laws explain some architectural design decisions; local regulations require a continuous façade at least eight meters high. In addition, the height of the building is also obtained from the local rules, which indicates maximum constructability and height.

Figure 3: *In red, the future location of the building. Three blocks from the main square in a border condition facing the Coyhaique River. Source: Google Earth.*

1.4 THE LOCAL CONTEXT

Chile has a strong forestry vocation, 22.3% of the country's surface, equivalent to 16.9 million hectares, is covered by forests -14.6 million hectares are native forests, and 2.3 million hectares are forest plantations- [3]. However, the country is also part of the current challenges that the world of construction is experiencing, such as:

1. How to achieve, from the construction sector respond to the demanding environmental goals? Chile committed to being carbon neutral by 2050, but when this building was designed, it emitted 111 million TCO2, although it also captured 65 million tons through the forests. Thus, it is possible to contribute to the reduction of the so-called "30/30/30" of construction -36% of the final use of energy, 35% of solid waste, and 39% of emissions of CO2 [4]- through wooden structures.

2. How can we increase the productivity of the construction sector? For example, Chile is capable of building 0.24m2/person/day, in contrast with developed countries where are capable to build 0.37/m2/person/day are made, that is, ten floors versus fifteen in the same amount of time [5], which indicates the need for a profound change in the way of building.

However, currently it has been seen that between 2012 and 2020 progress was made from having 14% of homes with wood as the predominant material to 20% in 2020, having the realistic goal of reaching 30% by 2030.

Currently, proposing tall wooden buildings in Chile represents a great challenge and innovation, because in that country there are almost no buildings higher than four floors and all the buildings from 7 stories upwards are made in concrete and steel [6].

The phenomenon described above is aligned with the Chilean seismic code, which limits "inelastic drift" to 0.2%, one of the most restrictive seismic regulations worldwide.

1.5 THE MATERIAL

The idea of using engineered wood was, from the beginning, having to achieve competitive structural values but also using the advantages of wood in terms of: the use of a renewable resource and sustainability, its greater precision in manufacturing, its lower weight (470kg/m3 vs. 2500kg/m3) that would help to have fewer operations, faster assembly in a town located in the far south, and better-quality finishes.

For this, in parallel with the design of the building, a management process was carried out since in January 2020, when nine engineered wood suppliers from around the world were contacted, selecting the final supplier in March 2021, after an exhaustive evaluation that considered the following parameters: price; technical support during design; technical support during assembly; availability, type and quality of material; experience; and interest in the project.

https://doi.org/10.52202/069179-0515

Figure 4: *Wooden elements to be used in the project.*

1.6 THE ASSIGNMENT

The offer, with residential apartments with eight apartments per floor, is mainly addressed to two types of clients: families from Coyhaique who travel permanently and prefer to have an apartment in the city as their residence, and young families who are emigrating from the center to the south of Chile searching for new job opportunities, a better quality of life, or more significant contact with nature.

Thus, due to the conditions of the place, the client's interest, the land regulations, and the local context of the construction industry previously mentioned, the project also requested -among other parameters and requirements- that part of these structural elements of Engineered-Wood will be exposed, generating the following questions and challenges for the team of architects and structural engineers in charge of the design:

According to the order and the maximum height allowed on the land: How should a 12-story building in Coyhaique be designed with wooden structures?

According to the architectural program: Should the plinth or "podium" be designed in reinforced concrete or wood?

Considering the height and the architectural program: What structural typology is ideal for this type of building, which will have apartments between floors 3 and 12 and is located in a seismic country?

In the case of using composite or hybrid structures: How to solve the aerial floors making concrete and wood compatible, considering the seismic regulations of Chile?

One of the main conditions that were considered was the seismic recurrence of Coyhaique, with an average of 7 grade 7 earthquakes every 40 years, which is why the challenge of the Tamango building was unique in the combination of: Pre-existing real estate requirements of engineered-wood structures for tall buildings, and an area of high seismic risk.

2 METHODOLOGY

For the development of the architecture design, engineering, and management of the building, an interdisciplinary team of professionals with extensive experience in wooden projects -as well as in the development of public policies, academic activities, and industries- was formed, bringing together authors of pioneering works in wood in Chile -neighborhoods for 360 homes, 6-story light-framed towers and architecture with high-performance standards- and also, called the support of world-class international advisors from Finland, Slovakia, Poland, Germany, and Canada.

The initial design considered programmatic, regulatory, and economic requirements, coming from a previous study and pre-design developed by the real estate company -the client-, which was necessary to maintain:

Table 1: *Programmatic, regulatory, and economic requirements, from a previous study and pre-design developed by the real estate company -the client-which it was necessary to maintain.*

Nº	Requirement
1.	Three basements, with residential and rental parking capacity, warehouses, and technical rooms.
2.	Continuous façade of at least 8 meters high (by regulatory requirement) with approximately 2,000 m2 for commercial premises, equipment, and offices.
3.	Approximately 8,000m2 with apartments between 90 and 140 m2 in a maximum of 12 floors.
4.	Final sales values of approximately €3,200/m2, being competitive with the local market.
5..	Demonstrate compliance with all local structural engineering, fire resistance, and acoustic performance standards and regulations.
6.	Check the characteristics of sustainability and energy efficiency of the building.
7.	Leave some structural wood exposed.

Before the iteration with different models that would help to answer the questions posed by the project, basic design parameters were established, both from architecture and engineering, which served as a basis.

2.1 ARCHITECTURE PARAMETERS

After determining the theoretical volume using local regulations that establish plinth, constructability, and maximum height, initially, we had an elongated tower, with only four corners, on a 2-story shopping plaza.

2.1.1 Double deck plate

One of the first design decisions was to use a regulatory instance that allows 30% of the continuous façade to be transferred to the public space, creating a public access courtyard that connects with galleries and interior public terraces. One of the project's main goals was to make the

https://doi.org/10.52202/069179-0515

first-floor program responsive to the urgent needs of the city and open it to the public.

Figure 5: *Architectural design decisions for the two-story commercial plate.*

2.1.2 Six-cornered tower

A second significant move was to divide the building's block in two, in such a way as to make better use of the geometry of the terrain providing six corners with good views, ventilation, and sunlight instead of the initial four corners, which would eventually allow both towers to function, independently, when dilated.

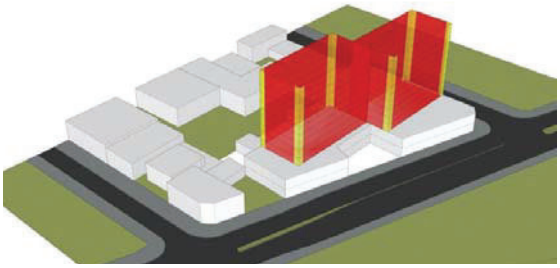

Figure 6: *Architectural design decisions for the six-cornered tower.*

2.1.3 Inclined upper faces

A third important design decision was to use the municipal requirement for roof slopes to generate "duplex" -two-story- and "triplex" -three-story- apartments on the upper level, with more commercial value, better views, and a more flexible architectural program.

Thus, due to the geometric characteristics of the site, the residential building was conceived as two independent volumes connected by circulations, making maximum use of views and sunlight.

From the beginning, all of these design decisions were accompanied with the engineering team, making models and testing different combinations and structural typologies until meeting the high standards required by both the team of professionals involved and international standards, as required by current seismic regulations.

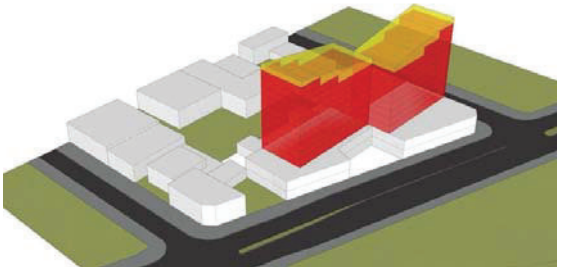

Figure 7: *Architectural design decisions for roof slope and top floors with two and three-story apartments on the upper level.*

2.2 ENGINEERING PARAMETERS

Considering the requirements indicated in the Chilean seismic standard, based on the different constructive and structural typologies [7] that have been part of the growth of this type of building globally [8], as well as consulting other design manuals, the following general criteria were adopted:

2.2.1 First two floors of reinforced concrete

The podium configuring the continuous façade and containing the commercial places and offices was designed from the beginning in concrete. Coyhaique is a city with a lot of precipitation and sporadic accumulation of snow, which is why, in any case, the design required protection for the wooden structures in contact with the natural terrain.

In addition, due to multiple environmental benefits, such as evapotranspiration for cooling, retention, and drainage of rainwater and a contribution to biodiversity through native flora, green roofs were included over the slabs, which added loads to the large slabs already projected.

2.2.2 Vertical cores of reinforced concrete

To provide stability for the seismic design, comply with the Chilean Standard, which allows a maximum relative displacement between two consecutive floors, measured at the center of mass in each of the directions of the analysis, which must not be greater than the height of mezzanine multiplied by 0.002 [9], makes it practically impossible for tall wooden buildings in Chile to comply with the deformations of the standard without having a reinforced concrete core that is capable of absorbing dynamic stresses.

Also, as well as based on similar experiences, such as the Brock Commons building, by Acton Ostry located in Vancouver [10], the project incorporated from the beginning the idea of using vertical cores of reinforced concrete, which were capable of stiffening the tower.

Preliminary analyzes suggested a maximum distance of approximately 12 meters from the edges of the wooden structure to the Reinforced Concrete cores. Therefore, in the first instance, it was decided to include two cores.

https://doi.org/10.52202/069179-0515

2.2.3 Aerial floors of wooden posts and beams and CLT composite slabs - reinforced concrete.

Also, was defined from the beginning to use a mixed slab. In this case, of 170mm CLT. and reinforced concrete of 100mm.

Thus, metal reinforcements would connect these slabs to the concrete cores, generating the necessary solidarity between both structural elements.

2.3 PARAMETERS OF OTHER SPECIALTIES

Among the more than 30 specialties involved, the following criteria were used for fire resistance, acoustic performance, and thermal performance, which directly affected the architecture and structure of the building:

2.3.1 Fire Resistance

According to the General Urban Planning and Construction Ordinance of Chile (OGUC), due to its size and use, the structure of the Tamango building must have a fire resistance of 120 minutes [11]. Bearing this in mind, engineers specialized in the field considered three main criteria:

Table 2: *Three main criteria for calculating fire resistance*.

Nº	Criteria
1.	Projected real fire (Burnout) using local regulations, Eurocode 5, and other technical texts.
2.	Carbonization and delamination analysis for exposed structural members.
3.	Carbonization and delamination analysis for protected structural elements.

The analysis with these criteria determined sections of structural elements and the necessary conditions to achieve "exposed wood" inside the apartments.

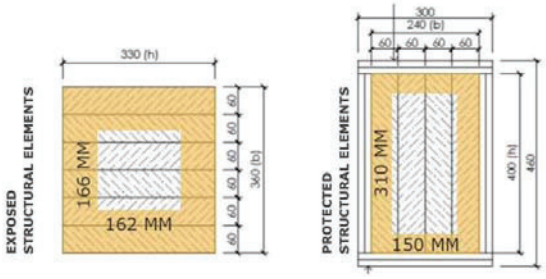

Figure 8: *Exposed and protected structural elements fire resistance analysis. The traditional carbonization factor of 0,7mm/min., modified according to delamination calculation.*

2.3.2 Acoustic performance

The acoustic performance of the dividing elements was analyzed to comply with the requirements for airborne noise and impact noise.

In Chile, for slabs, according to the General Urban Planning and Construction Ordinance of Chile (OGUC), a normalized impact sound pressure level (Ln,w) less than or equal to 75 dB is required. And for walls and floors, an acoustic reduction index (Rw+C) greater than or equal to 45 dB. Compliance with these requirements can be demonstrated by belonging to the List of Constructive Solutions for Acoustic Insulation of the Ministry of Housing and Urban Planning (MINVU) or by carrying out Test Reports or Inspection Reports issued by a laboratory with current registration.

Table 3: *According to the General Urban Planning and Construction Ordinance of Chile (OGUC), permissible decibels for airborne noise and impact noise*.

Noise Type	Requirement
Impact noise	Normalized impact sound pressure level (Ln,w) less than or equal to 75dB
Airborne noise	Acoustic reduction index (Rw+C) greater than or equal to 45dB.

This affected the sizes and stamps of the dividing elements. Not only local regulations considered but also international standards, assuming that the new inhabitant of the apartments, when faced with new materials and construction systems, can be more demanding than usual, even if it is comfortably complying with acoustic requirements established in the Chilean regulation.

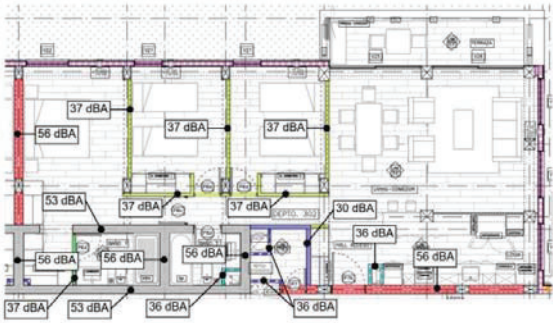

Figure 9: *Acoustic performance of elements in a typical department of the Tamango building.*

2.3.3 Sustainability and Energy Efficiency

Another fundamental specialty to integrate from the outset was Sustainability and Energy Efficiency, which had two fronts: the carbon footprint, which helps to explain, to a certain extent, the use of this amount of wood, and the performance during its use, that in addition to complying with the requirements of the "Coyhaique Atmospheric Decontamination Plan (PDA)" -a measure established to help reduce particulate material emissions that have Coyhaique as one of the most polluted cities of America- explains, to a certain extent, the design of the envelopes and the percentage of windows in the building.

Table 4: *Maximum allowable thermal transmittance [W/m2K]*

Thermal Zone	Roofs W/m2K	Walls W/m2K	Ventilated floors W/m2K	Doors W/m2K
Coyhaique	0,25	0,35	0,32	1,70

https://doi.org/10.52202/069179-0515

Regarding the carbon footprint, the building has 1,870m3 of wooden structure, which captures 1,230 tons of CO2 equivalent, discounting what is emitted in its manufacture and transport from Finland and Austria.

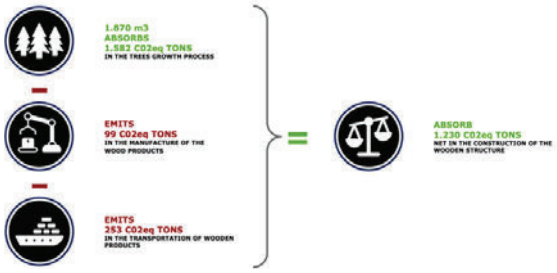

Figure 10: *Carbon footprint of the wooden structural elements of the building.*

Regarding the performance during use, five available heating systems were analyzed, resulting in the best evaluation of the "electric heat pumps" that heat the water for underfloor heating, reaching a 67% reduction in emissions according to a "base case" that It was used for the study and a 75% savings in monthly expenses by department.

This was also achieved thanks to an envelope designed with insulation, ventilated facades, and mechanical ventilation, which achieves a 60% saving in energy demand compared to a typical home with an equivalent classification from the Chilean Ministry of Housing and Urbanism (MINVU).

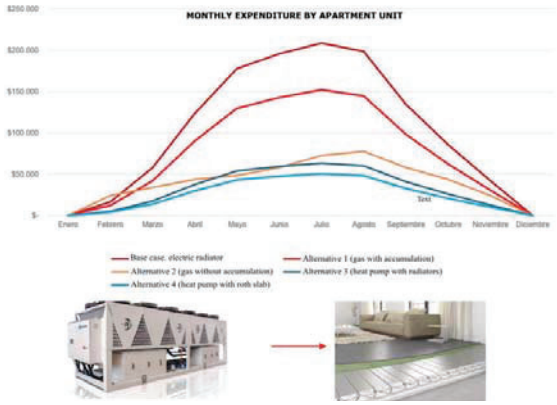

Figure 11: *Monthly expenditure by apartment unit, comparing five alternatives: Base case (electric radiator); Alternative 1 (gas with accumulation); Alternative 2 (gas without accumulation); Alternative 3 (heat pump with radiators); Alternative 4 (heat pump with roth slab).*

3 STAGES AND RESULTS

Once the essential criteria described above were agreed upon and having carried out a series of preliminary economic evaluations complying with precise real estate requirements, the design phase began, incorporating all the new needs.

Thus, different iterations of the architectural program and the structural elements were made during the project's development. In general, there were three main iterations:

3.1 CLT WALLS AND TWO REINFORCED CONCRETE CORES

The residential building, comprised of two independent volumes linked by circulations, was initially conceived with two reinforced concrete cores containing elevators and stairs. The preliminary analysis suggested a maximum distance of 12 meters from the edges of the wooden structure to these cores, so the architectural design was oriented under this premise at this stage.

The housing programs -unlike others, such as commercial premises and offices- are characterized by having a more significant number of enclosures and linear meters of wall. This, added to the client's requirement to leave the wood in sight, initially determined the decision to structure the apartments with CLT walls.

Following modeling and structural study, the projected CLT walls experienced significant stress, resulting in the modification factor being adjusted to reflect the system mentioned above accurately. This adjustment caused an increase in the base shear, causing a drift that more than doubled the permissible limit established in the Chilean code.

Figure 12: *Plan with CLT walls and two reinforced concrete cores.*

The CLT walls received a considerable amount of the total seismic cut, implying that the reduction factor used for the seismic analysis was associated with CLT. Although some studies suggest it may be higher, the consensus is to use R=2. This resulted in high seismic demand and a much higher than allowable drift.

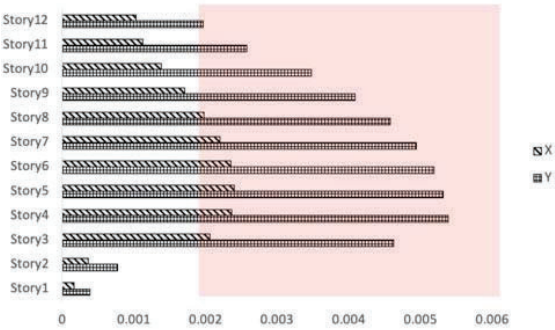

Figure 13: *Graph showing CLT walls received a considerable amount of the total seismic cut.*

https://doi.org/10.52202/069179-0515

Due to the lack of characterization of the CLT in the regulations, for the calculation of the structural model, a seismic reduction factor R=2 was used for the CLT compared to R=7 for reinforced concrete. The modeling results showed displacements greater than the 0.002*h allowed in the Chilean standard since it was considered during the calculation analysis that the CLT walls took the horizontal forces to a large extent, causing the earthquake to increase since most of the structures assumed R=2. Therefore, for the building to comply with the drift required by the standard, it would have been necessary to add a considerable amount of CLT walls, which was not viable from the habitability or commercial point of view.

Seeing the great distance that still existed for the viability of the proposed structure, it was decided to carry out a typological study of all the buildings with wooden structures of similar characteristics with the available information.

At the end of this stage, it was also decided to test a new model in which the concrete cores would mainly absorb the movements between floors. This test determined that the distance from the edges of the timber structure to the concrete cores needed to be reduced from 12 to 8 meters.

3.2 LVL COLUMNS AND BEAMS, FACADE WITH DIAGONALS AND TWO REINFORCED CONCRETE CORES

In this intermediate stage, the CLT walls were downsized to give the building rigidity and reduce previous deformations, and wooden bracing was installed on the facades. LVL columns and beams -material proposed because it achieves smaller sections than GLULAM to resist the same loads- replaced practically all of the CLT walls, leaving only a few, mainly in the living rooms, to expose the wood structure. These walls of the room continued towards the terrace - exterior balcony, which would later bring consequences after the criteria of wood protection from the design.

Programmatically, wet areas were left in the concrete cores to reduce eventual water infiltration problems in areas with wooden structures. In addition, during this stage, a third central core of CLT was configured, which contained the vertical circulations -elevator and stairs of the security area-.

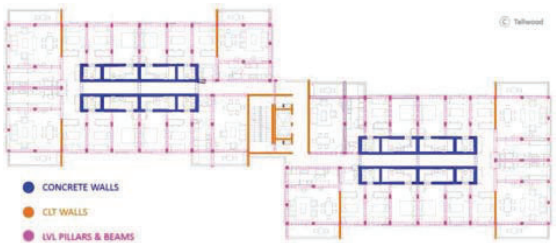

Figure 14: *Plan with LVL pillars and beams, facade with diagonals and two reinforced concrete cores.*

The models of the previous stage had presented more significant deformations at the ends of the tower, so at this stage, it was decided to incorporate diagonals in the short façades of the building. But, a milestone marked a change in this process: it was found that there is no consolidated criteria in Chilean regulations to determine what percentage of the shear, in the event of an earthquake, each element takes in hybrid structures.

Therefore, it was impossible to determine how much was assumed by a seismic reduction factor of R=2 for CLT walls or how much of R=7 for reinforced concrete core walls. Therefore, it was agreed, between the engineering team and the independent calculation reviewers, that only the R=7 of the reinforced concrete cores would be considered for calculating the cut. Therefore, it was necessary to eliminate all the wooden structural elements that would absorb lateral forces during earthquakes and eliminate from the design all the CLT walls and the LVL diagonals of the facades.

The bracing elements also experienced significant axial forces, resulting in the reduction factor being applied to the timber bracing system, the same as that used for the CLT walls in the previous iteration per Chilean code. This ultimately led to a similar level of deformation.

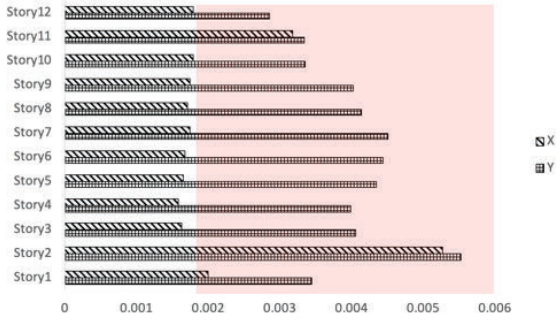

Figure 15: *Graph showing that the reduction factor being applied to the bracing timber system, which is the same as the one used for CLT walls, led to a similar level of deformation.*

3.3 LVL PILLARS AND BEAMS, THREE REINFORCED CONCRETE CORES AND EXPANSION JOINT

The third and final stage began with removing all CLT walls and LVL diagonals, which were replaced by a grid of LVL pillars at 3-4 meters connected by LVL beams.

One of the essential architectural requirements was to achieve large spaces without interference in the living areas, whose maximum spans of 5 meters dominated the design of the thicknesses of the CLT slabs.

https://doi.org/10.52202/069179-0515

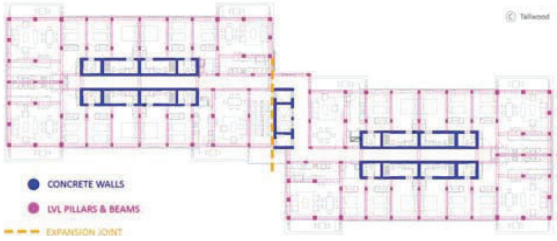

Figure 16: *Plan with LVL pillars and beams, three reinforced concrete cores and expansion joint.*

In this stage, a detailed analysis of the fire resistance for 120 minutes of the structural elements was carried out, as required by the Chilean standard for buildings with more than five floors for exposed and protected wooden structural components. Also, a detailed architectural evaluation accompanied this analysis to meet the requirements for element dimensions, concealed connector design, and the amount of exposed wood to meet the client's needs.

Various construction solutions certified and cataloged by the Ministry of Housing and Urbanism of Chile (MINVU) were used for the dividing walls. In the case of using unlisted construction solutions, they were tested and approved.

Another requirement -difficult for structural calculation and wood durability- was maintaining the usual Chilean standard for balconies or terraces. In this case, to avoid thermal and humidity conflicts caused by the continuity of the exterior-interior CLT slabs, it was decided to design the prefabricated metal balconies independently, with a fixing system using cranes to the load-bearing wooden structure. All the facades were designed to be prefabricated and assembled with cranes without scaffolding.

By not including additional lateral resistant elements to the concrete core, the modification factor was based solely on the reinforced concrete (RC) system. This resulted in the deformation of the building being within the permissible range established in the Chilean code.

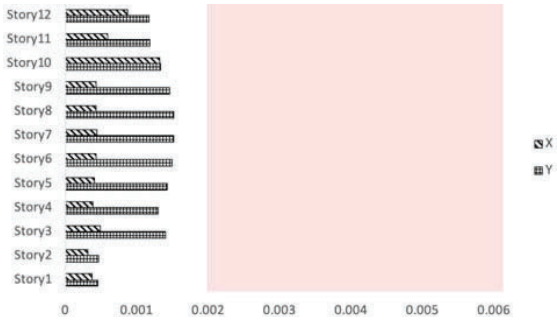

Figure 17: *Graph showing that not including additional lateral resistant elements other than the concrete core, resulted in the building's deformation within the permissible range stated in the Chilean code.*

Already having new structural models with positive results, complying with NCH 433, a consultancy was carried out to review the criteria with the Canadian structural engineering consultancy Timber Engineering Inc., which endorsed the results, suggesting adding a third central core of concrete for elevator. Subsequently, the independent calculation review, asked to include an expansion joint at the meeting of the two volumes of the residential tower.

4 CONCLUSIONS

The design of a hybrid high-rise structure of wood and reinforced concrete -in an area of high seismicity- was a complex process that forced innovation and required coordination and joint work, from its beginnings, between architecture, engineering and the more than 30 specialties that participated. Each of these stages required long study processes and iterations to arrive at these solutions, which are shown here in a simplified way.

The Tamango building now has a construction permit and a competitive budget. The main conclusion after this two-year work is that this experience shows that it is possible to build hybrid structures in wood and reinforced concrete in areas of high seismicity, complying with the highest standards. Also, the spatial conditions required for habitability, commercial requirements, and the requirements of Chilean law and international standards are met.

Figure 18: *Renderings with exterior views of the building.*

After this typological exploration process, a final design was reached with three vertically reinforced concrete cores, LVL beams and columns, and CLT - reinforced concrete composite slabs, where the maximum distance between the edges of the structure and the concrete

https://doi.org/10.52202/069179-0515

supports is 8 meters, requiring an expansion joint in the intermediate area.

For a 12-story building of these characteristics and in this location, a design of composite reinforced concrete structures is necessary to absorb shear forces and engineered-wood (LVL posts and beams + CLT slabs) for gravitational forces, being an viable option with the current technologies, economic conditions, and regulations.

The mixed slab of CLT + reinforced concrete, connected and solidary with concrete supports is a viable alternative to transfer the shear force to the reinforced concrete cores. A distance of 8 meters between the edge of the wooden structure and the concrete cores is feasible. Therefore, it is possible to comply with the Chilean regulation of fire resistance of 120 min with exposed and protected wooden structures. It is recommended that the balcony structures be independent of the main load-bearing wooden structure.

To arrive at the information required for the assembly of prefabricated structures, developing the so-called "Digital Twin" was critical, from which the data for manufacturing, machining, and all on-site assembly plans are obtained.

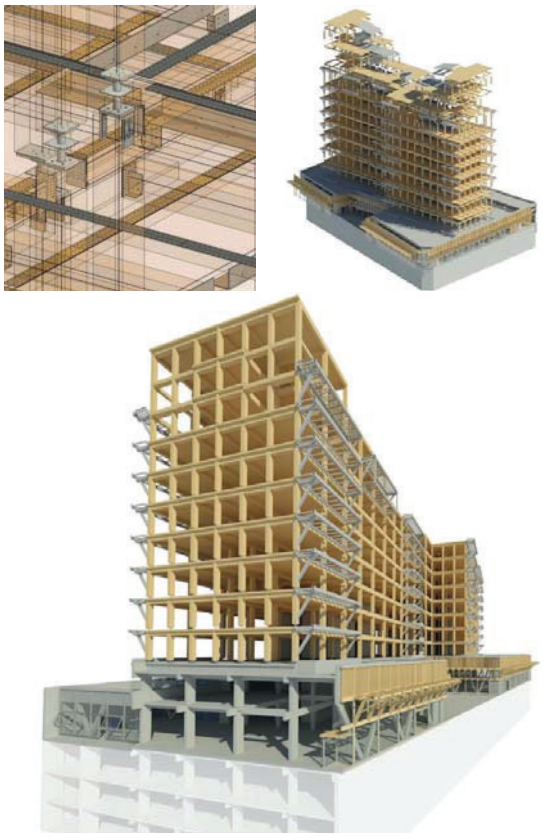

Figure 19: *Images of the BIM model with all the necessary information, so-called "Digital Twin".*

This digital model with the structure's detailing in BIM format allows the concept of "Build before Building," which produces the efficiency and quality of the on-site assembly, and also in this case, a “storyboard” or illustrative assembly sequence, which allows the constructor to be guided in the general evaluation of the project. Thus, an assembly speed of 200 m2/day is calculated, including facades. The wooden structure is assembled in 45 days, estimating a saving of 3 months of work.

According to the version delivered for bidding to construction companies, as well as for obtaining the Building Permit granted by the Coyhaique Municipal Works Directorate, Tamango building, has the following areas:

Table 5: *Architectural program and areas of the Tamango building*

Architectural program	Area
The total area of the project, with a mixed program and structure.	21.112 m2
Three underground floors, with 220 parking spaces, 95 warehouses, and the building's technical team.	8.778 m2
Two-story platform, with shops and offices.	2.806m2
Ten-story tower -between 3rd and 12th floor-, with 68 apartments, between 90 and 140m2 each.	9.528m2

Considered from the ground level, the wooden structure has also the following characteristics:

Table 6: *Characteristics of the building, related to the topic of this article*.

Structure Material	Area
The Total area of the project (100% from the ground level).	12.334m2
Wood Structure -CLT, LVL- (60%)	7.272m2
Reinforced Concrete Structure (35%)	4.370m2
Steel Structure -terraces- (5%)	692m2
Elements	**Quantity**
LVL elements -beams and columns-	2.446
CLT elements -slabs-	624
Metal connectors	6.141
Screws	339.417

https://doi.org/10.52202/069179-0515

Figure 20: *Rendering with interior view of the building.*

Finally, Tamango's experience also leaves many possibilities for improvement for new construction solutions and, at the same time, it can help to improve local regulations, incorporating new materials for Chile.

MORPHOLOGIC STUDY OF HYBRID TALL BUILDING TOWARDS AN INTERDISCIPLINARY DESIGN

Sebastian Carcamo[1], Diego Valdivieso[2]

ABSTRACT: Interdisciplinary design for tall wood buildings (TWBs) is a challenging task mainly due to the ongoing research on the behaviour of TWBs and to achieve cost-effective designs that allow the construction industry to improve the sustainability of the building inventory. Although more than 40 TWBs projects have been built, the lack of a guide regarding the distribution of structural elements increases the time that preliminary design requires, which commonly implies several iterations of different proposals. Based on the morphologic study of six TWBs, this paper analyses qualitatively timber buildings with reinforced concrete cores and study different parameters that should be taken into consideration in the early stage of the project, in order to achieve a healthy structure in a reduced time period. A comparative table with a range of values for each proposed parameter is presented. A range of values for the different studied parameters are presented as a guideline for the RC core typology.

KEYWORDS: Tallwood Buildings, Interdisciplinary Design, Morphological Parameters, CLT, RC, RC Core

1 INTRODUCTION

In recent years, the construction of tall wood buildings (TWBs) has become increasingly popular due to its sustainability, energy efficiency, and aesthetic appeal. However, designing such buildings is still a challenge, as there are few precedents to follow. As a result, designing the static dimensions of such buildings can be difficult. Even more challenging is the design of lateral bracing elements for seismic events, as most timber buildings in the world have been constructed in non-seismic areas.

To address this challenge, interdisciplinary collaboration between architects and engineers is encouraged. In order to have a successful design process, the evaluation in early stages of the structural performance is crucial for an efficient design process. The definition of a representative floor plan defines, through the analysis of geometrical or morphological parameters, relevant decisions that impact its performance.

Therefore, the objective of this study is to provide guidelines for designers to develop tall timber buildings that are structurally healthy and safe, using a collaborative approach that combines the expertise of architects and engineers. By doing so, reducing the time and resources invested in the design process.

2 METHODOLOGY

The aim of this study is to investigate morphological parameters that help in early stages of TWBs design. To approach this challenge, only hybrid timber buildings with concrete cores as lateral system were studied. The decision is based on the potential use of the proposed morphological parameters in seismic zones. Taking in consideration the results of the Tamango project [1], the use of CLT shear walls on highly seismic prone areas, such as Chile, implies the definition of restrictive architectural programs due to the amount of shear walls needed versus a similar program with reinforced concrete (RC) shear walls. The reason is the modification factor associated with the ductility of each material, where the seismic coefficient of a building with CLT shear walls is more than three times higher than a building with RC shear walls in the Chilean code. Different studies have analyzed these values, but according to the studies presented by FPinnovations [2], the modification factor for CLT shear walls used on these calculations seems to be representative.

To select the correct buildings to study, only built projects with concrete cores were taken into account. A literature review of these buildings was performed, were several publications of TWBs inventories were presented, among them are the work done by Wiegand[3], Huseyin Emre[4], Fryer[5], Green[6] Ražnjevi´c[7] and Foster [8]. From these sources, only six tall timber buildings with the mentioned conditions and with available information were found: the WoodCube Building (2013) in Germany, LCT One (2012) in Austria, Brock Commons (2017) in Canada, Hault (2020) in the Netherlands, HoHo (2020) in Austria, and Ascent (2022) in the USA. Further details of these last two buildings, the most recent ones, were taken in consideration from the investigation of Fernandez[9] and Verhaegh[10].

https://doi.org/10.52202/069179-0516

For each building, a qualitative analysis of a representative structural floor plan was performed, which were redrawn approximately to study their morphological parameters. These parameters aim to quantify different structural properties regarding its performance. To define them a simplification of a typical floor plan is presented on Figure 1:

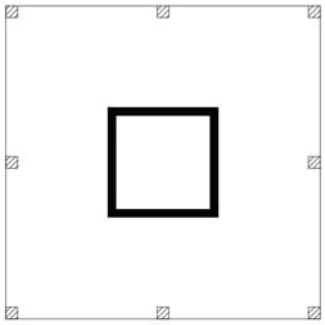

Figure 1: *Simplification of a TWB with concrete core*

Here, the RC core is painted in black, the vertical timber elements are painted with a light hatch and the perimeter of the slab y represented by a continuous line. From these idealization of a building plan, the morphological parameters studied are described:

- Eccentricities by direction (Ecc): The distance in both the X and Y directions between the center of rigidity (CR) and the center of mass (CM) of each floor. The center of mass was calculated as the approximate geometric centroid of the floor, ignoring any openings. The center of rigidity was calculated based only on the reinforced concrete shear walls. To represent them graphically on the studied buildings, they are drawn with a circle and a square, respectably, and their perpendicular distances are represented by a discontinued line rectangle. See Figure 2. This parameter is crucial to understanding the symmetry of the project and the possible torsion that it may experiment.

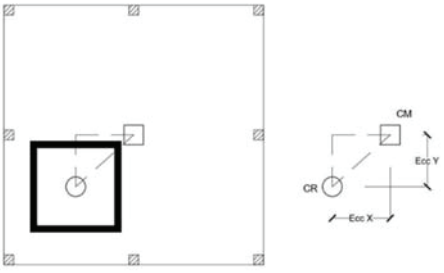

Figure 2: *•Eccentricities by direction (Ecc)*

- Density of shear walls by direction (ρ): The total area of reinforced concrete shear walls per floor in both the X and Y directions divided by the total floor area. Is possible to relate the overall stiffness per direction with the total area of the RC walls, which are graphically represented on Figure 3.

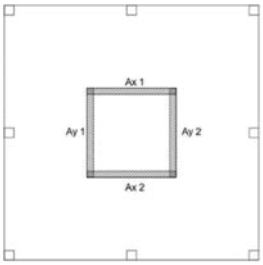

Figure 3: *• Density of shear walls by direction (ρ)*

- Slenderness ratio (S): This involved calculating the ratio of the longer length to the shorter length of each floor. This parameter is related to the deformation modes that the building may incur, and also quantifies symmetry. (Figure 4).

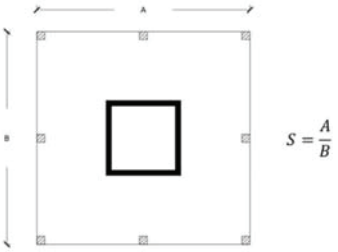

Figure 4: *• Slenderness ratio (S)*

- Maximum distance between the concrete core and the edge of the building (D): The distance between the concrete core and the farthest point of the slab. This parameter quantifies the amount of stresses on the slab, and in consequence, the level of deformation demand that the building may experience (Figure 5)

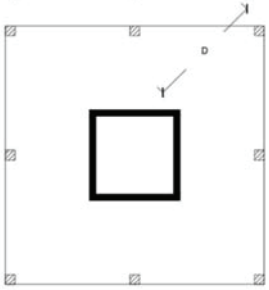

Figure 5: *• Maximum distance between the concrete core and the edge of the building (D)*

In Figure 06, all the representative floor plans of the studied buildings are presented in the same scale to demonstrate the proportion of each building relative to the others. The reinforced concrete shear walls are depicted in black, while the timber elements are shown with a light hatch. In addition, the maximum distance between the concrete core and the edge of the building is measured and annotated, and the center of mass (represented as a square) and the center of rigidity (represented as a circle) are graphically shown, both connected by a dashed rectangle to illustrate the eccentricity of each building. These visual representations provide a comprehensive understanding of the morphological parameters studied, and how each building's design differs.

3 RESULTS

The parameters studied for each building are summarized in Table 1. The country of origin is included to represent the seismic hazard that each building may face. Additionally, the material composition of the floor slab has been included as a relevant parameter, as it should directly relate to the capacity to increase the distance to the edge of the building from the RC core. These parameters provide insight into the morphological characteristics of each building, and how they are influenced by their respective loads' sources and location.

It is crucial to understand that the parameters presented in Table 1 should be considered only as rough approximations, and thus, they define a range of values rather than a statistically valid value. The purpose of the analysis was to identify morphological parameters that can provide guidance for designing TWBs with RC cores based on existing constructions, rather than conducting specific calculations for verifying the proposed design. Therefore, the parameters presented in Table 1 provides a general idea of the characteristics of the analysed buildings and should be used as reference values for similar design projects. It is important to keep in mind that specific designs may require further analysis and consideration of additional parameters to ensure the safety and stability of the building.

Table 1: Summary of Proposed Parameters

Case	Wood Cube	LCT One	BC	Hault	HoHo	Ascent
Stories	5	8	18	22	24	25
Height [m]	25	27	58	73	84	87
Year	2013	2012	2017	2020	2020	2022
Country	Germany	Austria	Canada	Netherlands	Austria	USA
Ecc $_x$ [m]	0,2	6,3	0,8	1,4	0,8	1,0
Ecc $_y$ [m]	0,2	6,7	4,6	0,2	2,0	2,3
ρ_x	1,4%	2,6%	1,8%	1,4%	1,7%	0,7%
ρ_y	0,8%	2,0%	0,6%	0,7%	4,0%	0,6%
S	0,89	0,54	0,27	0,42	0,87	0,52
D [m]	10	16	15	13	7	20
Slab	DLT	CLT-RC	CLT	CLT-RC	CLT RC	CLT

The eccentricities in both X and Y directions (see Figure 7) show that the center of rigidity and the center of mass do not necessarily coincide, which can affect the building's response to lateral loads. The shear wall density by direction (see Figure 8) indicates the amount of reinforced concrete shear walls needed to resist horizontal forces, which is influenced by the type of loads the building is subjected to. The slenderness ratio (see Figure 9) measures the elongation of the building in one direction and is an important factor in determining the building's lateral stability. The maximum distance between the concrete core and the edge of the building (see Figure 10) can give an indication of the distance lateral forces have to travel to be transferred to the core. Finally, the material of the slab is a relevant parameter to consider, as it affects the building's weight and stiffness.

4 DISCUSSION

The study of the six TWBs with RC cores provides information on the morphological parameters required to develop efficient designs for TWBs with RC cores. The qualitative analysis of each building's structural floor plans allows to identify and compare the eccentricities by direction, the density of shear walls by direction, the slenderness ratio, and the maximum distance between the concrete core and the edge of the building.

One of the most significant findings is that all six buildings had relatively low slenderness ratios, indicating that a squat and stable design is preferable for TWBs with RC cores, which is consistent with current design practices. Regarding the eccentricities, none of the studied buildings present perfect symmetry, and both BC and LC One have a considerable distance between their CM and CR. The density of shear walls varied significantly between the buildings, which indicates that there is no universal solution for designing TWBs with RC cores. However, there is some correlation between the slenderness of the building and the wall density indexes. The distance between the concrete core and the edge of the building also varied significantly between the analysed buildings, which may be related to different architectural requirements or loading conditions.

5 CONCLUSIONS

The analysis of the buildings reveals that the floor plans exhibit strong axes of symmetry and tend to be more square shaped in general. However, it is noteworthy that the buildings with lower slenderness ratios have the highest eccentricities. This can be attributed to the design approach of these buildings, which allows for larger open floor spaces compared to other buildings. There is a trade-off between maximizing floor space and minimizing eccentricities in the design of tall wood buildings. Designers should carefully balance these factors to ensure adequate structural performance and minimize the risk of structural failure.

In general, the studied parameters exhibit slight variations and fall within the following ranges: eccentricities ranging from 6 [m] to 0.2 [m], wall density ranging from 0.5% to 4%, slenderness ratios ranging from 0.3 to 0.6, and maximum distance from the core to the edge ranging from 7 [m] to 20 [m].

Although the study only considers six buildings, the number of wooden buildings with RC cores is not very high, and some of the buildings considered were identified as the tallest buildings with this typology according to Huseyin Emre [4]and Ražnjevi´c[7]. The building with the longest slab extension from the core is the most recent building, which is likely attributed to the development of the slabs used. It is noteworthy that this was achieved even with the use of cross-laminated timber (CLT) slabs instead of composite slabs (CLT RC). This suggests that advancements in timber technology are allowing for greater spans and more efficient use of materials in construction. Additionally, the use of timber slabs offers a more sustainable and environmentally friendly option compared to traditional concrete slabs.

It can be observed that there is no direct relationship between wall density and height or eccentricity. However,

https://doi.org/10.52202/069179-0516

some correlation between wall density and slenderness was founded. An example of this is the HoHo building, which has the highest wall density, but this is not necessarily due to lateral demands, but rather a design decision that allowed it to become the first 24-story wooden building. However, the variable of wall density appears to be particularly interesting in seismic territories when considering the study of damage in buildings after the Maule 2010 earthquake presented by Juneman[9], where it is defined that buildings with reinforced concrete walls that presented lower structural damage had a wall density greater than 2%. Given the great variability of wall densities in the studied buildings, and the lack of a clear trend on the seismicity of their zone, the study of wall density is proposed as an interesting topic by classifying their seismic zone. Nonetheless, the range defined can support the idea that timber buildings with RC cores should consider a wall density near a 2% on high seismic zones.

The performance of wooden buildings with RC cores has been studied due to the high applicability of this typology for buildings in seismic zones. The ductility of this material (i.e., using RC shear walls as lateral system) allows for much more favourable modification factors for seismic design, resulting in lower wall densities, if using CLT shear walls vs RC walls. However, the use of different lateral resistance systems implies uncertainty in the definition of the modification factor. It is recommended not to use CLT shear walls and RC shear walls together as lateral system in highly seismic zones. It is worth noting that two of the studied buildings, Hault and WoodCube, have CLT shear walls along concrete cores, but the studied parameters indicate that they could preliminarily do without them as stiffening elements, due to the amount of RC walls and the seismicity of their zones. This is particularly evident in the case of Hault, which has an RC core that varies along its height and replaces them with CLT walls, having more CLT walls and less RC walls in higher stories. This analysis is beyond the scope of this study and is proposed as a topic for further investigation.

The ranges for the morphological parameters studied in this article should be used only as references based on case studies, not as a design value, since no verification has been carried out and the dimensions used are approximate. Further research considering seismic zone and different typologies are being studied for future investigations.

AN INSIGHT INTO THE DEVELOPMENT OF TIMBER BRIDGES IN NORWAY AND SWEDEN

Martin Cepelka[1], Per-Anders Fjellström[2], Ashish Aeran[3]

ABSTRACT: Timber has historically played an important role as a building material for bridge construction both in Norway and Sweden. Although a decline was seen due to rise of other competing materials such as steel and concrete over the past century, it has regained popularity in recent decades due to pioneer developments in timber engineering including glued laminated timber and stress-laminated timber decks. There has been a specific focus on development of timber bridges in the Nordic countries after a Nordic Timber Bridge Project was started in 1994. Hundreds of bridges have been constructed throughout these countries including both pedestrian and heavy traffic bridges thereafter. Although the information about the number and type of these bridges can be found on several public administration sources, the information is very scattered and difficult to interpret. In the current study, several sources and databases were used to collect data on timber bridges in Norway and Sweden. Based on the collected data, a comparative view of the development of timber bridges in the two countries is presented with main focus on modern timber bridges built after year 2000. Detailed statistics are included in the study regarding year of construction, type of traffic, bridge types and bridge lengths. Discussions are presented in the end with focus on current trends and possible outlooks for use of timber bridges.

KEYWORDS: Timber, Bridges, Norway, Sweden, Statistics

1 INTRODUCTION

Timber bridges represent an environmentally friendly alternative to concrete bridges for medium-span bridges. As numerous LCA analyses have recently showed, by using timber instead of concrete, reduction of CO_2-equivalent can be achieved for bridge constructions [2]. Both in Norway and Sweden, number of modern timber bridges have been built since 1990's and good knowledge regarding the use of timber in modern bridge structures have been obtained [3]. An example of a modern timber bridge in Norway is shown in Figure 1. With today's focus on green transition, timber bridges can be utilized for lower environmental impact of infrastructure projects. Besides lower environmental impact, timber bridges feature low weight and rapid assembly on site due to large amount of prefabrication and manufacturing precision.

Lately, timber load-bearing structures have been facing tremendous growth in multi-story buildings in Norway and Sweden. According to Norwegian Byggfakta, timber was used in the load-bearing structure in about 40 % of all new school projects in Norway in 2021, while the share on the building market was about 10-20 % in past 10 years in average [1]. The reason behind the growth of share of timber buildings compared to other structural materials is believed to be facilitated mainly by use of a new technology by cross-laminated-timber (CLT), and increased focus on environmental impact of new projects. Given the large increase of use of timber in multi-story buildings, we were interested in investigating whether same trend can be observed for timber bridges. We found the available data being difficult to use directly and decided therefore to perform a statistical study based on own collected data for timber bridges in Norway and Sweden. The results of the investigation are presented in the current paper including details regarding bridge types and bridge lengths. The data are complemented with description of the current trends in timber bridge construction in order to provide an inspiration for bridge designers and bridge owners.

2 DATA COLLECTION

Neither in Sweden, nor in Norway, there exists an overall database governing all bridges within the countries. There are numerous bridge owners, each having their own databases with rather varying quality. In addition, the private owned bridges are not covered by any database. The collection of a total number of bridges is hence difficult. We have therefore chosen to collect data from the leading timber bridge contractors in Norway and Sweden: Moelven, Svenska Träbroar, Martinsons, and the central bridge databases Brutus (Norway) and BaTMan (Sweden), where most of road and pedestrian bridges over main roads are registered. In addition, some bridges were registered manually based on the authors' knowledge. All bridges were then checked across the different databases such that double-registration was avoided. For most bridges, GPS coordinates were available which gave possibility to plot the bridge locations for validation.
Besides data on timber bridges, we have also used Brutus and BaTMan to provide number of bridges built in concrete and steel for comparison and overall trend on the number of built bridges.

For most of the bridges, we have collected additional information in terms of bridge length, type of traffic on bridge (road, or pedestrian), and bridge type. This gave a possibility to look deeper into the development of timber bridges over time, as presented in Section 4.

We have chosen to focus on "larger" bridges built since year 2000. We were interested in bridges that either carry vehicle loads or pedestrian bridges that cross main roads or larger rivers. That means that smaller bridges, as for example park bridges, were disregarded. In some plots, we have also included data on bridges built before year 2000 to visualise a particular trend. However, it must be kept in mind that the data on older bridges bear higher uncertainty. All registered bridges are currently in operation, i.e. bridges that have been replaced or removed were disregarded (this is mainly relevant for older bridges).

The authors are of opinion that the vast majority of larger timber bridges in Norway and Sweden are covered in the study. However, it must be emphasized that the study does not cover all timber bridges due to the limitation of the data collection as it is very difficult, if not impossible, to obtain data on all bridges within the countries.

3 RESULTS ON NUMBER OF BRIDGES

This section presents an overview of the number of timber bridges built in Norway and Sweden. Additional statistics on bridge types is presented in Section 4. As the study does not cover all timber bridges, it must be kept in mind that trends, rather than absolute numbers, should be interpreted.

3.1 Timber bridges in Norway

The number of timber bridges in Norway since 2000 are presented in Figure 2. The number of bridges seems to be rather stable, and it fluctuates around a year-average of about 10 timber bridges per year. The bridge number is particularly high in 2019 due to contribution of 11 flyover arch road bridges on large motorway projects Rv. 3/Rv. 25 Løten–Elverum (8 bridges), and E6 Brumunddal-Moelv (3 bridges). Figure 3 presents the distribution of road and pedestrian bridges in Norway and it is fairly even in general. The total percentage of road bridges are 47 % compared to 53 % pedestrian bridges during the considered period. The total built lengths of these bridges are also presented in Figure 4. Although the total built length of road bridges is much higher in some years, the overall length is nearly the same during the considered period (4.47 km for road bridges and 4.03 km for pedestrian bridges). The historical development of road and pedestrian timber bridges over past decades is also presented and shown in Figure 5. Here, a clear trend in increase of number of road bridges can be observed after 1990s.

Figure 2: *Number of timber bridges built in Norway (both pedestrian and road bridges), based on selected database. The dotted line represents moving average with period of 2 years.*

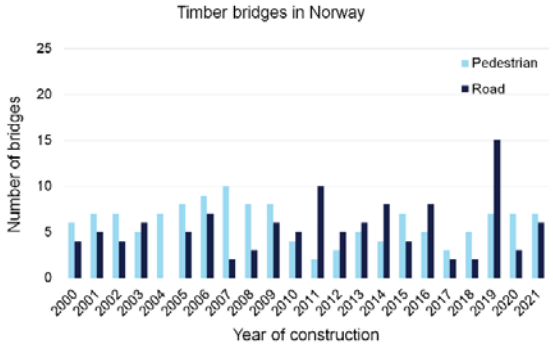

Figure 3: *Number of road and pedestrian timber bridges built in Norway, based on selected database*

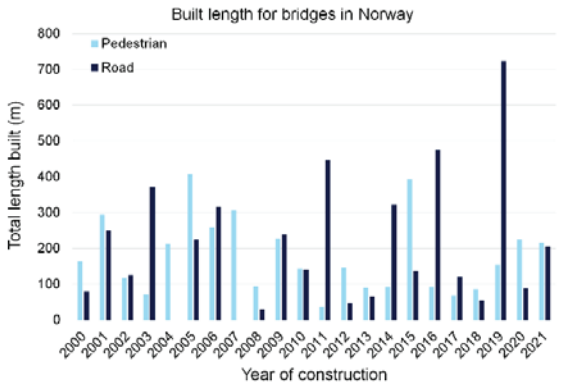

Figure 4: *Built length of road and pedestrian timber bridges built in Norway (2000-2021), based on selected database*

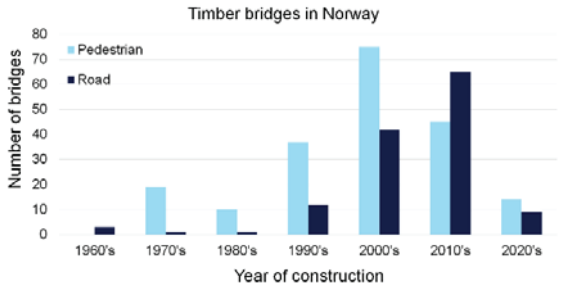

Figure 5: *Built length of road and pedestrian timber bridges built in Norway (1960-2021), based on selected database. Note that data on older bridges are less reliable.*

Figure 6 shows a comparison between share of timber, concrete, and steel bridges built in Norway. The share of timber bridges is relatively stable, and it fluctuates around 5 % every year for studied period.

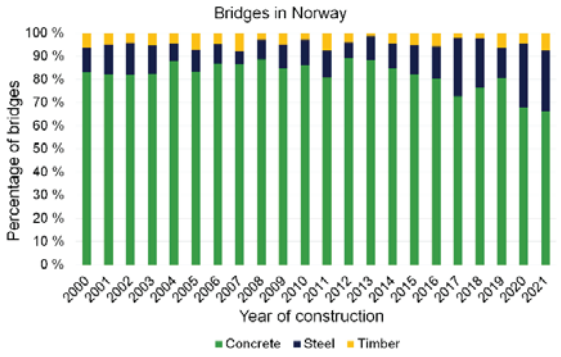

Figure 6: *Comparison of share between concrete, steel, and timber bridges built in Norway in period 2000-2021 as registered in Norwegian bridge database Brutus.*

3.2 Timber bridges in Sweden

The number of timber bridges in Sweden are presented in Figure 7. The number of bridges built in the early 2000's is around 50 bridges per year, and the trend seems to be decreasing in last 10 years.

Figure 7: *Number of timber bridges built in Sweden (both pedestrian and road bridges), based on the selected database. The dotted line represents moving average with period of 2 years.*

The distribution between road and pedestrian bridges is shown in Figure 8. Almost 70 % of the bridges are pedestrian during the considered period, although this gap seems to be decreasing in the recent years. The total built lengths of road and pedestrian bridges are shown in Figure 9 with pedestrian bridges around 15 km as compared to 4 km road bridges.

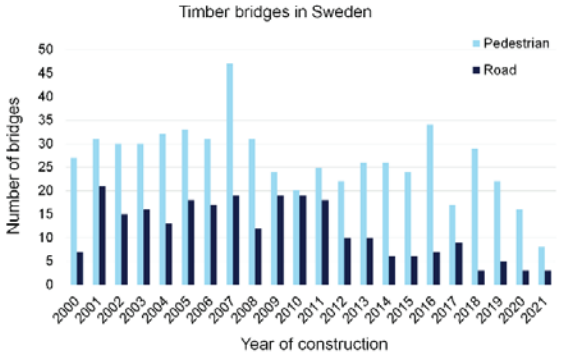

Figure 8: *Number of road and pedestrian timber bridges built in Sweden (2000-2021), based on selected database*

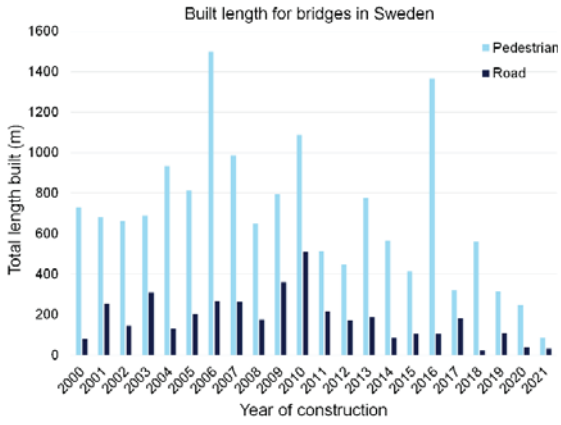

Figure 9: *Built length of road and pedestrian timber bridges built in Sweden (2000-2021), based on selected database*

https://doi.org/10.52202/069179-0517

Figure 10 shows a comparison between share of timber, concrete, and steel bridges built in Sweden based on the bridges registered in the national database BaTMan. The share of timber bridges is relatively stable, and it fluctuates between 3-7 % for studied period besides year 2021, for which no timber bridge has been registered in the database.

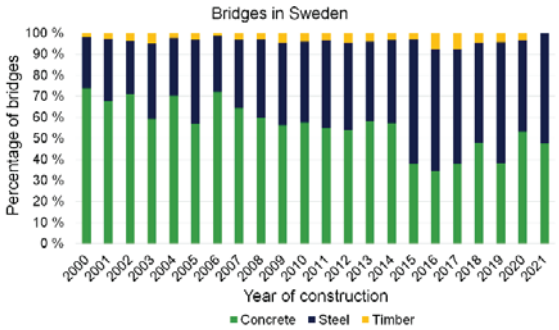

Figure 10: *Comparison of distribution between concrete, steel, and timber bridges built in Sweden in period 2000-2021. The data are only valid for state owned bridges registered in the Swedish Road Administrations bridge database BaTMan.*

3.3 Comparison of bridges in Norway and Sweden

A comparative study is done for timber bridges in Norway and Sweden as shown in Figure 11. The number of bridges is substantially higher in Sweden as compared to Norway. This is primarily due to a larger number of pedestrian bridges in Sweden as shown in Figure 12, annual built length, and Figure 13 the total built length. However, as also mentioned earlier, the gap between the number of road and pedestrian bridges is getting closer in the recent years, both in Norway and Sweden.

The number of road bridges is also much higher in Sweden, and this number is more than twice of that in Norway. However, interestingly, the total built length of road bridges is higher in Norway than Sweden, see Figure 14. Same trend can be observed for pedestrian bridges for which the factor of 6 in difference between Norway and Sweden in terms of number of bridges is reduced to 3 when comparing accumulated bridge length. This indicates that a typical timber bridge in Norway is longer compared to a typical timber bridge in Sweden.

4 CURRENT TRENDS AND BRIDGE TYPES

4.1 From historical to modern timber bridges

Use of timber in bridges in the main load-bearing elemens has a long tradition both in Norway and Sweden. Up to the 20th century, timber was the main building material for both pedestrian and road bridges. Two examples of old timber bridges are Gamle bybro (1861) in Trondheim, Norway, and Lejonströmsbron (1737) in Skellefteå, Sweden shown in Figure 15. With the development of steel and concrete, timber bridges became less popular and up to 1990's, use of timber was limited to mainly smaller pedestrian bridges.

Figure 15: *The Lejonström bridge built in 1737 with a combined kingpost strut-frame design is still open for road traffic. Location Skellefteå, Sweden. Photo: Per-Anders Fjellström.*

Three Nordic Timber Bridge research projects were carried out from 1994 to 2001. The purpose of these projects was to increase knowledge and competitiveness for timber bridges in Norway, Sweden and Finland. Denmark and Estonia were also involved in some parts of the projects. In Norway, the focus was on developing the typical trusses and arches with dowel joints in combination with creosote treated glulam used today. In Sweden, focus was on the use of stress-laminated decks made of glulam of spruce, in combination with wood protection by design and structural health monitoring. In Finland, they focused on wood-concrete composite bridges and shear connections in treated glulam. The Nordic Timber Bridge projects represent a gamechanger in use of timber in bridges in Norway and Sweden. As can be seen in Figure 16 and Figure 17, both the number of bridges and bridge length accelerated noticeably in 1990s and 2000s, especially for road bridges.

4.2 Current trends in Norway

In addition to Nordic Timber Bridge project, important contribution to use of timber in load-bearing structures were Olympic games in Lillehammer in 1994. As there was a wish for more extensive use of timber in larger structures, a connection technique with slotted-in steel plates and dowels was developed allowing strong joints for large truss structures. In addition, production of glued laminated timber became more controlled and effective, which allowed for production of stronger and larger timber elements. For bridges, increased quality of pavement and need for improved durability of timber decks was required and later efficiently facilitated by using stress-laminated decks. This type of deck provides sufficient stiffness for asphalt pavements and can be protected by moisture membrane, similarly to concrete bridges [4]. In 1996, Evenstad bridge was erected, facilitating all afore mentioned techniques. This is widely considered as a new start, or renaissance, for timber bridge construction in Norway. The vast development in 1990s allowed for use of timber in road bridges that could compete with concrete bridges. These new types of bridges have normally stress-laminated plate decks that are either directly supported by substructure (plate bridges), or by transversal beams connected to arches (arch bridges) or trusses (truss bridges).

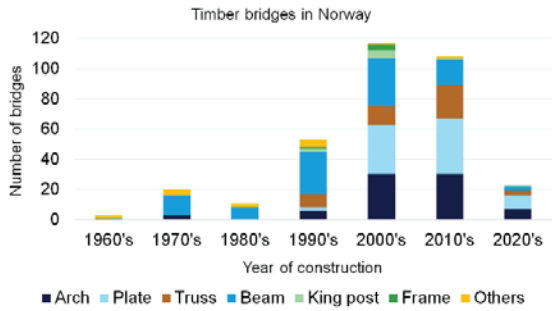

Figure 16: *Distribution of built timber bridges in Norway per bridge type and decade, based on selected database. Note that data are missing for some few bridges, and data on older bridges are less reliable.*

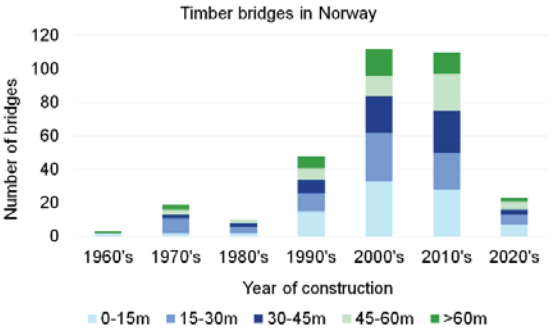

Figure 17: *Distribution of built timber bridges in Norway per built bridge length and decade, based on selected database. Note that data are missing for some few bridges, and data on older bridges are less reliable.*

https://doi.org/10.52202/069179-0517

As the statistics in Figure 16 shows, majority of timber bridges built in 1970s and up to approximately 1990s were beam bridges. These were typically pedestrian bridges with shorter spans and simple timber plank decks. As can be seen in Figure 18, the use of beam bridges has decreased over the past decades, and it is nowadays typically limited to shorter pedestrian bridges crossing streams or small rivers. These bridges are competitive due its simplicity and low weight allowing for fast and easy erection for cases where shorter service life than standard 100 years is acceptable. There were built few girder bridges where the beams were connected together with stress-laminated plate creating a T-beam. However, the low number of such bridges indicates that this structural system is probably not competitive to concrete bridges with prefabricated beams.

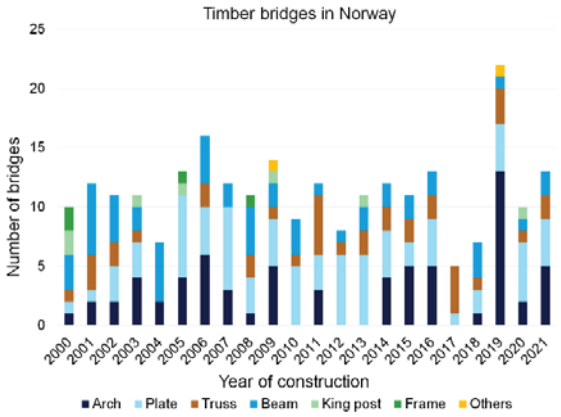

Figure 18: *Distribution of timber bridges per bridge type (2000-2021) in Norway, based on selected database.*

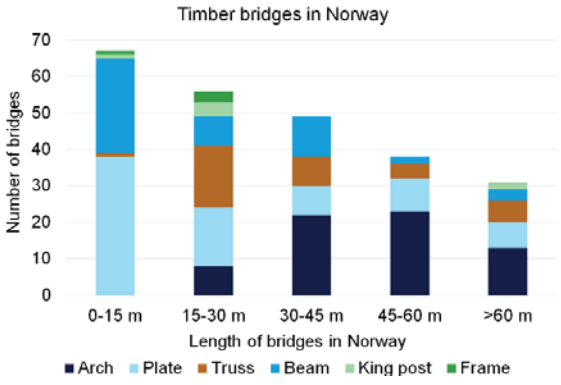

Figure 19: *Distribution of timber bridges per bridge type and built length (2000-2021) in Norway, based on selected database.*

Figure 18 shows a steadily increasing trend in use of plate bridges and arch bridges both for pedestrian and vehicle bridges. Plate bridges are used either as simply supported plates for shorter bridges over rivers or streams (often on secondary roads), or as continuous plates over several spans. The advantage of plate bridges is their low weight and low depth allowing for effective flyover bridges over existing roads and railways, see example in Figure 20. They facilitate normally very fast assembly, reducing considerably closure time of infrastructure beneath them. Typically, plate bridges are used for spans up to 15 m for road bridges, and up to 20 m for pedestrian bridges.

Figure 20: *Plate bridge with stress-laminated deck in Hell, Norway as flyover road bridge over railway from 2009. Photo: Martin Cepelka.*

Larger spans can be achieved by hanging the stress-laminated decks on arches or trusses. Arch bridges have lately been used as flyover bridges on numerous motorway projects. The arches can normally span 40-50 m which is sufficient to avoid any intermediate support in the road profile, as shown in example in Figure 21. This increases safety on motorways and provides high aesthetical value. For simple road geometry on the bridge (straight and narrow bridges), the arch bridges seem to give an effective and competitive solution.

Figure 21: *Arch bridge as flyover road bridge over E6 near Sorperoa, Norway from 2016. Photo: Google.*

Lately, several arch bridges with large spans over rivers have been obtained by combining timber arches and concrete decks together with network configuration of hangers. There is in total 6 such bridges built in period 2016-2022. Steibrua, shown in Figure 22, is the largest of those, and it is with its 88 m the longest spanning bridge with timber load-bearing structure in the world [5].

Figure 22: *Network arch bridge with concrete deck and timber arches. Steibrua in Alvdal, Norway from 2016. Photo: Martin Cepelka.*

Alternatively, truss structures have been used to obtain large spans. The longest spanning truss bridge is Flisa bru with 77 m span. Unfortunately, one of the largest timber truss bridges, Tretten bru, collapsed suddenly in August 2022. As the cause of the collapse could not easily be determined, Norwegian Public Road Administration decided to close several other truss bridges to allow for their thorough inspection. For the time being, the cause of Tretten bru collapse is still under investigation and the future use of truss bridges in Norway remains somewhat unclear.

An overall distribution of bridge types and built lengths for years 2000-2021 is shown in Figure 23 and Figure 24. Figure 23 shows that most timber bridges built in period 2000-2021 in Norway are plate bridges (32 %) and together with arch bridges, they represent around 60 % of all timber bridges. Figure 24 shows rather uniform distribution of bridge lengths sorted in groups per 15m for lengths 0-15 m, 15-20 m, and 30-45 m with approximately 25 % contribution each. Bridges with lengths 45-60 m, and more than 60 m represent 16 %, and 12 %, respectively. There are in total 14 bridges with lengths larger than 100 m. Flisa bru is the longest road bridge with 196 m length, and Midgardsormen bru is the longest pedestrian bridge with 230 m length.

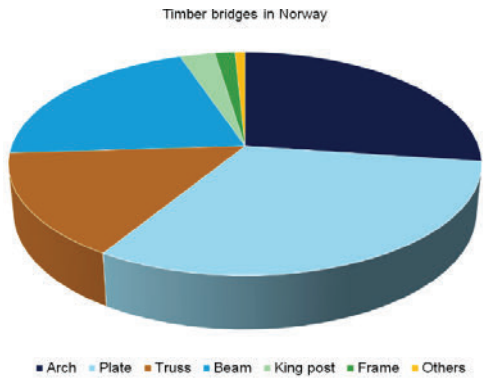

Figure 23: *Distribution of timber bridges per bridge type built in years 2000-2021 in Norway, based on selected database*

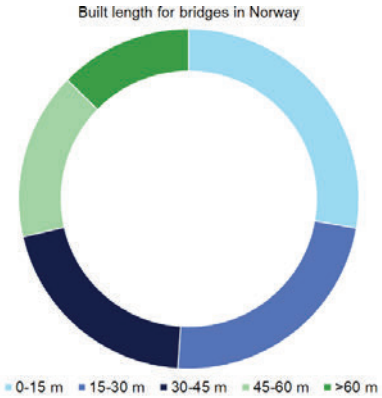

Figure 24: *Distribution of timber bridges per built length built in years 2000-2021 in Norway, based on selected database*

Since the new generation of timber bridges raised in 1990's, there is still increasing focus on durability. In Norway, required bridge service life is 100 years (independent of material). For timber bridges, this is believed to be achieved by use of both structural protection (load-bearing members are mechanically covered/protected by cladding or sheeting) and chemical treatment. In Norway, it is common to use double level of chemical treatment, typically salt treatment for single laminations and creosote treatment for the whole glued-laminated element. The creosote treatment provides very good protection against fungi and insects, in addition to reduction of moisture sorption. As a result, it is not necessary to cover timber elements entirely. This reduces maintenance need and gives more freedom to designers in choice of the structural scheme. In last 20 years, numerous spectacular truss bridges have been built. This is particular for Norway, as the use of creosote is not allowed in most other countries. It is expected that creosote will eventually be restricted in Norway as well, and the design of timber bridges will most likely turn towards trends in other countries where structural protection is the primer measure to obtain durability, as for example in Sweden as discussed further in Section 4.3. It can also be expected that new structural systems will appear in Norway. For example, in Germany and Switzerland, numerous modern bridges have lately been built with timber-concrete composite layout [6], [7]. Besides protection from weather, concrete deck in composite action with timber girders give effective structural system and allows for larger spans. Consequently, we might see a growth in use of beam bridges in Norway again.

4.3 Current trends in Sweden

As in Norway, the trend is to use more renewable materials as wood in larger constructions and buildings. However, the use of wood in bridges has been decreasing for the last decade. There are some obvious reasons for this:

https://doi.org/10.52202/069179-0517

One is that the market for building large timber structures is increasing rapidly and it is an easier and better market than in building timber bridges. The two dominating timber bridge producers are also two of the three largest glulam manufacturers in Sweden. A second reason or a factor is the Swedish road administrations moderate interest in developing and using timber bridges, opposite to the situation in Norway. Another minor reason is that the use of spruce in bridges have shown to be a little more complicated than first expected. Especially railings, cladding and the edges of stress-laminated decks were found to suffer from durability problems. This is a problem for the large forest companies, that owns a lot of small timber bridges, and they are now starting to replace damaged bridges with new steel bridges.

If we look back att the timber bridges built early last century, we will find that Sweden had a large number of strut frame bridges in one or several span often in combination with a kingpost on top of the strut frame, as the Lejonströms bridge. For larger spans, 50 – 125 m, it was common to build suspension bridges with timber towers. A couple of these bridges are still in use in Dalarna region. Another type of bridge that was used for crossing rivers, were floating bridges, two off that design remains over Dalälven, but not in their original design. Covered bridges were not so common in Sweden and only one remains, Vaholms Brohus built in the late 19th century.

For reasons there are very few remaining timber bridges built between 1940 - 1980. One obvious reason for this is that most of them have been replaced, and another is that most road bridges were built in concrete or steel. However, there is a large number of steel girder bridges built with timber deck in that period of time, many of them still in use.
The new era of timber bridges was started by the Nordic TB-project. It opened a new market for factory built modern timber bridges for both pedestrians and road traffic. In the early 1990's most bridges were built with chemically treated wood, NTR A. Now it's used only in pedestrian bridges with truss or beam design designed for 40 years' service life, and some smaller and temporary road bridges, mainly for the forest industry.
Most timber bridges are built of spruce, and they are designed for 80 years' service life.

Road bridges
The first road bridge with a stress laminated deck of spruce was built in 1994, followed by the first stress laminated bridge deck with a T-section of treated wood, one year after. The stress-laminated deck slab of spruce has become a very popular design with over 400 bridges built since 2000. For road bridges it's the most common design to use as a single- or multi span deck. The design is simple, robust and bridges are easy to produce and transport to the bridge site. One big difference between Norway and Sweden is the use of the stress-laminated design in combination with arches, kingpost or trusses. If we compare the number of arch bridges for road traffic, only one is built in Sweden, while in Norway, there is a quite large number of arch bridges.

Figure 25: *A typical stress-laminated timber bridge over railroad. Built 2017 in Hörle, Sweden, by Moelven Töreboda. Photo: Per-Anders Fjellström.*

Pedestrian bridges
The pedestrian bridges built from 2000 to today shows a great variation in both length and design. Some typical Swedish pedestrian timber bridges are the long span cable-stay-, medium span truss- and short span beam bridges and a number of stress laminated decks.

The most common designs are beam bridges and different combinations with a stress-laminated deck with more than 200 bridges built of each type.

Figure 26: *Pedestrian bridge to Strömsholmen in Eskilstuna, Sweden. The design is a 48 m 3-span beam bridge with a transverse plank deck. Built 2001 by Svenska Träbroar. Photo: Per-Anders Fjellström.*

The small Howe Truss bridge is another popular bridge design in spans up to 30 m with close to 100 bridges built the last 20 years.

https://doi.org/10.52202/069179-0517

Figure 27: *Pedestrian Howe Truss bridge to Kållandsö close to Lidköping, Sweden. The design is a 25m truss bridge with a transverse plank deck. Built 2017 by Martinsons. Photo: Per-Anders Fjellström.*

The modern version of the old suspension bridge in timber is the cable-stay design. It is a popular design and there is at least one ongoing project to build one next year in Ängelholm, Sweden. The Älvsbacka bridge in Skellefteå is the longest with a main span of 130 m. A total of 8 bridges have been built since 2000.

Figure 28: *Älvsbackabron is a cable-stay pedestrian bridge with a 129m span built 2012 over Skellefteälven, Sweden, by Martinsons. Photo: Per-Anders Fjellström.*

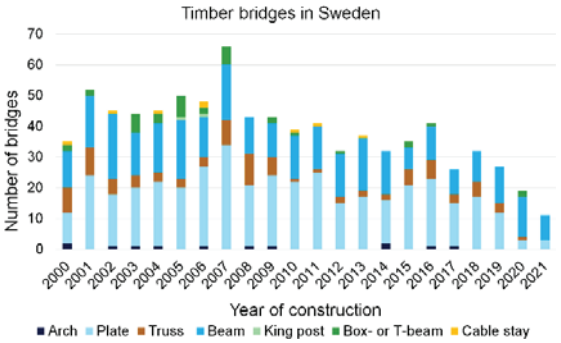

Figure 29: *Distribution of timber bridges per bridge type (2000-2021) in Sweden, based on selected database.*

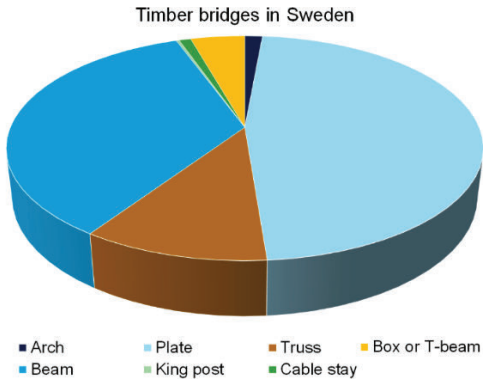

Figure 30: *Distribution of timber bridges per bridge type built in years 2000-2021 in Sweden, based on selected database*

A lot of work has been done to improve wood protection and durability over the years. Good wood protection by design in combination with factory installed sensors for moisture content measurements is the Swedish way to meet the demands for a long service life. It's an environmentally friendly and hopefully a cost-effective approach to durability. The use of spruce, a not durable species, in a bridge superstructure requires a different approach to inspections and there is still some work to do regarding reliable inspection methods. In the next years, we think that we will see new designs on the Swedish market such as timber-concrete composite, light weight long span designs as the InfraLIGHer winner BIFROST and, hopefully, new state of the art covered bridges.
The biggest question in Sweden is how the market and production of timber bridges will adapt to the fact that the two largest producers have closed down their timber bridge production from 2022.

Figure 31: *Factory installed M.C-sensors in a stress-laminated deck provide the owner with reliable data from inspections. Road bridge built 2022 by TBS, Junsele Sweden. Photo: Per-Anders Fjellström.*

https://doi.org/10.52202/069179-0517

5 CONCLUDING REMARKS

The current study reveals a great potential for use of timber in bridges as a possible measure for reducing environmental impact of infrastructure projects.

The results presented in Section 3 show an opposite trend in number of bridges compared to the recent growth of use of timber in buildings. In Norway, the number of timber bridges built every year is fairly constant, while in Sweden, a clear decreasing trend can be observed.

As demonstrated in Section 4, several modern timber bridge concepts have been developed since 1990s that can represent a competitive, and more environmentally friendly alternative to concrete bridges.

The choice is in the hands of bridge designers and bridge owners.

6 ACKNOWLEDGEMENTS

The authors would like to acknowledge Moelven and Martinsons for sharing their data. This was an important input into the study, and it is much appreciated.
We would also like to acknowledge Sara Holm for her contribution with data gathering in the beginning of the project.

NEBY BRU: ONE FOOTWAY, THREE WAYS OF SUSTAINABILITY

Manuel Sánchez-Solís[1], Gaute Mo[2], Fernando Ibáñez[3]

ABSTRACT: Degree of Freedom, in collaboration with the municipality of Tynset, has developed the detail design of a pedestrian bridge that will join the neighbourhood of Neby with the rest of the city, crossing the river Glåma. This project had a limited budget, so the design stage has been influenced by the materials optimization, the use of local resources and suppliers and the consideration of conventional constructive methodologies. The bridge was opened to pedestrian traffic in May 2020. This text describes the main characteristics of the structure and the methodology considered in the design.

KEYWORDS: Footway, cable, suspension, timber, steel, truss, sustainability, social, commitment

1 INTRODUCTION

Degree of Freedom has collaborated with the Municipality of Tynset (Norway) in the design of a pedestrian bridge crossing the river Glåma.

The original idea of the design was to create a light pedestrian timber bridge integrated in the natural environment and landscape where it is placed.

The new suspension footbridge will reconnect the neighbourhood of Neby with the rest of the city of Tynset, laying on the foundations of an old bridge destroyed during the World War II.

Given the social approach of the project, it has been decided to use local resources and suppliers, seeking their collaboration when providing their services: from the cables, which are provided by a Norwegian company, to the steel plates, which are delivered by a local workshop.

The bridge will also be constructed by local people and using technology available in the area, which has largely conditioned the conception of the construction process.

Since the design process, the economy of the project has been considered by optimizing the materials as much as possible.

Figure 1: *View of the Neby pedestrian bridge*

2 DESCRIPTION OF THE STRUCTURE

The Neby Bru is a suspension bridge, consisting in a continuous timber truss deck with steel diagonals, suspended from catenary cables by means of vertical hangers. There are towers at each riverbank, plus two intermediate towers supported over two existing isles. The bridge is then divided into three spans approximately 30m, 33m and 30m long, respectively.

The deck has a minimum horizontal clearance of 1.5m between handrails, which is extended up to 5m at the central towers to create a balcony. The balcony makes the top and bottom chord truss to be discontinuous at the central towers since top chord is stopped. An extra diagonal hanger connected to the central towers is then required in order not to overload the bottom chord adjacent to the balcony (refer to Figure 4).

The bridge main structural elements are described in the following sections.

2.1 MAIN CABLES

The bridge has two main cables 6x36 IWRC with 36mm nominal diameter, parallel in the longitudinal direction of the bridge, suspended from the towers and anchored to concrete anchorages blocks.

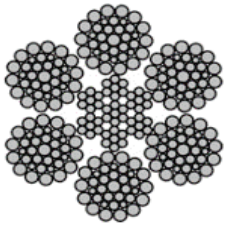

Figure 2: *Main cables section*

[1] Manuel Sánchez-Solís, Degree of Freedom SLU, Valencia, Spain, m.sanchez@dofengineers.com
[2] Gaute Mo, Degree of Freedom AS, Oslo, Norway, g.mo@dofengineers.com
[3] Fernando Ibáñez, Degree of Freedom SLU, Valencia, Spain, f.ibanez@dofengineers.com

https://doi.org/10.52202/069179-0518

Main cables rest over the four towers though steel saddles bolted at the top of the towers.

2.2 TOWERS

The towers on the river sides are composed by two timber columns and two lintels joining the top of them.

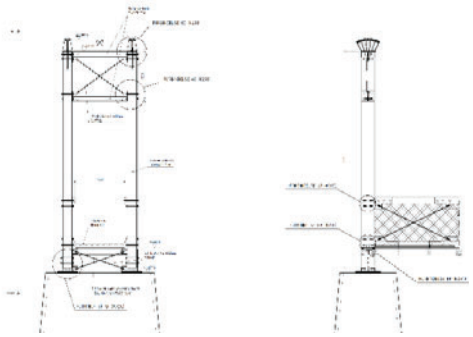

Figure 3: *Extreme towers*

For the towers in the central piles, in order to provide them with more stability they are designed with an A shape.

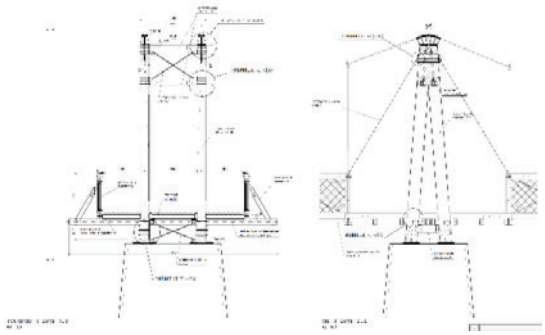

Figure 4: *Intermediate towers*

The height of the towers has been calculated assuming a ratio span/height = 5.25 which has been proved to work fine for this type of bridges. Then considering the central span we have:

H_{towers} = 33/5.25= 6.30 m

2.3 VERTICAL HANGERS

Vertical hangers are 16mm steel bars suspended from the main cables, supporting the bridge deck at a spacing of 33/12 = 2.75m.

Hangers are connected to the main cables though clamps and fork sockets.

The bottom meter portion of the hangers is threaded to be able to adjust the deck levels (adjusting nuts) at the required level in every construction stage.

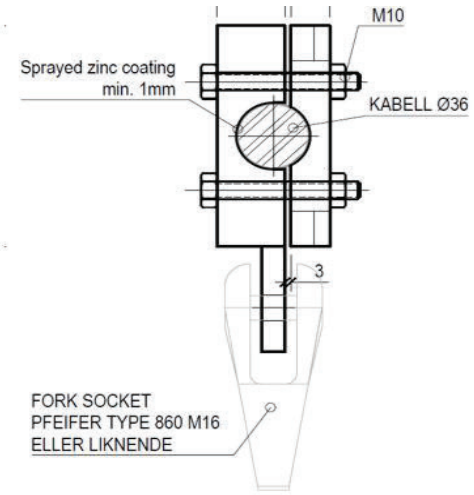

Figure 5: *Hangers clamp and fork socket*

2.4 TIMBER TRUSS DECK

The timber frames form two vertical trusses connected between them at the bottom by another horizontal truss that gives lateral stiffness to the bridge to resist loads in the gravity direction but also lateral forces from the wind. These three trusses form an open U-shaped section, so the top chord is also the handrail.

The following pictures show the preliminary design for a typical module of the bridge deck, which would be repeated every 2.75m.

The bridge deck will be ensembled in double and single 2.75m modules to facilitate the construction sequence.

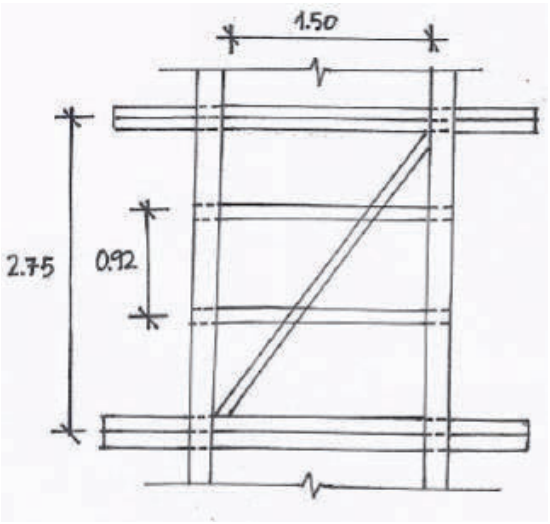

Figure 6: *Truss plan view*

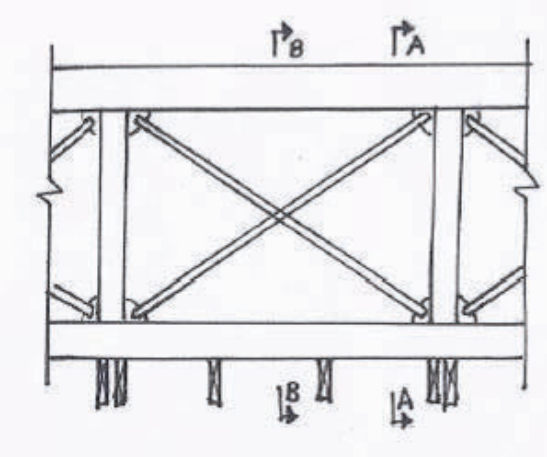

Figure 7: *Truss elevation*

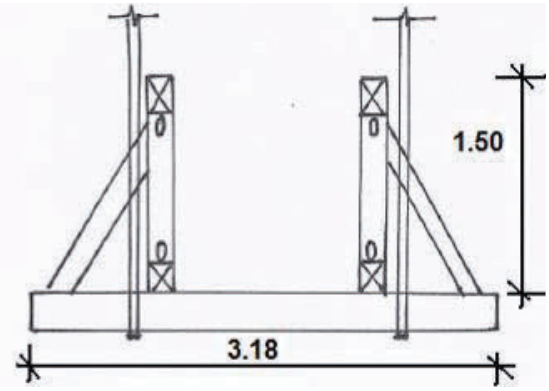

Figure 8: *Truss section A-A*

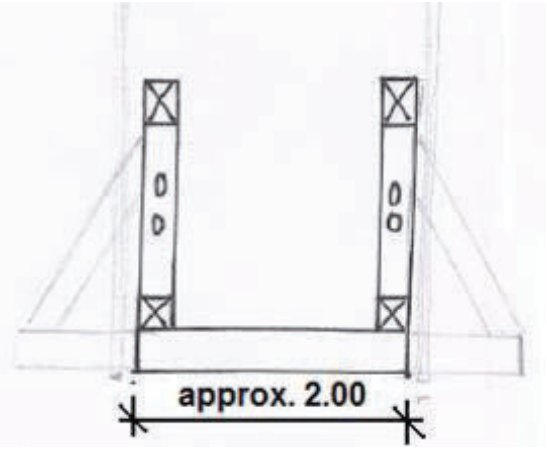

Figure 9: *Truss section B-B*

2.5 CONCRETE ANCHORAGE BLOCKS

Concrete anchorage blocks are located on both river sides, they are capable to resist the forces from the main cables.

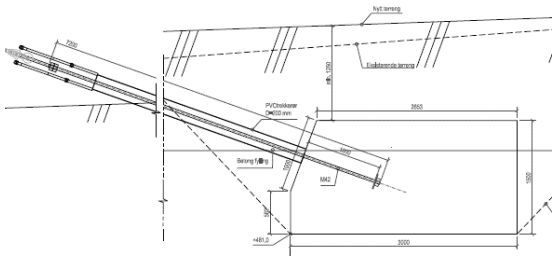

Figure 10: *Anchorage block*

3 BRIDGE ERECTION SEQUENCE

Bridge erection takes a leading role on the conception and design of the bridge as the construction sequence needs to use conventional methods able to be undertaken by the available local resources in Tynset.

It is assumed that the bridge will be erected following this simplified procedure:

1) Erect the supports (towers) over the concrete foundations (piers, abutments).
2) Hang the main cables from the supports and adjust it to have the required shape.
3) Hang the double modules from the hangers.
4) Erect the balconies modules, hanging them from the hangers and connecting them to the towers.

Figure 11: *Bridge erection (central span)*

5) Prestress the hangers (by adjusting nuts) to bring each module to the same vertical position (horizontal). Truss diagonals are not fixed during these phases (not taking loads).
6) Join the single modules by assembling on site the gaps between them.
7) Stretch all diagonals (by adjusting nuts), so they take just zero efforts.
8) Install horizontal bracing elements (steel L profiles).
9) Install deck floor except at modules adjacent to balconies.
10) Rise the deck (creating a parabolic shape) prestressing the hangers (by adjusting nuts)

https://doi.org/10.52202/069179-0518

11) Prestress end cables at the same time as previous phase (by adjusting anchorage element) to bring the extreme towers to the vertical position
11) Install remaining deck floor
12) Stretch non-tensioned diagonals, so they take just zero efforts
13) Install and adjust balcony ties, so they take just zero efforts.
The bridge construction sequence as detailed above has been included in the FEM model, so the accumulated loads and deformations of the bridge elements are considered.

Figure 12: *Bridge erection (lateral span)*

4 DESIGN CRITERIA

4.1 MATERIALS

4.1.1 TIMBER

The bridge main material is timber. Its strength, light weight, and energy-absorbing properties make it highly desirable for bridge construction. Main advantages of using timber as principal construction material are detailed below.
DURABILITY: Wood is inherently very durable when properly protected against rotting, shrinking, twisting, insect attack and everyday exposure to the elements. Properly treated timber will not crumble like concrete, will not rust like steel and can be used in any environment regardless of climate. Wood is not damaged by continuous freezing and thawing and resists harmful effects of de-icing agents, which cause deterioration in other bridge materials.
LOW MAINTENANCE: wood treated with preservatives requires little maintenance and no painting.
COST COMPETITIVE: From an economic point of view, wood is competitive with other materials on a first-cost basis and shows advantages when life cycle costs are compared.
QUICK CONSTRUCTION: Design constraints of using steel or concrete will slow down the installation process, whereas timber is a readily available resource and installation is quicker. Timber bridge construction can occur in any weather conditions, without detriment to the material.
Both solid timber and glulam are used in Neby pedestrian bridge. Glulam, an engineered timber product, provides greater strength than solid timber for longer span applications.
Glulam is manufactured by laminating individual pieces of sawn lumber together with waterproof structural adhesives.
GL 30c: Used in bridge towers and in bottom chord and transversal beam of balconies area.
$f_{m,g,k}$ = 30 N/mm² (bending strength)
$f_{t,0,g,k}$ = 19.5 N/mm² (tensile strength)
$f_{c,0,g,k}$ = 24.5 N/mm² (compression strength)
$\rho_{g,\,mean}$ = 430kg/m3
C24: Solid timber used in deck structural elements (transverse beams, vertical and diagonal posts, top and bottom chords)
$f_{m,k}$ = 24 N/mm² (bending strength)
$f_{t,0,k}$ = 14.5 N/mm² (tensile strength parallel)
$f_{c,0,k}$ = 21 N/mm² (compression strength parallel)
$\rho_{g,\,mean}$ = 420kg/m3

4.1.2 STEEL

S275J2: Used in connection plates and steel elements in the bridge deck (saddles and clamps)
f_y = 275 N/mm²
f_u = 390 N/mm²
S355J2: Used in steel rods (hangers and diagonals bars)
f_y = 355 N/mm²
f_u = 490 N/mm²

4.1.3 Concrete

B45: Used in the piers
f_{ck} = 45 N/mm²
B30: Used in concrete anchor block
f_{ck} = 30 N/mm²

4.2 LOADS

In addition to Self-weight, Superimposed dead load from the timber boards deck is set to 0.25kN/m^2. Parapet net attached to the handrail is treated separately as 0.05kN/m (each side). Permanent loads also include cable and hangers pre-stressing loads, modelled as temperature.
Uniformly distributed traffic load dependant on the loaded length has been considered, with a maximum UDL of 5kN/m^2 and a minimum of 2.5kN/m^2. With respect to horizontal loads, 10% of traffic vertical loads are considered longitudinally. When required, loads on pedestrian parapet were set to 1.5kN/m, vertical or horizontal.
Snow loads have been considered in combinations with just climatic actions as it cannot be combined with traffic loads.
Wind on deck is 0.6kN/m transversally, 0.3kN/m in the longitudinal direction and ±2.3kN/m in the vertical direction. Wind load in main cables has been set as 0.04KN/m and 0.02KN/m in hangers. Wind in towers is 0.57KN/m transversally and 0.19KN/m longitudinally.
Finally, thermal actions include ΔT expansion of 36ºC and contraction of 55ºC. For each situation, the unfavourable structural element (timber or steel) should have the extreme temperature, ΔT N,exp or ΔT N,con, and the other element should have a reduction ΔT=15ºC in relation to the extreme temperature.

https://doi.org/10.52202/069179-0518

4.3 FE MODEL

4.3.1 MODEL DESCRIPTION

A three-dimensional finite element model (FEM) was created to carry out the global analysis of the suspension bridge, consisting of frame elements modelling the main structural members and link elements modelling the connections between them, also considering the frame section offsets.

The global analysis allows the calculation of the whole bridge for determining the joint displacements and the internal forces at the different elements. This model was created and calculated considering the construction phases and two specific dates in the bridge life – at traffic opening (short term situation) and at infinite time (long term situation).

Deck truss chords, diagonals, transversal beams and bracings have been modelled using frame elements, placed at the centroid of the real element. These frame elements are interconnected at nodes by link elements, modelling frame section offsets and the stiffness of the connections between timber elements (Kser).

Piers have been modelled using frame elements and cables have been modelled using frame elements with no flexure stiffness.

Figure 13: *View of the FE model*

Two different groups of support restraints have been defined in the model:

1) End cables and timber towers rest onto concrete anchorage blocks and concrete piers, respectively, though simply supported joint restraints (rigid).

2) Timber deck rest vertically and transversally onto all the timber towers, while it is longitudinally supported just onto the central timber towers. All these supports are modelled considering the stiffness Kser of the connections (flexible).

4.3.2 ANALYSIS METHODOLOGY

An analysis which captures the cable behaviour is crucial when evaluating a suspension bridge.

P-Delta effect is a very important contributor to the stiffness of suspension bridges, as the lateral stiffness of cables is due almost entirely to tension since they are very flexible when unstressed.

A non-linear analysis which considers P-Delta effect plus large-displacements has been set.

In addition, the erection sequence is also fundamental in this kind of structures, as the operations carried out at each stage affect the shape of the cable, and therefore, the distribution of axial forces.

A stage construction analysis is carried out to evaluate the effects of the permanent loads by considering the erection sequence. The following analyses, which consider the effects of the different combination of variable loads, start from the results of this initial analysis.

Two different stage construction analysis are set, depending on the limit state which is evaluated (SLS/ULS).

In accordance with Premissedokument, as the distribution of member forces and moments is affected by the stiffness distribution in the structure, two different stiffness must be considered when modelling the timber elements. This leads to two design situation (short-term and long-term), where the elasticity modulus (E), the shear modulus (G) and the slip modulus (K_{ser}) are divided by a factor 3 when evaluating the long-term situation.

4.4 RESULTS

4.4.1 SLS VERIFICATIONS

In accordance with Eurocode 5, deflections should be limited under characteristic traffic loads to L/200 = 150mm. The maximum vertical sag occurs at midspan of every span for the different loading conditions considered. Maximum vertical deflection is 124mm, under the L/200 limit.

The main results of the modal analysis carried show that the 1st relevant lateral mode is 2.34 Hz and the 1st relevant vertical mode is 3.48 Hz. It is checked that, in accordance with the frequency range classification given by SETRA, the footbridge has a low risk of resonance for standard loading situations, both for vertical/longitudinal vibrations and for transverse horizontal vibrations.

Range 1: maximum risk of resonance.
Range 2: medium risk of resonance.
Range 3: low risk of resonance for standard loading situations.
Range 4: negligible risk of resonance.
Table 2.3 defines the frequency ranges for vertical vibrations and for longitudinal horizontal vibrations. Table 2.4 concerns transverse horizontal vibrations.

Table 2.3: Frequency ranges (Hz) of the vertical and longitudinal vibrations

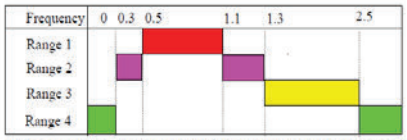

Table 2.4: Frequency ranges (Hz) of the transverse horizontal vibrations

Figure 14: *Frequency ranges given by SETRA*

4.4.2 ULS VERIFICATIONS

The tension in the cables varies during the life of the structure due to the long-term timber effect and to the temperature variation. The maximum values calculated are 270 kN for the main cables, 20 kN for the hangers and 100KN for the vertical truss bracing.

https://doi.org/10.52202/069179-0518

The timber sections of the bridge deck and towers and the connections between the different timber frames have been post-processed in order to check its capacity.
As expected, there is compression at top chord and tension at the bottom chord under vertical loads. In order to make the top and bottom chord profiles more effective and avoid increasing their size, the prestress of the hangers was used to create a precamber of the bridge that produces the opposite effect to the chords than the expected under normal loading condition (top chord is thus pre-tensioned and the bottom chord is pre-compressed). By this, they can resist a greater UDL, similarly to the prestress concrete theory.
All timber connections are designed with steel plates and bolts. They have been evaluated separately in order to optimize the number of bolts and the steel plates.

5 CONCLUSIONS

The design of Neby pedestrian bridge has been undertaken considering that it is a social project with a limited budget that is being built by local people. This makes material optimization more important than the duration of the construction period.
Timber quantities have been optimized by using the precamber of the truss to compress the bottom chord and tense the top chord, so they become more effective under normal loading condition.
An optimization of the connections has been considered by evaluating any connection separately, so the utilization is close to 1.
It has been decided to use local resources and suppliers, as well as local people to build the bridge with technology available in the area.
The use of wood as the main building material of the bridge, enhance the local industry and contributes to an environmental benefit.
Thus, it can be said that the Neby Bru project generates a clear social commitment, promoting sustainability from three different points of view: economic, environmental, and social.

ACKNOWLEDGEMENT

The authors would like to acknowledge the Municipality of Tynset and specially the contractor Ola Grønn-Hagen, chief engineer in Nordøstkonsult AS, for being collaborative and showing interest and skills during the detail design of the bridge.
Specialist advice on the tension elements design has been provided by Pfeifer Group.

SKYTEBANEN BRIDGE – A TIMBER TRUSS BRIDGE WITH AN INTERMEDIATE SUSPENDED CONCRETE DECK

Alfred Skartveit[1], Kristian Mæland Rasmussen[2], Kristian B. Dahl[3]

ABSTRACT: Skytebanen bridge is a timber truss bridge built for the Norwegian Public Roads Administration in 2019. It has a single span length of 40.0 m and a width of 5.0 m with one notional traffic lane. It is constructed with two dual pitch timber frames, with a concrete deck between. The timber frames are mounted in an asymmetrical manner which gives an irregular aesthetical expression. The timber frames have a total height of 10.8 m. The bridge combines timber in its primary load carrying system with concrete deck and steel floor beams. In this paper some aspects of special interest from the design perspective are highlighted.

KEYWORDS: Timber truss bridge, Concrete deck, Stainless steel, Dowel type joints, Aesthetics, Norway

1 INTRODUCTION

This paper gives is a brief description of the Skytebanen bridge. Furthermore, it addresses some topics that can be of special interest for designers and architects working with timber bridges.

Figure 1: *Skytebanen bridge. Photo: Jan Inge Larsen*

2 STRUCTURAL CONCEPT

2.1 BEHIND THE DESIGN

The bridge is crossing highway E6 in Grane municipality, just south of the polar circle, in the northern part of Norway. Grane has a considerable wooden industry, and the nearest producer of wooden trusses is located just a few kilometres from the bridge site. The surroundings are scenic, located between two national parks. As a future portal to Grane it was a strong desire for a wooden bridge, and the choice of a truss bridge was partly because of the link to the local industry, and partly because it offered some interesting architectural opportunities.

Figure 2: *The bridge seen from the east side. Photo: Jan Inge Larsen*

2.2 ARCHITECTURAL EXPRESSION

The architectural design of the bridge was done by Karen Hatleskog Zeiner, Multiconsult, who described the idea behind as following:

"The design is a classic truss bridge with a twist. The trusses on each side of the bridge are mirrored, which creates a dynamic appearance, that changes depending on the point of view. The shape of the bridge reflects the surrounding mountains.

The lighting plays an important role, especially in the polar dark period, which lasts from November to February. The lighting emphasises the truss construction, and makes the bridge visible from afar, creating a landmark on the E6."

https://doi.org/10.52202/069179-0519

Figure 3: *Skytebanen bridge by night. Photo: Jan Inge Larsen*

To give the construction a simple aesthetical expression, it was emphasised that the underside of the bridge should look as smooth as possible, with no visible beams underneath.

2.3 TECHNICAL PREMISES

2.3.1 General regulations

All relevant Eurocodes as well as directions from the Norwegian Public Roads Administration (NPRA) valid in 2016 was applied in the bridge design.

2.3.2 General design - common solutions

The bridge is founded on drilled steel-pipe-piles supporting the concrete abutments. Horizontal forces are handled by friction-plates at the bottom of the abutments.

Figure 4: *Overview of the complete bridge*

The superstructure is a timber through truss with the deck located at the level of the bottom chord. The static system is based on a simple statically determinate system which is easy to check by simple means. However, some modifications are made to the system, like two pinned bearings, and a partly fixed bridge deck, resulting in a somewhat more complex system. Nevertheless, the horizontal stiffness of the abutments is very low, implying that the system is acting mainly as a simply supported truss.

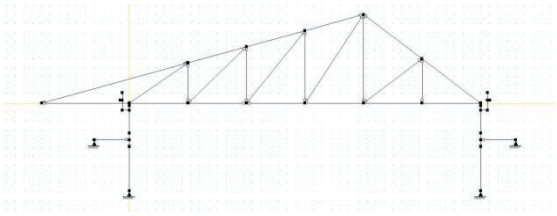

Figure 5: *Basic static system*

Stability of the upper chord against wind and buckling is mainly provided by a stiff connection between the floor beams and the vertical posts. The bridge is also provided with a top strut to transfer wind loads between the trusses, in addition to two upper lateral bracings with mainly aesthetical purposes. All truss members are made of homogenous glulam GL30h [1] to ensure that the dowel based connections have sufficient strength. The truss joints are mainly based on slotted in steel plates with dowels, a method frequently used for timber bridges in Norway, with detailed design rules given in [2]. All glulam parts are treated with copper preservatives in addition to creosote. All horizontal or sloped surfaces are protected against rain with zink fittings.

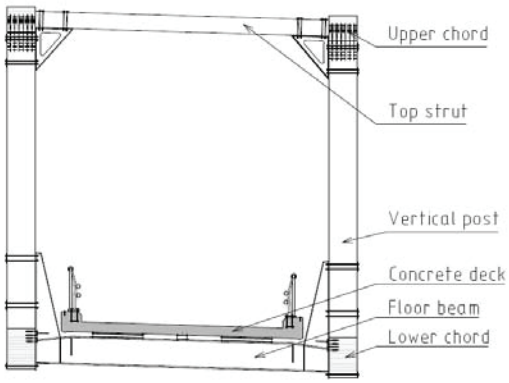

Figure 6: *Cross section of the bridge*

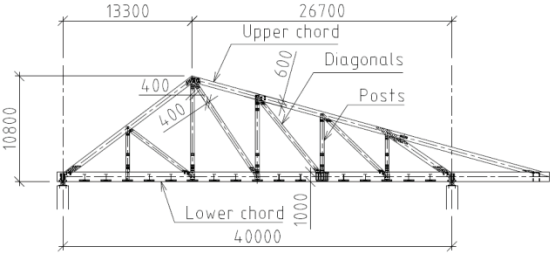

Figure 7: *Side elevation of bridge*

2.3.3 Bridge deck material

Most timber bridges in Norway are built with stress-laminated timber decks with waterproof membrane and asphalt. During preliminary design there was a general discussion regarding the durability of stress-laminated timber decks, and the client was concerned that a service

https://doi.org/10.52202/069179-0519

life of 100 years could not be achieved. Hence, it was decided that the bridge should be designed with a reinforced concrete deck.
A concrete deck is a robust solution, being durable and easy to maintain. However, a stress laminated timber deck may be a better solution for many timber truss bridges. In this particular case, the span width between floor beams could have been made larger due to lower self-weight. Hence, floor beams could have been supported at truss joints only, instead of also in-between. Moreover, a timber deck induces less constraining forces due to temperature and moisture fluctuations.
With the prohibition of creosote from 2023 it is expected that Skytebanen is not the last wooden bridge with a concrete deck in Norway.

2.3.4 Suspension of the bridge deck

The typical solution for timber truss bridges in Norway is to arrange the bridge-deck on transverse steel beams suspended below the truss joints in the lower chord, as shown in Figure 8.

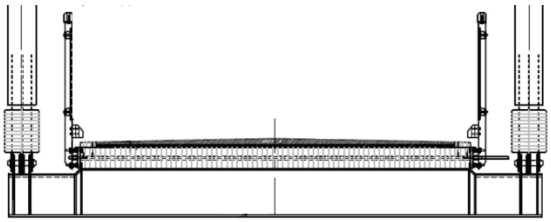

Figure 8: *Typical solution based on stress laminated deck and beams suspended under the lower chord*

For architectural reasons the distance between truss joints was chosen to be 6,67 m. In order to limit the required thickness and hence weight of the concrete deck, it was decided to use floor beams of steel every 2,22 m, i.e. with 2 supports between the truss joints, introduction bending moments in addition to truss forces in the lower chord. As outlined in Ch. 2.2 the floor beams were placed between the lower chords instead of underneath them, as illustrated in Figure 9.

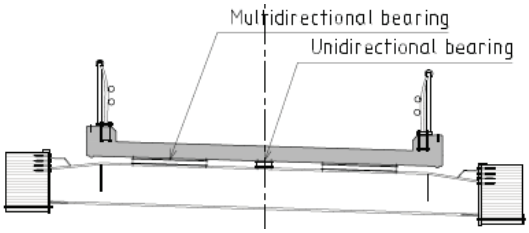

Figure 9: *Beams connected with lag screws to the lower chord*

In retrospect it is acknowledged that there are good reasons for suspending the floor beams underneath the lower chord, as shown on Figure 8, and that this design is easier to build and maintain. If there are architectural reasons to hide floor beams, this might be better solved by glulam panels mounted on the outside of the beam ends.

3 TECHNICAL CHALLENGES

Choosing a concrete deck combined with hidden floor beams led to some challenges that we had to overcome in the design. These challenges will be discussed in the following.

3.1 DIMENSIONAL CHANGES

Compared to concrete, timber has other properties for temperature, creep, shrinkage and moisture fluctuations. Thus, wood and concrete may be challenging materials to combine.
The effect of temperature on the strength and stiffness of wood is described, e.g. by [3] and [5], indicating a reduction of 2-5% for the maximum temperature. Temperatures above 20 °C for many hours will rarely occur at the bridge site. High temperatures will usually reduce the moisture content, and this will counteract the temperature effect. For temperatures below approximately 20 °C the strength and stiffness will be higher than the values used in design. Hence, the effects from temperature on stiffness and strength were ignored. Elastic deformations and creep were handled by the structural analysis and subsequent modifications.

3.1.1 Moisture content

In addition to dimensional changes, moisture fluctuations affect stiffness and strength of wood. The effect on strength and deformations was handled by estimating climate factors according to [2].
The moisture content of wood is highly dependent on the relative humidity in the environment, and not so much on the temperature [3], [4]. Based on conclusions in [6] an equilibrium moisture content of 12,5 % was assumed. To our knowledge there is no recognized method to determine the moisture fluctuations in massive wood constructions. Based on [6], [7] and [8] a maximum variation of ± 8 % was assumed, which resulted in a total free elongation of ± 16 mm for the lower chord in the length direction of the bridge.
Dimensional changes perpendicular to grain are much larger than in the longitudinal direction. Based on [7] and [8] the free dimensional change of the lower chord was calculated to ± 8 mm vertically. This affected design of the large joints in the lower chord, as further described in chapter 3.3.

3.1.2 Shrinkage in concrete

The total free shrinkage strain in the deck was, based on [9] and 80 % RH, calculated to be - 9 mm (i.e. contraction).

3.1.3 Temperature

Temperature expansion was estimated according to [8]. The free thermal expansion of the lower chord was calculated to be + 5 mm and - 8 mm in the length direction of the bridge. The thermal expansion of the concrete deck was calculated to be + 8 mm and -17 mm.

https://doi.org/10.52202/069179-0519

3.1.4 Combination of strains due to temperature and moisture

How effects from temperature and moisture expansion should be combined are not clearly described in the Eurocodes. It was assumed that the highest temperature will occur simultaneously with the lowest moisture content. This is conservative for the connection between deck and lower chord, because it gives the highest difference in movement between concrete deck and lower chord. For the design of the lower chord this will not be conservative, as the bridge is fixed at both bearings. However, temperature effects will give small constraint forces due to flexible abutments.

Table 1: *Comparison of different combinations of temperature and moisture content, and effect on chord elongation*

Load combination	Elongation (mm)
Lower chord: Lowest temperature occurring simultaneously with the highest moisture content.	8
Lower chord: Lowest temperature occurring simultaneously with the lowest moisture content.	-24
Bridge deck: Lowest temperature occurring simultaneously with maximum shrinkage.	-26

The assumption that high temperature/low moisture content and low temperature/high moisture content will occur simultaneously was questioned by the third party controller. Probably the most accurate assumption is somewhere in between. However, the conclusion is, regardless of how this is treated, that the structural integrity is sufficient.

3.2 CONNECTION DECK – FLOOR BEAMS

As described in chapter 3.1 the deformations in deck and lower chord are quite different. Without any measures introduced, this would have resulted in significant constraining forces. Based on discussions with NPRA it was concluded to install bearings between deck and floor beams, except for the seven beams at the centre of the main span, see Figure 9 and Figure 10. It is admitted that this solution is rather costly, and also introduces some challenges due to maintenance of the bridge.

Figure 10: *Bearings visible in the formwork shell. Photo: Viggo Jakobsen, Consto Nord AS*

3.3 CONNECTION FLOOR BEAMS - TRUSS

The connection between floor beams and the lower chord was designed with laterally loaded lag screws. Since the load is applied eccentrically it was also installed bolts in the bottom of the beam to reduce the action of torsional moments on the lower chord. Since the distance between the lag screw group and the lower bolts where quite big, the lower bolts were placed in vertically oversized holes to enable the wood to expand and contract due to moisture content, as outlined in Ch. 3.1.1.

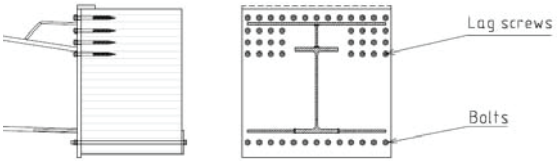

Figure 11: *Detail of connection floor beam to lower truss*

To ensure horizontal stability of the truss against wind and buckling a stiff bracket between each floor beam and vertical post was arranged. The bracket was designed to transfer bending moments only. Normal forces were handled by the dowel based connections in the truss, see Figure 6. Movements of the wood were enabled with oversized bolt holes also here.

3.4 CORROSION

It was decided to use acid proof stainless steel for all steel structures, instead of steel with a duplex coating consisting of hot-dip galvanizing and powder coating.

The background for the material choices is the required service life of 100 years, with low need for maintenance. Moreover, the design of the detail with the large steel-plate connected to the lower chord of the timber truss has some disadvantages regarding maintenance of a coating system:

- The plate has a large surface that is not available for inspection and maintenance
- Cracking of wood due to drying, in combination with rain and wind, may cause water to enter

https://doi.org/10.52202/069179-0519

behind the steel plate. The coated plate may then be exposed to moisture, which over time will increase the corrosivity and the risk of steel degradation

- The copper preservatives used to protect the wood are corrosive to steel if the coating is damaged or degraded over time

Figure 12: *Floor beams connected to lower chord. Photo: Viggo Jakobsen, Consto Nord AS*

4 CONSTRUCTION

The bridge was built for the NPRA, by Consto Nord AS. Glulam and steel constructions were delivered by Moelven Limtre AS. The bridge parts were produced in factory and the trusses assembled on site, before each truss and the transverse beams were erected by crane. The concrete deck was casted in-situ after erection of the trusses.

Figure 13: *Trusses after erection. Photo: Viggo Jakobsen, Consto Nord AS*

5 EXAMINATION AFTER TIMBER TRUSS BRIDGE COLLAPSES

Two major timber truss bridges in Norway have collapsed in recent years, Perkolo (2016) and Tretten (2022). The paper "Design flaws on Norwegian Timber Bridges" [15] summarizes some important findings and conclusions from the investigations after the collapse of Perkolo bridge. After the collapse of Tretten bridge, the NPRA have examined 14 timber truss bridges, among them Skytebanen. For Skytebanen bridge the examination concluded that there were some deviations/uncertainties in the design report, especially related to the handling of temperature and moisture variations. Moreover, it was pointed out some uncertainties regarding the rotational stiffness of the floor beams. The choices of climate class and strength modification factors were however deemed conservative. It was concluded that the bridge safety was satisfactory without any reinforcements or restrictions, and Skytebanen bridge is now, as one of the first of the investigated bridges, reopened for traffic [14].

6 CONCLUSIONS

It is concluded that using a concrete deck for timber truss bridges works well. It can also be noted that placing the floor beams between the lower chords, instead of underneath, is fully possible.

After the design of Skytebanen bridge was started, Norway has experienced two collapses of timber through truss bridges. Regardless of the reasons, both cases have reminded us that such bridges often are fracture-critical, and thus vulnerable to unforeseen actions, deficiencies and deviations during design and construction. On this background it is concluded that for these bridges a simple and clear static system which is easy to verify, build and maintain should be preferred.

Figure 14: *Skytebanen bridge at dawn. Photo: Jan Inge Larsen*

ACKNOWLEDGEMENT

The authors would like to thank colleagues in Multiconsult and all collaborating parties for their great efforts and contributions to Skytebanen bridge, a successful project and beautiful new landmark for the region. In particular thanks go to the NPRA for emphasizing architecture and aesthetics, and for the desire to try new design concepts and material combinations. Special thanks go to Moelven Limtre AS and Consto Nord AS for good collaboration during the execution phase.

METHODOLOGY OF REHABILITATION OF TIMBER STRUCTURES IN HISTORIC BUILDINGS

Amorim Faria, José[1]

ABSTRACT: The objective of this paper is to present a methodology of the design process for the rehabilitation of Timber structures in Historic buildings. The methodology is based on the author's experience and on recognized standard knowledge, available on heritage documents and standards and expert's Principles of Intervention such as those defined in the 1964 Venice Charter. A real case study related with a roof Timber structure existing in the University of Coimbra, and originally built in the 16th century is used to illustrate the methodology. It is concluded that this type of interventions, on existing structures with a very high patrimonial interest, highly benefits from mixing full restoration principles with innovative tools and in situ modern construction processes and methodologies.

KEYWORDS: Design methodology; Rehabilitation of timber structures; Historic Constructions; Case study

1 INTRODUCTION

Rehabilitating heritage buildings for new uses, or modernizing an existing building with heritage value, introducing modern features, improving its habitability and healthiness and also functional performance in thermal and acoustic terms, is a very difficult task, in many cases, and requires a careful approach in the design phase in order to be able to meet the objectives of the program in terms of the quality of the intervention, respecting the historical memory of the buildings.

This article is mainly based on the experience of the author as a design engineer of wooden structures, and as Consultant of Site Supervision teams of rehabilitation works of ancient buildings with patrimonial value, developed on end-of-life buildings and/or with obsolete construction systems and/or very significant constructive anomalies.

It also benefits from the author's teaching experience in the rehabilitation of timber structures, exercised mainly in the last 20 years at the Faculty of Engineering but also in the Faculty of Architecture in Porto in several postgraduate courses attended by Architects and Engineers with experience in this activity.

In terms of bibliography, it is mainly based on books in which the author collaborated [6] and [7] and reference bibliography that the author regularly uses such as [1] and [2], as well as several articles previously published by the author on similar subjects, such us, [10].

Part of the inspiration of the methodology can also be attributed to Italian standard, UNI 11119, identified in bibliographic references as [3], and other more recent standards and recommendations such as [4] and [5], as well as in the fundamental updated documents of principles of restoration and rehabilitation published by ICOMOS, [8] and [9].

This paper aims to point out that historic buildings need to be used so that they last and are appreciated by the community and that this means that they should be updated technologically on a permanent basis.

Therefore, historic timber structures must be restored but, at the same time, the building needs to be updated and this implies a rehabilitation methodology done in parallel with the restoration process of the historic structures.

The proposed approach is multidisciplinary and integrated, although it gives special emphasis to architecture in all its components but especially in the 'construction' aspect and to foundations and structures, while still considering the issues associated with infrastructure (water supply, sanitation, rainwater, electrical installations, mechanical installations and Data networks), fire safety, thermal and acoustic comfort and general Health and Habitability, mainly measured by sustainability indicators of the projected intervention.

In the context of this Conference, the case presented concerns only the issues relating to wooden structures and refers to a case that is relatively unintrusive and almost totally 'non-destructive', on preexistence and considering the enormous size of the case used as an example, only addressing the rehabilitation of a small part of the current roof area and the existing space between the ceiling of the last floor and the roof in which the space is intended to be occupied with new uses.

2 GENERAL DESIGN PROCESSES IN PATRIMONIAL BUILDINGS - MAIN PHASES

2.1 MAIN SPECIFICITIES OF A REHABILITATION PROJECT

The existing building (or built set) design processes are quite different from the processes adopted for new construction, since, in existing buildings and especially when the interventions to be carried out are not intrusive, the project is carried out on an existing object and at least this one must be previously well characterized and analyzed in all its components.

In this context, there are steps prior to the development of the project that must be carried out with great care and adequate development.

Thus, the main phases of a rehabilitation project are presented below, highlighting in parallel the specificities associated with the need to design on something existing, hereinafter referred to in this article as "pre-existence" as is usual in the specific language of restoration and rehabilitation of buildings.

2.2 MAIN PHASES OF THE REHABILITATION DESIGN PROCESS - A BRIEF DESCRIPTION

2.2.1 Preliminary survey

This initial phase includes:

- architectural, structural and geometric survey;

- survey of existing building systems (evaluation and complete characterization including foundations, structure, non-structural interior partitions, walls, roofing, facades, coatings and finishes, water, sanitation, electrical and other installations);

- survey of links to service providers in terms of water, sanitation, electricity, gas, rainwater and others, that may exist;

- geotechnical characterization of foundation and surrounding soils, including assessment of groundwater levels and their variation throughout the year.

2.2.2 Inspection and diagnosis

The inspection and diagnosis phase represents an essential preliminary work of the rehabilitation project process. It includes, inter alia, the performance of the following tasks:

- assessment of existing anomalies in existing construction and of their causes;

- characterization of the most relevant materials and components, namely the composition of masonry, physical and mechanical characteristics of stones and woods, characterization of the main coatings and finishes to be maintained, among others;

- definition of generic intervention suggestions to eliminate the causes of anomalies.

2.2.3 Propose an adequate program

This is one of the fundamental phases of the rehabilitation project process, since, often, it is incomplete or sometimes completely misadjusted to the pre-existence which may lead to completely failed rehabilitation works in terms of objectives.

In the restoration processes with maintenance of previous uses this is a less important problem, since it treats the existing building as a "museological object" of itself which facilitates the initial phase of project necessarily more creative and potentially intrusive compared to the existing one (this is the case of the example presented in this article).

In any case, it should be emphasized at the outset that doing a restoration with maintenance of previous use is often a strategic mistake, because it can miss "an opportunity" to rejuvenate and reorient the building to new uses compatible with pre-existence, more or less intrusive according to the needs and /or options of the designers in charge of the project and then with very positive implications in terms of cost-benefit of the future operation and maintenance of the building.

Generally speaking, this phase includes:

- the definition of a future use compatible with the existing object;

- the definition of a methodology of restoration or rehabilitation, more or less intrusive and appropriate to the future use, previously defined, and that allows to find a good cost-benefit ratio for the intervention.

2.2.4 Execution Design phase (D)

This article omits all project previous phases, prior to the “final execution design project” phase, for reasons of simplification of the approach.

Once the fundamental licensing issues associated with the need not to comply with the Regulations applicable for new works have been resolved, the design team starts the implementation project phase working on all documents and studies previously produced in the previous phases, as well as the knowledge of the pre-existence to be rehabilitated/restored, resulting from site visits and all preliminary studies.

This is the main specificity of any rehabilitation project. To detail, without respecting pre-existence, is to perform useless work. Designing new work on an existing building, without solving existing problems, leads to the new work being born with defects that will later be much more difficult to solve.

3 EXECUTION DESIGN PHASE – A METHODOLOGICAL PROPOSAL

3.1 INTRODUCTION

The methodology presented in this article is based mainly on this reality: to build a new work from scratch is mainly based on a well-thought-out and detailed project that can translate what the designer team

https://doi.org/10.52202/069179-0520

imagined and conceived; rehabilitating or restoring an existing building set presupposes "knowing" well the existing object and conceiving "on" something that already exists and that has already been designed and built by others and that has already been used, has undergone changes in construction systems and spaces, volumetric additions, changes in use, among others, i.e. a whole panoply of events that "strongly condition" the process of the restoration/rehabilitation project to prepare for the site.

Table 1 illustrates in a schematic way the methodological proposal presented in this article. In general terms, this proposal is based on the definition of ordered steps, defining the action of the Architects and Engineers and also on their interaction, aiming to produce the best job possible.

This methodology has a fundamental action at the beginning of the process (steps D1, D2, D3 and D4) and also it cannot fail to solve all the challenges in steps D5 and D6 with all the rigor, see Table 1.

Steps D5 to D8 are similar to common projects to be built on new “clean” plots, without pre-existences to be saved.

Table 1: *Design methodology*

Phase of design	Description
D1 (Arch., Fire Safety engineer)	Definition access building; Definition of vertical and horizontal communications
D2 (Architect ,Networks engineers)	Define complete paths of infrastructure networks
D3 (Architect)	Base design: Geometric tuning; Indoor/outdoor connection;
D4 (Structural engineer)	Resolve ventilation issues; Eliminate moisture problems ; Identify and solve existing problems 1 by 1;
D5 (Networks engineers)	Detailing; respect paths defined in phases D1, D2, D3
D6 (Structural engineer)	Detailing – Finish execution design; respect what has been previously established
D7 (Architect)	Detailing – Finish execution design; Finishes/Partitions
D8 (Other engineers)	Detailing – work close to architects to specify in complete match with them

3.2 VERTICAL AND HORIZONTAL ACCESS AND COMMUNICATIONS (D1)

In a process of rehabilitation of buildings with patrimonial value, with structure formed by exterior walls in stone or wood masonry and walls, floors, stairs and roofs in wooden structure, for new modern uses and fulfilling as much as possible current performance requirements, the first fundamental action of the project is associated with the complete and in-depth study of all the logic of access and movement of people in the areas of collective use, as well as in the areas of private use.

Nothing should advance in the execution project before solving the puzzle that often this issue represents, considering the need to be as intrusive as possible in pre-existence. Often this process is very conditioned and aggravated by the need to maintain larger value zones within the spaces, which can often greatly condition the new solutions to be designed, such as an existing chapel, although small, in the case study (problem not presented and discussed in detail in the article).

It will not often be possible to comply with the applicable regulations for new work and decisions will have to be made! Also often, with regard to the aspects of thermal and acoustic comfort and the general use of the building, difficult decisions should be made, especially with regard to the slope of stairs, the possibility or not of installing an elevator for vertical communications and the possible incompatibility between the maintenance of walls, doors and other building elements and the "will" to improve the thermal and acoustic performance of the building, among others.

In this first stage of the process, fire safety is of particular importance, since in general it is impossible to comply with regulatory requirements for new work and it will be necessary to agree with the licensing authorities the mitigating measures to be taken to improve existing behaviour, situations that often strongly condition the architectural options to be taken.

3.3 SCHEMATIC PATHS OF NETWORKS (D2)

Today, modern buildings include water supply infrastructure networks, other networks, such as sanitation, data, electricity and gas, mechanical and natural ventilation and air conditioning, that occupy large areas and volumes of the construction, and strongly condition the freedom of architectural design.
This problem is substantially aggravated in an existing building set, due to its complete absence in the original construction. It will therefore be necessary to integrate into existing buildings all the new networks needed for their operation in a modern context, using "paths" perhaps already existing or to be created, in a way compatible with the new use to be given to spaces and their own new configuration, trying to affect as little as possible the non-technical uses to be given to the sites and, at the same time, minimizing the occupation of areas and paths of technical infrastructure.
It is generally a very difficult exercise to solve, this should therefore be dealt with, as a priority, before moving forward with everything else.

https://doi.org/10.52202/069179-0520

3.4 GEOMETRICAL TUNING (D3)

The existing old buildings with heritage value, because of having been built using techniques and equipment less sophisticated than those currently available, have many "defects" of origin that translate into very inclined stairs, uncomfortable steps, narrow corridors, non-orthogonal walls to each other, walls "out of plumb", among others. It will therefore be necessary to consider all these problems in the Architecture design, thinking about "places of closing the spaces / volumes" and solutions of eventual disguise of existing defects such as false ceilings, steps, fillers or simply, assume these imperfections by conceiving spaces and solutions where they are properly "integrated" or assuming, quite simply, their geometric specificities i.e. their original geometric imperfections that occurred throughout the use of the building.

3.5 FUNDAMENTALS OF STRUCTURAL DESIGN (D4)

After stabilizing the geometry of the internal and external spaces, it is time for the structural engineer to assume the main role, evaluating and resolving all the situations resulting from the previous steps, namely:

- eliminating existing structural anomalies;
- introducing new structural systems compatible with the new uses, downgrading the service levels of existing structures, when they can not fulfill the new performances needed, always respecting the architectural design (done in cooperation);
- improving the "habitability" of environments with regard to the health of structures, in particular wooden ones (naturally ventilate spaces and eliminate all causes of moisture);
- solving problems caused by new infrastructure network paths;
- reinforcing/rehabilitating structures for possible new uses;
- solving problems of previous malfunction (vibrations, deformations, defects of original design, defects resulting from previous works poorly conceived or executed.).

The project design process should not move forward without, at least at design level, all structural problems being identified and generally addressed at the level of the principles and methodologies of resolution and the dimensions and location of existing and new structural elements.

3.6 CLOSURE OF THE DESIGN PROCESS (D5 TO D8)

Now, all designers can advance in parallel in the implementation project, respecting everything that was previously agreed.

In the border areas between engineering specialties and these with architecture everything should be properly detailed and compatible.

It should be noted that, at this stage of the process, the project methodology is totally analogous to the design of a new work done in a plot without pre-existence...

4 SPECIFIC RECOMMENDATIONS FOR TIMBER STRUCTURES

4.1 GENERAL RULES

Timber structures have their own specificities that justify the consideration of an autonomous subgroup in terms of rehabilitation. These specificities are essentially the result of the fact that the raw material of which they are made is of trees origin, which gives them a degradation process very different from that foreseen for structures executed based on materials of mineral origin. The main causes of wood degradation in structures are as follows:

- firstly, biological degradation by the effect of fungi, insects, mollusks and crustaceans (the latter in a marine environment);
- secondly, aging by effect of the hygrometric term action (wood is a material with anisotropic mechanical behavior and varies its dimensions and physical, chemical and mechanical properties depending on its water content, in turn variable with the absolute humidity of the environment that surrounds it);
- inadequate structural use due to inadequate design of the elements/components of each substructure, and also of their supports and connections.

It should be noted that humidity is not in itself a fact of degradation of wooden structures. The careless permanence of the structure in humid environments and in poor ventilation provides ideal living conditions to biological agents of wood degradation, which are a direct cause of wood degradation in these contexts. The following are a set of general concrete rules to be applied in the restoration of wooden structures:

- always check other structural systems (foundations, walls, bracings, ...) - stability and level of degradation;
- avoid disassembling the structural elements in wood: the future assembly will place these elements in different states of tension as a result of the new connections to be made;
- use strong solutions: use higher safety coefficients than in current “new” projects;
- make periodic inspections of structures (control the following factors: temperature, humidity, air renewal rate, wood water content, deformations and defects of structural elements, ...);
- improve the service conditions of wood parts: avoid connections with steel or glass if they do not allow the wood to be ventilated or to favor condensations;
- improve the general and localized ventilation of the spaces (air renewal is essential for wood);
- carry out periodic cleaning of the structure;

https://doi.org/10.52202/069179-0520

- eliminate all external causes of degradation (especially those arising from the surroundings of the building - walls and roofs);
- whenever possible, leave after the restoration intervention, the possibility of all structures being examined from the nearby physical and/or visual point of view;
- always place the wooden elements in the same class of service in environmental terms;
- ensure proper ventilation of the supports by avoiding direct contact of wood in these places, as far as possible, with other materials which may retain moisture or prevent wood from "breathing";
- avoid hiding the structural elements in wood with finishing materials mainly ceilings and false ceilings – the degradation will not be detectable;
- restore the building from the roof to the foundation, if it has not foundation problems– in this case, first solve the foundation problems;
- always ensure the stability and low deformability of the supporting elements before intervening in the wooden structures supported by them;
- always initially restore the most important elements – more robust and/or more degraded.

5 THE CASE OF TIMBER ROOFS

In a concrete case of rehabilitation of a wooden roof of a Historic Building four specific situations can occur:

- repair and point replacement of degraded elements using old techniques;
- repair and point replacement of degraded elements using old techniques and modern connecting solutions;
- integral replacement of the structure using old woods, modern materials and connecting techniques and architectural designs similar to the old ones;
- integral replacement of the structure by modern design solutions, wood elements, materials and connecting techniques to be used.

For historic buildings the ideal solution will be that which corresponds to situations a) or b). It is the author's opinion, however, that the ideal solution will preferably be a hybrid of approaches b) and d) as it ensures improved performance, higher economic value and a much higher durability of the rehabilitation intervention. Materials that ensure higher durability should be used as far as possible.

This can be justified by the following. In many cases, the existing timber structures cannot fulfill the “new design demands” without highly intrusive and expensive reinforcements, and it is very common to consider that it is not convenient to reinforce the existing systems and, therefore, solution b) coexists with “new structures” that occupy the same volumes and liberate architects for an eventually more intrusive program, which we may consider as a hybrid situation of approach b) and d). This is the situation presented in this case study, see section 6.

5.1 SUBSTITUTION AND PUNCTUAL REPAIRS USING TRADITIONAL CONNECTIONS

It's the most current situation in historic buildings in a restoration process, when the architectural program does not change significantly the performance demands of the structures. It assumes that the various elements in wood are generally in good condition, allowing the structure of the roof to remain in place with the existing form, before the intervention. The connections between partially replaced parts will be made using traditional solutions, similar to the original ones.

The most serious mistakes made in the past with wooden structures concern the poor ventilation of the structure, especially in the supports, which implies the biological degradation that is also transmitted rapidly to the support of the parts/connection with the masonry walls. In a specific intervention, adequate ventilation and protection against insects, namely termites, of the new elements/systems should be ensured.

5.2 SUBSTITUTION AND PUNCTUAL REPAIRS USING MODERN CONNECTIONS

It is a situation analogous to the one described above, but in which we seek to solve problems of connections using modern methods and techniques. The author thinks this is the most appropriate solution in general. It makes no sense to use nowadays handmade nails, with a relatively high corrosion speed, when it is possible to resort to stainless steel connecting systems, for example, that are much more durable and equally resistant and that also allow the reversibility of the assemblies by unscrewing.

With regard to support prostheses, the solution to be adopted will be influenced by the extension and strength of the eventually existing xylophagous attacks. If there are no major aesthetic limitations, the use of metal prostheses in situations of exclusive degradation of the elements near the supports will generally be more economical in the case of more extensive degradations. There are no universal rules indicating the best solution for each case. All operations involve the removal of roof tiles, and all other secondary elements of the roof, in order to access the structure both below and above, so that the reinforcements and substitutions may be done.

5.3 SUBSTITUTION OF TIMBER ELEMENTS AND SOLUTIONS USING “USED WOODS” AND MODERN CONNECTIONS

In some cases, for architectural or constructive reasons, it is not possible to carry out the restoration work

https://doi.org/10.52202/069179-0520

without dismantling the structure. In these cases, the pieces are carefully dismantled and put back on site following modern connecting techniques and using, when it is possible, used woods of equal or similar species, quality and eventually age.

Elements with degraded parts at the ends can be used to obtain smaller elements that can be used in other works or in other places in this same work. It should be noted that an old wood structural part of a durable species is a structural material of high value and should always be carefully assembled and stored for future use.

For example, a beam of 7 m long with 0.5 m of degraded parts on each side allows to realize a beam of 6m in length in optimal conditions, cutting the degraded tops from both sides. The geometry of the new structure is not necessarily coincident with the original structure and, as far as possible, follow the original design models so that one can maintain the memory of the building.

5.4 INTRODUCTION OF A NEW STRUCTURE MAINTAINING OR NOT THE EXISTING ONE

In many cases, the existing structures are not able to withstand the new performance demands. Still, they have historic value and in general should be kept in place as a memory, without structural function, or eventually fulfilling less demanding structural tasks such as supporting the ceilings of the last floor below (in many cases with very high patrimonial value, with “frescos” or decorated carved timber ceilings).

6 CASE STUDY

6.1 GENERAL DESCRIPTION OF THE BUILDING

The College of Arts is part of the University of Coimbra, founded in 1290. Currently, it is used as Faculty of Architecture. The construction of the College of Arts began in 1568, see Figure 1.

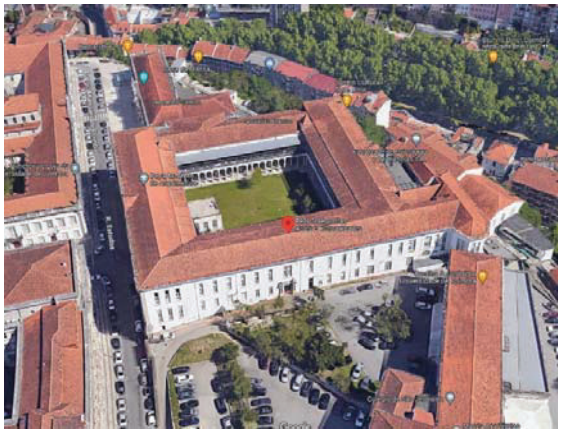

Figure 1: General view of the building

The building has undergone successive changes over time in terms of volumetry and use, highlighting a major reform on the early twentieth century, with the expansion of the construction in height and the use of new materials, such as cast iron columns on the raised floor, for the installation of the University Hospital of Coimbra, operating at this site until 1986.

The building belongs to the designated first University Pole of the University of Coimbra and currently presents a deployment area of about 6600m2.

The College of Arts belongs to the architectural ensemble of the University of Coimbra, which since 2013 has been classified as a World Heritage Site by UNESCO.

6.2 ARCHITECTURAL PROGRAM

The architectural program provides for the rehabilitation, restoration and refurbishment of the building of the College of Arts, of high heritage value and that today is naturally aged and weakened, with many conservation problems of various types.

In addition to the spatial and constructive aspects, the infrastructure sits outdated in view of the multipurpose functions it currently has, namely museum and higher education equipment (faculty of architecture).

In addition to the rehabilitation and conservation work of the existing construction systems to be maintained, the Architecture project provides for the demolition of some additions and annexes that were carried out on the northern outskirts of the building, during the operation as a university hospital.

Figure 2 shows a 3D image of the building after completion of the works that are today still in the design phase and beginning of the demolition works.

Figure 2: *3D view of the designed building at the end of the works*

6.3 FLOORS UNDER THE ROOF

The architectural design foresees that this space will become accessible, with offices, study and meeting

rooms, along the east, south and west parts of the building.

The floor under the roof on the north side is lower than the rest, so it will not be accessible. In this area, it is expected the complete demolition of the plastered ceilings of the floors below, so that the rooms and spaces of those lower floors obtain a double ceiling with the roof structure in sight. This part of the roof will essentially be restored, although improved in performance.

6.4 DESCRIPTION OF THE CURRENT CONSTRUCTIVE SITUATION

The roof analyzed in this article is of the traditional inclined type, with accessible floors under the roof, which are not used, today. The main current structure consists of wooden trusses that support girders and ceramic tiles. The trusses and the external walls support the floor structures that also support the stucco works of the ceiling of the floors below.

Figure 3 presents a roof plan, divided by zones with different constructive constitution.

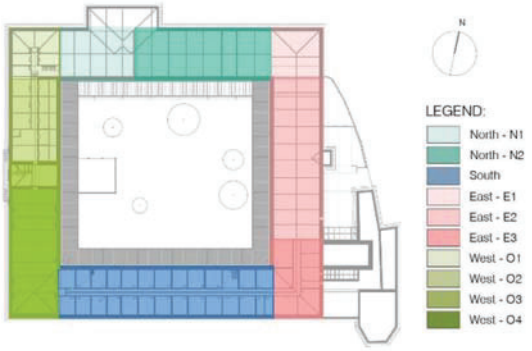

Figure 3: *Roof schematic plan*

This article refers only to the East, West, and South zones, that are all like each other.

6.5 EXISTING WOODEN STRUCTURES AND COATINGS

6.5.1 Exterior coatings

The coating of the roof in the different wings consist of ceramic tiles placed on wooden slats 45x30mm//0.35m and supported on wooden beams 70x110mm//0.50m.

6.5.2 Girders

The coatings of the roof are supported by wooden girders in solid wood, two by slope and one on the ridge, separated from each other around 1.9m to 2.3m approximately, see **Error! Reference source not found.**.

Figure 4: *General view of the roof*

On the top of the external walls in masonry, there are timber components of 100x100mm to 130x150mm in very bad condition, in many cases substituted by mortars or covered by mortars.

6.5.3 Trusses

The trusses are composed of elements in solid wood, overcome spans of approximately 11m and are separated from each other, about 3.5m and 4.3m.

The current truss presents a constitution as shown in figure 5 below. This design is not very common in Portugal and, also for this, has high patrimonial and historic values, although almost all the wooden elements are no longer original, having in general, the oldest, between 100 and 150 years.

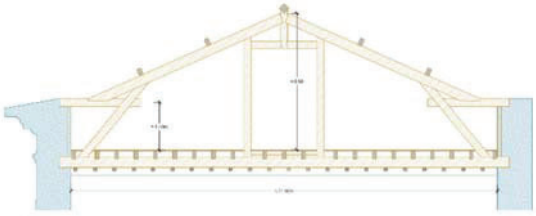

Figure 5: *Current truss*

Occasionally, some of these trusses received reinforcements, the most usual being the additional two timber elements that help to support the legs, see Figure 6.

https://doi.org/10.52202/069179-0520

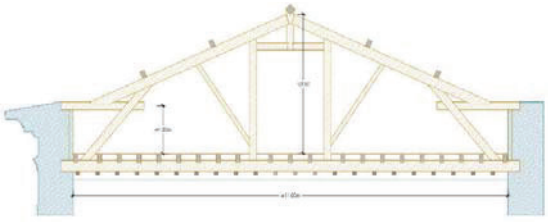

Figure 6: *Casual reinforcements on trusses*

6.5.4 Connections and supports

The connections between the different parts of the trusses are traditional, materialized by carpentry joints and with some metal connectors, see figures 4 and 7.

6.5.5 Floors under the roofs

The current floor is made of solid wood and has approximately 1560m2 along the east, south and west wings of the building, see Figures 4 and 7.

Figure 7: *Floor structure under the roof*

6.6 ANOMALIES IN EXISTING STRUCTURES

6.6.1 General anomalies

At the level of the roof, the coatings are partially fulfilling their function, but there are problems of water tightness, with traces of water and moisture entering the stone masonry walls, especially near the top of the roof.

The floors under the roof have no conditions to be used for any purpose, as they are today.

6.6.2 Structural anomalies

Regarding the trusses, despite the good general condition of most wooden parts, there are several indications of structural problems.

Some trusses have torsions, high deformations, excessive cracking, weakened and inadequate connections, and rot-damaged supports. There are also some reinforcements, carried out in previous apparently loose interventions, which aimed to correct some of those problems, but which were sometimes inadequate.

The girders and the wooden structures that support the floors are in a good state of conservation and have an adequate structural behavior, with malfunction problems in some places.

Most wooden parts do not appear to respect the levels of stress resistance and deformation in service, in accordance with the actual regulations, and it is also stressed that there are some critical situations, with a risk of local collapse, which must be corrected quickly, particularly in the trusses.

6.7 SOLUTION – APPLICATION OF THE INTEGRATED METHODOLOGY

The fundamental principle to follow is to restore the existing structure, applying the principles of restoration and start using it only as a support of ceilings on the lower floor.

Simultaneously, introduce a new wooden structure and coatings and finishes with current modern design fully suited to the new uses, involving the coatings of the roof and the new floors to be executed.

The architectural design is thus completely free to comply with the current, more demanding construction regulations, at the level of walls and infrastructure networks and above all to introduce solutions that allow to meet fire safety requirements and improve thermal and acoustic performance and water and air tightness and natural and artificial ventilation and lighting.

The solutions to be adopted include:

- Maintain the exterior image in ceramic tile and use a sub tile, lining in wood derivatives and waterproofing system with steam-permeable screens; Incorporate zenithal lighting, using skylights and windows in new mansards to be integrated following a geometrical pass compatible with the existing facades view;

-Integrate all new infrastructures (electricity, water, data, ventilation, air conditioning) in the new roof space. Ensure natural ventilation;

- Solve the problem of sanitation (the most difficult), using localized shafts and false ceilings to disguise the corresponding tubes networks.

On the floor below the roof, it is possible to take advantage of a large part of the existing floor structure, which is in good condition, and some current stuccoes (on the lower floor) should be repaired considering the cracking they present.

6.8 SOLUTION – STRUCTURAL INTERVENTION

The option of keeping the current trusses as the main structural element is not feasible because it involves very significant reinforcements that would completely change existing structures and make them loose their current historic authenticity.

The option to introduce new structures, more modern and efficient, keeping existing ones with lighter functions, allows greater protection of the heritage and allows to design a floor with the carrying capacity, comfort, vibration levels and deformation compatible with the new intended use, also avoiding at the same time to transmit the vibrations from the use of the floor to the current trusses, floors and stuccoes and thereby increasing the longevity of these existing structures and construction systems.

7 CONCLUSION

Historic buildings need to be used to increase their durability and economic interest.

The principles of the restoration of existing buildings with patrimonial value must be respected.

It is possible to respect "difficult" and demanding architectural programs following a methodology in which the introduction of modern construction systems and solutions walks in parallel with the restoration processes of the existing construction systems to preserve, occupying the same volumetric space without the two types of solutions imposing themselves on each other.

This is the solution that was chosen for the case presented in this paper in section 6, which means that the approach followed in the case study is a mix of systems b), restoration using modern connections and eventually materials, and system d), introducing completely new structures and materials, using a modern and highly performative design and approach, see section 5 for a more detailed explanation of the two design approaches.

The case under study represents an excellent example where this methodology is being successfully applied.

WEB-GIS-TOOL: ESTIMATION OF GREENHOUSE GAS SAVINGS DUE TIMBER USE IN THE URBAN BUILT ENVIRONMENT

Caya Zernicke[1], Annette Hafner[1], Andreas Abecker [2], Harro Stolpe [3]

ABSTRACT: The development of German cities, municipalities and urban areas requires a high amount of material and energy. Responding to this requires a commitment to achieving national climate change targets, as they have different options for sustainable development. Especially urban planning can create linkages for climate protection measures through its interdisciplinary field of activity. Further, urban planning has an impact by directly affecting the construction and housing sector, one of the major emitters of greenhouse gas emissions. To support decision-making processes or measures for climate protection in urban areas, the web-GIS system Holzbau-GIS has been developed. This GIS-based web-tool calculates the GHG reduction potentials and temporal carbon storage for new construction and refurbishment with wood. This paper summarizes the method to calculate these potential GHG reductions due to timber use in the urban built environment. Through the intersection of spatial geodata and recent building-specific research data, various conclusions can be drawn within the web-GIS system regarding basic data, new construction, and refurbishment with wood. The paper also shows illustrative examples and their visualization in the web-GIS system. It became apparent that the Holzbau-GIS could serve as part of the digital transformation of municipalities and emphasize the contribution of timber buildings.

KEYWORDS: geographic information system GIS, timber construction, temporal carbon storage, climate protection

1 INTRODUCTION

1.1 GENERAL

Municipal self-governance is one of the essential principles of the political structure of the Federal Republic of Germany. In the increasing variety of multidisciplinary activities, municipal self-government plays a key role today more than ever before. Issues of municipal policy include, especially recently, the protection of the environment and natural resources, budgeting, and privatization. Here, the different spatial, socio-political, structural and geographical conditions will be considered specifically. [1] Consequently, cities, municipalities and urban areas must contribute to achieve the national climate protection targets, as they have various directing options toward a sustainable development. By acting responsibly, they can have a direct impact on regional urban development, especially with the focus on climate mitigation and climate adaptation. The building sector can be a key element of municipal climate protection since buildings usually have a central impact on urban development. They significantly shape the structure of the city by defining its use in terms of working, housing and infrastructure. [2-8]

In the past, the German construction industry has focused primarily on energy efficiency to meet climate protection targets. Now, the focus is shifting increasingly towards the material choice for new construction or refurbishment and, in terms of urban planning, wood as a building material is gaining in significance since. [4] In the future, the use of sustainable renewable materials will play a significant role in this context. [7, 9, 10] Therefore, the carbon footprint of building materials and the additional reduction potentials using life cycle assessments (LCA) move further into the spotlight. The emissions of building materials in production, processing and deconstruction must be considered in terms of their environmental impact, but also regarding the consumption of raw materials, flexibility, service life and recyclability, for instance. [2, 11]

1.2 MOTIVATION AND SIGNIFICANCE

Not just since Glasgow 2021, fundamental changes are needed to meet the 1.5°C target. In order to limit the temperature increase to this level, great efforts are required, especially at the regional level. Municipalities have to play a significant role in the implementation of these targets. Thus, the perspective must be directed towards the mechanisms and possibilities of urban planning. Especially urban planning can create possible

linkages for climate protection measures through its interdisciplinary field of activity. [2-7]

Digital solutions are gaining importance and supporting innovative decision-making. For this purpose, digital solutions are increasingly being developed and offered to cities for sustainable development. Geographic information systems (GIS), for example, has been a common tool even in urban planning for many years. A GIS, in general, is a computer-based system, which processes geospatial data. This system consists of hardware, software, data, applications, and services (HSDA model). With these four components, geospatial data can be digitally captured, stored, managed, updated, analysed, and presented alphanumerically and graphically. Thus, complex issues can be presented in a structured way. Especially for urban development, GIS systems have become indispensable tools for planning and decision making. By linking spatial or locational data, solutions can be crystallized more quickly and effectively from GIS-based decision-making templates. [12-18]

In general, urban environmental protection including the construction of timber buildings is partially combined with the development of intelligent software solutions. The measures shown in the web-tool Holzbau-GIS certainly have the potential to contribute to environmental relief. However, the right parameters and framework conditions for realising these potentials must be established. [13]

2 PROJECT DESCRIPTION

The R&D project Holzbau-GIS (Timber Construction - GIS) provides information on potential greenhouse gas (GHG) reduction due to timber construction and contextualizes the results of the GHG calculation on a municipality-wide consideration. It is focusing on possible climate protection measures through buildings including potentials using renewable building materials. By intersecting spatial geodata and building-specific research data, various conclusions can be drawn within the web-tool regarding basic data, new construction, and refurbishment with wood. Different scenarios project feasible reduction potentials for new timber buildings or refurbishment measures on existing buildings.

2.1 SOFTWARE ARCHITECTURE

An interdisciplinary team (architects, software developers, environmental engineers) developed the web-GIS system Holzbau-GIS and piloted it in close collaboration with the sample municipality of Menden (Sauerland) in Germany. The project combined contributions from four operating areas:

- Geodata-Management (lead partner: eE+E)
- GHG-Calculation (lead partner: ReB)
- Scenario-Management (lead partner: ReB)
- Web-GIS system (lead partner: disy)

The Geodata-Management classifies the building level based on available geodata. Various available municipal geodata like building footprints, 3D building models, historical satellite images, etc. are utilised to set up basic data to provide a sound starting point for the GHG-Calculation by the research partner Environmental Engineering+Ecology (eE+E).

The GHG-Calculation defines the GHG reduction potential by replacing mineral constructions with timber constructions. In order to quantify this potential, established methods for the LCA of buildings according to DIN EN 15978 [19] and research data [9, 20-22] are utilised for new construction scenarios. For a more detailed description, see Chapter 3.1. For refurbishment, the calculation of potential reductions due to the material choice, it is necessary to introduce a new methodology for LCA of refurbishment measures, which can be found in [23, 24] and summarized in Chapter 3.2. Based on this, the research partner Resource efficient Buildings (ReB) calculates the GHG reduction potentials.

The Scenario-Management defines the total amount of GHG reductions, extrapolated to the study area of the test municipality of Menden (Sauerland). It is the first time of connecting geospatial data of a whole municipality with the results of recent developed methods of LCA for refurbishment and valid LCA data for new constructed buildings. Both, the geodata management and the development of the method for calculating the GHG reduction potentials enable the derivation of various scenarios for new constructions or refurbishment measurements.

Referring to the web-GIS system, the research partner Disy Informationssysteme GmbH provides the Holzbau-GIS tool, based on its business intelligence and geodata analytics platform disy Cadenza [25] Figure 1 shows main technical aspects of the client-server based web-GIS system. The data is stored in a PostgreSQL DBMS with the PostGIS extension for managing spatial data. The database is managed by the disy Cadenza platform, which provides services such as user, roles and rights management, logging functionalities, as well as interactive data access, visualizations, and analytics.

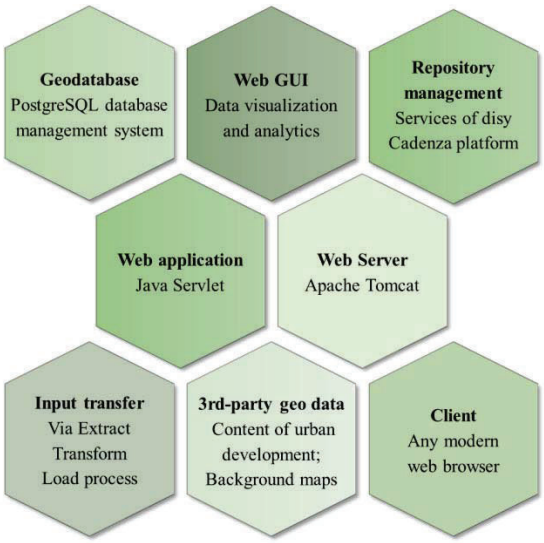

Figure 1. *The different components of the web-GIS system (random order)*

https://doi.org/10.52202/069179-0521

2.2 SOFTWARE FUNTIONALITY

Holzbau-GIS is an interactive web-based tool, which offers the option of selecting individual topics via the main menu. The display levels range from a very global overview down to the individual building. The data visualizations can be adapted or filtered according to the user's needs. The currently version provides basic functions, new construction scenario and refurbishment scenario. The data can be presented as interactive tables and charts or in a map view. Multidimensional data can also be aggregated on different spatial and temporal scales.

3 METHOD DESCRIPTION

In addition to the general data on the existing building stock, the web-GIS system contains further data on urban land use planning and environmental planning, among other things. This is followed by the results of the calculation scenarios.

This next section describes the procedures and methods utilised in these scenarios, while the main elements of the methodologies are presented in the following subsections 3.1 refers to the new construction scenario, while 3.2 describes the refurbishment scenario.

3.1 NEW CONSTRUCTION

Referring to Figure 2, the method of the new construction scenario starts with a compiled LCA data basis on new buildings. Therefore, data of former research projects "THG-Holzbau" [9, 21] for residential buildings and "HolzImBauDat" [20, 22] for non-residential buildings are operating as the general data basis for this scenario. In both projects, LCAs were conducted for the timber buildings and their functionally equivalent mineral buildings. By using this data, it is possible to obtain holistic statements on residential and non-residential buildings, shown here in Figure 2 in "building use". Further differentiations are also applied within the "building type", subdividing residential buildings into single-family and multi-family houses. For non-residential buildings, the new construction scenario provides conclusions for these different building types: agricultural or non-agricultural buildings, office and administrative buildings or other non-residential buildings.

These different "LCA results" were elaborated for each building type of new construction scenario: (1) GHG emissions of new buildings constructed with timber or as mineral buildings (2) GHG reduction potential by replacing mineral structures with wooden structures and (3) temporary carbon storage of the implemented renewable building materials. The outcomes of GHG emissions, GHG reduction potential, and temporary carbon storage refer to the gross external area (GEA) and thus the resulting units are given in kg CO2 Eq. /m² GEA.

The final phase of this methodology for new constructions includes the linkage of the LCA results (building-scale) to the "municipal level". Since new buildings are maximally planned without being built yet, those urban land use planning of the municipality can serve as the linking element, in detail, data of the urban land use planning is utilised to establish this connection.

Within the urban land use planning process, new construction areas are elaborated, ultimately permitted, and publicized in development plans. Using parameters which must be defined within this planning process and published as part of the development plans, we can calculate the maximum permitted GEA of the new construction areas. This output is given in m² GEA, which allows us to extrapolate the LCA results related to future construction activities of the municipality.

Summarized, this section described the methods of the new construction scenario including the differentiation of building types and LCA results. By combining given parameters of development plans and LCA results, quantitative data can be provided for GHG emissions, GHG reduction potential and temporary carbon storage for new construction.

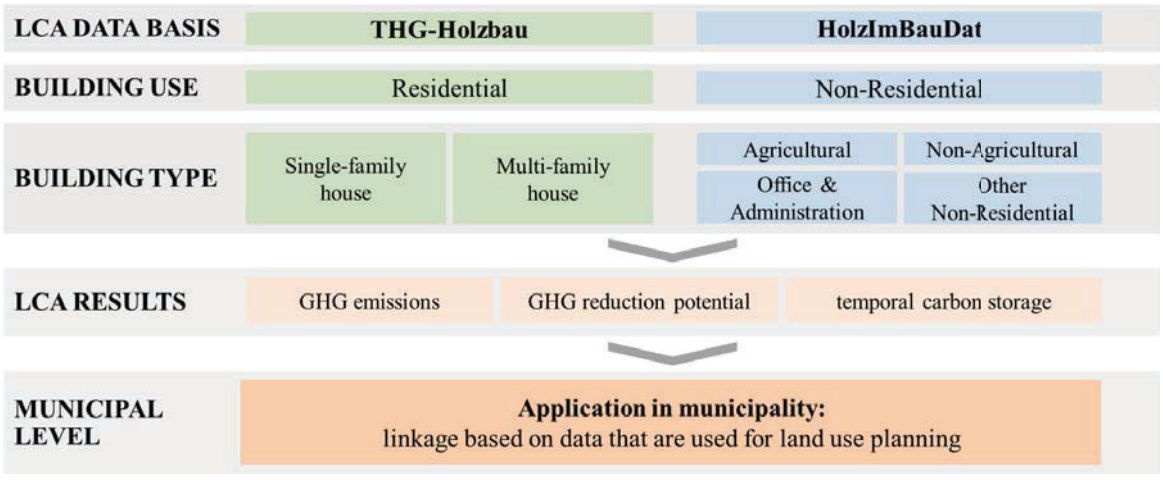

Figure 2. *Methodical structure, data basis and differentiations of the "new construction" scenario*

https://doi.org/10.52202/069179-0521

3.2 REFURBISHMENT

The following section will discuss the refurbishment of the municipal building stock. In detail, the scenario focuses on the energy-efficient refurbishment of the existing residential buildings. To provide a holistic and comprehensive tool for the municipality, it is essential to consider current issues such as the refurbishment of the building stock regarding climate protection measures related to the building sector. More precisely, refurbishment can be considered as a climate and environmentally friendly approach to reduce operating energy consumption at the municipal level. In addition, environmental aspects will become more prominent in public construction projects and their tendering. [26]

Figure 3 highlights the different elements and methods that characterize this refurbishment scenario. Starting with the left-hand element of Figure 3, various "geospatial data" were provided, already processed, and compiled by Geodata-Management, mentioned in Chapter 2.

One of the main features of a building is its geometric characteristic. Taking the outline of a building, the footprint of a building can be calculated. The representation in a three-dimensional format [27] allows the determination of further geometric data of the buildings, such as height, sloping roof surfaces or the building exterior surfaces. The building use is important for the differentiation between residential and non-residential buildings, which show differences in terms of structure and operating energy, among other things. Here, only the residential buildings are considered, since for these, the research results are more advanced and valid than for the heterogeneous non-residential building stock. The building type (single-family house, row house, multi-family house, etc.) is another aspect that is important for assessing the refurbishment potential. The building age is one more important feature for estimating the refurbishment potential. The GHG reduction potential increases with the age of the building because, in contrast, the materials and techniques applied in buildings have continuously gained in efficiency.

Since not every building is equally suitable for refurbishment, distinctions must be drawn between the type and age of residential buildings. Here, the differentiation bases on the German residential building typology of the Institute for Housing and Environment – Institut Wohnen und Umwelt GmbH (IWU) [28]. The term building typology contains several aspects, including the building's age, size, construction method and material, which can be identified for typical structures in certain architectural periods. The building typology represents a methodical classification of residential buildings into certain building age categories and building types based on technical, structural, and energy-relevant characteristics, which results in a national building type matrix. According to IWU, a building typology is a combination of defining these characteristics, groupings of individual buildings and the illustration of representative features with the help of exemplary buildings, which simplifies the energy evaluation of the buildings. [28] In order to provide decision guidance, the German residential building typology of IWU offers two refurbishment scenarios which are assigned to each of the exemplary buildings. These two standards correspond to the energy savings regulation EnEV 2014 [29] and the passive house standard [30]. Exemplary refurbishment measures are also indicated for the individual building elements, such as the external walls, roof, top floor ceiling, among others. In addition, the environmental impact of heating and hot water consumption is given for each exemplary building, for the current energy standard, but also for the refurbishment measures. [28]

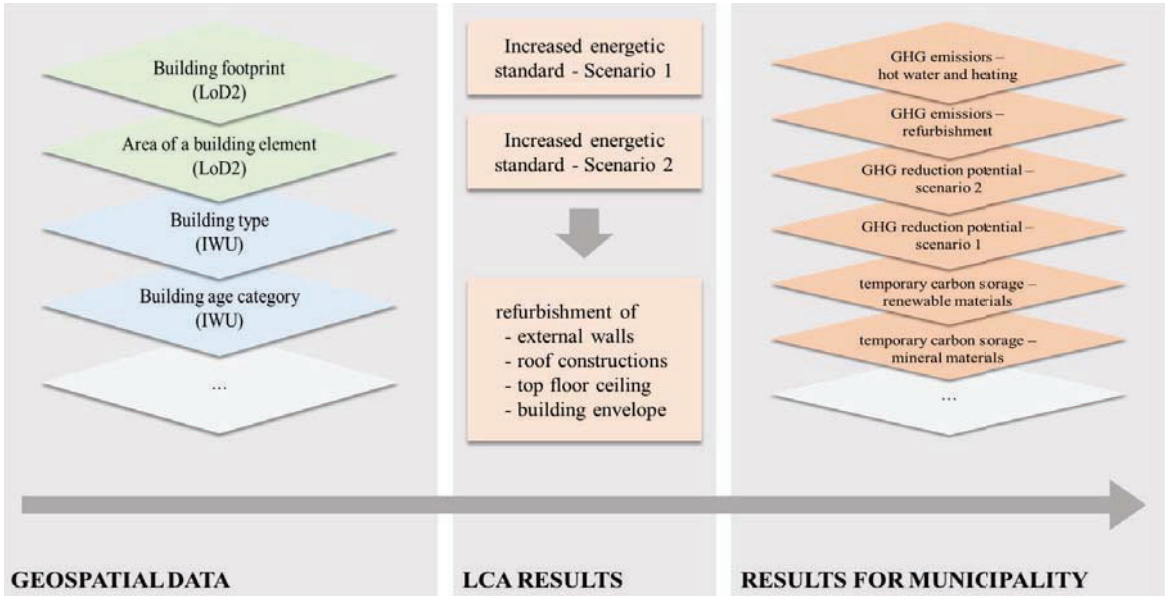

Figure 3. *Methodical structure, geospatial data and LCA procedures of the "refurbishment" scenario*

https://doi.org/10.52202/069179-0521

In case of Holzbau-GIS, an algorithm was developed, which automatically assigns the national building type matrix of the German residential building typology to the buildings in Menden using an iterative process and various geospatial data. Verification showed a high level of agreement, resulting in the continued implementation of this method. As a result, each residential building in Menden is assigned a building type, which is important as a main parameter for transferring the refurbishment potential to Menden. The building age was also identified with great effort for the entire building stock in Menden. More information on the procedure can be found in Menz et al. [31].

Continuing with the second element of the refurbishment scenario in Figure 3, the surface area of building elements, such as the external walls, roof, top floor ceiling or the exterior surface of the whole building envelope were calculated. Therewith, the geospatial data now provides enough information to apply "LCA results" of refurbishment measures to the building stock of Menden (Sauerland) utilizing the German residential building typology. The subsection 3.2.1 focuses on LCA methodology of refurbishment measures at the municipal level.

Analogous to the new construction scenario, various "results for the municipality" are provided: (1) GHG emissions for refurbishment measures constructed with timber or mineral materials (2) GHG reduction potential by replacing mineral structures with wooden structures and (3) temporary carbon storage of the implemented renewable building materials. Further results can be found in Figure 3 in the right-hand element.

3.2.1 LCA of refurbishment measures.

The following subsection focuses on LCA methodology of refurbishment measures at the municipal level. To explain the methodology further, it is necessary to give a more detailed account of LCA for refurbishments in the following section.

There is no common scientific consensus in the literature regarding the actual implementation of LCA for refurbishment measures. [32, 33] Consequently, a coherent LCA approach is needed for refurbishment measures as well as an extension of the framework to the municipal level.

Refurbishment measures are defined as changes to the structural substance of the exterior envelope of the building as well as to the technical installations of the building. [23]

For a municipal level of consideration, structural and material changes are primarily applied to the exterior walls, the roof, or the top ceiling of the building. The replacement of the building's cooling or heating system is also considered an energetic refurbishment but is usually covered at the municipal level by literature values and extrapolations.

Figure 4 displays the framework for LCA of refurbishment at municipal level. The scale of the municipality is not significant in the methodology, as the LCA of refurbishment measures is applied via extrapolations to the municipal level. The LCA is realized using a bottom-up approach for the building components, mainly the exterior building envelope, highlighted colourful in Figure 4. The buildings of the national building type matrix of IWU [28] have been included, whereas they differ in building type and age, indicated in Figure 4 with the colour subdivision of the building symbols.

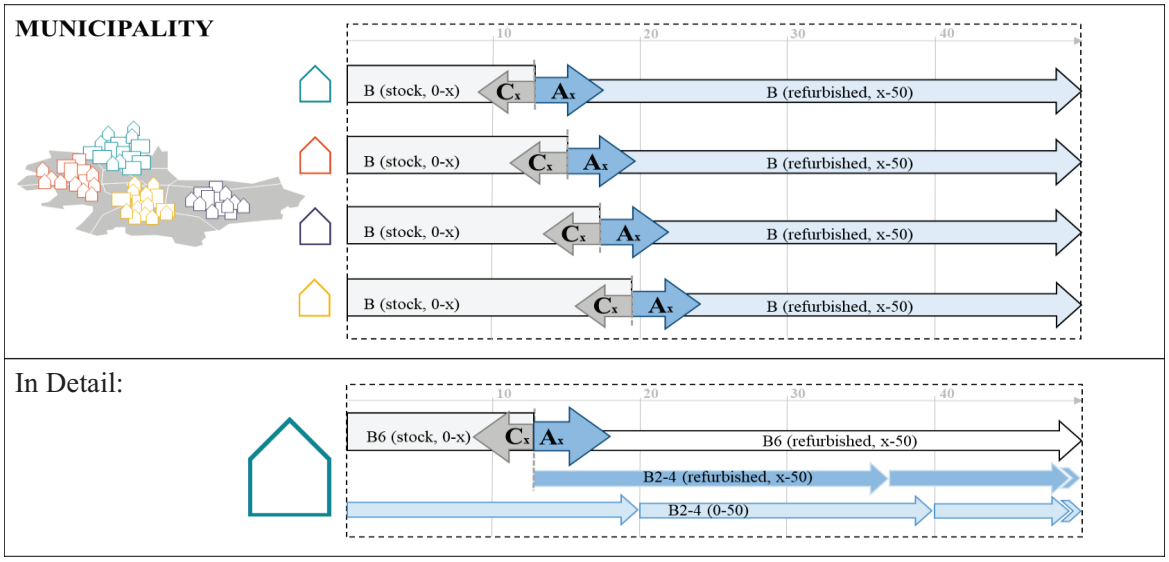

Figure 4. *Framework for LCA of refurbishment measures at municipal level – residential buildings categorized in building type and age (colour scheme) – module A includes production A1-A3 - module B includes maintenance B2, replacement B4 and operational energy consumption B6 – module C includes End-of-Life C1-C4*

The general framework for LCA of refurbishment at municipal level starts with these parameters:

- objects of assessment: building components
- system boundary: exterior envelope components
- Functional equivalent: 1 m² GEA
- reference study period: 50 years

Following DIN EN 15978:2011 [19] and DIN prEN 15978:2021 [34], the production and transport of all new building components and the disposal of removed components of any necessary construction measures are a part of this methodological approach, disregarding the actual time of refurbishment, see Figure 4.

Now, moving into the details of the LCA methodology for refurbishment, the starting point is year 0 of the reference study period. Here, the modules maintenance B2(0-x), replacement B4(x-0) and operational energy consumption B6(0-x) of the exterior building envelope are applied in the LCA approach. The moment within the reference study period where the refurbishment is executed, is symbolized with an x in Figure 4 of the LCA framework. Now, the life cycle phases for the refurbishment components will be supplemented. The modules End-of-Life C1-C4(x) will be added for the exterior envelope components that have to be demolished due to the refurbishment. Analogously, the modules production A1-A3(x) are included for the newly added building materials. At time x, the refurbishment is completed, the modules maintenance B2(x-50) and replacement B4(x-50) are additionally applied for the new exterior envelope components. In contrast, the modules maintenance B2(0-50) and replacement B4(0-50) of in-situ building components do not change during the refurbishment and therefore remain consistent since year 0. The operational energy consumption B6(x-50) continues as part of the LCA after the refurbishment but is reduced according to the now existing energetic standard to include the impacts of the refurbishment. By the end of the reference study period of 50 years, it is assumed that the municipality being studied will not be demolished leaving the existing buildings in place. As a result, the modules End-of-Life C1-C4(50) and Benefits and Loads D are not considered in the LCA framework.

Referring to Figure 4, the LCA approach is adapted to the spatial context of the municipality. Here, the German residential building typology of the IWU [28] provides the input for the LCA of the exterior envelope of municipal buildings. As mentioned before, the typology offers descriptions of the example buildings, including information on refurbishment options with data on the structure of the building envelope before and after refurbishment measures. With this information, the LCA of the exterior building envelope can proceed as described. Therefore, two linking parameters are used for extrapolation: the German residential building typology and the area of the building envelope components. Using the national building type matrix, a reference to the building stock in Menden can be established. Using the area of the building envelope components, the results of the LCA for refurbishment of the building envelope can be extrapolated. Then, the calculations can be performed for the entire municipality using the m² GEA for the residential buildings.

The material choice for the refurbishment can also be considered and compared within the LCA framework. In this way, the carbon storage can be accounted for each refurbishment approach. Additionally, by comparing different materials with the same measure, GHG reductions due to the material choice can be reported.

In this subsection, it was explained that the methodology requires a new approach for LCA of refurbishments. The following section deals with the demonstration of the results.

4 ILLUSTRATIVE EXAMPLES

In this section, some impressions and first results of the new construction scenario and refurbishment scenario within the web-GIS system Holzbau-GIS are presented.

After the initial log-in procedure, the user sees a short introduction page in the web interface and a view of a basic map of the research area of the sample municipality of Menden (Sauerland). Now, the user can select the topics of interest via a menu tree:

General data (Basisdaten): This category contains general building-specific information on the building stock, such as the building type or the building age, that was compiled by the project partners. [35]

Spatial overall planning (Räumliche Gesamtplanung): The spatial overall planning is subdivided into the categories of urban land use planning, specialized planning, and protected areas. Here, the forest inventory, nature reserves and biotopes are displayed. Among others, these issues are crucial for a comprehensive urban planning process.

Calculation scenarios (Berechnungsszenarien): There are two levels of consideration within the framework of Holzbau-GIS: new construction case studies of already passed development plans (what could have been...?) and GHG reduction potentials if the municipal residential building stock is energetically refurbished. The GHG emissions, GHG reduction potentials and temporary carbon storage are quantified and can be visualized in the web-GIS system.

In Figure 5, data of the the folder environmental planning (Fachplanungen) and subfolders forest (Wald) are shown. The map view of Figure 5 contains a range of different geodata like forest type (Waldart) and forest function (Waldfunktion). The forest type ist categorized in hardwood and softwood. Depending on the formation of the forest types, the category changes. The forest function gives information on recreation, emssion, climate or noise protection of the different forest areas.

https://doi.org/10.52202/069179-0521

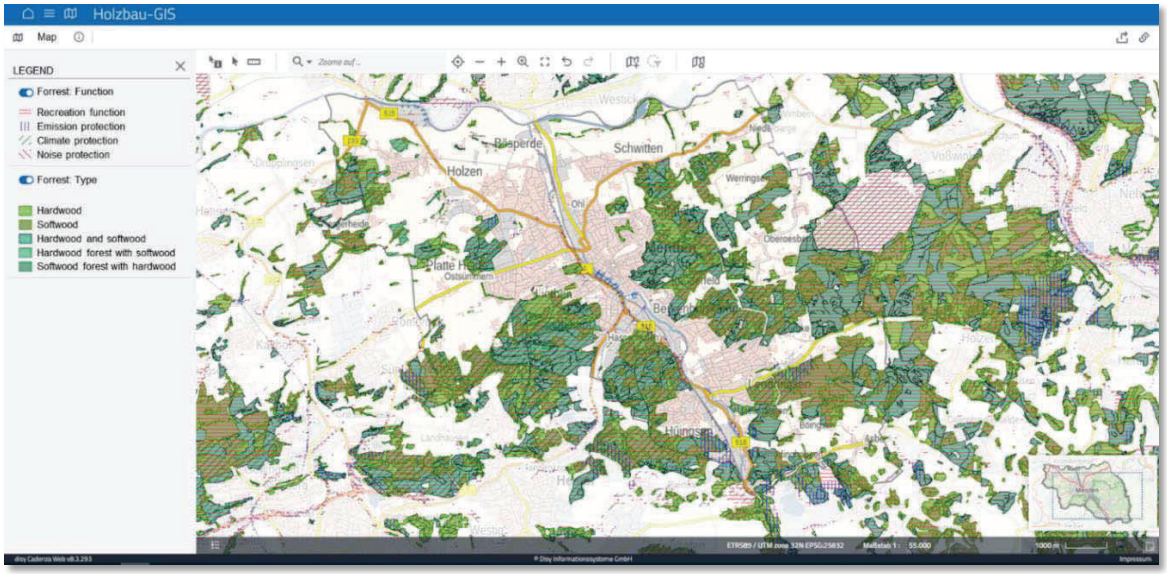

Figure 5: *Display of web-tool Holzbau-GIS: environmental planning*

4.1 NEW CONSTRUCTION

In Figure 6, the web interface shows a dashboard view, customised to the user's individual requirements as well as considering the presented data. Here, the dashbord includes a map view, two charts and a overall sum of one selected resulting parameter.

Figure 6 contains a component of the new construction scenario. A case study approach was chosen to gain a detailed understanding regarding the impact of material choices and to provide detailed illustrations of quantitative GHG reduction potentials and temporary carbon storage for new constructions mesures. This component of the new construction scenario gives an overview of five case studies, exemplifying new constructions in Menden (Sauerland). Development plans contain information on the permitted land uses and building types, as well as further information on permitted building characteristics. The development plans of the five case studies differ in terms of land uses and building types. [36, 37]

In Figure 6 the case study no. 221 as one of the five case studies is displayed. [38] The map view shows the location of the future construction areas according to the development plan no. 221. Within development plan no. 221 for eight construction areas, single-family houses (SFH) were permitted, visible via map view (white).

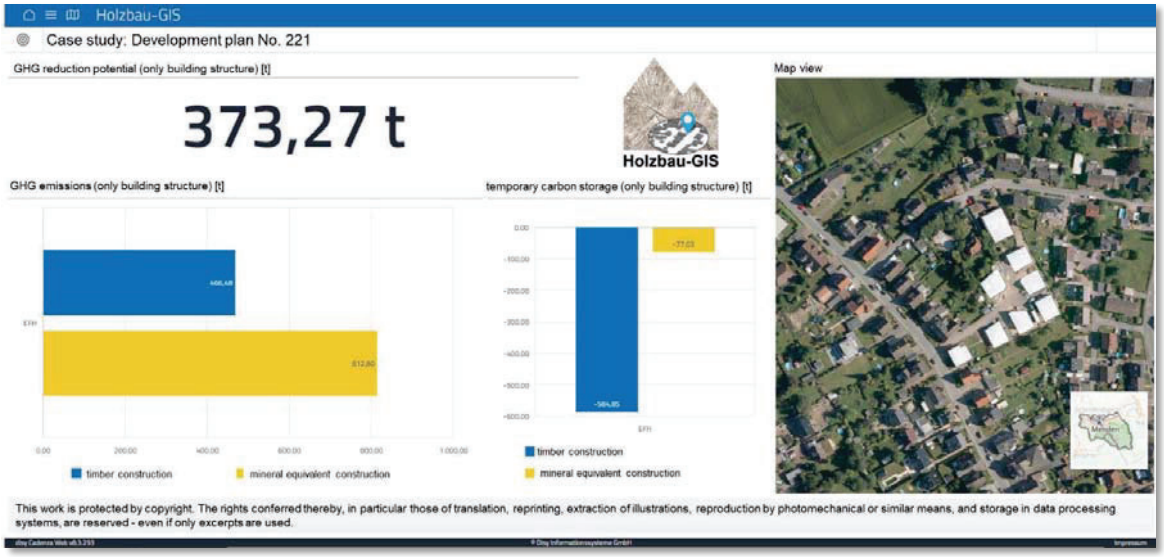

Figure 6: *Display of web-tool Holzbau-GIS: new construction*

The differences between the construction methods of the new building structure are highlighted in the left-hand chart in Figure 6. It shows the GHG emissions [t CO2-Eq.] for each construction method for the maximum permitted GEA, for the corresponding building type.

If the building structure of the SFHs will be a timber construction (blue), the GHG emissions will be at 466.48 t CO2-Eq. If the building structure of the SFHs will be built as a mineral construction (yellow), the GHG emissions will be about 812.80 t CO2-Eq.

The sum of total GHG reduction potential is additionally indicated as an absolute value in the dashboard. Overall, around 373 t CO2-Eq. GHG emissions could be saved for development plan 221.

The right-hand chart shows additional data about the temporary carbon storage for new constructions mesures. If the building structure of the SFHs will be a timber construction (blue), the temporary carbon storage will be at -584.85 t CO2-Eq. If the building structure of the SFHs will be built as a mineral construction (yellow), the temporary carbon storage will be about -77.03 t CO2-Eq.

4.2 REFURBISHMENT

For the refurbishment scenario, the GHG reduction potential is divided into two components: the GHG reduction potential from thermal refurbishment to passive house standard is given within this scenario. In this case, the GHG reduction potentials refer to the CO_2 emissions from heating and hot water. The second component includes the GHG reduction potentials by using timber for the refurbishment instead or mineral materials, that are illustrated in the web-tool Holzbau-GIS and shown in Figure 7. Here, the dashbord includes a map view and a chart. The dashboard displays the refurbishment potential of the municipality of Menden (Sauerland) subdivided into district specific data.

The map view contains the boundaries of the districts with additional data given as pie charts. These charts provide information on the GHG reduction potentials in percentage due to the refurbishment of the whole building envelopes, classified by the residential building type. The overall GHG reduction potential of the district is given within the pie chart, again in percentage. The pie charts display the GHG reduction potential for single-family houses (blue), row houses (yellow), multi-family houses (green), and large multi-family houses (not visible due to the small amount and consequently impact) for each district.

The right-hand chart of Figure 7 contains information as well on the GHG reduction potentials due to the refurbishment of the whole building envelopes, classified by the residential building type. Now the results are given as absolute values in t CO2-Eq. The GHG reduction potential are split by each district, giving summed-up results for single-family houses (blue), row houses (green), multi-family houses (yellow), and large multi-family houses (pink) for each district.

In Lendringsen, for example, a total GHG reduction potential of 6 660.71 t CO2-Eq. is given, if the whole building stock of this district is refurbished to passive house standard. Considering the SHFs, a GHG reduction potential of 4 146.01 t CO2-Eq. is provided for Lendringsen. Referring to the left-hand map view, these buildings generate 12.23 % less GHG emissions if the refurbishment measures are realized using renewable building materials.

In summary, these results show that the web-GIS system can provide different analysis capabilities and levels of analytical complexity for the presented data. By quantifying GHG emissions, GHG reduction potentials, and temporary carbon storage, differences resulting from building type, reference area, and material choice can be highlighted.

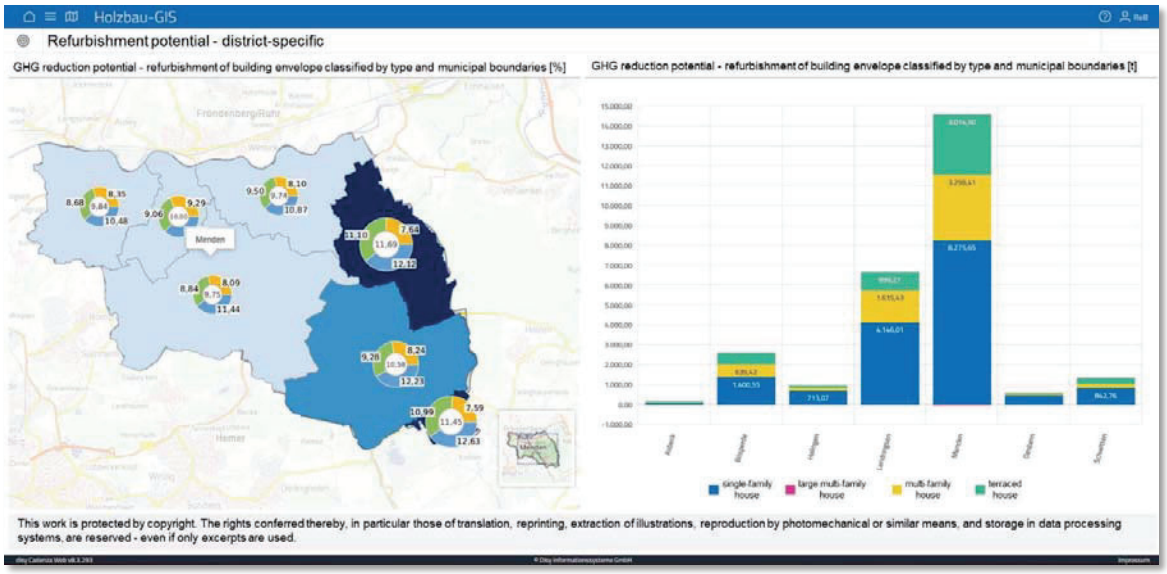

Figure 7: *Display of web-tool Holzbau-GIS: refurbishment*

https://doi.org/10.52202/069179-0521

5 IMPACT

In summary, there are two levels of consideration within the framework of Holzbau-GIS: new construction case studies of already passed development plans (what could have been...?) and GHG reduction potentials if the municipal residential building stock is energetically refurbished. The GHG emissions, GHG reduction potentials and temporary carbon storage are quantified and can be visualized in the web-GIS system. This creates an initial successful combination of geospatial data with LCA data for new construction and refurbishment. The LCAs of refurbishment measures represent a novelty in research which not only satisfies methodologically, but also generates significant LCA outcomes.

Starting with the new building scenario, this study establishes a quantitative framework for an extrapolation of valid building specific LCA data on a municipal scale, subdivided into different land uses and building types.

Referring to the refurbishment scenario, it was necessary to introduce a new methodology for LCA of refurbishment measures. For the implementation of the LCA the German residential building typology of the IWU [28] has been applied. In addition, for the first time, the data for the refurbishment measures of the residential building typology of the IWU were combined with practice-oriented building component structures and material quantities to perform the LCA.

Together, the current data highlights the importance of valid extrapolation to generate an initial estimation of potential GHG reductions at the municipal level. The focus in this context is on reducing environmental pollution and protecting resources, but also on utilizing the carbon storage capacity of renewable raw materials. Additionally, further provided data, e.g. the urban land use planning, support decision-making processes or planning measures for climate protection in urban areas.

6 CONCLUSIONS

The aim of the present study was to serve as a representative calculation to demonstrate the potential of timber construction to the decision makers of a municipality. The web-GIS system "Holzbau-GIS" enables a quantitative analysis of GHG reduction potentials for new buildings and refurbishment measures based on the city of Menden as a case model. The web-GIS system examines the impacts resulting from the use of renewable materials in the building sector at the municipal level. Consequently, we investigate the influence of various materials utilised during constructing new buildings or refurbishing existing ones.

However, these data should be interpreted with caution as certain assumptions must be applied. For an individual building, the calculated data is limited in its preciseness since various calculations were based on average values for standardized building types. A case-by-case assessment remains crucial in order obtain building-related information. To quantify the GHG reductions for a specific building, a comprehensive LCA should be considered in each case.

Regarding the significant role of refurbishment measures for the achievement of climate protection targets, it is necessary to use their potential as far as feasible. In other words, a high level of energy-efficient refurbishment is as essential as an increase of the refurbishment rate. [39]

Referring to the new construction scenario, with the assistance of an online application, users can determine data for future new construction projects. By entering the land use type, building use type, and proposed building type along with the corresponding GEA, the GHG emissions, GHG reduction potential, and temporary carbon storage can be projected. Further development should be pursued in the future to allow an open access tool available to the German municipalities to enable a large application.

The tool supports the sustainable and holistic transformation of the municipal building stock and offers different stakeholders and authorities the possibility to evaluate the environmental quality of refurbishment measures or new construction projects.

In future, we expect criteria such as GHG reduction potentials to play an increasing role when municipal projects will apply for funding.

Overall, constructing with timber, will take an important role regarding climate protection for the building sector, as suggested in the European Union Green Deal [40] and the European Bauhaus Initiative [41]. In this context, the "Holzbau-GIS" can support municipalities by integrating renewable materials as an additional option in their municipal climate protection concept.

Especially on a larger scale, carbon storage through technologies in and on buildings should be taken into consideration in the built environment. [39]

ACKNOWLEDGEMENT

This study was carried out based on the research project “Holzbau-GIS: Reduction of greenhouse gas emissions by building and renovating with wood” funded by the Federal Ministry of Food and Agriculture (BMEL) and the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU), Waldklimafonds. The authors gratefully acknowledge the assistance of all concerned.

In-plane Shear Test and Application Study of Seismic Retrofit Timber Frame with CFRTP Strands

Hina Takizawa[1],Nobuji Sakurai[2], Yuya Takaiwa[3]

ABSTRACT: In this study, we conducted a static in-plane shear test of a seismic retrofitted timber frame using CFRTP strands for the purpose of clarifying the usefulness of seismic retrofitting of timber buildings using CFRTP strands.The results were analysed to clarify the deformation mechanism. Based on the results, seismic retrofitting was carried out on the actual building, and the usefulness of seismic retrofitting and the area of application of the experimental results and design method were clarified.

KEYWORDS: Timber Frame, In-Plane Shear Test, Carbon Fiber, Thermoplastic, Seismic Retrofitting

1 Introduction

Carbon fiber-reinforced materials are advanced materials used in a wide range of fields in engineering, and are also attracting attention in the field of construction[1] Since carbon fiber composite materials have the characteristics of high strength, no rust, and no dew condensation, there are cases where they are suitable for seismic retrofitting of timber buildings instead of building steel materials [2]. In the previous study, the authors have developed an end fixing structure for CFRTP strands with toughness [3] [4] [5]. An in-plane shear test was conducted on a timber frame reinforced using CFRTP strands to clarify the in-plane shear performance. [6]. However, in the actual seismic retrofitting of timber buildings, there are cases where it is applied to a structure whose aspect ratio is different from that of the specimen, and it is not possible to adopt the same connection details as the specimen. At present, the design supervisors and contractors make decisions on a case-by-case basis at the construction site and many issues remain from the perspective of adapting to actual buildings. Therefore, we will conduct research aimed at clarifying the usefulness of seismic retrofitting of timber buildings using CFRTP strands. In order to achieve the purpose, in this report, the in-plane shear test was carried out and analyzed by adding a new specimen specification to the experimental result of the previous study [6].Then, the in-plane shear performance and deformation mechanism were clarified, and the usefulness was clarified by conducting a trial construction test by seismic retrofitting to the actual building. Therefore, it is possible to clarify the differences that may occur when applying the specimen specifications and the actual building, and to clarify the area of application and design method of the test results. Here, most of the previous study on the development of seismic retrofitting members for timber buildings is limited to understanding the in-plane shear performance when adapted to the specimens. On the other hand, in this study, the effectiveness is clarified not only by grasping the in-plane shear performance but also by performing adaptation verification by trial construction test s on actual buildings and hat is the feature of this research.

2 In-Plane Shear Test

An in-plane shear test was performed on a timber frame reinforced with CFRTP strands to examine the possibility of adapting the CFRTP strands to the vertical surface of a timber building.

2.1 The Outline of Specimen

2.1.1 Timber Frame

Assuming a general timber house, specimen were subjected to a static in-plane shear test using a timber frame with a wall height of 2910 mm, a wall width of 910 mm, and a wall width of 1820 mm. A total of 10 specimen were tested, 5 pieces each for a specimen with a wall width of 910 mm (910 specimens) and a specimen with a wall width of 1820 mm (1820 specimens). Figure 1 and Figure 2 show the specimens diagram, and Table 1 shows elements of specimen. The specifications of the specimen are shown in Table 2 and Table 3.and compared by 5 parameters. The first is the torque value of the stainless bolt at one end of the CFRTP strand, which was controlled by hand tightening at 2Nm and 10Nm. The second is whether or not the wood (a corbel) is fixed to attach the CFRTP strand to the column. Specimen 910-3,910-4,910-5,1820-1,1820-2,1820-3,1820-5 were fixed in 4 places with screws. The third is the difference in the shape of the holes made in the column to penetrate CFRTP strands.

https://doi.org/10.52202/069179-0522

The hole shape of specimen 910-1.910-2,910-3,1820-1,1820-2,1820-3 were circular, and the hole shape of specimens 910-4,910-5,1820-4,1820-5 are square. Figure 3 shows the fixing method of a corbel fixed with screws and the shape of the through hole of the CFRTP strand. The fourth is the presence or absence of side protrusions (protrusions of CFRTP socket) that are created when making a CFRTP socket. Specimens 910-1,910-2,910-3 and 1820 Specimen were designed to remove the protrusions of CFRTP socket, and Specimen 910-4 and 910-5 were specified to leave them. The fifth is the difference in the order when fixing the corbel of the CFRTP strand and the column. Specimen 910-1,910-2,910-3,1820-1,1820-2 and 1820-3 adjusted the torque value of the CFRTP strands after fixing the corbel to the column. Specimen 910-4,910-5,1820-4 and 1820-5 fixed the corbel to the column after tensioning the CFRTP strands.

1820-5	2Nm	screwed	Square	Not Available	tightening a bolt of CFRTP strand ↓ Fixing cobels	30Ø

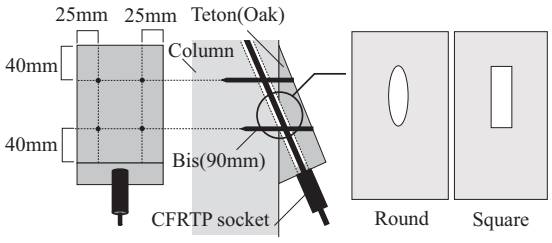

Figure 3: How to fix a corbel and The shape of hole of CFRTP

2.1.2 CFRTP strand

The CFRTP strand used in the test composed 7 twisted wires with a diameter of 2.1mm, and the cross-sectional area is 24 mm^2 and the tensile modulus of it is 110 kN/mm^2. The end fixing structure consists of two types. One side is a CFRTP socket, which is known to be ductile fracture at about 15 kN from experiments. The other side

https://doi.org/10.52202/069179-0522

is a bonding method of stainless bolt, which breaks brittlely with a load larger than 15 kN. Since the CFRTP socket yields before the stainless bolt, the CFRTP strand has toughness. Figure 4 shows the results of a pull-out test of a CFRTP strand suitable for this test. The test method was based on previous studies. As a result of the test, it was confirmed that the behavior of the CFRTP socket was that there was no brittle fracture even if a first yield point due to adhesive yielding, a second yielding point when the maximum yield strength was reached, and then a displacement of 40 mm occurred.

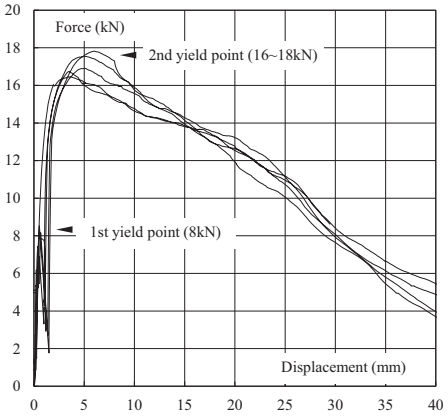

Figure 4: CFRTP socket Force-Displacement Relationship[6]

2.2 Method and measurement plan of the test

The loading device adopts a column base fixed type. It is fixed to the specimen with an in-plane restraint jig on the beam of the specimens, and the base is fixed to the specimen fixed beam. An oil jack is used to horizontally apply a positive and negative load to the specimen. In the loading cycle (repetition history), the apparent shear deformation angle of the specimen is ± 1/450, ± 1/300, ± 1/200, ± 1/150, ± 1/100, ± 1/75, ± 1/50 rad. Deformation control is performed three times, and a positive and negative load is performed once with a deformation angle of ± 1/30 rad. After that, the specimen is loaded until the maximum load is reached and the load drops (0.8Pmax) or a deformation angle reaches 1/10 rad or more. A total of 7 displacements are measured: horizontal displacement of the top of the specimen, horizontal displacement of the base of the specimen, vertical displacement of the column (2 points), horizontal displacement of the fixed beam, and vertical displacement of the jig (2 points). In addition, the strain is measured with a strain gauge at two points on the front and back of the CFRTP strands. Figure 6 and Figure 7 show respectively the displacement measurement points and strain gauge mounting positions. An in-plane shear test of a timber frame reinforced with CFRTP strands is performed to confirm the strength and fracture morphology. The shear deformation angle of the timber frame obtained by the displacement meter 1 and the displacement meter 2 was used for control.

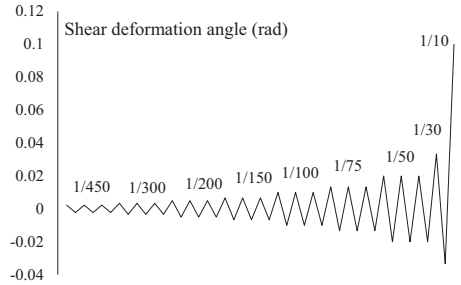

Figure 5: Repetition History

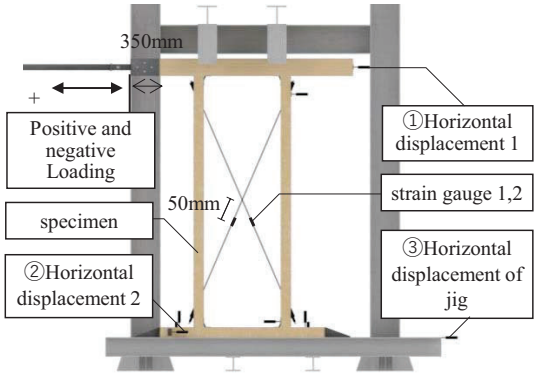

Figure 6: The Experimental Device and Specimen

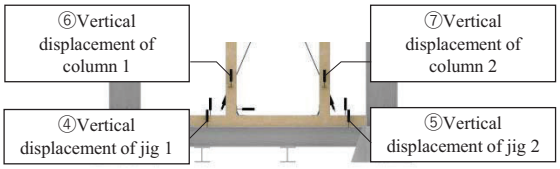

Figure 7: Points of Measurements on the Back

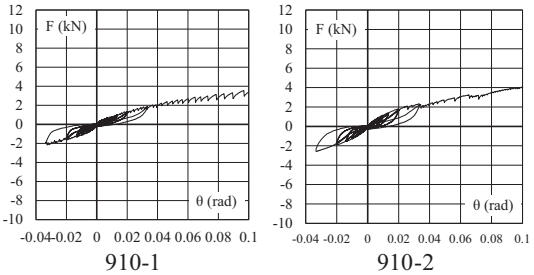
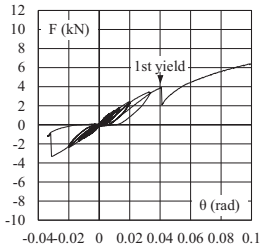
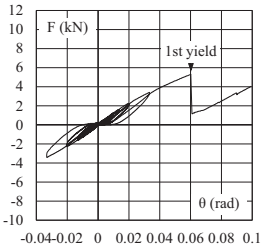
2.3 Result of the test

Figure 8 and Figure 9 show the relationship between the shear force (F) and the shear deformation angle (θ) of the 910 specimen and 1820 specimen, respectively. Tables 4 and 5 show the shear deformation angles of the 910 specimen and 1820 specimen at the first yield(θ_{yield}), the shear force of the timber frame at the first yield(P_{yield}), and the maximum shear force(P_{max}), respectively.







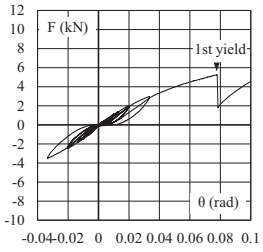


Table 4: Result of the test (910 specimen)

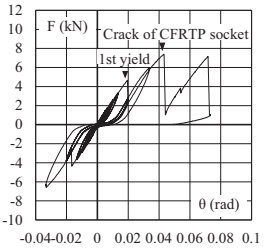
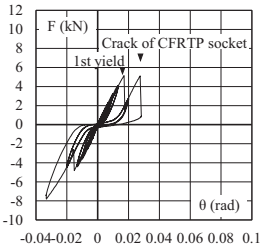
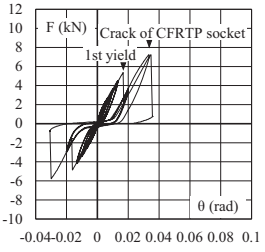
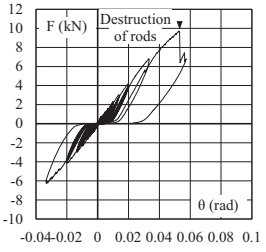
	θ_{yield} (rad)	P_{yield} (kN)	P_{max} (kN)
910-1	×	×	3.8
910-2	×	×	4.0
910-3	1/25	3.9	6.4
910-4	1/17	5.3	5.3
910-5	1/13	5.2	5.2

Figure 8: Shear Force-Shear Deformation Angle Relationship (910 specimen)









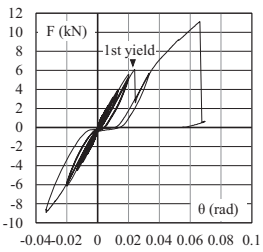


Table 5: Result of the test (1820 specimen)

	θ_{yield} (rad)	P_{yield} (kN)	P_{max} (kN)
1820-1	1/51	4.6	7.3
1820-2	1/58	5.1	5.1
1820-3	1/60	5.3	7.2
1820-4	×	×	9.6
1820-5	1/42	6.1	11.1

Figure 9: Shear Force-Shear Deformation Angle Relationship (1820 specimen)

2.4 Analysis

Analysis is performed based on the differences in the specifications of the specimens and the test results..

2.4.1 Torque value of stainless bolt

specimen 910-2 with a torque value of 2 Nm at one end of the CFRTP strand was compared with specimen 910-1 with a torque value of 10 Nm. Figure 10 shows the relationship between the shear deformation angle and the shear force of the specimen 910-1 and specimen 910-2. The specimen 910-1 with a large torque value had a maximum share force of 0.3 kN smaller than that of the specimen 910-2. It is considered that this is because the specimen bends inward when the torque value is large, and the force opposite to the shearing force of the timber frame is applied to it.

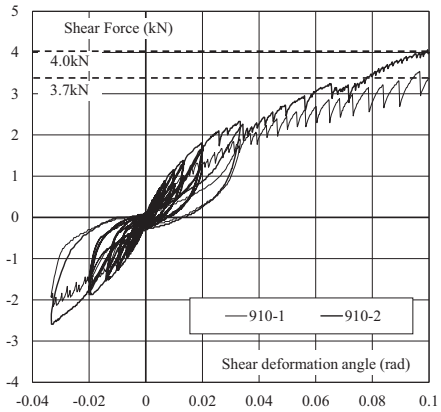

Figure 10: Shear Force-Shear Deformation Angle Relationship (910-1,910-2)

2.4.2 Fixing corbels

Specimen 910-2 and 1820-4, which allowed movement without fixing the corbels, and Specimen 910-3 and 1820-5, which had the corbels fixed with screws, were compared. Figure 11 and Figure 12 show the relationship between the shear deformation angle and the shear force of the specimen 910-2,910-3,1820-4 and 1820-5 respectively. specimen 910-2 and 1820-4 that did not fix the corbel allow the timber frame to be deformed by the corbel slipping on the column surface. Therefore, the CFRTP socket did not first yield. In the specimen 1820-4, the rod of the CFRTP strand broke. The CFRTP socket first yielded at 1/25 rad for the specimen 910-3 and 1/42 rad for the test body 1820-5 with the corbel fixed. When the corbel is not fixed, the deformation performance of the timber frame can be improved. It was confirmed that when the corbel is fixed, the maximum share force is 2.4kN for the 910 specimen 1.4kN for the 1820 specimen compared to the case where the corbel is not fixed.

https://doi.org/10.52202/069179-0522

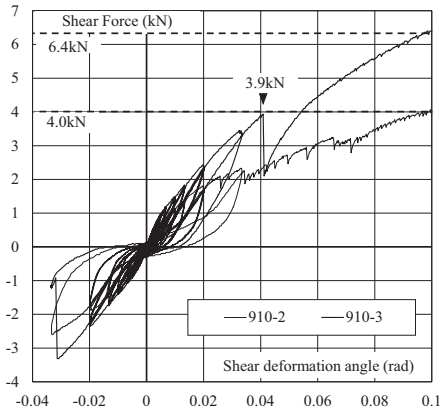

Figure 11: Shear Force-Shear Deformation Angle Relationship (910-2,910-3)

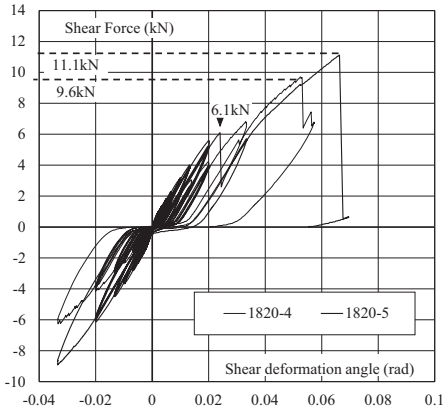

Figure 12: Shear Force-Shear Deformation Angle Relationship (1820-4,1820-5)

2.4.3 Protuberance of CFRTP socket

Specimen 910-3 without protuberance of CFRTP socket and specimens with it were compared with specimen 910-4 and 910-5. Figure 13 shows the relationship between the shear deformation angle and the shear force of the specimen 910-3, 910-4 and 910-5. Specimen 910-3 without protuberance of CFRTP socket occurred first yield at 1 / 25rad, and specimen 910-4 and 910-5 with it occurred first yield at 1/17 rad and at 1/13 rad, respectively. The maximum shear force was 6.4 kN at the shear deformation angle of 1/10 rad for the specimen 910-3, and 5.3 kN and 5.2 kN at the first yield for the specimen 910-4 and 910-5, respectively. If there is a protuberance of CFRTP socket, the timber frame is given nearly twice the deformation performance of 1/30 rad, which is the design criteria of a traditional timber building. n the other hand, when the CFRTP socket had no protuberance of CFRTP socket, the maximum yield strength was about 1 kN larger than that with it.

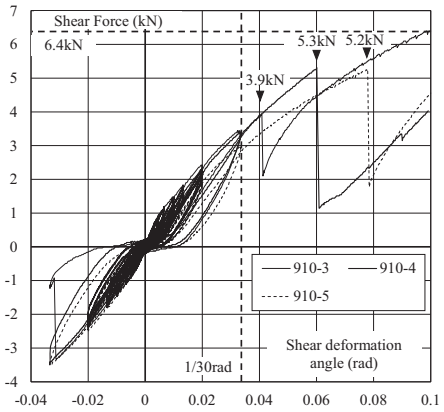

Figure 13: Shear Force-Shear Deformation Angle Relationship (910-3,910-4,910-5)

2.4.4 The shape of a hole of CFRTP strand

Specimen 910-3, which uses a circular hole to make a CFRTP strand through a column, and specimen 910-4 and 910-5 which have a square hole, are compared. Figure 14 shows the initial stiffness of a timber frame with a shear deformation angle of 0 rad to 1/450 rad, and Figure 15 shows difference of embedment due to the shape of a hole of CFRTP strand. Specimen 910-3 with circular holes for CFRTP strands have 1.3 to 1.8 times higher initial stiffness than specimen 910-4 and 910-5 with square holes. When the shape of the hole for the CFRTP strand is circular, it is considered that it is difficult to dig in because the contact area between the CFRTP strand and the wood is large.

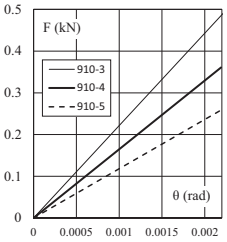

Figure 14: Initial stiffness (910-3,910-4,910-5)

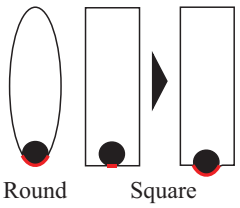

Figure 15: Difference of Embedment due to the shape of a hole of CFRTP strand

2.4.5 Construction procedure of CFRTP strands

The test results were compared due to the difference in the construction procedure when constructing the CFRTP strand. Figure 16 shows the difference in the construction procedure of the CFRTP strand. Specimen 910-3 tightened the bolt of the CFRTP strand after fixing the corbel. On the other hand, specimen 910-4 and 910-5 fixed the corbel after tightening the bolt of the CFRTP strand. When the receiving material of the CFRTP strand is fixed first, the hole for the CFRTP strand of the corbel and the column are fixed in the same position, so that the CFRTP strand easily sinks column inside the timber frame. On the other hand, if the bolt of the CFRTP strand is

https://doi.org/10.52202/069179-0522

tightened first, the position of the hole for the CFRTP strand of the corbel and the column is misaligned, so that it is easy to sink column the outside of the timber frame. The outer embedment of the timber frame has a greater contribution to the shear displacement of the timber frame than the inner.

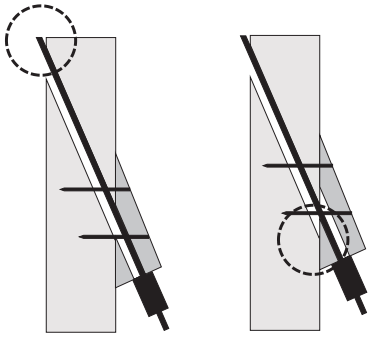

Figure 16: The Difference of Embedment of CFRTP Strand due to Construction Procedure

2.4.6 Diameter of CFRTP socket

A specimen 1820-1 using a CFRTP socket with a diameter of 20 mm and specimen 1820-5 using a CFRTP socket with a diameter of 30 mm were compared. Figure 17 shows the relationship between the shear deformation angle and the shear force of the specimen 1820-1 and 1820-5. When a CFRTP socket with a diameter of 20 mm was used, the shear force did not increase because the CFRTP socket cracked after the first yield, and the maximum shear force was 7.4 kN. On the other hand, the CFRTP socket with a diameter of 30 mm did not crack after the first yield, and the maximum shear force was 11.1 kN, which was the highest among all the specimens. By preventing the CFRTP socket from cracking, the shear force of the timber frame wall can be improved.

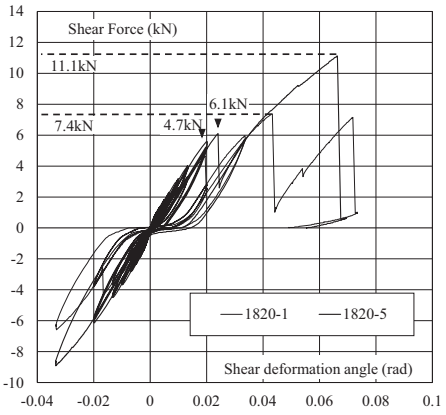

Figure 17: Shear Force-Shear Deformation Angle Relationship (1820-1,1820-5)

3 Analysis of Shear Deformation Mechanism of Specimen

3.1 The Outline of Analysis

It was analyzed how much the factors that cause shear displacement in the timber frame wall contribute to the actual shear displacement. Figure 18 shows each factor that causes shear displacement.

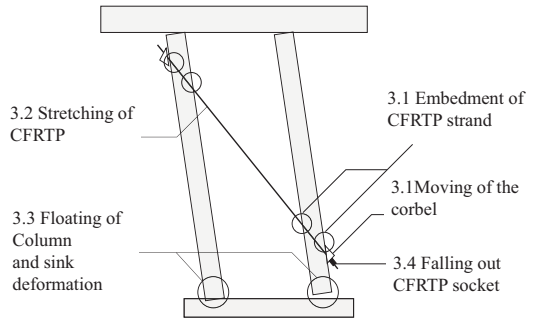

Figure 18: Factors Contributed to the Shear Deformation

3.2 How to Analyse

Using the analysis method of the factors that cause shear displacement of the timber frame proposed in the previous study [6], the contribution rate of each factor that causes shear displacement in the specimens is calculated.

3.3 The Results of Analysis

Tables 6 and Table 7 show the contribution rates of each factor that causes shear displacement of 910 specimen and 1820 specimen. In the tables, 3.1 shows Indentation deformation of CFRTP Strand and 3.2 shows axis deformation of CFRTP strand and 3.3 shows rotational deformation of the timber and 3.4 shows deformation of falling out CFRTP socket. In the 910 specimen, the shear displacements of the specimen 910-3, 910-4 and 910-5 with falling out the CFRTP socket account for about 30% of the total. In the 1820 specimen, when the CFRTP socket is fallen out, the effect on the shear displacement is larger than that in the 910 specimen. In specimen 1820-5, since all the sockets were fallen out, the shear displacement due to the sockets being fallen out was calculated to be larger than the actual one.

Table 6: Each Factor Causes the Shear Displacement (910 specimen)

	The Shear Displacement ration(%)				
	910-1	910-2	910-3	910-4	910-5
3.1	56.8	55.1	11.4	52.4	48.9
3.2	7.4	9.7	18.0	14.6	13.8
3.3	18.6	17.5	23.7	21.1	25.1
3.4	0	0	30.9	30	30.2
Total	82.8	82.4	84.2	118	118

4 Trial Construction Test by Applying to Actual Building

4.1 The Outline of the Building

The actual building, which has been seismically reinforced with CFRTP strands, is a timber building exhibited at National Museum of Ethnology. The actual building is shown in Photo 1 and Photo2, construction condition is shown in Photo 3, Adjustment of initial tension and the reinforcement drawing is shown in Figure 19.

Photo 1: View from outside of the building

Photo 2: View from inside of the building

Photo 3: Construction condition

Photo 4: Adjustment of initial tension

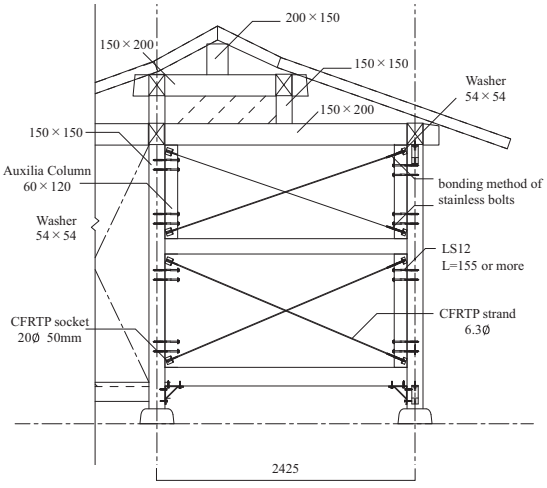

Figure 19: Drawing of Actual Building

4.2 Comparison of the Construction Status of the Specimen and the Actual Building

The construction status of the specimens and the actual building was compared. The difference between the specimens and the actual building will be described. There were the construction procedure when installing the CFRTP strand (4.3), the size of the washer installed between the CFRTP strand and the corbel (4.4), and the structural dimension of the wall reinforced by the CFRTP strand (4.5).

Table 8: The Difference specimens and actual building

		Specimens	Actual building
4.3	Construction procedure	(1) Fixing corbels ↓ Tightening a bolt of CFRTP strand (2) Tightening a bolt of CFRTP strand ↓ Fixing corbels	Fixing corbels ↓ tightening a bolt of CFRTP strand
4.4	The size of a washer (mm)	62×62	54×54
4.5	The size of a wall(mm)	(1)910×2767.5 (2)1820×2767.5	case-by-case

4.3 Impact of Construction Procedure

When constructing a real building, first tighten the bolts of the CFRTP strand and then fix the corbel. Therefore, it is considered that the CFRTP strands are easily sunk on the outside of the timber frame, and the deformation performance of timber frame is improved.

4.4 Impact of The Size of a Washer

A washer is installed between the CFRTP strand and the corbel. A washer of 62 mm x 62 mm was used in specimen, but a washer of 54 mm x 54 mm was used in the actual building. Using the formula (1), it was confirmed whether or not the washer would be dented due to the smaller washer. The allowable bearing stress is 23.3 kN. Since the axial force that can be borne by the CFRTP strand is 15 kN, it was confirmed that the washer does not sink into the corbel until the CFRTP strand breaks.

$$Fcv \times \frac{2}{3} \times \mathrm{A} \qquad (1)$$

F_{cv} : Basic strength of bearing (12N/mm) [7]
A:The area of a washer(2910mm^2)

4.5 Impact of Aspect Ratio of the Timber Frame

In order to obtain the change in the stiffness of the timber frame due to the change in the aspect ratio of the wall, it was verified using the formulas (2) to (5). The change in

https://doi.org/10.52202/069179-0522

the stiffness of 910 specimen to 1820 specimen is considered to be influenced by the change in the aspect ratio of the timber frame and the change in the stiffness of the CFRTP strand. First, the effect of the change in the stiffness of the CFRTP strand is removed from the change in the stiffness of the wall.

$$\frac{P_{1820}}{P_{910}} \div \frac{L_{b910}}{L_{b1820}} \tag{2}$$

P_{910}: Shear force at a shear deformation angle of 1/30 rad in 910 specimen (3.37kN)
P_{1820}: Shear force at a shear deformation angle of 1/30 rad in 1820 specimen (6.59kN)
L_{b910} : Length of CFRTP Strand of 910 Specimen (2304mm)
L_{b1820} : Length of CFRTP Strand of 1820 Specimen (2792mm)

The effect of wall stiffness due to changes in the aspect ratio of the wall of the actual building is shown in the formula (3).

$$K = k_{910} \times \frac{P_{1820}}{P_{910}} \div \frac{L_{b910}}{L_{b1820}} \div \frac{W_{1820}/H_{1820}}{W_{910}/H_{910}} \times \frac{W'/H'}{W_{910}/H_{910}} \tag{3}$$

K: Stiffness of actual building wall affected by changes in wall aspect ratio
W_{910}: Width of 910 specimen (910mm)
W_{1820}: Width of 1820 specimen (1820mm)
W': Width of the wall of actual building (2425mm)
H_{910}: Height of 910 specimen (2767.5mm)
H_{1820}: Height of 1820 specimen (2767.5mm)
H': Height of the wall of actual building (1224.9mm)

The effect of the change in the stiffness of the CFRTP strand on the stiffness of the wall is added to the formula (3).

$$k' = K \times \frac{L_{b910}}{L_b{}'} \tag{4}$$

k':Stiffness of the wall of actual building
$L_b{}'$: Length of CFRTP Strand of the wall of actual building (2530mm)

The axial force borne by the CFRTP strand is calculated using the wall stiffness calculated by the formula (4).

$$k' \times \frac{H'}{30} \times \frac{L_b{}'}{W'} \tag{5}$$

When an example of the wall of an actual building is calculated using the formulas (2) to (5), the stiffness of the wall is 0.23 kN / mm, and the axial force borne by the CFRTP strand is estimated to be 9.6 kN. This is less than the axial force (15 kN) that the CFRTP strand can bear and is designed within the area of application of the experimental results.

Table 9: Impact of Aspect Ratio of the Timber Frame

		910 Specimen	1820 Specimen	Actual Building
				$\frac{W}{H}$	mm/mm	$\frac{W_{910}}{H_{910}}$	$\frac{W_{1820}}{H_{1820}}$	$\frac{W'}{H'}$
L_b	mm	$\sqrt{{W_{910}}^2 + (H_{910} - 2a)}$ $(=L_{b910})$	$\sqrt{{W_{1820}}^2 + (H_{1820} - 2a)^2}$ $(=L_{b1820})$	$\sqrt{(W')^2 + (H' - 2a)^2}$ $(=L_b{}')$
k_b	kN/mm	$\frac{E \cdot A}{L_{b910}}$	$\frac{E \cdot A}{L_{b1820}}$	$\frac{E \cdot A}{L_b{}'}$
P	kN	3.378 $(=P_{910})$	6.281 $(=P_{1820})$	$\frac{k_{1820} \times L_{1820} \times L_{b910} \times D' \times H_{1820}}{L_{910} \times L_b{}' \times H' \times D_{1820}} \times \frac{H'}{30}$
k	kN/mm	$P_{910} \cdot \frac{30}{H_{910}}$	$P_{1820} \cdot \frac{30}{H_{1820}}$	$\frac{k_{1820} \times L_{1820} \times L_{b910} \times D' \times H_{1820}}{L_{910} \times L_b{}' \times H' \times D_{1820}}$

W: Width of the wall
H: height of the wall
L_b: Length of CFRTP strand
k_b: Stiffness of CFRTP strand
P: Shear force at a shear deformation angle of 1/30 rad
k: Stiffness of the wall

5 Conclusion

A static in-plane shear test of a seismic retrofitted timber frame using CFRTP strands revealed the following.

(1) The initial tension of the CFRTP strand was examined using 910specimen. As a result, it was confirmed that when the torque value was changed from 2Nm to 10Nm, the shear force borne by the wall was reduced due to the initial deformation of the timber frame bending inward.
(2) It was confirmed that the stiffness of the timber frame in 910 specimen changes depending on whether or not the corbel of the CFRTP strand is fixed. It was clarified that when the corbel is not fixed, the corbel allows the sliding movement on the contact surface of the column and increases the shear deformation of timber frame.
(3) It was confirmed that the initial stiffness is affected when the shape of the hole for the CFRTP strand is different. It is presumed that this is because when the shape of the hole is circular, the contact area between the CFRTP strand and the timber is larger than when the shape of the hole is square, so it is less likely to be dented.
(4) It was confirmed that the deformation performance of the timber frame changes depending on the construction procedure of the CFRTP strand.It is clear that the procedure of tightening the bolts and then fixing the corbel has a larger shear displacement due to the digging of the columns of the CFRTP strand than the procedure of tightening the bolts of the CFRTP strand after fixing the corbel of the CFRTP strand.

Based on the findings mentioned above, we conducted an adaptation verification by construction experiments on

https://doi.org/10.52202/069179-0522

seismic retrofitting actual buildings using CFRTP strands. As a result, it was confirmed that seismic retrofitting is useful by considering the influence even if the specifications are different from the specimens. In this study, the effect of changing the aspect ratio of the wall was estimated using geometry, but experimental values that can verify the aspect ratio have not been obtained. In the future, in-plane shear test will need to be conducted to clarify the effects.

POST-EARTHQUAKE ASSESSMENT AND DOCUMENTATION OF TIMBER ROOFS

Mislav Stepinac[1], David Anđić[2], Juraj Pojatina[3]

ABSTRACT: In 2020 Croatia was struck by two strong earthquakes. Croatian building stock is in big part made of masonry with timber floor and roof structures. Given that masonry structures are highly vulnerable to seismic actions, damage occurred to more than 70.000 buildings. Due to widespread damage, there is a great need for a detailed and more comprehensive post-earthquake damage assessment. This paper briefly presents the post-earthquake damage assessment in the historic parts of Zagreb and the surrounding area after the recent earthquakes in 2020. Special focus is set on traditional timber roofs – traditional roof systems in Croatia, damages to the load-bearing elements due to earthquake excitations, maintenance issues, wrong renovation of the attics, etc. Also, the role of UAVs, photogrammetry and laser scanners in the assessment and preservation of heritage buildings is shown.

KEYWORDS: Earthquake, Timber Roofs, Assessment, Laser Scanning, UAV

1 INTRODUCTION

The European building stock consists of a large number of masonry buildings with roofs and floors made of wood. This type of structures often gives ancient European cities a recognizable identity, but are vulnerable to seismic excitation. Therefore, knowledge of their current condition and possible structural upgrading is beneficial. In this context, the continuous assessment and monitoring of the seismic safety and vulnerability of buildings must be carried out at the highest level and according to the most modern principles [1–3].

In 2020, Croatia was hit by two strong earthquakes. After the earthquake in Zagreb in March 2020 (M_L =5.5), which damaged about 25,000 buildings, Croatia was again hit by a destructive earthquake of magnitude 6.2 in December 2020. Sisak-Moslavina County suffered the most severe consequences; many historical and cultural buildings were severely damaged. According to the Croatian Center for Earthquake Engineering (HCPI - in Croatian), more than 57,000 buildings were damaged [4,5]. World Bank estimates the total financial damage from the Zagreb earthquake as EUR 11.3 billion [6] and EUR 5.1–5.5 billion for the Petrinja earthquake [7].

Cities in continental Croatia were built on the legacy and principles of construction in Austro-Hungary at the beginning of the 20th century. Most of the historic city centres were built before the enactment of modern earthquake standards, and the buildings were not designed to be earthquake resistant. After the 1963 Skopje earthquake, the standards were developed and building styles changed, and different materials were used for the construction of new structures. Before the introduction of the earthquake standards, the most common building material used was a combination of masonry and wood. The walls were made of masonry and the mezzanines and roofs were made of wood. A large number of such buildings were not adequately maintained, resulting in significant damage to these facilities. Since the mezzanine structures are mostly made of wood, the structures lack the box effect - they are too weak to withstand horizontal actions [8–12]. While masonry buildings have been severely damaged, recent earthquakes have shown that no wood buildings were extensively damaged by the earthquake. However, parts of the structural systems were damaged, especially the timber roofs of typical masonry buildings.

This paper presents the typology of timber roofs in Croatia and the damage caused by the recent earthquakes. The presented results of the damages and the identification of typical damages after an earthquake should be useful for policy makers and for the future implementation of development strategies in the renovation of cities. Since the roof systems in Zagreb and other historic urban areas are similar, shown figures and photos can be of use in assessment of other damaged roof systems.

2 TYPICAL TIMBER ROOF SYSTEMS IN CONTINENTAL CROATIA

In this paper, the focus is placed on the distinct parts of Zagreb, where older buildings predominate, most of which are built with traditional timber roof systems. The roof structure is usually a king or queen post truss, but there are also many combined forms of timber roof structures. The basic types of traditional timber roof systems in Zagreb are shown in Figure 1. The purlins are almost always supported by brick or parapet walls. Spatial roof stabilization (bracing) is usually not executed. A

small number of buildings have a concrete slab under the roof systems due to renovation works [13].

Figure 1: *Typical timber roof structures in Zagreb*

3 DAMAGES TO TIMBER STRUCTURES

The damage methodology for the roof elements and structure was divided into five damage levels: no damage, very minor damage, moderate damage, significant damage, severe damage. Figure 2 shows the extent of damage to roofing and wooden roof structures in the historic districts of Zagreb. In Donji Grad (Lower Town), the buildings are larger in plan than in Gornji Grad (Upper Town); therefore, the structural systems are also different. In the Upper Town, single-family houses and villas predominate, while in the Lower Town, multi-family houses with mostly 7 to 9 housing units are the most common buildings. According to the engineers' decision, the total number of severely damaged roofs was 274 in the Lower Town and 189 in the Upper Town. Damage to roofing was found on 598 buildings in the Lower Town and 516 buildings in the Upper Town [4,13].

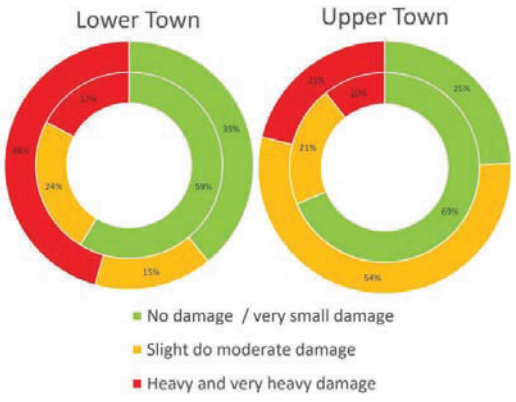

Figure 2: *Statistical data about damage to roofs (inner circle: damaged roof systems, outer circle: damaged roof coverings)*

In summary, the load-bearing parts of the roof structures remained mostly undamaged. The main damage observed at the roof level is damage to the roof coverings, i.e. tiles, decorative elements and non-structural elements.

The failure of non-structural elements such as chimneys and decorative elements on facades was observed on almost all buildings in the city center. Failure of gable walls, masonry columns, wall sections between or under windows, vaults, ceilings, staircases, etc. was common. Since the two materials (timber and masonry) have very different properties and masses, the post-earthquake damage was also very different. The two most typical masonry damages, due to the "pushing" of timber elements and the poor connection with masonry walls, are shown in Figures 3 & 4.

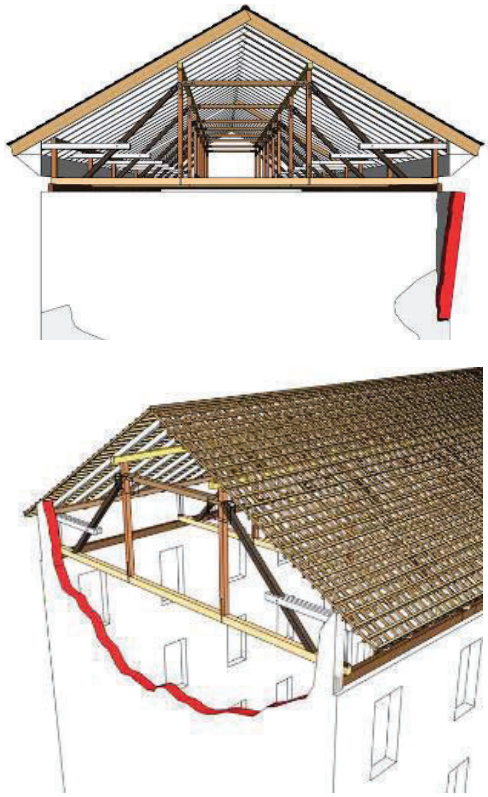

Figure 3: *Typical damages to masonry walls*

Figure 4: *Failure of gable walls (photo credit: M. Stepinac)*

https://doi.org/10.52202/069179-0523

Roof systems often become unstable due to the collapse of individual load-bearing walls beneath them or severe chimney failures (Figure 5 & 6). Post-earthquake inspections showed that many of the chimney failures resulted in direct damage to the roofs. In some locations, the chimneys damaged the supporting roof structure, but in most cases only the rafters broke and the integrity of the roof was maintained (Figures 7 and 8).

Figure 5: *Failure of timber elements due to chimney failure (photo credit: R. Gulić)*

Figure 6: *Timber roof collapse – Sisak cathedral (photo credit: Studio Arhing d.o.o.)*

Figure 7: *Failure of chimneys (from outside) (photo credit: M. Stepinac)*

Figure 8: *Failure of chimneys (from inside) (photo credit: M. Stepinac)*

Maintenance was identified as one of the most important aspects that contributed to the condition of buildings after the earthquake. Since a large number of buildings were poorly maintained or not maintained at all, the properties of the masonry deteriorated over the years, and the seismic performance of such buildings was worse [5]. In many cases, water penetration degraded the properties of both masonry and wood elements (Figure 9).

Figure 9: *Failure of timber elements due to water leakage and seismic excitations (photo credit: Studio Arhing d.o.o.)*

Timber beams on wall parapets along with attic ceiling wooden beams were severely deteriorated due to aforementioned lack of maintenance and due to original defects at the time of construction. The inadequate connections and bad detailing is common and one example is shown in Figure 10. As carpentry joint were used for connections, often, “secondary constructive” screws were missing. Although carpentry joints are considered good in terms of characteristic load combinations, when it comes to dynamic loading with cyclic nature, like earthquake, poor behavior was observed in several cases.

https://doi.org/10.52202/069179-0523

Figure 10: *Bad detailing (photo credit: Studio Arhing d.o.o.)*

Typical conversions of building spaces convert non-living spaces into living spaces (e.g., basements, attics, or utility rooms). This room conversion often involved demolition of partition walls, and undesirable intervention in the load-bearing walls is also common. The conversion of the attic for living purposes resulted in numerous changes to the roof structure. Often timber tie elements were cut to insert the door (Figure 11), which significantly changed the basic static system of the roof structure itself. Also, traditional timber structural systems were replaced by masonry or concrete elements as shown in Figure 12.

Figure 11: *Improper attic modifications (photo credit: HCPI* [4]*)*

Figure 12: *Improper attic modifications (photo credit: HCPI* [4]*)*

4 USING OF MODERN TECHNOLOGIES IN POST-EARTHQUAKE ASSESSMENTS

Regular post-earthquake assessments should be facilitated and improved by state-of-the-art technologies for preservation and digitization of cultural heritage buildings. The construction sector is the slowest to adopt new technologies and this should be changed [14,15]. This motivates the search for a technological solution for the safety assessment of existing structures and the digitization of cultural heritage buildings. The advantages and disadvantages of the new technologies, which are intended to complement the traditional methods, are discussed by [16–18].

Unmanned aerial vehicles (UAV) have proven very useful during the rapid assessment of roofs, as well as detecting defects/damage in hard- to-reach places. Figure 13 shows a post-earthquake assessment scenario using a UAV. An engineer cannot see what has happened on the higher floors or on the roof of a building during an on-site assessment from the street. With a UAV device the above information can be easily assessed.

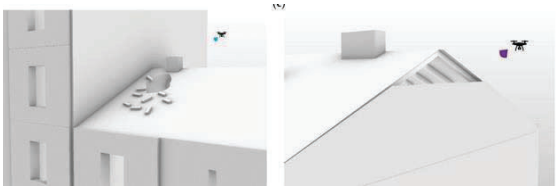

Figure 13: *Possible damage on the roof level of a building after an earthquake* [16]

While drones are very useful in rapid inspections of unreachable spots of buildings, detailed inspections, especially of heritage buildings, should be conducted in a more comprehensive manner. Since the entire city center of Zagreb is under heritage protection, special care was taken to document the building condition in terms of architectural style, details and design, but also in terms of structural impact and peculiarities.

In the following figures, an example of laser scanning is shown, which helped to better understand the structural system. Laser scanning was used to create a 3D point cloud of the interior and exterior of the building. The laser scanner used in the following case study is a Leica BLK360, a compact imaging laser scanner that uses a 360° laser distance meter and high-resolution panoramic images. The collected data is then processed using the Cyclone Register 360 software package. Using three spherical HDR panoramic cameras and a thermal imaging camera, 3D point clouds are delivered with millimetres accuracy. The point cloud can be further used to create an accurate 3D model, to create a precise 2D floor plan, or to convert it into a mesh for visualization. Since, in this particular buildings, it was not easy to see the force path, the point cloud of the laser scanner was very useful (Figures 14-16). Laser scanning has also proven to be a very useful tool for very complex geometries, both for heritage documentation and for easier navigation during post-processing to create 2D and 3D drawings. An added

value is also a 360° image for a specific location in the building. Figures 17 to 19 show the case study of the Zagreb Cathedral.

5 CONCLUSIONS

In this paper, a brief overview of damage to timber structural members after a moderate earthquake is presented. Basic statistical data on damage to roof structures after the Zagreb earthquake show the good behavior of timber roofs and give us an idea of why some of the roof structures collapsed.

When repairing roof structures, in most cases worn elements are replaced, elements with insufficient load-bearing capacity are strengthened and cracked elements are filled. During retrofitting, the influence of spatial stability of the roof structure is often forgotten, especially when spatial changes are made. The structural system

https://doi.org/10.52202/069179-0523

recognition and proper evaluation of former is also often miscarried. Unusual hybrid roof structures also add to the complexity of properly analysing and choosing the correct repair strategy. The influence of secondary elements such as chimneys and gables is also forgotten when the roof plays a stabilizing role in earthquake actions. In addition, the issue of details is questionable. The condition of the carpentry details is usually taken as given without considering the possibility that the distribution of forces in the system may change during lateral actions. In order to ensure the correct type of repair, it is important to have appropriate and high quality data on the condition of the structure and to use it for more detailed analysis so use of modern technologies is welcome. In this paper several benefits of laser scanners and UAVs is very briefly presented on two case studies.

EVALUATION OF VIBRATION CHARACTERISTICS OF EXISTING TIMBER ARCHITECTURE BY MICROTREMOR MEASUREMENT -EXAMINATION WHEN IT IS DIFFICULT TO INSTALL AN ACCELEROMETER IN THE ATTIC-

Hiroki Yoshinuma[1], Yuya Takaiwa[2]

ABSTRACT: In this paper, we investigate a method of understanding the natural frequency characteristics of existing two-story timber architecture by installing an accelerometer on the floor of the second floor and conducting microtremor measurement under the condition that an accelerometer cannot be installed in the attic. First, by surveying the trend of Registered Tangible Cultural Properties by the Agency for Cultural Affairs in Japan, we found that the architecture that needs seismic diagnosis in the future is two-story timber houses that are more than 50 years old. Next, we conducted a structural performance survey of existing timber architecture under the same conditions, using microtremor measurement and human excitation, and finite element analysis after the survey, and clarified the natural frequency characteristics of existing timber architecture by comprehensively judging the survey results.

KEYWORDS: Microtremor Measurement, Natural Frequency Characteristics, Seismic Diagnosis

1 INTRODUCTION

In Japan, the Law for the Protection of Cultural Properties was enacted in 1950 to protect and utilize architecture, paintings, sculptures, handicrafts, calligraphic works, classics, ancient documents, and other tangible cultural properties of high historical and artistic value, and to improve culture. In Japan, where earthquakes occur frequently, it is necessary to accurately understand the structural performance of old architecture and to reinforce it appropriately to utilize it. In 1996, the Agency for Cultural Affairs promulgated the "Guidelines for Ensuring Earthquake Safety of Cultural Property Buildings, etc." [1] to promote seismic retrofitting without compromising the cultural value of architectures. In this context, as a nondestructive seismic diagnosis method for architectures, microtremor measurement is utilized to grasp the structural characteristics of architecture on a global scale by installing highly sensitive accelerometers in the structure of the architecture to be investigated [2,3]. At present, earthquake-resistant diagnosis is steadily underway, and according to a survey on the current status of earthquake-resistant measures for national treasures and important cultural properties [4] conducted by the Agency for Cultural Affairs in 2019, 95% of national treasures and important cultural properties have been reinforced against earthquakes or measures have been taken to ensure the safety of users.

On the other hand, the Law for the Protection of Cultural Properties was revised in 1996 to introduce a system of registration of cultural properties to preserve more architectures with cultural value. Compared to national treasures and important cultural properties, the regulations of the cultural property protection system are less stringent, so registration is easier and the architectures are often small in scale. Nondestructive seismic diagnosis using microtremor measurement is desirable for such small architectures. However, most of the architectures, such as national treasures and important cultural properties, are relatively medium to large, and the accelerometers used for microtremor measurement were installed at any position by the investigator in the attic. However, in small architectures, it is difficult for the investigator to install the accelerometer at any position in the attic because the attic space is small and the cross-sectional dimensions of the components are small.

This study investigates a method to determine the natural frequency characteristics of an existing two-story timber architecture by installing an accelerometer on the floor of the second floor and conducting microtremor measurements under conditions where an accelerometer cannot be installed in the attic.

2 Structural Performance Survey of Existing Architectures

Registered Tangible Cultural Properties provide a modest measure of protection against the loss of cultural heritage from the modern era due to rapid national and urban development in recent years. Compared to the recognition of National Treasures and Important Cultural Properties, the examination required for approval is less stringent, and the regulations for maintenance and management after recognition are also less stringent, making it easier to apply for protection.

2.1 Current Status of Registered Tangible Cultural Properties

Fig. 1 shows the changes in the number of registered tangible cultural properties during the period 1996 to 2021. In 1996, when the system of registered tangible cultural properties was established, 83 items were registered, and the number of registered items has been increasing every year since then, reaching 12,7740 items in 2021. From the change in the number of registered items shown in fig. 1, it can be seen that the trend of increase has been constant since the system was introduced, and is expected to continue to increase in the future.

In Fig. 2, we show a breakdown of the registered tangible cultural properties by year of completion as of 2022. From Fig. 2, it can be confirmed that the number of registered buildings is dominated by young architecture. The largest proportion of the registered architectures is from 1900 to 1950. The reason why the number of registered architectures between 1950 and 2000, which are the youngest in fig. 2, is small is that the number of architectures that meet the condition of "more than 50 years old" is generally small. More time is needed before the value of architectures from this period will be recognized as having cultural value worthy of preservation, and as time passes, the number of registrations will increase, as it has for architectures from other periods, and they will become the element that accounts for the largest percentage in the future.

Fig. 3 shows the registered uses of architecture for each age group, with the lowest percentage of "House" registered for architecture built before 1600 to 1750, and similar percentages for other uses. For architecture built between 1750 and 1800, "House" accounted for the largest percentage of registrations, followed by "Industries". For architecture built between 1950 and 2000, the percentage of "House" is smaller again. In the case of buildings built between 1950 and 2000, the share of "House" is again small. This is thought to be because the number of houses with cultural value is small in younger architecture. In other words, the ratio of the use of architecture in this age group is expected to change in the future.

Fig. 4 shows the number of floors of houses certified as registered tangible cultural properties. Fig. 4 shows that most of the houses of any age are "One story" or "Two-story". The ratio of "One story" houses is higher in older houses and the ratio of "Two-story" houses is higher as the age of the houses decreases. This trend is consistent with the history of multi-story houses in Japan due to modernization. However, we cannot discuss the trend of houses built between 1950 and 2000 because the number of registered houses is small at this stage.

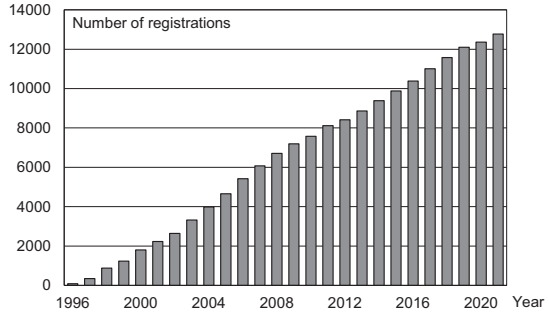

Fig. 1 *Number of registered tangible cultural properties*

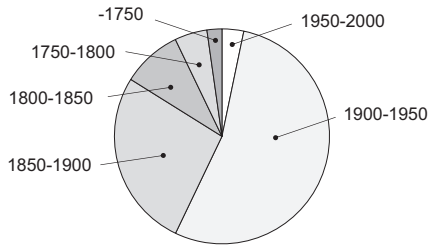

Fig. 2 *Breakdown of registered tangible cultural properties by year of completion*

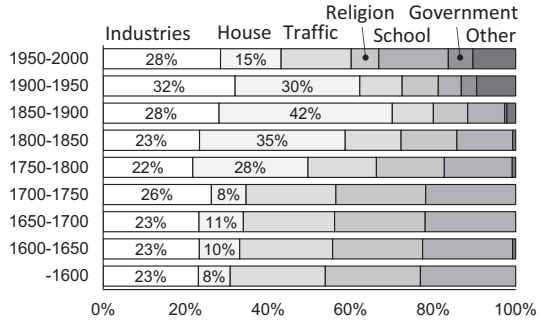

Fig. 3 *Architecture use*

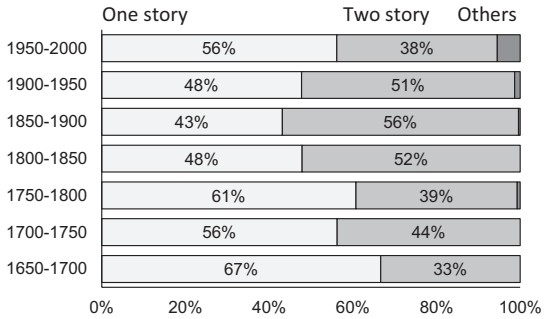

Fig. 4 *Number of Floors in Residential Architectures*

A survey of the trends in architectures recognized as registered tangible cultural properties revealed the following:

https://doi.org/10.52202/069179-0524

1. The number of registered architectures is increasing year by year.
2. The number of registered architectures that are young is high.
3. The number of registered architectures for housing use is high.
4. More two-story houses are registered.

Considering the above, a structural performance survey will be conducted for existing timber structures that are more than 50 years old and have a traditional building composition. In the survey, microtremor measurement will be carried out to understand the natural frequency characteristics of the housing scale structure.

2.2 Overview of the surveyed architectures

The architecture to be surveyed is an existing timber architecture in Taito-Ku, Tokyo. Built-in 1954, the architecture consists of four dwelling units surrounding a courtyard on the east side and another large dwelling unit on the west side. The architecture is located on the north side of the site, with a garden on the south side. Most of the architecture is one-story, and only the central part of the building is two-story. In the structural survey of the architecture, the area including the two-story part was chosen as the survey area.

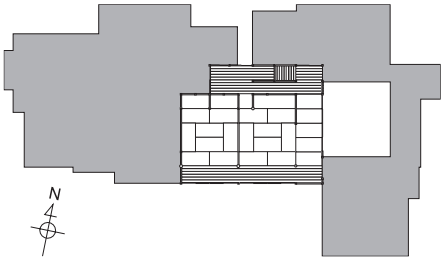

Fig. 5 *Scope of investigation*

Fig. 5 shows the survey area of the architecture. The horizontal force-resisting elements of the architecture are the full-wall and hanging walls, which consist of earthen walls, and the plank walls, which consist of three layers of small wide boards. The earthen walls have been in place since the construction of the architecture was completed, and the plank walls were replaced by earthen walls to improve the resistance of the architecture to seismic forces. The walls on the east and south sides of the survey area do not have any walls on all sides so that the view of the courtyard and garden can be seen from inside, and most of the bearing elements are hanging walls. On the other hand, the west and north sides of the architecture have many full-face walls as corridors and room boundaries.

In past earthquakes, one of the reasons for the collapse of timber architectures was the uneven distribution of load-bearing elements such as this architecture [5,6]. The uneven distribution of bearing elements has been observed in many existing architectures built before the establishment of seismic performance evaluation [7]. If the load-bearing elements are unevenly distributed, the architecture will exhibit twisting behavior during an earthquake, and the entire building will collapse in a twisting manner due to large deformation and destruction of the surface with few load-bearing elements (the surface facing the courtyard and garden in the present building).

2.2.1 Outline of the microtremor measurement

In the survey, multi-point simultaneous measurement using a total of six 3-axis wireless accelerometers is performed. Photo 1 shows the measurement system. Fig. 6, 7, and 8 show the installation locations of the accelerometers. The coordinate axes shown in the figures are the three-axis coordinates of the accelerometers, and the direction shown in the figures was chosen based on the installation conditions of the accelerometers. The measured acceleration waveforms were subjected to fast Fourier transform (FFT) to obtain the natural frequency from the transfer function. The input data of the transfer function is measured from one accelerometer installed in the garden, and the output data is measured from five accelerometers installed on the floor of the second floor.

Photo 1 *Measurement system*

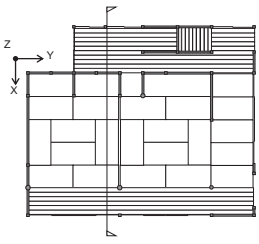

Fig. 6 *First floor plan*

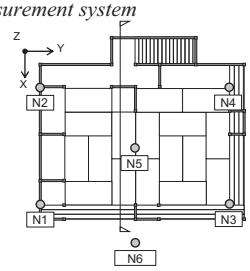

Fig. 7 *Second floor plan*

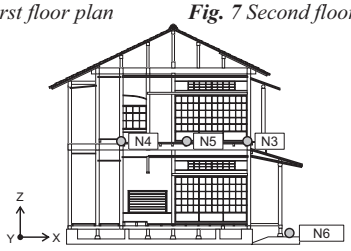

Fig. 8 *Cross-sectional view*

The sampling frequency of the measurement was set to 100 Hz so that the analysis frequency range would be 50 Hz, taking into consideration the fact that the main natural frequency of timber architectures is around 15 Hz at maximum and that the effect of aliasing caused by FFT should be eliminated. The measurement time is 360 seconds to accommodate a maximum FFT frame size of 32,768 points. When the FFT is performed on data with a sampling frequency of 100 Hz and a frame size of 32,768 points, the frequency resolution is approximately 0.00305 Hz, which enables analysis with fine precision. The FFT converts the sampled discontinuous microtremor waveform into a continuous waveform by using a window

https://doi.org/10.52202/069179-0524

function. The window function used is the Hanning window, considering that the microtremor is a continuous oscillation and that it can be analyzed with high-frequency resolution.

2.2.2 Human-powered excitation

An accelerometer was installed in the area to be investigated, and free vibration was induced by human force excitation. The natural frequencies are determined by the FFT of the acceleration data. Since the acceleration measurement is limited to the time when the vibration generated by human force excitation continues, the frame size for FFT is 1,024 points, which can be measured in about 10 seconds. As a result, the frequency resolution is inferior to that of FFT using a frame size of 32,768 points for constant microtremor measurement. Fig. 9 shows the direction of human-powered excitation, and Fig. 10 shows the locations of the accelerometers.

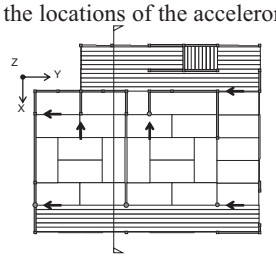

Fig. 9 *Direction of vibration*

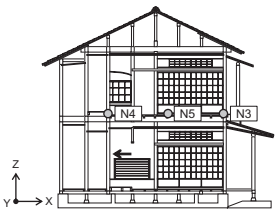

Fig. 10 *Installation location*

The locations of the accelerometers are the same as those used in the microtremor measurement, but accelerometer N6, which was installed in the garden in the microtremor measurement, is not used because the input vibration from the ground to the building does not need to be considered in the human force excitation measurement.

We decided to push the columns on the first floor so that the second mode, in which the horizontal movement of the second-floor floor dominates, would appear in the human power excitation. Some of the columns where the accelerometers were installed had walls attached to them, and such columns could not be physically pushed. Therefore, two pillars were pushed in the X-axis direction, and the pillars around N2 and the pillars directly below N1, N3 and N4 were pushed in the Y-axis direction. The pillars were chosen symmetrically in the direction of vibration to prevent artificial twisting due to excitation.

3 Results of various measurements

3.1 Results of normal microtremor measurement

The Fourier spectrum was obtained by FFT using the Hanning window as the window function for the acceleration data observed from the microtremor measurement. Next, the transfer function is obtained using the input waveform of accelerometer N6 installed in the garden and the output waveform of the other five accelerometers N1 to N5. The natural frequency of the architecture is determined to be the frequency at which the transfer function is dominant.

Fig. 11 and 12 show the frequency-transfer function relationship in the x-axis and y-axis directions. From the waveform, multiple excitations can be confirmed. This is probably because there are several architectures attached to the surveyed area, and the natural frequencies of these architectures were observed simultaneously. It is difficult to grasp the natural frequency of the surveyed area from this waveform alone.

From the graph in the X-axis direction, it can be confirmed that the waveforms of the combinations of N1 and N2 and N3 and N4 are identical. These combinations are located on a common beam in the X-axis direction. Next, from the graph in the Y-axis direction, it can be confirmed that the waveforms are identical for the combinations of N1 and N3, and N2 and N4. This combination is installed on a common beam in the Y-axis direction. The waveforms of the combinations of measuring points in each axis direction are identical, and the waveforms of the combinations of measuring points parallel to each axis are different, indicating that the shear deformation is caused by the low in-plane shear stiffness of the horizontal structure.

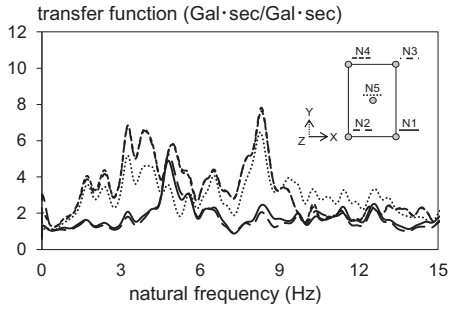

Fig. 11 *X-axis frequency-transfer function relationship*

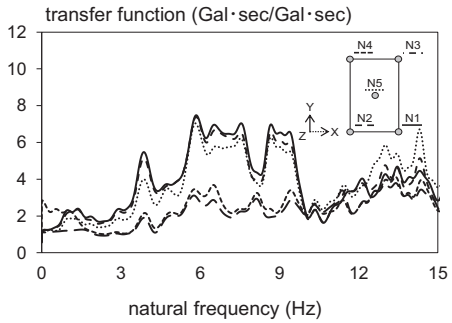

Fig. 12 *Y-axis frequency-transfer function relationship*

3.2 Results of Normal Microtremor Measurement and Manpower Excitation

In this survey, the natural frequency of the surveyed area could not be determined because multiple excitations were observed only by microtremor measurement. Therefore, the natural frequency was determined by combining the results of microtremor measurement with the results of free vibration by human power excitation. Fig. 13 and 14 show the results of constant microtremor measurement and free vibration in the X- and Y-axis directions. From the measurement results, it can be confirmed that there is a frequency that is dominant in the constant microtremor measurement but not in the free

https://doi.org/10.52202/069179-0524

vibration. This frequency is considered to be the natural frequency of the architecture in the range where no vibration is applied (outside the survey area) or the natural frequency of the first mode in the survey area. Therefore, the natural frequency of the second mode of the surveyed area is judged to be the frequency that shows excellence in both microtremor measurement and free vibration. From the measurement results, the natural frequency of the second mode in the investigated range is 3.26 Hz in the X-axis direction and 3.88 Hz in the Y-axis direction.

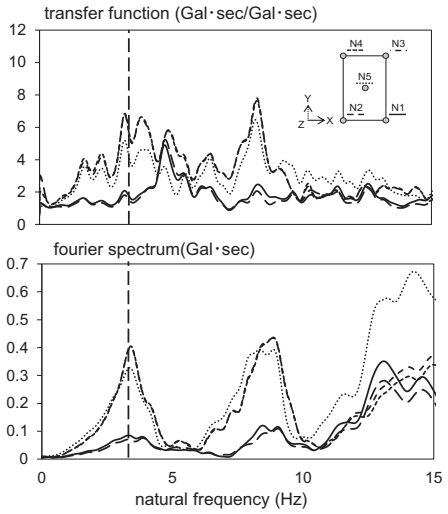

Fig. 13 *X-axis vibration*

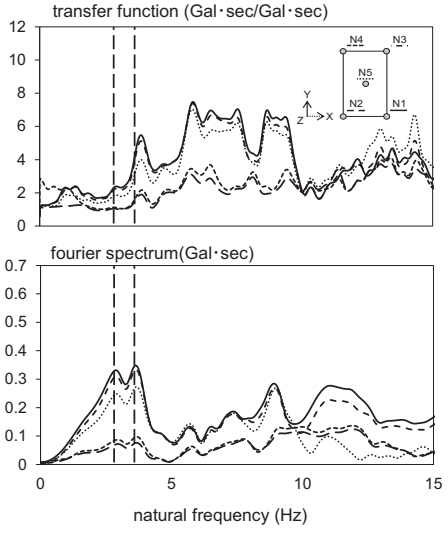

Fig. 14 *Y-axis vibration*

Fig. 15 shows the vibration modes at the dominant natural frequency. The vibration modes at 3.26 Hz and 3.88 Hz are the same, although the frequencies are different. From the vibration modes in the X-axis direction, it can be confirmed that the amplitudes of N1 and N2 are small, and those of N3 and N4 are large because the amplitudes of N1 and N2 are small due to the wall dividing the room. On the other hand, the amplitude of N3 and N4 is larger because they are adjacent to the courtyard and there is nothing to disturb the vibration. The amplitudes of N2 and N4 are small, and those of N1 and N3 are large because the walls of the corridor are placed on the N2 and N4 sides, which restricts the vibration. On the other hand, the amplitude of N1 and N3 is larger because they face the garden and there is no wall to disturb the vibration.

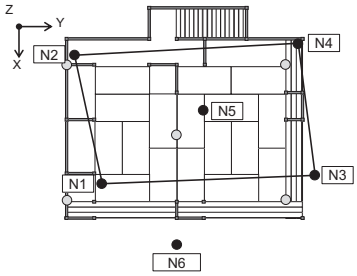

Fig. 15 *Vibration modes (3.26 Hz and 3.88 Hz)*

4 Finite element analysis

Fig. 16 shows an overview of the model. The columns and beams are "beam elements", and the walls are "braced elements". All joints are pin joints because rotational rigidity is not expected. The cross-sectional dimensions of each member were measured in the structural survey, and the column cross-sectional dimensions were approximately 105 mm square. The columns are made of cedar with a bending Young's modulus of 7 kN/mm2 and a density of 380 kg/m3, and the beams are made of cypress with a bending Young's modulus of 9 kN/mm2 and a density of 380 kg/m3 [8,9]. The stiffness of the earthen wall is based on the specific deformation angle of 1/250 rad by the Agency for Cultural Affairs [10]. The in-plane shear stiffness of the wall in the micro-deformation region observed by microtremor measurement is approximately three times the specified deformation angle [6], which is determined by the in-plane shear test. Since the purpose of the present finite element analysis is to determine the natural frequency in the small deformation region, the in-plane shear stiffness of the wall is set to be three times the stiffness at the specified deformation angle of 1/250 rad. The weight of the roof is 1250 N/m2 for a pier-tile roof and 100 N/m2 for a pole-vaulted ceiling [8].

Fig. 16 *Model overview*

4.1 Analysis results

Figs. 17, 19, and 23 show the natural frequencies and vibration modes of the finite element analysis model, and Figs. 18, 20, and 24 show the natural frequencies and vibration modes of the microtremor measurement results corresponding to the analysis model. Figs. 18, 20, and 24 show the natural frequencies of the finite element analysis

https://doi.org/10.52202/069179-0524

results and the microtremor measurement results in parentheses.

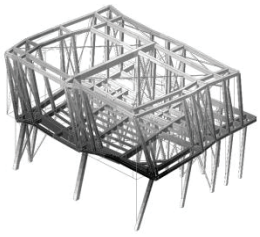

Fig. 17 *Eigen vibration mode (3.64 Hz)*

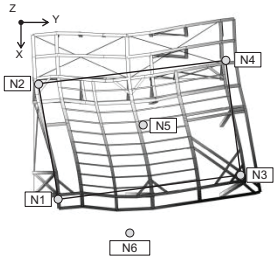

Fig. 18 *Natural modes of vibration (3.64Hz/3.26Hz)*

From the vibration mode of 3.64 Hz in the finite element analysis shown in Fig. 17, it can be confirmed that this is the second mode of architecture because only the floor of the second floor deforms horizontally. From the natural vibration mode shown in Fig. 18, it can be seen that the 3.64 Hz vibration mode of the finite element analysis and the 3.26 Hz vibration mode of the microtremor measurement coincide. This indicates that the dominant natural frequency of 3.26 Hz observed by human power excitation and microtremor measurement is the natural frequency of the second mode of the architecture, and confirms that the analytical model is correctly modeled.

The first modes of the eigenvalue analysis of the same model are shown below.

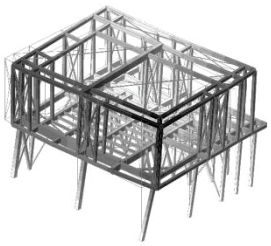

Fig. 19 *Eigenmode (0.91Hz)*

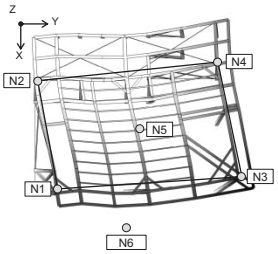

Fig. 20 Eigenmode (0.91Hz/1.05Hz)

From the vibration mode of 0.91 Hz in the finite element analysis shown in Fig. 19, it can be confirmed that 0.91 Hz is the natural frequency indicating the first mode of the architecture because the horizontal deformation of the entire second floor is large. Since the second floor has more walls than the first floor, the deformation of the first floor is dominant in the overall behavior, while the second floor behaves like a rigid body with little deformation. From the natural vibration modes shown in Fig. 20, it can be confirmed that the amplitude of N2 and N4 is small, while that of N1 and N3 is large. This is because the walls of the corridor restrain the vibration of N2 and N4, but there are no walls to restrain the vibration of N1 and N3 facing the edge.

Fig. 21 and 22 show the frequency-transfer function relationship in the X- and Y-axis directions. The natural frequency of the first mode of 0.91 Hz revealed by the eigenvalue analysis corresponds to the measured value of 0.98 Hz in the Y-axis direction, and there is no dominant value close to 0.91 Hz in the X-axis direction. In the finite element analysis, the horizontal displacement in the Y-axis direction is dominant, which confirms the validity of the observed waveforms in the X- and Y-axis directions.

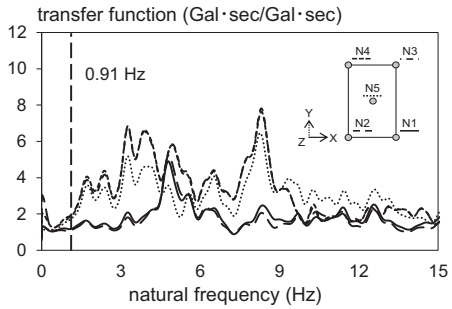

Fig. 21 *Relationship between frequency and transfer function in X-axis direction*

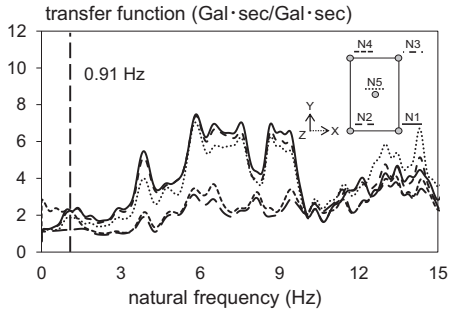

Fig. 22 *Y-axis frequency-transfer function relationship*

Among the results of the microtremor measurement where multiple excitations were observed, the excitation of the natural frequency of the first mode in the Y-axis direction was about 36% larger than that of the other frequencies, which would normally be ignored. In addition, despite the first mode, only N1 and N3 are dominant in the graph due to the difference in the amount of deformation of N1 and N3 and N2 and N4 caused by the uneven distribution of the wall, while N2 and N4 are not dominant. It is difficult to conclude that 0.98Hz is the natural frequency of the first mode under normal circumstances.

Fig. 23 *Eigenmode (1.68Hz)*

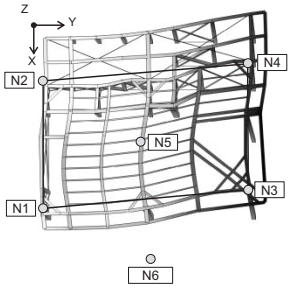

Fig. 24 *Eigenmode (1.68Hz/1.72Hz)*

Fig. 23 shows that the entire second floor deforms horizontally in the X-axis direction in the vibration mode of 1.68 Hz based on finite element analysis, indicating that 1.68 Hz is the natural frequency of the first mode of the architecture. The amplitudes of N1 and N2 are small, and those of N3 and N4 are large, according to the vibration modes in Fig. 24. This is because the vibration of N1 and

https://doi.org/10.52202/069179-0524

N2 is constrained by the wall dividing the room, but there is no wall to constrain the vibration of N3 and N4 facing the courtyard. Figs. 25 and 26 show the frequency-transfer function relationship in the x- and y-axis directions. The natural frequency of the first mode, 1.68 Hz, which was revealed by the eigenvalue analysis, corresponds to 1.72 Hz in the X-axis direction, and there is no dominant value close to 1.68 Hz in the Y-axis direction.

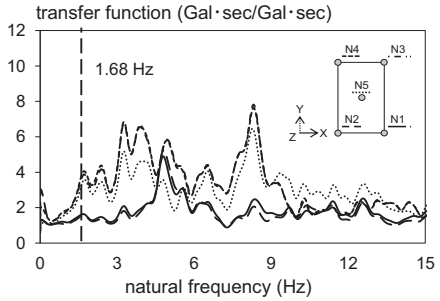

Fig. 25 *X-axis frequency-transfer function relationship*

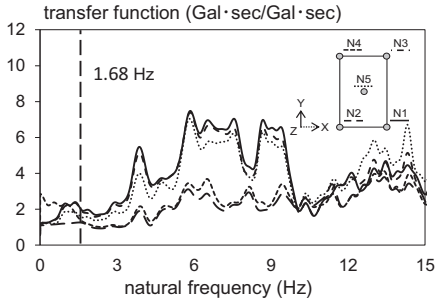

Since the horizontal displacement in the X-axis direction is dominant from the vibration modes of the finite element analysis, the validity of the observed waveforms in the X- and Y-axis directions can be confirmed. Among the results of the microtremor measurement where multiple excitations were observed, multiple excitations were observed near the natural frequency of the first mode in the X-axis direction, and it is difficult to determine the natural frequency only from the results of the microtremor measurement. In addition, only N3 and N4 show the predominance in the graph due to the difference in the amount of deformation of N1 and N2 and N3 and N4 caused by the uneven distribution of the wall, while N1 and N2 do not show any predominance. It is difficult to determine that 1.68 Hz is the natural frequency of the first mode under normal circumstances.

5 CONCLUSIONS

In Japan, the Law for the Protection of Cultural Properties was enacted to preserve the cultural value of historical architecture, and seismic diagnosis for national treasures and important cultural properties has been developed. However, there is no progress in the development of seismic diagnosis methods for registered tangible cultural properties, which are newly subject to preservation under the revised Law for the Protection of Cultural Properties. In this study, the following findings were obtained by conducting a structural survey of historical timber architecture with specifications similar to those of registered tangible cultural properties:

1. By analyzing the data on registered tangible cultural properties published by the Agency for Cultural Affairs, we found that the number of architectures of registered tangible cultural properties is large, and that two-story architecture accounts for half of the total.
2. By conducting microtremor measurement on the existing architecture, we observed multiple excitations of the architectures.
3. The dominant natural frequencies of the second modes were determined by analyzing the resonant frequencies of human power excitation on the first floor of the building.
4. The model was modeled by finite element analysis, and the correctness of the model was confirmed by using the natural frequencies of the second modes observed by microtremor measurement.
5. The natural frequencies of the first modes were determined using the analytical model whose correctness was confirmed, and by comparing them with the measurement results of the microtremor measurement, a slight predominance was confirmed, and the vibration mode was confirmed to be the first mode.

To understand the natural frequency characteristics of existing architecture, it was necessary to consider the results of three methods: microtremor measurement, human power excitation, and finite element analysis.

In this study, we have dealt with only one case of a structural survey, but there are various measurement environments for microtremor measurement, and it is necessary to develop seismic diagnosis methods that can cope with various measurement environments in the future.

DEVELOPMENT OF SIMPLE REPAIRING HARDWARE FOR DAMAGED ENDS OF WOODEN BEARING WALLS

Wataru Kambe[1]

ABSTRACT: This study investigated the repairing effect for wooden bearing walls (which wall length was 910 or 1820mm) which are repaired by developed hardware. The study found that the repair was effective in increasing the maximum load and energy by more than 100% and 120%, respectively, but not very effective in increasing stiffness, which was often less than half. Additionally, the structural performance of the load-bearing walls with only the repair hardware was found to be equivalent to that with only the joint hardware, suggesting that these performances contribute to the overall structural performance of the repaired specimens.

KEYWORDS: Bearing wall, Repairing hardware for brace-ends, Structural performance

1 INTRODUCTION

This study examines repair methods for braces in wooden bearing walls, specifically in the case of horizontal forces acting on bearing walls due to earthquakes or other causes. Conventional frame construction is the most common type of wooden house construction in Japan and in case of an earthquake, an emergency hazard assessment is made to evaluate the need for repair or reinforcement [1](***Fig. 1***). Repair techniques are used to restore the structural performance of damaged buildings to its pre-damage state, and reinforcement techniques are used to make it higher than the pre-damage state.

This study proposes a new steel hardware repair method, which is simple enough to be installed by DIY hobbyists using tools such as impact wrenches. The study aims to investigate the effect of this repair hardware on the structural performance of 1P and 2P wall-length, bearing walls under monotonic and cyclic loading. The repair hardware will be installed after a horizontal force test, and the structural performance will be compared before and after the repair. Additionally, a separate test will be conducted on a load-bearing wall with only the repair hardware installed to determine the basic structural performance when the repair hardware is used.

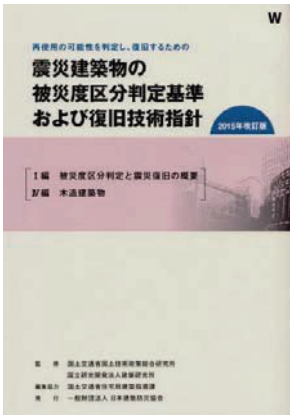

Figure 1: *Documentation*

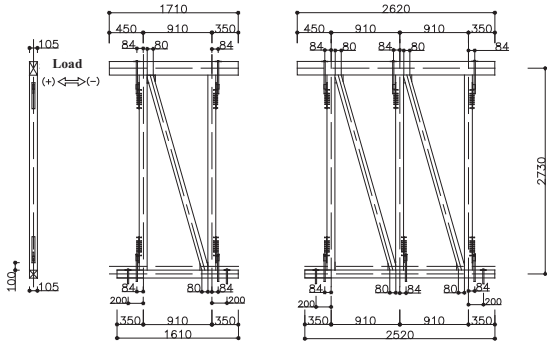

Figure 2: *Geometry of specimens(Unit:mm)*

2 SPECIMENS AND REPAIRING HARDWARE

2.1 SPECIMENS

In this study, horizontal load tests on 1P or 2P wall-length (indicated in ***Fig. 2***) with single-brace which were made of laminated veneer laminate (LVL) were conducted. The species of the LVL members was larch, grade 100E-1 (graded in Japan Agricultural Standard [2]), and the cross-sectional dimensions were 45 x 90 mm. The foundation, columns, and beams were made of laminated timbers of different grade compositions, grade E105-F300 (graded in

[1] Wataru Kambe, Kanto Gakuin Univeristy,Japan, wkambe@kanto-gakuin.ac.jp

https://doi.org/10.52202/069179-0525

Japan Agricultural Standard [3]) with cross-sectional dimensions of 105 x 105 mm for the foundation and columns, and 105 x 180 mm for the beams. The hardware used for the column legs was the screw-fastening type for Hold-down U 35 kN and "Justy Gusset Lite" were used for the joint hardware at the end of the brace. Monotonic and cyclic forces were applied to the specimens before and after repair. A total of 8 bearing walls were prepared, 4 of which were repaired, and 12 force tests were conducted indicated in ***Table 1***.

Table 1: *Specimens and test parameter*

Specimen	Wall length [mm]	Loading types	Type of joint in 1st test	Type of joint in 2nd test
A	910	Monotonic	Ordinally hard ware	Ordinally hardware + repair hardware
A-re				
B		Cyclic		
B-re				
C	1820	Monotonic		
C-re				
D		Cyclic		
D-re				
r-A	910	Monotonic	Only repair hardware	none
r-B		Cyclic		
r-C	1820	Monotonic		
r-D		Cyclic		

2.2 PAIRING HARDWARE

The repair hardware used in this study was a prototype developed in a previous study [4]. The shape of the repair hardware is shown in ***Fig. 3*** and ***4***, and it is larger than the joint hardware used in the study, with approximate dimensions of thickness t=1.6 mm, 200 x 120 x 55 mm. The screw holes are placed outside the edge of the joint hardware, allowing the repair hardware to be placed over the joint hardware and fastened with screws. The thickness of the steel plates of the joint hardware and the repair hardware are the same. The study used CPQ-45 screws to fasten four screws to the foundation and beams, six screws to the columns, and seven screws to the fascia side. Only one type of screw was used for the repair hardware to simplify the repair process.

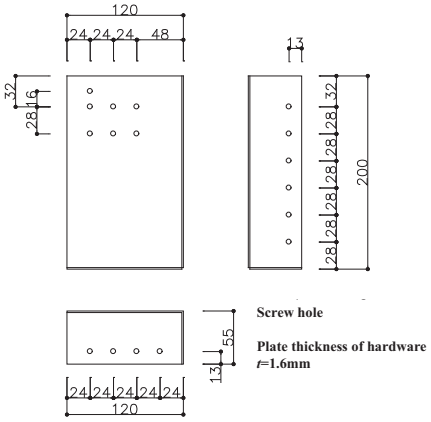

Figure 3: *Repair hardware*

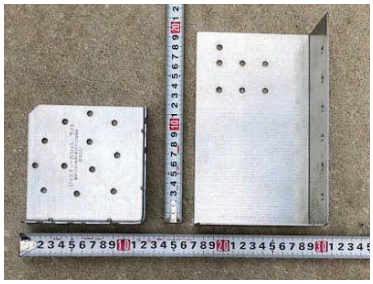

Figure 4: *Repair hardware*

2.3 REPAIR PROCESSING

This statement suggests that the study includes both a description of a test procedure and an installation procedure for reinforcement hardware in load-bearing walls. The test procedure likely describes the method used to evaluate the effectiveness of the reinforcement hardware in load-bearing walls, while the installation procedure describes the steps necessary to properly install the hardware in load-bearing walls. The procedure begins by applying a horizontal force to a specimen that has joint hardware attached. After the test is completed, the specimen is pushed back by the testing machine until the column is at right angles. The fastened hardware is not removed, and repair hardware is fastened over the fastened hardware. The repaired load-bearing wall is then subjected to another horizontal force. The flow of this procedure is illustrated in ***Fig. 5***.

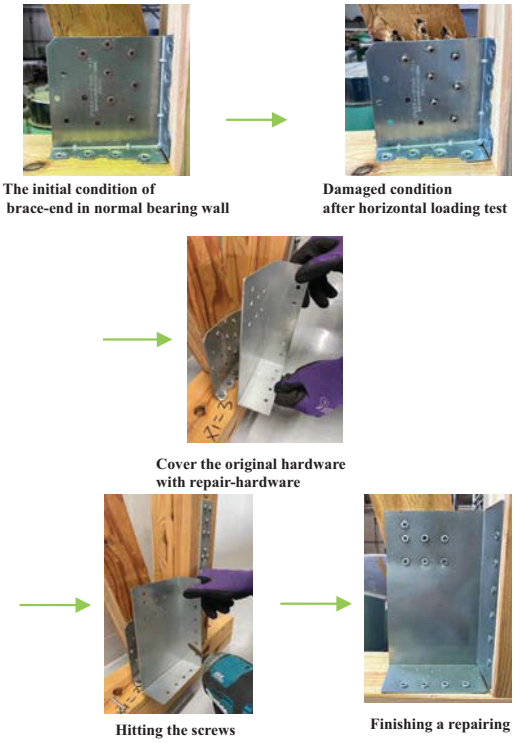

Figure 5: *Processing of tests and reinforcement of brace ends with hardware*

2.4 TEST METHODS

The test method in this study used a manual from the Japan Housing and Wood Technology Centre [5]. The

specimen was anchored to a foundation steel beam with anchor bolts and horizontal forces were applied to the top of the specimen with an oil jack. Loads were applied using load cells and displacement transducers were used to measure the displacement of the test top and foundation. The loads were applied by monotonic tensile and repetitive positive and negative forces and the test results were processed using "pickpoint" [6] to calculate the structural performance.

3 TEST RESULTS

3.1 DAMAGED CONDITIONS

The main failure conditions of the specimens are shown in ***Fig. 6-9*** and listed in ***Table 2***.

The study found that in the 1P and 2P specimens using joint hardware, the main failure type was the pulling-out of screws. This occurred when the screws fastened to the brace penetrated into the brace and subsequently pulled out. The degree of screw pull-out was greater at the outermost end of the brace-edge than at the end of the brace attached to the central column. However, no screws were pulled out at the foundation, beams or columns, and no bending deformation or other damage was observed in the hardware.

In the repaired specimens, deformation was observed in many of the repair hardware in both the 1P and 2P specimens. Additionally, cracks were observed in the fiber direction at the foundation, beams and columns, starting at the screw holes. In the 2P specimens, the degree of screw pull-out was greater on the foundation side where the repair hardware was fastened, particularly on the lower right-hand side of the specimen, compared to the fascia joint in the center of the specimen. The repair hardware fastened to the foundation, beams and columns showed screw pull-out, while the screws fastened to the fascia side did not show any pull-out.

The specimens that used repair hardware only showed deformation of the hardware and cracking similar to the specimens that underwent repair. The 2P specimens showed screw pull-out at the foundation, beams and columns, while the 1P specimens did not show any screw pull-out. The 2P specimens showed no screw pull-out at the foundation, beams and columns. However, the screws on the fascia did not pull out in both specimens. The only exception was the r-C specimen, where the deformation of the repair hardware at the joint in the middle of the specimen was greater than at the joint in the lower right-hand corner of the specimen. At the repair hardware joints, the hardware was deformed first, followed by damage around the screws.

The screws were found to be in good condition and had not undergone any bending deformations during those tests.

The study found that using joint hardware alone resulted in screw pull-out as the main type of damage, while the use of repair hardware resulted in a combination of screw pull-out and other types of damage. This could be misleading as it may suggest that repair hardware is more prone to damage. However, the study also found that when repair hardware was used, the deformation of the bearing walls was greater, resulting in greater deformation at the joints, which also caused other damage. Despite this, the study found that the use of repair hardware did not result in a reduction in bearing capacity, which is considered to be a useful aspect of the repair hardware.

The study found that when only joint hardware was used, the damage was more pronounced in the fascia, but when repair hardware was used, the damage was more pronounced in the foundations, columns and beams. This suggests that the resistance mechanism changed when repair hardware was used. However, it is possible that the repair hardware was not the only factor in this change, and that internal damage to the foundations, columns and beams may have also contributed to the change in the resistance mechanism.

3.2 LOAD-DISPLACEMENT RELATIONSHIPS

The load-deformation angle relationships for specimens with joint hardware and those with repair hardware only are shown in ***Fig. 10-13***.

The study found that when comparing the load-deformation relationship of specimens with joint hardware to those with repair hardware only, the specimens with only repair hardware tend to have a

https://doi.org/10.52202/069179-0525

smaller initial slope and behave differently in the initial phase of the applied force. After a period of stagnation, the load tends to rise again and the maximum load tends to reach the same level as the specimens with joint hardware. This behavior is likely due to plate buckling of the steel plate caused by the large unscrewed surface, and the transition to tensile deformation as the deformation progresses. This two-stage behavior is characteristic of the cases where this repair hardware is installed. The study found that the displacement at maximum load was clearly larger than that of the specimens with joint hardware, confirming that the hardware was designed to be a load-bearing wall with excellent deformation performance.

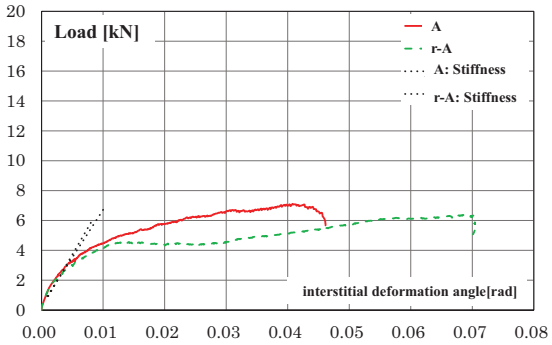

Figure 10: *Comparison with A and r-A(Load-angle)*

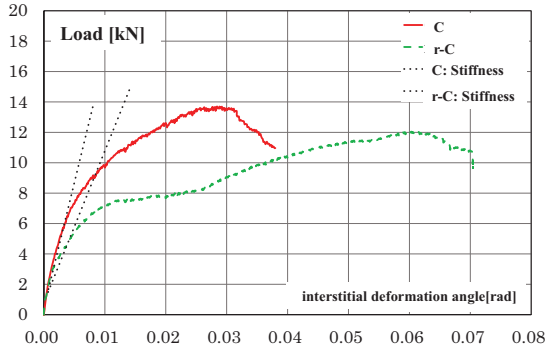

Figure 11: *Comparison with C and r-C(Load-angle)*

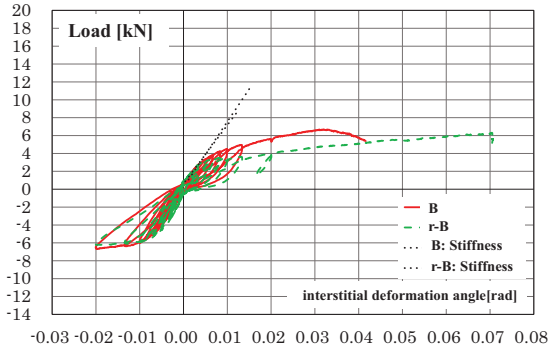

Figure 12: *Comparison with B and r-B(Load-angle)*

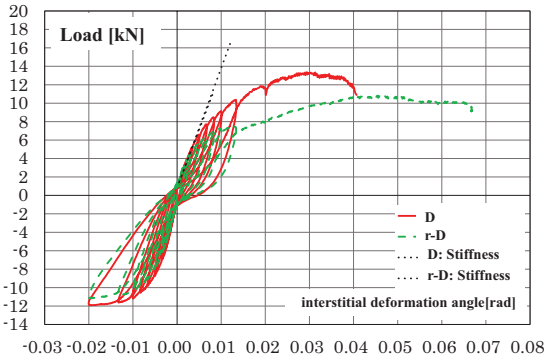

Fiure 13: *Comparison with D and r-D(Load-angle)*

The load-deformation angle relationships of the specimens with the joint hardware and after repair are then shown in ***Fig. 14-17***.

The study found that the initial stiffness of the specimens after repair tends to be smaller than before repair. This is likely due to the slightly smaller stiffness of the wall with only the repair hardware. However, the maximum load and displacement at maximum load of the specimens after repair were clearly larger than before repair. This suggests that the repair is effective in increasing the load-bearing capacity and deformation performance of the wall.

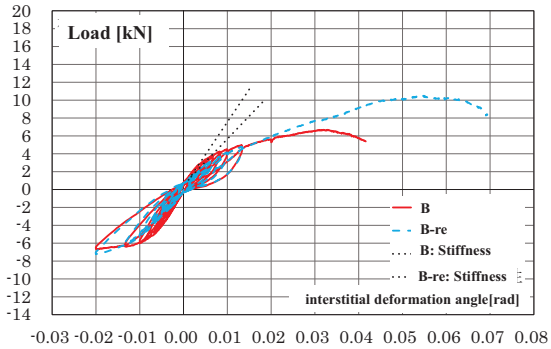

Figure 16: *Comparison with B and B-re(Load-angle)*

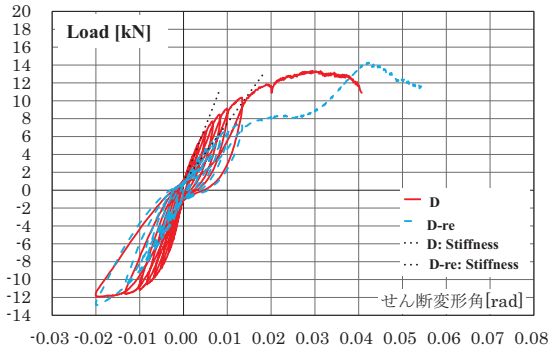

Figure 17: *Comparison with D and D-re(Load-angle)*

3.3 COMPARISON OF JOINTING HARDWARE AND REPAIR HARDWARE

The results using jointing and repair hardware are shown in ***Table 3*** and ***Fig. 18 -19***.

The study found that the maximum load on the specimens with repair hardware only was slightly lower than on the specimens with joint hardware, but the energy absorbed was higher. The ratio of the maximum load value of the repair hardware only divided by the value of the joint hardware was 89% for the r-A specimen, 94% for r-B, 88% for r-C and 80% for r-D. The ratio of energy absorbed was 136% for r-A, 153% for r-B, 158% for r-C and 138% for r-D.

The study found that the ratios of the load-bearing walls with repair hardware to those with joint hardware were more than 80% (88% on average) for maximum load, more than 60% (85% on average) for stiffness and more than 136% (146%) for energy. As shown in Figure 12, all were greater than the joining hardware with regard to energy, confirming that the effect was more akin to reinforcement than repair. Although the maximum load and stiffness values were not 100%, it was confirmed that the structural performance was at a level similar to that of a load-bearing wall with jointed metalwork. Based on these results, the study concludes that the repair hardware is considered to be effective in terms of repair for the joint hardware covered in this study.

Table 3*: Comparison of specimens with joint and repair hardware*

Specimen	Maximum load [kN]	Reparid/ Original	Stiffness [kN/mm]	Reparid/ Original	Energy [kN・mm]	Reparid/ Original
A	7.11	89.9%	0.26	88.5%	692.95	136.1%
r-A	6.39		0.23		943.09	
B	6.69	94.5%	0.27	88.9%	586.57	153.8%
r-B	6.32		0.24		902.28

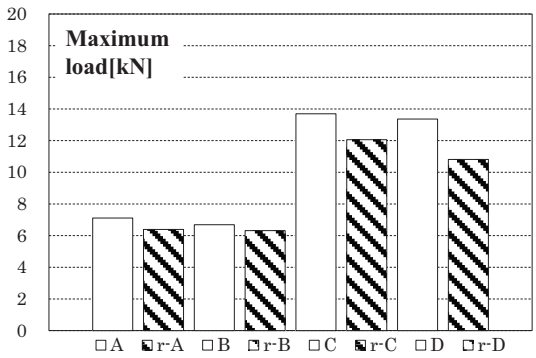

Figure 18: *Comparison of maximum loads on specimens with jointing hardware and reinforcing hardware*

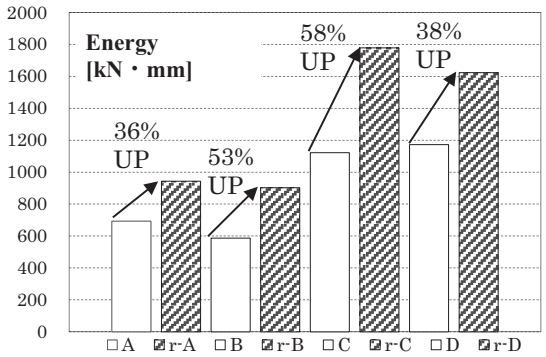

Figure 19: *Comparison of energy on specimens with jointing hardware and reinforcing hardware*

3.4 COMPARISON BEFORE AND AFTER REPAIR

Comparisons before and after repair are shown in ***Table 4***, maximum load comparisons in ***Fig. 20*** and energy comparisons in ***Fig. 21***.

The study found that compared to the specimens before repair, the specimens after repair had lower initial stiffness, but increased maximum load and energy. The ratio of the post-repaired value divided by the pre-repaired value for maximum load was 120% for the A-re specimens, 156% for the B-re, 136% for the C-re and 106% for the D-re. The energy ratios were 131% for the A-re specimens, 240% for the B-re, 173% for the C-re and 123% for the D-re. No trend was found within the scope of this study with respect to these repair effects for different wall lengths.

https://doi.org/10.52202/069179-0525

The study found that the use of repair hardware tends to increase the maximum load by more than 100% and the energy by more than 120%. Based on these results, it can be considered that repair hardware has a repair effect. However, it has been shown that the maximum load of those using only repair hardware is 85% of those using only joint hardware. It is believed that the joint hardware after damage also contributes to some extent, working in a combined manner and resulting in a higher maximum load. With regard to energy, the contribution of the repair hardware is considered to have been significant. In terms of stiffness, on the other hand, the results showed that there was no significant repair effect.

***Table 4**: Comparison of before and after repairing with hardware*

Specimen	Maximum load [kN]	Reparid/ Original	Stiffness [kN/mm]	Reparid/ Original	Energy [kN・mm]	Reparid/ Original
A	7.11	120.1%	0.26	38.5%	692.95	131.4%
A-re	8.54		0.10		910.37	
B	6.69	156.8%	0.27	44.4%	586.57	240.6%
B-re	10.49		0.12		1411.07	
C	13.70	136.6%	0.60	41.7%	1121.44	173.1%

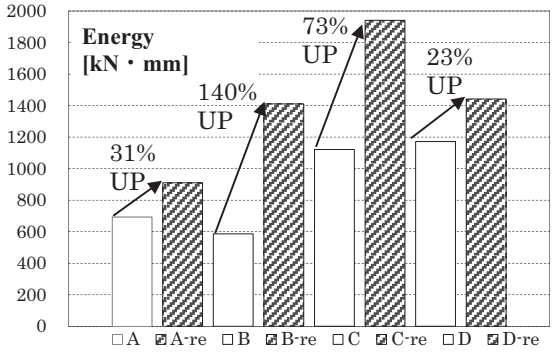

***Figure 21:** Comparison of energy on specimens before and after reinforcement*

4 CONCLUSION

The study investigated the effectiveness of repair hardware in reinforcing load-bearing walls that have undergone damage. The findings of the study are as follows:

1. The ratio of the structural performance of the repaired hardware alone to that of the joined hardware, the repaired hardware had values of around 88% for maximum load, 85% for stiffness and 146% for energy, confirming that the hardware is expected to be effective in repairing the damage.
2. The values obtained by dividing the post-repair by the pre-repair were more than 106% for maximum load and 123% for energy. It was confirmed that the repair was effective with regard to load capacity and deformation performance. However, with regard to stiffness, the repair effect was small. No influence of different wall lengths and application methods was found within the scope of this study with regard to these values.
3. The maximum load was considered to have been restored by the combined action of the damaged joint hardware and the repair hardware. The contribution of the repair hardware was considered to be the main contribution with regard to energy.
4. For stiffness, the effect was small. With regard to screw damage, the damage in the fascia was more pronounced in the case of the joint hardware only, whereas it was more pronounced in the foundation, columns and beams after the repair, suggesting that this difference in resistance mechanisms may have influenced the lack of increased stiffness.

In the current study, cyclic force tests were conducted incrementally. However, in recent years, research using more complex cyclic force tests such as fatigue tests has progressed [7],[8]. It is suggested that future research should examine this specimen using such force tests.

STUDY ON THE MECHANICAL PERFORMANCE OF MULTI-LAYERED BRACKET COMPLEX

Kohei Komatsu[1]

ABSTRACT: This document provides the experimental attempts for making sure the mechanical performance of the multi-layered bracket complex used on the upper parts of stone columns in a repaired ancient temple in China. Making model multi-layered test specimens having layer numbers from 1 to 5, a dynamic vibration test for evaluating the natural frequency and the damping factor was done. Further, using the same test specimens, a push-pull static cyclic loading test was done. It was a satisfactory result that the damping factor of the model multi-layered bracket complex was higher than the preliminary anticipation. Tentative nonlinear analyses using a commercial FEM program on the model multi-layered specimen, however, showed unsatisfactory prediction for the skeleton curves. A lot of further improvements are necessary to do a seismic FEM analysis of the real existing structure involving a multi-layered bracket complex.

KEYWORDS: Multi-layered bracket complex, Damping coefficient, Ancient temple in East Asia

1 INTRODUCTION

In a part of the existing *Kaiyuan* Temple *Tenno-den* (established in 979, largely repaired in 1980) in *Chaozhou* City, *Guangdong* Province, China, the upper part of the stone pillar is composed of the multi-layered bracket complex structure (Figure 1). This structure is a very rare structural form that can only be seen here even in China. This structure is quite motivating for such a researcher who is interested in the structural mechanism of ancient wooden architecture in East Asia. Why was such a multi-layered bracket complex structure adopted? The background and purpose of this research are to scientifically investigate even part of the reason.

Figure 1: *Multi-layered bracket complex structure in Kaiyuan Temple Tenno-den* (*Photo*:©*Kohei Komatsu*)

2 EXPERIMENTS

2.1 SPECIMEN DESIGN

To investigate the mechanical performance of the multi-layered bracket complex structure, a simplified model specimen was created to enable the moment distribution of the actual multi-layered structure shown on the left-hand side[1] of Figure 2 simulate.

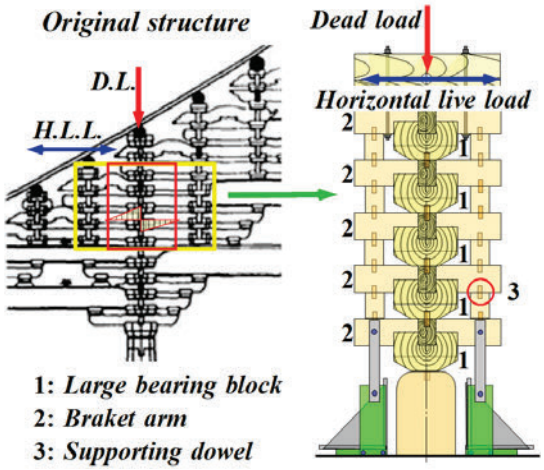

Figure 2: *Simplified model specimen for simulating a part of the actual multi-layered bracket complex structure*[1] *(Refer to Figure16 for the significance of the red-circled #3 dowel when subjected to a tensile force)*

In the yellow square area on the left-hand side of Figure 2, bracket arms are arranged on the large bearing brock

[1] Kohei Komatsu, RISH, Kyoto University, Japan
komatsu.kouhei.55z@st.kyoto-u.ac.jp

https://doi.org/10.52202/069179-0526

of each layer, and the rotation of the bracket arm is prevented by the vertical dead-load acting on the large bearing brock. This situation can be assumed to be a state in which an anti-symmetrical moment is generated in the bracket arm so as to balance the moment at the large bearing brock, and a zero-moment point in the bracket arm seems to exist around the middle of the two nodes. Therefore, a simplified model multi-layered bracket complex test specimen was proposed as shown in the right-hand side of Figure 2. In this model, the point of zero moment was simulated by setting a pin-joint at both ends of the bracket arm using a supporting wooden block fixed by a dowel.

2.2 KINDS OF MODEL SPECIMEN

To make clear the effect of the number of layers on the mechanical performance of the model specimen, five different kinds of specimens having one to five layers of the bracket complex as shown in Figure 3 were prepared.

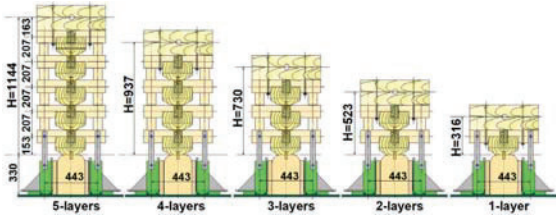

Figure 3: *Five different kinds of model specimens.*

2.3 DYNAMIC TEST SET-UP

To grasp the initial stiffness and damping factor of the model specimens, a sinusoidal sweep vibration test was first conducted by fixing a small exciter on the top of the model specimen as shown in Figure 4.
One accelerometer A_0 was fixed to the steel foundation and another A_1 was fixed to the center of the loading block to measure the response accelerations. At the same time, the horizontal displacement D_1 at the center point of the loading block and the horizontal displacement D_0 at the interface between the bottom of the lowest large bearing block and the column head were measured with displacement measuring devices.

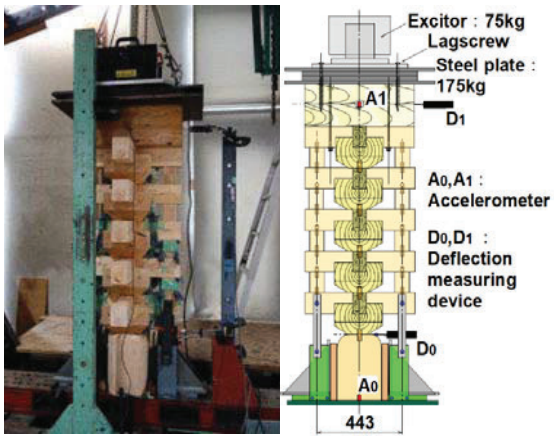

Figure 4: *Test set-up for the dynamic experiment*

The sinusoidal sweep tests were done by giving from 1Hz to 10Hz sin-wave step by step with 1Hz increment to detect the first rough resonance range then the fine sweep-out detections were done with 0.1Hz increment within the range of the first found-out rough region. For this dynamic test, a total of about 2.5 kN weight was loaded, including the weight of the exciter and the steel plates.

2.4 STATIC TEST SET-UP

After finishing the dynamic tests, the static push-pull cyclic horizontal loading tests were conducted using the same test specimens used for the dynamic test.
Figure 5 shows the static test set-up. The vertical dead load was applied on the top of the loading brock using a pulley and wire system which was pulled by an oil jack having 100kN capacity. While the horizontal load was applied at the geometrical center of the loading brock using an oil jack having 250kN capacity.
Horizontal loading protocol was first assigned so as to be set out as the following target values by the shear deformation angle (γ); γ= ±1/300, ±1/200, ±1/150, ±1/100, ±1/75, ±1/60, ±1/50, ±1/40, ±1/30, ±1/20 and ±1/15 rad. Actually, however, in many cases, as the #3 dowel shown in Figure 2 was pulled out when the shear deformation angle was beyond 1/20 rad, thus loading after 1/20 rad was cancelled in such cases. Within each ± target deformation angle, one cycle push-pull loading was given. For the dead load, two loading levels (5kN and 10kN) were adopted.

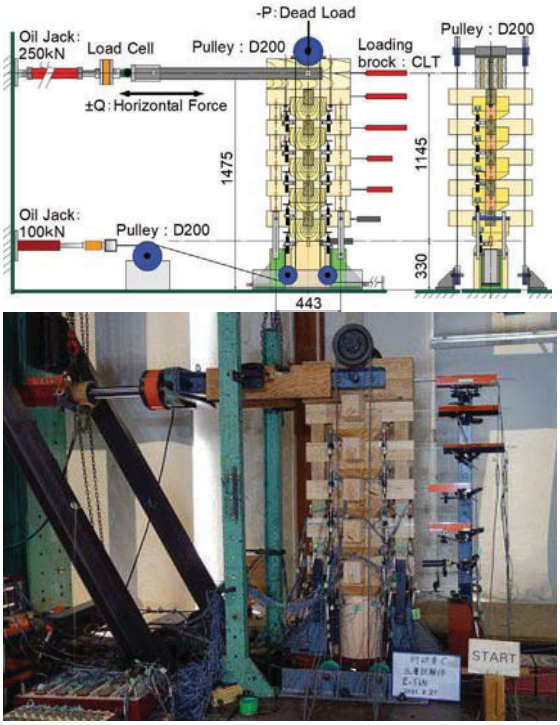

Figure 5: *Test set-up for the static experiment*

https://doi.org/10.52202/069179-0526

2.5 MATERIAL

The test material used was all high-quality solid wood of Japanese cypress (*Chamaecyparis obtusa*) which is preferably used for constructing traditional timber constructions in Japan. The moduli of elasticity of the materials (E0) were measured using an ultrasonic pulse velocity measuring device (PUNDIT-7) as shown in Figure 6. The moisture content was measured using a high-frequency capacitive moisture content meter (Kett HM-520). The result of the mechanical properties of materials is shown in Table 1.

Figure 6: *Measuring E0 using PUNDIT-7*

Table 1:*Mechanical properties of materials used*

	Large bearing brock			Bracket arm		
	ρ*1	MC	E0	ρ*1	MC	E0
	kg/m^3	%	kN/mm^2	kg/m^3	%	kN/mm^2
Mean	471.7	20.9	14.02	472.6	21.9	14.06

N	15	15	15	30	30	30

*1:Density
*2:Standard deviation based on the sample number N-1

2.6 ELEMENT TESTS

2.6.1 Dowel shear test

The shear performance of the wooden dowel (d=20mm, L=60mm) joint between the lowest large bearing block and the column head was evaluated by the experiment shown in Figure 7. For the dowel joints belonging to the upper layers than the lowest part, no dowel shear tests were done due to an incorrect judgment of the author.

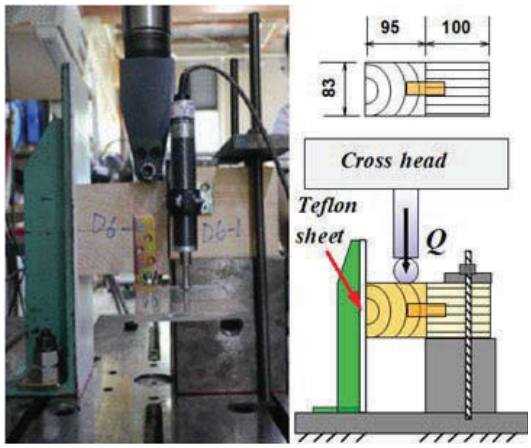

Figure 7: *Shear performance test of wooden dowel joint.*

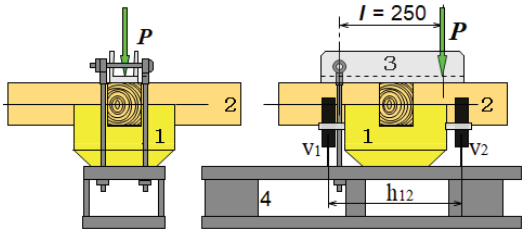
2.6.2 Moment-resisting test on the large bearing block

To evaluate the quantitative relationship between moment (M) and rotational angle (θ) of the large bearing block, a moment-resisting test shown in Figure 8 was preliminarily done in the elastic stress level using the large bearing blocks which are to be used for the multi-layered bracket complex test specimens.



1:Large bearing block (bottom size: 154×154mm)
2:Bracket arm (83×104×571mm)
3:U-shape steel jig
4:Steel base jig

Figure 8: *Moment-resisting test on large bearing block*

In this experiment, moment (M) and rotational angle (θ) were defined by equations (1) and (2).

$$M = P \times 0.25 \quad \text{(kNm)} \tag{1}$$

$$\theta = \frac{v_2 - v_1}{h_{12}} \tag{2}$$

2.6.3 Compressive strength perpendicular to the grain

Compressive strength perpendicular to the grain is an important factor for predicting the yielding performance of the joint between a wooden tie-beam and wooden column according to *Inayama*'s embedment theory [2] and *Kitamori*'s interpretations [3],[4], therefore the compressive strength tests shown in Figure 9 were done using the supporting wood blocks (69×75×102mm) after the main experiments were all finished.

Figure 9 *Compressive strength test of Japanese cypress block perpendicular to the grain.*

3 FINITE ELEMENT MODELING

As a preliminary attempt for predicting the skeleton curve of the multi-layered model specimens provided in this study, FEM analyses using a commercial FEM program were tentatively tried.

https://doi.org/10.52202/069179-0526

3.1 LARGE BEARING BLOCK

The elastic relationship between the moment (M) and the rotational angle (θ) of the large bearing block subjecting to a constant vertical load (P_0) and a moment (M) as shown in Figure 10 was derived based on *Kitamori*'s original proposal [5] as shown in eq. (3).

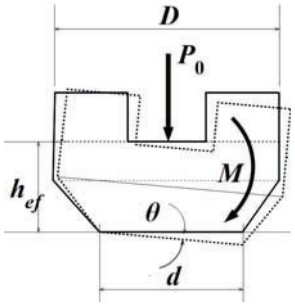


Figure 10: *Definition of the large bearing block subjecting to the moment M and the vertical load P_0*

$$M = \frac{b \cdot d^3 \cdot k_{w90}}{6} \cdot \theta = R_{D1} \cdot \theta \qquad (3)$$

where,

$$k_{w90} = \frac{E_{w90}}{h_{ef}} : \text{ bearing constant (kN/mm}^3) \qquad (4)$$

b: bottom width of the large bearing block (mm)
d: contact length of the large bearing block (mm)
R_{D1}: initial rotational stiffness of the large bearing block
E_{w90}: modulus of elasticity of the large bearing brock perpendicular to the grain estimated as 1/25 of that of the parallel to the grain (E_{w0}) (kN/mm^2)

The first yielding rotational angle was given in equation(5)[5].

$$\theta_{y1} = \frac{2P_0}{b \cdot d^2 \cdot k_{w90}} \qquad (5)$$

The second rotational stiffness was assumed to be smaller than the usual case [2] because the bottom surface of the large bearing block and the upper surface of the bracket arm are both perpendicular to the grain. The second stiffness was assumed as 1/12 of the first stiffness consequently.

$$R_{D2} = R_{D1}/12 \qquad (6)$$

3.2 BRACKET ARM

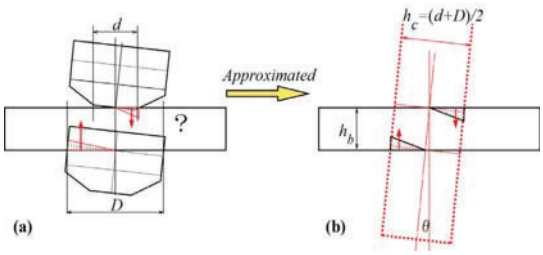

Figure 11: *An approximated mechanical model for the bracket arm contacting with two large bearing blocks.*

Mechanical modelling of the bracket arm seems to be complicated because the equilibrium condition of the vertical resultant forces is unknown as contact areas at the upper and bottom are not the same as shown in Figure 11-(a). Hence, in this study, this situation was approximated by assuming that the pressing condition by the upper and lower large bearing blocks is replaced by that given by a virtual column with an average width $h_c = (d + D)/2$ as shown in Figure 11-(b) and its longitudinal modulus of elasticity is E_{w90}. This assumption implies that the reactions from the virtual column surfaces are far softer than the normal column and tie-beam joint [3] [4] so no spring-back effect nor friction effect will not be considered in this soft contact model.

The moment (M)-rotational angle (θ) relationship for the virtual column-bracket arm joint shown in Figure 11-(b) was derived as equation (7) from *Kitamori* [3].

$$M = \frac{b \cdot {h_c}^3 \cdot k_{w90}}{12} \cdot \theta \qquad (7)$$

where,

b : width of the bracket arm.

$k_{w90} = \frac{E_{w90}}{h_b}$ bearing constant of the bracket arm

The rotational angle at the yielding was given by *Kitamori* [3] [4] as equation (8).

$$\theta_y = \frac{F_m}{h_c k_{w90}\left(1 + \frac{4h_b}{3h_c}\right)} \qquad (8)$$

where,

F_m : bracket arm's partial embedment strength (N/mm^2) =0.8×F_{c90}. In this study, F_{c90} (whole cross-sectional strength) was evaluated by the block compressive test shown in Figure 9.

Figure 12 shows an example of FEM modelling in the case of the three-layered specimen. In this modelling, the large bearing block was simulated by a single spring element having the axial stiffnesses and the rotational stiffness connected with short rigid beams for making the rotational behaviour of the spring element promote.

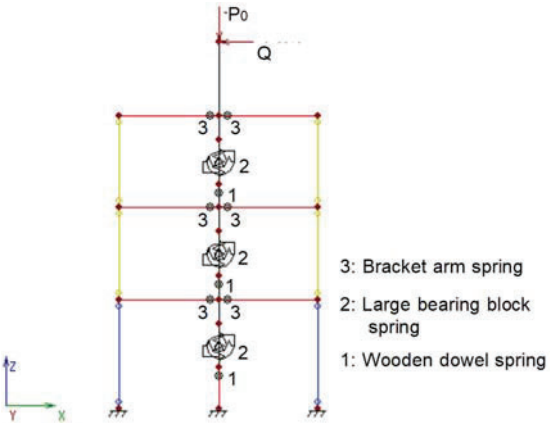

Figure 12: *An example of FEM modelling.*

https://doi.org/10.52202/069179-0526

4 RESULTS AND DISCUSSION

4.1 DOWEL SHEAR TEST RESULTS

Figure 13 shows wood-to-wood doweled shear joint test results. The grain directions of wooden members subject to the shear force were both perpendicular to the grain. While wood-to-wood doweled joints upper than the lowest layer were parallel to perpendicular joints. As no experiments, however, were done for the parallel-to-perpendicular joints, P-Δ curve approximated by a tetra-polygonal line in Figure 13 was applied to all FEM calculations for the multi-layered model specimens.

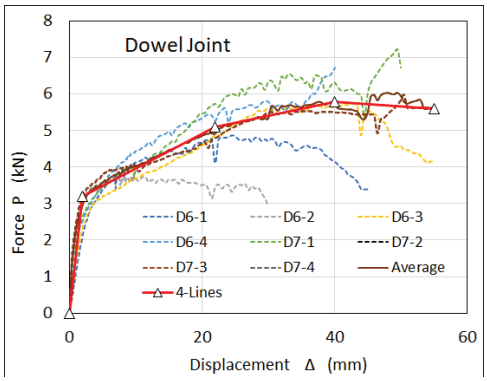

Figure 13: *Dowel joint shear test results and approximation by a tetra-linear polygonal line.*

4.2 VERIFICATION OF THE STIFFNESS OF THE LARGE BEARING BLOCKS

Figure 14 shows comparisons between the observed stiffness and the theoretical one calculated by equation (3) for the large bearing blocks subjecting to the moment shown in Figure 8. Theoretical value seems not to be bad, thus an application of the theoretical stiffness to the FEM models will be appropriate.

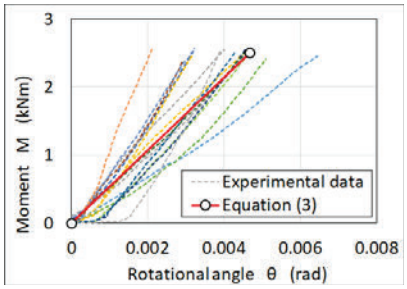

Figure 14: *Comparisons between observed stiffness and theoretical one [eq.(3)] for the large bearing blocks.*

4.3 DYNAMIC TEST RESULTS

In the dynamic test, the natural frequency (*f*) and the damping factor (*h*) of each test specimen were evaluated. The natural frequency (*f*) was evaluated using the Fourie spectral analysis method [e.g. 6]. For the actual calculations, an open computer program SPCANA-Ver4.92 created and provided by Dr. *Teruo Kamada*, an Emeritus Professor at Fukuyama University, was used.

The identification of the damping factor (*h*) was done by the Random Decrement (RD) method [e.g. 7]. For the actual identification, "Random Response Identification Program 3.0.xlsm" created by Dr. *Takehiro Wakita*, former Chubu University, Faculty of Engineering, Department of Architecture, was used.
When using the EXCEL macro, it was important to maintain the condition that the width of the bandpass filter was set so as to include the skirts on either side of the first-order peak of the Fourier spectrum, as described in previous studies [8], [9].

**Note: DPO means " pull-out" of #3 dowel shown in Figure 2. This was occurred due to lack of slotted hole at the pin joint in the steel bar for escaping from the tensile force.*

4.4 STATIC TEST RESULTS

The relationships between the shear force Q and the shear deformation angle γ of the test specimens subject to the constant dead load P=5kN and P=10kN are shown in Figure 16-(a), (b), (c), (d) and (e) with FEM analyses results. In the FEM analyses, an optional function for the "*P*Δ-effect" involved in the computer program [10] was used.

The static loading experiments were executed first starting from the 5-layers specimen, next using the same wooden column and a new wooden dowel, 4-layers, 3-layers, 2-layers, and finally 1-layer specimen, therefore in the last specimen (1-layer specimen), large slip occurred as shown in the right-hand side of Figure 16-(a) as the dowel hole became loose due to multiple re-uses of the same column member.

Agreements between the hysteresis curves of the observed Q-γ relationships and predicted skeleton curves by the commercial FEM analysis program were generally bad. One of the reasons for these discrepancies is the unmatured FEM modelling done by the author. Thus, to obtain more satisfactory results, a lot of improvement of the FEM modelling method and reconsiderations on the nonlinear spring constants of each element will be required. While, however, the stiffness (dotted red line) obtained by the dynamic test agreed generally well with the initial slopes of static experimental results.

Figure 17 shows the relationship among the equivalent stiffness (*K*), natural frequency (*f*), damping factor (*h*), and the number of layers of the specimen.

https://doi.org/10.52202/069179-0526

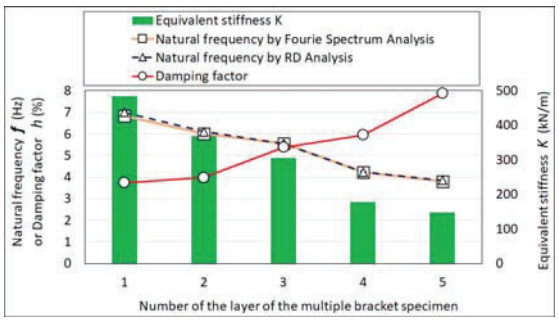

Figure 17: *Relationship among stiffness (K), natural frequency (f), damping factor (h), and number of layers*

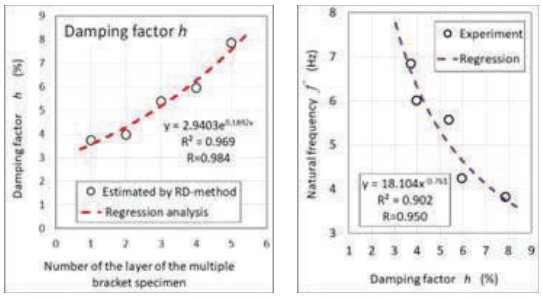

Figure 18: *Relationship among the damping factor (h), number of layers, and the natural frequency (f)*

As can be seen in Figure 17, the evaluated natural frequency (*f*) was considered to be reliable because almost the same values were obtained by both the Fourie Spectral Analysis method and the Random Decrement (RD) method.
There was a tendency for the equivalent stiffness (*K*) that gradually increased as the number of layers of the bracket complex decreased. This tendency seemed to be reasonable judging from the principle of layered structures.
Figure 18 shows the relationship among the damping factor (*h*), the number of layers of the specimen, and the natural frequency (*f*).
As expected preliminary, the damping factor (*h*) increased with the increase of the number of layers as shown in the left-hand side figure of Figure 18. The increasing tendency, however, showed an exponential rather than a linear. In addition, an inversely proportional relationship was observed between the natural frequency (*f*) and the damping factor (*h*) as shown in the right-side hand of Figure 18.

5 CONCLUSION

In this study, a very unique "multi-layered bracket complex structure", which can be seen in *Kaiyuan* Temple *Tenno-den* in *Chaozhou* City, *Guangdong* Province, China, was targeted as the research objective. To clarify at least a small part of the mechanical performance of this unique structure, simplified model layered bracket complex test specimens were created, and dynamic as well as static experimental investigations in conjunction with a tentative FEM modelling composed of beam and spring elements were attempted. Through experimental investigation and numerical analyses, the followings were concluded.

- The model multi-layered test specimens showed an increasing tendency of the damping factor (*h*) as the number of layers increased. This tendency gave an anticipation that this kind of multi-layered structure might have the potential to be a better energy dissipation function.

- Tentative numerical analyses using a commercial FEM program showed unsatisfactory agreements with the hysteresis curves obtained in the static push-pull cyclic loading experiments. Further improvements in the mechanical modelling of each structural element are necessary to obtain more satisfactory results.

- Hysteretic modelling of the multi-layered model specimens has not started yet hence the seismic analyses on the actual temple structure existing in China remained a future research subject.

ACKNOWLEDGEMENTS

This research is funded by the Japan Society for Promoting Science (JSPS) Grant-in-Aid for Scientific Research (C) [No. 21K04352 Principal Investigator: *Kohei Komatsu*].
For executing the experiments, various advice and technical support were given by Mr. *Horimoto Naohiro.* Dr. *Li Zherui*, and Ms. *Zhang Xiaolan* took part in the assistant roles not only for the dynamic and static experiments but also for all the element tests.
The author deeply appreciates not only the financial support from JSPS but also the help and technical support of the above-mentioned three persons.

EXPERIMENTAL STUDY ON LATERAL PERFORMANCE OF A FRAME WITH DEEP BEAMS AND HANGING MUD WALLS IN TRADITIONAL JAPANESE RESIDENTIAL HOUSES

Zherui Li[1], Hiroshi Isoda[2], Akihisa Kitamori[3], Takafumi Nakagawa[4], Yasuhiro Araki[5]

ABSTRACT: This study aimed to investigate the resistance of a frame with deep beams and hanging mud walls, clarify the working mechanisms and contributions of different load-bearing elements in the frame. A series of comparative experiments of the frames with and without hanging mud walls were carried out in the first step, as well as frames with hanging mud walls of different height aspect ratios. The contributions of main load-bearing elements, including mortise-tenon joints, deep beams, and hanging mud walls, were identified. Secondly, the performance of the deep beam and beam-column joints were discussed. Additionally, the parameter analysis of the height aspect ratios of hanging mud walls was also performed combined with component tests.

KEYWORDS: Traditional timber structure, Lateral resistance, Hanging mud wall, deep beam, interior notch

1 INTRODUCTION

Timber frame composites with mud walls constitute the basic structure for resisting lateral forces and are widely employed in both traditional oriental temples and castles in Japan. Specifically, the composition of hanging mud walls and deep beams have been promoted for use in traditional Japanese residential houses since 17th century (Edo-era) [1]. Due to the requirement of space permeability, the proportion of large-scale shear walls is relatively reduced and partially replaced by large-section timber frames with hanging walls in traditional-style houses (Figure 1). However, this practice may cause the risk of insufficient shear capacity according to current seismic design standards.

Figure 1: *Common structural systems in traditional Japanese residential houses.*

From the perspective of reinforcement of existing buildings, an accurate evaluation of the seismic performance of original structures is required for the need to maintain the appearance and minimize the expense in traditional residential houses. While the overall resistance of a frame with hanging wall height less than 750mm is underestimated according to the current seismic assessment method [2, 3], the resistance of mortise-tenon joints and deep beams are also not clearly involved in the evaluation of traditional residences in Japan. Simultaneously, considering that the shear force generated by hanging mud walls and deep beams and the moment of mortise-tenon joints all act on the column body and easily lead to bending deformation, the bending capacity of columns should be reassessed as a limiting factor of the drift-resisting capacity of the frame.

This study took the double-span frame with deep beams and hanging mud walls as the object (Figure 2) and investigated the working mechanisms and contributions of different load-bearing elements, including mortise-tenon joints, deep beams, and hanging mud walls. Then the influence of different wall heights on lateral resistance capacity and damage mode of the frame were discussed based on comparative experiments.

2 EXPERIMENT

2.1 FRAME TESTS

With the purpose of visualizing the load-bearing mechanism and the contribution of the structural elements, in-plane static cyclic tests were conducted on frames with and without hanging mud walls, marked as *FW-M* and *F-M*, respectively. Then, to grasp the resistance of hanging mud walls with different heights, comparative experiments were conducted on frames with hanging mud walls of two height aspect ratios, marked as *FW-S* and *FW-L*, respectively. The dimension of frame specimens and mortise- tenon joints are shown in Figures 3 and 4.

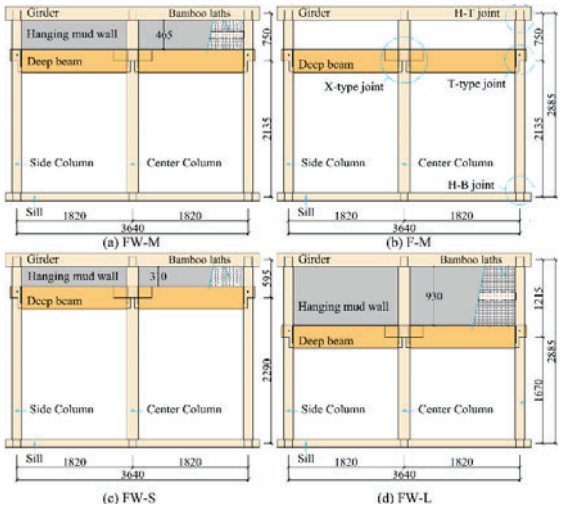

Figure 3: *Frame specimens (Unit: mm).*

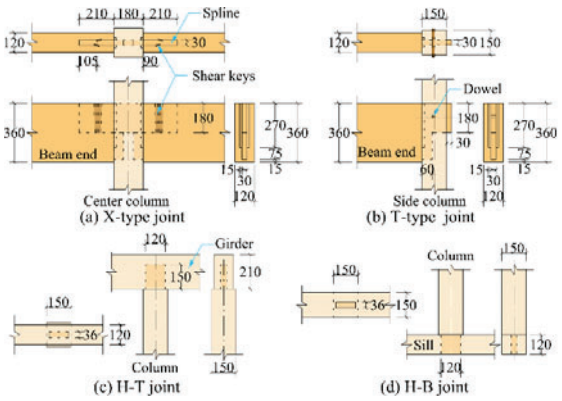

Figure 4: *Mortise-tenon joints in frame specimens (Unit: mm).*

For specimen FW-S, the clear height of the hanging mud wall was 310 mm. For specimens FW-M and FW-L, the wall height increased to 465 mm (1.5 times) and 930 mm (3 times). The aggregate thickness of the hanging mud wall was 70 mm, including the 40 mm thickness of rough-coated mud and 15 mm thickness of intermediate-coated mud. The dimensions, wood species and material properties of timber components in frame specimens are listed in Tables 1and 2.

Loading procedures of two groups of frame specimens were adapted from the standard ISO 16670. Cyclic load was applied along the centreline of the girder. Frame specimens were loaded with nine phases, each containing three fully revised cycles of equal amplitude. Target shear angles are raised from ±1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50, 1/30, to 1/15 rad, and then the load was added until the displacement limit of the hydraulic jack (approximately 1/10 rad) along the pull direction. Tie rods were installed along the side columns to control the vertical displacement and rotation of the frame, and the sill beam was fixed by sliding limit blocks.

Table 4: *Dimensions and wood species of members in frame specimens.*

Member	Dimension (mm)	Wood species
Side column	150×150×2720	Japanese cedar
Center Column	180×180×2720	Japanese cedar

	Girder	19.6	20.3	18.2	17.4
	Sill	20.0	22.6	22.4	23.0

2.2 ELEMENTAL TESTS

To clarify the resistance contribution and deformation characteristics of the main components in the frame, including the rotational performance of mortise-tenon joints, shear resistance of deep beams and hanging mud walls, as well as the bending performance of columns with mortise, elemental tests were carried out and compared with frame tests.

https://doi.org/10.52202/069179-0527

Cyclic loading tests on two types of mortise-tenon joints of column and deep beam connections, the column top and bottom joints, the single-span frame containing a deep beam and two side columns, and mud wall elements with different heights corresponding to frame tests (310 mm, 465 mm, 930 mm) were conducted (Figure 5). Loading protocol of all these elemental tests were all consistent with the frame tests. Then 3-point bending tests of columns with mortise were performed.

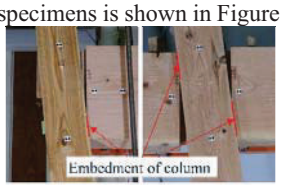
3 RESULTS AND DISCUSSION

3.1 LATERAL FORCE RESISTANCE OF OBJECT FRAMES

3.1.1 Observed damage

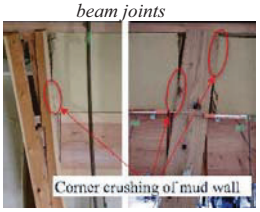
When the bare timber frame specimen F-M deformed under lateral force, there was an evident relative rotation between the columns and horizontal members (girder, deep beams, and sill). The effective length of deep beams gradually changed into the diagonal length and squeezed the columns on both sides. Although no obvious damage of joints or main components was observed even under a large displacement angle (1/10 rad), the outwardly bending tendency of both left- and right-side columns was very clearly observed. For specimen FW-M in contrast, the bending deformation of columns was not as significant as specimen F-M because of the restraint effect of hanging mud walls. Correspondingly, crushes of the left and right corners of the mud walls were observed as the displacement angle increased over 1/50 rad. Except for the shear failure that suddenly appeared on the top of the left column at 1/10 rad, there was no significant damage observed at mortise-tenon joints, and there was no clearly shear failure in the middle part of the hanging mud walls. The damage state of both specimens is shown in Figure 6.

(a) Deformation of F-M at 1/10 rad



(b) Relative rotation of column-deep beam joints

(c) Deformation of FW-M at 1/10 rad



(d) Shear failure of left column and corner crushing of mud wall

Figure 6: *Damage state of F-M and FW-M at 1/10 rad.*

For specimens FW-S and FW-L which contain hanging mud walls of different heights, the most significant differences between the two frames at the displacement angle of 1/10 rad are the failure mode of hanging mud walls (Figure 7). For hanging mud walls with a height aspect ratio of 0.19 in FW-S, no significant shear failure was observed. Except for crushes at the left and right corners, vertical cracking occurred at the upper and lower surfaces of the mud wall at about 1/4 length from the edge. For hanging mud walls with a height aspect ratio of 0.56 in FW-L in contrast, diagonal cracks occurred from the interior area of both mud walls and expanded towards the edge. And because of the more obvious lifting effect of mud walls, the crushing failures of upper and lower surfaces at the wall corners were observed. In addition, bending deformation of the side columns was also more significant than that in FW-S, due to the greater shear

force transmitted by hanging mud walls and closer action position to the mid-span of columns.

(c) Deformation of FW-L at 1/10 rad *(d) Diagonal cracks at center of mud walls*

Figure 7: *Damage state of FW-S and FW-L at 1/10 rad.*

3.1.2 Restoring characteristics

The restoring force characteristics of four frame specimens, and the main damage with corresponding displacement angles are shown in Figure 8. By comparing the skeleton curves of specimens F-M and FW-M, the contribution of hanging mud walls to the lateral resistance of the frame can be extracted (Figure 9(a)). When the hanging mud walls with a centreline height of 750 mm are included, the initial rigidity is increased by 1.57 times compared to the bare timber frame. After the peak value of lateral force reaches 15.73 kN at 0.06 rad, the load-carrying capacity of the FW-M slowly decreases with the occurrence of corner crushing of mud walls. In contrast, the lateral force added on F-M maintains an upward trend and reaches 13.11 kN at 0.1 rad, which is very close to that of FW-M.

From the perspective of the influence of wall height on the lateral resistance of the frame (Figure 9(b)), the initial rigidity of FW-L is 2.5 times higher than that of FW-S, and the peak load is also 1.34 higher. However, after the shear cracks occurred at 1/15 rad, the bearing capacity of FW-L decreased rapidly. As for FW-S, as the height aspect ratio of hanging mud walls is small and there is no shear failure occurs, the integral frame can maintain a stage lateral resistance even under large deformation. The result indicates that although the shear area of hanging mud walls remained the same, the stiffness as well as bearing capacity of the frame are positively correlated with the height of hanging mud walls.

The structural indices of frame specimens calculated according to the design method of JHWTC [4] as shown in Figure 9, including initial rigidity K, yield load P_y, maximum load P_{max}, ultimate load P_u, ductility factor μ, and short-term allowable lateral force P_a are listed in Table 3. P_a of the frame with different heights of hanging mud walls is derived by Eq. (1).

$$P_a = \alpha \cdot \min \begin{cases} P_y \\ 0.2\sqrt{(2\mu - 1)}P_u \\ 2/3 \cdot P_{max} \\ P_{120} \end{cases} \quad (1)$$

in which P_{120} is the lateral force at displacement angle of 1/120 rad, $\alpha = 1.0$.

Table 3: *Structural indices of frame specimens.*

Frame	K (kN/rad)	P_y (kN)	P_u (kN)	P_{max} (kN)	μ	P_a (kN)
F-M	362.46	7.60	11.79	13.11	3.08	3.83
FW-M	568.05	9.26	14.38	15.73	3.94	5.56
FW-S	408.31	11.11	17.08	19.53	2.32	3.73
FW-L	1026.95	18.47	22.94	26.14	4.57	8.99

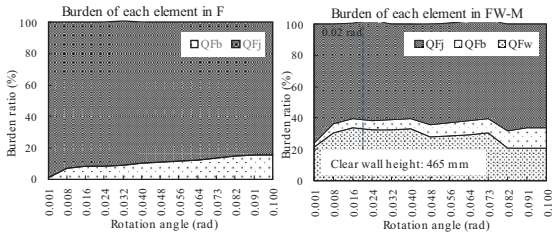
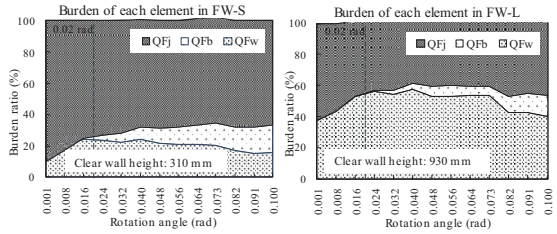
3.2 PERFORMANCE OF MAIN COMPONENTS IN THE FRAME

Based on the lateral force-deformation relationship obtained from elemental tests, the contributions of main load-bearing components, including the mortise-tenon joints (Q_{Fj}), deep beams (Q_{Fb}), and hanging mud walls (Q_{Fw}), are extracted from the entire frame. The burden ratio of them is shown in Figure 11. It is observed that the resistance proportion of mortise-tenon joints exceeds 60% when the centerline height of the hanging mud wall is less than 750 mm. For hanging mud walls, the resistance proportion of which is positively correlated to the wall height, the peak occurs at about 0.02 rad and then begins to decline. The resistance proportion of deep beams in the bare timber frame accounts for about 10-15%, while in frames with hanging mud walls, its resistance is manifested when the displacement angle is above 0.02 rad.



(a) Frames with and without hanging walls



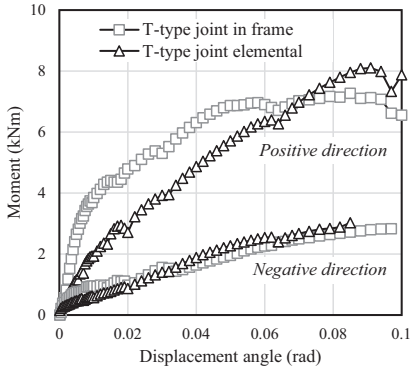
(b) frames with hanging walls of different heights

Figure 11: *Burden ratio of each element in frame specimens.*

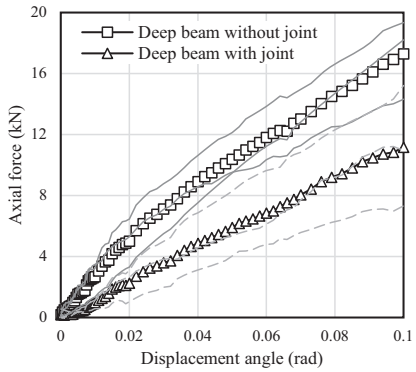
3.2.1 Interaction between mortise-tenon joints and deep beams

By comparing the results of the frame and elemental tests, the interaction between beam-column joints and deep beams is identified.

Firstly, from the experimental phenomenon, the displacement angle corresponding to shear damage of the column-deep beam joints in the frame tests is greater (0.1 rad) than that in joint elemental tests (0.06 rad). This is mainly caused by the compression effect generated by the rotation of the deep beam clamped between two columns, which delays the tenon removal. From the moment-displacement angle curve extracted from the frame, it can be seen that the initial rigidity of the column-deep beam joint in the frame is lower than that in elemental tests (Figure 12(a)). And due to the failure delay of mortise-tenon joints, the overall resistance of the frame can maintain an increasing trend at 0.1 rad. Conversely, due to the pressure generated by the rotation of the beam end joint being partially balanced by the tensile force generated by the dowel, the axial force transmitted along the diagonal direction of the deep beam decreases (Figure 12(b)).



(a) Moment of T-type joint with and without influence of deep beams



(b) Axial force on deep beams with and without influence of joints

Figure 12: *Interaction between deep beams and joints.*

3.2.2 Performance of hanging mud walls

Based on the elemental tests of squat mud walls, a positive correlation between the resistance of squat mud walls and the height aspect ratio is confirmed when the height aspect ratio is lower than 0.5 (Figure 13). Furthermore, the resistances generated by shear and corner compression are extracted respectively.

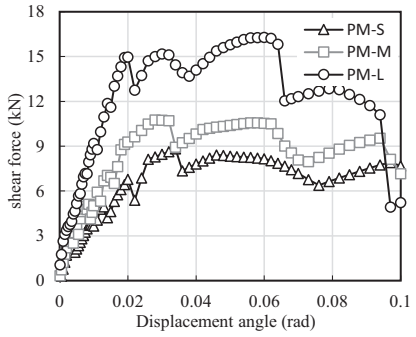


Figure 13: *Shear resistance of squat mud walls.*

3.2.3 Bending performance of columns

Although there was no bending failure occurred on the columns of both FW-S and FW-L specimens, the bending moments measured from the center and the leeward side columns of FW-L significantly increased as the concentrated load transmitted by hanging mud walls increased. Based on the comparative bending tests of columns with and without mortise at the loading point, the reduction coefficient β of bending moment (Eq. (2)), affected by the stress concentration of mortise is calculated. The experimental result shows that when the width lost ratio on the tensile side is lower than 0.4, the mean value of β is obtained as 1.0. Compared with the much lower coefficient (β=0.45~0.6) in the regulations in AIJ standard [5], it can be inferred that the continuous part out of the mortise plays an important role in relieving stress concentration.

$$M_{b-M} = \alpha \cdot \beta \cdot M_{b-0} \quad (2)$$

in which M_{b-0} is the bending moment of columns without mortise, M_{b-M} is the bending moment of columns with mortise, α is the nominal section modulus, calculated by the ratio between the weakest net section of mortise and the entire section.

4 CONCLUSIONS

The presented work focused on the lateral performance of a frame with deep beams and hanging mud walls in traditional Japanese residential houses. With the change of wall height, the initial rigidity, yield load, and ductility of the entire frame, as well as the resistance contribution of moment-resisting joints, deep beams, and hanging mud walls were evaluated.

The experimental results indicate that for the timber frame with deep beams and hanging mud walls, the lateral rigidity and lateral load-bearing capacity are positively correlated with the increase of the height of hanging mud walls. Regardless of whether the shear failure occurs on the hanging mud wall, its burden ratio of lateral force contribution reaches the peak at 0.02 rad. The collaborative working mechanism of mortise-tenon joints and deep beams ensures the good ductility of the entire frame. For the timber frame with the wall centerline height below 750 mm, the contribution of mortise-tenon joints to the lateral resistance accounts for over 60%.

ACKNOWLEDGEMENT

ASSESSMENT OF NAILED CONNECTIONS IN EXISTING STRUCTURES

Lars Völlmecke[1], Sascha Schwendner[2], Ai Phien Ho[3], Jens Fischer[4], Werner Seim[5]

ABSTRACT: This paper presents the development of an assessment scheme for a visual qualitative evaluation of nailed connections in existing structures, such as board trusses. In terms of further use and preservation, a quick visual inspection will help to evaluate the quality of a structure regarding its load-bearing capacity and deformation behaviour. Tests of old and new nailed joints in combination with a rating scheme point out the correlation between the load-bearing capacity and condition of a joint. Old joints of comparatively good condition tend to exhibit better results than those of poor condition. Moreover, aged joints are generally more load-bearing than newly assembled ones.

KEYWORDS: nailed trusses, nailed constructions, Corrosion, Preservation, Re-use, Structural Post-strengthening

1 INTRODUCTION

Carpentry-based timber construction in the 20th century underwent a strong development towards engineered timber construction, which was driven by the development of new materials (glulam, laminated veneer lumber, wood-based boards), on the one hand, and new connections, on the other. Moreover, steel structures were replaced by timber structures in times of material and resource scarcity, and in this context, nails played a decisive role.
Utilising nail construction, smaller board cross-sections could be economically connected to form efficient trusses with large spans, without having to pay attention to patents, as was the case with the various types of shear connectors, and could also be erected by untrained workers. A nailed truss construction from this time is depicted in Figure 1.

Figure 1: *Bailed truss Type-II*

However, acceptance of the structural use of the nail had to be created first. While dowels and bolts were widely used in many applications at the beginning of the last century, the nail in a load-bearing function was still prohibited. The nail only become part of the standardised codes after extensive basic research in the 1930s [1-3] and, thus, establish itself in the construction industry. Until the introduction of nail plates, countless roof trusses were built with nailed joints. Nailed trusses were still used in countries with a planned economy until about 1990.

The question of continued use and preservation is an important issue for many of these structures, leading to the need for engineering assessment. In this context, strongly varying conditions might be found. The nodes, which are, in many cases, decisive for the load bearing capacity, might especially exhibit deficiencies. A scheme is developed here for a simple, rapid evaluation of the condition of nailed connections in terms of load-bearing capacity and serviceability to generally support a decision about their further use.

With the help of this scheme, the condition of the nail connections is to be determined regarding nailing patters, edge distances and spacing, the presence of small or large cracks or fractures and moisture damage. The effort should be limited to the extent that non-destructive examinations are used almost exclusively. This means that the assessment is carried out mainly by visual inspection. In order to obtain information on the load-bearing behavior of nailed connections, the objectives of this paper are to determine the load-bearing capacities based on experimental tests on aged connections of nailed trusses, and combine these with visual classification based on the scheme presented.

The further use of such connections or load-bearing structures is to be supported by the combination of visual and experimental examinations. In addition to the examination utilising the scheme, the corrosion of the nails is also considered.

2 ASSESSMENT OF CONNECTIONS

2.1 CLASSIFICATION SCHEME

A comprehensible rating scheme had to be developed to support a visual qualitative evaluation. In this context, Imamura and Kiguchi [4] presented a scheme based solely on the degree of corrosion of the nails. In this case, the condition of the nail was assigned from completely intact to failure. This approach was extended to the evaluation scheme for nailed joints of roof trusses, which also considers the integrity of the wood. This scheme is shown in Figure 2.

Rating	Standard	Example
1	Scarcely rusted	
2	Partially rusted, no visible defect	3	Totally rusted, no defect inside	4	Partially defect, with original length	
5	Failure	

Figure 2: *Rating scheme of corrosion of the nails from* [4]

The classification into different categories is based only on the external appearance. Consequently, various conditions were imposed to enable the categorization of the individual nodes. These conditions are depicted in Figure 3. Each category is divided into a side and bottom view.

The reference to the load, depending on the grain direction, is established for this purpose. The assessment is carried out for the diagonal components loaded in the direction of the grain.

Category 1 is reached if the penetration length, the edge distance and the spacing are in accordance with the regulations applicable. In addition, at least 90 % of the nails must be hammered flush with the connecting timber, otherwise the joint falls directly into category 2. Category 1 should not generally show any visual damage.

A joint is classified as category 2 if either the penetration length, the edge distance or the spacing are not in accordance with the regulations applicable. No visible damage should be apparent in category 2 either.

Category 3 is divided into subcategories: 3a and 3b. In 3a, the joint complies with the penetration length, the edge distance and the spacing according to the regulations applicable. The joint is classified as 3b if any condition from 3a is not fulfilled. Basically, a joint is classified as category 3 if it has cracks smaller than 1 mm, less than 90 % of the nails are nailed flush with the connecting timber or there are first signs of deterioration of the wood.

In category 4, a distinction is again made between subcategories: 4a and 4b. The subcategories are the same as for condition 3. The criteria for classification as category 4 are any visible defects, including cracks larger than 1 mm wide, splitting, local moisture damage, wood decay or insect infestation.

Figure 3: *Classification scheme for aged nail joints*

Category		Description		Illustration		
				side view	bottom view	
					Type-I	Type-II
1		➢ Specifications for edge distance, penetration length and spacing are in accordance with the code regulation. ➢ > 90 % of the nails flush with connecting timber ➢ Timber without visible damage / cracks				2		➢ Specifications for edge distance, penetration length or spacing are in accordance with the code regulation. ➢ Timber without visible damage / cracks				
3	a	➢ small cracks, width < 1 mm ➢ < 90 % of the nails flush with connecting timber ➢ Indications of moisture impact	Specifications for edge distance, penetration length and spacing are in accordance with the code regulation.			
	b		Specifications for edge distance, penetration length or spacing are not in accordance with the code regulation.			
4	a	➢ crack width > 1 mm ➢ splitting and disconnection ➢ moisture impact ➢ timber decay ➢ insect infestations	Specifications for edge distance, penetration length and spacing are in accordance with the code regulation.			
	b		Specifications for edge distance, penetration length or spacing are not in accordance with the code regulation.			

https://doi.org/10.52202/069179-0528

2.2 APPLICATION OF THE CATEGORIZATION

The scheme was applied to two test series with the same roof shape, which was the mono-pitched roof. Type I consisted of a chord as the middle member and struts and posts as side members, respectively. The construction is shown in Figure 4 and 5. A total of 62 connections were tested. Furthermore, 11 connections of Type II were tested. In the latter, struts and posts are between two bottom chords, as shown in Figure 6 and 7.
The scheme to evaluate the condition was applied to all joints. Only timber members which are loaded in the direction of the grain were analysed. The chord, which is loaded orthogonal to the grain, can be neglected for the categorization.
The designations of the joints AH – "Adorf Hessen" and GH – "Gießen Hessen" refer to the region in Germany, while PD refers to the roof shape. In both cases the roof shape was a pitched roof.

Joint Type I

The connections were made with a different number of nails and two different nail diameters. The posts and struts are on the outside in this type. The chord between the posts and struts is a single beam with the dimensions 8 x 16 cm. The chord has not been categorized due to its full integrity and the loading, which is not parallel to the grain. The assessment of the diagonal side members with a geometry of 2.3 x 10 cm is illustrated by the examples in Figure 4 and 5.

(a)
side view A:
post cat. 2,
strut cat. 2

(b)
side view B:
post cat.: 3b,
strut cat.: 3b

Figure 4: Evaluation of Joint Type I B09

The post for joint B09 in Figure 4a was assigned to Category 2 based on a nonstandard nailing. No cracks could be found. The strut on this side was assigned to category 2 because no cracks were discernible here either and standard nailing was missing. On the other side of the connection, the post was assigned to category 3b due to nonstandard nailing and small cracks up to 1 mm wide.
The strut on side B was classified in category 3b as it also lacked standard nailing and showed small cracks up to 1 mm in the lower part of the board.

(a)
side view A:
post cat.: 4b,
strut cat.: 4b

(b)
side view B:
post cat.: 4b,
strut cat.: 4b

Figure 5: Evaluation of Joint Type I B12

The posts for joint B12 in Figures 5a and 5b were classified as category 4b due to nonstandard nailing and cracks larger than 1 mm. The struts on both sides were classified as category 4b because there were also cracks larger than 1 mm and a standard nailing was missing.

Joint Type II

The connections of Type II were made with a different number of nails. In this type, the posts and struts formed the middle parts. The chords were on the outside, each with dimensions of 2.3 x 10 cm. Since the direction of the force is not in the direction of the grain of the chord, it was assumed to have no influence on the evaluation. The middle members with a geometry of 2.3 x 10 cm have been evaluated using two examples in Figure 6.

bottom view:
cracks
→ post cat.: 4

Figure 6: Evaluation of Joint Type II A01

The post for Joint A01 is decisive for the evaluation of the entire joint. It was classified as category 4b due to the bottom view because there was a crack of more than 1 mm (see Fig. 6).

https://doi.org/10.52202/069179-0528

bottom view:
cracks →
post cat.: 4,
strut cat.: 4

Figure 7: Evaluation of Joint Type II A02

The post and the strut were again taken as significant for the evaluation of joint A02. These were classified as category 4 due to the bottom view, since cracks larger than 1 mm were present there (see Figure 7b).

3 ANALYTICAL CALCULATION

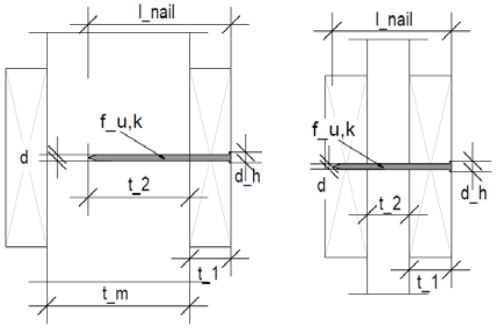
The characteristic lateral resistance for the shear loaded connections was calculated according to EN 1995-1-1:2010 for purposes of comparison [7]. The geometrical and the material parameters used in this calculation are documented in Table 1. The construction of each type with the geometrical parameters is shown in Figure 8.

Table 1: Parameters for the calculation of the two test series

$f_{u,k}$ [N/mm²]	ρ_m [kg/m³]	ρ_k [kg/m³]	f_{ax} [N/mm²]
600	420	350	2.45

Calculation of the load-bearing capacity

The following steps show the calculation of the shear capacity for the two test series.



(a) (b)

Figure 8: Geometry of (a) Type I and (b) Type II

It could be shown using pre-calculations that for all diameters of the nails, mechanism d was decisive for Type I, in which a yield hinge was formed in the middle timber, and mechanism c for Type II, with embedment failure in all timbers.

The yield moment $M_{y,Rk}$ is calculated as

$$M_{y,Rk} = 0.30 \cdot f_{u,k} \cdot d^{2.6} \quad (1)$$

where $f_{u,k}$ is the tensile strength and d the diameter of the nails. The embedment strength $f_{h,k}$ is calculated as

$$f_{h,k} = 0.082 \cdot \rho_k \cdot d^{-0.3} \quad (2)$$

where ρ_k is the characteristic density. The withdrawal strength $f_{ax,k}$ is calculated as

$$f_{ax,k} = 20 \cdot 10^{-6} \cdot \rho_k^2 \quad (3)$$

The head pull-through resistance is calculated as

$$f_{head,k} = 70 \cdot 10^{-6} \cdot \rho_k^2 \quad (4)$$

The ratio of embedment strength is calculated as

$$\beta = \frac{f_{h,2,k}}{f_{h,1,k}} = 1 \quad (5)$$

with $f_{h,2,k} = f_{h,1,k}$. The load-bearing capacity for the joints of Type I is calculated as

$$F_{v,Rk} = 1{,}05 \cdot \frac{f_{h,1,k} \cdot t_1 \cdot d}{2+\beta} \left[\sqrt{2 \cdot \beta \cdot (1+\beta) + \frac{4 \cdot \beta \cdot (2+\beta) \cdot M_{y,Rk}}{f_{h,1,k} \cdot t_1^2 \cdot d}} \right] - \beta \quad (6)$$

with the parameters determined previously. The load bearing capacity for Type II is calculated as

$$F_{v,Rk} = \frac{f_{h,1,k} \cdot t_1 \cdot d}{1+\beta} \cdot \left[\sqrt{\beta + 2 \cdot \beta^2 \cdot \left[1 + \frac{t_2}{t_1} + \left(\frac{t_2}{t_1} \right)^2 \right] + \beta \cdot \left(\frac{t_2}{t_1} \right)^2 - \beta \cdot \left(1 + \frac{t_2}{t_1} \right)} \right] \quad (7)$$

To include the rope effect $\Delta F_{ax,Rk}$, the significant withdrawal force is calculated as

$$F_{ax,Rk} = min \begin{cases} f_{ax,k} \cdot d \cdot t_2 \\ f_{ax,k} \cdot d \cdot t_1 + f_{head,k} \cdot d_h^2 \end{cases} \quad (8)$$

where d_h is the nail head diameter. The additional force is calculated as

$$\Delta F_{v,Rk} = min \begin{cases} 0.25 \cdot F_{ax,Rk} \\ 0.15 \cdot F_{v,Rk} \end{cases} \quad (9)$$

The total load capacity of a nail is calculated as

$$F_{v,Rk,total} = F_{v,Rk} + \Delta F_{v,Rk} \quad (10)$$

The dimensions of the nails correspond to those found in the components. The standard dimensions of nails nowadays are different. Nails with diameters of 2.8, 3.1 and 3.4 mm are used in these specimens.

The analytical calculated capacity according to EC5 is documented in Table 2 for each diameter.

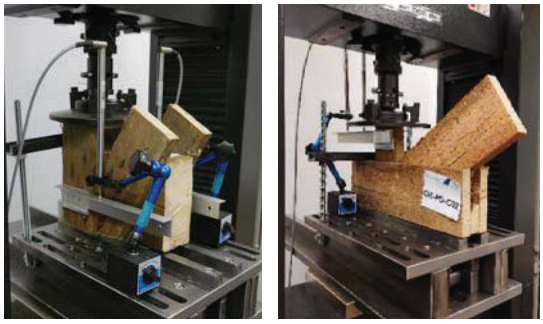
https://doi.org/10.52202/069179-0528

Table 2: Load capacity per nail diameter

d [mm]	d_h [mm]	t_m [mm]	t_1 [mm]	t_2 [mm]	$F_{v,k}$ [N]	$F_{ax,k}$ [N]	$F_{v,k,total}$ [N]
2.8	6	80	23	42	588	288	660
3.1	6	23	23	23	604	175	647
3.4	7	80	23	57	727	475	836

4 EXPERIMENTAL TESTING OF JOINTS

The joints evaluated with the scheme developed were finally tested to determine the capacity of the connections. The whole test programme included shear tests on specimens taken from trusses of existing structures and additional tests to determine material parameters. The evaluations of all tests are presented by Schwendner et al. [6].



(a) (b)

Figure 9: Test set-up for joints (a) Type I; (b) Type II

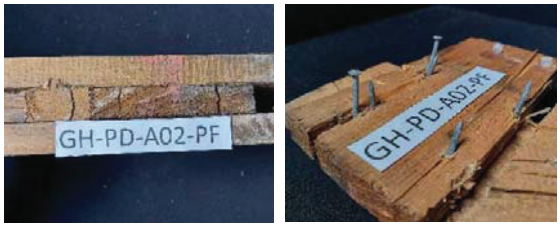
Only the experimental tests on joints will be discussed in this paper. The failure of the joints was defined corresponding to a displacement of 15 mm. Figure 9a shows the test set-up for Type I and Figure 9b for Type II. Both configurations can be tested with the set-up developed.

5 TEST RESULTS AND VALIDATION

In this section, the experimental test results are compared with the results of the analytical calculation according to EC5. In a second step, the scheme developed is validated. Therefore, the categories are compared with the ratio between the experimental test results and the strength calculated according to EC5.

5.1 TYPICAL FAILURE MODES

Application examples of the rating scheme show a correlation of the joint and the failure mode. The joints which are depicted in Figure 11a and b, for example, were evaluated in advance with condition 4 and show that not all nails have formed plastic hinges after the execution of the test; the wood was unable to contribute to the embedment strength due to the cracks and, thus, a lower load-bearing capacity of the joint results.



(a) (b)

Figure 10: Type II: joint GH-PD-A02 before and after testing

As a further example, Figure 11a and b show a test specimen of Type II before and after the shear test. Here, the rating 4 also indicates a lower load-bearing behaviour. After testing, it can be seen that the specimen could not reach its full load-bearing capacity in the area of the crack, due to the missing yield hinge. Consequently, not all nails reached their capacity.

(a) (b)

Figure 11: Type I: joint AH-PD-B06 before and after testing

5.2 COMPARISON BETWEEN EXPERIMENTAL TEST RESULTS AND ANALYTICAL CALCULATION

The geometrical components and the assessment category for each joint taken from the aged roof trusses are documented in Table 3 to 6. Additionally, the number of nails, the analytically calculated characteristic strength $F_{v,Rk}$ according to EC5 and the maximum strength F_{max} determined by the experimental tests are given. As a final result, the ratio between F_{max} and $F_{v,Rk}$ is calculated.

Nails with a diameter of $d = 3.4$ mm and $d = 2.8$ mm were used for Type I. The calculated load capacity in relation to the number and diameter of existing nails per joint are shown in Table 3 and 4.

Nails with a diameter of $d = 3.1$ mm were used for Type II. The calculated load capacity in relation to the number of nails per joint are shown in Table 5 and 6.

The experimental test results achieved a higher load than the calculation according the EC5 for all joints, with the exception of joint B01.

5.3 VALIDATION OF THE ASSESSMENT SCHEME

The results from experimental testing are used for the validation of the classification system. Thus, the characteristic capacity per nail was assigned to the respective category for each test.

Figure 12a shows the graphs for Type I. Based on the shear tests, it was possible to establish a trend line showing a clear tendency for a decreasing quality to correspond to a lower load-bearing capacity (see Figure 12). On average, a ratio of 2.6 between experimental and analytical results can be obtained for Category 2, 2.2 for Category 3 and 1.7 for Category 4.

Figure 12b shows the graph for Type II. By assigning the load-bearing capacities to the pre-rated categories, a trend line could again be generated here. This supports the hypothesis of the correlation of the assessed category and capacity. The average ratio of category 2 is 2.8, of category 3, 1.6 and of category 4, 1.4.

https://doi.org/10.52202/069179-0528

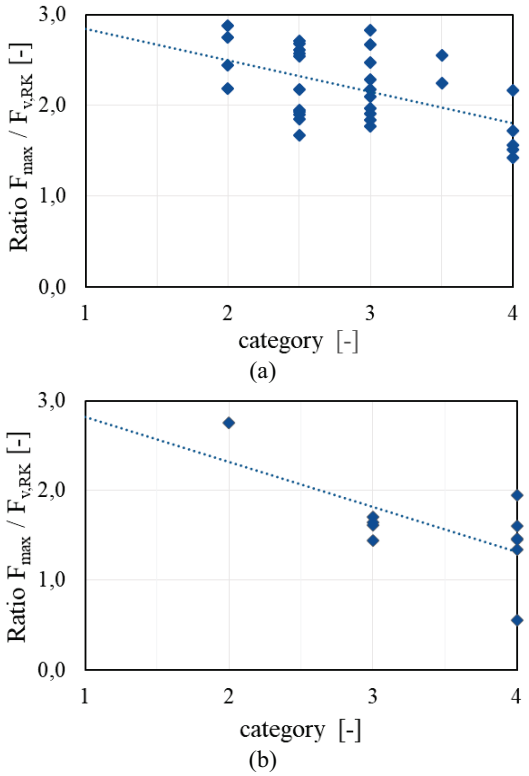

Figure 12: Load-bearing capacity per nail depending on the category, (a) Type I, (b) Type II

6 SUMMARY AND CONCLUSION

A classification scheme which is based on the visual inspection of individual joints was successfully applied and confirmed. It could be shown by investigating joints of aged nail trusses that a lower bearing capacity was reached on average with a decreasing rating.

In addition, the rating can also predict the possible form of failure, such as the preliminary splitting of the wood so that the nails cannot form a yield hinge. Cracks indicate that the nails cannot develop their full load-bearing capacity. The category and assignment correspond to the quality of the joints in terms of their load-bearing capacity.

Regarding further research on aged nail trusses, experiments should be carried out on complete trusses. An assessment of the load-bearing behaviour of the intact trusses is missing because only joints and their parameters have been investigated so far. This could be used to describe further factors, such as bending or buckling.

In addition to other component tests in the future, an exact evaluation of the load-bearing capacities measured so far per condition should be determined. This means that a percentage load-bearing capacity can be assigned per category of the connection according to Eurocode 5. The aim here is that the load-bearing capacity of worse joints may have to be corrected. For this purpose, further investigations are needed, for example, to check repair measures on aged structural members. The aim is to gain more knowledge about the compliance of the connections. Is it sufficient to hammer additional nails into a component to reactivate defective parts? How does a replaced board affect the whole system? Which joints need to be repaired?
Large-scale tests are necessary to answer these questions. In addition to determining the load-bearing capacity, other factors should also be considered. Due to the slenderness of the components, the fire protection class is often significantly lower than F30. A possible fire can have a direct influence on the nails and lead to an abrupt collapse of the construction. Measures should be considered to increase the stability in case of fire.

Another factor is the influence of moisture. Although the thinness of the component results in less swelling, the slenderness of the boards means that the full cross-section is probably saturated and could lead to a faster failure of the component in the long term.

In addition to these open points, an application of the evaluation scheme in existing buildings would be desirable. The target is to evaluate the load-bearing capacity of the roof structure without removing components in order to be able to plan possible replacement measures in an economical and sustainable way.

TESTING OF CONNECTIONS TAKEN FROM OLD NAILED ROOF TRUSSES

Sascha Schwendner[1], Lars Völlmecke[2], Phien Ho[3], Jens Fischer[4], Werner Seim[5]

ABSTRACT: Experimental testing of nailed connections taken from old roof trusses is presented in this paper. To enable the further use and preservation of nailed roof trusses, it is important to understand how the nail corrosion and aging processes of steel and wood affect the load-bearing capacity and deformation behaviour of such structures. The hypothesis was investigated whether corroded nails allow an increase in load-bearing capacity. Several old and new joints were tested in a first test series, and the results were very promising regarding the initial assumption. However, more tests must be carried out to verify the results.

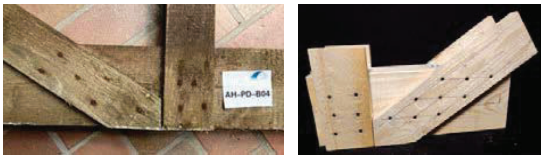
KEYWORDS: Nailed Connection, Corrosion, Degradation, Preservation, Withdrawal, Shear Loaded

1 INTRODUCTION

Connections with nails experienced a real boom in the middle of the 19th century and often turned out to be the construction method of choice, especially in times of material and resource scarcity. In addition, labour costs were significantly lower than today, which meant that the large amount of time required to create the trusses with many fasteners was still economical. Nevertheless, nails were not allowed for load-bearing purposes at the beginning of the 20th century in Germany until they were established as widely accepted fasteners through extensive basic research in the 1930s [1,2].
The combination of comparatively small timber sections and nails led to the development of trusses, which achieved large spans with a minimal use of materials. Moreover, nails were not subject to patent protection and could also be installed by untrained laborers, two important advantages compared, for example, to connections with dowels.

A large variety of different types of roof trusses were developed over the years. The load-bearing capacity of nailed trusses might be questioned today when it comes to discussing further use and preservation. Takanashi et al. [3] have already suggested an increase of the load-bearing capacity of nailed connections from existing structures based on their pull-out tests on artificially aged nail joints.

The aim of this paper is to investigate the load-bearing capacity of aged timber joints and the influence that corrosion of nails can have on this. Against this background, an investigation into how aging, especially nail corrosion, affects the load-bearing capacity and the deformation behaviour of the nailed joints was undertaken. The basic assumption of a potential increase in the load-bearing capacity due to partially corroded nails was investigated by tests on aged joints from nailed roof trusses taken from existing buildings. The truss nodes were examined with a newly developed testing device. Additional tests were carried out on single components to analyse their specific properties and determine parameters. This can provide conclusions about differences between the aged connections and new construction. Therefore, geometrically identical node connections were produced with new materials and tested (see Figure 1). All test results will be compared and discussed in the following.



(a) (b)

Figure 1: *(a) Type-I_old: joint B04 and (b) Type-I_new: joint SV-1947-01*

2 EXPERIMENTAL TESTING

In order to be able to investigate the behaviour of aged nodes, trusses were chosen from a structure which had been used primarily for roofing a car wash and later a beverage store. After demolition, the trusses were stored

outside under a tarp sheathing for several years (see Figure 2). This structure has been exposed over time to different climatic conditions, which have caused significant corrosion at the joints and local cracks to appear in the timber. On the other hand, some nodes are completely undamaged, so, there was a wide range between intact and considerably damaged nodes.

2.1 TESTING PROGRAMME

The test programme consists basically of two groups. The elements selected for the first group (Type I-old) are taken from the original trusses. These specimens showed cracks in the timber and corrosion of the nails, together with irregularities of the nailing pattern.
The elements selected for the second group (Type I-new) were made with new materials and served as a reference to evaluate the load-deformation behaviour of aged elements (see Figure 1). The specimens in the second group are identical to those taken from the trusses to be comparable to each other.

Figure 2: *Roof trusses*

In a first step, parameter tests were carried out to get an initial impression of the quality of the materials which were used for the joints. The parameters determined were

- the density of the timber,
- the embedment strength of the timber,
- the tensile strength of the steel,
- the yield moment of the nails and
- the withdrawal strength of the nails.

In terms of timber materials, a distinction was made between strut and chord. The position in the truss beam does not play a role in the determination of the parameters for the nails.

An overview of the whole test programme is given in Table 1. The tests to indicate the specific properties and the tests on connections are listed here.

Table 1: *Overview of the test programme*

Number of tests	Old	New
Density ρ_k	27	18
Embedment strength $f_{h,k}$	16	16
Tensile strength $f_{u,k}$	20	8
Yield moment $M_{y,k}$	10	10
Withdrawal strength $f_{ax,k}$	18	10
Connection I-old	8	15
Connection I-new	8	15

2.2 DENSITY AND EMBEDMENT STRENGTH

The density of the timber in both groups was tested according to DIN 52182 [4]. The test specimens were dried until the weight dropped to under 0.1 %.

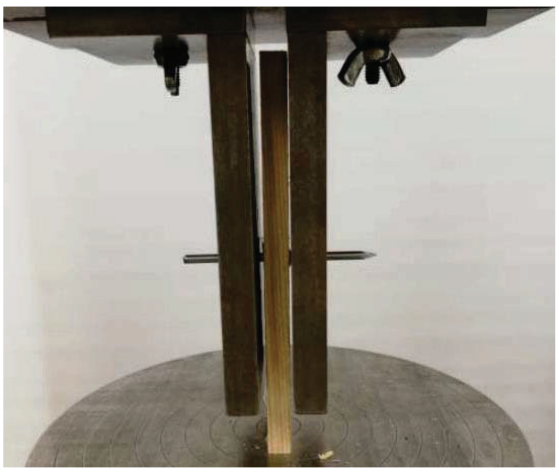

Figure 3: *Test set-up to determine the embedment strength of the timber*

The embedment strength of the timber was tested according to EN 383:2007 [5]. Figure 3 shows the test set-up to determine the embedment strength of the timer elements. The embedment strength is determined at a deformation of the specimen of 5 mm with the maximum force F, the thickness of the timber specimen t and the diameter of the fastener d, according to equation (1). Based on the code for all specimens, the loading was parallel to the grain.

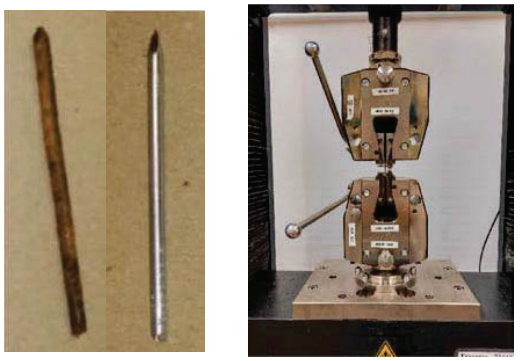
$$f_{h,k} = \frac{F_{\max}}{t \cdot d} \tag{1}$$

2.3 TENSILE STRENGTH AND YIELD MOMENT

The tensile strength of the fasteners was determined according to DIN 2002-001 [6] after the nail heads had been cut, whereby the clamping of the nails had to be reduced due to their length. This had no influence on the fracture pattern of the nails. Testing at a constant speed, the maximum strength is calculated with the maximum force and the cross-section for the original nominal diameter of 3.40 mm of the nail. Figure 4 shows the aged

https://doi.org/10.52202/069179-0529

and new nails and the test set-up to determine the tensile strength of single nails.



(a) (b)

Figure 4: *(a) Aged and new nail and (b) test set-up to determine the tensile strength of a single nail*

The yield moment of the nail was determined with a test set-up proposed by Werner and Siebert [7]. The construction is depicted in Figure 5. The nail in the frame can be deformed with a long cantilever with the length l_v. A load cell is located at the end of the lever arm. The yield moment of a single nail can be determined with the force F_{max} detected in the load cell and the length of the lever arm, see equation (2).

$$M_{y,Rk} = F_{max} \cdot l_v \tag{2}$$

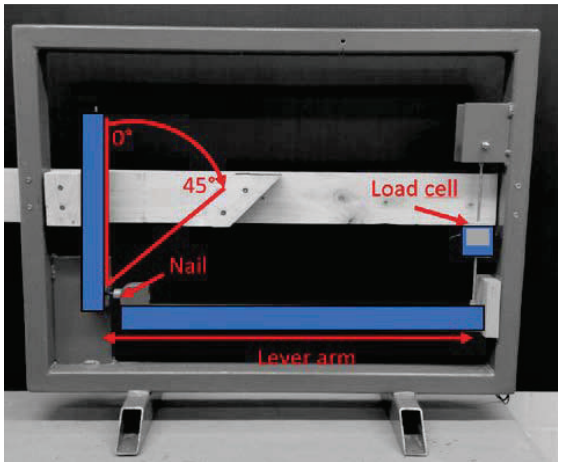


Figure 5: *Test set-up to determine the yield moment of a single nail*

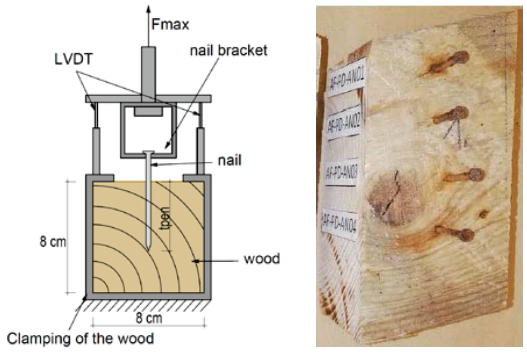
2.4 WITHDRAWAL STRENGTH

The withdrawal strength of the nails was determined according to EN 1382:2016-07 [8]. The test set-up is shown in Figure 6. To determine the withdrawal strength of the aged nails, parts of the truss beams were cut out to obtain realistic results. The test specimens were conditioned under a humidity of 65 ± 2 % at 20 ± 2 °C prior to testing.

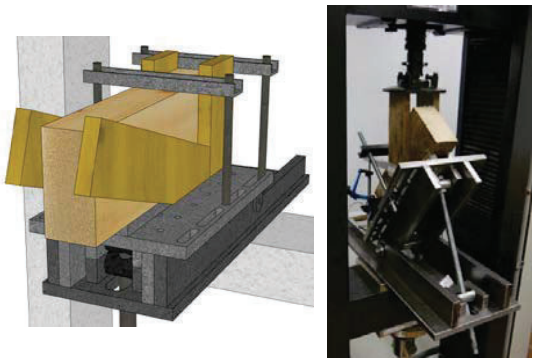


(a) (b)

Figure 6: *(a) Test set-up and (b) specimen for the determination of the withdrawal strength*

2.5 TESTS ON CONNECTIONS

In a second step, tests on joints cut out from the trusses were carried out. A special test set-up was developed for this so that the connection of posts and struts that act in a node can be tested separately, one after the other (see Figure 7). The set-up was designed in such a way that different inclinations of the struts could be tested. The chord of the truss beam ran continuously as one section between the two supports, whereas the posts and the struts were separated into two parts, each connected sideways to the chord. Each pair of posts or struts in the test set-up were loaded and could deform up to 50 mm, which ensured that the maximum load was achieved in the connections when the tests were carried out. The test set-up is depicted in Figure 7 (b). Due to the test set-up developed, it was necessary to test the posts first and then the struts.



(a) (b)

Figure 7: *Test set-up for joints (a), isometric view and (b) photo*

All tests were performed and evaluated under the monotonic loading protocol according to EN 26891 [9]. Displacement transducers were installed to measure the relative displacement between the chord and the posts and struts, respectively. The load-bearing capacity of the connections was, firstly, estimated at the mean value level to determine the loading rate. This resulted in a loading rate of 41.6 and 62.3 N/sec, depending on how many

https://doi.org/10.52202/069179-0529

fasteners were arranged in the node to be tested. This ensures that failure was achieved in a time span of 120 s ± 30 sec. The test specimens were conditioned under a humidity of 65 ± 2 % at 20 ± 2 °C prior to testing.

3 RESULTS AND DISCUSSION

The results of the experimental investigations are presented and evaluated in this section. Firstly, the experiments for determining the parameters of the single elements of the truss are discussed, followed by a consideration of the nodes. Finally, the 5 % fractile values are derived from experimental results which are then compared with the characteristic values from EC 5 [10]. This makes it possible to compare whether the aged trusses have similar properties to the nodes created with new materials. The values according to EC 5 are calculated as follows:

$$f_{h,k} = 0.082 \cdot \rho_k \cdot d^{-0.3} = 0.082 \cdot 350 \cdot 3.4^{-0.3} = 19.9 N/mm^2 \quad (3)$$

$$M_{y,k} = 0.3 \cdot f_{u,k} \cdot d^{2.6} = 0.3 \cdot 600 \cdot 3.4^{2.6} = 4336 Nmm \quad (4)$$

$$f_{ax,k} = 20 \cdot 10^{-6} \cdot \rho_k^{\,2} = 20 \cdot 10^{-6} \cdot 350^2 = 2.45 N/mm^2 \quad (5)$$

3.1 MATERIAL PARAMETERS

Table 2 summarises the parameters determined for the elements from the trusses and compares them to the specifications according to EC 5. The values are always given as characteristic values. The exact number of samples and the coefficient of variation (COV) are also given.

Despite considerable signs of aging of both nails and wood, the test results meet the specifications of EC 5 regarding density, embedment strength and tensile strength.

(a) (b)

Figure 8: *(a) Tensile failure of old and (b) new nails*

In terms of tensile strength, it is noticeable that the new nails have a significantly higher characteristic value. This is probably due to the standardised production and better steel quality compared to the nails from the old truss. Only the yield moment and withdrawal strength exhibit shortcomings for the specimen taken from the aged truss.

Table 2: *Truss Type I-old: results of parameter testing – characteristic values*

Parameter			Value	n [-]	COV [%]
Density ρ_k [kg/m³]		chord	401	27	1.6

** minimum value*

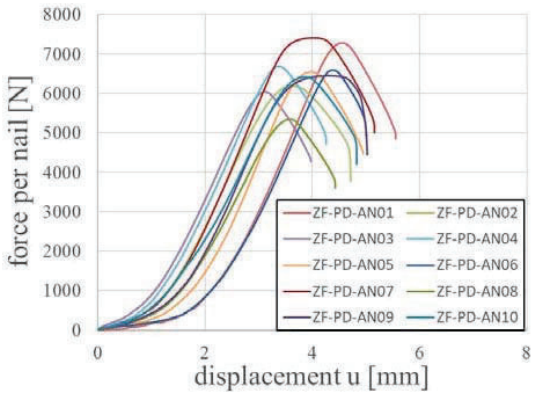

Figure 9: *Tensile strength test results with corroded nails*

Tensile strength

Three different test series were carried out to determine the tensile strength of the nails. Nails with corrosion were taken from the aged roof trusses for the first test series. The second series of tests was also on nails from aged roof trusses but with the difference that the nails were galvanized. This layer protected the nails from corrosion. The third test series was on new nails. When testing the tensile strength of the nails from the first test series, it was interesting to see failure always occurring in a zone of the nails which was originally situated close to the contact surface between the middle and side parts. This can be an indication of slightly higher corrosion in the small gap between the two timber parts. The specimens tested are

depicted in Figure 8. The test results are shown in Figure 9 to 11.

Yield moment

A very homogeneous result with a low COV is observed for the yield moment, both for the old and new nails. It can be seen that the old nails only achieve about 2/3 of the yield moment of the new nails. The value achieved by the old nails corresponds to that calculated according to EC5. New nails, thus, achieve significantly higher yield moments. The result of each test is given in Table 3.

Withdrawal strength

The withdrawal strength is generally subject to a high degree of scattering, which is why the results are not very robust and, together with the characteristic value, the minimum value determined in the tests is given in Table 2. Consequently, further tests are required. Old nails were assigned their original diameter for the calculation of the withdrawal strength due to the small amount of corroded material. The result of each test for the old nails is given in Table 4. The test results for corroded nails taken from the first test series with the tests AF-AN-01 to -09 are shown in Figure 12. The test results for galvanized nails taken from the second test series with the tests AF-BN-01 to -10 are shown in Figure 13.

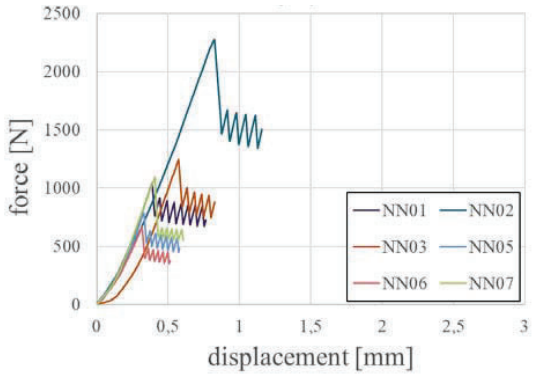

Figure 14: *Withdrawal strength test results with new nails*

Embedment strength

The test specimens for the embedment strength test are shown in Figure 15. As specified in the standard, all tests were performed perpendicular to the grain. The characteristic value of the embedment strength is almost identical for the chord and the strut, but the strut shows a significantly higher scattering. Results are summarised in Table 2.

Figure 15: *Embedment strength: specimens after the test*

3.2 TESTS ON JOINTS

Regarding the experimental tests on the connections, eight different nodes were cut out of two beams (A and B), and the posts and the struts were tested in each case. The results are summarised in Tables 6 to 9.

The connection of the struts could generally take a higher load per nail than the connection of the posts. This was most probably due to the larger contact area and the greater friction associated with it. Additionally, the spacing and the edge-distance of the fasteners were larger compared to the posts. Typical load-displacement curves of connections of struts and posts are depicted in Figure 16.

The comparison between the old joints and the new joints are shown in Figure 17. The average load-bearing capacity across all the tests of a series evaluated here can be considered similar for the old and the new connections. Nevertheless, the different deformation behaviour of the individual tests is clearly visible. The new nodes have significantly higher stiffnesses than the old ones. In addition, a hardening can be seen in the old nodes after about 5 mm of deformation. This could be due to a larger hole clearance in the old nodes or corrosion of the nails.

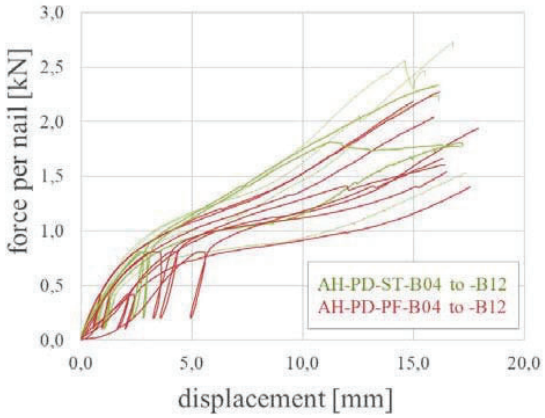

Figure 16: *Load-displacement curve – comparison between old strut and post*

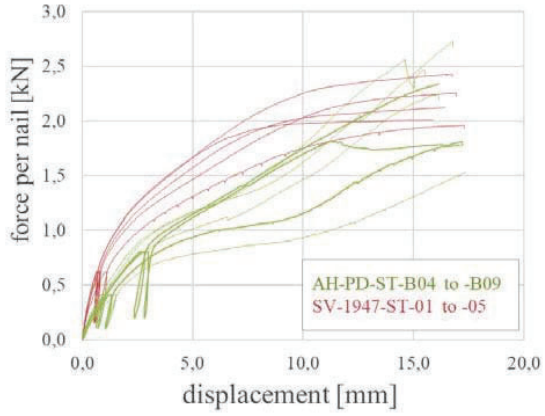

Figure 17: *Load-displacement curve – comparison between old and new joints*

The comparison between the load-bearing capacity per nail for Type I-old and I-new is presented in Table 10. The evaluation shows the higher load-bearing capacity of

https://doi.org/10.52202/069179-0529

Type I-old. Although the values of the old joints are scattered to a greater extent, the capacity of I-old connections exceeds that of the I-new connections slightly. The larger variation of Type I-old can be explained by different degradation conditions. Otherwise, it became apparent that Type I-new performed better in terms of initial stiffness.

The initial assumption that the "ageing" of joints could improve the load-bearing capacity due to nail corrosion seems to be partially confirmed, especially regarding the significantly lower tensile strengths and yield moments of the old nails in the testing of the individual parameters. Despite these lower strengths, higher load-bearing capacities can be achieved than with the new joints. However, it can also be seen that the assumed effect of the load increase does not seem to be significant at all. There is a clear scattering of the results, which refers mainly to the parameter testing. further investigations are still required to be able to assess whether aged constructions with corroded nails always have a higher load-bearing capacity.

Table 10: *Load capacity per nail for Types I-old and I-new with characteristic and mean values*

	EC5					836

4 CONCLUSIONS AND OUTLOOK

Test on connections which were taken from old, nailed trusses showed a good agreement between experimental results and characteristic resistance according to EC 5. This also applies to the relevant parameters, which are the tension strength and yield moment of the nails and embedment strength of the timber. Nevertheless, a positive effect of aging, such as an increase of the rope effect due to the slightly corroded nails, could not be confirmed. On the other hand, no negative effect of aging could be detected.

The large scattering of the withdrawal strength for the old connections indicates that this phenomenon should be studied in more detail. Another observation concerns the different condition of the joints in terms of spacing and edge distance, as well as cracks in the timber. An assessment schema to consider different forms and levels of irregularities is presented by Völlmecke et al. [11].

INFLUENCE OF MOISTURE CONTENT ON THE ASSESSMENT OF DECAY LEVELS BY MICRO-DRILLING MEASUREMENTS IN WOODEN FOUNDATION PILES

Michele Mirra[1], Giorgio Pagella[2], Wolfgang Gard[3], Geert Ravenshorst[4] , Jan-Willem van de Kuilen[5]

ABSTRACT: In the historic city centre of Amsterdam (NL), the most widespread foundation system consists of wooden piles. With the aim of modelling and predicting remaining service life of these foundations and the piles in particular, one of the possible methods for collecting data and monitoring their condition consists of micro-drilling (MD) measurements. This work evaluates the reliability of MD measurements in identifying decayed portions and specific features of wooden foundation piles, considering different moisture content (MC) values. To this end, 24 segments were selected, sawn from wooden piles extracted from site, and having time in service (TS) of 2 to 294 years (with reference to 2021, the year of extraction). 240 MD measurements were conducted at varying MC values of 7% to 212%. The obtained MD profiles showed for all TS a slight decrease in drilling resistance when increasing MC. However, from the MD signals it is possible to reliably detect the areas affected by biodegradation phenomena (e.g. bacterial decay) along the drilling depth, regardless the MC of the segment or its gradient along the drilling depth. The present study contributes to research aiming at utilizing (in-situ) MD techniques for reliably assessing and quantifying decay and to be used in remaining service life planning of wooden foundation piles.

KEYWORDS: Wooden foundation piles, Micro-drilling, Moisture content, Biodegradation, Service life prediction.

1 INTRODUCTION

The utilization of wooden piles as foundation system of historical or existing buildings has been widespread throughout Europe. In this context, the city of Amsterdam (NL) constitutes one of the reference examples for such foundation structures, since it is estimated that eleven millions wooden piles are present, still supporting existing and historical buildings as well as bridges and quay walls. Given the essential function of these foundations and their spatial extension, the estimation of the remaining service life of the piles is crucial for arranging timely maintenance interventions. Therefore, an extensive experimental campaign has been started in cooperation with the municipality of Amsterdam [1], aimed at characterising the current state of wooden foundation piles [2],[3], as well as providing solid input for service life prediction models [4].

Among the available techniques for monitoring timber piles, micro-drilling (MD) measurements are a promising option, because extensive in-situ sampling of a large number of piles could be realized. Yet, the use of MD signals for decay quantification requires still attention [5], thus a preliminary investigation of the reliability of this method for the specific context of wooden foundation piles in Amsterdam was necessary, including the development of a drill for underwater use.

When performing in-situ MD measurements on the piles, their moisture content (MC) is above fibre saturation point. Thus, it is important to ascertain that, also in submerged conditions, decayed portions of the cross section of the piles are correctly detected from the MD signals.

This work aims to assess whether MD measurements can provide reliable information on the decay levels of wooden foundation piles, independently of their moisture content (MC). These biodegradation phenomena on submerged wooden piles are caused by erosion bacteria [6]. The outer portion of the cross section is usually subjected to bacterial decay, since erosion bacteria can more easily attack the less durable sapwood [7]. Such decayed areas should also be visible from MD signals, independently of the actual MC, as this parameter is in principle unknown for the piles on site.

However, previous research works have shown opposite results on the effect of MC on MD measurements, showing that drilling resistance can both decrease [8] or

increase [9],[10] with increasing MC. This is because the outcomes from MD measurements can be influenced by different parameters besides MC itself, such as drill and feed speed, drilling depth, wood species, all factors influencing the shaft friction along the drill [8]–[10]. In light of these uncertainties, the reliability of MD measurements in correctly identifying decay in wooden foundation piles was evaluated in the present study, considering different MC values.
More specifically, segments from wooden foundation piles with a time in service (TS) ranging from 2 to 294 years (with reference to 2021, when their extraction took place) were selected, and MD measurements were conducted at varying MC values between 7% and 212%. To confirm large decay levels identified with MD measurements, compression tests were also conducted on the pile segments, after submerging them under water.

2 MATERIALS AND METHODS

2.1 MATERIALS

In this work, 8 wooden foundation piles were selected:

- 2 piles from 1727 (TS = 294 years as of 2021);
- 2 piles from 1886 (TS = 135 years as of 2021);
- 2 piles from 1922 (TS = 99 years as of 2021);
- 2 piles from 2019 (TS = 2 years as of 2021).

The piles from 1727, 1886, and 1922 were retrieved from the foundations of the piers of two bridges in the city centre of Amsterdam [3], whereas those from 2019 were extracted from a separate testing field [2] in the Overamstel area (Figure 1).

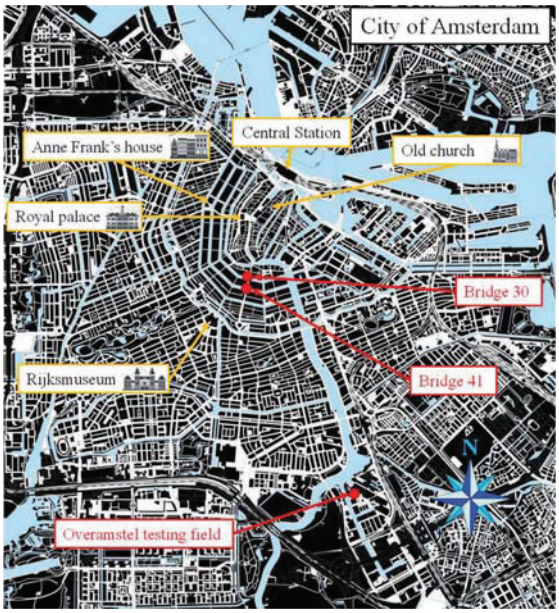

Figure 1: *Map of Amsterdam and locations (in red) from where the piles were extracted: to better highlight their position, some of the main monuments of the historic city centre are also reported as a reference. Adapted from [11].*

The piles had length of approximately 14 m, and diameters ranging from 175 to 290 mm at the head, and from 130 mm to 230 mm at the tip. All piles were made of spruce (*Picea abies*), with the exception of one pile from 1886, made of fir (*Abies alba*), and one from 2019, made of pine (*Pinus sylvestris*).
The retrieved piles were all subdivided in smaller segments, representative for the head, middle, and tip part of the piles (see also Section 2.2), for a total of 24 segments: Table 1 reports a detailed overview of the tested pile segments, their TS and MC range.

2.2 METHODS

2.2.1 General

The extracted full-length piles were cut in three parts (head, middle, tip), and delivered to TU Delft Stevin II Laboratory. From each part, a smaller segment to be tested in compression (Section 2.2.4) was sawn, having length equal to six times its diameter, following EN 14251 [12]. In this way, 24 segments were obtained (6 for each TS, see again Table 1) having lengths of 900, 1350, and 1800 mm, depending on their diameter. All segments were kept under water for two weeks to represent the on-site submerged conditions, and were characterised in terms of wet density [13] and moisture content, determined through the oven-dry method [14]. These compression tests allowed to mechanically characterise the pile segments, and to detect the presence of biodegradation phenomena (especially for the older piles), corresponding to a reduction of compressive strength with respect to fully sound samples.
MD measurements were performed on these segments, evaluating their reliability in capturing the features of the cross section (e.g. sound or decayed sapwood, knots, and so forth) for different MC values. This analysis was conducted considering the following two scenarios:

1. Assessment of the possible influence of different MC values referred to a whole segment on the corresponding drilling resistance (DR), thus an analysis at *global segment level* (see Section 2.2.3);
2. Evaluation, with reference to submerged conditions, of the possible influence of the MC gradient along the drilling depth on the MD signals, thus an analysis at *cross-sectional level* (see Section 2.2.4).

Table 1: *Overview of TS and MC of the tested pile segments.*

Number of segments	TS (years)	MC range (%)
6	294	14–212
6	135	8–57
6	99	12–100
6	2	7–84

2.2.2 Compression tests

Mechanical testing was performed to determine the compressive strength of the pile segments ($f_{c,0}$) in submerged conditions and confirm the information on the level of decay obtained with MD measurements. To this end, a displacement-controlled test setup was used (Figure 2), where the pile segments were subjected to an axial load in direction parallel to the fibres [12],[15].

The displacement between the two steel plates surrounding the pile segment was monitored with four linear potentiometers, placed on the four edges of the top plate and connected to the bottom plate. Four additional linear potentiometers, screwed to the segment, measured its deformation. The sensors were placed along the lateral surface of the piles, at 90° from each other, and had a variable length equal to 2/3 of that of the specimen.

The tests were conducted at a displacement rate of 0.02 mm/s, and the compressive strength was derived from the ratio between the maximum force reached in compression by each specimen and its average cross-sectional area.

2.2.3 Execution of MD measurements at different MC values (analysis at global segment level)

The MD measurements were conducted with an IML-RESI PD400 drill (Figure 3a). This device provides the profiles of drill and feed amplitude against drilling depth as output [8]. All measurements were taken 300 mm below the top of each segment, in two orthogonal directions (A and B in Figure 3b; see also [3]), and at approximately 1 cm distance from each other for every direction. A drill speed of 2500 r/min and a feed speed of 150 cm/min were adopted; the drill bit was 400 mm long, with a thin shaft of 1.5 mm diameter and a 3.1 mm wide triangular cutting part, with hard chrome coating.

The first two MD measurements on a segment were executed in submerged conditions, immediately prior to its compression test (Section 2.2.2), and were also used to evaluate the influence of MC gradient along the drilling depth (see Section 2.2.4). Other four MD measurement-pairs were then taken during the drying process of each segment after the compression test, recording every time the weight of the segment and determining the corresponding global MC. Thus, a total of 240 MD measurements were conducted.

Since the outer decayed areas of the pile segments are linked to lower basic densities compared to sound wood, a correspondingly low drilling resistance is observed at the beginning and at the end of the MD signals, showing the degraded portion. In order to objectively define which part of the MD signal pertains to decayed areas, and which part to sound wood, the procedure already proposed in [3] was adopted. Thus, the average drilling amplitude (DA) of the drilling resistance (DR) profiles along the drilling depth H was firstly determined. Following [5], this is defined as:

$$DA = \frac{\int_0^H DR \, dh}{H} \quad (1)$$

Figure 2: *Setup for compression tests.*

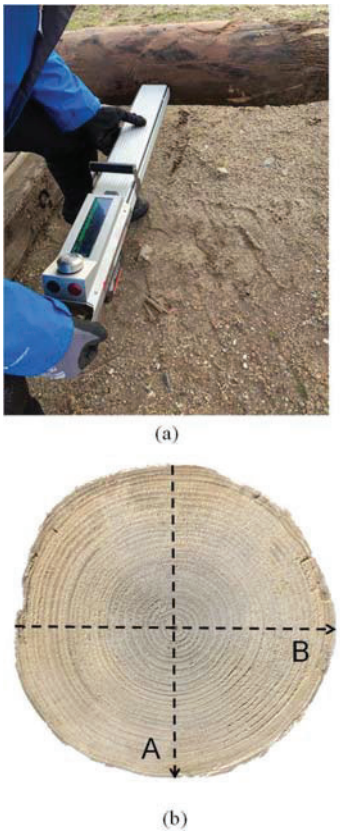

Figure 3: *Adopted MD device (a) and drilling directions (b).*

https://doi.org/10.52202/069179-0530

Then, the starting and ending sections of the signal portions identifying decayed areas were determined as the intersection between the average DA decreased by 30% and the MD profile [3] (Figure 4). This method has the advantage of detecting decayed areas relatively to the specific MD signal, without providing an absolute threshold in terms of DR. Finally, the independence from MC of the detected outer decayed portion was assessed.

2.2.4 Evaluation of MC gradient along the drilling depth (analysis at cross-sectional level)

After testing the segments in submerged conditions, the corresponding MC gradient along the drilling depth was determined as well [14], by retrieving five small prisms of dimensions 20×20×120 mm^3 (Figure 5). Sample 3 was taken in correspondence to the pith, whereas samples 1 and 5 included sapwood. These prisms allowed to detect the MC variations along the drilling depth: in this way, the influence of such variations on DR profiles could be evaluated for both sound and decayed pile segments.
Sound sapwood is associated to a higher density, but also larger MC than heartwood, whereas in presence of decay the basic density is reduced due to bacterial degradation, and the MC locally increases further. Thus, this analysis allowed to check that MD signals retrieved in underwater conditions can still enable the distinction between sound and decayed sapwood, independently of MC gradients.

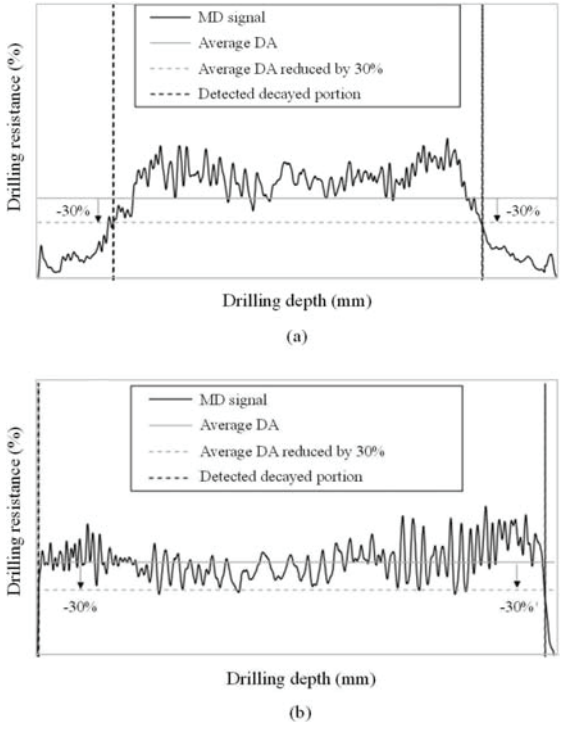

Figure 4: *Procedure adopted for determining the degraded portion of the pile segments from MD signals, corresponding to low drilling amplitudes at the beginning and at the end. Examples are shown in the case of a heavily decayed pile (a) and a sound pile (b). Adapted from [3].*

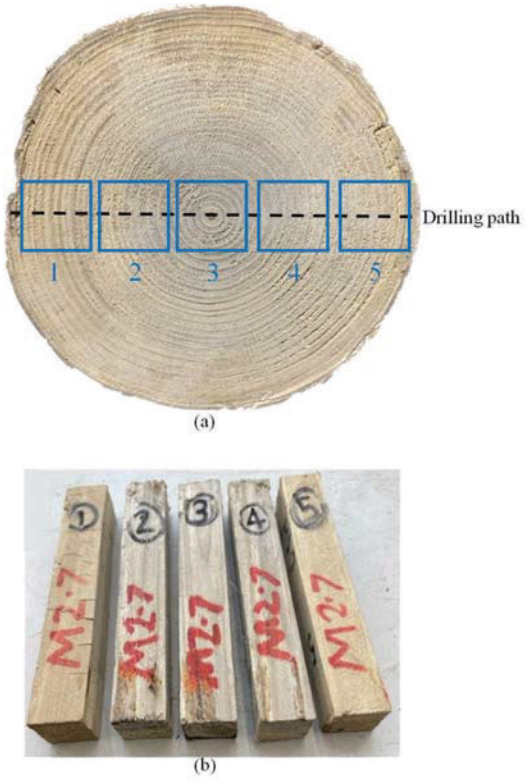

Figure 5: *(a) Location of the samples taken to determine MC variations among sapwood, heartwood, and pith; (b) example of prisms retrieved from a pile segment along the drilling depth.*

3 RESULTS

3.1 COMPRESSION TESTS

The 24 segments tested under compressive loading exhibited the values of compression strength $f_{c,0}$, wet density in submerged conditions ρ_w, and MC reported in Table 2.
A distinct drop in $f_{c,0}$ is observable for all pile segments from 1727, linked to large global MC values as well. Besides, as can be noticed, the wet density of such samples is comparable to that of piles from 2019: in combination with the large global MCs, this indicates a strong reduction of basic density due to bacterial decay for the pile segments from 1727. Such outcomes thus confirm the presence of biodegradation phenomena for the oldest piles, which were also detected with the MD measurements, as shown in the next section.
The other segments showed higher values of $f_{c,0}$, and closer to each other, suggesting that the extracted piles up to 1886 did not undergo significant decay. Only the 1886-2 segments exhibited lower compressive strengths, but these were also associated with low wet density and global MC.

Table 2: *Overview of the compressive strength of the tested pile segments after being submerged in water for two weeks; the corresponding wet density and moisture content is also reported. Samples with decay are reported in italic.*

Sample	$f_{c,0}$ (MPa)	ρ_w (kg/m^3)	MC of the segment (%)

1727-2-tip	5.8	784	139

3.2 MICRO-DRILLING MEASUREMENTS

Representative results from the 240 conducted measurements are shown in Figure 6 in terms of MD signals at different MC levels and TS.

In general, with the adopted drill and feed speed, it appears that a progressively lower drilling resistance is obtained when the moisture content increases. However, this does not influence the detection of specific features of a pile segment, such as denser sapwood for sound samples (Figure 6a-c), presence of an internal knot (Figure 6b), very low drilling amplitude when crossing outer decayed zones for the oldest pile segments (Figure 6d-e).

It is important to notice that this outer layer affected by decay and characterised by much lower drilling resistance could be detected, adopting the methodology described in Section 2.2.3, independently of the MC. This outcome, visible in Figure 6 for samples 1727-1-middle and 1727-2-head, was also obtained for all other segments from 1727, as shown in Table 3, reporting the detected decayed portions (calculated as average from those of each MD measurement-pair) as a function of the global MC of the segments.

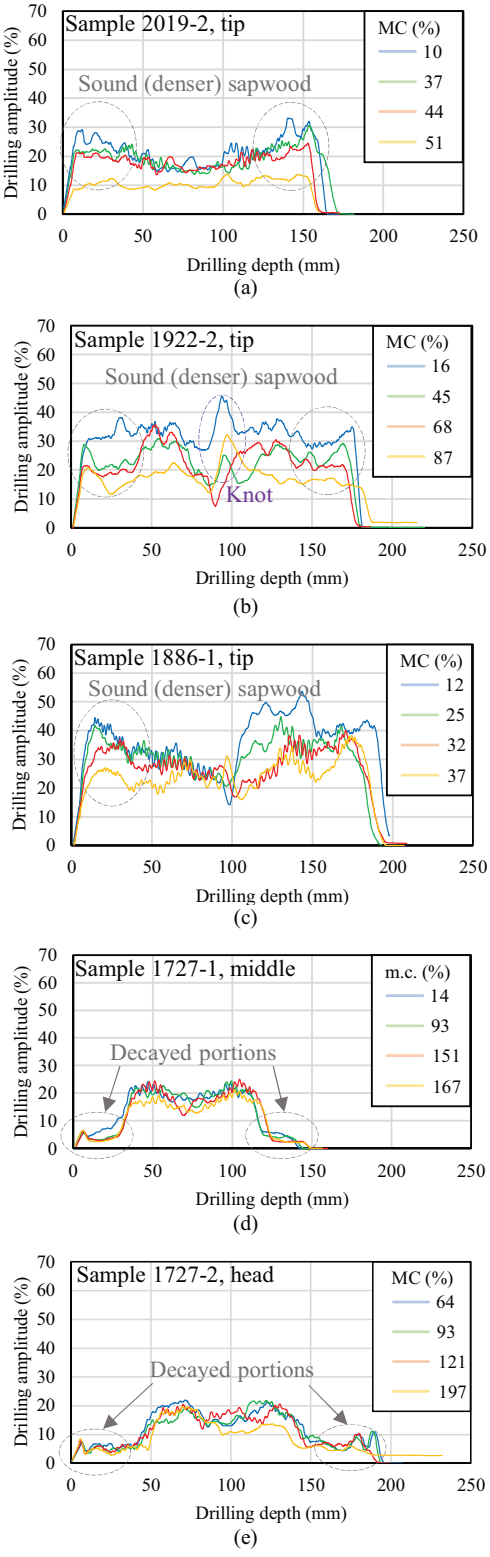

Figure 6: *MD signals (displayed in terms of a 100-mm moving average) ordered from lowest to highest MC for representative pile segments with TS = 2 years (a), 99 years (b), 135 years (c), and 294 years (d-e).*

https://doi.org/10.52202/069179-0530

Table 3: *Overview of the detected decayed portion, determined from the MD measurements according to the methodology presented in Section 2.2.3, as a function of MC for the 1727 samples.*

Samples with decay	Detected decayed portion (average from the two MD signals, mm)	MC of the segment (%)
1727-1-head	12	13
	10	94
	10	129
	9	153
	10	182
1727-1-middle	23	14
	25	93
	24	151
	24	167
	23	170
1727-1-tip	16	13
	17	88
	17	153
	17	188
	16	212
1727-2-head	40	64
	35	93
	36	107
	37	121
	36	197
1727-2-middle	34	105
	33	145
	36	164
	34	179
	35	184
1727-2-tip	24	84
	25	125
	26	139
	22	146
	26	175

As can be noticed, the zones of cross section affected by biodegradation phenomena only show small variations for different MC values (Table 3). This very limited scatter is unavoidable, as the MD measurements were conducted close to each other, but local variations along the drilling depth are very likely to be present.

The previous results referred to the MC of global segments, but they are also confirmed when examining at cross-sectional level the local MC gradients along the drilling depth (Figure 7). These MC gradients, determined with the five prisms retrieved from the cross sections of the segments (Section 2.2.4), show a typical profile, with larger MCs pertaining to the outer prisms (1 and 5 in Figure 5) containing sapwood.

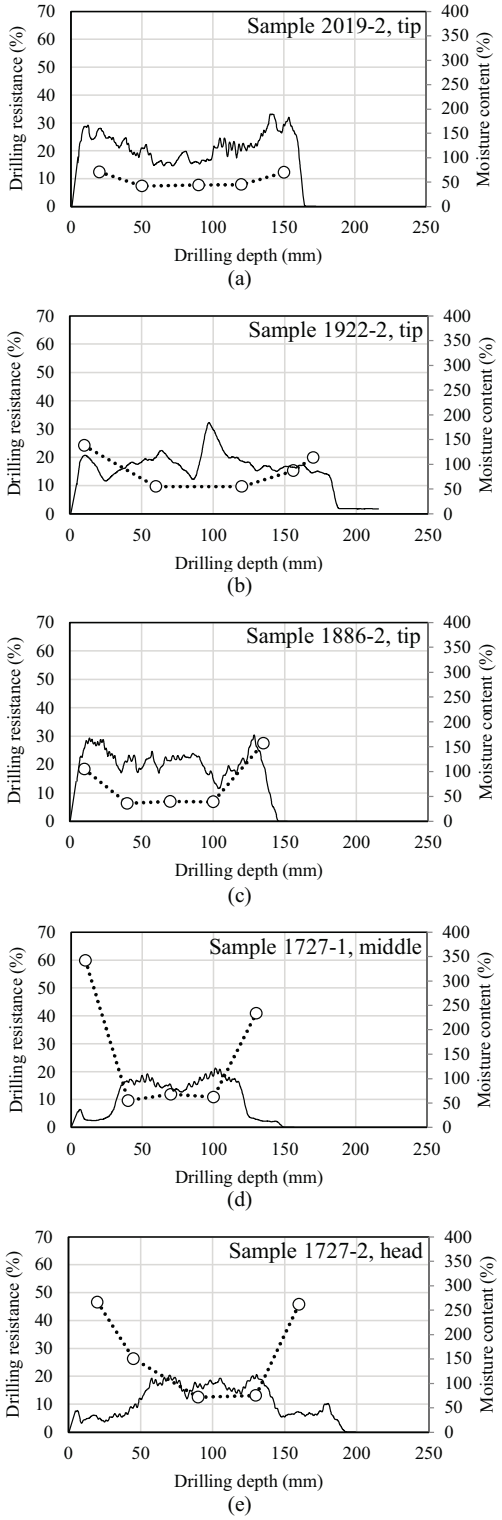

Figure 7: *Example of drilling resistance profile and MC gradient (dashed) for representative pile segments with TS = 2 years (a), 99 years (b), 135 years (c), and 294 years (d-e) in submerged conditions. For d-e, very large MC is observable in the decayed portions, which is not the case in sound samples.*

However, for sound cross sections (Figure 7a-c) the MCs range of prisms containing sapwood was 70–150%, whereas in decayed samples (Figure 7d), values up to 350% were determined.
On the contrary, when considering MCs of the heartwood and juvenile wood portions, these always fall in the range of 40–60%, also in the case of the decayed samples. This outcome is confirmed by the MD signals as well: the drilling resistance in the inner part of the cross section is in all cases close to 20%; for sound sapwood the larger amplitude correctly corresponds to its larger density, whereas in presence of decay a large drop in the drilling resistance is observed.

4 DISCUSSION

Based on the obtained results, it appears that MD signals can reliably identify decayed portions and their extent along the drilling depth independently of the MC (see once more Figure 6d-e). This outcome is relevant, since the determination of the actual MC of a large number of piles on site would not be practically feasible.
Furthermore, the distinction between sound and decayed parts of the cross section is also possible when comparing MD signals with the MC gradients determined in submerged conditions. All sound samples showed MC gradients in line with those expected for green spruce (around 50% in heartwood and 120% in sapwood [16]), confirming the results from MD signals and compression tests. Biodegradation phenomena seemed therefore to be limited to sapwood, since the heartwood and juvenile wood of the decayed pile segments featured MC and DR values comparable to those of the sound specimens (Figure 7).
Thus, the highly decayed portions of the degraded pile segments could be correctly identified with MD measurements, and were coherent with the low compressive strength obtained for these samples (see once more Table 2). Since the signals reported in Figure 7 refer to submerged conditions, it can be concluded that when performing MD measurements underwater, the specific features of the cross sections of the wooden foundation piles can be correctly captured, and independently of the MC gradient.

5 CONCLUSIONS

This work presented an extensive study to evaluate the underwater use of micro-drilling (MD) measurements for assessing the state of wooden foundation piles. In particular, the influence of their moisture content (MC) in the identification of largely decayed portions was evaluated for piles retrieved from the historic city centre of Amsterdam.
Thus, 24 pile segments having time in service (TS) from 2 years to 294 years were subjected to 240 MD measurements at various MC values, ranging from 7% to 212%. Compression tests were also performed on the segments after submerging them under water for two weeks, to determine their load-carrying capacity and compressive strength. These tests also allowed to confirm the decayed pile segments identified with MD measurements, for which a much lower compressive strength and a larger MC were determined.
For the adopted drill and feed speed, a decreasing drilling resistance with increasing MC was detected. Since in practice the on-site MD measurements would be conducted underwater by divers, the MC of the piles is in principle unknown. Yet, it has been proved that the detection of specific features or decayed portions of the cross section through the drilling profiles is not influenced neither by the global MC of a segment, nor by the MC gradient within its cross section. Thus, based on the obtained results, biological degradation phenomena can be reliably identified with MD signals also in underwater conditions, where it is not necessary to know the exact MC.
The results of this study can be further integrated with the data from the in-progress experimental campaign on additional pile segments, and can contribute to the research framework supporting the use of non-destructive testing for estimating decay, (residual) load-carrying capacity, and remaining service life of wooden foundation structures.

ACKNOWLEDGEMENTS

The Authors gratefully acknowledge the Municipality of Amsterdam, for having funded the research study and provided the analysed wooden foundation piles, as well as Michael Lee and Ruben Kunz, for their help in determining the moisture content gradients.

A STUDY ON COORDINATED EXPRESSION OF THE SEISMIC DIAGNOSIS SCORE AND ITS APPLICATION TO RETROFIT REINFORCEMENT PROJECTS UNDER COST CONTROL FOR JAPANESE TIMBER HOUSES

Daisuke Shimizu[1], Chikako Tabata[2], Yoshito Tomioka[3]

ABSTRACT: The seismic diagnosis score for a conventional timber house in Japan is normally calculated as the ${}_{ed}Q_p/Q_r$ ratio. This study presents its coordinated expression as (Q_r, ${}_{ed}Q_p$), making it possible to depict the individual effect and contribution of each specification employed in a retrofit reinforce project as a whole. This method could be used to knockdown not only the change in the force capacity of the whole building but also the level of independent elements, such as a wall or roof. Combining this method to add cost dimension to the coordination as (Q_r, ${}_{ed}Q_p$, *cost factor*) may be feasible in serving as a rational design tool that can achieve a better cost-performance in retrofit design practice. Four factors exist for each of the individual elements of retrofitting performed in seismic retrofit reinforcement, that is, required strength, potential strength, cost for applied element, and cost for eliminated element. In this study, a theoretical method is used to express each factor in a unified manner. This possibility is confirmed by applying the method to real retrofit reinforce design experiences obtained in Mie Prefecture, Japan.

KEYWORDS: Structural design method, Construction cost, Japanese conventional timber house

1 INTRODUCTION

This study explains the idea of the coordinated expression of the seismic diagnosis score and discusses its possible applications as a rational tool in designing retrofit reinforce projects of Japanese conventional timber houses. Its feasibility is estimated by applying it to real design experiences obtained in Mie Prefecture, Japan.

2 COORDINATED EXPRESSION OF THE SEISMIC DIAGNOSIS SCORE

2.1 BASIC THEORY

The seismic diagnosis score, used for the retrofit reinforcement of timber houses is calculated as follows:

$$S = {}_{ed}Q_p/Q_r \quad (1)$$

where S (non-dimensional) = seismic diagnosis score, ${}_{ed}Q_p$ (kN) = potential strength; lateral force capacity of the structure and Q_r (kN) = required strength; necessary lateral resistance led from the weight of supported building part.

The index = 1.0 means that the structure achieves minimum seismic safety. Although this approach may be good for a simple representation of the safety degree in a single number, it lacks the guidance ability for conducting a design rationally and is not a reinforcement cost consideration method. This study proposes its coordinated expression as [1]:

$$\vec{S} = (Q_r, {}_{ed}Q_p) \quad (2)$$

where $\vec{S}$ (non-dimensional) = coordinated expression of the seismic diagnosis score.

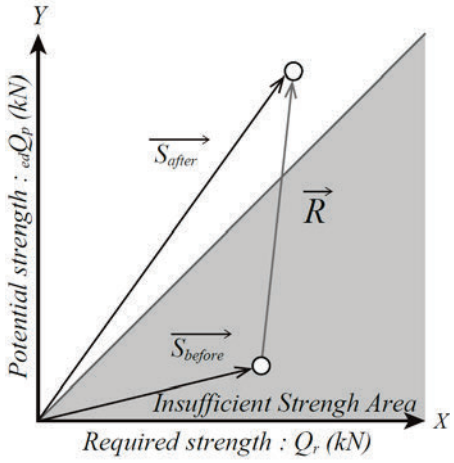

Figure 1: *Performance plot of the required strength vs potential strength*

[1] Daisuke Shimizu, Div. of Archi., Graduate School of Eng., Mie University, Japan, 422m406@m.mie-u.ac.jp
[2] Chikako Tabata, Assoc. Prof., Div. of Archi., Graduate School of Eng., Mie University, Japan, tabata@arch.mie-u.ac.jp
[3] Yoshito Tomioka, Professor, Div. of Archi., Graduate School of Eng., Mie University, Japan, tomioka@arch.mie-u.ac.jp

https://doi.org/10.52202/069179-0531

Figure 1 presents a two-dimensional (2D) theoretical coordination system. On this surface, the seismic performance of the existing building to be reinforced is plotted as "before," while the achieved performance is plotted as "after." Accordingly, the performance improvement due to reinforcement is expressed as a vector connecting both as $\vec{R}$.

$$\vec{R} = \overrightarrow{S_{after}} - \overrightarrow{S_{before}} \quad (3)$$

The minimum safety (i.e., Index = 1.0) is now expressed as a line of $Y = X$. The reinforcement design attempt is recognized to extend the reinforcement vector from "before" to "after," which is beyond the line.

Figure 2 shows breakdown into successive applications of reinforce elements. This case involves two elements, namely $\overrightarrow{E_1}$ and $\overrightarrow{E_2}$, representing two independent reinforcements that constitute the total. Reinforcement (E_1) is normally a combined elimination of a certain existing element (e_1') and an application of another specified element (e_1) that is structurally superior.

$$\vec{R} = \sum \vec{E} \quad (4)$$

$$\vec{E} = \vec{e} - \vec{e'} \quad (5)$$

where $\vec{E}$ = the specification vector representing the score transition due to the reinforcement of each element, $\vec{e}$ = the performance vector of the applied substitute element and $\vec{e'}$ = the performance vector of the eliminated existing element.

Using this expression, we understand the several observations of total reinforcements from all the structural elements employed in the design.
Figure 3 shows the further breakdown and characteristic vector of the element. The performance vector $\vec{e}$ of the structural element is normally cumulative according to its scalar amount (a: length (m) or area (m^2), typically). Therefore, it can be described as

$$\vec{e} = a \times \vec{p} \quad (6)$$

$$\vec{p} = (p_r, p_p) \quad (7)$$

where a (m and m^2) = scalar amount of the element, $\vec{p}$ = characteristic vector, p_r (kN/m, kN/m^2) = required strength of the element per scalar and p_p (kN/m, kN/m^2) = potential strength of the element per scalar.

2.2 COMBINED WITH THE COST DIMENSION

We consider the reinforcement design from a wider perspective by combining this method with a cost factor as an independent dimension. In Figure 4, we express this in a three-dimensional (3D) coordinate system combined with a cost factor. There are costs to apply the element (c_{ap}) and eliminate the element (c_{el}), which are different values.

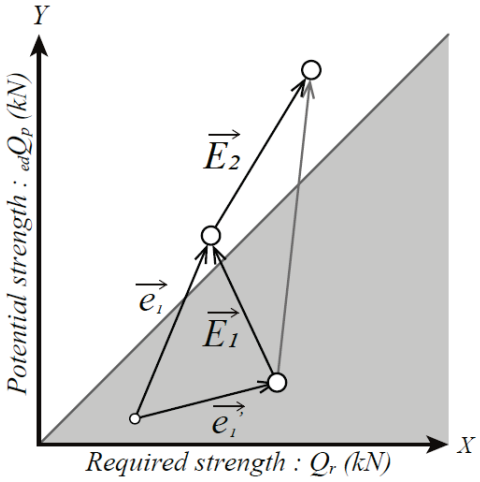

Figure 2: *Breakdown into successive applications of reinforce elements*

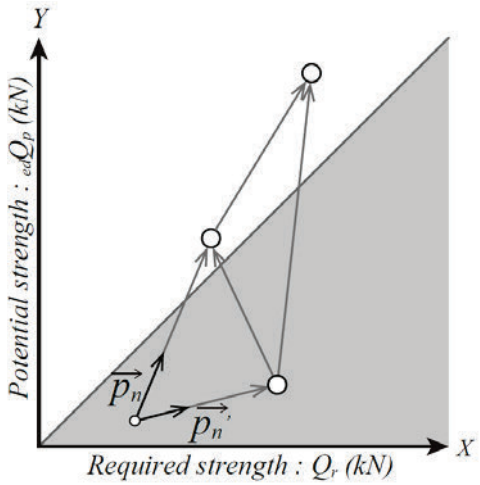

Figure 3: *Characteristic vector of the element*

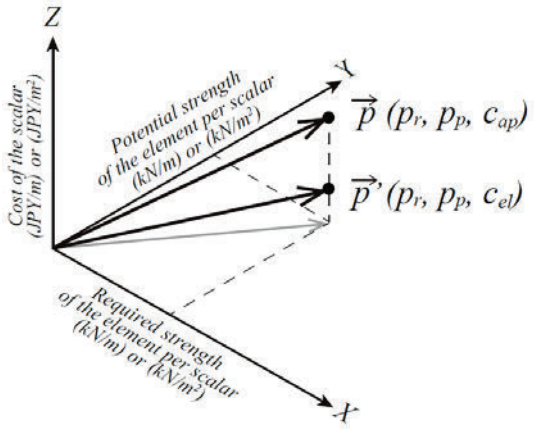

Figure 4: *Characteristic vector of the coordinate system combined with a cost dimension in a three-dimensional coordinate system*

https://doi.org/10.52202/069179-0531

We consider that it would be convenient to unify representation the four factors for the calculation. Therefore, we express the characteristic vector using a four-dimensional column vector as follows:

$$\vec{p} = \begin{pmatrix} p_r \\ p_p \\ c_{ap} \\ c_{el} \end{pmatrix} \quad (8)$$

where c_{ap} (JPY/m or JPY/m^2) = the cost per scalar for the applied element and c_{el} (JPY/m or JPY/m^2) = the cost per scalar for the eliminated element.

The characteristic vector can represent the element characteristics unifacially for both application and elimination. For the elimination, we multiply the characteristic vector by the elimination factor (F_{el}) as follows:

$$\overrightarrow{p'} = F_{el} \times \overrightarrow{p} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \end{pmatrix} \begin{pmatrix} p_r \\ p_p \\ c_{ap} \\ c_{el} \end{pmatrix} = \begin{pmatrix} p_r \\ p_p \\ -c_{el} \\ -c_{ap} \end{pmatrix} \quad (9)$$

where $\overrightarrow{p'}$ = characteristic vector of the eliminated element and F_{el} = elimination factor.

c_{ap} and c_{el} are transposed by multiplying by the elimination factor. Therefore, we can calculate the required strength in the first row, the potential strength in the second row, and the cost of application or elimination whichever is chosen in the third row.

The total reinforcement is expressed as the synthesis of all the above:

$$\vec{R} = \sum \vec{E} = \sum_n a_n(\overrightarrow{p_n} - \overrightarrow{p_n'}) \quad (10)$$

where a_n (m, m^2) = scalar of the nth characteristic element, $\overrightarrow{p_n}$ = nth characteristic vector of the applied substitute element and $\overrightarrow{p_n'}$ = nth characteristic vector of the eliminated existing element.

3 TRIAL ESTIMATIONS OF THE CHARACTERISTIC VECTOR

We explain herein the method for estimating the characteristic vector. A retrofit reinforcement is normally made by enforcing walls and changing roof materials.
For the walls, the characteristic strength and weight of materials are recognized by dividing the horizontal length (m) while fixing the height as 2.8 m.
For the roofs, the characteristic amounts were considered by dividing the surface (m^2).

A) Wall
The characteristic vectors of walls are calculated as follows:

1) The extra potential strength/length factor was taken from the book entitled "*MOKUZOJYUTAKU NO TAISHINSHINDAN TO HOKYOHOHO* (Seismic Diagnosis and Reinforcement on Timber Houses)" from Ref. [2]. Ref. [2] provides guidelines and explanations on the seismic diagnosis and reinforcement methods for Japanese timber houses.

2) The extra strength per length factor is calculated as follows:

$$p_r = 0.2 \times w \times g \times h \quad (11)$$

where *0.2* (non-dimensional) = theoretical coefficient to make the seismic force consistent at the time of a major earthquake with the evaluated value of the element's bearing capacity, w (kg/m^2) = weight of the specified wall per unit surface [3], g (m/s^2) = gravity acceleration and h (m) = height of the specified wall (i.e., 2.8 m is widely used).

3) The cost factors were taken from the recent report so-called "*BUKKABAN*." In Japan, "*SEKISAN SHIRYO"* [4, 5] and "*SEKISAN POKETTO TETYO"* [6] are the most popular publishers reporting the current construction and material costs of specified construction in each region. We prioritize Ref. [4] here.
We gathered information on the cost estimation from practitioners to fit the raw information of the combination of materials and construction for retrofit projects.

Figure 5 shows example characteristic vectors of the wall estimated by the foregoing.

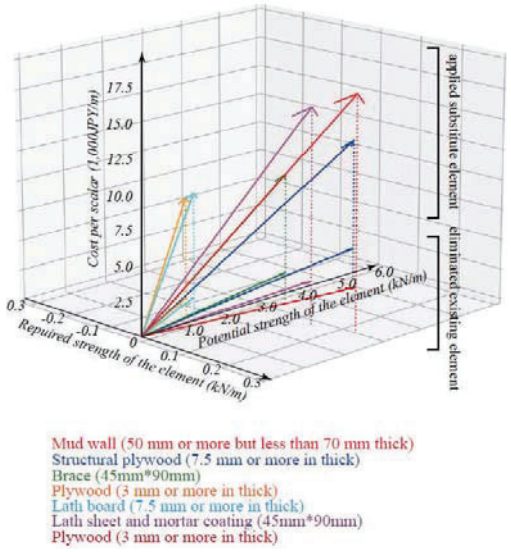

Figure 5: *Example characteristic vectors of the wall*

https://doi.org/10.52202/069179-0531

B) Roof

The characteristic vectors of roofs are calculated as follows:

1) The roof case is much simpler. Roofs normally do not affect strength accumulation but affect the weight reduction through the changing of roof materials. Therefore, the p_p is zero.

2) The extra strength per length factor is calculated as

$$p_r = 0.2 \times w \times g \tag{12}$$

where *0.2* (non-dimensional) = theoretical coefficient that makes the seismic force at the time of a major earthquake with the evaluated value of the element's bearing capacity, w (kg/m^2) = weight of the specified wall per unit surface [3], and g (m/s^2) = gravity acceleration.

3) The cost factors were taken from the recent report, "*BUKKABAN*."

Figure 6 shows example characteristic vectors of the roof estimated by the foregoing.

4 HOW TO USE THE THEORY IN THE STRUCTURAL RETROFIT DESIGN

4.1 COMBINED WITH THE CHARACTERISTIC VECTOR FOR PRACTICAL USE

There are many frequently used reinforcement methods at timber houses. Therefore, synthesizing vectors of application and elimination for each element is convenient (Figure 7). We define herein the element reinforcement vector $\overrightarrow{P_{syn}}$ calculated as follows:

$$\overrightarrow{P_{syn}} = \vec{p} - \overrightarrow{p'} = \begin{pmatrix} p_r \\ p_p \\ c_{ap} \\ c_{el} \end{pmatrix} - \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \end{pmatrix} \begin{pmatrix} p_r \\ p_p \\ c_{ap} \\ c_{el} \end{pmatrix} \tag{13}$$

where $\overrightarrow{P_{syn}}$ = element reinforcement vector.

A) Wall

Figure 8 shows an example of the element reinforcement vectors of the wall. These vectors are extracts frequently used in the reinforcement plans gathered from practitioners. We categorize the wall reinforcement work as follows:

1) Insertion: Insert a new wall where no wall exists.
2) Addition: Add an element to the existing wall.
3) Substitution: Substitute a structurally inferior existing wall with a structurally superior new wall.

Insertion uses $\vec{p}$ as is. Addition utilizes $\vec{p}$ of the added element only as is. Substitution is a combination of the characteristic vector of the eliminated existing structurally inferior element ($\overrightarrow{p'}$) and the characteristic vector of the applied structurally superior substitute element ($\vec{p}$).

Even when multiple elements are combined (e.g., a combination of structural plywood and brace), each characteristic vector can be combined and considered as an element reinforcement vector.

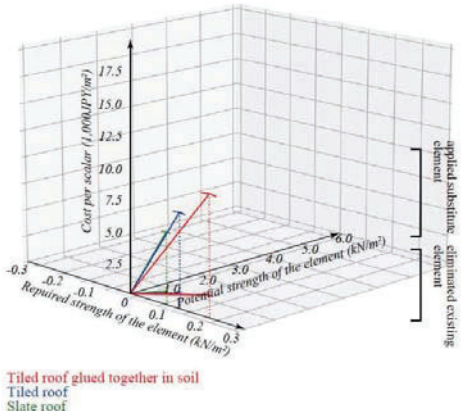

Figure 6: *Example characteristic vectors of the roof*

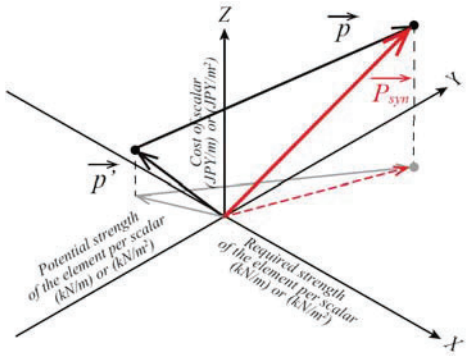

Figure 7: *Synthesizing vectors of application and elimination*

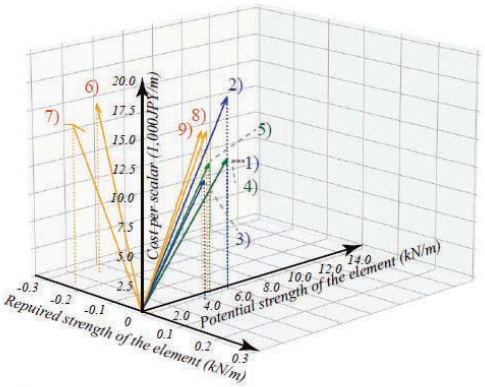

Figure 8: *Example of the element the reinforcement vectors of the wall*

https://doi.org/10.52202/069179-0531

B) Roof
Figure 9 shows an example of the element reinforcement vectors of the roof. For the roof, the heavy material roof is eliminated and substituted with a lighter roof. This can be considered a substitution for the wall case.

4.2 SELECTING THE MOST EFFECTIVE REINFORCEMENT

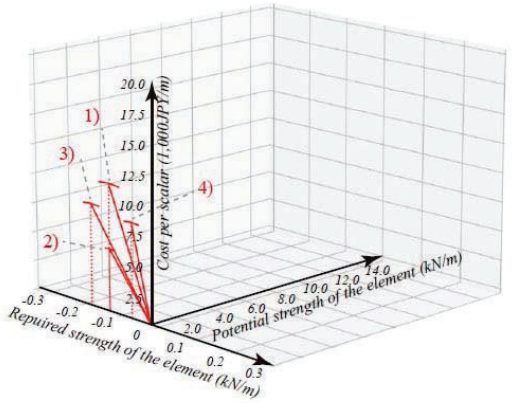
In seismic reinforcement, the required strength is reduced, for example, by changing the roof materials, while the potential strength is increased, for example, by reinforcing the walls. We consider the case in which the reinforcement method effectiveness is examined only by considering the transition between the required and potential strengths (i.e., using a 2D coordinate system). We can determine that the effective reinforcement is a scalar of inner product projected in the direction to the line $Y = -X$ (Figure 10) because it expresses a great effect on reduces the required strength and increases the potential strength. Therefore, when multiple reinforcement methods are considered, the most effective reinforcement approach is the one that result in the largest inner product, which can be calculated as follows.

$$\left(-\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}\right) \cdot \vec{P} = Max \tag{14}$$

By adopting our explained 3D coordinate system, we can consider the reinforcement cost in addition to the performance improvement (Figure 11). The reinforcement beyond the $Y = X$ perpendicular line must eliminate the existing elements and apply new ones. This means that both elimination and application costs will be required as the reinforcement cost. In some cases, the reinforcement vectors considered as inefficient in a 2D coordinate system (i.e., the reinforcement method that increases p_r and p_p because it does not require eliminate element.) may be optimal from a cost-effective standpoint.

4.3 VISUAL REPRESENTATION OF PERFORMANCE IMPROVEMENT ON CAD SCREEN

We believe that our method can be very useful in practical design works. The software [7] used for seismic reinforcement design is widely used in Japan. By combining our method with this software, the performance improvement caused by the element changes can be displayed on the same screen in real time (Figure 12). We can assume that the 3D theory is maintained here. However, the transition of Q_r and ${}_{ed}Q_p$ are examined in a 2D coordinate system with the change of the method of display. The reinforcement cost is provided as an accumulation on a separate adjacent graph.
The seismic reinforcement design is performed under various constrained conditions, such as the house layout and a limited budget. The ability of designers to watch the optimal cost efficiency in each case can be used as a rational design tool.



1) 【Substitution】 Tiled roof glued together in soil → Tiled roof
2) 【Substitution】 Tiled roof glued together in soil → Tiled roof (Reuse existing tiles)
3) 【Substitution】 Tiled roof glued together in soil → Slate roof
4) 【Substitution】 Tiled roof → Slate roof

5 CONCLUSIONS

This study explained the method of the coordinated expression of the seismic diagnosis score, derived relevant definitions, and demonstrated how to use the theory in practical design works to enable designers to observe cost efficiency during the design phase.

ACKNOWLEDGMENTS

We are grateful to *KADOWAKI* for theorizing on the early stages of this study, and to *IKEZAWA Associates* for advising us on the current state of seismic retrofit reinforcement design work.

This paper is an outcome of a research project funded by MEXT/JSPS KAKENHI, grant number (C) 21K04588.

We would like to thank Enago (www.enago.jp) for the English language review.

SCALING UP ENGINEERED TIMBER FOR NEIGHBOURHOOD SCALE DEEP RENOVATION: FINDINGS FROM A STUDY IN COIMBRA, PT

Nelson Brito[1], Thomas Thiis[2], Roberto Tomasi[2], Alice Airoldi[2], Andrea Penna[3]

ABSTRACT: European historic city centres embrace a high percentage of masonry buildings with varying materials and configurations, and successive layers of constructive practices. As "deep energy renovations" are progressively imposed in city centres across Europe, structural uncertainty often justifies interior demolitions and the construction of new buildings behind old facades. This linear approach, unsustainable in its´ economical, environmental, and social dimensions, is currently enforced by market players, but also by environmental financing schemes that exclude circular approaches like maintenance and improvement. Departing from a historical masonry building located in the UNESCO-protected area of Coimbra, Portugal, an engineered timber strengthening strategy is shown to solve more than one problem, and proposed as a scalable low-cost solution for entire neighbourhoods' holistic deep renovations. This paper proposes that the high compatibility and "dry" approaches of timber engineering can be scaled up to favour the mass customization, prefabrication and industrialization needed to deliver improved safety and sustainability with lower economic, environmental, and social costs. Taking part in holistic deep renovations will help the sector to solve some of its own difficulties, and to deliver quicker, less expensive, and more sustainable "2050-aligned" deep renovations of European neighbourhoods; and across the world.

KEYWORDS: historic buildings, deep renovation, seismic renovation, masonry buildings retrofit, experimental test

1 INTRODUCTION

Many European historic buildings and neighbourhoods are in-between gentrification and collapse.

These century-old buildings, versatile in attracting new roles and users, are often classified as "energy hogs" by energy efficiency regulations that either exclude them or impose "improvements" mismatched with their design [1]. Prejudice and lack of knowledge about their thermal and structural behaviour often lead to energy-intensive linear processes of demolition and "wet" construction of new buildings inside old facades, with high upfront costs and eviction of their inhabitants for over one year. This process often ends with unaffordable rents for the original inhabitants, leading to gentrification [2].

On the other hand, historic unreinforced masonry buildings—like the one depicted here—are often the least expensive dwellings of European city centres, housing older age/lower income populations vulnerable to (energy) poverty risks. Low rent values mean insufficient income for their maintenance, worsening traditional skilled labour scarcity and rendering them derelict and unstable. As documented in a video filmed nearby, lack of maintenance leads to instability, and collapse. [3]

This dichotomy between gentrification and collapse is not acceptable in a Europe of diversity and knowledge. The relation between structure, energy, materials, finance, architecture, and city planning was tackled in the SAFESUST workshop on "A roadmap for the improvement of earthquake resistance and eco-efficiency of existing buildings and cities", yet the problem is still pending. The cover page image [4], in Figure 1, alerts on the need to guarantee buildings' integrity, and the safety of their users, before "decarbonizing" them.

Figure 1: *Cover page depicting a collapsed "decarbonized" building after a seismic event. [4], Source: Telestense TV, Ferrara Italy - from "TV giornale", 2012 May 21st*

Inclusive deep renovations are at the forefront of European concerns, as stated in a recent call: a low-quality building stock impacts its' residents, "*including poorer health and lower levels of social inclusion. Transforming inefficient housing stock addresses a root cause of energy poverty, however, the topic also has as an objective to tackle the related high upfront costs, lack of information and trust, uncertainty about benefits of the measures, split incentives, and discomfort caused by renovation works, including the potential need to relocate, as barriers to household uptake.*" [5].

This paper proposes that scaling timber-engineered high compatibility and "dry" approaches can deliver quicker, less expensive, and more sustainable deep renovations. Departing from diverse backgrounds and ongoing needs [6] [7] [8] the authors propose engineered timber—a sustainable endogenous material enriched with knowledge—as an emergent solution for 2050 historic neighbourhoods' decarbonization efforts. To bridge the diverse areas this paper aims to engage, this introduction approaches the evolving frameworks and challenges for engineered timber towards the positive and inclusive neighbourhoods needed by 2050, setting the context with academic findings on a historic area under study. Timber in the renovation of existing structures approaches the current (lack of) use of engineered timber, while the discussion questions current legal and constructive practices: scale is needed for holistic views, and to make "deep" diagnosis and design viable before renovation. The conclusion emphasizes the conceptual contradiction of monothematic deep renovations, and the potential of neighbourhood-scale approaches to make interventions more attractive, inexpensive and aligned with 2050 goals.

1.1 ADDED ROLES FOR ENGINEERED TIMBER

Timber is a circular and sustainable alternative gaining momentum, with proven value in compatibility, reversibility, and/or recoverability of interventions.
Several technical timber products are available to improve existing buildings' earthquake safety, increase load solicitation capacity and enhance comfort. Yet the (vernacular) connection with timber lost the scale it once had, and those trained in timber-related arts & crafts can't tackle all the needed daily "repairs", currently performed by unskilled professionals with suboptimal results.
Timber became a technical material that requires highly trained staff—from engineers to onsite workforce—to deliver guaranteed solutions. The timber-based frame with OSB-sheathing panels used in this paper requires studies currently only viable within academic contexts, as trained staff—diagnosis, design, fabrication, construction and maintenance—is still scarce and expensive.
Assuming that historic/existing buildings are mostly similar in neighbourhoods, this paper proposes that engineered timber must take part in wider views, to regain the ubiquity it once had across Europe.

1.2 DEEP RENOVATION

"Deep renovation will boost innovation and investments in the entire construction value chain. Deep(er) renovations imply a need for competence and technical knowledge of high efficiency solutions and processes. Increasing the rate of deep renovation is an opportunity to develop industrialised solutions to renovation and to create even more high-quality jobs and boost the green economy. If deep renovation policies gain appropriate support and become mainstream, the construction sector could experience an important and stable boost comparable to Europe's post-war reconstruction in the 20th century." [9]

This bright future is hanging on "appropriate support" and "mainstream" adoption, yet legislation and practice are targeting linear "demolish" and "rebuild" approaches.
Deep energy renovations are gaining legal prominence and are often presented as an end in themselves. Minimum Energy Performance Standards (MEPS) requirements for existing buildings, already a practice in some European states, are imposed on homeowners that, unaware of alternatives and without negotiation power, opt for what they can afford: gentrification or abandonment/collapse.
Although the term "Deep renovation" is still missing a legally binding definition in Europe, several studies referenced in [9] already point to existing definitions and practices across Europe that support this discussion.
This paper proposes that deep renovations must go beyond energy to "*gain appropriate support and become mainstream"*, to include instead of exclude, to get the scale necessary for mass customization and industrialized prefabrication, and to engage a new generation of highly skilled "green jobs" professionals.

1.3 POSITIVE ENERGY DISTRICTS

As per 2023, the energy performance requirements of new buildings in the EU are in rapid improvement. EU has proposed that from 2030 all new buildings should be built as Zero Emission Buildings (ZEB) and transform the building stock into zero-emission buildings by 2050. This wave of renovation represents an opportunity to improve also other building qualities, such as seismic resilience. However, to take advantage of the characteristics of groups of buildings rather than individual buildings, the literature suggests moving the zero energy objective from the building to the district level [10]. Similar considerations are valid for seismic rehabilitations in historical areas where there are structural effects between buildings that are not accounted for when structural interventions focus on singular buildings only [11].
Moving to a district level implies that the diversity in load profiles, production and storage capabilities can be utilized as well as the possibility of sharing costs and resources in the construction and operational phase of the buildings. The principles have been developed for several years, and already there is an EU-funded program aiming to support the planning, deployment and replication of 100 Positive Energy Districts (PED) by 2025 [12].

1.4 LEARNING FROM A HISTORIC BUILDING

The Montarroio case study, spotted in red in Figure 2, is a three levels masonry building already pictured in 14th-century maps of Coimbra, Portugal. It faces the UNESCO and "Jardim da Manga National Monument" protection areas, closing a row of similar buildings.
This building is composed of load-bearing masonry walls made of undressed stone blocks, thinner towards the top level (Figure 3), with growing internal floor areas: 13.7 m2 at the lowest level; 15.3 m2 at the intermediate level; 20.7 m2 at the upper level. As found in many ancient buildings renovated century after century, openings are not regular in dimension and location, and some windows were closed with a thinner layer of masonry at the upper level, leaving alcoves. This translates into irregular

masonry structural elements and discontinuous transmission of loads to the ground. The roof structure illustrates a 1980s low-quality "repair" of irregularly shaped eucalyptus structure "glued" to the walls using cement, which explains many of the rotten connections.

Figure 2: *Contextual view of Montarroio case study, spotted in red, and neighbouring area (Source: Google Earth)*

This extreme irregularity, illustrated in the sections in Figure 4 imposes so much uncertainty that it ends up as a scientific challenge; yet the lower floors are more than 600 years old, the top floor almost 400; and both survived a foundation settlement from the excavation of south-facing monumental stairs, provoking its tilt around 1980s.

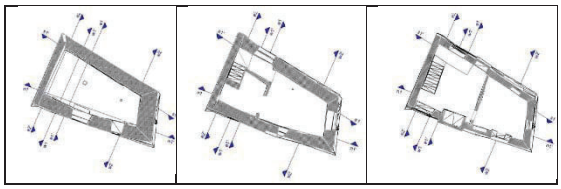

Figure 3: *Plans of the Montarroio case study (source: author)*

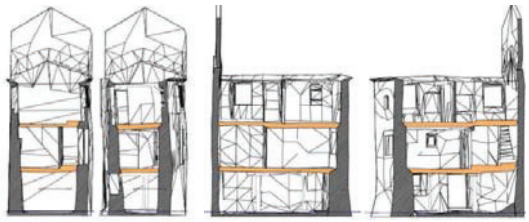

Figure 4: *Transversal and longitudinal sections of Montarroio case study (source: author)*

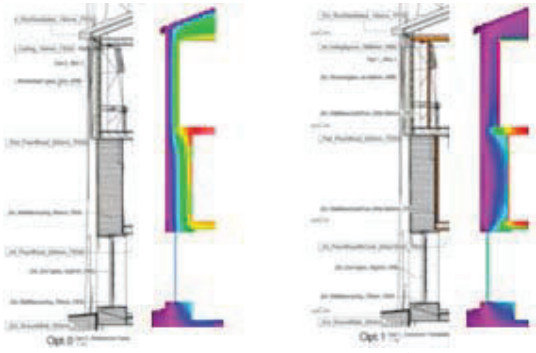
Visualizing thermal images allows a better grasp of the challenge and the risks of "improvements". Figure 5 shows a Building Information Model (BIM) and a thermal model illustrating the effect of interior insulation.
The original solution (a) displays a balanced "sandwich" of temperatures, cold to hot from the outside to inside, with asymmetries inside. The interior insulation (b) model presents stable indoor temperature, yet thermal stress in the floor connections. Low heat loss in insulated areas contrasts with punctual heated floor connections, enabling differential wet/dry and freeze/thaw cycles, and accelerated wall and timber degradation in those areas.



a) b)

Figure 5: *Comparison of the original situation (a) with an interior thermal insulation strategy (b) in a south wall section in a BIM model and thermal behaviour model using THERM* ***[13]****.*

2 TIMBER IN THE RENOVATION OF EXISTING STRUCTURES

This section tackles monothematic approaches to Seismic Renovation and Energy Renovation to demonstrate that the detailed processes they require have much to share.
The case study illustrated must not be seen as a guide, as it results from a limited number of views and assumptions. Nevertheless, the authors use this example to support debate and trigger new views and constructive input.

2.1 SEISMIC RENOVATION

Although Coimbra is not considered a high seismic risk area, this building has evolved through centuries with varied construction techniques, including timber floors and cross-layered timber walls that are probably the explanation for its survival. Nevertheless, it was subjected to significant changes, like the addition of an unbalanced bathroom in concrete, and risky "repairs" that make its´ stability questionable. The following study, documented in [14], tackles problems with assumed simplifications.

2.1.1 Stability refurbishment solution

The studied retrofitting technique consists of a timber-based frame (strong-back) and panels fixed to the internal side of walls using steel connections. The technique has been proposed and tested by Dizhur et al [15]], The result is a hybrid system where the two components, masonry and timber retrofitting, collaborate in resisting earthquake actions. Collaboration is ensured by mechanical bonding obtained through point-to-point connections. Posts act in flexure to transfer wall loads to the adjacent floor diaphragms, subdividing a large planar wall into several vertical buttressed segments. Posts are applied to the masonry wall and connected to it through steel angles (C2 and C3 in Figure 6 and to foundations or slabs through tie-down. In addition to such a system, horizontal nogging elements and OSB boards were added to increase also the in-plane capacity of masonry walls [14]. In-plane cyclic tests on retrofitted walls and shake-table tests on a full-scale retrofitted building demonstrated the validity of the chosen approach [16].

https://doi.org/10.52202/069179-0532

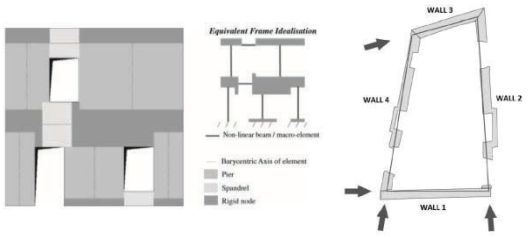
2.1.2 Mechanical model

The conceptual model was developed with the TREMURI computer program [17], an equivalent-frame macro-element model in which the wall structure is represented by an assembly of 2-nodes elements connected by rigid nodes. The macro-element model parameters rely on the experimental characterisation of masonry mechanical properties. If necessary, the use of non-linear beam elements allows the modelling of concrete curbs, wooden elements or reinforced masonry. Further technical detail can be found in [17].

Figure 6: *Example of strong-backs layout (Source:**[14]**)*

The "Equivalent Frame Modelling" approach is based on the identification of deformable structural elements that interact with each other through "rigid portions", connecting the two main macroscopic components. Piers, the main vertical resistant elements, hold both vertical and lateral loads. Spandrels, the secondary horizontal elements, couple the response of adjacent piers and allow or restrain rotations, significantly influencing walls' lateral capacity.

The retrofitted building has been modelled using a dense mesh and adding a non-linear beam as reinforcement. Posts have been located at both lateral ends of piers and with a spacing not higher than 0.9 m. The OSB panel contribution is modelled by increasing mechanical parameters of masonry shear strength.



(a) (b)

Figure 7: *Example of equivalent frame idealization for irregularly distributed openings (a)* ***[17]*** *and pushover directions performed (b).*

The seismic verification is carried out using pushover analysis, through the prescriptions suggested by the N2 procedure [18] [19] implemented in several codes [NTC18, EC8]. Pushover analysis is carried out under conditions of constant gravity loads and a horizontal load pattern with fixed distribution and controlled to monotonically increase the displacement of a control node. Four pushover analyses have been performed, parallel to each wall direction.

The verification consists of comparing the displacement capacity of the building with the seismic demand (in Coimbra a PGA of 0,07 g is expected for a return period of 475 years). However, the proposed analyses are valid also for evaluating the global behaviour of the structure before and after the retrofit intervention (local analysis, which should be evaluated with other tools that are out of the scope of this paper).

2.1.3 Results

The comparisons between unreinforced and strengthened masonry provide an idea of the potential of the retrofitting technique proposed.

Damage level in TREMURI software is represented through a graphic convention in which the cross shows the full development of a shear failure mechanism and straight lines at both ends of the element show damage caused by the flexural/rocking mechanism.

The shear damage level on each masonry element is identified through a chromatic scale in which red colour represents the achievement of the maximum shear resistance, while lighter colours identified the development of non-elastic sliding effects (see Table 1).

The result in terms of the capacity curve is reported in Figure 8 for wall 1 and pushover performed in Wall 1 Direction. In this case, the failure is reached for exceeding the flexural drift limit. Capacity curves show a remarkable increase in displacement capacity as well an increment in shear capacity.

Similar results obtained for the other cases in the analysis can lead to the following considerations:

- A significant (250%) increase in displacement capacity, of the whole structure and single walls, in pushover performed parallel to shorter walls
- Minor increments (10-50%) obtained along directions parallel to longer walls
- The retrofit intervention involves changes in the failure mechanism
- Lateral strength capacity increased in all directions in a range of 50-80%.

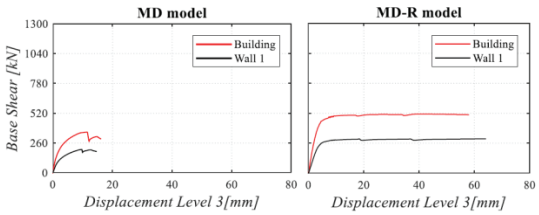


Figure 8: *Comparison of capacity curves between the entire building and Wall 1 of pushover performed in Wall 1 direction for unreinforced model(left) and strengthened model (right).*

To facilitate the comparison of the study [14] results Table 2 illustrates the pushover damage in unreinforced masonry walls, while Table 3 illustrates the added value of an engineered strengthening of these masonry walls.

Table 1: *Percentage variation of maximum shear and displacement of the unreinforced and strengthened models.*

	Base shear variation	***Displacement*** variation
Push_1	+ 72 %	+ 262 %
Push_2	+81 %	+ 10 %
Push_3	+ 53 %	+ 246 %
Push_4	+ 89 %	+ 58 %

Numerical modelling demonstrates that the proposed retrofit solution increases displacement capacity and base shear capacity, with a change of failure mechanism. That means collapse may be reduced due to a brittle mechanism favouring a more ductile behaviour, increasing seismic safety. Later in this text, the importance of a neighbourhood approach to adequately quantify and qualify several parameters will be highlighted.

https://doi.org/10.52202/069179-0532

2.2 ENERGY RENOVATION

Figure 17 maps Energy Performance Certificates (EPCs) issued around the case study, spotted in red. Investigation [1] demonstrated that between 2012 and 2022 only one-third (25 out of 76, those with letters overlaid) had EPCs, issued by 13 different experts on different dates and with varied levels of detail. The EPC process often implied two interactions: one EPC requested by the initial selling part—before advertising for sale, so unaware of buyers' or tenants' objectives— and, after renovation, another EPC per legally designated fraction.

The EPC process implies a) an initial service request by the original owner, b) collection of necessary legal data, c) a site visit to diagnose geometry and constructive solutions, d) calculation of a compared "baseline" according to current EPC rules[4], e) diagnosis of the needs and potential of the building, preferably produced together with the client f) identification and calculation of 10 improvement measures viable for this specific fraction, g) consultation of local availability and prices for evaluation of cost/return ratios, h) photos with scaled targets of all divisions and acclimatization equipment with ID tags i) preparation of reports with detailed constructive solutions and thermal bridges discretization, j) insertion of data in the EPC site, k) emission and payment of the EPC and m) explanation to the client.

The improvement measures proposed must follow the EPC portal typification for the whole country, from north to south: demand reduction by adding insulation, replacing single pane wood frame windows for highly efficient double pane glazing; efficient use of energy by electrification using (air-water) heat pumps; and renewable energy production at the end of the priorities.

The split-incentive barrier —requesting an EPC to a seller who pays the costs for benefits that might accrue to the new buyer or tenant—often results in a "lowest cost" market, with excessive simplifications often resulting in EPCs that miss the potential of the building and neighbourhood they sit in.

This mismatch explains a "re-issue" feature in the EPCs portal: only improvement measures listed in each EPC are accepted for financing, forcing candidates to request a new EPC mentioning those desired measures: another cost/difficulty to access prepaid[5] unguaranteed financing.

Figure 17: *In 10 years only 33% of these buildings were certified and most "rehabilitated" do not excel in performance. Source: author sketches over local GIS and Google maps.*

As all buildings in Figure 17 are inside a protection zone, exterior insulation is forbidden, the interior is not realistic for such small areas, and other limitations apply.

2.2.1 Reducing envelope energy demand

The effect of placing expanded cork in the hollow parts of the strengthening timber mesh proposed in 2.1.1 is illustrated in Table 4. A width of 0.05m, inferior to the available space, was chosen to avoid excessive U-values difference between the timber studs and cork, but studies are advised to evaluate the risk of condensation spots.

Table 4: *Effect of inserting 0.06m of expanded cork within the structural mesh proposed for the seismic retrofit.*

Wall width	Original U-value (W/(m².ºC)	U-value with 0.05m insulation (W/(m².ºC)
Level 2 (0,25m)	2.52	0.64
Level 1 (0,6m)	1.4	0,53
Level 0 (0,9m)	1.01	0,46

As for the windows, the estimated U-value defined for single pane windows is 5.1 W/(m².ºC) can be reduced to 3.4 W/(m².ºC) if low airflow external shutters exist. Installing a certified "Classe+" window, the only type financed in Portugal would ensure a U of 1.5 W/(m².ºC). Although these values may seem attractive to "improve" the envelope, an uncontrolled approach would reduce the available useful area and cancel the thermal delay: this would impose regular use of devices for heating and cooling that were previously unnecessary.

The same is true for airtight windows, as stopping infiltrations implies ventilation with extractors or self-regulated grilles: "if you build it tight, ventilate it right". Reducing envelope demand would increase dependence on equipment for heating, cooling, and ventilation, refuting the thermal resilience proven over centuries.

2.2.1 Reducing fossil energy demand

Energy loads such as domestic hot water and acclimatization are sure targets for improved efficiency. Contemporary improvement measures for domestic needs in this building would include improved efficiency water taps (more pressure with less hot water, a dual gain), better efficiency gas boilers and air-water heat pumps, together with similar systems for acclimatization.

In this area, external heat pump evaporators are not allowed, and air-water heat pumps occupy the scarce interior space available. Solar panels are allowed on the roof, but the unknown capacity of these old structures makes installation & maintenance risky in these buildings [1]. Efficient fossil-fueled equipment is both the least expensive/spacious, thus often the chosen solution.

[4] The EPC rules assume that the building is entirely and permanently acclimatized, not reflecting actual Portuguese habits of partial heating in a mostly mild climate [1].

[5] The current support mechanism requires families to invest first, and request funding after the investment is complete.

https://doi.org/10.52202/069179-0532

3 DISCUSSION

Engineered timber's role in deep renovation is dependent on a wider recognition of its arguments. Similarly looking solutions in amount, type and costs can use timber to hold insulation to walls or to deliver engineered improvement, yet only the second can add proven safety to owners/users: there is a value in knowledge. On the other hand, the costs of timber engineering/architecture are hard to charge for a single building, as the efforts for a correct diagnosis, study and design are still expensive, making them rare. The individual approaches to seismic and energetic renovation reported above show space for savings through base model optimizations for these and other future needs.

Yet going further opens new possibilities, as documenting a neighbourhood—often a repetition of construction techniques/materials within a limited area—allows for scaled holistic views, new visions and new strategies.

Departing from a current limitation—individual linear flows underlying energy guidelines/financing schemes—it is proposed that scale, with communities, can deliver what the EU needs: real decarbonization, energy security/poverty prevention, resilience, and a circular economy—with engaged citizens.

3.1 FROM LINEAR TO CIRCULAR ECONOMY

Circular economy combines the reduction, reuse and recycling activities through systemic shifts aligned with sustainable development. A circular intervention must follow the three dimensions of sustainability—economic, environmental and social—to deliver prosperity, environmental quality and social equity [20].

Although proclaiming circularity, many European public financing excludes maintenance/optimization of existent solutions or systems; like the windows referred to above. In Portugal, a window replacement can apply for 70% of public funding if such "improvement" is mentioned in the EPC and the original is replaced by windows classified as "Classe+", with a U-value of 1.5 W/(m^2.ºC). This implies the removal, transportation to a dump site, and all the embodied energy needed to produce/fit the new window into an often-irregular casing: more risks, and added costs. Retrofitting the existing windows can deliver similar results, as shown in Table 5, which depicts scientifically validated values [21] for some window retrofit solutions.

Table 5: *Extract from the "Research into the thermal performance of traditional windows: timber sash windows" comparing the results of several window retrofits [21]*

Details of the test assembly	Glass only: W/(m^2.ºC)	Glass & frame W/(m^2.ºC)
Window as found	5.3	4.3
Heavy curtains	3.3	2.5
Well-fitting shutters	2.0	1.7
Reflective roller blind	1.8	1.9

These values show that circular economy approaches in windows improvement can deliver results while 1) promoting local maintenance and optimization practices, 2) reducing waste and fostering reuse practices, alongside reduced embodied energy, thus 3) fostering sustainable practices—economic, environmental and social— and green jobs able to "spill" to neighbouring buildings.

However, it is more attractive for a private owner with investment capacity to buy a new window for which a grant of 70% may be attributed, instead of spending half of the economic cost retrofitting the existing window. Although having similar levels of performance, these improvements are not homologated by "Classe+" scheme, thus not recognized by the certification entity.

3.2 LINKING ENERGY TO COMMUNITIES

The current urge for electrification— heat pumps, electric cars, and modern electric gadgets—requires either a significant electric network capacity improvement, and/or local renewable production, and/or ICT connections for "virtual power plants" to turn off non-urgent energy needs (water heaters and other postpone-able energy uses) in exchange for retribution for delayed availability.

Instead of requiring homeowners to request an individual EPC, a neighbourhood pre-certification can be offered to overcome split-incentive issues, study scenarios and trigger action. District heating, renewable energy communities and other solutions already funded rarely find the collective necessary to proceed, and to upgrade a neighbourhood into a Positive Energy District.

3.3 ON THE VALUE OF NEIGHBOURHOOD APPROACHES

Scale is often necessary to deliver complete solutions.

The seismic reinforcement strategy presented is limited without out-of-plane (overturning) analysis of common walls. Figure 18 illustrates a study analysing the whole block [11] to characterize the effect of shared walls in the neighbourhood seismic behaviour.

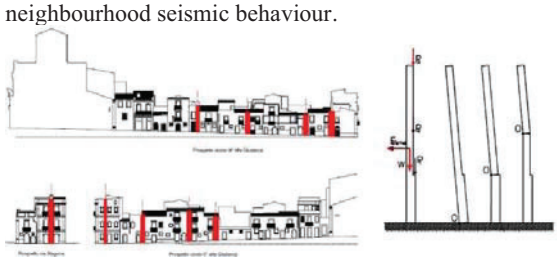

Figure 18: *Image illustrating 9 common walls analysed for overturning in a neighbourhood-scale seismic study [11].*

The energy efficiency neighbourhood scale approaches [1] also facilitate holistic thinking: is it wise to place solar systems in each of these unknown structural capacity roofs—without adequate access to the roof, thus implying cranes for installation and maintenance—when a unified space is available[6] in the blue areas in Figure 17?

Neighbourhoods have the scale and regularity for integrated diagnosis, planning and execution, as defined

[6] This proposal, named "Common Efficacy" was validated by the 2015 VINCI Innovation Awards (4mn video available) [22]

https://doi.org/10.52202/069179-0532

by EN16883 on "Guidelines for improving the energy performance of historic buildings".
Scale attracts new business models, and optimized learning curves while lowering contextual costs, from planning to maintenance, operation and optimization. Making it with local communities closes the circle, fostering new green jobs and the confidence necessary for sharing data in common initiatives.
Renewable Energy Communities are changing the landscape, as some support is already available for the design and implementation of neighbourhood-scale energy systems. Similar supports must be attributed to foster deep renovation strategies, and those will probably be first attributed to lower-income areas.

3.4 HOLISTIC DEEP RENOVATIONS

By 2030 the Renovation Wave aims to double the energy renovation rate and foster deep energy renovation uptake, meaning that "By 2030, 70% of the renovations taking place should be deep" [9].
Multiple benefits, from microeconomic to social, are referenced. From reduced bills/exposure to volatile fossil energy prices to improved Indoor Environmental Quality (IEQ), comfort, well-being and productivity, reduced morbidity and mortality during extreme phenomena, to new green jobs, the advantages are many but not always linked to the proposed metrics.
If deep renovations are to deliver Climate Change mitigation and adaptation—from lower carbon emissions to flexibility on demand, from distributed production to increased resilience and guarantee basic energy services while "*including poorer health and lower levels of social inclusion"* [5]—then the industrialized solutions anticipated require holistic views and a solid legislative background to start moving.

3.5 LINKING ENGINEERED TIMBER TO COLLECTIVE CHALLENGES

It is probably strange to suggest to highly qualified engineered timber professionals that part of their future success may reside in helping the lower levels of society fight (energy) poverty, bad living conditions and safety risks at a time when engineered timber is engaged in high-level design and construction challenges.
Yet the engineered timber sector faces significant challenges—from insurance added costs to concerns on construction and maintenance crews and limited investment for industrialization—to which a European-wide interest would be appreciated.
The advantages of engineered timber are significant: dry and quick onsite responses to energy and safety issues, potential for integral/stagged deep renovation to include natural trigger points, and the use of an endogenous european material enriched by knowledge, among others.
With such edges in this emerging context, will the sector continue waiting for occasional orders, or take the lead, subcontracting the easy parts—infrastructures, systems, renewables—to other partners and stakeholders?

4 CONCLUSIONS

Scaling up timber-engineered supported strategies in neighbourhoods can deliver sustainable, inexpensive, and holistic deep renovations aligned with 2050 goals.
The contemporary individualist monothematic strategies in place to solve collective issues conceptually contradict the Beautiful | Sustainable | Together"[7] European goals.
Holistic deep renovations, at the neighbourhood scale, can deliver more—energy efficiency, (seismic) safety, quality of life, comfort and community well-being—with lower economic, social and environmental costs.
Neighbourhoods, characterized by their repetition, similarity, complementarity and interdependence, have the scale to optimize processes and reduce design, contracting, operation, maintenance and optimization costs; and trust is essential for sharing the resources and information required to achieve Positive Energy Districts.
Future-proofing neighbourhoods with climate adaptation and anticipation—a practice in which the sector has significant experience—can make a difference in most European historic centres, and in many countries that look to Europe as an example. And providing added safety, circularity and sustainability is of no minor importance.
Engineered timber strategies facilitate multistage deep renovations able to match the financial capacity of owners and users with natural trigger points of existing materials and equipment, making the most of historic areas without requiring excessive initial investments. Decarbonizing energy needs, fostering local renewable energy production and peak management generates income for investment payback and other sustainable interventions.
Low embodied energy deep renovations and circular maintenance/optimization procedures must be recognized /funded across Europe. By delivering solutions to wider problems in partnership with other stakeholders, and by defining viable roadmaps, the sector can lead the huge market of deep renovations; and their optimization.
The engineered-timber sector must demonstrate that an endogenous economically, environmentally and socially sustainable material, enriched by knowledge, can redefine the future of deep renovation.

ACKNOWLEDGEMENTS

This research evolved with the support of the "Sustainable Energy Systems" University of Coimbra/MIT Portugal Program (SFRH/BD/51017/2010 FCT grant) and engaged commitment of modular, arq:i+d, lda, Snapmaker & TUCAB (https://snapmaker.com/) (https://www.tucab.pt) for the models to be displayed in the conference. Part of the work presented in the paper was carried out within the framework of the WP5 "Low-impact and integrated rapid execution interventions" of the ReLUIS Research Programmes 2019-21 and 2022-24 funded by the Italian Department of Civil Protection.

World Conference on Timber Engineering Oslo 2023

MODIFICATION OF ROOF STRUCTURE OF THE TRADITIONAL WOOD HOUSES IN THE URBAN AREA OF DAEGU, KOREA DURING MID TWENTIETH CENTURY

Jaemo Cho[1]

ABSTRACT: This study focuses on the roof structure modification of hanok, the traditional Korean timber frame house, in the central urban area of Daegu city, Korea during mid twentieth century. It is based on the 2 years survey of 10,753 cases of hanok architectures in this city. The urban sprawl and population growth gave an impetus to house builders developing new residential areas with modifing traditional plan and structure of hanok.

Instead of traditional way, the wood house builders of this period choose simpler and cheaper roof structure for housing in the dense urban area. They wanted to make the familiar and popular image of tile-roofed traditional wood house using heavy timber frame with cheaper cost and shorter construction time for adapting to housing market. New method using sparsely arranged small square cross-section rafters was in fashion. Other roof type with short and asymmetric eaves was used at small sites. Some special houses have newly designed structure for long span, too.

These modified wood houses shows that there were diverse needs at the housing market. But after this period wood house lost the popularity in the market as modern house building technology, and reinforced concrete construction was widely utilized.

KEYWORDS: Roof structure, thin rafter, Asymmetric eave, Korean timber frame house hanok, housing market

1 INTRODUCTION

This article focuses on the roof structure of hanok in Daegu that is one of the biggest cities in Korea. Hanok is the traditional wood house of Korea made of heavy timber frame structure. The roof structure is usually composed with heavy crossbeam, purlins and circular cross-sectional cantilever rafters supporting eaves covered with roof tiles on the amount of soil.

At the period of mid-twentieth century, there was heavy urban sprawl and population growth at the major cities in Korea. Many citizens wanted cheaper house near central city and the house builders needed to develop new residential areas for them. In the newly developed residential area, the builders made almost same mass houses to reduce construction time with less cost.

This study is based on the 2 years survey of 10,753 cases of hanok architectures in this city. The survey was carried out by Kyungpook National University (2012) and Keimyung University (2013) supported by AURI National Hanok Center. It was the first complete metropolitan council scale enumeration survey for hanok architecture.

The focus of this article is to understand new methodology of roof structure of hanok in Daegu. There were diverse rood structural types for responding market demand. In this article, two major types and one unique case will be presented.

Before this study, there were several researches about hanok architecture of Daegu. J. M. Ha's one was on the typology of the urban traditional housing focused on hanok in Daegu area [1], and J. W. Yoon surveyed the architectural composition of them [2].

2 PREPARATORY STUDY ON KOREAN WOOD HOUSE

2.1 HOUSING MARKET OF MID TWENTIETH CENTURY IN DAEGU

Daegu had been the main administrative city of southeast part of Korea, Gyeongsangdo province, since the beginning of the seventeenth century and is fourth biggest city with about 2.5 million population now.

Since the end of nineteenth century the cities of Korean peninsula has been getting bigger very fast. Busan, Incheon and Wonsan opened ports to foreign trade and the nationwide trunk railway network was built. Among them, Gyeongbuseon railway from Seoul to Busan was one of the main route and Daegu station was the main point for trade. More and more people including both native Korean and the people from other countries mainly Japanese came to this city for industry employment or commercial business during Japanese colonial period of early twentieth century. The central area old town where had been in the city wall before demolish at 1906 was very crowded with population increase. During Korean War,

[1] Jaemo Cho, Kyungpook National University, Rep. of Korea, zozemo@gmail.com

https://doi.org/10.52202/069179-0533

Daegu was in the marginal front of the UN forces, so there was not serious damage at the central area.
More people from north area of peninsula gathered to this city, so the city needed big amount of housing construction for incoming population. For example, the housing problem of Daegu was most serious among big metropolises of Korea at the year of 1970. According to the news on 16 May, 1970 of The Dong-a Ilbo newspaper, while the shortages of house in Seoul was 50.6% and Busan was 56%, Daegu's house shortages was about 60% then.
In the Korean Peninsula, people's house had been only traditional wood structure of hanok, but at the beginning of the twentieth century the new building structures came from foreign countries. Brick wall structure of China or simple and light wood structure of Japan were increasing in the construction field. Also concrete structure was emerging even in the people's housing field. These new structures could make higher and wider building. Moreover the material price of wood building had increased more sharply than other materials.
In this situation, traditional hanok technology met several matter to solve.

(1) For price competitiveness, the construction cost of hanok must be down.
(2) In the urban site condition for housing, the composition of hanok must be more compact in the small site.
(3) To get good marketability, hanok must meet the needs and the sense of beauty of the ordinary people.
(4) Also, for some needs of larger inner living space adapting contemporary life, the traditional method of hanok structure must be changed to make span of column free space longer than before.

For these, the hanok builders had to develop their technology traditionally used for long time.

2.2 TRADITIONAL ROOF STRUCTURE OF KOREAN WOOD HOUSE

The traditional roof of hanok is a kind of cantilever structure. The timber cross beam is put on the columns of front and rear side and shout vertical column (daegong) is supporting purlin on it. If roof need more height, the second beam is used between daegong and top purlin. The purlins located at peak of roof slope and on the front / rear columns make triangle of roof shape and supporting rafters. The rafters make surface for roof slope with soil and rood tiles. This traditional method is similar to other countries like Chinese and Japanese wood structure, so it can be regarded as East Asian ancient wood structure shared in wide area.
In the research field of Chinese ancient architecture, there were 3 major types for making roof structure. For the biggest building, they used big girder and purlins; for smaller buildings such as local residence house, they used more thin columns and purlins without girder, otherwise, horizontally layered timbers are used like log house for small storage; but it is not so commonplace.
The traditional hanok is belong to the first type above even if it is not so big building. So hanok structure is very heavy not only because the girder has usually big cross sectional area but also the roof itself is heavy. The construction cost is also high. If the builders want light structure with cheap cost, they have to make newly modified structure instead of using traditional method.
Additionally, the roof of hanok has about 1 meter's eaves protruding for protect wood timbers and soil wall against rain fall from eaves' end. The cantilever rafters can make it. But in the small site, this outer space under eaves surrounding building mass should be located between the border line of lot and outer wall of building. It is not so effective land use method because there remains narrow and useless space behind the building.

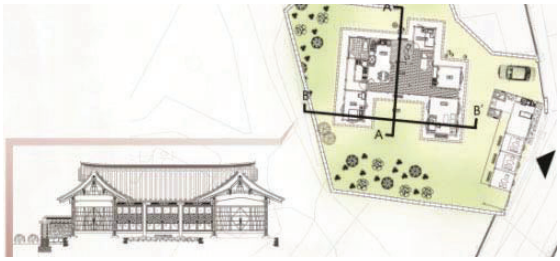

Figure 1: *traditional style hanok in Daegu*

3 GENERAL FEATURE OF WOOD HOUSE IN DAEGU

3.1 INTRODUCTION OF SURVEY

According to the survey, there remained 10,753 hanok architectures in the metropolitan Daegu city. This study is based on the survey the carried out for two years of 2012 and 2013 as mentioned above. Hanok is the typical architecture in Korea so the sizable of wood houses are belong to this type, but there are other types of wood structure such as Japanese or western style wood architecture. [3]
In the building register of Korea, the typology of structure is assorted like masonry structure (brick, block, stone and etc.), concrete, steel, wood, panel and so forth. In the category of wood structure, general timber structure, log house, and others are included; there is not specific tag of hanok or Korean traditional timber structure.
Before this survey there was not the official list of hanok, so the list of whole wood architecture including other types like Japanese, Chinese or western style wood buildings had to be listed up out of the whole building register. So the survey team had to define what makes hanok distinguished from other wood structure. Secondly, the investigators checked on each spot and confirmed 10,753 hanok buildings among 15,344 wood architectures in the list by on-site confirmation.
The ratio of hanok in the whole wood buildings was about 70% average; 35% at the central city (Jung-gu) whereas 87% at outskirt suburban area (Dalseong-gun). Hanok had been normally constructed wherever in the central area or outskirt, but after 1950 most cases were pointed at the

https://doi.org/10.52202/069179-0533

central city. It shows the population growth and urban centralization need more houses in the central city.
By district in detail, Dalseong-gun, the southwest suburban area, has 2,420 hanok and Juon-gu, central urban district, has 1,788 ones. The cases of Dalseong-gun where is the rural area with the largest district and lowest population density are traditional and dilapidated hanok houses while the cases of Jung-gu, the smallest district with high density are newly designed ones built from early to mid-twentieth century. The outskirt area surrounding central district has mass constructed hanok houses against housing requirements with population growth of 1960-1970s period. About 93% hanok (10,015 cases) are used for dwelling and others for commercial, religious, public use and empty houses.

Table 1: *distribution by year and district of hanok in Daegu*

District	~50	50s	60s	70s	80s	90~	null
Jung	552	283	261	208	190	1	256
Dong	491	199	232	313	146	44	35
Seo	235	260	316	191	561	1	4
Nam	46	164	415	300	148	6	27
Buk	165	143	303	278	198	6	4
Suseong	88	189	279	228	161	18	33
Dalseo	58	25	53	107	81	29	2
Dalseong	1,028	608	253	212	118	78	123

3.2 TYPOLOGY OF ARCHITECTRUAL PLAN AND ROOF

The investigating items are as follows; shape of plan and roof, materials of roof, rafters, columns, door & window's frame, outer wall, main gate, fence and the pavement of access alley. The major type of plan is I-shape in rural area and L-shape in central area while hanok with both wings is majority in Seoul. [4]

Table 2: *roof shape of hanok in Daegu*

Type	Number(case)	Ratio(%)
Gambrel roof	7,082	65.9
Hipped roof	1,917	17.8
Gable roof	1,085	10.1
Others	65	0.6
Unidentified	604	5.6
Total	10,753	100.0

In the whole city, L-shape and I-shape's ratio is 45.2% and 43.0% each. Even though L-shape is more difficult to build than linear shape hanok, L-shape of same building area could be built in smaller site. So, it is more efficient in the dense central area.
For the roof shape, 65.9% of hanok used the gambrel roof regarded as quality type. But the roof surface material was not so good. Traditional roof tile made of baked soil had only 5.2% whereas thin cement roof tile occupied 61.7%. Most of surveyed hanok cases were built at mid twentieth century when the fast construction with cheap cost house was needed. Wood house was commensurate with this kind of social need at the first time. But other materials that were supplied to the construction site like bricks, concrete and steel made change to the housing market. So, hanok builders had to develop or modify their traditional technique and construction method.

Figure 2: *examples of urban hanok Residential Areas composed with gambrel roofed L-shape hanok housing (Samdeok-dong 2ga and Namsan-dong 4ga, Jung-gu district)*

4 METHODS OF ROOF STRUCTURE MODIFICATION

4.1 LIFTED SQUARE SECTION RAFTERS

The major roof shape of hanok in Daegu is gambrel type; it means normally people like that roof shape and it has good marketability. But gambrel roof needs more expensive construction cost than other roof types. For both of price competitiveness and marketability, the roof structure had to be changed. Otherwise, the wood architecture of Korea uses timbers not only as structure but also as finishing materials itself. If the structural method is changed, the shape of the house also has the possibility to be changed. So structural modification also should be limited in the range of the similar shape of traditional hanok.
The house builders of that period wanted to make the familiar and popular image of tile-roofed traditional wood house using heavy timber frames with less cost in shorter construction time for adapting to housing market. Some of the builders chose the new simple method using sparsely arranged small square cross-section rafters affected by foreign architectural technology.
In detail, the structural elements from ground level to the purlins on the outer columns supporting rafters are designed like traditional ones while the cross sectional area of members such as columns, cross beams and purlins is smaller than traditional mothed. On the outer purlins, they put short vertical lumbers to lift up extra purlins with square sectional wood bar. On these new purlins, simple lumber rafters are put to make roof surficial structure. Also on the center of cross beam they put the lifter (daegong) to make roof triangle.

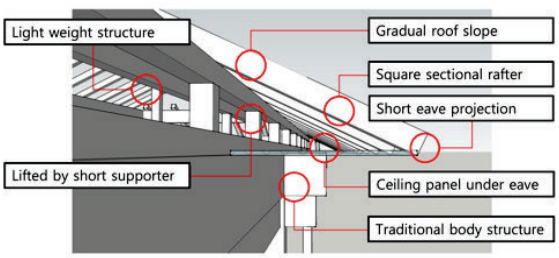

Figure 3: *Lifted square cross section rafters roof structure*

https://doi.org/10.52202/069179-0533

This newly modified roof structure is more simple and light in weight than traditional one, also the construction cost is cheaper.
Especially square sectional rafter is cheaper to make than traditional circular one. But the exterior of the house could not be qualified. So, they added ceiling panel under eave hiding small square sectional rafters lifted with short supporter on the purlin.
Though the roof structure had been changed, the main body and roof of the house has traditional image of hanok only except under eaves partially. So it looks like traditional hanok at the first glance. It can be called as hybrid wood structure. [5]

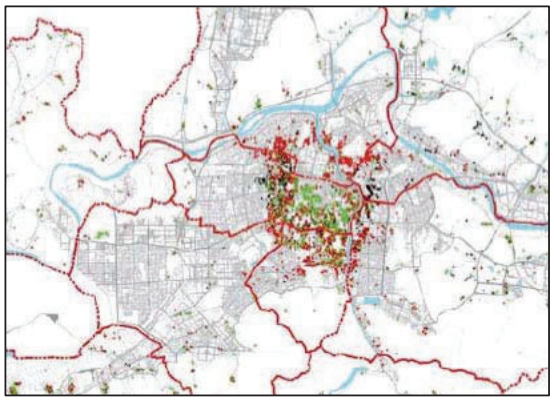

Figure 4: *spatial distribution of 'no rafter type' (red dots)*

In the survey, this kind of hanok is categorized as 'no (traditional) rafter type'. The number of cases is 4,633 and it is about 43.1% cases. These houses are located at the surrounding areas of Jung-gu district and most of them were built during 1960-1970s when the economic condition of the city was not so good. Most of them were built at very small site, so the courtyard is smaller than cases of other decades.

4.2 GAMBREL ROOF OF ASYMMETRIC EAVES

Other method for the urban hanok is making eaves asymmetric. The cases using this kind of eaves were distributed over all urban area of Daegu city, too.
For example, the case of 2504 Namsan-dong, Jung-gu hankok block can be focused where hanok on a similar type were regularly arranged on also typical lots. Actually this urban area was unified one lot of farmland located at the suburban area on the cadastral map of 1911. It belonged to one person named Sihoo Kim and was changed to building site by land readjustment project during 1960s. It was divided into more than 20 small lots of about 136-145 square meters at 1972-1973 and transferred its ownership to each other person right after land dividing. Every 4 or 5 lots were arranged into a line from south to north and 2 meters wide alley was put between each line of lots. This method of land readjustment work was normally applied whole urban area surrounding old central area. But 136-145 square meters' lot is not enough size to build traditional hanok. [6]

Figure 5: *case of urban hanok area of 2504 Namsan-dong, Jung-gu (now destructed)*

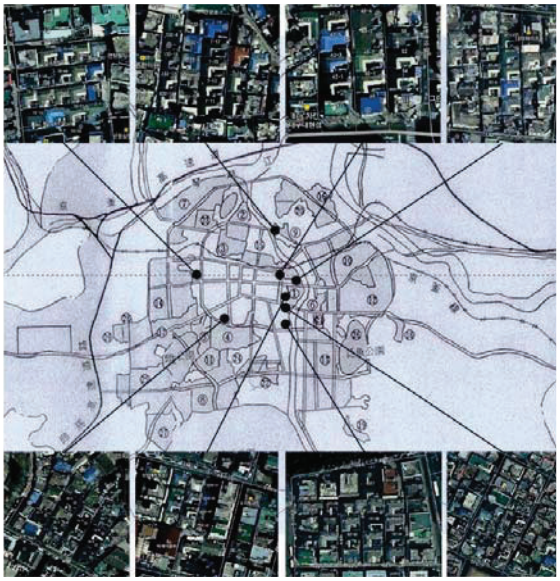

Figure 6: *hanok block made by land readjustment project*

On each lot, the house builder made typical L-shape plan house similar to each other. On the north part there was master bedroom, living room and 2 more bedrooms from west to east and kitchen and 1 more bedroom were at the west wing with courtyard on the southern east part of lot. This type of L-shape hanok was typical shape in Daegu city.
Usually hanok has 1,000~1,200mm projected eaves from outer wall. It is for shading inner space and preventing rain drop into the house. If the roof is gambrel or hipped roof, the eaves are surrounding the main body while gable roof has only 2 side eaves of the house.
People wanted the gambrel roof house, but it needs larger site area. House builders had to modify gambrel roof that could be built in the small area.
The normal eave projection length of more than 1,000mm is used at only 2 concave faces of L-shape plan house toward inner courtyard. Other faces have short eaves of about 400mm projected that is not enough to shading or preventing rain drops. From the structural viewpoint, this asymmetric eave roof is not good for balancing because angle rafter cannot be put on the exact position forming an angle of 45 degrees. But it is more attractive to housing market.

https://doi.org/10.52202/069179-0533

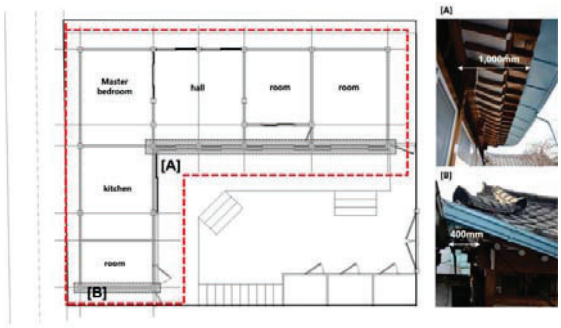

Figure 7: *Gambrel roof with asymmetric eaves*

4.3 NEWLY DEVELOPED ROOF STRUCTURE FOR LONG SPAN HALL

Using the lifted square sectional rafters and asymmetric eaves aims cheaper construction cost of hanok architecture for adaptation housing market's condition. But someone wanted to make bigger hanok with affordable cost. Usually residential hanok's longitudinal span is about 3.6m including 2.4-2.7m's room span and 0.9-1.2m width corridor. If the span is bigger, the cross beam has to more depth for supporting roof weight. But it needs more cost, too.

The case of 66-5, Jong-ro 2ga is the noteworthy one. It is located at the narrow long alley of Jin-golmok where is southern east part of central old quarter used to be inside of Daegu city wall of Joseon Dynasty (1392-1910). Land near Jin-golmok belonged to Dalseong Seo family's ownership. This rich and famous family made diverse style houses such as Western villa (now Dr.Jeong's children hospital), 2-story brick house (now Daegu Korean Chinese Association building) and several hanok houses designed by each architect or house builder. It means 66-5 hanok was also designed not for mass housing even though there is no documental evidence.

Figure 8: *changing of the site of Byeongwon Seo's mansion (1911, 1938, 1949, 1957 and 1977)*

66-5 hanok was the part of Byeongwon Seo's mansion and had been used as restaurant (Jin-golmok Sikdang, now closed) recently. His mansion was composed more than four buildings of family's residential part, reception and living part and 2 more attached buildings of servant's quarters. Buildings of Seo's mansion were built during 1920s. These three parts are used for each commercial function of restaurant on each lot, now. On the first a land registration map of 1911, there was large lot including all buildings of the mansion. It is very deferent from the case of 2504, Namsan-dong. [7]

66-5 hanok was the reception and living part of the mansion. This reception room needed bigger space than traditional hanok so the designer had to make new structural method for it. This 66-5 hanok is also L-shape but the longitudinal span of the north wing is about half as large again as normal hanok.

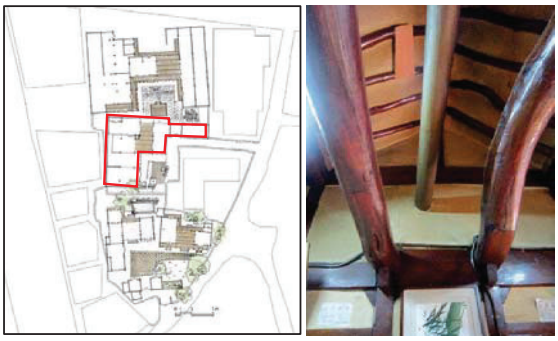

Figure 9: *plan of Byeongwon Seo's mansion and structure of 66-5 hanok*

The 66-5 building is composed with 2 narrow wings of 3-purlins span and they made L-shape structural frame. Additionally wider 2-purlins span is added forward courtyard side for making 5-purlins span. For this wider span, this building has two more cross beams orthogonal direction to the main cross beam. It is so abnormal case among hanok structure. In this way, the builder could make long span with only small sectional timbers.

The rafter is traditional one but thin and sparsely laid. And they didn't put ceiling hiding roof structure. If the builder used the light weight roof structure of lifted square sectional rafters, ceiling had to hide the roof structure and could not make the traditional image of hanok.

Figure 10: *worm's eye view of 66-5, Jong-ro 2ga, Jung-gu*

5 CONCLUSIONS

Daegu's housing market of mid twentieth century was diversified so fast. Hanok builders had to develop their own technique to catch up with the new market trend struggling against other emerging house types. They had to build hanok with low cost in short time. Modified roof

https://doi.org/10.52202/069179-0533

structures such as using lifted square section rafter or asymmetric eaves were their strategy to survive in the market. And the case of 66-5 hanok shows that the traditional technique also could make wider span than before. These modified wood houses shows that there were diverse needs at the housing market.

But after this period wood house lost the popularity in the market as modern house building technology, and reinforced concrete construction was widely utilized.

Traditional carpenters were replaced not only in the housing market but also wood construction field. New wood architecture technology such as lightweight wood frame house was imported and nowadays most of wood houses are built with 2x4 style engineered lumber hided in the wall panel. The traditional carpenter's technology is also used for new hanok with high cost; it is still popular partially. Recently, so called 'neo-hanok' is developed using BIM based automatic design technology, precut with CNC, engineered lumber, metal joint and others.

But it shows possibility and tendency of the evolution of hanok.

Hybridization of Western Timber Truss and Traditional Korean Roof Shape in the Early 20th Century

Jeonghyun Kim[1], Jihong Kim[2], BongHee Jeon[3*]

ABSTRACT: During the Japanese colonial period of Korea(1910-1945), the Japanese colonial government built Korean style buildings using Western timber truss. Although these buildings look like traditional Korean pavilions in terms of exterior form, they have significantly different structural frames. The architectural features originated from Korean tradition, such as protruding eaves and curved roof shape, were achieved by different structural system and methods which were developed from late 19th to early 20th centuries in Japan. In this study, we analyzed the hybridized roof structure and how the prototypical methods and their variants were implemented.

KEYWORDS: Japanese colonial period of Korea, tradition, Western truss, eclectic roof structure, roof shape

1 Introduction

Every culture has their way of constructing a building, which is repeatedly used throughout its history. Wooden roof structures, composed of orthogonal columns, beams, purlins and inclined rafters, were one of the most conventional methods used in East Asian architectural tradition. As modernization came to East Asian countries, Western architecture was introduced. Governmental offices, hospitals and courthouses which symbolized new political and social order began to be built in Western styles such as Neoclassicism. Also, traditional-style buildings, whether they are newly built or renovated, were influenced by Western technologies such as truss structures and metal reinforcements.

Adoption of Western truss became the focus of architectural discourse in this time of transition. However, it was not an easy task to adopt Western truss directly to the traditional structural system. East Asian traditional buildings have curved roof profile which is different from linear roof profile generated by trussed structure. In addition, the roof shapes are not only relevant to the roof structures but also closely related to the entire structural system of a building.

While other East Asian countries underwent more complicated transition, Western truss was adopted by Japan during Meiji period after the devastating earthquake of 1891. During the Japanese colonial period of Korea(1910-1945), expositions were held in cities of Japan and Korea by Japanese colonial Authorities. To promote their colonial reign, they built Korean Pavilion, *Cho-seon-kwan*. (Kang, 2004) These buildings look like a Korean traditional pavilions in terms of exterior forms, they have significantly different roof structures. Architectural features from Korean tradition, such as protruding eaves and curved roof shapes, were implemented while Western truss was adopted and hybridized to the roof structures. They have eclectic features which have not been addressed in East Asian Modern architectural studies.

data base of buildings built in Japanese colonial period. The data base contains schematic plans and detailed drawings of the buildings. It allowed us not only grasp a concept of the design principle, but also understand the structural frames and the concrete methods of construction. (National archives of Korea, 2008) For this study, we selected 22 cases which showed eclectic roof structure and Korean-style roof shape. The drawings include very detailed information so that we need to abstract them into diagrams. (Fig.1)

2 Adoption of Western Truss in Japan and Korea

1861 in Japan, Western wooden truss had been introduced to the Nagasaki steel plant. After a heavy earthquake had struck the Nobi province, the traditional wooden structure was questioned in terms of its safety. Japanese architects and scholars began to pay attention to Western truss and applied it to their projects. (Im, 2011)

Even in repair work for the traditional building, which is national monument, like Todai-ji, Western truss was applied. Daibusuden of Todai-ji had been through precarious situation since 19th century because of the structural defect. It had enormous size of roof which needed structural reinforcement. Although the problem had been addressed since 1880s, the repair work was not started until early 20th century. Architects and scholars who were educated in Western society led the repair work.

The repair work of Daibusuden of Todai-ji, had been continued from 1906 to 1913. According to the construction record, we could find out that the box truss structure had been used to reinforce the roof. (Fig.2) Central structure was replaced by truss and the principle of truss was widely used to replace wooden structural members. Wooden joints were reinforced by bolts and nuts. (Fig.3) Using Western roof tile reduced the roof load by 12%. (Coaldrake, 1994)

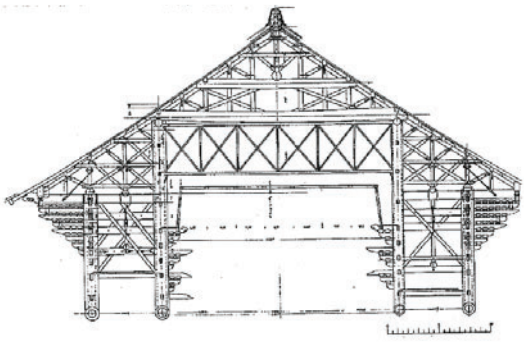

Fig.2. Daibusuden of Todai-ji: sectional detail of restored and rebuilt truss after Meiji restoration project (Coaldrake, 1994)

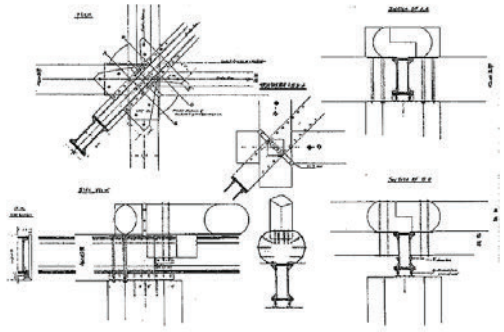

Fig.3. Daibusuden of Todai-ji: Iron pins and plates added to reinforce framing at the time of the Meiji restoration project (Coaldrake, 1994)

In Korea, figuring out the conditions of western influence on roof structure in this era is more complex because the modernization process was led by multiple political groups, the Korean government, Western and Japanese colonialists. In the late 19th century, the first building, *Beon-sa-chang*(1884) (Fig.4) which have a trussed roof was constructed by the Korean government. (Im, 2011)

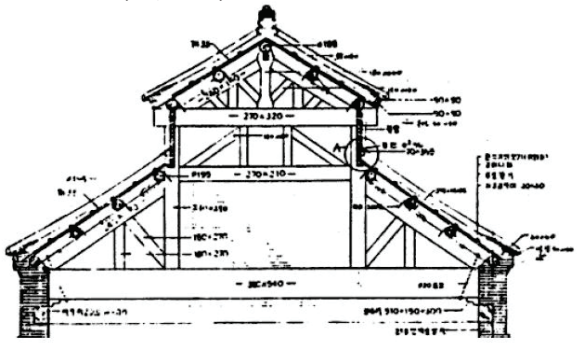

Fig.4. Section Drawing of *Beon-sa-chang* (Im, 2011)

Meanwhile, many other trussed structures were built by western people, mostly for religious purpose. Those buildings had totally western style roof both aesthetically and structurally. In prior studies, these eclectic roofs were classified into three groups, Korean style, Japanese style and eclectic style. Although the classification is clear, it does not represent the eclectic feature embedded. For example, the eclectic style, according to the prior classification, includes too many different types of roofs. It should have been classified much more carefully. In this study, we suggest two points of view to investigate the eclectic roof structure. The first one includes the technic and design integrity of eclectic roof structure and the second one includes the historical origin of the technology. Through this study, we get to expand the scope of discussion about eclectic roof structure in that period.

https://doi.org/10.52202/069179-0534

3 Eclectic Features of Roof Structure

The roof of traditional Korean pavilions is characterized by protruding eaves, curved roof shape and wooden frame composed of rafters and purlins.

Rafters are supported by purlins and categorized into two kinds, short and long rafter. (Fig.5) In order to achieve a desired roof profile, each kind of rafters have different slope. By piling soil on the rafters, a smooth roof profile is achieved. Another noticeable feature of traditional Korean roof is that the long rafter acts like a cantilever to make protruding eaves.

Fig.5. Roof structure of Korean traditional building

Fig.6. Structural diagram of Western truss (Queen truss)

Western Truss, on the other hand, consists of different set of building elements. The most significant difference is the use of diagonal members. (Fig.6) The diagonal part of a trussed roof is not composed of multiple building elements. Rather, the side part of the roof consists of a single long rafter and supporting columns. This structure does not have protruding eaves or curved roof shape.

The complexity in representing the traditional shape of roof emerges here. The typical Western truss itself does not allow for the traditional elements implemented. Several technological references published around 1910s-1930s suggest solutions to this problem. Fig.7 is a drawing from 'Improved Japanese House Structure(改良日本家屋構造)' which was published in 1919. The illustration shows how to adopt a truss structure having protruding eaves and curved roof shape. Based on this reference, we infer that using some additional building elements was a relatively ordinary method to represent a traditional shape of roof with truss structure.

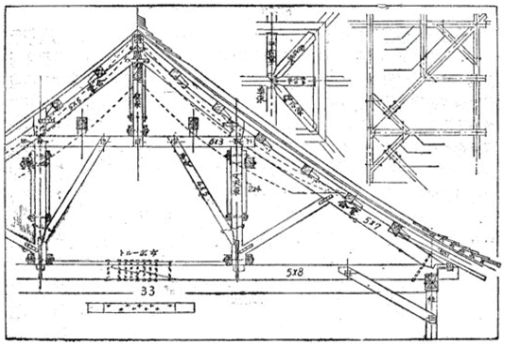

Fig.7. Roof structure of Korean traditional building (Tamotsu, 1919)

4 Structural Characteristics of Hybrid Roof

In this chapter, we will investigate roof structure of eclectic roofs and figure out what methods are specifically implemented. In doing so, we hope to answer the following questions: How are Korean and Japanese traditional timber frame structure and Western truss integrated in hybridized manner? How are the traditional shapes, such as roof curvature, protruding eaves, ornamental elements generated?

As shown in Fig 8, the use of Western truss is a remarkable attribute of the eclectic roofs. While King Truss and Queen Truss structure were widely used, there were several variations of structure which reveal the hybridized characteristic of the eclectic roofs. Case D and Case C show how the King and Queen Truss are implemented.

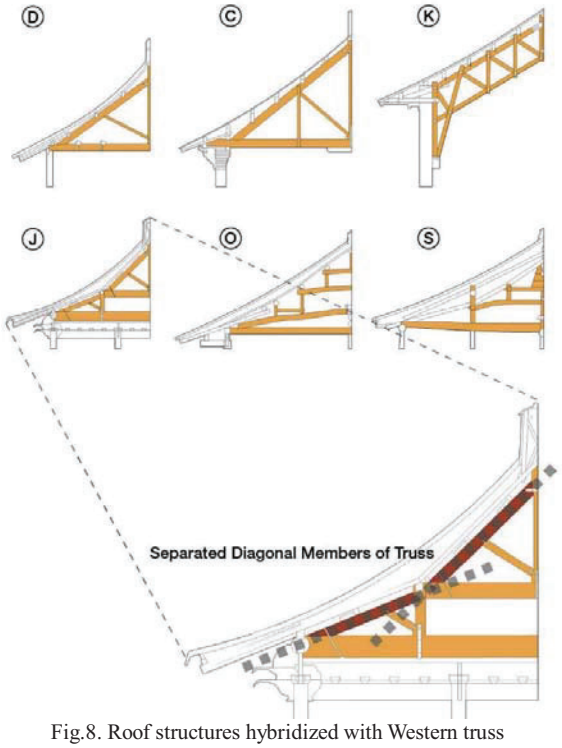

Fig.8. Roof structures hybridized with Western truss

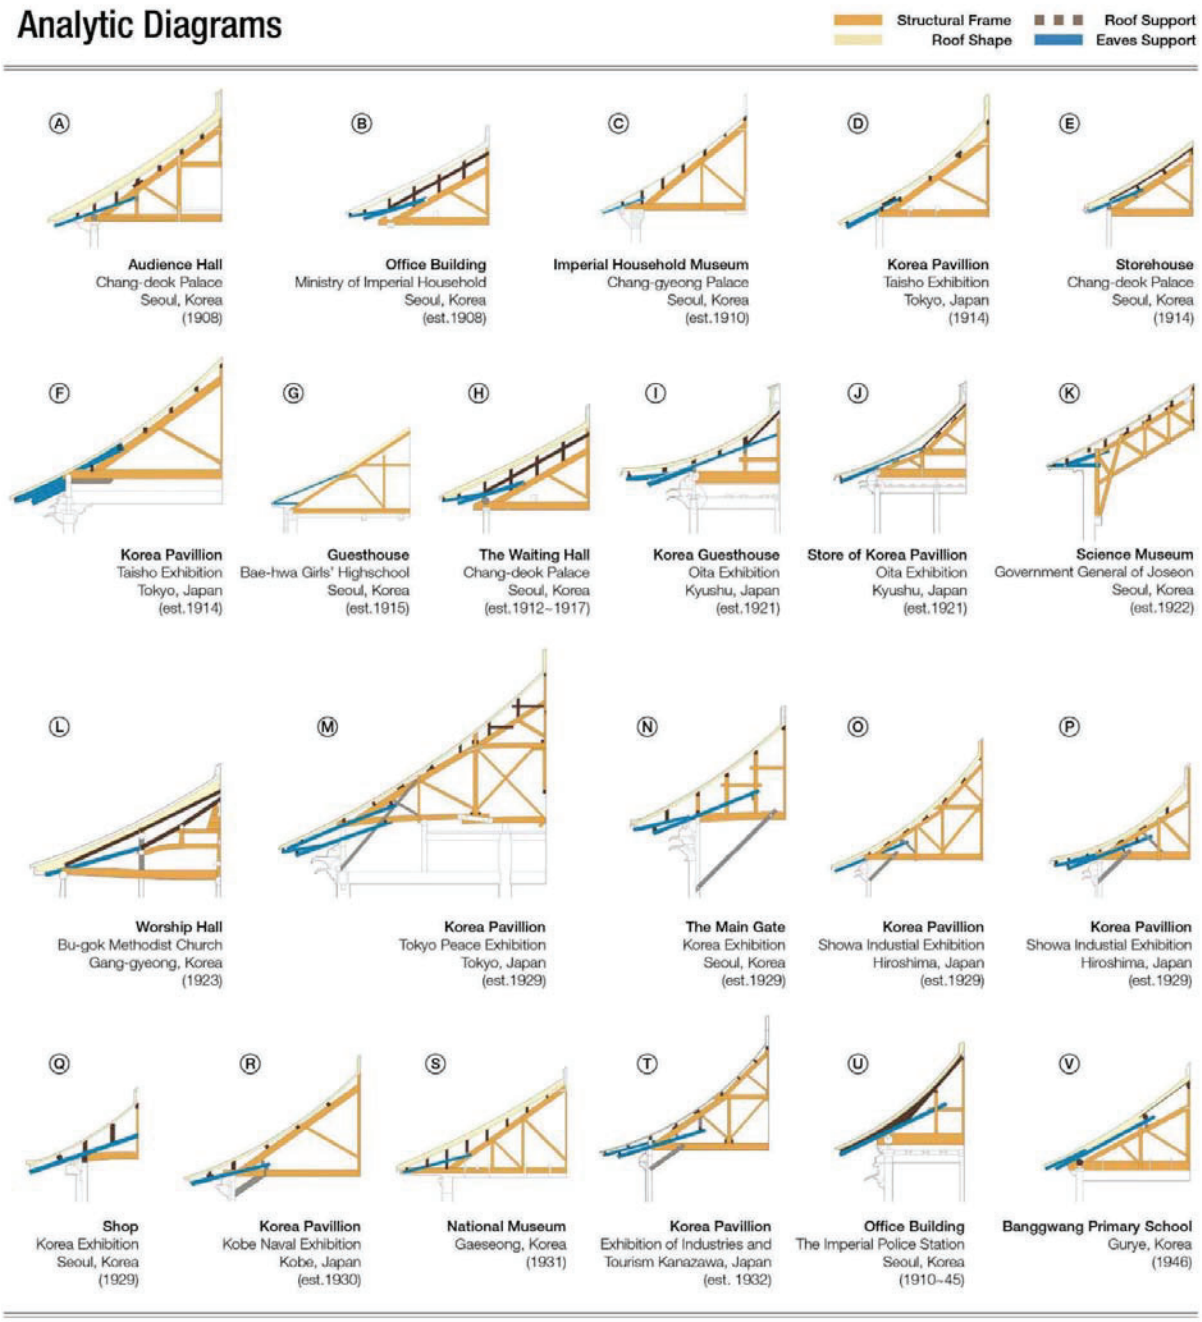
In Case J, we note the separation of a diagonal member of truss structure. The upper and lower

https://doi.org/10.52202/069179-0534

diagonal members have different angles to make the curved roof profile. Case K shows a very unique roof structure which provides higher space for exhibition. In Case O and Case S, the features from traditional Japanese and Korean roof structures were still dominant over truss. However, both of them have double-layered roof structure to avoid piling soil.



https://doi.org/10.52202/069179-0534

In most cases, the ways of making a curved roof profile are similar. To generate a curved form, vertical supports are added on top of the diagonal member of the truss structure. This seems to be the most common method of making curved roof shape. (Fig.9) The significance of this method is that it reduces the load of the roof considerably by making double-layered roof structure instead of heavy soil.

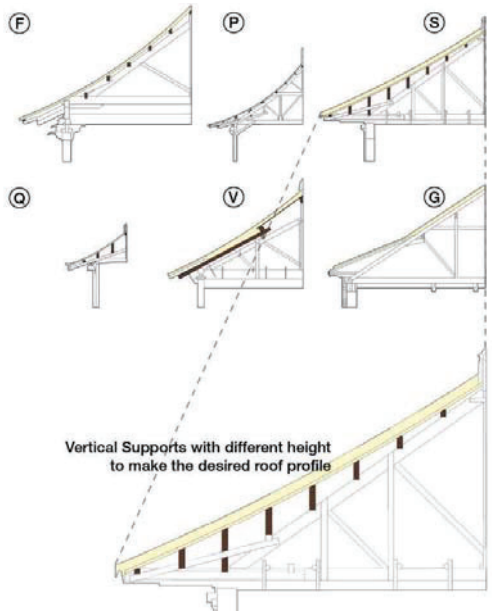


Fig.9. Roof profile generated by vertical supports on truss

Protruding eaves are an essential part for a roof structure because it prevents rain water from entering the enclosure. Unlike traditional protruding eaves, auxiliary rafters are added to the main trussed frame usually on a diagonal member. (Fig.10) Several kinds of auxiliary rafters are used case by case. The connections between auxiliary rafters and the main truss structure are usually located upon a diagonal member of truss structure.

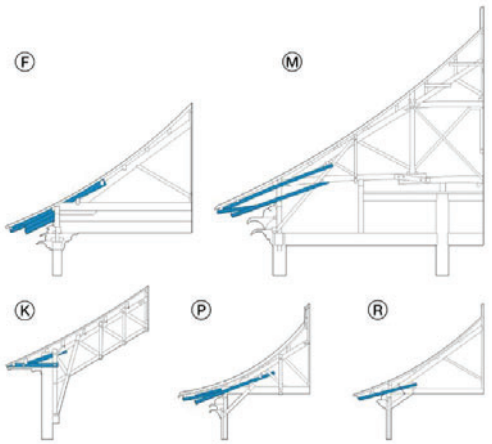

Fig.10. Protruding eaves generated by axillary rafters

We also found similar method of making protruding eaves in 'Improved Japanese House Structure(改良日本家屋構造)' published in 1919. Four methods are illustrated in this book and the second one from the top shows the same method as our cases. (Fig.11) It is a noticeable fact that a particular building element called "桔木"(tied building element) was used. Fig.12 illustrates the positions and the intervals of rafters.

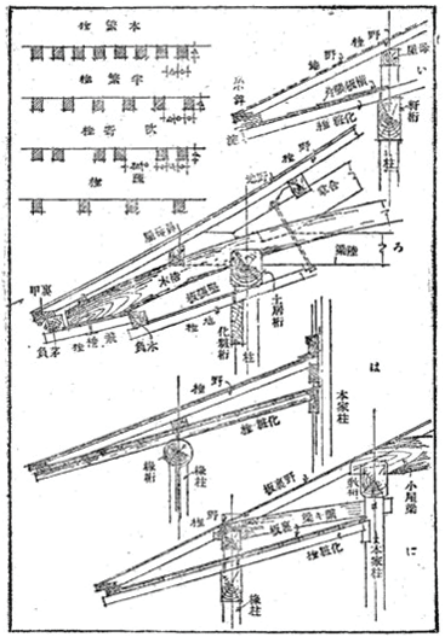

Fig.11. Protruding eaves
(Tamotsu, 1919)

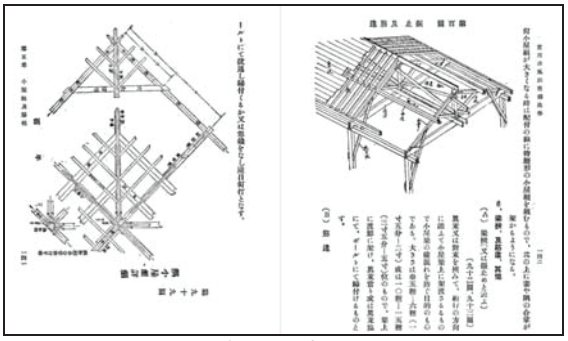

Fig.12. Rafters
(Tamotsu, 1919)

While the main structural frame is replaced by truss, some specific parts of the traditional building elements still remain without structural function. They separated the ornamental part from the building elements and attached to the façade. For example, the end parts of a traditional beam maintain its sculptural shape even though the beam itself does not exist anymore. (Fig.13)

https://doi.org/10.52202/069179-0534

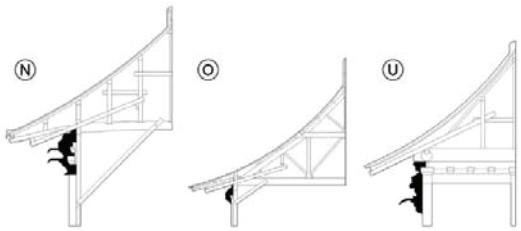

Fig.13. Ornaments from traditional building elements.

5 Conclusion

The cases from the Japanese colonial period of Korea clearly exhibit the eclectic features. Through this study, we found the prototypical method of construction of these buildings and the variations shown in each case. The eclectic features in these cases can be summarized in three points. For the structural frame, adopting the Western truss was a main issue. The cases have different degrees of hybridization as a result of integrating traditional roof structure and Western truss. While most cases clearly represent an embrace of Western truss, certain components and connections of them had been modified to generate traditional roof shapes. Architectural features from traditional Korean pavilion, such as protruding eaves and curved roof shape, were implemented through various new methods instead of traditional way. Roof curvature is implemented by using vertical support on top of truss and the protruding eaves are formed by auxiliary rafters. Ornaments from traditional building elements which lost their original function and lacked authenticity were selectively retained to mimic traditional roof shapes.

Through reviewing the eclectic roofs of the colonial period buildings in Korea, we found an underlying eclecticism between the intention to pursue traditional Korean roof shape and the actual implementation of adopted-technology during cultural exchanges in the earth 20th century.

Seismic Performance Evaluation of a Traditional Wooden Townhouse that did not Collapse in the 2016 Kumamoto Earthquake

Yasuhiro Nambu[1], Toshihiko Ninakawa[2], Hiroki Tabata[3] and Akio Kitahara[4]

ABSTRACT: This study presented the results of the structural investigation of a *machiya*, a traditional Japanese wooden townhouse, located in Kumamoto City, which is not significantly damaged during the 2016 Kumamoto earthquake. The seismic performance of the house was evaluated using the limit strength calculations. In addition, the effect of through columns, which were present various parts of the house, was considered using a simplified model. Time history response analyses were conducted using the observed ground motion records, and the differences in the maximum response story drift due to the presence or absence of through columns were investigated. The following findings were obtained. 1) The main house had no full mud walls in the ridge direction on the first story, and most of the columns were through columns. 2) The base shear coefficients for the main house were 0.02 in the ridge direction for a story drift of 1/60 rad. The horizontal resistance was considerably small. However, the house did not collapse during the 2016 Kumamoto earthquake. 3) Time history response analyses were conducted with and without considering through columns, and the results showed that the maximum response story drift in the first story was reduced by 10-45% when the effect of through columns was considered.

KEYWORDS: Traditional wooden building, Japanese townhouse, time history response analysis

1 INTRODUCTION

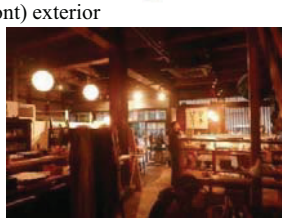
In 2016, a series of earthquakes struck Kumamoto, a prefecture in Japan's southern island of Kyushu. The first earthquake, with a magnitude of 6.2, occurred on April 14th, followed by a second earthquake, with a magnitude of 7.0, on April 16th. These earthquakes caused widespread damage and loss of lives in the region. Many traditional wooden townhouses called *machiya* in Furumachi, Kumamoto-shi were also damaged by earthquakes (the PGA of the nearest earthquake observation record was 432 gal for the foreshock and 552 gal for the mainshock [1]), and several *machiyas* confirmed to have collapsed [2, 3]. However, not all *machiyas* that do not meet current Japanese seismic regulations suffered serious damage. To gain new insights into improving the seismic performance evaluation method of *machiyas*, we focused on several *machiyas* that were not severely damaged by the earthquakes and still exist in the town. Therefore, we investigated one existing *machiya* in Furumachi to understand the structure and evaluated its seismic performance at the time of the earthquakes. This paper reports the results of the structural investigation and the evaluation of seismic performance through time history response analysis.

2 TARGET HOUSE AND DAMAGE SITUATION

Figure 1 shows the exterior and interior of the target house. The target house was built around 1915–1917.

(a) South (front) exterior

(b) Interior (2nd story, facing north)



(c) Interior (1st story, facing south)

***Figure 1**: Exterior and interior views (taken on 10/18/2019)*

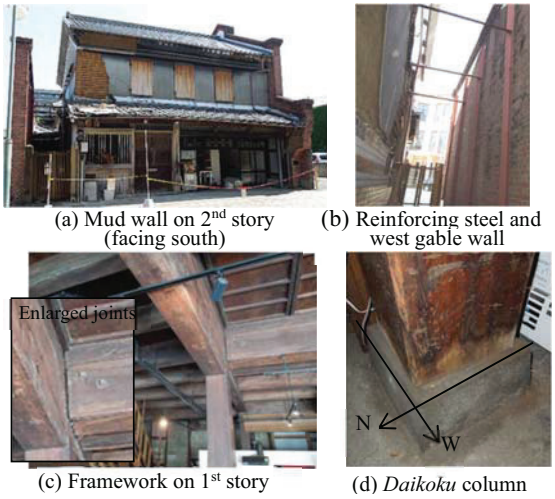
https://doi.org/10.52202/069179-0535

The building was originally a store that handled oil and wheat; thus, brick walls were built on the gable side of the site boundary from the beginning to prevent fire. In 1992 and 2007, renovation work was carried out on the main building, and reinforcing steels were attached to the brick wall on the west side at that time. Then, the damage situation during the 2016 Kumamoto earthquake is described.

Figure 2 shows the damage situation of the main house of the residence (taken on May 14, 2016).



(a) Mud wall on 2nd story (facing south) (b) Reinforcing steel and west gable wall

(c) Framework on 1st story (d) *Daikoku* column

***Figure 2**: Damage after the earthquake (Photo taken 5/14/2016)*

As shown in Figure 2(a), the mud wall on the west side collapsed on the south (front) and north (back) sides of the 2nd story of the house. On the west gable end, as shown in Figure 2(b), the mud wall around the column where the reinforcing steels of the brick wall are connected collapsed. Inside the house, there was some deformation at some of the joints in the framing where wooden pegs were used, and there was some looseness, such as the horizontal timber coming out of the column, as shown in Figure 2(c), but no major damage, such as a broken column, was confirmed. As shown in Figure 2(d), the base of the pillar of the *daikoku* column located near the center of the house had rotated slightly clockwise, based on the marks remaining on the foundation stone, and had moved about 1 cm to the east as a whole. As there was no major damage, the house was repaired by repainting the mud wall and is still in use today [3].

3 STRUCTURAL INVESTIGATION

We conducted a field survey of the house on November 18, 2019. We measured each part of the house as part of a structural investigation, created floor plans and elevation drawings, and identified the structural elements and types of the house. In addition, we conducted microtremor measurements as a vibration survey, but the results are not reported in this paper (refer to [4 for the results]).

The structure of each part is shown in Figure 3, and the framework and floor plan of the house are shown in Figures 4 and 5, respectively.

(a) Cross beam (b) Diagonal strut

***Figure 3**: Structure of each part (taken on the day of the structural investigation)*

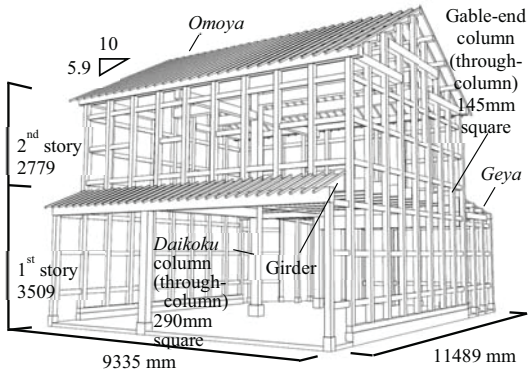


***Figure 4**: Framework of target house (from the south)*

The house consists of a two-story main house called *Omoya* and attached east and west side structures called *Geya*. The height of each story is 3,509 mm (from the ground to the top of the beam) for the first story and 2,799 mm (from the top of the second-floor beam to the top of the purlins) for the second story. The column bases are placed on the top of the foundation stones and not anchored to them. All the gable-end columns are 145 mm square cross-section, and the *daikoku* column (central supporting pillar) is 290 mm square cross-section.

The gable-end columns are spaced at 910-mm intervals and are through columns that reached the purlins, with ridge beams and purlins tenoned into them to form through-column structures. Here, the "cross beams" in Figure 5 represent the beams mortised into the columns. The species of the framework could not be identified. The gable-end exterior walls of the *Omoya* are entirely mud walls, while the non-gable sides have no exterior walls on the first story and are mainly mud walls on the second story. The wall thickness of the exterior walls is approximately 130 mm on both the gable-end and non-gable sides. Additionally, the visible penetrating tenons (called *nukis*) are in the interior side of the exterior walls. The cross-sectional dimensions of the *nuki* includes a width of 30 mm and a depth of 145 mm, with three levels installed on each story's mud walls. There are no interior walls. The first floor is a dirt floor, and the second floor is a board floor. At the level of the roof beam level, diagonal struts measuring 120-mm width and 160-mm depth were installed. The roof is covered in pantile roof for both the *Omoya* and *Geya*. The east-west brick walls are laid in English bond with a thickness of 460 mm. The west brick wall is reinforced with equal-angle steel sections with a width of 100 mm and height of 100 mm (thickness unmeasured) and is connected to the gable-end columns of the *Omoya*, with three reinforcements installed at 910-

https://doi.org/10.52202/069179-0535

***Figure 5**: Floor Plan (mm)*

mm intervals. The east brick wall and the gable-end of the *Omoya* are in contact, but the details of the contact area are not visible. It should be noted that there is a wooden detached house on the north side of the property, separated by a courtyard, but it is not structurally connected to the *Omoya*.

4 SEISMIC PERFORMANCE EVALUATION BY LIMIT STRENGTH CALCULATION

The seismic performance of the target house was evaluated using the limit strength calculation, which is generally used to evaluate the seismic performance of traditional wooden buildings. The calculations were based on [6]. The skeletal curves of the house were calculated from the bearing elements, such as the full mud walls, hanging walls, and column-beam joints, and the response values during earthquakes were obtained using the response spectrum method with equivalent linearization. This report gives an overview of the influence of through columns as a starting point for evaluating the seismic performance of the target house. Therefore, the influence of the *Geya* and brick walls were ignored to simplify the analysis.

4.1 CALCULATION OF WEIGHT

The weight of the first story was calculated as the weight from the upper half of the first story to the lower half of the second story, and the weight of the second story was calculated as the weight from the upper half of the second story to the roof. The weight was calculated by multiplying the area of each part of the house by the fixed and live loads specified in Articles 84 and 85 of Order for Enforcement of the Building Standards Act of Japan, respectively, and the values in [5]. The live load is 600 N/m^2 in residential rooms when calculating seismic forces. The thickness of the mud wall is assumed to be 127 mm (obtained by subtracting the distance of 18 mm between the column surface and the wall surface from the column section dimension of 145 mm), and the roof is assumed to be covered with clay pantiles. The weight of the structural frame was calculated by multiplying the volume of each member by the specific gravity provided in [5] and assuming cedar for the columns and Oregon pine for the beams. Table 1 presents the calculated values of weight and mass, along with the floor area and height of each story.

***Table 1**: Results of weight and mass calculation*

	Weight [kN]	Mass [kg]	Floor area [m^2]	Story height [m]	Weight per unit area [kN/m^2]
2nd story	236.9	24150	71.1	2.799	3.33
1st story	183.8	18740	71.1	3.509	2.58
Total	420.7	42890	142.2	6.308	2.96

4.2 SKELETON CURVES

The skeleton curve of the target house was obtained by summing the skeleton curves of the bearing elements for each story and direction. The bearing elements considered include the full mud wall, hanging wall, *nukis*, and column-beam joints. The skeleton curves for each bearing element were determined based on [6]. It is assumed that all mud walls fail in shear. The skeleton curve of the column-beam joints was obtained by assuming that the bending moment M at the joint (using the dowel-and-

mortise joint "*one-hozo komisen-uchi*") is equally distributed between the upper and lower floor columns. Then, the resulting M was divided by the height of each story to obtain the shear force Q and R curves. The M and θ curves used here for the dowel-and-mortise joint were determined based on [6], and it was assumed that θ was equal to the story drift angle R. The results of the skeleton curve calculation are shown in Figure 3.

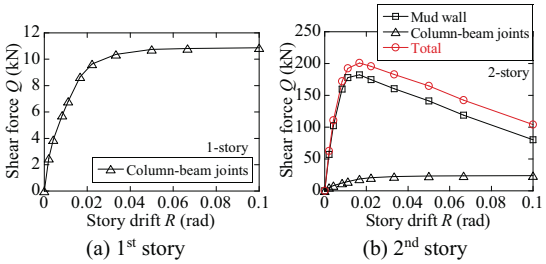

***Figure 6**: Skeleton curves for each story*

In the ridge direction, the lateral resistance of the first story is extremely small compared to that of the second story. It should be noted that the base shear coefficient C_y, which is obtained by dividing the shear force at the first story drift of 1/60 rad by the total weight of the *Omoya*, is 0.40 in the span direction and 0.02 in the ridge direction, indicating that the value in the ridge direction is extremely small.

4.3 MAXIMUM RESPONSE STORY DRIFT

The limit strength calculations were performed using the weight and skeleton curve data. The input data is based on the Japanese design response spectrum, which assumes Type 2 ground classification. The damage limit for rare earthquakes was evaluated using a story drift angle of 1/120 rad, while the safety limit for very rare earthquakes was evaluated using a story drift angle of 1/20 rad [6]. The maximum response story drift angle in each direction is listed in Table 2. Here, "rare earthquakes" and "very rare earthquakes" are input seismic motions used in the structural design in Japan. These earthquakes are classified based on their rarity and represent the maximum seismic force that a building may experience during its lifetime. Specifically, "rare earthquakes" refer to earthquakes that are expected to occur once in approximately 50 years, while "very rare earthquakes" refer to those that are expected to occur once in 500 years.

***Table 2**: Results of weight and mass calculation*

	Target response spectrum	Limit [rad]	Max. response story drift [rad]	
			1st story	2nd story
Span direction	Rare	1/120	1/309	1/518
	Very rare	1/20	1/24	1/242
Ridge direction	Rare	1/120	1/47	1/2731
	Very rare	1/20	No response	

The maximum response story drift in the span direction is within the damage and safety limits for each story. However, the maximum response story drift in the ridge direction is significantly larger on the first story compared to the span direction, and the response value cannot be obtained in the event of a very rare earthquake, resulting in significant seismic performance deficiencies.

As a result, the target house did not collapse during the Kumamoto earthquake even though, based on the limit strength calculations, it would experience a significantly large maximum response story drift in the ridge direction when subjected to seismic motion equivalent to a very rare earthquake. The target house has relatively large through columns, which are not considered in the limit strength calculations. It is speculated that these through columns may affect the seismic performance because the horizontal resistance in the ridge direction at the first story is extremely low. In the following section, we investigate this possibility using time history response analysis.

5 SEISMIC PERFORMANCE EVALUATION BY TIME HISTORY RESPONSE ANALYSIS

In this section, time history response analysis is conducted using a model that considers through columns and a model that does not consider them in the ridge direction of the target house, and the seismic performance of the house is evaluated based on the results.

5.1 ANALYSIS METHOD

We assumed the house to have no torsional motion on a rigid floor and modeled it as a two-mass system. An overview of the analysis model is shown in Figure 7. For the ridge direction, two types of models were used: a model without through columns (referred to as the NTC model; see Figure 7(a)) and a model with through columns (referred to as the TC model; see Figure 7(b)). The through columns were assumed to be linear elastic bodies and modeled with pinned connections to each mass point via rigid beams. Note that the connections between the through columns and the ground were assumed to be pinned.

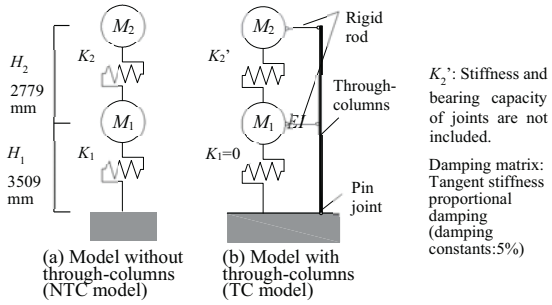

***Figure 7**: Overview of analysis models*

The restoring force characteristics (skeleton curve + history characteristics) of the equivalent shear springs K_1 and K_2 on each story are determined by the bi-linear + slip model, which is the sum of the bi-linear and tri-linear slip

https://doi.org/10.52202/069179-0535

models, representing the history characteristics of the wooden structure (Figure 8).

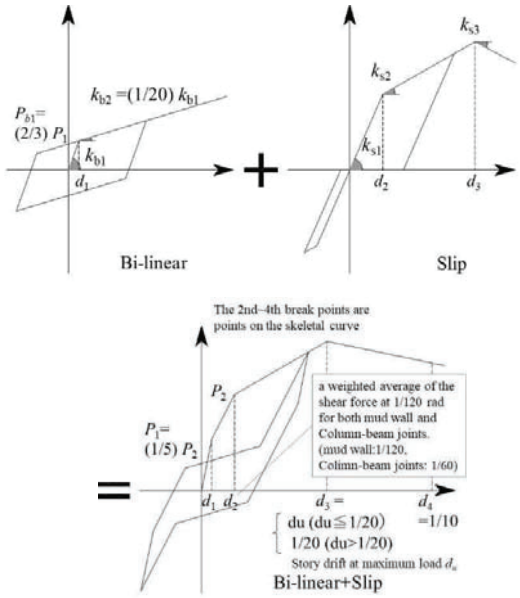

***Figure 8**: Hysteresis model*

The equivalent shear springs K_1, K_2, and K_2' on each model's story are determined as follows: K_1 and K_2 are based on the skeleton curve calculated in the previous section, while K_2' is based on the skeleton curve obtained by subtracting the skeleton curves of the column-beam joints from the skeleton curve of K_2.

The skeleton curves of the equivalent shear springs K_1, K_2, and K_2' for each model are determined as follows:

1) The second breaking point (yield point) was determined as a point on the skeleton curve of each story of the target house, and the story drift at the breaking point was determined based on the inter-story shear force ratio of the mud walls and column-beam joints. Specifically, the story drift of the second breaking point was assumed to be 1/120 rad when only the mud wall was present, and it was assumed to be 1/60 rad when only the column-beam joint was present. When both elements were present, the inter-story shear force at 1/120 rad of both elements was used as a weight to determine the story drift of the second breaking point by weighted averaging.

2) The third breaking point (ultimate point) was taken as a point on the skeleton curve of each story of the target house and set to the value of the story drift R_u at the maximum load. However, if R_u > 1/20, it was taken as the point at 1/20 rad.

3) The degraded stiffness was set to the stiffness connecting the third breaking point and the point on the skeleton curve of the target house at a story drift of 1/10 rad.

The validity of the above settings must be verified in future studies. Figure 9 shows the skeleton curves of the shear springs on each story used in this study, together with the skeleton curves calculated in the previous section. The analysis limit was the intersection of the degraded stiffness of the slip model and the horizontal axis (inter-story shear force = 0), and the analysis was terminated at the point of intersection.

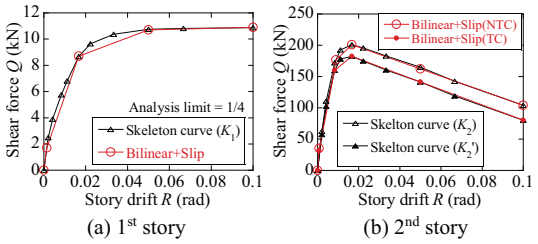

***Figure 9**: Skeleton curves of shear springs for each story*

The history characteristics were assumed to be the same as in [7]. The relationship between the first breaking point load P_1 and the second breaking point load P_2 for the bi-linear + slip skeleton curve is expressed by the following equation [7]:

$$P_1/P_2 = 1/5. \quad (1)$$

The ratio of the bi-linear component at the first breaking point P_{b1}/P_1 is given by the following equation [7]:

$$P_{b1}/P_1 = 2/3. \quad (2)$$

The ratio of the second to first bi-linear component stiffness k_{b2}/k_{b1} is assumed as the following [7]:

$$k_{b2}/k_{b1} = 1/20. \quad (3)$$

The through columns exert horizontal resistance when there is a difference in the story drift between the first and second stories. The relationship between the external force and the deformation acting on through columns is shown in Figure 10 [8].

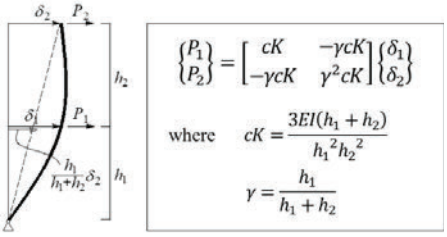

***Figure 10**: Through columns modeling* [8]

Through columns are assumed to be linear elastic. The stiffness matrix of the TC model was obtained by adding the stiffness matrix of the through columns shown in the figure to that of the NTC model. The second moment of area I for the through columns was calculated by adding the second moment of area I_c and I_{cd} for each of the 18 gable-end columns with a cross-section of 145 mm and the central column (*Daikoku* column) with a cross-section of 290 mm. The columns were assumed to be made of

cedar, and the elastic modulus E was used as the basic elastic modulus for an ungraded lumber, E_0 = 7.0 kN/mm^2, from [9].

In addition, for the through columns, the failure due to bending moments M_c and M_{cd} at the first-floor column head of each of the gable-end and *daikokubashira* columns, respectively, is considered based on the difference in story drifts between the first and second stories. M_c and M_{cd} were calculated using the following equations based on the maximum difference in story drifts $|R_2 - R_1|_{max}$ obtained from the time history response analysis:

$$M_c = \frac{3EI_c}{H_1 + H_2}|R_2 - R_1|_{max} + M_\theta, \quad (4)$$

$$M_{cd} = \frac{3EI_{cd}}{H_1 + H_2}|R_2 - R_1|_{max} + 2M_\theta, \quad (5)$$

where M_θ is taken as the maximum bending moment at the column-beam joint (M_θ = 4.0 kNm). H_1 and H_2 indicate the height of each story, respectively.

An additional $2M_\theta$ is added for the *Daikoku* column as two beams are attached in the ridge direction. However, when considering through column failure, it does not consider the maximum bending moment at the column-beam joints M_θ in the TC model. The bending strength of each column $M_{cu}$and M_{cdu} was calculated by multiplying the reference strength F_b of the column by the effective section modulus Z_e, where Z_e is 3/4 of the full section modulus Z of the column considering the section deficiency (M_{cu} = 8.5 kNm and M_{cdu} = 67.7 kNm). The bending strength F_b of the column was taken as the average value of H1, E70 (cedar) in [10], which was 40.9 kN/mm^2. If the bending moment M_c or M_{cd} generated in each column exceeds the bending strength (M_{cu} or M_{cdu}), the column was considered to have failed.

The mass matrix was calculated using the masses of each story, M_1 and M_2, as determined in the previous chapter. The story heights, H_1 and H_2, were determined based on the results of the structural investigation presented in Section 3. The damping was assumed to be proportional to the instantaneous stiffness, and the damping coefficient was set to 5%. The P-Δ effect was not considered in this study.

Figures 11 and 12 show observation points of the input seismic waves and the seismic waveforms and acceleration response spectra, respectively.

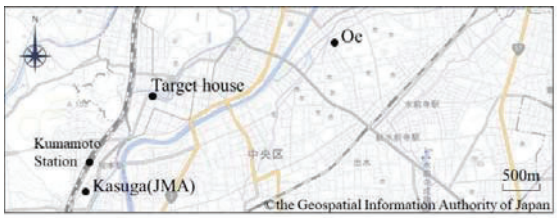

***Figure 11**: Target house and earthquake observation sites*

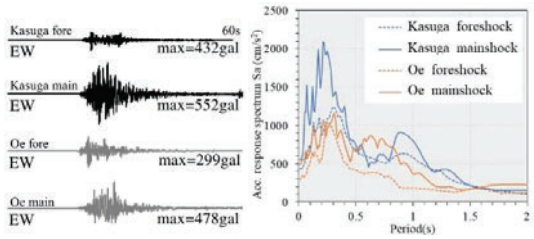


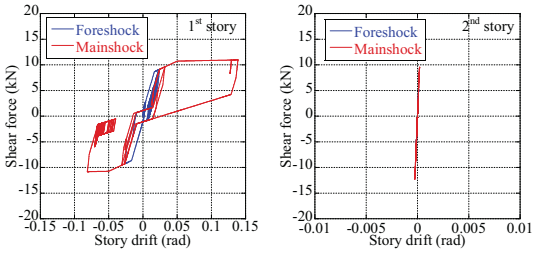
(a) Input earthquake (b) Response Spectrum

***Figure 12**: Target house and earthquake observation sites*

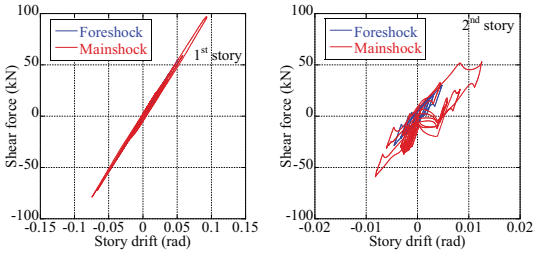
The input seismic waves were based on the observed seismic waves of the 2016 Kumamoto earthquake [11], using the fore and main shock observed seismic waves at the observation points near the target house in Kasuga, Nishi-ku, Kumamoto City and Oe, Chuo-ku, Kumamoto City. The seismic waves used were the EW component corresponding to the ridge direction of the target house. In addition to the input of the mainshock, continuous earthquake ground motions with an interval of 60 s between the fore and main shock were also considered in this study.

5.2 ANALYSIS RESULTS AND EFFECT OF THROUGH COLUMNS

In this study, the relationship between the inter-story shear force and the story drift for each floor obtained from the analysis is shown in Figure 13 using the example of continuous input of observed earthquake waves in Oe. The results of the NTC model are shown in (a) and (b) while those of the TC model are shown in (c) and (d). Furthermore, the time history changes of the story drift for the first story are shown in Figure 14.



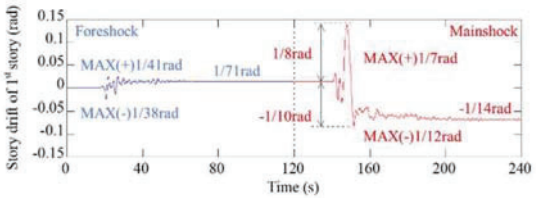
(a) NTC model



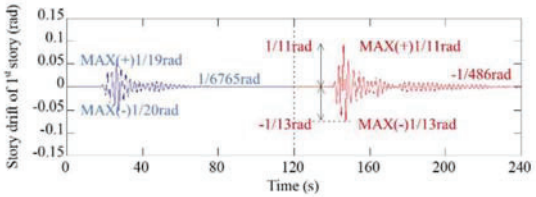
(b) TC model

***Figure 13**: Relationship between the inter-story shear force and the story drift (input: Oe continuity)*

https://doi.org/10.52202/069179-0535



(a) NTC model



(b) TC model

***Figure 14**: Time history changes of story drift for the first story (input: Oe continuity)*

In the TC model, the second story deforms elastically within its range, while only the first story undergoes significant deformation. In comparison to the NTC model, the maximum response story drift of the first story in the TC model decreases by approximately 36% from 1/7 rad to 1/11 rad. Furthermore, for the second story, the ratio of the maximum response story drift to that of the first story is approximately 0.2% in the NTC model, but it increases to approximately 14% in the TC model, and the second story undergoes plastic deformation in the TC model. These results confirm the effectiveness of through columns in equalizing the story drifts of each story. It is apparent that residual deformation from the foreshock remains in the NTC model based on the observation of the time history response of the story drift of the first story, while it is not observed in the TC model. These tendencies were also observed with the Kasuga seismic input.

Table 3 summarizes the results of time history response analysis for four input ground motions, each analyzed in eight patterns with and without through columns considered. M_c/M_{cu} and M_{cd}/M_{cdu} represent the ratios of the bending moment to the bending strength of the gable-end columns and the Daikoku column, respectively. The ratio of 1.0 or greater indicates that the column is prone to breaking.

***Table 3**: Analysis results*

Earthquake		Model	Max. response story drift (rad)		Residual story drift of 1st story (rad)	Max. bending moment of column (kNm)		M_c/M_{cu}	M_{cd}/M_{cdu}
			1st story	2nd story		M_c	M_{cd}		
Kasuga	main shock	NTC	1/15	1/4122	1/20	12.0	135.5	0.8	1.1
		TC	1/17	1/178	1/4216	6.5	104.3	0.4	0.8
	continuity	NTC	1/9	1/4595	1/44	17.3	220.5	1.1	1.8
		TC	1/17	1/181	1/4900	6.5	104.4	0.4	0.8
Oe	main shock	NTC	1/9	1/3644	1/22	17.9	230.7	1.1	1.9
		TC	1/11	1/79	1/531	10.0	159.6	0.6	1.3
	continuity	NTC	1/7	1/3819	1/14	21.0	280.2	1.3	2.2
		TC	1/11	1/80	1/486	10.0	159.7	0.6	1.3

The results of the time history response analysis for the NTC model show that the maximum response story drift of the first story exceeded the safety limit of 1/20 rad, reaching 1/15 and 1/9 rad for the Kasuga and Oe mainshocks, respectively (Table 3). However, the limit strength calculations indicate that the NTC model collapses in a very rare earthquake, as shown in Table 2. Although the earthquake characteristics and intensities assumed in the time history response analysis and the limit strength calculations are different, the results of both methods are not significantly contradictory.

Figure 15 shows the maximum response story drift of the first story for each model and input.

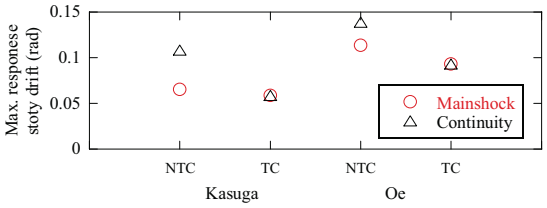


***Figure 15**: Absolute value of the maximum response story drift for the 1st story*

The response story drift of the first story is larger for the continuous input than for the mainshock input. In the TC model, the maximum response story drift of the first story was reduced by approximately 10–20% for the mainshock input and 33–45% for the continuous input compared to the NTC model. Additionally, in the TC model, no residual deformation was observed in the foreshock due to the seismic input used in this study, resulting in similar response values for the continuous input and mainshock input alone. Although the maximum response story drift of the first story exceeded the safety limit of 1/20 rad established in Section 4.3 for both models, the analytical results suggest that the through columns act as bearing elements and suppress the story drift of the first story.

In the target house, according to Table 3, the result of the Kasuga and Oe mainshocks was the breaking of the gable-end column or the Daikoku column in the NTC model, while only the Daikoku column broke due to continuous input from the Oe mainshock in the TC model. It should be noted that there were no through column breakage that was confirmed as damage in the 2016 Kumamoto earthquake for the target house.

Subsequently, the residual story drift for each model and each seismic input for first story is shown in Table 3 and Figure 16.

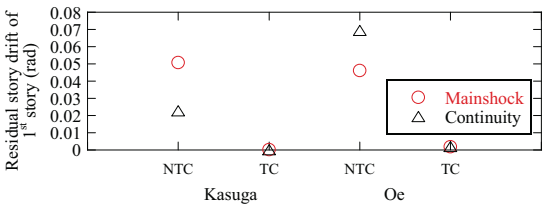

***Figure 16**: Absolute value of the residual story drift for 1st story*

For all cases, the residual story drift for each model was smaller in the TC model than in the NT model, suggesting that the through-column had the effect of reducing the residual story drift. However, in this study, it should be noted that for the TC model, there was no plasticization observed for the second story to generate residual story drift during the foreshock. Moreover, the assumption was made that the through column was a linear elastic body, and that the through column and each mass point were connected by rigid bars (rigid floor assumption), which may have increased the effect of the through column.

6 CONCLUSIONS

This study presented the results of the structural investigation of a machiya, a traditional Japanese wooden townhouse, located in the historic district of Furumachi in Kumamoto City, which is not significantly damaged during the 2016 Kumamoto earthquake. The seismic performance of the house was evaluated using the limit strength calculations commonly used for assessing the seismic performance of traditional wooden townhouses. In addition, the effect of through columns, which were present various parts of the house, was considered using a simplified model. Time history response analyses were conducted using the observed ground motion records from the earthquakes that occurred in Kasuga and Oe in 2016, and the differences in the maximum response story drift due to the presence or absence of through columns were investigated. The following findings were obtained.

1. The main house (Omoya) had no full mud walls in the ridge direction on the first story, and the gable-end columns (145 mm square cross-section) and a Daikoku column (290 mm square cross-section) were reached to the purlins, forming a post-dominant structure.
2. The base shear coefficients for the main house were 0.4 in the span direction and 0.02 in the ridge direction for a story drift of 1/60 rad. The horizontal resistance in the ridge direction was considerably small. If the effect of through columns is not considered in the limit strength calculation, the maximum response story drift in the first story in the ridge direction would be extremely large, but the house did not collapse during the 2016 Kumamoto earthquake.
3. Time history response analyses were conducted with and without considering through columns, and the results showed that the maximum response story drift in the first story was reduced by 10–20% during the mainshock and by 33–45% during continuous input when the effect of through columns was considered.

Therefore, it is suggested that through columns act as bearing elements, potentially reducing the maximum response story drift in the first story. However, it should be noted that the results are subject to assumptions, such as the validity of the rigid floor assumption and the linear elastic behavior of through columns. Furthermore, the stiffness of the second story was much larger than that of the first story. Based on these results, we developed a method for incorporating the effect of through columns into the limit strength calculations.

ACKNOWLEDGEMENT

We would like to express our sincere gratitude to the owners and stakeholders of the target house, Mr. Michikiyo Yamakawa of Kumamoto Association of Architects & Building Engineers, and the students of the Kitahara Laboratory at Prefectural University of Kumamoto and the Ninakawa Laboratory at Kyushu University for their invaluable support in conducting the structural investigation. Without their generous cooperation, this study would not have been possible.

Development of Timber Roof Frames in Korean Modern Architecture

Kangmin Lee[1], Don-Son Woo[2]

ABSTRACT: This study tracks the introduction of foreign timber roof frames into Korean architecture. The foreign timber roof frame introduced in the modern era had not only Western truss but also Japanese conventional timber structure. The traditional roof structure in Korea involves stacking horizontal timber members in a grid shape and placing rafters on top, resulting in thick and heavy horizontal members. To accommodate the introduction of Western trusses, a compromise form was created based on this traditional understanding. However, during the Japanese colonial period, the two foreign roof frames occupied a more dominant position in state-run architecture than that of traditional Korean architecture. Japanese roof frames were applied to small and complex buildings, and Western trusses were applied to large buildings with simple functions. The hidden part of the roof of traditional Korean buildings was also replaced by truss or Japanese roof frame. Both foreign roof frames were designed using *Roof Framing Plan*, and the span and spacing of the structures were determined according to the traditional measuring unit, K. The two types of roof frames shared roles based on their respective strengths and could be used interchangeably. These foreign roof frames were mainstream in modern Korean architecture until reinforced concrete structures became widely distributed.

KEYWORDS: Korean modern architecture, roof frame, timber truss, Japanese roof structure, scale unit

1 INTRODUCTION

Korea has a rich tradition of wood construction, dating back centuries. At the end of the 19th century, two foreign technologies were introduced. This resulted in three types of timber roof frames being used in buildings: the traditional Korean roof frame, the Western truss structure, and the Japanese conventional roof structure. These structures were influenced by one another and coexisted in the majority of buildings until the reinforced concrete structure became more common. This paper aims to summarize the development process of the modern Korean timber roof frames, focusing primarily on the drawings of state-run architecture preserved in the National Archives of Korea.

2 TRADITIONAL TIMBER STRUCTURE AND INTRODUCTION OF FOREIGN ROOF FRAMES

2.1 TRADITION OF KOREAN ROOF CONSRUCTION

One of the defining features of traditional Korean roof structures is the absence of trusses. Instead, horizontal beams are stacked on vertical columns to create right-angled frames, with the beams and short posts supporting the purlins directly. The number of the purlins was limited because they were not only bulky and weighty, but also given Confucian symbolism. [1] It is common for five or seven purlins to be used in formal buildings. The building with the largest number of the purlins in Korea is *Gyeonghoeru* Pavilion in *Gyeongbokgung* Palace, which was rebuilt in 1867, with 11 purlins arranged in a 28.5m span. Therefore, in Korean architecture, the purlin is conceptually more like a longitudinal beam than the purlin used in typical truss structures. Above the purlins, a series of rafters are arranged, and then topped with earth and roof tiles to create a heavy roof.

Figure 1: *The Anglican Church, Ganghwado Island, built in 1900.*

Because the horizontal beams transmit the load to the columns at the intersection with the purlins, the arrangement of the columns creates a square module, which is called *Kan*. *Kan* was the basic unit for combining and dividing spaces. The size of *Kan* determines the horizontal length of the members in the roof structure, which is usually consistent with the dimensions of the

[1] Kangmin Lee, Korea National University of Arts, Republic of Korea, leekaang@karts.ac.kr
[2] Don-Son Woo, Korea National University of Arts, Republic of Korea, woods@karts.ac.kr

https://doi.org/10.52202/069179-0536

Kan or is twice or three times as long. This consistency in structure and space is a shared feature of East Asian wood structures, including China, Korea, and Japan. Prior to the 20th century, one *Kan* was typically about 2.4 meter in houses and more than 3 meter in public buildings in Korean architecture, while it was recognized as about 1.8 meter in Japanese architecture. [2]

Although Western-style architecture had become prevalent in modern large-scale construction, traditional Korean roof frames are still used in some cases. For example, the Anglican Church of Figure 1, built in *Ganghwado* Island in 1900, is an example of how the basilica structure can be completed using Korean traditional building techniques. This reflects the missionaries' desire for self-sustaining church architecture in Korea. [3] From *Janglim* Church in 1892 to *Pyeongbuk Jeongju* Church in 1938, a total of 38 churches with Korean traditional timber structures were identified. These structures evolved to emphasize the facade of the basilica, add bell towers, and widely use brick walls. [4]

2.2 INTRODUCTION OF FOREIGN ROOF FRAMES IN KOREA

In the late 19th century, foreign timber roof frames were introduced along with buildings that served new functions such as factories, government offices, and churches. Since most of these buildings were designed by foreign architects, their space, design, and structure were all different from traditional Korean architecture. However, the brick walls and the two- or three-story buildings with trussed roofs became the representative form of modern Korean architecture. Western-style houses began to be built in the palaces as well as the foreign settlement at the open ports. Starting with *Gwanmungak* Pavilion in *Gyeongbokgung* Palace in 1888, several Western-style buildings were built in *Gyeongunggung* Palace during the Great *Han* Empire (1897-1910). [5] Accordingly, the use of Western truss frames became widespread in high-level architecture. The truss structure was also applied to repair the traditional buildings in 1908 in the project of renovating the *Injeongjeon* Hall of *Changdeokgung* Palace in pursuit of the *Meiji* Palace in Japan, replacing the invisible part of the existing traditional roof frame. [6] Based on the traditional understanding of building techniques, in some cases, structures were compromised with each other. *Beonsachang* Factory of Figure 2, Korea's first timber trussed building, was built in 1884 as a weapon-making factory. Its trusses were fabricated within the traditional concept of placing posts on a thick beam. All members are thick and heavy, and traditional mortise and tenon joints that do not use hardware have been applied. The use of cylinder-shaped round purlins can also be seen as an inheritance of the Korean building tradition. [7] The cross-sectional areas of the top chord, bottom chord, and post of the trusses at *Beonsachang* Factory are 648 ㎠, 2,052 ㎠, and 375 ㎠, respectively. These dimensions are from two to seven times larger than the average cross-sectional area of truss members since the 1920s. [8] This use of larger members can also be observed in the trusses of *Yongsan* Theological School, which was constructed in 1892. It can be interpreted as an adaptation process in the early stages of the truss structure's introduction.

Figure 2: *The Beonsachang Factory, Seoul, built in 1884.*

3 TIMBER ROOF FRAMES UNDER JAPANESE COLONIAL RULE

3.1 CHARACTERISTICS OF JAPANESE CONVENTIONAL TIMBER STRUCTURE

With the introduction of Western structural engineering in the *Meiji* period (1868-1912), traditional Japanese timber structures were criticized for being heavy in their roof design, having isolated columns, significant timber loss for joints, and temporary member fixation [9]. Especially in Japan, where there was a high risk of earthquakes, the traditional timber structure was improved to focus on enhancing seismic performance. This process led to the reinforcement of structures through braces, the use of hardware, and a method for tightening the foundation and column, which is known as *the Conventional Construction Method* in Japan, distinguishing it from the traditional one.

The Japanese conventional construction method favored the *kyouro-gumi* method, which was popular in private houses during the *Edo* period. The *kyouro-gumi* method involves first combining purlins that act as beams on columns to form an outer frame and then placing transverse beams on top of it [10]. This method has the advantage of being easier to add and move roof structures compared to the *orioki-gumi* method, in which transverse beams are joined first on the columns and purlins are placed on them. In addition, the *kyouro-gumi* structure is relatively lightweight. The conventional construction method was widely used not only in the private sector but also in public buildings by governments because it allowed for improved building performance while still preserving traditional building practices.

3.2 COLONIAL RULE AND STANDARDIZATION OF MODERN SPACES

The Joseon Government-General's government facilities were supplied with wood through *Yeongrimchang*, which was established during the Korean Empire. *Yeongrimchang* opened its headquarters in *Sinuiju* in

https://doi.org/10.52202/069179-0536

1907 to develop abundant timber in the two river basins bordering China, and later oversaw the entire Korean forest organization. *Yeongrimchang* began operating a direct sawmill in *Sinuiju* in 1909 and supplied timber for construction in earnest. [11]

In *Yeongrimchang*'s sawmill, logs were cut into lumber using the traditional measurement units S and K used in East Asia. One K translates into six S. Since one S corresponds to 30.303cm, one K corresponds to 1.818m. The lumber produced in the *Yeongrimchang* sawmill had general dimensions of 1S in width and depth and 4K in length, which corresponds to 7.272m. This lumber was superior in quality and size compared to that supplied to the private sector. [12] Additionally, various standardized 2K-long construction timbers were supplied with names indicating where they should be used. In some cases, timber was supplied by separately ordering the type and dimensions of timber according to the design document of the specific construction work.

As a result of Japan's annexation of Korea as a colony in 1910, the urgent need to establish colonial governance facilities quickly and affordably led to the construction of numerous timber structures. In this process, *the Joseon Government-General Building Standards* were enacted in 1916, and standard regulations were applied to buildings such as government offices, schools, hospitals, prisons, and official residences. Standardized designs were repeatedly reproduced through *the Common Drawings*. Among the blueprints of the 1910s, the application examples of *the Common Drawings* were found in the drawings of local courts, weather stations, secondary education facilities, national hospitals, and other facilities. [13] The use of standardized construction members and building plans became widespread and characterized the typical form of roof structures.

3.3 DECLINE OF TRADITIONAL KOREAN ROOF STRUCTURE

During the modernization process, traditional Korean roof frames were marginalized in favor of Western-style truss structures and improved Japanese-style roof structures, which were exclusively used for constructing modern facilities. In the 1910s, many Korean traditional buildings were renovated and repurposed as government offices or schools, but these renovations were limited to changes in floor plan and elevation. Moreover, any new additions were constructed in Western or Japanese styles, rather than in the traditional Korean style. The use of traditional Korean timber structures was limited to community facilities in rural areas with strong national conservatism or houses for Koreans. While the number of such buildings was not insignificant, the potential for expanding and developing traditional Korean architecture was limited.

The decline of traditional Korean timber structures can be attributed to the malicious intent of colonial rule. However, weaknesses in the architectural industry contributed to this decline as well. The large and heavy structures of traditional Korean buildings made construction economically inefficient, and their lack of braces and hardware were considered vulnerable to earthquakes. Specifically, the government sawmill did not provide timber of an appropriate size for Korean-style structures. The cross-sectional width and depth of timber used in modern trusses in Korea ranged about 120-180×120-240mm, with a decreasing trend after 1920. [14] In contrast, traditional Korean structures utilized large, rounded sections for their members. As a consequence, architects were unable to effectively represent the Korean roof structure through efficient design drawings.

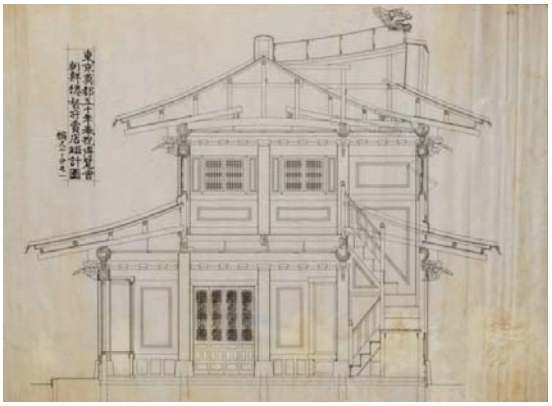

Figure 3: *The section drawing of a Korean-style pavilion with Japanese roof frame at the 50th anniversary Expo of Tokyo's capitalization, 1917, source: National Archives of Korea.*

Even in special situations where Korean-style buildings needed to be reproduced, Western trusses and Japanese roof structures were used as roof structures that were not visible from the outside. Several instances of Korean-style buildings having their roof structures replaced with trusses or Japanese roof structures can be observed in various buildings at *Gyeongbokgung* Palace and *Changdeokgung* Palace. Additionally, many Korean pavilions built at the *Taisho* Expo (1914), the 50th anniversary Expo of *Tokyo*'s capitalization (1917) of Figure 3, the Peace Memorial *Tokyo* Expo (1922), and the *Joseon* Expo (1929) were representative, and there were buildings with strong national colors such as the *Kaesong* Museum (1931) and the *Suungyo* Headquarters memorial service house (1936). [15]

4 CHARACTERISTICS OF TIMBER ROOF FRAMES IN KOREAN MODERN ARCHITECTURE

4.1 COMBINATION OF TRUSS AND JAPANESE ROOF FRAME

Most of Korea's early modern architecture had a western appearance. Until reinforced concrete construction became popular, the most monumental buildings, such as *Seokjojeon* Hall of *Gyeongunggung* Palace, were built of stone, while important government offices, such as the Ministry of the Interior in Figure 4, were made of brick, and the rest were built of wood. In either case, a timber roof frame was an essential requirement for building a

sloped roof. The choice of roof frame was determined by the span of the building. *Shoukou Hikkei*, translated into the Builders Manual, written by *Shishikichi Shibada* in 1886, explained that the king post truss could span up to 30S (9m), the queen post truss could span up to 45S (13.5m), and the compound one could span up to 60S (18m). [9] The truss was able to create a large space that was not easily achievable with traditional roof structures. Therefore, large and important buildings were built with trusses, while smaller buildings were built using Japanese conventional methods.

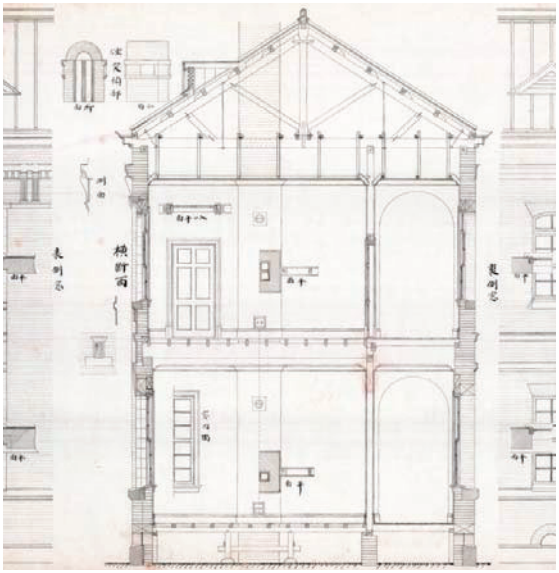

Figure 4: *The section drawing of the Ministry of the Interior, part, built in 1910, source: National Archives of Korea.*

The central government offices in Seoul, customs offices in ports, provincial government offices, police stations, and state-owned factories in each region used trusses in their roof structures, while Japanese official residences, local offices, branch offices, and weather stations used Japanese roof frames. [16] However, some hospitals, schools, courthouses, and prisons, which required rapid construction in the early colonial period, were built using Japanese roof frames regardless of size.

In modern state-run architecture in Korea, it was popular to arrange the main building and annexes in parallel, connecting them with a corridor to form an H-shape or extending wings from both ends of the main building to the rear. At this time, the use of timber structures was allocated specific roles in the architecture. For example, the main building was constructed with trusses, and Japanese roof frames were applied to the wings or other annexes. Even when trusses were applied to the main building, it was common to use a Japanese roof frame for the entrance.

The *Gyeongnam* Provincial Government Office, built in 1924, is an exceptional example of architecture that incorporates both Japanese roof structures and truss structures. Initially designed as a prefectural hospital, the main building was constructed with a Japanese roof frame. [17] Later, both wings were extended to the second floor, and trusses were added to the roofs of the wings. The main building is approximately 13.5 meters wide, with a 2.7-meter-wide (9K) corridor in the middle. The Japanese roof frames were adopted using 280mm thick log beams. In comparison, the left and right wings were approximately 8 meters wide and were built using a king post truss structure. The distance between the king post and the side post of truss is 1.8 meters (6K). The truss timbers were 120mm wide and varied in thickness, and as seen in Figure 5, they differed from the logs used in the main building in terms of size and species of tree.

Figure 5: *Original roof frames from the Gyeongnam Provincial Government Office, built in 1924, expanded in 1931, source: Seokdang Museum of Dong-A University.*

While truss could form large spaces, the advantage of the Japanese roof frame was that it allowed for a greater degree of flexibility in shaping the roof surface. By supporting purlins with standing posts on a stable foundation, a complex or curved roof shape could be achieved more easily. A hybrid structure was also created by combining trusses and Japanese roof structures. The roof volume could be expanded by adding posts on top of the truss and arranging purlins, allowing for the creation of curved domes or arches. This was a simple method even when the building was expanded horizontally. Additionally, the Japanese roof frame could protect the building and its walls made of wood by extending the eaves, and the use of both log and timber as building materials was advantageous.

4.2 STANDARDIZATION TRENDS DEPENDENT ON FLOOR PLAN

In the context of modern state-run architecture in Korea, both Japanese roof structures and Western-style trusses were extensively used, with the latter being considered structurally superior. This was due to the fact that the tradition of wood construction could not be easily abandoned given the circumstances of the building production system of that time. Particularly, in a situation where the construction organization and distribution system were not sufficiently mature, the truss structure did not have an overwhelming comparative advantage in terms of price or mass production. The market share of

https://doi.org/10.52202/069179-0536

trusses depended on the industrialization of lumbering and sawmills, the standardization of timber, the expansion of transportation networks such as railways for delivery from production sites, communication between designers and builders, construction methods on the site, and other factors. From the perspective of consumers, converting long-standing living customs to the Western style was also a challenge for both Korean and Japanese architecture. However, during the era of colonial rule, the Japanese-style timber frame was chosen as an alternative to the truss, while the Korean timber structure became increasingly marginalized.

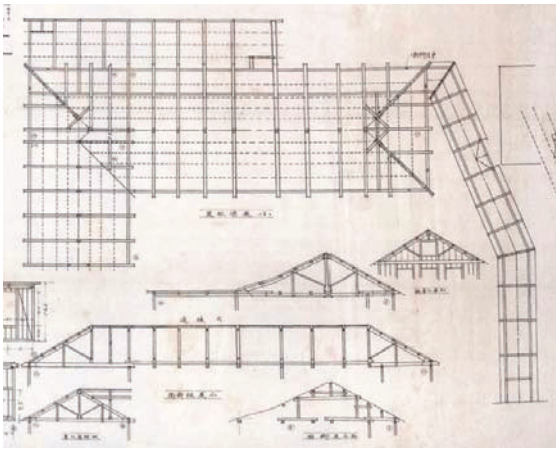

Figure 6: *The Roof Framing Plan of the Pyeongbuk Provincial Government Office, part, built in 1918, source: National Archives of Korea.*

To address the large-scale construction demands, it was imperative to adhere to familiar construction methods that were based on traditional metrology units. In 1921, the Japanese government enforced *the Weights and Measures Act* with the primary aim of mandating the use of the metric system, and in 1926, *the Joseon Government-General* declared *the Joseon Weights and Measures Ordinance*, making it obligatory to use only meters in all tasks. However, due to strong opposition from the industry, a grace period was soon granted. Although the government office buildings were given a grace period of 10 years and others 20 years, the implementation of the law was essentially postponed indefinitely, and it was only after World War II that it was effectively enforced. Hence, the truss structure in the modern era was also inevitably designed based on the traditional unit.

The drawings prepared by the modern government office for construction include various detailed drawings as well as floor plans, elevation drawings, and cross-sectional drawings. One of these drawings is *the Roof Framing Plan* drawing, which displays the horizontal arrangement of the roof structure. *the Roof Framing Plan* helps to determine the location and quantity of timber required for the roof structure by indicating the layout of beams, purlins, hip rafter ridges, and other components. This drawing is comparable to the field drawings traditionally produced by craftsmen on wooden boards. *The Roof Framing Plan* was useful not only for the Japanese-style roof frame but also for the arrangement of trusses. Nonetheless, it is often challenging to differentiate between trusses and Japanese-style roof frame shown in construction plans such as Figure 6. This is because the spacing between the members is similar, and their location is frequently determined by the same traditional dimensional unit.

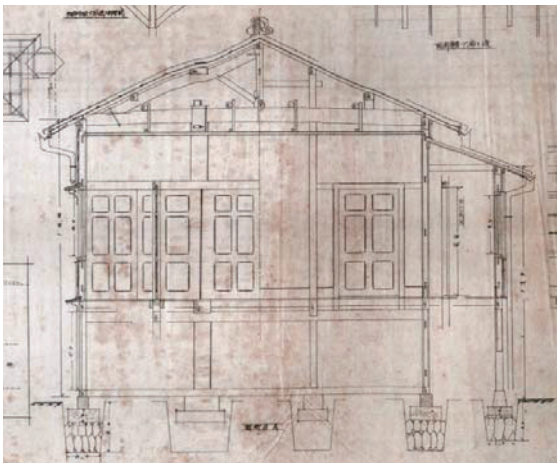

Figure 7: *The Section Drawing of Hwanghae Provincial Government Office, part, built in 1910, source: National Archives of Korea.*

The size and layout of the roof structure became more typical as floor plan was standardized for the rapid dissemination of colonial governance facilities. For example, in school architecture, the width of the school building was fixed at approximately 10m (5.5K) and the width of the students' waiting room and auditorium was fixed at approximately 14.5m (8K), in accordance with the standardization of educational space. [18] Accordingly, the role of each roof structure became clearer, and the possibility of interchangeability between different types of roof structures increased.

For spaces that did not require a large span, the Japanese timber roof frame could replace the truss. About 50% of the existing modern trusses in Korea have a span of less than 10m, and about 80% have a span of less than 12.5m. In addition, the spacing between trusses is often 1.8m, with most of them being less than 3m apart. [8] This means that in many cases, a Japanese-style roof frame, which is not suitable for creating a large space, can be used instead. If columns are inserted indoors to partition the rooms, the possibility of replacing the truss with a Japanese roof frame is further increased.

The spacing between trusses was often determined as a multiple of the traditional metrology unit S or K, which made it similar to that of the Japanese roof frame and suited the standardized floor plan. However, there were exceptions to this pattern, such as the *Myeongdong* Cathedral in *Seoul* (1898), Bell Memorial Chapel of Jennie Speer Memorial School for Girls in *Gwangju*

(1925), *Eonyang* Cathedral in *Ulsan* (1932), where the spacing between trusses was more than 5m. Interestingly, these buildings were all constructed by Western missionaries and did not follow Japanese standardized architectural methods.

5 CONCLUSIONS

In modern Korea, timber roof frames existed alongside Korean, Japanese, and Western styles. However, Korean-style was not used for state-run architecture and was limited to buildings with strong ethnic features such as houses and temples. Public buildings were constructed using Western and Japanese styles. Large-scale buildings were built using trusses, and small-sized buildings were built using Japanese-style roof frames. However, in some cases, the two roof frames were interchangeable as they were designed with the same module that uses traditional metrological dimensions.

After the Great Kanto Earthquake in 1923, the importance of earthquake-resistant structures increased, and reinforced concrete structures rapidly expanded. In addition, the revitalization of private commercial activities and the active involvement of private architects led to the trend of modernism, resulting in the reduction of sloped roofs. The design trend of reinforced concrete structures and modernism began to break away from the long tradition of timber construction.

COMBINATION OF NDT AND DESTRUCTIVE TESTS FOR GRADING THE STRENGTH CLASS OF TIMBER TO REHABILITATE STRUCTURES

Marcel Vilches-Casals[1], Eduard Correal-Mòdol[1], Carles Labèrnia Badia[1], M.P Giraldo[1]

ABSTRACT: Non-destructive techniques (NDT) are being implemented in the rehabilitation of the wooden structures of many old and historical buildings trying to assign the strength class of the timber. In Spain, acoustic inspection techniques are commonly used since the wave speed it can be easily predicted the modulus of elasticity. Nevertheless, the correlation with the bending strength usually is not accurate enough. By combining NDTs with destructive tests, the prediction should be significantly improved. To contrast, this hypothesis a study was carried out with the data obtained at the inspection of the timber structure in the refurbishment works done on a late 19th century Barcelona storey building. 724 beams were inspected with acoustic methods onsite and the information was complemented by testing 5 beams according to EN 408: modulus of elasticity, bending strength, density, and moisture. Finally, both sources of information were combined to develop a statistical model to assign the strength class to the beams. This study presents how the data obtained on difficult environments by NDT can be improved with destructive laboratory tests.

KEYWORDS: Non-destructive techniques, rehabilitation, strength class, timber, acoustic methods

1 INTRODUCTION

Timber was the most common material used in load-bearing structures on buildings before the massive introduction of steel and concrete in early 20th century in Catalonia. In consequence, nowadays most refurbishment works that are done on historical buildings have timber structures and old structural elements lack information about their quality or strength class. Therefore, grading all the elements is necessary to know the loadbearing capacity and minimize unexpected structural safety issues. Unfortunately, although the information obtained by the destructive tests according to EN 408 is the most accurate, destroying the elements in service to evaluate them is useless. On the other hand, Non-Destructive Testing (NDT) has a worse correlation but does not damage wood, gives valuable information and is cost-effective. A comprehensive way to evaluate an old structure is to grade visually all the elements, use acoustic waves to complement the inspection and perform destructive tests on some replaced elements. This study focuses on how to optimize the data obtained on the inspection of an existing wood structure.

2 OBJECTIVES

Improve the prediction of the load-bearing capacity of the wooden elements of an old structure in service by developing a cost-effective model based on acoustic techniques and the standardized procedure to determine the MOR, the MOE and the density.

3 METHODS

3.1 FIELDWORK

The case study is the timber structure of a five-storey building placed at 26 Trafalgar Street in Barcelona built in 1878 (Figure 1). Its constructive system was very typical in late 19th and early 20th centuries in the cities of Catalonia: masonry walls, wrought iron pillars and timber beams. The species of the beams was not determined but the gender was Pinus sp. The most common species used by that time in Barcelona was Scots pine (*Pinus sylvestris*) from the Pyrenees, but the authors also found in other contemporary buildings different common local species like Black pine (*Pinus nigra* subsp. *salzmanii*) and poplars (*Populus* sp.). In addition, also the American southern yellow pines from overseas were very common. The timber structure was in a generally good condition

although there were elements that had issues produced by biotic agents.

The study was ordered to evaluate the safety of the new usage of the building. The inspection was done on four wood beam slabs by checking 212 beams on the ground floor, 198 on the first floor, 209 on the second floor and 105 on the third floor (Figure 2). All the 724 wood elements were inspected with a set of analysis techniques and equipment: capacitance handheld moisture meter, microsecond timer, electric drill and hand tools like hammer, awl and measuring tools. The most relevant items checked were the dimensions of the section, the span, the existence of woodworm holes and termites, the relevant splits and cracks, the biggest knots, the hardness and rot, the soundness, the moisture content and the speed of the impact waves.

Figure 1. *Façade of the building on Trafalgar Street*

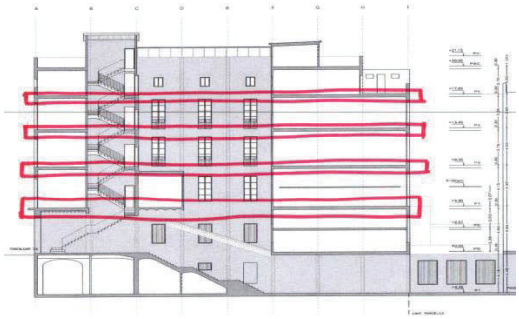

Figure 2. *Section of the building*

The microsecond timer generates impact waves with a frequency of resonance of 23 kHz and measures the time of flight between the transmitter and the receiver sensor (Figure 3). Impact waves are generated by hitting the transmitter with a hammer. Both sensors are metal nail alike transducers, they must be nailed into the wood, and the distance between them must be measured. In this case, the transducers were placed underneath the beams (Figure 4). The principle of this technique is based on the different propagation speeds of the impact waves depending on the soundness of the wood.

Figure 3. *FAKOPP Microsecond timer used in the study*

Figure 4. *Beam inspection with acoustic waves in the building*

3.2 LABORATORY TESTS

The specimens were chosen randomly between those to be removed due to the new distribution of the building. Several minor modifications and a new staircase were planned to connect the ground floor with the first floor. Five timber beams were selected for being tested at the laboratory. Three were from the new staircase on the ground floor, one was from the first floor and the other was from the second floor. The beams of the first and second floors were chosen randomly among those easier to extract. No beam was selected depending on its apparent state of conservation and all were representative of the batch. All the beams were of the same species, there were no abnormal density deviations, and the dimensions were 220×100×4000 mm. MOR, MOE, density, moisture content and stress wave tests were performed. The four-point bending test was done according to UNE EN 408:2011+A1:2012 [4] on a Hoytom bending test Machine. The test samples were symmetrically placed with a span eighteen times the depth (3960 mm) and the two load points were at six times the depth from the support point (1320 mm) (Table 2 and Figure 6).

https://doi.org/10.52202/069179-0537

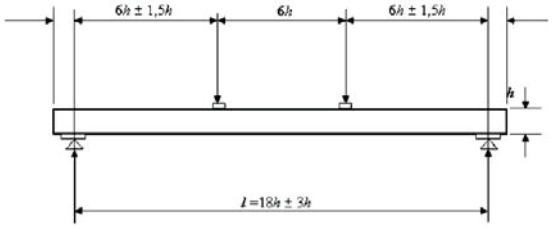

Figure 5. *Bending test geometry according to EN 408 [4]*

Figure 6. *Bending test machine at INCAFUST-CTFC*

The global static modulus of elasticity (MOE) was calculated as follows (See Equation (1):

$$MOE = \frac{3al^2 - 4a^3}{2bh^3\left(2\frac{w_2 - w_1}{F_2 - F_1} - \frac{6a}{5Gbh}\right)} \quad (1)$$

Where MOE = static modulus of elasticity (N/mm^2), l = effective span distance (mm), F = load difference between 10% and 40% of maximum load (N), w = deflection difference at 10% and 40% of maximum load (mm) b = width (mm), h = height (mm), a = distance between loading point and nearest support point (mm).

The Modulus of rupture (MOR) was calculated as follows. See Equation (2) below:

$$MOR = \frac{3Fa}{bh^2} \quad (2)$$

Where MOE = static modulus of rupture (N/mm^2), F = maximum load (N), b = width (mm), h = height (mm), a = distance between loading point and nearest support point (mm).

The density was measured by drying with an oven at 103ºC up to the anhydrous state a full cross-section slice 50 mm thick cut as close as possible from the breakage point. Controlling wood moisture is necessary to correct the MOE as the stiffness varies with the water content. The five beams were checked too with the microsecond timer to correlate the stress wave speed with the MOR and the MOE. The measuring procedure was the same as the one used in the building. Finally, correlation models were developed to predict the MOE and the MOR from the dynamic modulus of elasticity (MOE_{Dyn}) (Table 4).
The dynamic modulus of elasticity (MOE_{Dyn}) was calculated by measuring the wave speed. See Equation (3) below.

$$MOE_{Dyn} = \rho \cdot v^2 \quad (3)$$

Where MOE_{Dyn} = dynamic modulus of elasticity (N/mm^2), ρ = density (kg/m^3), v = wave velocity (m/s).

Finally, the relationship between MOEDyn-MOE and MOEDyn-MOR was analysed through regression models created from the field work data and the laboratory tests results (See Table 4, Figure 9 and Figure 10). The values of the MOE the MOR and the density were corrected according to the standard EN 384 [3]. The MOE was calculated from the global MOE and adjusted by the moisture content. See equation (4) below. The density was also corrected by the moisture content to the reference conditions of 20 °C and 65% of relative humidity. The MOR was adjusted by the depth of the beam.

$$E_0 = E_0(u)\left(1 + 0{,}01\left(u - u_{ref}\right)\right) \quad (4)$$

Where E_0 = modulus of elasticity (N/mm^2), u = moisture content in the moment of the test.

4 RESULTS

Table 1, Figure 7 and Figure 8 show the wave speed on the 724 beams of the building calculated from the time of flight and the distance between transmitters. According to the Shapiro-Wilk test significant results suggest a deviation from normality (p<0,001). The coefficient of variation of the wave speed was 9.1%. Therefore, there was little variability in the data set and the arithmetic mean is a robust parameter for defining the population.

Table 1. *Beams wave speed descriptive statistics*

Descriptive Statistics	Unit	Value
Number of beams	Ut	724
Mean	m/s	5,130.348
Standard deviation	m/s	464,763
Coefficient of variation	%	9.1
Range	m/s	2,689.000
Minimum	m/s	3,543.690
25th percentile	m/s	4,823.560
50th percentile	m/s	5,176.035
75th percentile	m/s	5,483.735
Maximum	m/s	6,232.690

https://doi.org/10.52202/069179-0537

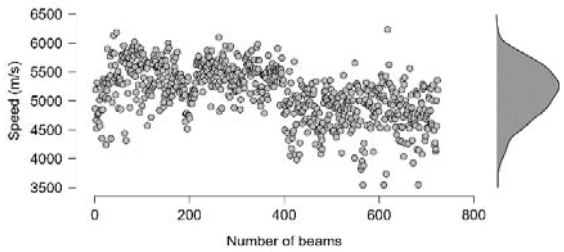

Figure 7: *Scatter plot of all the wave speed measurements (m/s) taken in the building*

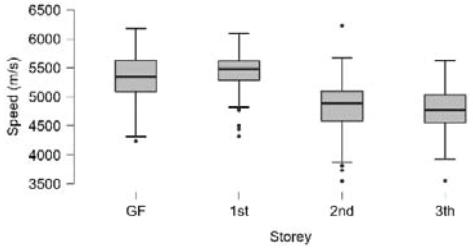

Figure 8: *Wave speed of the 724 beams divided by floors*

The wave speed of the beams split by floors showed statistical differences in accordance with the analysis of variance ($p < 0.001$) (Figure 8). The speed is slower on the upper than on the lower floors, but this difference is considered not to be intentional, and all the building was analysed as one batch.

Table 2 and Table 3 show the results of MOR, MOE, density, moisture content and wave speed of the five beams tested in the laboratory.

Table 2. *Results of the five laboratory tests*

Id. beam	MOE (N/mm^2)	MOR (N/mm^2)	Density (kg/m^3)	%H	Wave speed (m/s)

Table 4 shows the results of the models created between MOE_{Dyn}-MOE and MOE_{Dyn}-MOR with the field work data and laboratory test results.

Table 4. *Models that correlate the MOE_{Dyn} (N/mm^2) with the MOR (N/mm^2) and the MOE (N/mm^2)*

Models developed	Correlation (R^2)
$MOE = 13767.63 - 0.15 \cdot MOE_{Dyn}$	0,76
$MOR = 24.99 + 0.00092 \cdot MOE_{Dyn}$	0,51

5 DISCUSSION

The automatic procedure to assign a strength class to a timber element is conceived to be carried out on an industrial production control where density, modulus of elasticity (MOE) and modulus of rupture (MOR) are determined with a set of advanced NDTs. Portable acoustic methods have a good theoretical correlation with the MOE but a low relationship with the MOR and the density. In fact, the correlation between the values of stiffness and strength predicted with this type of NDTs and the actual values may have a deviation between 20% and 50% [1, 2, 6-13].

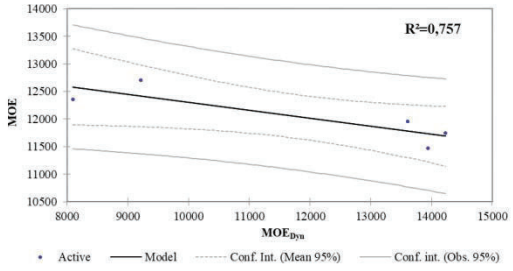

Figure 9: *Graphic of correlation between MOE_{Dyn} (N/mm^2) and MOE (N/mm^2)*

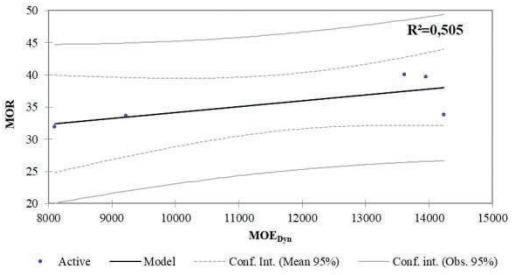

Figure 10: *Graphic of correlation between MOE_{Dyn} (N/mm^2) and MOR (N/mm^2)*

The correlation between the MOE_{Dyn}-MOE and the MOE_{Dyn}-MOR was below 80% (Figure 9 and Figure 10) like in the reviewed references [1, 2, 6-13].

According to the UNE EN 338:2010 [5] the 724 beams had a characteristic MOE of 11,855 N/mm^2, a characteristic MOR of 23 N/mm^2 and a density of 446 kg/m^3. In consequence, the sample should be considered C27 according to the MOE, C22 for the MOR and C50 for the density. Therefore, the strength class of the 724 beams should be around C22 (Table 5).

https://doi.org/10.52202/069179-0537

Table 5. *Characteristic values and strength class of the 724 beams according to the model*

Property	Characteristic Value	Strength class	Final class
Bending strength (N/mm^2)	23	C22	C22
Modulus of elasticity (N/mm^2)	11,855	C27	
Density (kg/m^3)	446	C50	

The models were specifically developed to predict the properties of the beams of the building. It must be considered that all the elements of the structure were of the same kind, and all were in a quite good condition. Therefore, in such a case the accuracy of the model should improve with an increase in the number of destructive tests.

A model with a coefficient of determination of $R^2 = 0.76$ was obtained using the MOE_{Dyn} as an independent variable and MOE as dependent variable. The results are like those discussed in other works. Arriaga *et al*. [1] found coefficients of determination for Scots pine (*Pinus sylvestris*) of 0.76 for linear regressions. Görgün and Dündar [6] obtained coefficients of determination of 0.64 for Turkish black pine (*Pinus nigra*), while Vega *et al*. [13] reported of values up to 0.68 for Sweet chestnut (*Castanea sativa*). Hermoso *et al*. [8] obtained coefficients of determination for logs of Spanish Black Pine (*Pinus nigra*) of up to 0.68. Kovryga *et al*. [10] obtained coefficients of determination of 0.65, 0.39, 0.67, 0.55 for the common ash (*Fraxinus excelsior*), the beech (*Fagus sylvatica*), the maples (*Acer spp*.), and the oaks (*Quercus spp*.) respectively. Both Hermoso *et al.* [8] and Kovryga *et al.* [10] used a Sylvatest.

The coefficients of determination of the MOR were lower and between 0.12 and 0.37. Görgün and Dündar [6] obtained a value of 0.37 for Turkish Black Pine (*Pinus nigra* var *pallasiana*), Vega *et al*. [13] found coefficients of determination of 0.11 for sweet chestnut (*Castanea sativa*) and Kovryga *et al*. [10] 0.12, 0.20, 0.16, 0.31 for the common ash (*Fraxinus excelsior*), the beech (*Fagus sylvatica*), the maples (*Acer spp.*), and the oaks (*Quercus spp.*) respectively.

In addition, the results of the study were also used to run the general model of Arriaga *et al*. [1] (Table 6) but the predicted load capacity resulted lower.

Table 6. *Strength class predicted using the model of Arriaga et al. [1]*

Method	MOR (N/mm^2)	MOE (N/mm^2)	Strength class
MOE_{Dyn} + bibliography*	23.18	9511.46	C18

* $MOE = A + B \cdot MOE_{Dyn} = 579,5 + 0,7548 \cdot MOE_{Dyn}$
* $MOR = A + B \cdot MOE_{Dyn} = -4,84 + 0,0034 \cdot MOE_{Dyn}$

6 CONCLUSIONS

Combining NDTs with destructive tests is useful to reduce the uncertainty of the prediction of the load capacity of the structural timber elements in use.

Assigning a strength class to elements that are out of the requirements of the standards is not normatively possible, but the combination of different techniques might help to make a more precise approach.

NDTs show to be a good source of information. However, proper knowledge of the material and solid experience is essential to correctly manage the data of the NDTs.

ACKNOWLEDGEMENTS

The data of the beams were obtained by the researchers on the previous inspection of the timber structure at the refurbishment works done by Laebon S.A. at number 26 Trafalgar Street in Barcelona.

THE PRESENT STATE AND ISSUES ON RETROFITTING OF HISTORIC TIMBER-FRAMED BRICK CONSTRUCTION BUILDINGS IN JAPAN

Manabu Fujimoto[1], Naoyuki Matsumoto[2], Mikio Koshihara[3]

ABSTRACT: In the late 19th century, the method of timber-framed brick construction (TFBC, "mokkotsu-rengazo" in Japanese) was introduced to Japan as a western technique. After a while, it became apparent that the TFBC method was vulnerable to earthquakes, and hence, it was not used anymore. However, some TFBC buildings remain in Japan, and several of them require reinforcement. To ensure appropriate and smooth repairs, this paper summarizes the history, past retrofitting works, and current situation and issues regarding the restorations of TFBC buildings in Japan through document survey and building investigations.
We reveal that only a few buildings have been retrofitted seismically, and several buildings still require appropriate restoration. In the current Japanese administration of cultural properties, retrofitting entails highly detailed seismic assessment and reinforcement methods, which results in a limited number of restorations. In addition, lost techniques, including the TFBC method, has not been treated as a significant subject of research. Hence, relevant literature is limited, and detailed knowledge on the topic is lacking. As predicting the occurrence of large earthquakes is not possible, development of reinforcement methods, expansion of systems to support repairs, and study on technical-historical evaluations are necessary.

KEYWORDS: Timber Framing, Brick, Reinforcement, Earthquake, Architectural Conservation, Cultural Property

1. INTRODUCTION

In the late 19th century, the Japanese government hired foreign experts to import the latest technology and systems that modernized and westernized the country. Bricks were the first architectural materials to be implemented as a part of this policy. They were considered cutting-edge materials that had fire resistance and could represent advances. In addition to piling them up, another method for brick construction was timber-framed brick construction (TFBC, "mokkotsu-rengazo [木骨煉瓦造]" in Japanese). The TFBC is a construction method that combines timber frames and brick masonry walls to form walls, primarily exterior walls. However, the use of this method was discontinued after several TFBC buildings were damaged by the earthquakes. However, some TFBC buildings still exist, many of which require restoration.
In this study, we examined the current situation and issues regarding the restoration of TFBC buildings in Japan. The remainder of the paper is organized as follows. Section 2 introduces existing TFBC buildings and their history. Section 3 describes past restoration works. In Section 4, we discuss issues regarding current restoration from the perspective of the system of cultural property protection and historical evaluation in Japan. Section 5 provides the conclusion and future research directions.
The TFBC buildings covered in this study are all national cultural properties.

2. TIMBER-FRAMED BRICK CONSTRUCTION IN JAPAN

2.1 EXISTING BUILDINGS

According to the database of the Agency for Cultural Affairs and the author's research [1], there are 23 TFBC buildings among the national cultural properties in Japan (Figure1, Table 1).

2.2 BRIEF HISTORY [1,2]

2.2.1 The 1860s – the 1880s: Import of TFBC

From the end of the Edo era to the Meiji era, French engineers, such as Edmond Auguste Bastien began the construction of Yokosuka Naval Shipyard in 1865 and Tomioka Silk Mill in 1871. With the start of trade with foreign countries, housing for foreigners, such as the Jugobankan Building in the Former Kobe Foreign Concession (1881) was also built. Similarly, Marc Marie de Rotz, who was a Christian missionary, designed their religious facilities, such as the Former Latin Seminario (1875). Thus, timber-framed masonry was used in relatively large public buildings during this period. The main constructional feature in this period was brick walls filled inside the frame (wall type A, Figure 2).

2.2.2 The 1890s – 1910s: Modification of TFBC

In 1891, the Mino-Owari Earthquake (Nobi Earthquake) caused severe damage to brick buildings. Subsequently, TFBC was used less frequently in public buildings.

*The numbers correspond to Table 1.

Figure 1: *Location of existing TFBC buildings in Japan*

However, as the domestic production of bricks increased, TFBC was used more in private residences and corporate buildings, such as the Former Kabuto Beer Factory (1898). Some TFBC warehouses built in houses are fused with traditional Japanese construction methods. The main constructional feature in this period was brick walls covering the exterior of the timber frame (wall types B or C, Figure 2).

2.2.3 The 1920s and beyond: Decline of TFBC

In 1923, the Tokyo-Yokohama earthquake (Kanto Earthquake) devastated masonry buildings (Figure 3). The following year, the Urban Building Law (Shigaichi kenchikubutsu hou [市街地建築物法]) (1919) became stricter, which made it difficult to construct masonry buildings in Japan. The use of TFBC was rapidly decreased. This strict standard was implemented into the current the Building Standard Law (Kenchiku kijun hou [建築基準法]) enacted in 1950.

***Figure 3**: Damage to TFBC building during Tokyo-Yokohama Earthquake (1923) [3]*

2.3 VULNERABILITY TO EARTHQUAKES

Timber frames and brick walls are not structurally joined together; therefore, their vibration characteristics are different during earthquakes. Consequently, there is a high risk of failure in the out-of-plane direction. In 1995, the Kobe earthquake destroyed the Jugobankan Building in the Former Kobe Foreign Concession (Figure 4).

***Figure 4**: The Jugobankan Building before (left) and after (right) the Kobe Earthquake (1995) [4]*

3. PAST RESTORATION WORKS

3.1 THE JUGOBANKAN BUILDING IN THE FORMER KOBE FOREIGN CONCESSION

This building is located in Kobe City in the southern part of Hyogo Prefecture, and is designated as an important national cultural property. After its collapse in the Kobe earthquake in 1995, it was reconstructed and reinforced from 1995 to 1998. Two goals were set for seismic retrofitting. First, seismic isolators were installed in the foundation to decrease the seismic forces. Second, to increase the horizontal load-carrying capacity, two steel reinforced concrete (SRC) columns (Figure 6) were set up in place of the original chimneys and connected to steel frames added inside the roof truss and second-floor framing [4].

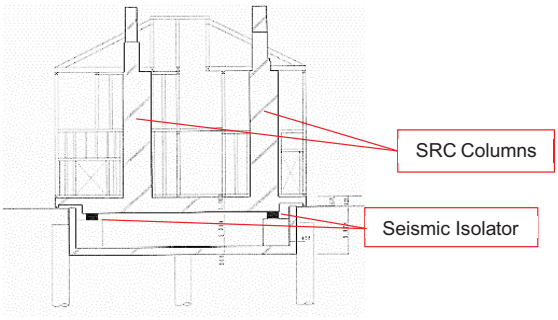

***Figure 5**: Cross-section of Reinforcements (SRC columns and seismic isolators) of the Jugobankan Building [4]*

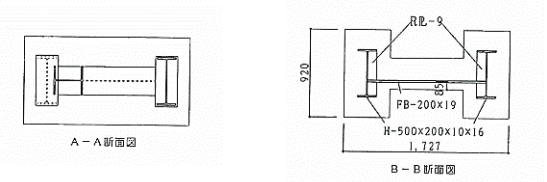

***Figure 6**: Cross-sectional view of SRC columns [4]*

3.2 THE FORMER KABUTO BEER FACTORY

This building is located in Handa City in the southern part of Aichi Prefecture. It is registered as a national tangible cultural property and was restored in 2014. Steel braces and buttresses were installed to increase the horizontal load-carrying capacity, and pillar legs and beams were reinforced with metal fittings.

***Figure 7**: Reinforcements of the Former Kabuto Beer Factory (left: steel frame and brace, right: steel buttresses)*

3.3 THE WEST COCOON WAREHOUSE OF FORMER TOMIOKA SILK MILL

This building is located in Tomioka City in the southern part of Gunma Prefecture and is designated as a national treasure and UNESCO World Heritage Site. It was restored between 2014 and 2020. Two main goals were set for seismic retrofitting. First, to increase the horizontal load-carrying capacity, a variety of reinforcements were installed, such as steel frames, braces, and glass ceilings,

https://doi.org/10.52202/069179-0538

which had less influence on the original interior design. Second, to increase the in-plane strength of brick walls, aramid fibre-reinforced plastic (AFRP) rods were embedded in masonry joints [5].

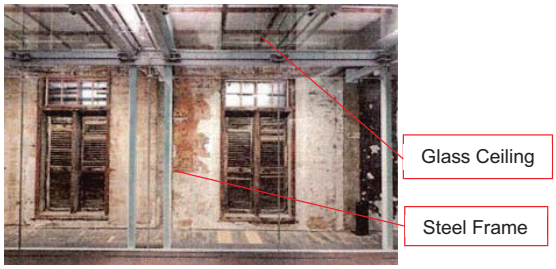

***Figure 8**: Reinforcements at the West Cocoon Warehouse: interior view [5]*

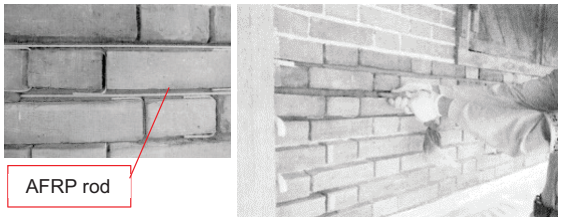

***Figure 9**: Inserting of AFRP rods into brick wall of the West Cocoon Warehouse [5]*

3.4 THE EAST COCOON WAREHOUSE OF FORMER TOMIOKA SILK MILL

This building is a counterpart to the West Cocoon Warehouse, and is also a national treasure and a UNESCO World Heritage Site. Although not yet fully reinforced, transitional reinforcement work was conducted between 2011 and 2012 to reduce the out-of-plane damage from earthquakes. The work includes the following: filling the gaps between the top of the brick wall and wooden girder with mortar, setting up wire meshes, and reinforcing columns and beams on the brick walls facing a busy passageway [6].

***Figure 10**: Reinforcements at the East Cocoon Warehouse (left: zoom out view, right: zoom in view), (Date of shooting: July 4, 2022)*

3.5 FORMER ENGINE ROOM OF KOSAKA MINE MANUFACTURING DIVISION

This building is located in Kosaka Town in the northern part of Akita Prefecture and is registered as a national tangible cultural property. Originally part of a mining facility, it was relocated and restored in 2015, and is now a coffee shop. During relocation, a new reinforced concrete foundation was cast, and reinforcing columns and beams made of laminated wood were added to the interior of the building.

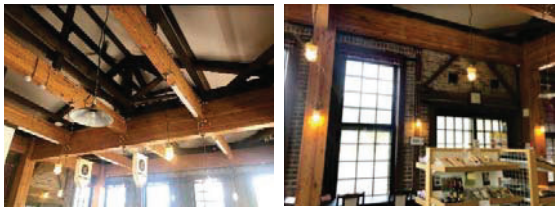

***Figure 11**: Reinforcements at the Former Engine Room of Kosaka Mine Manufacturing Division: interior view (Date of shooting: Sep. 10, 2019)*

4. RETROFITTING ROADBLOCKS

4.1 "AUTHENTICITY" PERSPECTIVE

The concept of "authenticity" in architectural conservation comprises the following sources: design, materials, craftsmanship, setting, use and function, and spirit and feeling. The Nara Document on Authenticity (1994) states that "the respect due to all cultures requires that heritage properties must be considered and judged within the cultural contexts to which they belong [7]." However, the frequent disasters and humid temperate climate make it to be difficult to perfectly preserve the materials and elements which made using the techniques of the time. Therefore, these factors are not equal, and design is often considered the most important factor. For examples, the original joint material was lost when embedding AFRP rods into the joints of brick walls of the West Cocoon Warehouse (Figure 9), and the original foundations were excavated when installing a seismic isolator under the Jugobankan Building (Figure 5).

4.2 JAPANESE ADMINISTRATION OF CULTURAL PROPERTIES

4.2.1 Framework of Cultural Property Building and Subsidy System

In the Japanese Administration of Cultural Properties, national cultural property buildings are classified into two categories. First is important cultural properties (ICP) and national treasures (NT), and the other is registered tangible cultural properties (RTCP). The former is a designation system with strict regulations on their restorations, and ICP of especially high value are designated as NT to safeguard the material, structural system, and building techniques. In these conservation projects, after an assessment by the government, the national treasury pays 50% of the repair costs: repair work costs, disaster prevention work costs, other construction costs, information dissemination costs, design, and construction supervision costs (additional amounts might be added depending on the subsidized organization, project size, region, etc.). In addition, when using government subsidies, the person in charge of the design and construction supervision must be a conservation architect certified by the Agency for Cultural Affairs.

https://doi.org/10.52202/069179-0538

Conversely, the latter is a registration system based on requests from owners and local governments and allows for relatively flexible preservation and utilization, including renovation and conversion. In these conservation projects, after an assessment by the government, the national treasury mainly pays 50% of the design and construction supervision costs. As with ICP and NT, the amount of subsidy can be more in some cases, and the person in charge of design and construction supervision must be a conservation architect certified by the Agency for Cultural Affairs [8-10].
Most TFBC buildings, including non-cultural properties, currently remain unrestored because seismic retrofitting of such vulnerable structures requires a large amount of funding, and the evaluation system for the historical value of TFBC method has not adequately been established.

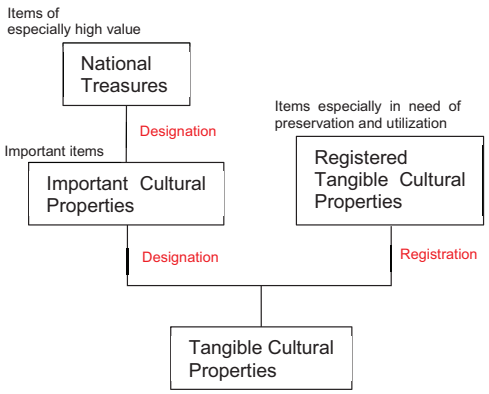

***Figure 12**: Schematic diagram of Japanese cultural properties (structures) [8]*

4.2.2 Steps to Seismic Retrofitting

The repair and management of cultural property buildings is the responsibility of the owner. However, because seismic retrofitting requires a high degree of expertise, technical assistance is provided from the local and national governments during the entire process.
In the case of wooden ICP and NT, under the Law of Protection of Cultural Properties (Bunkazai hogo hou [文化財保護法] in Japanese), before repair work, seismic assessment must be conducted, which is divided into three stages (Figure 13): preliminary seismic assessment (PSA), basic seismic assessment (BSA), and expert seismic assessment (ESA). PSA is sufficiently simple; the owners can perform it by themselves, and it is used to determine the urgency of repair or a more detailed assessment. Both BSA and ESA are used to quantitatively evaluate seismic resistance through structural surveys and structural analysis; however, the difference is that the former is non-destructive, while the latter is more detailed because it includes destructive surveys with dismantling and repair, as required. In the case of non-wooden ICP and NT, PSA might not be conducted and the process may start with BSA or ESA, depending on the characteristics of the building. If this assessment process reveals that the current seismic capacity does not meet the criteria, seismic retrofitting is planned as soon as the budget is available. Conversely, RTCP buildings are restored in accordance with the Building Standard Law, which is the standard for new buildings (however, an exemption from the Building Standard Law might be permitted through a third-party committee assessment) [6].
Thus, there is a strict assessment process to complete the seismic retrofitting of cultural properties; this process might require to a year or occasionally even more. Seismic retrofitting without a correct understanding of the structural characteristics of the building may result in significant earthquake damage and hence must be performed carefully. In particular, seismic assessment of TFBC buildings tends to take long because of large-scale structural experiments and material experiments [5], and the restoration experience is still limited. Therefore, it is necessary to not only conduct a structural survey of individual buildings but also elucidate the general structural characteristics of TFBC.

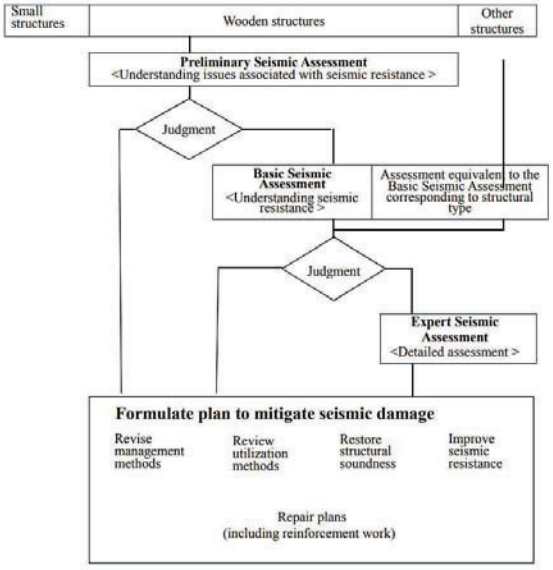

***Figure 13**: Flow chart of seismic assessment and formulation plan [11]*

4.3 TECHNICAL-HISTORICAL EVALUATION OF TFBC

As discussed in Section 2, the TFBC method was introduced and subsequently abandoned. However, the details of TFBC, namely, what type of technology TFBC is, how it is merged with the local methods, and how it is transformed, have not yet been adequately discussed. For example, the database of the Agency of Cultural Affairs lists buildings that are categorized as TFBC but are purely brick masonry or use two construction methods separately in single buildings. Similarly, it contains TFBC buildings, which are categorized as brick masonry buildings. This suggests that the TFBC method is not clearly defined, and that there is no common view of the method among experts, municipalities, and building owners. Specifically, the accumulation of knowledge about the lost technique is insufficient.

https://doi.org/10.52202/069179-0538

In Japan, the few studies on TFBC to date have not obtained its complete view, either because they are case studies [12, 13] or take some of the features of TFBC and place them in technical history [3, 14]. Therefore, in the future, it is necessary to typify the original form and the form that has subsequently changed in Japan, to compare them with the TFBC structures in France and other European countries, to reveal the mechanism of the transition and the decline of foreign construction methods in Japan, and to establish and apply more appropriate survey and historical evaluation methods for existing buildings.

5. CONCLUSIONS

In Japan, the TFBC structure is a Western-derived construction method that was in use for approximately 70 years. There are 23 existing buildings, but only five of them have been reinforced to withstand earthquakes. To repair earthquake-vulnerable cultural property buildings, including TFBC buildings, a precise seismic assessment is required. Currently, because of the significant time and cost involved, adequate earthquake countermeasures have not yet been taken.

Since it is impossible to predict when a large earthquake will occur, it is necessary to develop reinforcement methods, including transitional reinforcement, as shown in the East Cocoon Warehouse of the Tomioka Silk Mill; expand systems to support repairs; study technical-historical evaluations to ensure appropriate and smooth repair work.

REUSE OF WOOD – LEARNING ABOUT THE BENEFITS AND CHALLENGES OF HIGH- AND LOW-TECH DIAGNOSTIC METHODS THROUGH ACTION RESEARCH IN NORWAY

Wendy Wuyts[1], Artur Tomczak[2], Kristine Nore[3], Lizhen Huang[4], Thomas Haavi[5]

ABSTRACT: Digital technologies for the diagnosis of underused timber construction and the reclamation and reuse of wood in timber construction have not been widely deployed. One of the reasons is the need for diagnosis processes with large amounts of data. This paper is a product of the learning process in the Norwegian project SirkTRE, and specifically, the sub-project SirkLåve (Circular Barns), which aims to address the problem of underused and vacant barns and other agricultural buildings in Norway. Moreover, this multiple-case project aims at understanding the feasibility, costs, and benefits of circularity strategies, such as deconstruction and reuse of wood in new projects or renovations. The learning processes draw upon explorative desktop-based research, interviews with key informants, and our own experiments and experiences with various cases of barns. The scope of this paper is the reuse of wood from barns that is deemed ineligible for renovation. This paper describes low- and high-tech methods for surveying redundant buildings to applying extracted components in new designs. This multiple-case study reflects on the preconditions of the context in which these best practices may succeed, as well as on the benefits and the challenges.

KEYWORDS: Digital technologies, Empty barns, Engineering for the circular built environment; Innovation and learning processes; Rural circularity practice

1 INTRODUCTION

Globally, millions of tonnes of wood waste is generated in different phases of the value chain and incinerated after being applied only in one building. The EU-27 produced 60 million tons of wood waste in 2014 (1). There are several categories of wood waste treatment across countries, the most common being energy recovery (incineration) and recycling (panel board industry) (1). European policymakers are adopting circular economy policies and digitalisation strategies that are changing the way we produce and consume timber as well as handle wood waste. The European forests are under stress, and circularity and the cascading use of wood will significantly contribute to reducing the pressure on forests. The cascading use of wood refers to reuse over multiple use cycles, that is, using wood materials more than once, first for the originally intended purpose and then reusing for other purposes, finally recycling it into other wood products before its energy is recovered. Wood cascading delays emitting carbon into the atmosphere by several decades and allows natural resources to be used for a long time in different products instead of mining virgin forests. In countries like Norway, Switzerland, and Belgium, constellations of different actors (e.g. architects, deconstruction companies, local governments, and building owners) are investigating and implementing the reuse of timber in new constructions and renovations. A trend that can foster circularity transitions is digital technologies, such as laser scanning, blockchain, material passports, and artificial intelligence (2,3).

However, digital technologies have not been widely deployed for sustainability goals due to legislative and economic reasons, and investment lock-ins (3, 4). The renewal of new European and national laws and digital transformation strategies are opening new opportunities for circularity (5).

This paper is a product of the learning process in the Norwegian project SirkTRE (6), and specifically, the sub-project SirkLåve (Circular Barns), and aims to address the problem of underused and vacant barns and other agricultural buildings in Norway. This multiple-case project aims at understanding the feasibility, costs and benefits of circularity strategies such as deconstruction and reuse of wood in new projects or renovations. In 2022,

around 10 barns were selected within the SirkTRE project. The scope of this manuscript is the reuse of wood from barns deemed ineligible for renovation. Reuse of elements and components is one of the circularity strategies in the built environment, which can create value in different ways: "1) coherent financial structure and viability of the case company, 2) employment and value creation for partners in the value chain network, 3) customer value, 4) environmental impact reductions" (7). However, the reuse of timber is not widely deployed. One reason is that the environmental benefits of reusing timber are not adequately measured under the current carbon metrics (8). Notwithstanding, a low deployment of reuse has not always been the case in the Norwegian AEC sector. Before the Second World War, Norwegian society used to reuse building elements, but after the introduction of new materials and widespread education, accompanied by a new consumption culture, it adopted a linear and throw-away model (9), hence, missing opportunities in creating environmental, financial and social value.

One of the principles behind the SirkTre consortium is supporting the Norwegian industry to become a pioneer in wood reuse while leveraging new digital technologies not available in pre-war times. Back in 2021, the first questions we asked were *what are the best practices of reusing wood,* and *what are the lessons that pilot projects and the growing ecosystems of actors in European countries can provide us* for the Norwegian wood industry to leapfrog to a pioneering position in timber engineering for the circular built environment.

Different scholars investigated the barriers (10, 11, 35), as well as the factors that could enable the reuse of building components (12). Lack of data, as well as the fragmented coordination and exchange of information between key actors in an urban or regional ecosystem or a seamless data pipeline management, where circular systemic solutions could operate, is often pinpointed as one of the big obstacles in digital transformations for circularity (e.g. 14, 15, 16). Digital technologies can help address this perceived barrier of information asymmetry (16). Nordby (9) investigated the barriers and opportunities for reuse in Norway, pointing out technical and organisational, legal restrictions, and information needs. Nordby advocates for an information system that allows the transfer of the right information and data to the right stakeholders at the right moment (9). In literature and practice, there is evidence of an emergence in research, development, and implementation of digital technologies, and in particular information and communication technologies (ICT) enabling circular economy in the architecture, engineering, construction, and demolition sector (17,18). Bellini and Bang (18) did interviews in Norway on data management and also highlighted the lack of data availability and interoperability, lack of competencies, and unwillingness to share data as barriers.

Another concern that we encountered in the first phases of SirkLåve is the lack of a (perceived) fair distribution of costs, benefits, and risks in all the organisations involved in the phase of deconstruction, logistics, relocating, and environmental and economic valuation and reselling. One of the distributional aspects is related to data sharing and trust. Research on the success of Industrial symbiosis projects in the United Kingdom, (19) demonstrated that "the economic benefits should fulfil the desired economic expectation of any actor, and a fair benefit-sharing mechanism is essential to motivate the collaborative behaviours". Different stakeholders can benefit from these inventories, but this requires information facilitation and stakeholder collaboration. There are different stakeholders (users and suppliers of materials and information) who have their different information, personal, collaboration needs and requirements, but also *want* distributional justice and a *perceived* fair distribution of risks, costs and added value/benefits. Hence, we followed the process from the stage of reuse surveys to the actual reuse and map out which actors were involved and why.

2 ACTION RESEARCH

This multiple-case study is action research in engineering and management in the construction sector, addressing practical problems, and creating and extending existing theoretical frameworks (13). This paper should be regarded as an intermediate report of a still ongoing action research within SirkTRE tackling practical problems related to information requirements for reclamation and reuse of wood elements in construction.

2.1 Authors' roles and perspectives

SirkLåve is an applied research project in which learning and innovation are iterative processes. We wish to understand the challenges, costs, and benefits of new digital technologies with the objective of increasing the wider uptake of reclaimed wood. The authors involved in circWOOD and SirkTRE projects (6) had roles ranging from project managers or work package leaders to researchers and solution designers. We had access to internal documents and participated in meetings to discuss, for example, data collection. In 2022, the first author assumed the role of critical researcher, and in early 2023, joined the start-up leading this sub-project in SirkTRE. Thus, this manuscript reflects and describes the learning processes and decisions from a practitioners' perspective. The remainder of this paper includes reflections about mistakes and failures that hindered the authors in calculating the precise impacts at each stage in the life cycle of the different wood elements, as even failures and mistakes can provide valuable insights for the future phases of SirkTRE and SirkLåve, planned for 2023-2024). Consequently, the *learning by doing* was an organic but messy process, which constitutes the foreground in our discussion.

2.2 Desktop-based research and consulting key informants

The first phase involved desktop-based research during 2022. We sought insights on wood reuse workflows and their dataflows on Google Scholar and Scopus. We

reached out to our European networks of circular economy and construction to learn about processes in different life cycle phases and digital solutions which (can) support these practices. We held conversations with key informants and attended international networking events on digital technologies for the built environment and wood reuse. We had talks with key informants and partners in the SirkTRE consortium and read their reports and blogs. We drew from previous research and reflected on circularity in the (timber) construction sector in Norway, Japan, and Belgium. In this sense, we did not do a systematic but rather a critical literature review, relying on academic and industrial circles (20). The risk of this approach is cherry picking potentially missing relevant solutions. On the other hand, as we consider this as an interactive learning process in which we keep our options open, we acknowledge the risk of this approach. The exploratory desktop-based research led to the adoption of an existing framework which helped us to frame and structure the different solutions and information needs we encountered in reclaiming wood from barns to integrate them in new applications.

2.3 'Follow the Thing'

For transparency, we were not present in every stage in every barn case in SirkLåve. The first author was not often on-site and embraced the role of critical investigator in this case study. On the other hand, as we were also interested in tracing and tracking wood elements, the first author applied the 'Follow the Thing' approach to comprehend the relations between the wood elements and the stakeholders and how digital solutions did or did not help. The 'Follow the Thing' approach is inspired by the work of Appudarai, and developed by Cooke and his colleagues as some sort of 'geographical detective work' (21). In this approach, you start with a product and investigate which people were involved in the creation of this product. Thus, we followed both the material and the data. In some cases, we started with the wood elements in a storage place and asked where it came from and where it might end up. In other barn cases, we started with the barn itself and traced what happened afterwards with the wood elements, which data was created and collected, and used afterwards. This detective-style process became our *modus operandi*.

3 THE FIVE "D"s FRAMEWORK

This conference paper focuses on digital technologies that can assist in the identification of material stock hibernating in vacant constructions that will not serve society anymore (otherwise, it would be more circular to sustain the structure and repurpose them, see (22)) to the relocation of these materials for a new purpose. The structure of this paper follows the 5"D"s-framework by Catherine De Wolf: Data, Detection, Disassembly, Distribution, and Design (23).

3.1 Data (for sourcing)

Data stands for the collection of macro-level data to track which material stocks are or will be available soon which helps planners to prioritise which stocks to reclaim (24). Stock tracking can be done with geographical information systems (GIS) and estimation models of vacancy (see e.g. 25, 26). However, this macro-level data -or estimations- is often not detailed enough for reclaimed wood scouting professionals. Other data that should be collected is which organisations own how much wood waste and in which fractions they are sorted and stacked, for example.

3.2 Detection

Detection refers to the collection of micro-level data and the creation of material, building passports, or building information models. Scholars have investigated designs of digital tools or proposed design criteria for tools to enable reuse of building materials and components. For instance, Durmisevic et al. (48) designed reversible Building Information Model (BIM) to estimate reuse potential, however not with enough data on which function these building components could be reused. Other scholars investigated digital technologies surrounding material banks and platforms where materials get stored and exchanged for value, foregrounding BIM objects as a key intermediary product (27-29). All these technologies need data inputs, and therefore wood reuse surveys or diagnostic tools are required. Starting from available material stocks which can be reclaimed, we can distinguish between different material sources for reuse, which implies several stakeholders. The first group of key actors are the owners of the materials that can sell or donate their timber. In the case of timber in buildings, urban miners, specialised demolition companies, or deconstruction companies, can harvest the materials, often after a reuse survey. In the current state-of-art, these reuse surveys are often done by visual inspection, but sometimes digital scans are also used as a basis for BIM models. Some researchers suggest transcribing such information into Material Passports, which is a tool for value tracking (3).

3.3 Disassembly

Disassembly is a type of non-destructive deconstruction where the objective is to harvest components or materials which are needed for later design. Unlike demolition, where the final product is pure waste, disassembly aims at

https://doi.org/10.52202/069179-0539

waste reduction and mining as many useful elements as possible. In addition, other information that is needed concerns how to disassemble and evaluate safety and feasibility. These reuse surveys can reduce health and safety risk for the deconstruction staff in later phases. OPALIS (30) calls to consider the health and safety risks to be included in the reuse surveys, such as the presence of hazardous substances or if dismantling and subsequent operations would present a safety risk.

3.4 Distribution

Distribution encompasses the logistics: transport and storage. As materials are often not reused directly after mining, the workflow requires a physical circular hub, material banks, and other spaces where the material is collected and pre-treated. They are often at the periphery of cities unless the public authorities provide a space (e.g. Material bank in Trondheim, Norway, RotorDc in Brussels). There, the reclaimed material is often separated according to quality, and which functions they can serve as well as pre-treated. The pre-treatment is a time-intense process, because each reclaimed material is different. For example, in reclaimed wood, nails and hazards have to be removed, while metals (e.g. steel) could be melted. Some of these materials must be treated locally. For example, concrete that has to be recycled locally, not only for environmental reasons, but technical feasibility too (31), while reclaimed wood can be sold to manufacturing companies who integrate them into building components (32).

3.5 Design

Following the above, these building components can return to the supply chain and be sold to those who build new or renovate existing buildings. However, consecutive design requires knowledge, processes, and competencies that are scarce in the current market. Standardisation can help reduce the need for all these "knowledge search costs". A potential enabler is the parametric design approach, where multiple alternatives can be compared in a short time, but it requires proper preparation of the input information, both geometrical and alphanumeric, as well as computational engineering competencies.

4 DIGITAL SOLUTIONS USE CASES

We read the SirkLåve experiments through distributional justice goggles. It is pivotal to ask who benefits, who pays, and who will be accounted for the risk. Some benefits can be perceived as valuable for society, but not for certain stakeholders. For example, interviews on platforms for industrial symbiosis in Norway indicated that managers see sustainability often as a profit-losing business, with benefits for society, but not for the company itself (15). Implicitly, each task requires *specialised* labour with the associated costs for the business itself. In the next section, we focus on costs, benefits, and risks for the *specialised* labour force, using the chosen method, and drawing from live experiences and participatory and marginal observations in SirkLåve.

By winter 2022, we traced wood elements from 6 barns. Table 1 provides an overview of the barns and who got involved in which phases.

4.1 Data

This stage of collecting data on where and how much reclaimable wood was available, was skipped in the first phase of SirkLåve. Firstly, because the problem of obsolete barns is known, and secondly because the empty barns offered free by their owners were located far, implying a high demolition and waste management costs making it necessary to look into alternatives. The only information that was required for deciding to take this project was the distance costs between the location of the barn and the involved actors of the next D-stages. Noteworthy, barns are widely spread over the countryside which implies longer travel time and transport costs for labour, equipment, and tools; hence, reclaiming the wood might not be economically viable.

4.2 Detection

Different reuse survey methods or diagnostic tools were explored in the Sirklåve project in 2022. Table 2 lists the diagnostic tools and the data analysed by the different stakeholders. In case (6), we observed an expert (with material and building knowledge and surveyance experience), who judged by visual inspection and verified with a crowbar that there was not enough suitable wood for reuse, although no laser scanning was performed. The C6 project ended there; it got demolished in the traditional way. In cooperation with students, partners who are certified to grade materials did destructive testing on elements of cases C2-3. The timber elements were graded as C30 and above (47).

In cases C1-3, a LEICA scanner was used for on-site diagnosis. The scanning took a full day. The 2 students involved in transferring the scans to BIM-objects needed 2-3 weeks, partly because they struggled with material identification and the lack of data of the interior (Fig 2). Please refer to (33) for the technical details. The process was slow, implying high specialised labour costs (i.e. BIM). This issue with scanners has been reported in previous research (4).

Fig. 2. Before and after processing the scan by the two NTNU students. Source (33).

In all these six cases, different basic tools and methods were used to make a data inventory. The reclaimers took mostly photographs and short notes, and made lists of photographs, inserted in templates or cost-benefit reports and invoices. In research projects, the focus is mostly on high-technologies, like scan-to-BIM, and often coupled with automation detection or artificial intelligence (i.e. deep learning methods), which requires large training datasets. We tried different methods, including the use of LEICA scanners, but there was no data availability downstream in the value chain.

Table 2: Overview of diagnostic methods

Data collection method	Technology	Data stored	Barn cases
Destructive quality test	Press test	Reports	C2-3
Non-destructive	X-ray	Compressed images	None.
Scan (of barn onsite)	Laser scanning	Point cloud , processed into BIM object	C1-3
Scan of elements (in sorting centre)	Photogram metry	Mesh, texture	C4
Modelling / estimating	GIS	Graph data, tabular data	None
Visiting the site and measuring with analogue tools	based on hindsight experiences	Photographs (JPEG, PNG); Excel	All
Archive work		PDFs, plans, etc.	C1-C3

4.3 Disassembly

The footprint of one barn (C4; Fig. 1) was ca. 600 m2 and 12–15 m height. There were 158 timber framing elements that ended up in the material bank of Omtre AS, where they were measured and assessed. Then, 66 were selected and further integrated in the new construction, substituting 144 elements from the design of Slettelokka project in Oslo (34). This was made possible by cutting out some elements and assigning them to multiple locations in the model. An important step was labelling (i.e. tagging, adding unique identifiers) for later tracking and tracing wood elements. In most cases, the tagging was performed in the storage places. Numbers, added manually, corresponded with the excel lists that include the inventory, and data about dimensions of these wood elements, next to the descriptions of the faults, such as potholes and carvings. This included those elements that we know are of lower quality (8%) (visual test). Different people measured in two different days (one day in August, and a second day in November 2022) 158 elements with a total volume of 18,4 cubic metres (8,2 cubic metres and 10,2 cubic metres in November). We took photographs of all the elements, including special features, like pockets and carvings. Some scans were captured with a handheld scanner and the Leica scanner, but the process was slow and inefficient.

4.4 Distribution

The distribution and relocation of the wood emits CO2, depending on the means of transport, which is again dependent on the existing logistic infrastructures and systems. There are questions on how much CO2 would be emitted in the deconstruction, manufacture, and transport, especially from the wood products used in the new construction. Most barns are in the periphery of cities like Oslo and Trondheim where they will be integrated, and long travel distances are unavoidable. We needed to critically examine if the CO2 that is avoided and/or captured compensates enough the CO2 emitted in the process.

In case of barn 1, we estimated that the travel distance of one wood element from source (empty barn) to the new construction was 270 km. This is still low compared with the travel distances that virgin wood often travels in the global timber markets. However, we are not certain, as we did not have advanced tags with geolocation data.

Barn C5 was an ideal project from an economic and environmental cost-benefit perspective; the barn and the new project both were and will be located in the same municipality, reducing transport costs in a significant way. Barn C6 was close to the storage space. However, the quality of the reclaimable wood was not deemed as high value.

Additionally, the materials are stored somewhere and for a period. Storage space and time have a cost, which was covered by the SirkTRE project's funding. In the case of these barns, it took at least a year before some building elements were reintegrated. More research is needed on governance and business models to reduce the cost of the storage requirements enabling reuse.

4.5 Design

A fraction of the reclaimed wood from C4 would be integrated in the Sletteloka construction project in Oslo in spring 2023 (34). The designers will use the spreadsheet

https://doi.org/10.52202/069179-0539

list, made after Disassembly and the few images to select the elements for the integration in the Slettelokka design. This led to reflections if scan-to-BIM are needed, and if useful information for design can be used in a more controlled environment, with fast scanners that can label, process, and separate wood elements.

5 DISCUSSION

5.1 Information requirements

In all the D-stages, there are different data requirements, for the different possible users of this information (see e.g. 35). These follow the information requirements in any construction project (see 36); however, there are some new roles and stages that need an expansion in these lists. Sustainability consultants and researchers need data inventories that help them calculate environmental life cycle costs in their Life Cycle Assessment (LCA), and specialised demolition companies need lists with geographic coordinates to harvest reusable components before demolition, etc. We observed indeed the need and emergence of new actors with their own information requirements, as echoed in Table 2. The actors involved in collecting the data and making decisions in the experimentation stages, were the urban miners and specialised demolition companies (●; ⬢) , environmental impact researchers and consultants for the economic and environmental validation (◆; ▲), and designers (★). They have their own information requirements and this D-framework helps mapping the information flows and requirements, which in turn helps collecting data on environmental and economic risks and benefits and assess if this circular economy practice is really sustainable. Figure 3 outlines the workflow for 2022.

Noteworthy, the data collection for diagnosis and data flows are partly subsidised by education institutes (employing students) and research and innovation funds. Not many high-tech digital solutions were used, and this was a (specialised) labour-intensive action research project. On the other hand, this organic and messy learning process and experimentation has led to insights about requirements and specifications for digital solutions (e.g. scanner specifications), which will inform the purchase of equipment in the next phase of SirkTRE. One of the specifications is a result of learning about unintended negative impacts. While learning about all these different tools, we became aware of the growing evidence on the environmental costs of data spaces, programming languages, data formats and their consumption of resources (e.g. 37 about the energy consumption of more than 20 software programming languages).

5.2 Limit in tracking and tracing the wood elements in the case study

We applied the 'Follow-the-Thing' approach to investigate who used which digital solutions during all these phases. However, we did not apply advanced tags to enable tracking and tracing of different wood elements reclaimed from all these six barns, which presented a severe limitation for understanding and collecting data about environmental and economic impacts. Additionally, it was a challenge for the first author to have an overview of the different material and data flows for the different barns: identifying who did what, what did not happen, and the logics behind the different decisions in the material and data flows. In the next phase of SirkTRE, we will investigate different tagging tools to improve traceability and tracking, from QR-codes, bar codes to even wood print solutions (i.e. the constellations of knots can serve as unique identifiers). This would also include deeper studies on data formats, interoperability protocols, and data pipeline management. Currently, our reflections on what happened in 2022 are informing the design of a more standardised workflow for the barns-to-construction projects to be implemented in the following years.

5.3 Tensions with social impact

Barns are part of the cultural heritage of rural landscapes in Norway. There is an observation in the literature (e.g. 38) that cultural heritage and rural circularity practices such as renovation and reuse are interlinked. However, there might also be tensions. In SirkLåve, the barns were offered by the barn owners until now. As long as empty constructions are offered, the circular business model should work, while reducing costs. In Japan, the problem of empty houses is in some cases transformed in opportunities for new purposes creating positive social impacts (39). However, there can also be negative impacts. Altering the rural landscapes in this way might create tensions with sustainability goals of heritage and identity (40). Besides the legal owners, there are neighbours who are culturally the inheritors of these rural landscapes, where barns are considered as inherent landscape scenery, and might feel distressed by changes in the landscape and features that make them feel at home (41). In some places, the constructions will be restored to preserve the identity, but mostly deconstruction, or worse demolition, takes place. By deconstructing the barn, there is the risk that we erode the Norwegian rural identity of that landscape. On the other hand, in interviews with urban miners active in rural southern Norway, we heard about the supporting communication and branding practice for preserving the story of the reclaimed materials. Thus, they can sell the materials if it comes from a building with a historical value. The idea is to collect these stories in the Detection stage (or relabel these steps as part of the Documentation stage). This would contribute to tracing the source of these materials too. However, it was out of the scope to document complaints of neighbours and look into renovation and rural revitalisation strategies. This is one of the potential social value creations—or destructions which can occur in a project such as SirkLåve. Social value creation (or destruction) through circular economy is still under-researched (42).

5.4 Reflecting on the Ds-framework and diverse value creation

The Ds-framework helped us to structure fragmented actions and knowledge creation in different life cycle phases but is focused on data collection and processing for the technical aspects surrounding reuse, namely enabling logistics, design and calculations.

The Detection stage can encompass different diagnoses or detections. One important stage, especially for a material such as wood, is the quality testing and grading. Destructive testing was done by certified stakeholders for elements of barns C2-3. The elements were graded as C30 or above (see 48). However, not all elements can be destructively tested, if we want to reuse them. Then there is also the critique on the current 'virgin wood' grading system. Thus. there is a new standard being developed for reclaimed material. That standardisation work is part of SirkTre consortium (in another work package). The current grading system does hinder a wider uptake because of the uncertainty about ownership of the risks that cannot be covered by the current grading system. The legal research on accountability is outside the scope of this paper, but we mention the legal research to stress out that there is a need for a D-stage of (legal) documentation.

Documentation is the negotiation process where risks are documented through experts or digital technologies. One of the reasons behind documentation and data storage is risk reduction for stakeholders in the construction projects itself, especially in the case of larger projects using reclaimed matters in structures and load-bearing functions. Documentation should include data and information (which implies qualitative data) about social and other values for the different stakeholders, including neighbours and even full landscapes.

Dissemination is the ongoing process that attracts the required suppliers, users of information, and materials. This includes materials for public authorities that want to monitor circularity and the diverse value creations but also materials for training. Universities and other educational institutions are essential for training and educating the required workforce, as well as for monitoring the life cycle costs and advising other key actors about the potential for value creation of the various circularity strategies such as reuse.

5.5 Preconditions for scalability

Early 2023, the reclaiming of wood from abandoned barns is still a small-scale endeavour within the SirkTRE project. One reason is that barns are small-scale sources of materials and require time and effort. Another bottlenecks is the diagnostic tool in reuse surveys. Both high- and low-tech reuse survey methods are time consuming, not only for collecting but also the processing of the complex data (4). Additionally, high-tech methods require large investment and operation costs because of equipment like laser scanning (4). On the other hand, this is a rapidly changing market and we have become more knowledgeable about new diagnostic tools (e.g. 43) which addresses these problems. However, we have noted two concerns.

First, those reuse methods are often tested and applied in high-density areas like cities, while barns are located in remote settings, deep in land and far away from cost effective infrastructure such as river and maritime ways. Therefore, space matters. In the past 1-2 years of the SirkTre experimentations, we have applied a critical lens to the contexts or territories in which these pilot cases and constellations emerge, as different studies already demonstrated how spatial aspects are important for sustainability transitions (44), including for circularity (39). We have to note that actors behind these innovations are situated in economic regions in the periphery with high to moderate levels of cooperation and innovation (e.g. Gjøvik, Asker), but also in less cooperative and innovative regions (e.g. Hønefoss) (45). A more territorial approach on the economic geography of innovations can bring better insights on where urban mining businesses, using diagnostic methods, can thrive.

Second, in other projects in Belgian, Swiss, and Dutch constellations, such as the BAMB project (3), the reuse survey included visits to the building to make a diagnosis of how many and which elements can be reclaimed. This would include tagging and giving all reclaimable elements an unique identifier on-site. However, the tagging of every wood element is only possible after deconstruction. In our experiments, the tagging (and start of tracing) happened in the first temporary storage space, which is often a more controlled and more comfortable environment than a 'chaotic' deconstruction site. In the Nordic timber construction sector, off-site prefab manufacturing is encouraged, and off-site diagnosing, integrated in other off-site processes such as sorting, might be safer and more efficient than on-site diagnosis.

5.6. The risk of linearity at industrial scale

One of the remaining important questions in the iterative learning process is how to scale up to an industrial scale. This activity at industrial scale should compete with the forestry sector and linear waste management practices in a country like Norway. Early 2023, we evaluated the fractions of barns as a possible input for an industrial processing plant. However, the fractions arrive in small volumes, are heterogeneous and not secure, while industrial processing prefers the opposite. This can lead to the risk that reclaimed wood from barns might not be selected for a reuse economy at the industrial scale in the next phase of the consortium. The reuse economy, like the recycling economy, can fall into the profit-oriented logic trap of capitalism. There is considerable critical literature on reuse centres, e.g. in the clothing sector, highlighting how such centres do not address the roots of high consumption, and might even lead to more guilt-free consumption and waste creation of often low-quality items (e.g. 46). Ironically, while the barns in five of these six cases contain enough amounts of high-quality wood, our observations and reflections suggest that the barns might not be considered in a portfolio of industrialised processes. Even more ironically, if this decision of

https://doi.org/10.52202/069179-0539

exclusion would happen, this would render the need for high-cost digital solutions obsolete, instead allowing human creativity and cooperative work, or pushing more circular activities such as repurposing the building and extending the service and lifetime of this construction, or even better, addressing the reasons why such buildings become obsolete in the first place.

6 CONCLUSION

In early 2023, the SirkTRE consortium is still in the first stage of the process of innovation, learning, and unlearning about what circularity means for the wood and timber construction sector, citizens, and public authorities. A fair distribution of costs, benefits, and risks is important, but as long the costs are higher than that in these other industries, and the benefits and other diverse value creations by such activities (e.g. safety, environmental health/toxicity, community cohesion, climate change mitigation and adaptation) do not get monetised or rewarded and valued by policy makers and other decision makers, the problems that circular economy intends to solve will only increase.

Different stakeholders require different data and information, which leads to additional costs. However, in a project like SirkLåve, these data flows are partly subsidised by education institutes (by employing students) and research and innovation funds. Not much high-tech was used, like fast wood scanners, and this was a (specialised) labour intensive action research project. Our final observation is that this model is not competitive on its own. These insights can help formulating the research design for future studies diving into where to draw the line between the cost of collecting and storing the data and information and the benefits of the actors, for different regulatory and economic scenarios. This can be part of a larger systems engineering framework, where this can be integrated in especial technical (e.g. requirement analysis) and agreement processes (e.g. which stakeholder takes responsibility and accountability for which risk and cost). Although the technology readiness level for the proposed methods is high, the market readiness and integration level of these circular systemic solutions in the timber Architecture, engineering, construction and demolition sector is low. Future research should focus more on the actual costs and the identification of sustainable business models and project governance for the required data and information management enabling reuse of materials in new constructions, as well as evaluating the phases in which data is collected and processed and where (e.g. onsite versus offsite) and when to integrate which digital solution.

FERROCEMENT WOODEN HOUSE: LEARNING FROM POST-DISASTER RECONSTRUCTION IN INDONESIA

Andry Widyowijatnoko[1], Dibya Kusyala[2], Fajar Ikhwan Harnomo[3]

ABSTRACT: Earthquakes are the most common natural disasters in Indonesia, frequently causing not just deaths but also considerable damage to buildings and infrastructure. As a result, a quick and effective post-disaster reconstruction infrastructure is required to ensure that recovery operations can begin as soon as feasible. The need for temporary shelters that are adequate and ready to be upgraded to permanent housing in order to reduce the cost involved and reduce construction waste. In response to these constraints, this paper aims to offer an alternative viewpoint on developing a post-disaster architecture reconstruction system leveraging local wood as an affordable material resource that integrates Ferrocement as part of the architectural elements. In addition, the involvement of local workers addresses the shortage of skilled labour and creates employment opportunities for local communities. The paper provides a comprehensive review of the advantages and limitations of the technique and recommends future research and development.

KEYWORDS: Post Disaster, Rehabilitation, Reconstruction, Local Wood

1 INTRODUCTION

Due to its location on the "Pacific Ring of Fire," an active subduction zone area, Indonesia is a country with considerable earthquake activity. Most earthquake disasters in Indonesia have a significant influence on people's life, resulting in deaths, material losses, and severe psychological suffering. Many big earthquakes have occurred in Indonesia in the previous 20 years, according to documented data [1] including the 2004 Aceh earthquake, the 2006 Yogyakarta earthquake, the 2010 Mentawai earthquake, and the 2018 Lombok earthquake. The greatest earthquake to date was the Aceh Earthquake, which measured 9.1 on the Richter scale and produced a massive tsunami wave to impact the coast of Sumatra, including Aceh. Additionally, the most recent earthquake in Indonesia was the Cianjur Earthquake [2], which occurred in 2022 and had a magnitude of 5.6. According to data from the National Disaster Management Agency, 272 persons were killed, 2,046 were wounded, and 62,545 were displaced. There were 56,311 dwellings affected, with 22,267 badly damaged, 11,836 moderately damaged, and 22,208 lightly damaged.

The Indonesian government and elements of society continue to improve preparedness and handling in the face of earthquake disasters. The first step when an earthquake occurs in order of time is to collect information and distribute assistance to institutions and donors to distribute aid. Further steps rebuild damaged infrastructure, one of which is public buildings, and continue with efforts to rebuild housing for affected communities. The earliest emergency effort that needs to be done is the provision of health facilities by building posts and initial buildings so that people can continue their activities and slowly improve their quality of life.

On the other hand, mobility is usually a constraint in the post-disaster restoration procedure on the spot. According to Sinaga [2], the handling of the Mentawai Earthquake rebuilding and rehabilitation in 2010 was constrained by cross-sectoral coordination, which was still difficult to carry properly. Furthermore, the difficulty of post-disaster rebuilding is tied to a wide range of interests and a considerable expenditure. As a result, for two years following the Mentawai Earthquake, victims of the earthquake and tsunami were housed in insufficient temporary shelters.

2 RESIDENTIAL REHABILITATION OF THE COMMUNITY IMPACTED

In responding to the impact of the disaster, the Indonesian government and humanitarian agencies have so far worked together to provide shelter. The Indonesian government usually works with international organizations such as the United Nations (UN) and the International Committee of the Red Cross and Red Crescent (ICRC) to provide shelter assistance for earthquake victims. In addition, many non-governmental organizations are also involved in relief efforts for earthquake victims in Indonesia.
Here are some of the forms of housing reconstruction that are usually provided:

[1] Andry Widyowijatnoko, Institut Teknologi Bandung, Indonesia, andry@itb.ac.id
[2] Dibya Kusyala, Institut Teknologi Bandung, Indonesia, dibja@itb.ac.id
[3] Fajar Ikhwan Harnomo, Institut Teknologi Nasional Bandung (Itenas), Bandung, fajarharnomo@gmail.com

https://doi.org/10.52202/069179-0540

1. Temporary shelter. Once earthquake victims lose their homes, the government and humanitarian organizations offer temporary shelters such as tents, posts, or emergency houses for victims to use while they recover.
2. Home rehabilitation. After the earthquake, the government and humanitarian organizations assist victims in rebuilding or renovating their earthquake-damaged houses. This aid might take the shape of building supplies, financial assistance, or skilled technical advice.
3. Housing programs: Long-term housing programs can be implemented to help earthquake victims obtain liveable homes. These programs can take the form of government assistance to build new houses or provide low-interest housing loans for earthquake victims.

Furthermore, the Institut Teknologi Bandung (ITB), with the assistance of Rumah Amal Salman and the Institute for Research and Community Service, took some action by creating drawings and specifications for refugee shelter. The design and structure were designed to be safe, earthquake resistant, quick to assemble and disassemble, and capable of comfortably accommodating numerous migrants. Moreover, the materials and resources required to construct the refugee barracks must be made accessible during implementation. This includes construction supplies, tools and equipment, and on-the-job labour. In actuality, inexperienced victims are frequently accessible. To guarantee that the refugee barracks are erected appropriately and safely, careful construction and oversight are required.

Standardized designs and standards are necessary, and all of the structure's components must be tested before usage. Additionally, measures to maintain and care for these shared facilities are required to keep refugees safe and comfortable. Other fundamental facility requirements, such as clean water, sanitation, and health care. The government, non-governmental organizations (NGOs), and communities must also collaborate to ensure that evacuees' needs are fulfilled and that they receive the appropriate help during the disaster recovery phase.

3 MATERIAL MATTERS

3.1 INDUSTRIAL MATERIALS vs BIO-BASED MATERIALS

For the speed of on-site construction, the solutions that are now widely used are industrial materials such as concrete and lightweight steel (Figure 1 and Figure 2). While buildings made from concrete and steel materials can provide the stability and strength needed to withstand earthquakes, some drawbacks need to be considered when using these types of buildings for post-earthquake relief, including:

1 Because of the expensive materials and intricate construction procedure, buildings composed of concrete and steel have high expenses.

2 The construction of concrete and steel buildings takes a long time and necessitates a large amount of work as well as specialized equipment. This has the potential to stymie the post-earthquake reconstruction effort.

3 Concrete and steel materials are not ecologically friendly since their production and transportation consume a lot of energy and emit a lot of carbon dioxide.

4 Because of the frequent vibrations induced by earthquakes, concrete and steel constructions are prone to material fatigue. This might result in serious damage to the structure, especially if it is built in an earthquake-prone location.

5 Concrete and steel structures are difficult to demolish and recycle. This might cause environmental and social issues, especially if the building needs to be demolished to return the area to its former state when the post-earthquake relief is finished.

Figure 1: *Shelters built in Petobo, Palu, using light steel, spandex roofs and GRC walls.*

Figure 2: *Model house using risha concrete frame and GRC wall covering.*

On the other hand, bio-based materials are materials derived from natural sources, especially trees that are widely available in nature in Indonesia, and have several advantages as post-earthquake building materials, including:

1 Bio-based materials are manufactured from recyclable natural resources and have a lesser environmental effect than traditional materials like concrete and steel.

2 Certain bio-based materials, such as bamboo and laminated wood, have high strength and durability and may be utilized to construct sturdy and earthquake-resistant structures.

3 Bio-based materials such as bamboo and wood are widely available and reasonably priced in many regions of Indonesia.

4 Because some bio-based materials, such as coconut fibre and straw, disintegrate naturally, they do not cause environmental or social difficulties when the structure is demolished.

5 Since bio-based materials have natural colours and textures, they may improve the appearance of buildings while also enriching local cultural values and traditions.

6 Bio-based materials, such as bamboo, can absorb and minimize seismic vibrations, reducing building damage.

7 Certain bio-based materials offer high thermal qualities, such as heat and sound insulation, which can aid in the creation of comfortable and healthy

3.2 WOOD MATERIAL

Timber has long been utilized in Indonesian buildings and is one of the finest solutions for reducing earthquake damage. It is recommended to utilize high-quality lumber that meets international standards such as SNI or ISO for post-earthquake use. Low-grade timber can cause structural problems and make a building more prone to earthquakes. The following premise is to use the appropriate building system. The proper building system can assist minimize the danger of seismic damage. The wood frame system and the timber beam system resting on poles are two building techniques that are suited for timber materials. The correct construction system should take into account the building's strength, stiffness, and stability. For this reason, it is essential to think about the upkeep and durability features before to use by paying attention to the material's drying process, protection from insects and mildew, and systems that make it protected from weather attacks, particularly rain and high humidity.

There are various varieties of rapid wooden dwellings used for disaster relief in Indonesia. Some of them are:

1. Basic Wooden House (RKS) The RKS is the most often utilized form of a wooden house in Indonesia for disaster relief. The roof is made of zinc and the home is made of wood. RKSs are typically 4x6 meters in size and can accommodate 4-6 persons.
2. Earthquake Resistant House (RTG) An earthquake-resistant house (RTG) is a type of wooden building that is meant to be earthquake resistant and robust enough to withstand natural calamities such as earthquakes. Other constructions, such as steel and thin concrete walls, are generally installed in this dwelling. RTGs vary in size according to the application.
3. Health-House (Rukesa) Rukesa is a type of wooden hut used as a health station in rural or difficult-to-reach places. This residence has medical amenities such as examination rooms, waiting rooms, and sleeping rooms. Rukesa is also often provided with safe drinking water and sanitary services.
4. Ready-to-Use House (RSP) RSP is a sort of wooden home that is meant to be rapidly and readily erected. It generally has basic furniture and home necessities including mattresses, tables, and chairs. RSPs can be utilized as either temporary or permanent buildings.
5. Community House A communal home is a form of wooden structure designed to host numerous families or groups. This house has several bedrooms, living rooms, kitchens, and bathrooms that are shared by several families. Communal houses are usually built in areas affected by natural disasters such as floods or landslides.

4 CASE STUDY

4.1 CASE STUDY I: FERROCEMENT WOODEN CONSTRUCTION IN MAMUJU, SULAWESI

The Mamuju earthquake [3] with a magnitude of M 6.2 that occurred on January 15, 2021, was an aftershock of an earlier earthquake with a magnitude of M 5.9 that occurred on January 14, 2021, where this disaster event occurred when it coincided with a period of activity restrictions due to the Covid 19 Pandemic. Travel restrictions were still in effect in Indonesia at the time. Getting to the field was equally challenging for the ITB team. Disaster management in Mamuju is inextricably linked to the prior program in Palu. The Palu earthquake, which was followed by liquefaction and a tsunami, happened before the Mamuju earthquake. A group of volunteers was trained in timber building there to build communal shelters and a permanent mosque (Figure 3 and Figure 4).

https://doi.org/10.52202/069179-0540

Figure 3: *Vault Structure-based Shelter*

Figure 4: *Nurul Hasanah Wooden Mosque in Palu*

Having developed solid networks with volunteers who had worked together in the previous post-disaster response in Palu, the Mamuju post-disaster response was carried out by activating these volunteers to go to the field with materials and equipment from Palu, which is a 9-hour drive away. Travel restrictions due to the pandemic, especially air travel, made this the most appropriate option. A prefabrication system was employed to keep work on the ground in unfavourable conditions to a minimum. Four shelters similar to the wooden shelters in Figure 3 were built in Mamuju at several evacuation sites plus two wooden Ferrocement houses (see Figure 5).

Figure 5: *Timber + Ferrocement House 24m^2 (above) and 35m^2 (below)*

Ferrocement timber homes are built using a semi-fabricated technology in which hardwood wall frames are combined with chicken wire mesh in a wood workshop in Palu. The manufacture of the wall frame (Figure 6 and Figure 7) took place in areas that were not impacted by the disaster and had accessibility to timber raw materials. This was also done to lower the expense of mobilizing field supervision staff. Another factor to consider was that Mamuju's situation at the time was still affected by the earthquake, thus the availability of labour, materials, and equipment, as well as electricity, was still uncertain. Because of the pandemic circumstances that prohibited travel by plane, supervisor monitoring was conducted by phone, video conference, and Zoom Meetings.

Figure 6: *Prefabrication of timber and chicken wire wall frame modules at the workshop in Palu.*

Figure 7: *Local foundation construction at a house site in Mamuju.*

The basic building method is used to build Ferrocement timber houses, which includes clamping chicken wire between vertical and horizontal logs. The size of the wall frame modules was defined by the measurements of the timber utilized, with as little material as possible left over. Bracing was added to the wall frame, both at the top and at the height of the wall plane on the side of the structure, to give stiffness against horizontal forces such as earthquakes and wind forces, as illustrated in Figure 5. Once the wall frames were finished, they were transported by truck to Palu (Figure 8 and Figure 9). Ferrocement wooden house modules for two dwelling units may be shipped in a single shipment.

Figure 8: *Delivery of Rukaf (Ferrocement wooden house) modules from Palu to Mamuju (left-below) and house construction (right).*

Figure 9: *Ferrocement wooden house before plastering and after plastering*

4.2 CASE STUDY II: FERROCEMENT TIMBER HOUSE CONSTRUCTION IN PASAMAN, WEST SUMATRA

The Ferrocement wood wall method was utilized as well during the construction of a musholla at Pasaman, West Sumatra, following the February 25, 2022 earthquake. The prefabrication system was carried out locally, with the production of the timber wall frame panels and chicken wire mesh taking place in the same area as the building phase. The benefit of this approach is that the

https://doi.org/10.52202/069179-0540

frame panels are made on the ground and beneath the shade of a tarpaulin tent, making the labour considerably easier than standing work. Furthermore, because it does not require vehicle transportation from the workshop to the building site, the wall panel module may be larger.

The application of wood construction integrated with Ferrocement is also carried out as a partition and at the same time provides shear strength in the construction of the Al-Munawarrah Mamuju Musholla (Figure 10). The wood used as the structure of the Musholla is Coconut Wood. Ferrocement-based walls are used as dividers for the imam's room at the front of the Musholla and also on the sides of the Musholla.

Figure 30: *Musholla in Pasaman (left) and Al Munawarrah mosque in Mamuju (right) using ferrocement wood wall construction.*

5 CONCLUSIONS

Based on previous cases, post-disaster rehabilitation in Indonesia has depended more on large industrial materials supplied from outside the region. Steel, GRC, precast concrete, lightweight bricks, and other materials can enable to create of temporary or permanent housing in large quantities fast. Nevertheless, because these industrial inputs are imported from outside the disaster region, the majority of the economic turnover from the aforementioned technique occurs outside the disaster area.

Timber and Ferrocement wall technology are long-established but largely neglected technology. Timber is a renewable building material with huge potential in Indonesia, including coconut wood. Meanwhile, Ferrocement is an old technology that is very efficient to apply due to the relatively minimal use of materials. A wall thickness of 2-3 cm can be achieved with Ferrocement technology. Compared to plastered brick walls on both sides that are up to 15 cm thick, Ferrocement walls are much more cost-effective and much lighter. Combining Ferrocement walls with timber can improve construction performance because they can make up for the shortcomings of each material. Timber framing has the advantages of low carbon footprint, earthquake resistance and speed of construction. The weakness of fire can be covered by Ferrocement, in addition to being a barrier to the exposure of wood to the climate.

HARVESTING THE URBAN FOREST: A CASE STUDY OF THE CIRCULAR BUILDING SEMINAR AT UHASSELT IN BELGIUM

Rafael Novais Passarelli[1], Peggy Winkels[2], Ronald Rovers[3], Elke Knapen[4], Griet Verbeeck[5]

ABSTRACT: The transition to a circular economy (CE) offers an alternative path to the current high-polluting and wasteful practices in construction. However, this transition will require a drastic shift from the way products and services are designed, produced, and used, also in the architecture and construction industry. This paper aims to contribute to the body of knowledge of novel methodologies to integrate CE into architectural design and wood construction education. This paper analyses the 2021-22 edition of the Circular Building Seminar at UHasselt in the Faculty of Architecture and Arts. In this study, we first provide a brief introduction to the course mission and its approach. Then we describe in-depth the 2021-22 winter semester assignment of urban harvesting and the role of wood in it. At the end, we evaluate and discuss the outcomes of the course, its relevance as well as possibilities for improvement in the next editions.

KEYWORDS: Wood Architecture, Timber Education, Circular Economy, Design for Circularity, Bio-based materials

1 INTRODUCTION

The construction sector is responsible for the largest individual share of greenhouse gas (GHG) emissions, accounting for 37% of all emissions [1], due to energy-intensive activities of material extraction, transportation, construction, and energy to operate buildings. Building construction activities alone represent 10% of all emissions [1]. Hence, the high emissions in the sector worsen the continuing heat up of the planet and contribute to the climate crisis. Moreover, the construction industry consumes 40% of the global resources [2] and is one of the leading producers of solid waste generated during the production of materials, construction, and demolition of buildings [3]. That means a large share of emission-intensive building materials produced from precious finite resources end up wasted in landfills at manufacturing, construction, or end-of-life.

The transition to a circular economy (CE) thus offers an alternative path to the current linear high-polluting and wasteful practices in construction [4]. The concept of CE is quickly gaining traction among both scholars and practitioners, indicated by its fast-growing number of peer-reviewed articles [5]. A CE is "restorative and regenerative by design and aims to keep products, components, and materials at their highest utility and value at all times (...)" [6]. By decoupling wealth generation from resource consumption, a CE can simultaneously tackle many pressing challenges of our time, such as climate change, resource depletion, water, and energy scarcity [7]. However, a transition to a CE requires a drastic shift from the conventional way products and services are designed, produced, and used, including construction.

Previous studies emphasized the critical role of education in this transition [8], [9]. More specifically, higher education institutions can be strategic agents supporting a CE due to its dual impact of promoting behavioural change at the personal level and professional implementation in practice [10]. Hence, there is a growing interest in education for a Circular Economy (ECE) as educators from diverse fields start to develop educational approaches to incorporate a CE in their courses [8]. However, a recent literature review on ECE found institutions are still slow to adopt it as a fundamental part of the curriculum [11]. Specifically, in the field of architectural design, there is even less information addressing education from a CE perspective, with only a couple of published cases [12], [13]. Therefore, there is a significant knowledge gap regarding architectural design education in the context of circularity.

Ironically, among the several different fields of application of a CE, design sciences are of particular relevance. The literature on CE consistently identifies design as an enabling activity for the transition from a linear to a circular economy [4], [7], [14]. However, unlike the standard design process, designing for increased circularity requires more complex cognitive skills to approach the design problem from a lifecycle

https://doi.org/10.52202/069179-0541

perspective. That means designers have an expanded work scope and must consider the design process from the origin of materials to multiple appropriate service spans and possible future uses [14].

To address the knowledge gap mentioned above, we must develop new methods to integrate design for circularity into the architectural design curriculum, so it also becomes an implicit part of the practice. This paper aims to contribute to the body of knowledge of novel methodologies to integrate CE into architectural design and education, and training of aspiring architects with new design skills required in the context of circularity.

2 MATERIALS AND METHODS

This study analyses the 2021-22 winter semester edition of the Circular Building Research Seminar at UHasselt in the Faculty of Architecture and Arts. The goal is to contribute to the discussion on education for sustainability and wood construction from the lens of circularity. It is worth noting that although wood was not the primary focus of the course, it consistently emerged as a critical topic in the discussion of circularity throughout the course. In this study, firstly, we provide a brief introduction to the mission of the Circular Building Research Seminar at its inception and its main approach. Then we describe in-depth the 2021-22 winter semester assignment of urban harvesting and the role wood construction had in it. Afterwards, we evaluate the outcomes of the course qualitatively. Finally, we discuss some strengths and weaknesses perceived as well as possibilities for improvement in the next editions.

3 RESULTS

3.1 THE CIRCULAR BUILDING RESEARCH SEMINAR

The Circular Building Research Seminar is a 2-semester course for students in the master program, offered at UHasselt, Faculty of Architecture and Arts, every year since 2017. Originally the semester assignment alternated between an experiment-based and a reality check one. In the former, students were challenged to develop out-of-the-box thinking when considering the design and build assignment, whereas in the latter, students started from standard or established materials and processes in the built environment with the goal to pursue circular innovation. It is worth noting that over the years the relationship between both semesters has become more blurred.

From an educational standpoint, the course aims to uncover the possibilities for circular thinking in architectural design, thus providing an opportunity for students to explore new ways to transform buildings from a liability in terms of environmental impact to positive generators of biodiversity, energy and material resources. The instructional approach consists of a combination of research-based and design exercises. Moreover, at the Circular Building Research Seminar, theory and data operate as the foundation to master circular thinking and action to create innovation. This is further supported by reading assignments and discussion sessions on multifaceted topics that go beyond the mere theme of circularity in the construction sector. The goal is to familiarize students with the wider societal and economic context that is driving the need for more sustainable resource use.

The learning outcomes intended are triple-fold. 1) To contribute to the relatively novel and unexplored theme of circular construction with regenerative materials to inspire colleagues and decision-makers. 2) To stimulate students to engage with circular thinking to become better designers and builders. 3) To provide an opportunity for students to engage with scholarly research as an essential part of the design process.

Over the years, the course experimented with a variety of topics to pursue its goals, namely Circular Building Renovation (2017-18), Circular Building Systems for Cavity Walls (2018-19), use of Regenerative Materials (2019-20), and Prefabricated Building Concepts with Regenerative Materials (2020-21). The 2021-22 run of the Circular Building Research Seminar proposed the topic of Urban Harvesting as a means to advance the discussion of circularity in design and education. Every edition aims at incorporating hands-on experimenting through design-build assignments, as well as conceptual reflections on circularity under the existing frameworks.

In the 2017-18 edition on Circular Building Renovation, students first got familiar with the concept of circularity by exploring the RESOLVE framework [15] (Ellen McArthur Foundation) through different case studies, and then developed six circular renovation scenarios for their main faculty building - a concrete building from the 80s designed according to the principles of Herzberger, perceived as highly flexible, but actually quite rigid. Each scenario started from a perceived challenging issue, such as better water management, making the building fit for a broader use, and using the building as a display for regenerative materials. In the 2018-19 edition, students assembled and disassembled 3 walls (3x3m each) with market-available circular building systems for cavity walls, and evaluated their circular performance with the circularity framework developed by Vandenbroucke [16], also proposing improvements for specific aspects [17] (Figure 1). In the 2019-20 edition, students took part in a 1-day hands-on workshop on 4 bio-regenerative materials (mycelium, willow, earth, lime hemp), and then explored the opportunities of these materials through hands-on experiments (Figure 1). This resulted in the design and execution of a wide range of objects, later exhibited at the construction fair Batibouw 2020 as part of the stand of two organizations promoting sustainable construction. The stand itself was also fully circular and developed by the students and their teachers in collaboration with the organizations. In the 2020-21 students were tasked to rethink and redesign an existing tiny living unit with the

goal to make it fully circular and bio-based. Because of COVID 19, no hands-on activities or experiments were possible in this edition, so the outcome was limited to architectural sketches, drawings, and 3d modelling.

Figure 1: *Outcomes of editions 2018-19 (top) and 2019-20 (bottom) of the Circular Building Research Seminar.*

3.2 THE 2021-22 EDITION OF THE CIRCULAR BUILDING RESEARCH SEMINAR

The 2021-22 edition builds back on the repertoire developed in the previous editions of the Circular Building Research Seminar and tackles the theme of Urban Harvesting, understood as the possibility to leverage existing, readily available material flows in the environment that are currently perceived as waste. The idea opposes the conservative approach of extracting and processing virgin materials, that even if sustainably designed, can contribute up to some extent to resource depletion and environmental impact.

To explore the theme, the course instructors provided a list to the students with four distinct geographic regions to choose from: the municipality of Genk, the city of Hasselt, Hoge Kempen National Park, and UHasselt Campus in Diepenbeek. Each option presented a different context with a fresh batch of challenges to solve, ranging from more consolidated urban areas to a natural reserve. The course flowed through three main phases as follows.

Phase 1: The 2021-22 edition started with an Urban Harvesting workshop. Here lecturers introduced critical concepts of material and energy flows of and in our built environment. The goal is for the students to grasp the challenges and possibilities of combining flows to pursue added value.

Phase 2: Next, the participants mapped, documented, and visualized local flows of raw materials from the surroundings of their chosen areas. (Figure 2) The idea was to brainstorm a diverse range of applications and products based on the mapped resources and flows. For the brainstorm, the positive impact workshop was used, as developed in the Erasmus+ KA Active8 Planet project [18]. In this workshop, four lenses are used to reflect on the opportunities to create positive impact with the local material flows: a local social lens to reflect on the positive impact that can be created locally on social aspects such as jobs, income, community, etc, a local ecological lens to reflect on the positive impact that can be created locally on ecological aspects such as water management, biodiversity, etc. and, likewise, a global social lens and a global ecological lens that induces a reflection on how decisions made locally can have a positive impact globally [19].

Phase 3: The final phase consists of a design exercise in response to the findings from Phase 2. In other words, the design solutions had to answer a realistic challenge or need as detected during the mapping. This phase also encourages a hands-on verification of the design propositions feasibility through prototyping and scale models.

3.3 SCALES OF INTERVENTION AND USE OF WOOD

Students organized themselves into four groups (one per region), with eight participants each on average. Based on the results from the mapping exercise and positive impact brainstorm of Phase 2, students decided the focus of their design proposals between four scales of intervention, namely urban, building, element, and material scale.

https://doi.org/10.52202/069179-0541

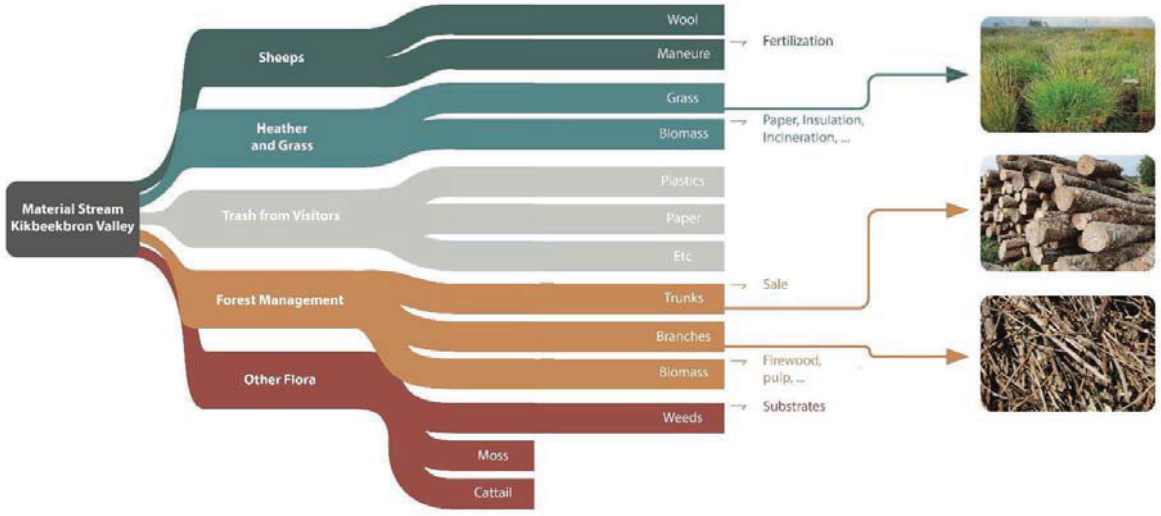

Figure 2: *Material Flow Map of National Park Group*

The UHasselt Campus group focused on the urban scale. In this scale, the challenge was to look for synergies with what is already consolidated and optimize the resource flows to foresee efficient, future-proof land uses. Furthermore, the group linked their research to a real-life ongoing project on the campus related to some perceived mobility issues, such as the limited use of bikes and public transport, and excess of private car use by students and staff, which results in a lack of parking space and plans to build a large allegedly circular parking building. In response to that, the group proposed and developed a multi-modal transportation master plan for the campus, employing locally harvested wood species as engineered wood-based products for the construction of the transportation facilities on campus.

The National Park group focused on the building scale. In this scale, it was critical to couple the development of a given building with its surroundings as to create a virtuous circle during its whole lifecycle. The group looked into ways to use logs obtained from thinning and pruning of forests in the park as the structure for small off-grid holiday units (Figure 3). Their design was a critical reflection and a counter-proposal to a new development of allegedly sustainable, high-end, luxurious holiday units in the National Park.

The city of Hasselt group focused on the element scale. In this scale, versatility, durability, and reuse were key criteria to guarantee an extended lifespan of the materials harvested and used. The group proposed to employ prefabricated panels using reclaimed wood from the demolition of blighted houses for repurposing vacant commercial buildings into temporary student rooms, in response to a real need for extra student rooms offer, due to a growing number of students at UHasselt and nearby university colleges (PXL and UCLL). (Figure 4)

The Genk City group focused on the material scale. In this scale, the investigation of potential materials and methods that prevent further depletion of resources had a prominent role. The group aimed to design affordable DIY furniture kits, reusing wood from discarded pallets from the port. (Figure 5)

Figure 3: *Scale Model of proposed off-grid holiday units*

https://doi.org/10.52202/069179-0541

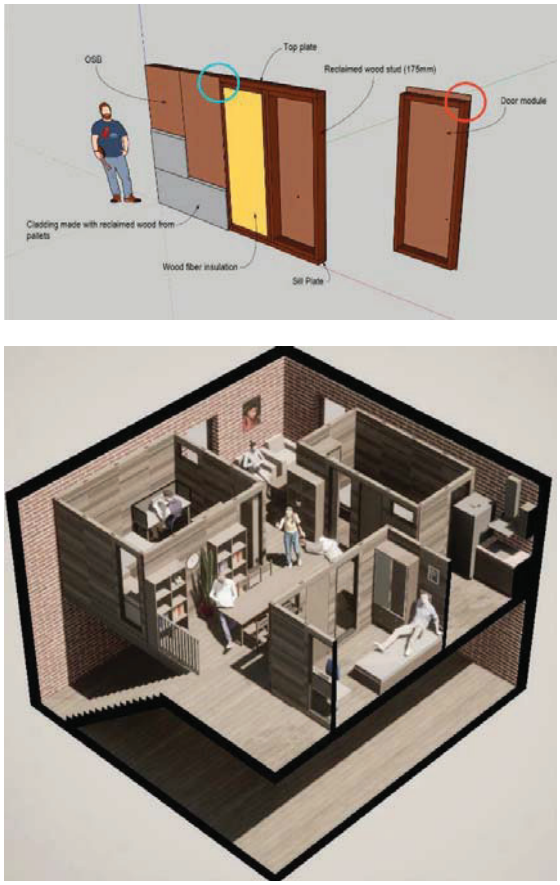

Figure 4: *Visualization of prefabricated panels(top) and retrofit proposal of a vacant commercial building (bottom)*

4 DISCUSSION

Even though the Circular building Research Seminar was not focused on wood construction, the search for materials to harvest in both urban and natural settings, as well as less impactful design solutions led all groups to investigate at least one possible way to utilize wood. In most cases, the information gathered during Phases 1 and 2 pointed to wood as a potential answer for a regenerative and low-impact design. That endorses the critical role that wood as a building material now plays in the broad topic of education for sustainability and design from the lens of circularity. Hence, to generate change through education, it seems relevant that curricula from schools of architecture actively find ways to provide the opportunity for students to engage with the material in both focused and unfocused disciplines.

Furthermore, the Circular Building Research Seminar intended to introduce a new mindset to students related to tackling design problems and finding solutions. More specifically, the seminar works backwards compared to a "traditional" design studio approach. Conventionally, students start pursuing formal and functional aspects by

developing a holistic design concept. Then, students confront the feasibility of their design concepts in terms

Figure 5: *Mock-up of DIY chair using reclaimed wood from pallets*

of materiality, dimensions, and technical performance. The result of this reality check is the design solution. In the Circular Building Research Seminar, students first face a tangible context to understand and interact with, which provides them with only a limited set of resources in terms of materiality, performance, and technology. From the available resources, students must then conceive innovative design solutions that meet a specific need. In this case, the final result is a holistic design concept or approach as an answer to the possibilities and limitations offered by the context.

Likewise, the course also proposes a more scientific approach to the design process, in which theory and data must guide design decisions. Because the course challenges the participants with a fresh new design approach, most likely for the first time in their education, mindset adjustments and new skills development are needed. That, of course, requires time and effort on the part of the participants and instructors. We understand it as a positive part of the learning process and growth of the students as designers, also supporting the expected learning outcomes 2 and 3 (item 3.1). However, the relatively large volume of new information and skills needed also partly hinders the depth of the explorations.

Particularly in the 2021-22 edition of the seminar, it was noticeably difficult to gather the necessary information on material flows, attesting to the still lack of such valuable information publicly available or with enough detail. Additionally, the ambitious goal to achieve innovative

https://doi.org/10.52202/069179-0541

circular design solutions in the period of a single semester (15 weeks) can be hindered by an overall lack of previous experience with basic woodwork skills by the students, leading to a lack of depth and quality of the outcomes both from an aesthetic and circular point of view, such as in the Genk City group.

5 CONCLUSIONS

This paper presented the Circular Building Research Seminar in the Faculty of Architecture & Arts at UHasselt and described its 2021-22 edition in detail. The chosen topic of urban harvesting yielded a diverse scope of design approaches, ranging from the urban to the object scale. In the view of the instructors, it successfully introduced to the students a flipped way of thinking about the design process, developing a holistic design concept from the availability of given resources instead of assigning materiality to a pre-defined design concept. Furthermore, even though wood-based materials were not the particular focus of the course, they had a distinctive role in all four projects, attesting to the relevance of including wood-based design and construction-oriented courses in the traditional curriculum of architecture schools. On the other hand, the overall quality of design solutions was below expectations, partially due to the combination of a lack of primary information on waste flows and unfamiliarity with basic fabrication and construction techniques. It is also noteworthy that the ongoing corona crisis at that time, hindered the possibility of more hands-on activities. Regardless, the two groups that actively integrated physical modelling and prototyping in their workflow achieved slightly better results. That also attests to the relevance of introducing hands-on activities as part of the learning process in balance with more traditional theoretical activities. By sharing and evaluating the experience in the Circular Building Research Seminar, this paper aimed to contribute to the body of knowledge of novel methodologies to integrate CE into architectural design and wood construction education.

ACKNOWLEDGEMENT

The authors gratefully acknowledge the effort and commitment of students enrolled in the multiple editions of the Circular Building Research Seminar.

ADHESIVELY BONDED TIMBER-CONCRETE COMPOSITE CONSTRUCTION METHOD (ATCC) – PILOT APPLICATION IN A SCHOOL BUILDING IN GERMANY

Jens Frohnmüller [1], Werner Seim[2], Christian Umbach [3], Johannes Hummel[4]

ABSTRACT: A pilot-application of adhesively bonded timber-concrete composite (ATCC) slab elements with prefabricated concrete parts in a school building in Germany is presented in this paper. Firstly, the concept and the relevant points of the planning process are outlined. The construction and the materials of the ATCC slab are then presented. After the introduction of a suitable calculation model for ATCC beams with discontinuous arrangement of the adhesive bond, a validation in the form of a full-scale bending test follows. Finally, the quality control concept which has been developed for this project is presented.

KEYWORDS: Adhesives, Timber-Concrete-Composite, Pilot Project, Full-Scale Testing, Quality Control, Monitoring

1 INTRODUCTION

The new building of the "Ernst-Leinius Schule" in Kassel, Germany (Figure 1), was planned as a timber construction. Due to the requirements to limit floor vibration, a hybrid timber-concrete composite (TCC) construction with notches as shear connections and cast-in-place concrete is to be used for the slab elements.

Figure 1: *School building "Ernst-Leinius Schule Kassel" (From Baufrösche • Architekten und Stadtplaner GmbH)*

Although TCC constructions with cast-in-place concrete offer great advantages as an end-product and contribute significantly to improving the competitiveness of timber construction in multi-storey construction, there are some disadvantages. The disruption of the construction process particularly plays a decisive role here: the assembly of the timber construction as a classic dry construction with surfaces that are largely ready for use (ceiling soffit, columns, walls) is considerably slowed down by the concrete work: reinforcement has to be laid, joints sealed, surfaces protected, and the concrete has to cure. All this takes time and delays the construction progress. In addition, the risk of water damage increases significantly during the time the reinforcement is being installed and the concrete is poured.

With that in mind, it appears astonishing that there have been comparatively few attempts to eliminate these disadvantages by using dry, prefabricated concrete parts. Apart from a method with plastic sleeves inserted in the precast reinforced concrete elements for subsequent screwing [1], using adhesives is an obvious solution for implementing the composite. The most important advantages of adhesively bonded timber-concrete composites (ATCC) are:

- full bond and optimized mechanical interaction,
- rapid construction progress,
- low moisture penetration into the building due to the use of precast reinforced concrete components and the quick assembly process,
- ready for load-bearing after one day of curing, fully loadable after approximately seven days,
- no contact pressure required when using epoxy resins,
- possibility of producing the floors on-site or in the factory,
- reduction of the influence from concrete shrinkage, and
- comparatively easy separation of components in terms of deconstruction and reuse.

The client and the specialist planners involved in the project of the school building have created the framework conditions to apply the construction method of ATCC with prefabricated concrete parts for the first time out of the laboratory into the building industry. The pilot application represents the result of many years of development in which several members of the team of the University of Kassel have participated [2]-[8].

2 CONSTRUCTION

2.1 BASIC INFORMATION

The floor is characterised by a span of 7.68 m and design loads ($g_d + q_d$) of about 12.1 kN/m². The pilot project is located in an area of about 30 m², where the static system changes from a two-span to a single-span beam (see Figure 2).

Figure 2: *Top view of the building with marked area for the pilot application*

The composite action is realised by applying the adhesive with a mortar sledge on the timber part and placing the concrete-prefab, which has a weigth of approximately two tons, on top with the help of a crane (see Figure 3 and Figure 4).

Figure 3: *Handling of precast concrete elements*

The adhesive is arranged in stripes perpendicular to the span (Figure 7) which are spaced closer together towards the support according to the shear force distribution. The notches along the edges of the prefabricated concrete parts (Figure 4) do not participate in the shear load transfer due to vertical loading. They are filled with concrete subsequently after bonding to create an in-plane diaphragm action of the slab.

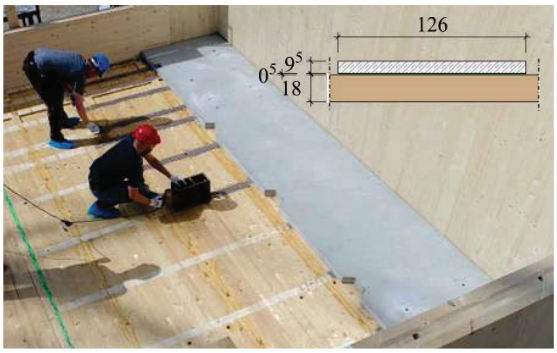

Figure 4: *Application of the adhesive on the timber part*

2.2 MATERIALS

Regarding the timber part, glulam of the quality GL28c with a height of 18 cm has been used throughout the entire slab area. The moisture content was tested at several measuring points on the floor, with values ranging from 13.0 to 15.4 %. Because the shear strength, which can be identified as the most relevant parameter regarding the determination of the bond strength, could not be determined on site, the surface tensile strength of the timber has been determined instead. The parameter was determined according to EN 311 [9] to $f_{ttm,surf} = 2.3$ N/mm² ($n = 6$, $COV = 13$ %).

The concrete parts were ordered with a thickness of 9.5 cm. According to the test certificates of the manufacturer, the concrete parts have a compressive strength $f_{cm,cube}$ of 58.8 N/mm² and can, therefore, be assigned to the strength class C40/50. The underside of the slab has been sandblasted (see Figure 5).

Figure 5: *Sandblasted underside of the prefab concrete part*

The average surface tensile strength $f_{ctm,surf}$ of the concrete has been determined as 3.4 N/mm² ($n = 10$, $COV = 13$ %), according to EN 1542 [10]. The moisture content of the concrete has been determined by weighting and drying (Darr drying-method) to about 0.9 %.

https://doi.org/10.52202/069179-0542

The polymer mortar "Epument 130/2-14_B1" from RAMPF Group was used as an adhesive [11]. This product exhibits an average cylindrical compressive strength $f_{adh,c,mean}$ in the range of 140 N/mm², a flexural tensile strength $f_{adh,t,mean}$ of 28.7 N/mm² (n = 6, COV = 7 %) and an adhesion strength on a sandblasted steel plate of $f_{adh\text{-}steel,t,mean}$ = 13.8 N/mm² (n = 24, COV = 6 %). The mean thickness of the adhesive joint was set to 0.5 cm. The total height of the construction, therefore, was 28.0 cm.

2.3 EVENNESS OF THE SURFACES

The evenness of the surfaces plays a decisive role regarding the success of the bonding, as has been unanimously established in preliminary work on the adhesively bonded joint [5], [12]-[14]. With reference to the construction tolerances for planarity regulated by standards [15], a maximum deviation of ± 1 mm over a length of 0.20 m or ± 3 mm over a length of 1.00 m can be assumed for the flatness of the formwork side of the concrete part, according to DIN 18202 [16]. Regarding the timber, a construction tolerance of ± 4 mm per 2.00 m length can be assumed, according to DIN 18203-3 [17]. This leads to the conclusion that a maximum gap of 7 mm must be assumed in the case that the largest unevenness of timber and concrete are superimposed. In the course of the development of the adhesive system and the application technique, it was found that a gap of 7 mm can be bridged reliably if the adhesive is applied with a toothed spatula, with the height of each tooth of 12 mm (see Figure 6).

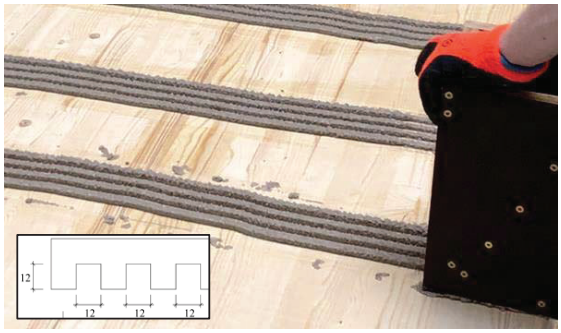

Figure 6: *Application of the adhesive with a toothed spatula, installed in a mortar sledge*

The evenness of the timber elements has been measured on-site with an aluminium batten of 2.0 m length in the range of 0.0 to 3.0 mm. After the concrete part has been placed on top of the timber, the actual gap at the edges of the precast concrete part was measured with a measuring-wedge in the range of 0.0 to 2.0 mm.

3 ANALYTICAL MODEL AND CALCULATION

3.1 PRINCIPLES

Due to the adhesive-bond, the connection between the timber and the concrete can be assumed as rigid, which means that the stresses can be determined analytically with basic, mechanic principles based on the theory of elasticity. This approach is commonly applied in literature [18], [19] and can also be used for TCC constructions with adhesives and cast-in-place concrete [13], as well as for TCC constructions with micro notches, for which, according to Müller and Frangi [20], a rigid bond can be assumed if the notches are arranged continuously over a large area of the span.

The basic relationships that are indispensable for understanding the calculation are briefly listed below. In a first step, the position of the stress zero line z_0 is calculated.

$$z_0 = \frac{\sum_{i=1}^{i} E_i \cdot A_i \cdot z_i}{\sum_{i=1}^{i} E_i \cdot A_i} \tag{1}$$

An effective bending stiffness $(EI)_{cal}$ is then calculated for the composite cross-section, taking into account the different Young's moduli E_i of the partial cross-sections A_i using Steiner's theorem. The geometrical parameter a_i is the distance between the neutral axis of the total cross-section and the neutral axis of the partial cross-sections.

$$(EI)_{cal} = \sum_{i=1}^{i} E_i \cdot I_i + E_i \cdot A_i \cdot a_i^2 \tag{2}$$

Knowing the effective bending stiffness, the bending stresses σ_i at each point of the composite section can be calculated.

$$\sigma_i = M \cdot z \cdot \frac{E_i}{(EI)_{cal}} \tag{3}$$

The maximum stress values at the top and bottom of the composite member are given by substituting the maximum distance between the neutral axis of the composite beam to the outer edges of the cross-section.

With knowledge of the bending stresses σ_i, the relevant criteria for the limit state design of the timber parts and the concrete according to Eurocode 2 [21] and Eurocode 5 [22] have to be fulfilled. For the latter, both bending and tensile strength should be considered.

Further guidelines regarding the long-term behaviour at time t = 3…7 a and t = ∞ are given in CEN TS 19103 [23]. Regarding the verifications in the serviceability limit state, the criteria of deformations and vibrations are of particular relevance, similar to with most other wide-span timber structures for residual use [26]. CEN TS 19103 recommends carrying out the design according to Eurocode 5.

https://doi.org/10.52202/069179-0542

3.2 STRESS CALCULATION FOR ATCC BEAMS WITH DISCONTINUOUS BOND

If the adhesive bond is not continuous along the entire length of the beam but discontinuous (e.g. lateral stripes) as in case of the pilot application, new questions arise with regard to the uniform transmission of shear stresses: How is the shear flow distributed into the adhesive areas and which bond stripe is decisive for the design?

Possible calculation methods to determine the shear flow T_b for a discontinuous bond arrangement are strut-and-tie models, two- or three-dimensional finite element models and analytical models. Because the analytical model offers advantages regarding its simplicity, which has currently only been applied to ATCC composites with a continuous bond, an extension is necessary. The geometric relationships are depicted in Figure 7.

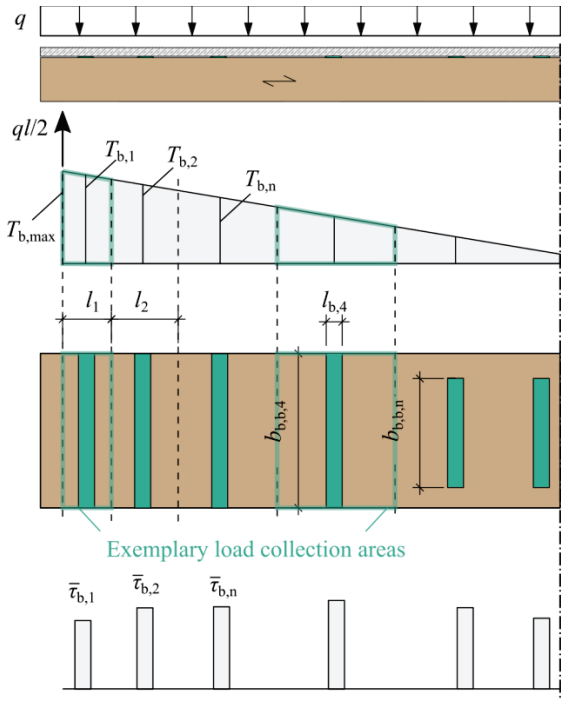

Figure 7: *Composite beam with discontinuous bond – geometric relationships for the analytical calculation model in case of a uniformly distributed load*

Firstly, the shear flow in the bondline $T_{b,i}$ at the stripe i is obtained considering the shear force $V_{n,i}$ at the corresponding stripe and the static moment in the bondline $S_{b,1}$.

$$T_{b,i} = V_{n,i} \cdot \frac{E_1 \cdot S_{b,1}}{(EI)_{cal}} \tag{4}$$

The shear stress in the bondline, which is transmitted at one strip, can then be determined by integration over the partial length. A medium value $\bar{\tau}_b$ can be calculated subsequently by referring the load-collection area to the area of the single strip n.

$$\bar{\tau}_{b,n} = \frac{T_n}{b_{b,n}} \cdot \frac{l_n}{l_{b,n}} \tag{5}$$

3.3 BOND STRENGTH

There are no generally applicable regulations for the verification of the adhesive bond between timber and concrete to date. However, comparable approaches can be found in the literature, whereby the bond failure could usually be attributed to a pure failure in the timber [1], [3]. However, if lower strength concrete, lightweight concrete or hardwood with a high shear strength is used, then the composite failure may be transferred into the top concrete layer [6], [13], [19].

It is generally concluded that the bond failure can be attributed to the substrates timber and concrete if a suitable adhesive is used where adhesion and cohesion failure can be excluded. In the case of the analytical model, where no stresses perpendicular to the joint occur, the bond strength f_b can be set as the minimum of the shear strength of the timber $f_{t,v}$ and the shear strength of the concrete $f_{c,v}$.

$$f_b = \min(f_{t,v}; f_{c,v}) \tag{6}$$

The characteristic value of the shear strength of the timber $f_{t,v,k}$ is defined in the respective product data sheet or the relevant standards of the wood-based material. In addition, according to EN 1995 [22], the modification coefficient k_{cr} should be used to take into account the increased shear stresses due to shrinkage. If k_{cr} is to be considered at the resistance level, the shear strength of GL28c is $f_{t,v,k}$ = 2.50 N/mm².

The determination of the shear strength of the unreinforced concrete surface $f_{c,v,d}$ is less well-supported by systematic studies than it is with timber. Some characteristic values, however, can be found in the literature. They are in the range of $f_{v,c}$ = 3.3 N/mm² for a concrete in the strength class C30/37 (according to the German Committee for Reinforced Concrete [DAfStb] in the guideline for post-reinforcing concrete with glued-on steel plates [25]; where $f_{v,c}$ is a function of the compressive strength and the surface tensile strength) to $f_{v,c}$ = 11,1 N/mm² (according to CEN TS 19103 [23] assuming an angle θ of 45°). Based on own investigations [24], a clear correlation between bond strength and surface tensile strength could be found.

$$f_{c,v} = 2{,}0 \cdot f_{ct,surf} \tag{7}$$

The characteristic surface tensile strength is estimated to be $f_{ctk,surf}$ = 2.20 N/mm², which results in a characteristic shear strength of $f_{c,v,k}$ = 4.40 N/mm².

The design shear strength can be determined if the parameters k_{mod} for the timber and the parameter α_{ct} for the concrete are considered. Furthermore, the safety factor γ_M for the corresponding material is to be included.

https://doi.org/10.52202/069179-0542

The resulting parameters are $f_{t,v,d}$ = 1.54 N/mm² and $f_{c,v,d}$ = 2.49 N/mm², respectively.

A consideration of the factors k_{b1} and k_{b2} is proposed for the last step of the verification of the adhesive bond. These parameters are recommended in accordance with the investigations on steel and CFRP laminates bonded to concrete [25], where comparable factors (e.g. k_{b1}-k_{b4}, k_{sys}) are proposed.

$$\frac{\tau_{b,max}}{k_{b1} \cdot k_{b2} \cdot f_{b,d}} \leq 1 \tag{8}$$

Regarding ATCCs, the coefficient k_{b1} considers possible degradation effects due to swelling and shrinkage depending on the adhesive used for bonding. With the coefficient k_{b2}, it is possible to consider more complex stress situations, for example, due to a varying bond width or stress peaks. Both coefficients are currently under investigation at the University of Kassel.

4 FULL-SCALE TEST

One full-scale test in the laboratory in a four-point bending configuration was carried out to validate the calculation model and the considerations regarding the bond strength. The test was designed as a single-span girder with a span of 7.68 m. The same materials were used as for the construction of the school building; the prefabricated concrete parts were manufactured in the same batch as the concrete parts for the construction site.

The test set-up is depicted in Figure 8. The force was measured with a load cell with a measuring range of up to 500 kN. In addition to the displacement of the hydraulic cylinder (S0), the deflections were measured with six displacement transducers: S1/S2 for the mid-span deflection and S3–S6 for the relative deflection between the concrete and timber. The deflection w at the mid-span of the composite beam was calculated as the average of transducers S1 and S2. Furthermore, the strains in the bondline were measured using fibre-optical sensors.

The specimens were loaded in a quasi-static procedure applying a constant displacement with a rate of 0.2 mm/s. The global failure of the ATCC beam occurred at a load level of $F_{u,exp}$ = 387 kN ($F_{u,exp}$ = sum of the load-bearing construction and machine load, without the self-weight of the specimen) as a combined bond failure in the timber and the concrete (see Figure 9).

Figure 9: *Bond failure in the timber and the concrete substrate, as predicted from the calculation.*

Before loading to failure, the specimen was, firstly, loaded up to 120 kN, which is approximately 30 % of the ultimate failure load, and then unloaded again up to 20 kN in order to visualise the hysteretic effects. The load was held for 30 seconds at each of these loading points. The full-scale test exhibited a quasi linear-elastic behaviour. No hysteresic behaviour was observed visible (see Figure 10).

The calculation of the full-scale specimen was carried out with the calculation model mentioned above. The prediction of the failure load was referred to mean material properties. The shear strength of the concrete $f_{c,v,m}$ was determined with reference to the experimentally determined surface tensile strength of the concrete ($f_{ctm,surf}$ = 3.0) as $f_{c,v,m}$ = 6.0 N/mm².

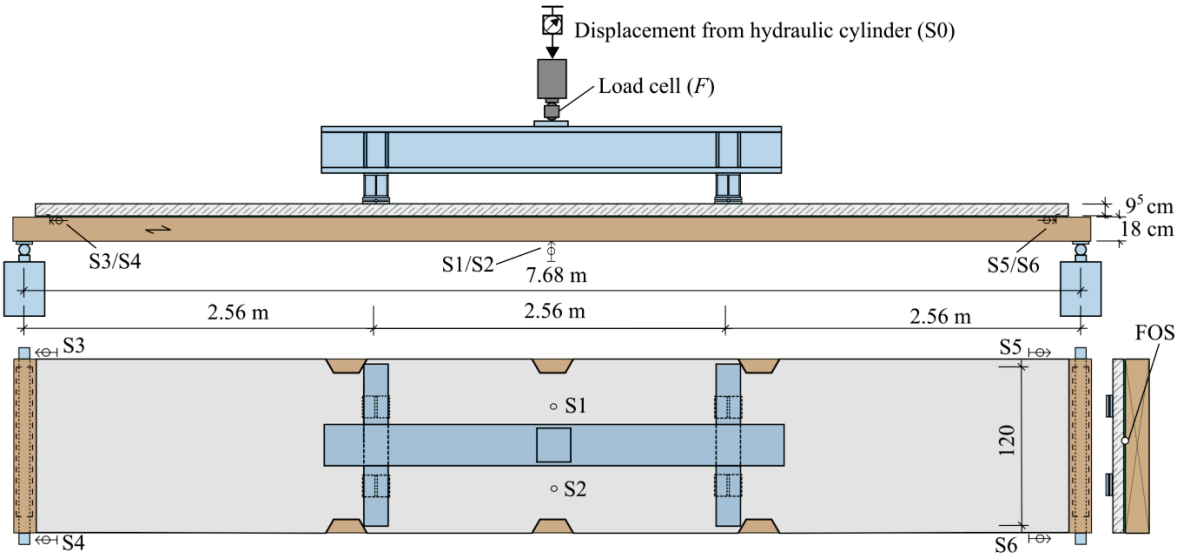

Figure 8: *Test set-up for the full-scale test: four-point bending configuration*

https://doi.org/10.52202/069179-0542

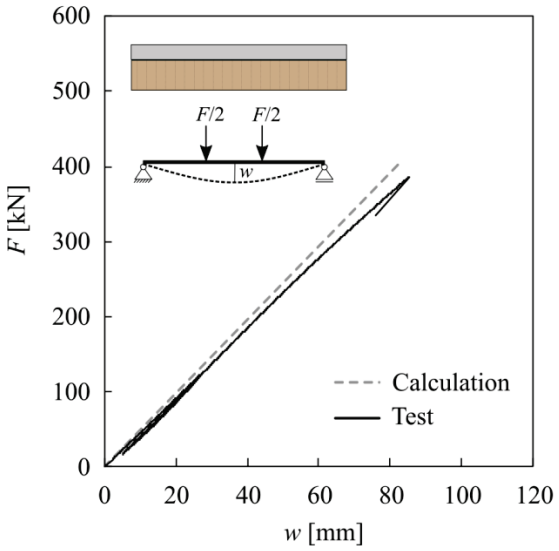

Figure 10: *Load-displacement behaviour of the full-scale test*

The shear strength of the timber was estimated according to Blaß and Krüger [27] as $f_{t,v,m}$(GL28c) = 4.2 N/mm². The resulting bond strength is the minimum of both $f_{b,mean}$ = min($f_{t,v,m,}$; $f_{c,v,m}$) = 4.2 N/mm².

As a result, the failure of the beam is expected to take place in the bondline at a load of $F_{u,cal}$ = 406 kN. The corresponding, predicted failure loads for a bending failure in the timber ($F_{u,cal,m+t}$ = 421 kN) and compression failure in the concrete ($F_{u,cal,c}$ = 438 kN) are higher and, therefore not expected to happen in the test.

The agreement between the test $F_{u,exp}$ = 387 kN and the calculation model is very good, for both the predicted failure mechanism (bond failure) and the failure load ($F_{u,exp}$ = 95 % of $F_{u,cal}$ = 406 kN).

5 QUALITY CONTROL

5.1 CONCEPT

The procedure of the construction work has been planned carefully and diligently to ensure successful bonding. In this context, a reliability concept has been implemented. The aim is to prevent the following potential defects:

- insufficient adhesion formation, or adhesion failure between the adhesive and joined part (due to insufficient surface preparation, too high or too low temperature, humidity or other inappropriate climatic conditions),
- insufficient cohesion strength of the adhesive due to a disturbed curing or an incorrect mixing ratio,
- insufficient load-bearing capacity of the concrete or timber surfaces, and
- contamination of the bonding surfaces.

5.2 PREPARATION

Some universal requirements for the components themselves and the weather and environmental conditions during the first 24 hours of adhesive curing on site were defined and checked before starting the execution process (see Tab. 1).

The requirements have been defined based on EN 14080 [28] and Part 3 of the DAfStb guideline on the bonding of concrete components [25]. Special attention has been paid to the surface tensile strength of the concrete because experience has shown that this particular parameter is a key factor for the success of the bond. Minimum requirements on the surface tensile strength in literature can be found in the range of $f_{ctm,surf}$ > 1.0 N/mm² [25]. A minimum value of 2.0 N/mm² has been defined in this project.

Table 1: *Requirements for the quality control of the pilot application*

Category	Criterion	Requirement
Weather conditions	Outdoor temp.	> 8 °C
	Rel. humidity	< 75 %
Concrete	moisture	< 4 %
	Surface temperature	3 K above the dew point
	Strength class (delivery receipt)	C30/37
	Surface tensile strength $f_{ctm,surf}$	≥ 2.0 N/mm²
Timber	Moisture	< 16 %
	Cleanliness of the surface	Free of dust and loose parts, free of grease
	Planing or grinding the surface	24 hours before starting the bonding
	Strength class (delivery receipt)	GL28c
Tolerance	Evenness timber	± 4 mm (on 2000 mm)
	Evenness concrete	± 1 m (on 200 mm) and ± 3 mm (on 1000 mm)
	Gap between timber and concrete	< 7.0 mm

https://doi.org/10.52202/069179-0542

5.3 GLUING

The environmental conditions (temperature and moisture) can strongly influence the hardening of the adhesive, therefore, bond samples were manufactured in-situ under on-site conditions. After seven days, the samples were tested in the laboratory. The gluing was carried out on 18 May 2022. The weather that day was very sunny and over 25 °C warm. It had rained the previous day, and although the ceiling area was covered, some moisture had entered the timber elements. However, since the moisture content of the timber elements were in the range of 13.0 to 15.4 %, the works could still take place.

The work was carried out in such a manner that the timber elements were lifted by a crane and fixed against displacement. As soon as the surrounding walls were in place, the timber surfaces were checked for evenness using an aluminium batten. The precast concrete elements were then lifted in on a trial basis and the unevenness between the timber and concrete was checked again with a measuring wedge.

In a next step, the position of the subsequent adhesive strips was marked and then freshly planed with a planing depth of about 1 mm. After the gluing surfaces had been planed, careful attention was paid during the work to ensure that no dirt, dust or grease residues got onto the gluing surfaces. This was achieved by wearing disposable gloves and disposable shoe covers. After cleaning with a vacuum cleaner, the adhesive was mixed and applied area by area with a mortar sledge for one precast concrete part at a time.

The pot-life of the adhesive was controlled by a time measurement. The concrete slab was then placed and fixed to the timber part with 12 assembly screws per precast concrete part by means of holes which had been installed in the precast part before pouring.

5.4 SAMPLE MANUFACTURING DURING THE GLUING PROCESS

Accompanying the gluing work, selected test specimens of each adhesive batch were produced directly on-site (see Tab. 2).

Table 2: *Quality assurance – tests during the bonding process*

Category	Criterion	Number of tests
Adhesive	Flexural tensile strength	2 per batch
	Surface tensile strength on a sandblasted steel plate	3 per batch
Bond to concrete	Surface tensile strength of the concrete prefab on-site with polymer mortar as adhesive	3 per batch

The number of specimens produced for the bending tensile prisms were chosen according to the technical approval Z-10.7-282 [29] as a related adhesive construction method is regulated there. At least two specimens should be produced for each adhesive batch according to EN 12350-1 [30] and tested after seven days of curing, according to EN 12390-5 [31]. Since all adhesive containers were manufactured in one batch at the production factory, two test specimens would theoretically have been sufficient due to the relatively small surface area and the resulting small quantity of adhesive. However, it was decided in this case to take samples from each container which was opened and mixed.

A similar procedure was followed for the tensile adhesion tests on a sand-blasted steel plate, and three specimens were taken per mixture. The surface tensile strength of the concrete was also tested again on a separate concrete plate to verify whether the adhesive formed a sufficient bond to the concrete. The surface tensile strength of $f_{ctm,surf}$ = 3.4 N/mm² was above the value of 3.0 N/mm² determined previously in the laboratory and also larger than the value of 2.0 N/mm² required. All further tests which were conducted in-situ also show no loss of strength compared to the reference value taken in the laboratory (Table 3).

Table 3: *Comparison of strength parameters from laboratory and in-situ*

Parameter	Lab.	In-situ
Flexural tensile strength $f_{adh,t,mean}$	28.7	30.0
Surface tensile strength $f_{ctm,surf}$	3.0	3.4

6 CONCLUSIONS

The pilot application of the ATCC construction method under realistic conditions on the construction site has been proved to be successful.

The construction process could be significantly accelerated compared to the conventional construction method with in-situ concrete, as the gluing operations of the prefabricated concrete parts were executed quickly and efficiently. It can be seen that it is possible to integrate ATCC constructions into the planning and construction process with the combination of a validated calculation method, a diligent planning process and a solid quality control concept. The economic use of prefabricated concrete parts for use in TCCs opens up new, promising possibilities for the whole building industry.

https://doi.org/10.52202/069179-0542

ACKNOWLEDGEMENTS

The period between the first tests on adhesively bonded TCCs and the practical implementation in construction as shown in this paper is about 15 years. During this time, extensive experience was gained in an intensive and fruitful collaboration between science and practice. The work would not have been possible without the financial support of:

- IGF research project 17274 N ("BestKleb"), finished 2015
- ZIM research project KF2512006KI4 (Co-operation with Schaffitzel Holzbau GmbH & Co. KG), finished 2017
- IGF research project 19417 N ("SpeedTeCC", Co-operation with WKI Fraunhofer Institute and Technical University Braunschweig), finished 2020
- ZIM research project (Co-operation with BEWO – Betonwerk Oberessendorf GmbH & Co. KG), finished 2022

The authors would like to thank the funding agencies, the colleagues named in the bibliography and, last but not least, the representatives of the companies involved in the projects and the associated project committees for their contributions.

APPLICATION OF A WOODEN PREFABRICATED SHELL EXOSKELETON FOR THE INTEGRATED AND SUSTAINABLE RETROFIT OF A RESIDENTIAL BUILDING

Jacopo Zanni[1], Chiara Passoni[2], Alessandra Marini[3], Ezio Giuriani[4], Andrea Belleri[5], Simone Labò[6], Giovanni Brumana[7], Simone Castelli[8], Claudio Abrami[9], Stefano Santini[10], Giuliano Venturelli[11], Angelo L. Marchetti[12]

ABSTRACT: The ambitious target of decarbonization requires a deep transformation of the construction sector and a systematic renovation of the existing building stock. Such a transition requires the adoption of new technologies conceived with a Life Cycle Thinking approach and implementing digital tools, maximizing performances, while enabling reduction of impacts and costs along the building life cycle. In the paper, a wooden construction technology for the deep renovation of existing buildings is presented. The solution is prefabricated off-site, made of a renewable bio-based material, and adopts innovative dry, standardized connections, enabling concentrating damage in case of earthquakes. The system is applied from the outside, without relocating inhabitants, that might otherwise hinder the renovation. An additional CLT engineered shell, coupled with an optimized thermal layer and new plants along the building perimeters, allow the combined energy and structural upgrade of the building. Finally, specific sensors are added for the continuous monitoring of structural health and environmental parameters. The proposed solution was developed within an industrial project integrating academic research and industrial leading-edge technologies and was applied to a typical post-WWII masonry building.

KEYWORDS: Wooden exoskeleton, Cross-Laminated Timber (CLT), Life Cycle Thinking (LCT), Holistic renovation.

1 INTRODUCTION

A great effort is required to the construction sector to become more sustainable and to proactively contribute to the European goal of carbon neutrality by 2050 [1]. In this transition, the deep renovation of the existing building stock is critical, as highlighted by the recent European "renovation wave" roadmap [2] and by the "New European Bauhaus", since existing buildings are expected to constitute about 85% of the 2050 European construction heritage [3].

In this scenario, it may be observed that the effort to build a few new sustainable green buildings or to renovate buildings targeting the sole energy efficiency is totally insufficient. To reach the ambitious EU goals, a complete transformation of the construction industry and of the concept of building renovation inspired by the Life Cycle Thinking (LCT) approach is required [4,5]. Adopting a LCT approach in the building renovation process means considering the fulfillment of the building needs and the reduction of potential impacts along its whole life cycle, from renovation to end of life. For example, at the product stage, impacts due to material supply and production should be minimized; at the construction stage, impacts connected to the transport and to the construction process should be limited; in the use stage, the energy consumption should be minimized together with impacts connected to maintenance, to the possible change of destination use, or, even more importantly, to possible hazards such as earthquakes or superstorms; finally, impacts connected to demolition/deconstruction of buildings and to waste management should be addressed since the earlier steps of the design phases. When the LCT approach is considered during the selection of a retrofit strategy, the role of structural engineers become critical in the definition and the detailing of the techniques. Life Cycle Structural Engineering (LCSE) should thus be adopted, including new LCT design principles, such as prefabrication, standardization, off-site production, adoption of eco-efficient materials, etc., to conceive and design truly sustainable retrofit techniques [6].

Economic sustainability of the interventions should also be considered when a LCT approach is pursuit. To overcome the economic and operational barriers that arise

for the rehabilitation of buildings in case of restricted budgets, the incremental rehabilitation approach may thus be adopted. This concept, introduced in [7] and further explored in [8], among others, involves planning a comprehensive intervention through a series of steps distributed over time and organized according to structural (minimum intervention), economic (budget limitations) and functional criteria (site sharing with planned maintenance interventions) so as to ensure the feasibility and effectiveness of the intervention.

From these premises comes the idea of employing holistic renovation techniques built from the outside of the building, coupling seismic reinforcement exoskeletons with energy and plant efficiency systems and with customizable architectural finishes, designed to meet the LCT principles and to be realized according to an incremental rehabilitation perspective [9].

Among these solutions, some of the authors recently proposed the AdESA System [10, 11], a wooden shell exoskeleton composed of a structural, energy, and architectural layer, able not just to guarantee maximum structural, energy and comfort performances, but also to minimize environmental, social, and economic impacts along the retrofitted building's life cycle, being conceived including some LCT principles such as material eco-efficiency, prefabrication, standardization, damage control, demountability, and reusability, among others. In this context, the use of wood-based materials allows, on the one hand, to limit the environmental impacts thanks to the use of a material with a positive CO_2 emission rate, and, on the other hand, to take advantage of the great potential offered by wood in structural and technological terms, such as prefabrication, standardization of connections, speed of assembly, ease of work on site and integration with insulation and finishing systems.

With respect to the first concept of the AdESA project, this paper presents an advancement of the solution. The system was here further engineered by improving the foundation connection system to enhance the demountability of the structural system, by introducing new plants from the outside, and by introducing a continuous monitoring of performances to ensure the building safety, efficiency and durability. The paper present the application of the enhanced system to a real case study, developed within the SCC Innovation Hub & Living Lab Network project (financed by Regione Lombardia, Italy), which, thanks to the collaboration between university and industrial partners involved in the construction and telecommunications sectors, has made it possible to conceive and implement an LCT-based integrated rehabilitation intervention on a social housing residential building featuring an additional prefabricated wooden shell exoskeleton.

2 GLOBAL CONCEPT OF THE INTERVENTION

The goal of the project was to design and apply an LCT-based integrated retrofit intervention to a residential social housing building, in order to achieve better performances and reduce the impacts of the building along its life cycle. The main constraints imposed by the project include adherence to planned budget limits and the need to not interfere with the functionality of the building by ensuring inhabitants full access to living spaces during the renovation works.

The proposed solution, developed from previous studies and applications within an ongoing research project carried out by the University of Bergamo and other partners, involves working from the outside through the implementation of an additional skin (the AdESA system [11]), arranged along the perimeter of the building in adherence to the existing walls, and consisting of three functional layers: structural, energetic and architectural.

The inner layer, which is a structural shell exoskeleton, constitutes a new seismic-resistant system that works in parallel with the building to which it is connected, ensuring an increase in overall strength and stiffness. The thickness of this layer can vary depending on the materials used and the structural solution adopted (e.g. single walls, coupled walls, shell). This is overlaid with the energy layer, made of thermal insulating materials capable of reducing the transmittance of opaque walls by limiting heat loss between inside and outside. A variety of thermal insulating materials are available to reach the same final energy performance. The choice of the best material depends on the transmittance and thermal capacity of the existing walls and of the structural layer selected, on the environmental impacts related to the materials, and on the total allowable thickness for the exoskeleton according to local building codes and functional needs. Finally, the architectural layer encloses the finishing of the new envelope and has both an aesthetic and protective value for the underlying layers. Since this layer does not have to perform energy/structural functions, it is highly customizable and can range from traditional solutions with painted plaster to panelized cladding with a variety of geometric and material textures.

From the LCT perspective, the system is studied to implement dry-mounted elements that, on the one hand, limit the use of raw materials and operations for on-site installation, and, on the other hand, ensure easy disassembly for the purpose of inspecting and maintaining the layers behind as well, and to enhance recyclability and reusability of the elements at the end-of-life stage. In addition, the system is also design to minimize the impacts due to earthquakes.

An important innovation introduced by the SCC Innovation Hub & Living Lab Network project concerns the implementation of a new plant distribution system integrated into the energy layer. The system, called Fluxus Ring®, is developed to substitute traditional wall and in-wall water supply pipes and electric wiring with a new type of pre-assembled isolated pipes, with the aim of making them easy to locate, inspect and implement over time thanks to a removable sheet metal cover and the use of special components that allow new utilities to be moved or added within the building without requiring any masonry work. In addition, another advantage is to create,

along the perimeter of each floor, equipotential rings that limit energy losses at the various utilities. The system consists of modules made up of extruded aluminum C-shaped profiles and sheet metal covers with a small footprint (103x265 mm) designed as a multi-service physical infrastructure able to accommodate all the plant ductwork expected for a residential building (hydraulic, electric, multimedia and building & automation control systems, optic fiber) (Figure 1).

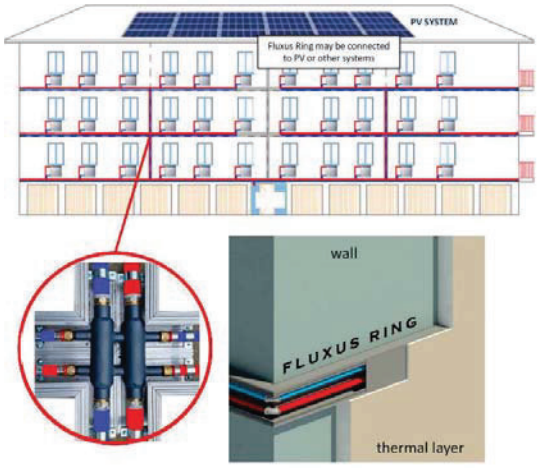

Figure 1: *Fluxus Ring system (©Italia Smart Building)*

In order to guarantee the building performances during its use phase, an aspect of great importance concerns the continuous structural health monitoring (SHM) [12]. This process involves the observation of the structure over time, the extraction of features from measures sensitive to structural damage, and, finally, the statistical analysis for the automatic detection of the state of health.

To this end, SHM systems consisting of tools for acquiring, processing, storing and sharing data on digital platforms were designed (Figure 2). The monitored parameters are the building's vibration frequencies, through the acquisition of accelerations induced by environmental vibrations and seismic events, and the state of preservation of the material constituting the structural exoskeleton, by measuring the moisture content in the CLT panels. These parameters, compared with the targets used in the design and construction phase, can provide important feedback on any damage or deterioration phenomena not directly detectable by visual inspections.

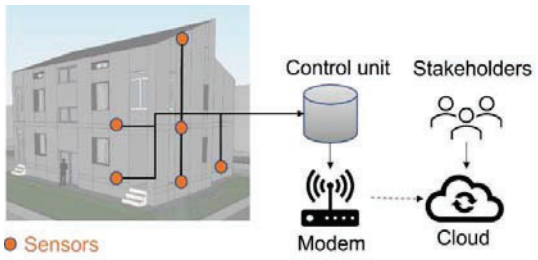

Figure 2: *Structural Health Monitoring concept*

3 DESCRIPTION OF THE REFERENCE BUILDING

In the project, the proposed LCT-based wooden retrofit solution was applied to a residential building. The case study is a social housing building constructed in 1960, located in northern Italy. The building has two floors above-ground, each featuring two apartments, and an attic with roofing on staggered levels having a practicable part, used for storage and cellars, and a non-walkable part under the lower pitch.

The plan organization is regular, with a gross surface of about 131 m^2. The main façade has an extension of 13.6 m, the rear façade has an extension of 12.4 m, and the side façades have an extension of 10 m and an indentation of about 0.60 m in the middle of the length as shown in Figure 3.

The load-bearing structure presents masonry walls made of clay hollow blocks (245x245x120) mm^3, with the holes arranged horizontally, and cement-based mortar. In the corners between orthogonal walls and at the ends of longitudinal walls the masonry is made of solid brick; while the walls of the crawl space between the foundations and the first-floor slab (75 cm above ground level) are made of solid brick and cement mortar, resting on continuous perimetral foundation made of unreinforced concrete mixed with stones. The floor slabs consist of 20 cm-high RC beam and clay block system, with spans of 4.20 and 5.00 m and perimeter curbs above the masonry walls made of poor quality weakly reinforced concrete.

The two-roof pitches, arranged at different heights, consists of reinforced brick joists and hollow-core lacking the extrados screed.

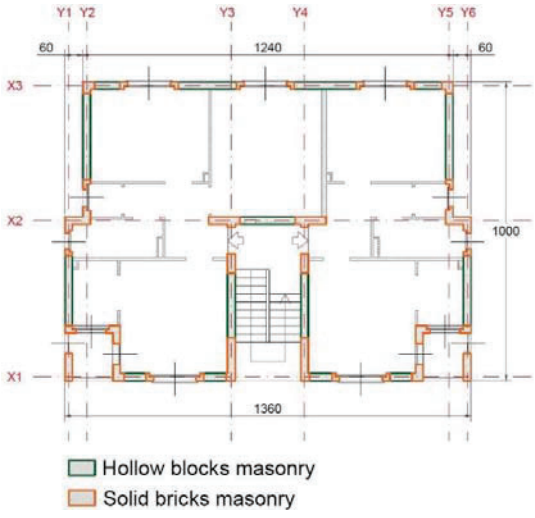

Figure 3: *Floor plan of the building*

Under a structural point of view, masonry walls exhibit vulnerability both with respect to out-of-plane actions, due to the absence of roof diaphragm providing effective constraint against overturning, and with respect to in-plane actions, due to the masonry quality that exhibits

https://doi.org/10.52202/069179-0543

poor mechanical performances and more brittle behavior than traditional masonry type due to the arrangement of hollow blocks [13]. The reference seismic spectrum at LSLS is obtained, according to Italian code [14], from the following parameters: $a_g = 0.158$ g, $F_0 = 2.463$, $T_c^* = 0.266$ s, S = 1.200. The main vulnerability of the building is represented by the local out-of-plane collapse mechanisms of the masonry on the attic floor, associated with a safety index of 0.12. The seismic retrofit is therefore necessary.

Moving to the energy considerations, the selected building represents the classic example of social housing of the '60 and was not improved during the years. The envelope obsolescence is the cause of a poor energy performance, as quite usual of buildings of those years. The walls are covered with plaster and the roof with tiles; all the surfaces lack thermal insulation, and different types of cold bridges can thus be identified. Single glass windows with old frames affect the energy performance and drive a high air infiltration ratio. In addition, the stairwell, which is centrally placed to the main façade, is open to the outer courtyard (Figure 4). The facilities are outdated and inadequate. The combination of these factors leads to a large energy consumption for space heating and a low indoor comfort for the users.

Finally, under an architectural point of view, the building presented poor conditions and a bad state of preservation with widespread deterioration on the façades and low living comfort for the inhabitants, needing renovation both under an aesthetic and a functional point of view.

Figure 4: *Picture of the main façade*

4 DESIGN OF THE RETROFIT INTERVENTION

4.1 STRUCTURAL LAYER OF THE INTERVENTION

The choice to intervene from the outside to avoid inhabitants' relocation implies the introduction of new seismic-resistant systems that cooperate with those of the existing building, called exoskeletons [15,16]. This requires special attention in the evaluation of the actions transferred at the floor and foundation levels and in the definition of the relevant construction details. Furthermore, to enable the transfer of actions between the exoskeleton and the existing building, preliminary verification and possible reinforcement of the existing floor diaphragms is necessary as they represent indispensable elements of the seismic force resistant system [17,18].

Exoskeletons can be divided into two main categories according to their structural organization: bi-dimensional and three-dimensional systems.

Bi-dimensional (or wall) systems are those applied on individual building façades, designed to make a resistant contribution only in the reference direction without interacting with systems arranged on adjacent façades. Three-dimensional systems (or shell structures), on the other hand, are characterized by the widespread presence of structural elements along all façades that cover the entire exterior surface of the building. This has significant advantages from a structural point of view since orthogonal walls, being connected to each other, make it possible to increase overall stiffness and strength by reducing stress on individual elements and in the foundation.

For the definition of the seismic retrofitting intervention, performance targets that are stricter than those required by the Italian national standard [14] have been identified to respect those LCT principles connected with the damage and downtime minimization. According to such principles, in addition to the fundamental criterion of structural safety, it is also important to ensure building resilience through damage control for high intensity earthquakes so as to minimize the economic and social impacts resulting from a seismic event.

Based on these considerations, the Life Safety Limit State (LSLS) was taken as a reference, and it was imposed that: the exoskeleton must be able to transfer the entire seismic action expected for the building; the structure must experience a maximum limit drift of 0.2%, dictated by the poor masonry quality and the need to preserve its strength against vertical loads; residual drift must be limited so as not to compromise disassembly and repairability of components; a ductile collapse mechanism for the building must be ensured.

According to the previous design objectives, the structural exoskeleton applied to the case study building, represented in Figure 5, is composed of a new foundation system, a wooden shell made of 10cm-thick five layers CLT panels connected each other and with existing floors, and an extrados roof diaphragm made with plywood panels.

The foundation system consists of a RC perimetral curb placed in adherence to the existing foundation to support the CLT panels and transfer their actions to 16 small-diameter piles, deeply driven into the ground (15 m), to support the tensile and compressive actions induced by the wooden shell, and an outer RC diaphragm (100x20)cm^2 to collect the seismic load of the entire building and ensure its shear-slip resistance with respect to the ground.

Figure 5: *Layout of the structural intervention*

Given the geometry of the building, the CLT panels are arranged vertically adjacent to the existing wall piers and shaped to contour existing openings (Figure 6). A shear connection is placed between adjacent panels to obtain a coupled wall system with high stiffness, comparable to that of the existing building. The shear connections between panels, shown in Figure 7, were ad-hoc designed to ensure ductile and dissipative behavior by avoiding damage in the CLT panels and keeping the other connections in the elastic range, thus ensuring the minimization of damage and replacement actions in the aftermath of the earthquake. These connections are made with segments of HEA100 welded along the flanges, exhibiting hysteretic behavior due to bending plasticization of web plates, whose ductility was tested through an experimental campaign conducted by University of Bergamo [19]. The connection is prefabricated and mounted to the CLT panels on site by into millings prepared on the edge of the panels and fixed with over-resistant self-drilling dowels.

CLT panels are then connected to the building floors by means of dowels (φ20/30) and tie rods (2φ12/panel) grouted in the RC curbs, designed with elastic and over-resistant behavior.

The continuous connections between adjacent panels and between orthogonal panels were realized by means of cross-connecting screws (φ9x140mm) designed for shear and tensile strength with overstrength behavior.

The panels are restrained to the new foundation by means of unbonded steel ties (Dywidag 18WR) for transferring the high tensile stresses induced by the exoskeleton, and shear keys inserted at the base of the panels (φ50 tubular studs, of 3 mm thickness, welded to the base plate nailed to the panel). The ties are prepared and pre-installed off-site inside the panel and jointed in place with coupler, while the shear keys are housed in special recesses prepared in the cast-in-place foundation curbs (Figure 8) and sealed with high-performance mortar after assembly operations are completed.

The development of this connection system arose from the need to transfer higher shear and tensile actions for which the traditional connections used in new wooden construction (hold-down and angle brackets) are insufficient, but especially to ensure easy assembly and disassembly of the system in the LCT perspective.

The roof diaphragms, built at the extrados of the two pitches of the existing roof, consist of 3-cm-thick plywood panels joined together with nailed strips (Figure 9) and perimeter chords made of steel plates connected to the existing RC curbs by dowels and tie rods and to the CLT walls by nails.

Figure 6: *Prefabricated CLT panels ready to be installed*

https://doi.org/10.52202/069179-0543

Figure 8: *Panels arranged on the façade and connected with the new foundation*

Figure 9: *Construction of the diaphragm at the extrados of the existing roof*

To evaluate the effectiveness of the structural intervention, two finite element models of the building were developed with Midas Gen and nonlinear static analysis were carried out.

The first model represents the building in the as-is condition in the hypotheses that the local mechanisms were inhibited. Given the regularity and simplicity of the structure, equivalent frame modelling was employed.

The masonry piers were introduced with beam elements with an extension equal to the interstory height, connected by the RC curbs. To both elements were assigned concentrated plastic hinges in shear and bending; in particular, the shear-slip mechanism was evaluated for masonry.

In the second model, shown in Figure 10, the wooden exoskeleton is overlapped to the initial configuration. CLT panels were introduced adopting plate elements and considering the orthotropic properties of the material and the actual geometry and stratigraphy of the adopted panels. Connections were modelled as distributed general links with calibrated stiffness and elastic strength based on the theoretical and experimental behavior of individual connectors. At the base of the panels, compression-only type point spring supports, to simulate the vertical interaction with the reinforced concrete foundation, and rigid shear constraints were introduced.

Figure 10: *Finite Element Model of the retrofitted building*

The building in the as-is condition develops a soft story mechanism in which capacity is dictated by the achievement of the ultimate flexural drift of the slender wall piers arranged on the main façade. The displacement demand at LSLS is therefore not satisfied.

The results, reported as a comparison of pushover curves in Figure 11, show that, with the introduction of the exoskeleton, the structure gains stiffness and strength, and the displacement demand at LSLS is lower than capacity. At this point, plasticization of some dissipative connections is reached while the connections between panels and foundation are all found to remain in the elastic range; internal stresses in CLT panels, evaluated in accordance with [20] and considering the actual panel stratigraphy, are lower than the prescribed limits. In the existing structure some masonry walls reach the plasticization; however, the maximum drift recorded is 0.12%, lower than the maximum imposed limit of 0.20%. The ultimate displacement capacity of the building also increases by moving from a weak storey mechanism to a global mechanism that allows an increase in the ductility of the structure.

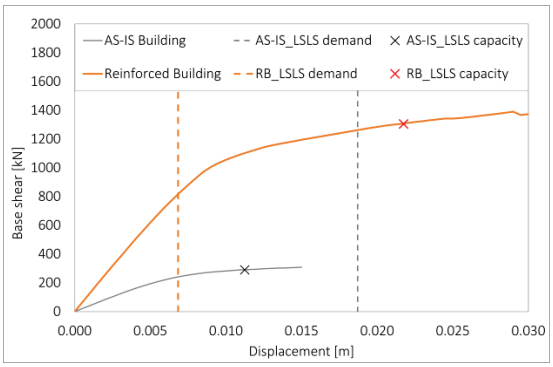

Figure 11: *Comparison between the pushover curve of the As-is building and retrofitted building for the main direction*

https://doi.org/10.52202/069179-0543

4.2 ENERGY AND ARCHITECTURAL LAYERS OF THE INTERVENTION

The final stratigraphy of the integrated intervention, shown in Figure 12, includes a structural layer with 10-cm-thick CLT panels, covered with an energy layer consisting of 12-cm-thick rock wool panels and completed by a finish with painted plaster. Several proposals were developed for the design of the outer architectural layer to explore the expressive potential of the system, an example is shown in Figure 13; however, the final choice was dictated by the budget constraints.
The energy efficiency intervention also includes closing and insulating the stairwell, insulating the attic floor with 16-cm-thick XPS panels and windows replacement.

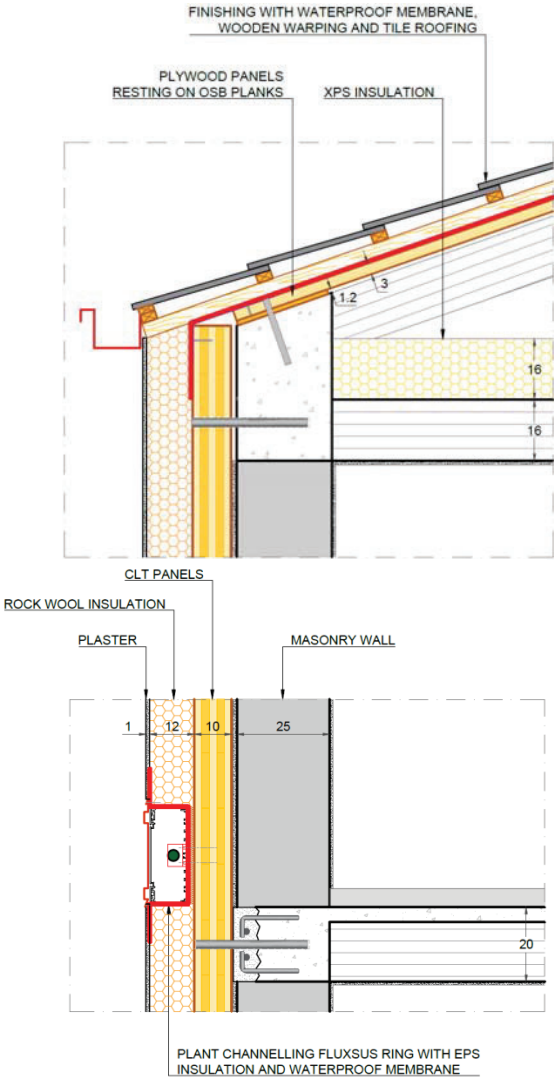

Figure 12: *Stratigraphy of the retrofitted building*

Figure 13: *Rendering of one of the proposed architectural solutions*

From the energy point of view, coupling the structural layer with an energy layer allows to reduce the thermal transmittance of the opaque elements from 0.96 to 0.22 W/(m^{2}K) and avoid cold bridges.
A detailed transient analysis has been carried out adopting a numerical Trnsys simulation. Starting from a 3D geometrical model, the evaluation considers the behavior of the building including the physical properties of walls and the internal gains (occupancy, appliances, and lights) on hourly basis in terms of temporal and spatial distribution. The results showed a reduction of primary energy requirement for the space heating, compared with the as-is conditions. In fact, as shown in Figure 14, the forecasted peak load shifts from 22 kW to 9 kW; whilst, on annual basis, the heating load drops from 54 MWh to 15 MW, with an energy savings of 72%.

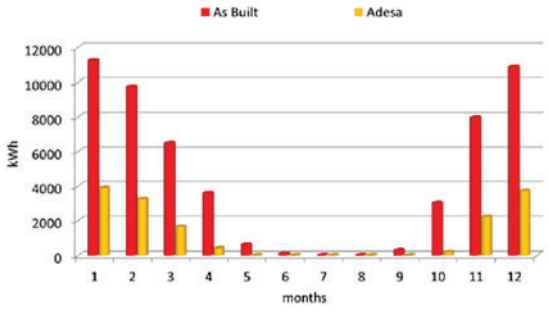

Figure 14: *Comparison between the energy performances of the building in the as-is and retrofitted conditions*

4.3 ADDITIONAL PLANTS FROM THE OUTSIDE AND MONITORING SYSTEM

With respect to the traditional AdESA system, in this project, the integrated renovation solution was further engineered to ensure both the adaptability of the plant system and the monitoring of the building performances along its life cycle. To this aim, the Fluxus Ring ® plant system was installed along the perimeter of the building close to the structural layer, to which it is connected by screws, and, inside it, it was housed the monitoring system (Figure 15) with associated wiring connecting the acquisition instrument to the control unit located in the

https://doi.org/10.52202/069179-0543

attic of the building where the collected data are processed, stored and shared on a cloud platform.
Eight uniaxial accelerometers, oriented in the three main directions, are placed on the structural layer; two hygrometers are placed on the CLT panels of the north and south façades and one inside the plywood panel of the roof diaphragm. Finally, a weather station is placed on the roof of the building to collect environmental parameters such as humidity, temperature, pressure and wind speed.

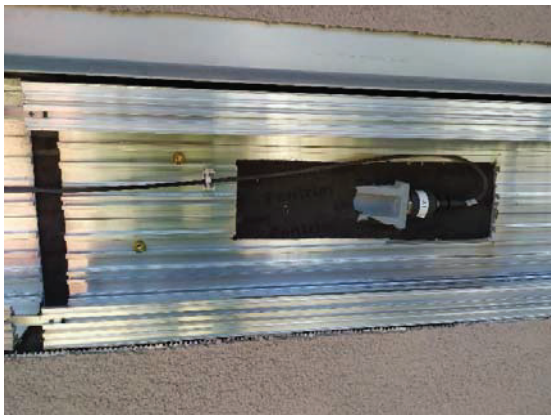

Figure 15: *Placement of an accelerometer within the Fluxus system*

The adoption of Fluxus Ring would allow the substitution and/or future modification of the plants without the relocation of inhabitants, according to the evolving needs of its occupants and in line with the LCT and incremental rehabilitation approaches, thus allowing the building owners to fulfill the requirements of building flexibility and adaptability.

5 CONCLUDING REMARKS

The need to make the building stock more resilient and sustainable requires a deep change of the current practices adopted in the construction sector. In the present paper, a new wooden retrofit technology inspired by the principles of Life Cycle Thinking and Incremental Rehabilitation integrated with innovative digital tools for Structural Health Monitoring is proposed and applied for the holistic and smart renovation of a residential building, which shows important structural, energetic and architectural deficiencies. The solution consists in a prefabricated multi-layered wooden exoskeleton, implementing bio-based materials, standardized elements, and dry and demountable connections. An innovative system to introduce new plants without relocating inhabitants is provided, and sensors are installed for monitoring of the structural health of the building.
The presented solution, which results from the collaboration of academic and industrial partners, represents the evolution of the prototype AdESA system [11], which is here further enhanced by enforcing the application of the LCT principles and by implementing digital technologies to improve building performances and comfort of the inhabitants.
In particular, the choice of a material such as wooden panels for the realization of exoskeletons is favorable for intervening on small regular buildings, due to limitations imposed by the mechanical properties of the material and by production and assembly operations. In addition, wooden exoskeletons may be easily conceived to comply with sustainable LCT criteria; timber is in fact an eco-friendly material, produced in certified factories and employed with dry technologies thanks to the use of standardized mechanical connections that reduce site operations. Moreover, wood is easily workable and adaptable on the construction site for the management of interference and assembly tolerances, and it also offers excellent support for the fixing of additional elements such as windowsills, parapets, ventilated façades, technological installations, etc... Also, from the energy point of view, thanks to its thermal properties, timber offers a contribution in terms of insulation, which has positive effects on the thickness of the insulating layer. On the other hand, special attention should be paid to fire and moisture protection of wood in order to ensure durability.
In this paper, the proposed wooden prefabricated shell system was applied for the renovation of a social housing building. The design of the integrated retrofit intervention was discussed, and the enhancement of the seismic and energy performances of the building after the retrofit were shown by means of numerical analyses.
To complete the retrofit intervention, the construction site took 6 months, including 5 months for the structural works; the most time-consuming operations involved the construction of the new foundations, while the installation of 20 vertical CLT panels, with maximum dimension of (250x790x10)cm^3 and the 8 connecting panels took only one week. Figure 16 shows the new building envelope following the completion of the intervention.
Observations from this pilot application will enable further enhancement of the proposed technology and will improve the replicability of the solution.

BUILDING WITH WOOD STRUCTURES – SUCCESFULL DESIGN PROCESS

Alain Bradette[1], Geir Glasø[2], Tor Øistein Andresen[3]

ABSTRACT: Building with wood construction (glulam, CLT, LVL etc.) poses challenges compared to conventional buildings in steel and concrete. Load bearing systems, stability, spans (thickness and vibration of floor elements), connections between structural elements, the behaviour in case of fire and sound insulation properties are the main characteristics that must be addressed individually.

These challenges grow in importance when one desires to display the wood construction as much as possible. The reasons for building with timber are many. To name some: low CO_2-emissions, reduced duration of the building phase, low noise on building site, architectural properties as well as use of prefabricated elements and design processes combining virtual design and construction (VDC) with building information modelling (BIM) that reduces risk and cost compared to on-site building systems.

Planning building projects with normal design phase level of development is in our experience not appropriate to successfully plan and execute building projects with visible timber structures. The reason being that the necessary multidisciplinary aspect of the design is not sufficiently considered.

In this paper we will, through case studies, showcase some of the multidisciplinary design challenges with exposed timber structures and show how a multidisciplinary design process can help to achieve project goals and meet design requirements.

KEYWORDS: Collaboration, Sustainability, building design, structural design, acoustics, fire safety, timber structures, Building information model (BIM), project management, large timber buildings, multidisciplinary engineering, WCTE 2023, Oslo, Norway.

1 INTRODUCTION

Using timber as material for structure in buildings is following an exponential growth in recent years as part of the efforts in reducing CO2-emissions from the construction industry.

To build with timber structures poses more challenges compared to conventional buildings with steel and concrete. These challenges grow in importance with the increasing technical complexity resulting from timber material properties, the number of stories or when one aspires to exhibit the timber construction as much as possible.

Use of modern prefabrications and design processes such as virtual design and construction (VDC) and building information modelling (BIM) are very useful tools, but the design process is also very crucial. Indeed, our experience is that planning massive timber project with normal phase maturity in early project phases will not address properly the engineering challenges posed by larger building projects, especially when some of the massive timber structure is apparent. The main reasons being insufficient multidisciplinary design and level of development.

In this paper we will, through case studies, investigate some of the challenges with exposed timber structures and explain how to achieve project goals and meet design requirements through multidisciplinary design. The case studies focus on CLT and Glulam buildings.

2 SHOWING TIMBER STRUCTURES

2.1 REASONS TO SHOW TIMBER STRUCTURE

There are several reasons for showing timber structures compared to embedding the timber material in other materials such as gypsum boards:

[1] Alain Bradette M.Sc., Sweco Norway AS, Norway, alain.bradette@sweco.no
[2] Geir Glasø, Sweco Norway AS, Norway, geir.glaso@sweco.no
[3] Tor Øistein Andresen, Sweco Norway AS, Norway, tor.andresen@sweco.no

https://doi.org/10.52202/069179-0544

- Architectural expression: visible wood is growingly sought after as it gives to the architects a new palette of forms, textures, and colours to exploit in their research of building identity and impression.
- CO2-emission: Fewer linings and false ceilings mean less materials and therefore less emissions.
- Reduced costs: Fewer linings and false ceilings lead to less material and less time spent on execution, both contributing to reduce the costs.
- Reduces execution time: As less operations are required, the execution time is consequently reduced.
- Indoor climate: Exposed massive timber helps to regulate the indoor climate with its ability to absorb and release humidity and its thermal insulating properties.
- Psychological effect: This field is currently the topic of research. Strong evidence and conclusions are still to come, but feedbacks from projects indicate that apparent massive timber is generally beneficial for the "feel good" of users. Wood is perceived as a natural material and the presence of natural elements may have positive psychological effect. The physical touch is also felt soft and warm, which may procure a calming effect. Other feedback is that pupils in schools tend to be quieter and calmer in schools with visible wood. Studies of positive effect on patient's recovery in rooms with visible wood constructions are undergoing.

2.2 CHALLENGES

Structure

Timber structures require a different design approach due to the properties of the material compared to other structural materials such as steel and concrete. The design of timber members, such as beams and columns, depend heavily on the design and load capacity of the connections as the connections give the requirements for the associated elements. This means that connection design needs to start early, at the same time as the structural members.

The integrity of visible connections in case of fire loads is also a design requirement that needs to be attended by a structural engineer.

The aesthetic of the connections is an architectural opportunity. However, as showed above, any aesthetic consideration must be part of the connection design right from the start as an input like loads, associated member dimensions and fire safety requirements.

The fact that timber elements and the connections are not standardized gives place to a large degree of innovation. However, new assemblies require in-depth knowledge of wood properties. Advanced calculation and laboratory tests may be needed to reach sufficient confidence and documentation of the solutions.

Fire safety

Fire safety is a crucial aspect for timber buildings. Timber constructions are combustible and as such will contribute to increase the amount of combustible material and hence, the development of the fire.

Height, use and location of the building are determining factors for fire safety requirements imposed by the local legislation.

Fire codes are commonly based on the use of non-flammable materials and approved construction and details providing a known fire resistance. Since timber is a flammable material, the fix fire resistance logic of the fire codes is not directly applicable for apparent timber constructions. The dynamic fire behavior of the load bearing structure in massive timber is therefore established through calculations of the fire energy over time, taking into account both the contribution from the burning structure and the charring insulating effect. This is an iterative process leading to the balance between the amount of exposed timber structure and the required integrity duration for the structure.

The calculated charring layer must be added to the dimensions of the timber elements and solutions for fireproofing the connections must be designed. These two elements are of great influence for the properties and appearance of the bearing structure, proving necessary to integrate fire safety in the early design of any timber construction with exposed timber.

Acoustics

Massive timber has a density around one-fifth of concrete. Sound insulation and impact noise properties of massive timber are therefore quite different from concrete. For instance, for a given thickness, a massive timber element will typically provide sound insulation 15 – 18 dB lower than a concrete element.

As a basic rule, massive timber walls alone do not provide sufficient sound insulation to meet most of the acoustical requirements between rooms. Concerning floors, the combination of limited airborne insulation and high impact noise makes it impossible to have bare elements without any improving construction such as a floating floor and/or a sound insulating ceiling.

The low mass of timber also makes flanking transmission through wall and floor elements an important issue to address. The simplest solution is to use gypsum board linings and ceilings. The flip side is that more operations and material are needed, with their consequences on time, costs, and the environment.

As described above in section 2.1, there are many reasons for showing massive timber structure. The adequate approach to optimizing visible massive timber while taking care of the Acoustics is as follow:

- Use fire safety measures for sound insulation: Fire safety may require non-flammable material in a corridor. Mounting a gypsum board directly on the CLT-wall will barely improve the sound insulation, 1 - 2 dB. Using the same gypsum board as a lining with an air space can improve the sound insulation by 10 or 15 dB.
- Coordinate fire safety measures with sound insulation: Avoid having situations where

https://doi.org/10.52202/069179-0544

gypsum board is applied on one side of a wall for fire safety reasons and a lining is mounted on the other side because of the sound insulation.

- Use decoupling to reduce flanking transmission: Elastomer strips between wall and floor elements are commonly used for that purpose, but the connections often "short circuit" the elastomer, significantly reducing the effect of the decoupling. Split of floors can also be used, but this measure has important consequences on the load bearing system and the architecture since supplementary beams and columns can be necessary as well as changes of the layout.

Given the important implications of the approach explained above, the acoustical design must absolutely be integrated at an early stage of the design when alternatives for solutions are still there.

Contrary to common expectation, sound absorption properties of massive timber are very low. That means that a building solely made of massive timber will not even get close to fulfilling standard requirements for reverberation time. Additional sound absorbing elements such as false ceiling, free hanging units and wall absorbers are unavoidable.

3 SOLUTIONS

When facing the technical complexity of designing massive timber buildings, it is not uncommon to see architects, builders or property developers asking for a reduction of the requirements.

On a general basis, we do not agree with this approach. For instance, we cannot have less firesafe buildings. Furthermore, people do not want less comfortable buildings than what they are accustomed to. To take an example, electric cars' popularity began the day they became as performant as cars with combustion engine. Likewise, less comfortable timber buildings will lead to reduced buyers' and users' interest.

On the other hand, we believe that better understanding of the material could lead to more harmonized and more adapted requirements for fire safety.

The standard design process is sequential with the architect drawings, then structural design, then fire safety and acoustics. Our experience is that this sequential design is not adapted to massive timber constructions and is the major reason for the perceived added complexity and disappointing results. Changing the design approach rather than the requirements appears then to be the right option.

Based on our experience with successful projects, we strongly believe that early involvement of fire safety and acoustics in the design process and tight coordination between disciplines, especially with structure, are key to success. This approach is explained and exemplified in the paragraphs below.

3.1 DESIGN PROCESS

All building design process goes through different design phases, from the beginning to the end. There are many different definitions and scales of each phase depending on the project size and complexity. Professionals have developed methodologies and tools to handle, standardize and optimize project design processes. In our company Sweco, we do this through our platform *sweco@work* which provides an overview as well as tools and routines for concrete tasks in each phase (Figure 1).

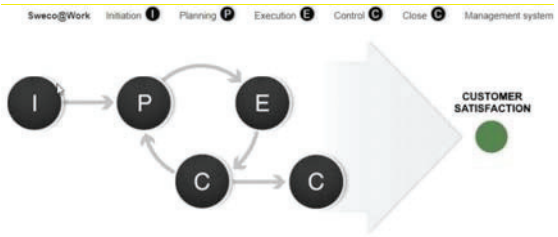

Figure 1: *Sweco@work project planning and execution process overview*

For all project participants, such as decision makers, architects, and consultants, the level of design freedom and influence on project costs evolve during the design and construction process (Figure 2). As the project advances, design changes become increasingly complex and more expensive.

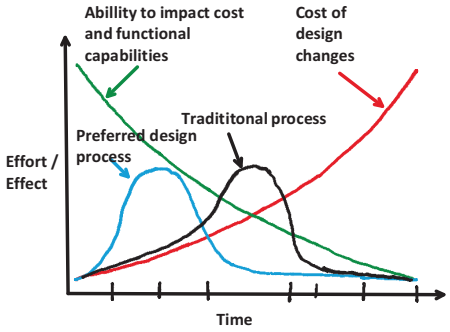

Figure 2*: Illustration of design freedom, cost of changes and design process versus timeline*

Building information modeling, hereafter referred to as "BIM"[1], allows in general building design processes to create digital prototypes during the design process. BIM evolves with increased level of development (or detail) during the design phase.

By sharing BIM during the design process with different disciplines and using design processes like Virtual Design and Construction (VDC)[2] and Integrated Concurrent Engineering (ICE), a greater level of development can be achieved in earlier design phases. This, because design participants share their work before it's finished and by doing so, enables an efficient process where design challenges are identified through a continuous and multidisciplinary process rather than at the end of each deliverable. Design requirements and feedback need to be visualized for all participants to achieve this process. BIM

https://doi.org/10.52202/069179-0544

and VDC methodology are preferred tools for that purpose.

Know-how
Timber construction is for many stakeholders new and the skills and experience in the design teams may vary more than in common building constructions.

An example of this is found in structural engineering. The most common design criteria for the cross section of beams and columns with steel and concrete construction is the moment and shear forces in each member. For timber construction, it is the member connections design that most of the time govern the type of cross section to use.

The same type of alternative engineering is found in fire safety and acoustics as well as the design management and the building team. Without the knowledge of timber properties and of the know-how of building techniques with timber construction, there is a great risk of not achieving the project goals.

4 CASE STUDIES

The projects below showcase some of the multi-disciplinary design challenges and solutions with exposed timber structures.

4.1 SCHOOOL AND KINDERGARTEN

Biri elementary school and kindergarten
Biri elementary school and kindergarten is under construction and is expected to be completed in January 2024. The buildings are erected right by the existing high school. The elementary school is approx. 6 150 m^2 and consists of two stories plus technical room on the roof. The kindergarten is approx. 2 220 m^2 over one story with technical room on the roof.

Figure 5. *Biri elementary school and kindergarten. Illustration courtesy* of *JAF arkitekskontor AS.*

The kindergarten is formed as a circle to best adopt to the existing forest around the building site. The roof had originally a fixed inclination from one end to the other in the schematic design model. In the detail project this inclination, together with the circular form, gave some challenges for production of the prefabricated elements and on building site. The level of development in the schematic design phase could in this case had been prolonged in time and resources to better address these challenges before the detail design process. The solution was to have a fixed level between each load bearing axis and to level up the roof from one load bearing axis to the next.

Both buildings are designed with timber construction in the form of CLT slabs and CLT walls and glulam beams. The roof of the kindergarten is built with CLT elements while the school has prefabricated light weight roof elements.

The load bearing system for the elementary school was changed in the detail design phase. These last-minute changes resulted in more steel beams than in the earlier phase of the project. Further glulam beams had to be changed to steel beams to make space (free height) for the ventilation ducts in the detail phase.

Figure 8. *Biri elementary school – Atrium. Picture by Sweco*

To maintain the progress on building site and to meet the delivery deadline, the design of the CLT elements went through a cross disciplinary engineering process early in the detail phase so that all the necessary detailing could be transferred into the production model. The production model was built by the CLT manufacturer based on the structural BIM model. The production model was then verified by the structural engineer before the production of CLT elements started.

Plan drawings of visible side of CLT elements were established early on based on input from fire engineer and acoustic demands.

4.2 HEALTCARE

Frøya healthcare center and nursing home
Frøya is a project that consists of two buildings, one healthcare center and one nursing home, together approx. 8 800 m^2. The healthcare center is a traditionally prefabricated hollow-core concrete element and steel building while the nursing home is mainly a timber construction. The two buildings are connected with a bridge between them for easy access between the buildings.

https://doi.org/10.52202/069179-0544

Figure 7: *Frøya healthcare center and nursing home. Illustration courtesy of Link Architects.*

The project had ambitious environmental goals. Hence, the use of timber construction together with solar panels on the roof that make the buildings self-sufficient with energy.

The load bearing system for the roof in both buildings consists of prefabricated wood trusses. The timber building consists mainly of CLT panels for walls and slabs. In more open areas, the load bearing system consists of steel beams (HSQ) and glulam columns. Steel beams are used mainly to achieve better access and space for the ventilation ducts going through the building. The exterior walls are built as light frame stud walls.

The stability of the timber building relies on CLT shear walls and CLT shear slabs to withstand the high wind loads in this area located on the Norwegian coastline.

The patients of the center have neuropsychological deficiencies and are often confused. They have limited capacity to escape by themselves during a fire incident. The fire strategy is based on a fire resistance R60 for the load bearing system. The CLT slabs in the ceiling up to the roof are designed for R60 because of low load bearing resistance in case of burning roof trusses. The buildings are fully sprinklered and every CLT wall in resident rooms facing the corridor (and escape route) has EI60 demands.

Sound insulation between resident rooms and between resident rooms and corridors is solved with CLT slabs with concrete topping floating on insulation.

The design team on this project had variable experience with timber buildings. Some had little and some had very long experience. Those with less experience had to learn and/or adapt to the following elements:

- Communicate early multidisciplinary challenges with use of timber and CLT.
- Multidisciplinary design to make sure all the necessary cuts, splits and holes are in the production model of CLT-elements.
- How to achieve and document sound and fire demands with timber solution
- How to achieve rational load bearing solution with ventilation ducts and pipes trough the building.
- Produce a plan of which side of the CLT elements can be visible and which side needs to have a gypsum board lining.

4.3 OFFICE BUILDINGS

Lumber Bygg 4

Lumber Bygg 4 is a massive timber building with a commercial area at the ground floor and office area from the first to fifth floor to be delivered in April 2023. The brief includes BREEAM-NOR 2016 certification, and the ambition was to have as much visible massive timber as possible.

The project started with a multidisciplinary design/build phase with involvement of fire safety and acoustics at each meeting. Hence, every aspect of the different load bearing system alternatives was covered simultaneously. This resulted in an efficient design process and robust principal solutions minimizing changes to be made in the detailed phase.

Figure 3: *Illustration courtesy of VEF Entreprenør AS*

The chosen load bearing system is based on glulam columns and beams. The floors are a hybrid type with CLT combined with concrete slab, both components are mechanically connected. Hence, a larger span was possible, and the number of columns was reduced which led to beneficial consequences for the overall construction layout and the construction costs.

This hybrid solution is also interesting for the point of view of acoustics. Thanks to the good sound insulation properties, it was not necessary to add a floating floor and/or a false ceiling to meet the sound insulation requirements vertically and solve the flanking transmission horizontally.

Strict requirements for reverberation time would normally lead to a sound absorbing false ceiling over the whole office areas. The fire safety engineer has, however, established that an area of around 350 m^2 could be in exposed massive timber in each story. Visible elements in massive timber are the glulam columns and beams as well as part of the CLT-slab underneath. In order to keep that area in visible timber, a great deal of the façade was use for sound absorption using large area of wood wool board instead of wood paneling on the inside of the outer walls.

https://doi.org/10.52202/069179-0544

The fire proofing of the floor required the use of gypsum boards while the acoustics required the addition of a layer of mineral wool and ceiling tiles underneath. Efforts were put to simplify this construction and showed that the gypsum boards could be replaced with a specific type of mineral wool with sufficient thickness. The sound absorptive properties of the product were investigated and proved to be adequate. Fire safety and sound absorption were then combined in this simple solution consisting in a 70 mm mineral wool layer with wood wool ceiling tiles for the finishing aspect.

Close cooperation between the structural engineer and the acoustician was established right at the beginning of the design when different floor construction alternatives were investigated. It resulted in a cost-efficient construction allowing great flexibility for the fit-out layout with a great deal of visible massive timber. Further on, in the design phase, the cooperation between the fire safety engineer and the acoustician led to a reduction of the costs for the ceilings.

Fredrik Selmers vei 5 (Pilar)

The project Pilar consists of renovating and extending an existing concrete and steel building from 1937 and building a new timber building above the existing building.

The new building is planned to have ten stories, approx. 18 000 m² and to house commercial activities such as offices and café, and/or restaurants. The project is in the schematic design phase when this article is written. The project has ambitious environmental goals and aims to be certified BREEAM NOR Excellent and Paris Proof.

Figure 4: *Fredrik Selmers vei (Pilar) Illustration courtesy of Grape Architects*

The load bearing system consists of glulam timber columns and beams. The two internal stairs and elevator shafts consist of cast-in-place concrete that maintain horizontal stability together with steel and glulam bracing in the facade. The superstructure works therefore as a hybrid structure with concrete, steel, and timber elements.

The building and the floor plans are being planned for future flexibility within a defined technical grid that corresponds to the structural grid.

Local regulation limits the building's overall height and thereby also the height of each story. From the very beginning of the project, this issue is addressed by having coordination between structural engineers, MEP engineers, the builder and the architects. The result of this is that the glulam beam system includes cantilevers to make room for MEP installations. This solution reduces the floor height and also allows to expose beams below the ceiling in most areas.

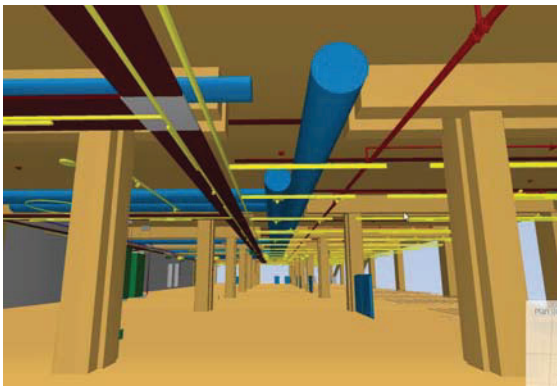

Figure 5: *Cantilever beams designed to reduce floor height due to ventilation ducts.*

Another example of analysis is the calculation of the real fire development curves considering how the fire would evolve rather than to use the pre-accepted fire development curves. The goal being to reduce the timber cross-sections, hence creating more free space between the glulam columns for the technical grids.

The project uses BIM, VDC and ICE sessions to plan and coordinate the design. An example of the visual plan used during the ICE-sessions is shown in Figure 6. By having by-weekly ICE-sessions with work meetings and activities in between, the design participants can plan, share design, coordinate, and provide design information as required to reach the project milestones. The process also measures the completed activities on schedules and keeps track of reasons why activities were not completed as planned.

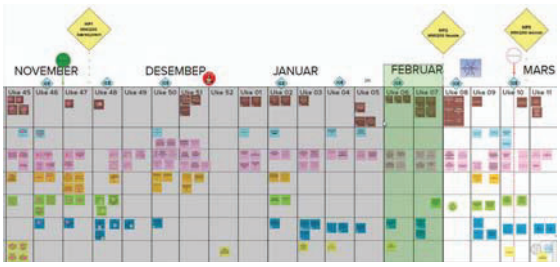

Figure 6*: Visual planning*

One of the first milestones in the planning was for the structural design to achieve a level of development (LOD) of 200. That meant that the sections and members for all the structure had to be designed from very early on. By doing this, the entire cross-disciplinary team of architects,

https://doi.org/10.52202/069179-0544

builder and consultants got an early idea of the required dimensions and the challenges this posed.

The design process also includes an iteration of the amount of visible timber with the first goal to visually expose all timber columns. The number of beams is still under consideration due to space requirements. However, by addressing this issue at this early phase the project can handle the challenges and design the building accordingly.

The whole design team consists of consultants with experience with timber buildings.

5 DISCUSSION

In the following section we highlight some of our findings from the case studies we've presented in this paper and experience with other projects.

Level of development vs. timeline
The *Macleamy curve[3]* is in our experience a good visualization of a preferred process where the effort of design and the level of development LOD[4] is higher in earlier phases as to highlight and solve more issues and reach goals early. By having a high LOD in the early phases, more project risks can be identified and addressed, and changes and optimizations are much easier to implement. This requires building owners and the project managers to involve all the consultants from an early stage and thus invest more in engineering work in early phases.

Timber buildings have always a certain level of complexity, which means that the costs associated with changes made late in the design process will contribute to making the technical and economic consequences even greater. That implies that timber buildings must be designed as such from the beginning. Adapting a concrete and steel building to a timber construction in the detail design phase cannot be done without restarting the design process from the beginning.

Objectives related to timber structures should be set as early as possible and eventually adjusted along the way if needed. A common example of this is the amount and location of visible timber surfaces. Answering this means choosing the type of structures with a strong involvement of fire safety and acoustics to find solutions that meet requirements and are cost-efficient. Having a BIM with a sufficient level of development helps to visualize these design intentions early on.

Timber elements are prefabricated and assembled on site. All the design aspects affecting the elements must therefore be coordinated in advance of manufacturing to achieve time efficient assembly on site.

Adaptation of design management
It is important for project design managers and contractors unfamiliar with timber design process to establish an understanding of the different challenges that timber construction poses, to acknowledge that goals related to visible timber needs to be set early and to establish good processes to solve the details.

Timber buildings often require a larger design team as specialists in timber are hired in supplement to a general design team. The larger team results in more interfaces to coordinate, making the need for efficient coordinating tools and methodology even more important.

Efficient design methods
By frequently sharing preliminary design by means of ICE and VDC processes, the discipline challenges are solved along the way between milestones and deliverables. This is key to achieve an efficient multidisciplinary process. By sharing work-in-progress, more design issues are being addressed and participants have more time to solve them compared to processes that are more linear and top-down.

Design culture
Communication with digital platforms that keeps record of changes together with BIM-software support the multidisciplinary design process. However, these are just tools and add little value if not combined with participants that have the know-how to solve the issues, not just from their own discipline's perspective, but also in incorporating other disciplines' requirements and issues. Indeed, technical issues with timber buildings are very seldom solved adequately when disciplines work independently but rather solved by a multidisciplinary team. delivering one integrated solution that often solves multiple requirements. This is especially important when solving issues related to visible timber structure.

Communication
Solving the multiple issues related to visible timber requires to communicate during early stages of the design process. This communication should be directly between architects, design consultants and specialists. In our cases, the most successful projects had consultants that communicated horizontally and solved issues together first, and then presented solutions to the rest of the team and design management.

Knowledge and experience
In our successful cases, project consultants had experience with timber construction, also often combined with a positive attitude towards problem solving, innovation and applying or improving solutions from previous projects.

Proactive participation from the specialist consultants as fire safety engineer and acoustician is essential as their requirements define a frame for the possible solutions.

No need to compromise
It's worth mentioning that in all the above case studies, no compromises were made on the technical requirements, not even on the acoustics although the Norwegian regulation is quite strict in that field.

The costs had also to be equivalent to a standard construction. Hence, the owners' aim of affordable, environmentally friendly, functional, and esthetical buildings were fulfilled.

6 CONCLUSION

In this paper, we showcased some of the multidisciplinary design challenges with exposed timber structures and explained through case studies how a multidisciplinary design process can help to achieve project goals and meet design requirements. Other essential key factors are design effort in early phase, consultants with experience in massive timber, and efficient design management tools.

World Conference on Timber Engineering Oslo 2023

CAN RISING DEMAND FOR TIMBER IN CONSTRUCTION ACCELERATE DEFORESTATION?

AUTHOR

Eduardo Rojas Briales[1], Simon Flinn[2]

ABSTRACT

Timber, and increasingly Mass Engineered Timber (MET), plays a key role in green building programmes around the world. Its use addresses the UN Sustainable Development Goals, especially SDG 11 – Sustainable Cities and Communities, SDG 13-Climate action, SDG 15-Life on Land and many others that are directly or indirectly linked to forests and construction. Many Life Cycle Assessments (LCAs) recognize the environmental benefits of Mass Engineered Timber in comparison to traditional construction materials such as steel and concrete. The importance of timber in the construction industry has led asset specialists to estimate that over the next 30 years, timber consumption could rise by over 140%. In the EU alone, wood consumption is estimated to be 3.5 times higher than the global average.

Sustainable Forest Management has been fundamental in ensuring both forest resource preservation with the highest possible sustainable supply of forest products and environmental services. 233 million ha of forests globally were under management plans in 2000, increasing to 2.05 billion ha in 2020. Nevertheless, between 1990 and 2020, both growing stock and forest carbon stock at the global scale have fallen, though the rate of loss has declined significantly over the same period. In 2020, the forest and carbon stocks reached an even balance due to reduced tropical deforestation and significant forest recovery in Asia-Pacific, Europe, and North America. Research into forest management (FM) practices has shown that producing the same volume of wood in different ways, may result in substantially different performance regarding biodiversity and other environmental services, including carbon sequestration or rural livelihoods. Therefore, while continuous improvement in FM is beneficial to the timber industry, it is also vital for biodiversity, environmental services, and rural livelihoods.

Finding the balance between demand for forest products and preserving forests through FM will ultimately rely on robust Chain of Custody (CoC) data - informing policy; purchasing strategy; and due diligence, especially if aligned with consistent domestic policies in the areas of tenure, land use and forestry. PEFC's role is to ensure, through certification, that built environment professionals can be confident that they are sourcing timber responsibly and avoiding unsustainable and/or illegal timber or wood products. Technology and specifically blockchain (including the PEFC sponsored Wood-chain Project), will have an important role to play in not only facilitating traceability operations, but also in providing visibility, accountability, and the ability to extend to other enhancements such as carbon credit systems or related to other environmental services.

KEY WORDS

Sustainable Forest Management: Responsible Sourcing: Mass Engineered Timber: Built Environment: Carbon Balance

1 INTRODUCTION

Built environment professionals from around the globe increasingly recognise the importance of timber as a low

[1] Eduardo is Chair of the Board of Directors of PEFC International and Chair of the Spanish Board of MSc. Foresters. He has previously been a Director of the Catalan Forest Owners Association, Associate Professor at the University of Lleida, Head of the forest policy area of the Forest Science and Technology Centre of Catalonia and Vice-Dean of the Life Science Faculty of the Polytechnic University of Valencia, where he is presently a professor in forestry. From 2010-2015 he was Assistant Director-General and Head of the Forestry Department at FAO, UN Commissioner General for Expo Milan in 2015 and co-chair of UNREDD.

[2] Simon is Senior Systems Development Officer with the Soil Association Forestry team, working on digital transformation and business improvement projects of their PEFC and FSC certification systems, for Forest Management, Chain of Custody and Carbon Schemes.

https://doi.org/10.52202/069179-0545

carbon, renewable and recyclable building material. But some are concerned that this rush to timber could accelerate deforestation.

Forests are a vital natural resource for the planet. It is important that their multiple functions – environmental, social, and economic – are balanced.

The Sustainable Forest Management (SFM) tool has been developed to help maintain this balance. as demand for timber continues to grow, PEFC (Programme for Endorsement of Forest Certification), regularly engages with built environment professionals - architects, contractors, engineers, and their clients - to increase their understanding of SFM and the importance of responsible sourcing,

Sustainability has become integral to all areas of industry and society, and the built environment has become one of the crucial priorities for sustainable change. As life-cycle assessments (LCAs) highlight energy and carbon intensive building materials, namely steel and concrete, the focus has been placed on developing and using carbon neutral alternatives. Mass or Mass Engineered Timber (MET) has been identified through numerous LCAs to be a viable and sustainable building material. It is increasingly being embraced by architects, builders, and engineers around the globe.

However, if the building industry turns toward mass engineered timber (MET) as a less carbon intensive material, will this create a sustainability paradox? As demand for timber grows, what impact will this have upon the global timber supply or the resource that provides it (forests)? Is this rising global demand for timber compatible with sustainable forest management?

2 SUSTAINABLE FOREST MANAGEMENT

In 1713, Carlowitz defined the *Nachhaltigkeit* principle [1] in a time where wood was the main source both of materials and energy, causing restricted availability and frequent signs of exhaustion - important societal challenges. This concept was later operationalised at the end of that century, establishing the starting point for forest science as one of the legacies of the Enlightenment. If wood was a renewable resource, the way to avoid its exhaustion is to know its renewable rate and optimize where and when to extract it. During the 19th and early 20th Centuries, forest science expanded from Central Europe to the rest of the World. The increased use of fossil and mineral materials and their ready availability through the rail network, reduced the potential impact that the increased population and available income (GDP/per capita) would have had potentially for forests.

When Brundtland [2] (1987) presented the key document for the Río 1992 Conference, her inspiration for sustainability was the Carlowitz forest science paradigm[1]. In fact, in the two predominant languages in Central Europe (German and French), the modern term for sustainability is identical to the forest one (Nachhaltigkeit, durabilité). In fact, misunderstanding around that intellectual linkage was caused by the restricted English translation as “sustained yield” if compared to the French, German or even Spanish (persistencia) terms.

In the process to the Rio Conference 1992, four environmental conventions were negotiated (Climate Change, Biodiversity, Desertification and Forests). While the first three reached broad consensus and entered into force during the decade, the forest convention was not agreed, but negotiations were kept open until they were institutionalised in the form of the UN Forum on Forests, as a time bound setting, extended twice in 2006 and 2015.

In the absence of a convention, many formerly non legally binding documents have been approved since Rio, starting with the Rio Forest Principles (known officially as the Non-Legally Binding Authoritative Statement of Principles for a Global Consensus on the Management, Conservation and Sustainable Development of All Types of Forests), established that while forests are essential to economic progress, sustainable development and management should be the guiding principles that nations should follow.

An intensive process was conducted during the rest of the decade with the International Panel/Forum on Forests agreeing 300 proposals for action in the expectation of a later agreement on a convention that failed to materialise. It became obvious that sustainable forest management could not be further defined at a global scale, because of strong regional and climatic differences, other than the basic principles and the structure of criteria and indicators (C&I). However, nine regional processes started that decade to agree on criteria and indicators for sustainable forest management and were agreed at regional scale.

For the European region, including the countries of the former Soviet Union, the framework of the 1990 Ministerial Conference on Protection of Forests held in Strasburg, was agreed as the basis for the regional Criteria and Indicators. The following Ministerial Conference held in 1993 in Helsinki, first agreed on a regional definition for sustainability in forestry: "The stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality and their potential to fulfil, now and in the future, relevant ecological, economic and social functions, at local, national, and global levels, and that does not cause damage to other ecosystems." [3]. On that basis, the Criteria were agreed during the same

https://doi.org/10.52202/069179-0545

conference while the indicators during the following one held in Lisbon in 1998.

At a global scale, the pressure for action, especially around deforestation, grew as the aspiration for a global convention on forests remained unfulfilled as two major players in the OECD and G-7, plus China, USA and Brazil, were clearly opposed to the convention on forests. The demand for alternative solutions in the absence of a convention grew. The eNGO community proposed consideration of the important growth in ISO certification during this period, as a solution to address the failure of states suffering deforestation, to establish sustainable forest management certification mechanisms.

The application of forest certification was first introduced by the Forest Stewardship Council (FSC) in 1994 driven by WWF, as a direct response to the Rio Forest Principles. Certification soon became accepted across the globe, and by 1999, 10 million hectares of forest were certified to FSC standards and the first book was printed on FSC-certified paper [4].

Figure 1: Map of global PEFC certified forest area [13]

PEFC was founded in 1999 by the national forestry organisations of 11 European countries, responding to demand from small and family forest owners who encountered considerable difficulties accessing certification through existing schemes, especially because of audit costs. Later, PEFC expanded beyond Europe to include other regional or national existing certification schemes such as SFI in North America and Responsible Wood, Australia.

PEFC "endorses national forest certifications systems developed through multi-stakeholder processes and tailored to local priorities and conditions."[5] Its standards are oriented to the Criteria & Indicators agreed at regional level by governments in formal processes. PEFC firmly believes that forest certification functions most effectively when the impetus, intent and influence come from local and national organisations, through bottom-up processes.

By December 2022, 288,154,245[6] hectares of Forest area were managed and conformed to PEFC's Internationally accepted sustainability bench marks – 71% of all certified forests globally are certified to PEFC. This has allowed more than 20,000 companies to achieve chain of custody certification in more than 70 countries. PEFC now has 55 national members with 48 endorsed national certification systems.

It should be noted that wood regrows in a reasonable time frame (100 years on average), and that it continues to store carbon when used in long term uses like buildings. Additionally, it requires much less energy to harvest and process than conventional building materials.

Wood used in construction globally is more than 95% coniferous and sourced from boreal and temperate forests, where no deforestation has recently been recorded. FAO has repeatedly confirmed that less than 10% of deforestation is linked to wood use being the primary cause (>80%) agriculture[7]. 50% of the global wood use is for energy, mostly in the countries of the global south and this is the main cause of forest degradation, especially in the dryland forests of Sub-Saharan Africa; a problem exacerbated by unclear land tenure rights.

2.1 BENEFITS OF SUSTAINABLE FOREST MANAGEMENT

The benefits of sustainable forest management are numerous and complex. Marchi et al[8] describe five key performance indicators of SFM – Economics, Ergonomics, Environment, People and Society and Quality optimisation. And these five indicators can be used to understand the complex web of benefits and relationships, including air quality, cost optimisation, energy consumption, health, training, etc. They argue that SFM leads to resource optimisation in forest operations; the promotion of timber as an environmentally renewable and sustainable material; the ability of forest owners to adapt and influence climate change; reducing the impacts of harvesting; and finally promotes workers' rights, thereby improving conditions and safety.

2.1.1 Biodiversity

Forests are the most diverse ecosystems on the planet. 80% of Earth's land animals and plants live in forests. Biodiversity provides natural pollination, fertilisation, and seed pollination. Biodiversity benefits in several ways from SFM. SFM promotes the UNFCCC Warsaw framework REDD+ activities - the reduction in emissions from deforestation and forest degradation plus conservation and enhancement of forest carbon stocks. SFM practices such as reduced impact harvesting, fire management, reforestation and restoration have had a direct effect in halting bio-diversity loss [9]. An example of this impact has been measured in Sabah, Borneo where vertebrate diversity is greater in SFM forests than conventionally managed forests[10]. In fact, several publications have confirmed that locally managed forests, often by indigenous communities in the tropics, show better performance (e.g., on forest fires), than protected areas, state managed or concessions).[11]

2.1.2 Carbon Storage

Forests are also nature's best form of carbon capture and storage. Well managed forests remain carbon sinks while at the same time, contributing to economic development. Figure 2 below shows how SFM maintains a steady carbon sink through harvesting.

Figure 2: Patchwork of Emissions and removals from Forest Harvesting, source Harris et al [12]

The PAFC Congo Basin project is endorsed by PEFC. The Republic of Congo, Cameroon and Gabon have jointly developed a regional forest certification system. The PAFC Congo Basin project is "the first to contain two new requirements linked to current climate issues: the mapping of the carbon stock in a forest, and a greenhouse gas (GHG) emissions assessment linked to forestry operations. Born during the standard development process, the innovative requirements are a response to the new expectations that companies and forests owners are facing." [13]

EU forests alone currently provide a net sink of 300 million tonnes of CO^2, around 10% of the EU's greenhouse gas emissions.[14] It has been estimated that reduced-impact logging in tropical forests, could reduce between 29% and 50% of net carbon emissions from tropical deforestation and land use changes whilst supplying 45% of global roundwood timber demand[15]

2.1.3 Water

Forested catchments supply 75% of fresh water, and millions of people from around the world depend on high-quality, fresh flowing, forest water. Forest trees absorb water through their roots from the ground in a process known as evapo-transpiration – a key element of the global water cycle.

2.1.4 Products & Energy

Sustainable forests deliver sustainable products; from raw materials transformed into books, packaging, and buildings, to pharmaceuticals, textiles, and personal care goods. Forests that are managed sustainably need not be finite but continue to provide sources of income to forest owners, sawmills, factories, and business within the supply chain.

Energy from forests is recognised as the single most important resource, providing 9% of the global total of primary energy supply and above 60% of the total renewable one, especially in Sub Saharan Africa. In fact, it is astonishing to note the marginal recent and present attention paid to forest-based biomass when comparing it to its historical and present contribution to renewable energy supply.

2.1.5 Social

The livelihoods 1.6 billion people worldwide have some impact from forests, including 60 million indigenous people who are fully dependent on them. In developing countries, forest-based enterprises provide about 13–35% of all rural, non-farm employment; equivalent to 17 million formal sector and 30 million informal sector jobs[16].

Sustainable Forest management is focussed on ensuring not only that forest workers' rights and safety are respected, but also those of workers along the supply chain, through chain of custody certification.

It is a core value of SFM, that cultural values and traditions are respected, protecting indigenous people and their cultural, social, and spiritual mores.

2.2 TIMBER CERTIFICATION

Timber certification allows organisations, businesses, and consumers to have a direct link to and impact on SFM. There are a range of reasons for different organisations to certify their forests and/or choose to specify certified material. According to Zubizarreta et al [17] in a case study on forest certification in Spain, the two main certification drivers for forests and companies are accessing new markets and improving corporate image. However, fundamentally, the value of forestry certification only works if it is understood and recognised by consumers and therefore affects consumption behaviour.

Certified products can bring economic benefits as materials can add premiums to prices. Zanchini et al [18] analysed customer behaviour and forestry certification, through a consumer study. They demonstrated that while price was the main attribute affecting consumer choice, the second most important, was the presence of recognised forest certification labels such as PEFC and FSC. Consumers will not only choose to make an ethical purchase, but will also perceive labels to have an added value[18].

Certified products can help companies penetrate new markets. The European and UK Timber Regulations, United States Lacey Act, and the Japanese Clean Wood act, have all placed legislative barriers on the trading of timber. Adopting SFM practices through certification allows companies around the world to find new and valuable customers. The positive effects on biodiversity protection and development, may also be used for

https://doi.org/10.52202/069179-0545

political advantage or to demonstrate corporate values [19].

Owari et al [20] identified that companies adopting forestry certification gained recognition from environmentally sensitive customers; better retention of existing customers; improved public reputation; and increased customer satisfaction.

PEFC through its partners, makes SFM certification available to 750,000 forest owners globally and chain of custody certification to more than 20,000 companies. PEFC SFM certification respects ecological, social, and cultural frameworks, while improving economic values. It supports healthy forest ecosystems, while securing livelihoods for workers and local communities.

Chain of custody certification enables companies and consumers to identify products from responsibly sourced raw material. It provides confidence that products are legal and from a verifiable supply chain. It allows organisations to demonstrate their commitment to, and business leadership on, sustainability.

3 SUSTAINABLE BUILDING MATERIALS

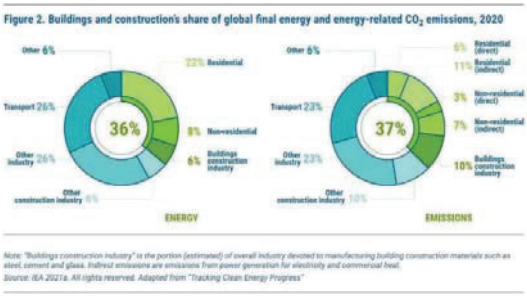

Figure 3: Graph taken from the 2021 UN Global status report for buildings and construction. [21]

Although building operations and construction industry together accounted for up to 37% of the global CO^2 emissions, much of this comes directly or indirectly from fossil fuels. Figure 3, from the UN Global Status Report for Buildings and Construction, shows that this sector used 36% of the global energy resource in 2020. Whilst there has been a shift away from the direct use of coal and oil for energy to electricity, the high dependency of electrical generation on fossil fuels, has contributed to an increase in emissions from the buildings and construction sector. Governments and institutions globally have unsurprisingly turned their attention towards sustainable buildings, construction, and maintenance. Inger Andersen, Executive Director of the UN Environment Programme states "Rising emissions in the buildings and construction sector emphasize the urgent need for a triple strategy to aggressively reduce energy demand in the built environment, decarbonize the power sector and implement materials strategies that reduce lifecycle carbon emissions" [21]. Additionally high insulation performance, earthquake resistance and recyclability should be recalled in this context.

Cross-laminated timber (CLT) and glulam are both examples that provide an exciting glimpse into the possibilies for engineered wood. Commonly made from PEFC-certified spruce, pine, fir and larch from European and North American forests, they can reduce the carbon impact of steel and concrete.

As a lightweight building material, timber can provide time and cost savings due to reduced foundation work as the structural loads required with CLT are small compared to those from concrete and steel.

CLT and glulam are prefabricated within a precision, factory-controlled environment, using accurate data from BIM modelling and CNC processes. Openings can also be pre-cut or routed in the factory for windows, doors, or services, facilitating quick and easy installation. This means that it is easier to timetable the construction critical path and eliminate site delays, while improving working conditions and reducing on-site accidents.

The drive to improve the sustainability of buildings has caused wood to be substituted in place of materials such as steel and cement, which all have higher carbon emissions. The manufacture of concrete and steel each contribute about 5% of global emissions. MET is a material specifically engineered to deliver high strength ratings for the construction industry. It is formed by gluing together strands or panels of wood to create outstanding strength.

The structural properties that MET products offer as a sustainable alternative have been widely recognized, and resulted in the 2021 International Building Code allowing the use of wood in buildings up to 18 storeys[22]. Indeed, Zanchini et al state "several recent studies have shown that substituting MET for steel and concrete in mid-rise buildings can reduce the emissions associated with manufacturing, transporting, and installing building materials by 13%-26.5%."[18]

The Mjøstårnet building in Brumunddal, Norway is a testament to the properties and potential of both CLT and Glulam. Standing at 85.3 metres tall, the 18 storey MET development contains a hotel, restaurants, offices and apartments [23]. As they are substantially lighter, such buildings necessitate specialist engineering to overcome challenges including fire safety, and resistance to the extremities of nature such as earthquakes. However, the entire building meets Eurocode 5 and can withstand extensive fire. It is thought that similar buildings can reduce emissions from material production by up to 85%, while timber absorbs CO^2 from the atmosphere. Additionally, a higher timber use would reduce sand and concrete demand in the construction

sector reducing the impact of river sand drain or open pit limestone mines.

3.1 LIFECYCLE ASSESSMENTS

Many life-cycle assessments of MET have provided evidence of its excellent environmental credentials. Duan [24] et al found that the average embodied energy of MET construction is 23% higher than that of reinforced concrete alternatives, and the average embodied greenhouse gas emissions of reinforced concrete buildings are 42.68% higher than that of MET alternatives. They concluded that "mass timber buildings generally have lower GHG [greenhouse gas] and life cycle primary energy than RC [reinforced concrete] and steel buildings, indicating that the use of mass timber to substitute conventional materials could help mitigate climate change and promote sustainable construction."

Nevertheless, within the circular economy, caution does need to be applied when considering the environmental benefits of MET. Hart and Pomponi reason that while re-use of structural steel is possible, it is "hindered by current regulations and a poor financial case". Structural timber provides a similar challenge including the fact that "engineered structural timber is typically a composite of organic and mineral substances that may be impossible to separate in a controlled way. [25]"

In a study published in 2020, Chen et al used the Athena life-cycle impact assessment for buildings to compare those using concrete and CLT. The team followed the scope, adapted and shown in figure 3, following the EN15978 guidelines but going beyond the building life cycle to look at recycle and recovery of materials.

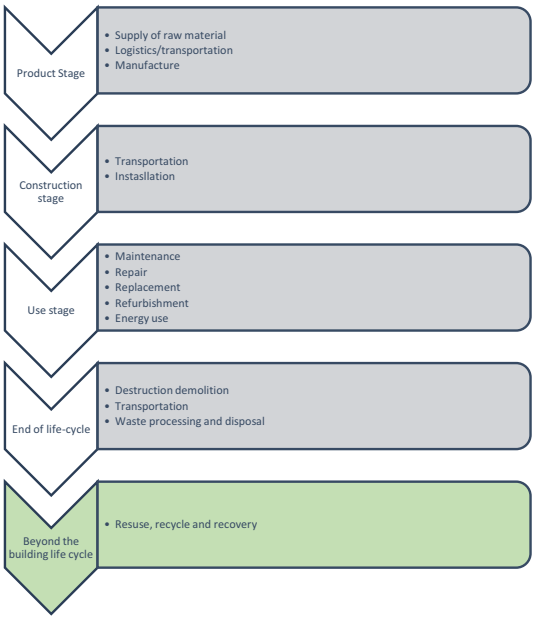

Figure 4: Adapted from an assessment system boundary from Zhongija Chen et al [26]

The study showed that the total of greenhouse gas emissions, shown in figure 5 below, from mass-timber buildings walls and floor were reduced from 50% to 80% between mass timber buildings and reinforced concrete buildings.

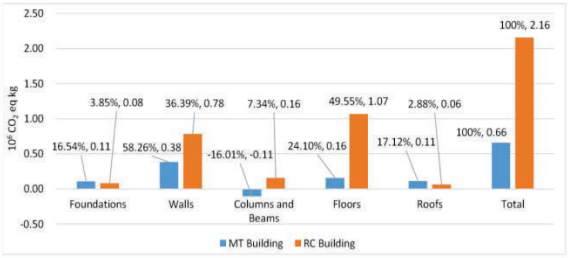

Figure 5: From Chen et al[26]. A comparison of global warming impact.

4 DEMAND FOR TIMBER AND FOREST PROTECTION

In pursuit of cleaner, sustainable building materials, the growth and promotion of MET as a potential solution might seem somewhat incompatible with forestry conservation. This should not be of concern, as Churkina et al state[27] "although global mass timber production has increased rapidly in recent years, it still constitutes a small fraction of total global wood consumption (less than 1% global softwood lumber consumption)". Still, this understates the prediction that by 2034 North American 16.3 million cubic metres of MET panels would be required, meaning that "manufacturers would need to boost their current capacities by a factor of nearly 40 to meet those demand projections." [28]

Academic research has recently focused on unravelling this apparent paradox. The Global Mass Timber Impact Assessment (GMTIA) is a collaborative research programme, commissioned by The Nature Conservancy which focuses on five phases of work[29] which are:

- Whole-building Life Cycle Assessment
- Regional demand assessments
- Global Trade Modelling
- Regional forest modelling
- Integration and communication.

The aim of the project will be to capture those impacts of MET which are not normally captured by traditional life-cycle assessments. This will include examining the effects of MET demand on forest carbon stock; understanding the implications for biodiversity; whether there is an increase or decrease on embodied carbon (transportation, harvest, production); carbon storage in wood products; and end of life cycle of MET.

Higher demand supposes higher prices and incentives to preserve and manage forests according to the best standards. The dynamic nature of forests is frequently

https://doi.org/10.52202/069179-0545

overlooked when the risk of deforestation is considered as a trade off against increasing demand. Through clear tenure and rule of law and with land use planning as a prerequisite, increased demand does not negatively affect forests.

4.1 FORESTRY IMPACT

The critical phases of the GMTIA will officially report in 2023. Still, in a 2021 related study about the effects on global forests as a result of the increased demand for MET, Nepal et al [22] identified four key findings:

- That increase in MET demand will lead to price inflation for products using MET. The price inflation will correlate directly with timber demand.
- Conversely the levels of product prices directly effects "production, consumption and trade of forest products in a country and accordingly alter its timber harvest, forest growth and forest stock level."
- The increased demand for MET will lead to increased competition for softwood, reducing consumption for less valuable present uses.

Moreover,

- They found that with sustainable forest management "most of the projected depletion in aggregate forest stock due to mass timber-induced increases in removals will be replaced by biological forest growth occurring over time, suggesting relatively smaller impacts on forest stock at aggregate national, regional, and global levels."[22]

In their projection, there is negligible effect of increased MET demand in a model which assumes sustainable forest management practices – "that is, mass timber-induced increases in demand for timber and harvest activities do not lead to deforestation." [22]

Therefore, if wood for MET is sourced solely from sustainably certified forests with well managed stock levels, the effects of price inflation and substitution, will ensure that demand has no negative effect upon forest stocks.

In a recent example published in 2022, Comnick et al [30] examined the increasing consumption of MET in the USA against the timber supply. They arrived at the following conclusion:

- The current rate of harvesting and consumption of softwood in the United States is currently 56% that of growth.
- The most aggressive estimate for increase in MET demand by 2035 would amount to a 17% increase in current softwood consumption.
- This most optimistic of MET growth rate would still only represent a consumption of 68% of growth, or 82% of lowest projected growth estimates.

The sustainable benefits of MET cannot be realized in the material alone, it must be accompanied by ensuring the raw products come from certified forests. As Mark Wishnie, Director of Forestry and Wood Products at the Nature Conservancy states, "We must ensure that mass timber drives sustainable forestry management, otherwise all of these benefits are lost"[31]

The study by Chen et al[26] referenced in 3.1 above, demonstrated that if forests continue to be renewed after logging, there will be a continual offset of greenhouse gas emissions. In the study they demonstrated significant impact on carbon out of a MET building, estimating a saving of 150,000 ton of CO^2 when compared to a reinforced concrete equivalent. It is this measurable benefit which will help drive the promotion of SFM and ensure that sustainable MET continues to be preferred.

Ultimately though, the popularity of MET is not only attributable to its durability and versatility as a construction material. One of the primary recognized motivations for adopting MET is its sustainability credentials, and the associated benefits that this brings along the commercial supply chain. Therefore, while sustainability prompts customers to demand this material, it is sustainability which will surely determine how the raw material is sourced. As certification will ensure that MET continues to be recognised as environmentally responsible choice, then sustainable forest management practices demanded by certification will ensure that demand does not exceed sustainable supply.

Increased demand for higher value uses like construction would suppose an additional incentive to increase rotations, to improve degraded stands, to prioritize valuable species, to implement quality driven thinnings or to expand forests by planting and paying more attention to forest management by local actors than was the case in the past when wood prices were lower.

4.2 PEFC AND SUSTAINABLE TIMBER

While PEFC supports the advancement of mass engineered wood as the future of architecture and construction, this can only be positive for ecological progress if underpinned by certification. In the long run, in comparison to concrete, steel, cement and glass, buildings made with engineered wood from sustainably managed forests require less energy and emit less carbon.

"PEFC-certified timber, whether it is solid wood or engineered wood such as CLT and glulam, comes from a

PEFC-certified forest – a forest managed sustainably in line with strict international requirements.

This means that forest owners manage their forest in a way that provides a good supply of timber and other forest products, while at the same time ensuring that the forest will be around for generations to come.

Certification matters. It not only demonstrates that wood used in construction is sourced sustainably, but that a positive choice has been made to design and build with a future for healthy forests in mind." [32]

PEFC-certified timber and engineered wood products for the construction industry are available globally, with a steadily increasing range of global suppliers. Furthermore, construction projects can also obtain PEFC Project Chain of Custody certification to demonstrate excellence in responsible sourcing. The impact of certification is not only crucial for the preservation of our forests, but also demonstrates the integrity and innovation of companies that choose to specify these materials.

While recognizing the benefits of timber in construction, PEFC is committed to supporting its certificate holders. PEFC is currently working with online product platform 2050 Materials [32] to help drive generational change in choosing certified forest-base products at all stages of a construction project. The platform will be a user-friendly way to find PEFC-certified suppliers,

5 THE FUTURE OF SUSTAINABLE FOREST MANAGEMENT AND CHAIN OF CUSTODY

The future of sound forest management and sustainable timber products undoubtedly lie within the effectiveness of chain of custody procedures, monitored by certification bodies. PEFC wants to ensure that customers throughout the chain of custody can have full confidence in the procedures that protect the authenticity and integrity of sustainable products. As highlighted earlier, the growth in use of MET products within the construction industry will result in increased scrutiny of both forest management and chain of custody practices. The benefits of MET as a sustainable, low carbon alternative to traditional building materials can only be assured by demanding certification audits throughout the supply chain.

An efficient chain of custody process relies on a rigorous monitoring of critical control points such as observing processes around segregation of timber and processing of timber products. Ensuring that personnel along the chain understand the importance of PEFC principles is crucial and that possibility of tampering and fraud is minimised; PEFC recognises that efficiency within this process can only come from ongoing innovation in chain of custody processes.

5.1 BLOCKCHAIN AND RFID

The success and efficiency in balancing timber demand with sustainable forest practices is likely to rely on PEFC, certification bodies and certificate holders adapting to new technology. Figorilli et al[33], for example, showed how the use of blockchain technology can be used to record the traceability of a finished product. The use of Radio Frequency Identification RFID might be able to reduce the information gaps in critical control points such as logistics. This could help certificate holders optimize valuable operational factors such as time, materials, and costs.

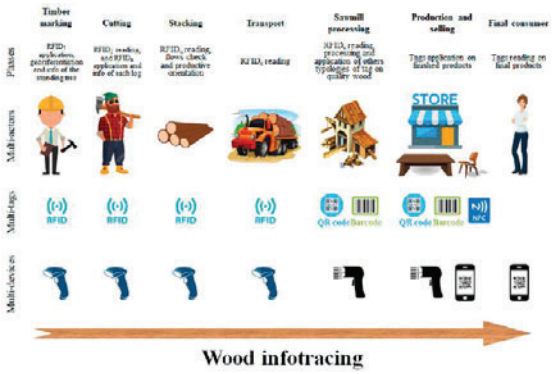

Figure 6: Figorelli et al [33]

Figorelli et al showed the potential of this technology by tagging and monitoring the progress of chestnut trees felled in Cardinale, Italy. After the trees were felled and cut, RFID tags were inserted into each of the logs. The progress of the logs could be monitored through to the sawmill where they were processed into boards and marked with a QR code. They then demonstrated that a final consumer product could be created and tagged allowing the consumer to know exactly where the tree was felled. It is perhaps this final step that might prove the most powerful aspect of blockchain technology, giving information to the consumer such as exactly where the tree was felled and how far the timber has travelled. This would certainly ensure that a premium could be applied to blockchain timber and timber products.

PEFC is committed to exploring the value of technology in improving the strength of traceability within the chain of custody. To this end, PEFC International funded a project with Italian and French partners in 2019, known as the Wood-chain project[34]. The project was designed to test the application of blockchain technology for forestry and wood applications.

https://doi.org/10.52202/069179-0545

The project's specific goal was to explore blockchain in the creation of secure, dependable data chains that could improve the efficiency and accuracy of forest management certification.

5.2 FUTURE GROWTH OF SUSTAINABLE FOREST MANAGEMENT

The future growth of responsible forest management and the security of MET as a sustainable resource relies on careful and adaptable sustainable forestry policy making. Daigneault et al [35], in 2022 released a study on the relationship between the global forest carbon sink and timber demand. They concluded that in areas where SFM is applied "strengthening forest product markets, expanding forest areas and boosting forest productivity can…be successful climate mitigation strategies".

Future growth of SFM can only happen with continued investment in training and certification training. PEFC are committed to investing in innovation and technology to ensure that the growth in SFM continues:

- PEFC UK [36] have developed an online certification application, a forestry tool to assist group managers and small to medium-sized woodland owners participle in forest certification.
- PEFC Italy[37] are working with the Foundation Euro-Mediterranean Center on Climate Change on digital projects that use tree sensors to help forest owners monitor the health of their forests. This will help provide certification bodies with valuable-pre audit data, thereby boosting efficiency.
- PEFC Spain [38] are also involved in a similar project, which will use GIS technology and remote systems to monitor SFMs.

6 CONCLUSIONS

This paper set out to examine the relationship between increased consumption of mass engineered timber and its supply through sustainable forest management, as well as the potential risk of increased deforestation. Some of the latest available studies and research have been reviewed to ascertain whether a positive or negative correlation has been confirmed. Firstly, SFM was summarised from conception at the 1992 Rio Summit, before looking at the rewards it provides, and the tools used to help deliver it, via certification. It also examined the drivers behind the rush to mass engineered timber in the built environment and the evidence supporting its sustainability claims. The potentially paradoxical paradigm behind the growth and values of SFM and MET was then compared, and the available evidence reviewed.

MET promises to provide architects, engineers, towns, cities, and their inhabitants with a building material that could potentially diminish the harmful by-products of steel and concrete and their implicit consequences in the form of mines and increasing sand extraction. In both cases, they can either not be recycled (concrete) or require high energy inputs to be recycled (steel). And while these MET materials are in their relative infancy, the benefits in terms of reduced carbon emissions and LCAs are promising. Ultimately, timber is a natural, renewable, and precious resource that contributes to the livelihoods of an estimated 33 million people employed in the forestry sector globally. Where mining provides income to very limited areas, sustainable forestry provides income to extensive disadvantaged areas of the world that cover 40% of the terrestrial area. This is currently the single most significant income they receive for preserving the global forests and their key contributions in terms of environmental services like climate, erosion, water, or biodiversity.

Evidence reviewed shows that the growth in MET can aid and strengthen the growth of Forests if SFM practices are adhered to and monitored through certification and labelling.

PEFC and other forestry certification bodies have an important role to play in helping to ensure that, MET can deliver global benefits in a sustainable way. By improving and developing access to forestry certification, PEFC can give forest owners, and wood product suppliers, the benefits of certified products, while ensuring that sustainable forestry practices continue.

Through continued investment in innovation and research, PEFC can continue its contribution to SFM practices globally. MET can contribute to the health and growth of forests globally, but only if it is responsibly sourced. It is therefore crucial that certification schemes such as PEFC's, encourage MET manufacturers to source their raw materials from certified forests. If they do, then the full potential LCA and reduced carbon benefits of timber as a construction material can be realised.

RIGID JOINTS ON GLUED-IN RODS OF BENDING AND COMPRESSION-BENDING ELEMENTS OF LARGE-SPAN LAMINATED TIMBER STRUCTURES

Alexander Pogoreltsev[1], Stanislav Turkovsky[2], Vladimir Stoyanov[3]

ABSTRACT: Elements of large-span laminated wood structures can have a long length, which causes difficulties for manufacturing and transportation. This is especially true for bent laminated elements of arches, frames, meridional ribs of domes and other structures. There is a need to break down long structures into technological elements with implementation of consolidation rigid joints. Russia has developed a system of node joints of wooden structures on inclined glued-in rods - the "TSNIISK System". The basic principle of rigid joints is to fasten the embedded part to the wooden element by means of obliquely glued rods. Two types of rigid joints are proposed: with unidirectional inclined glued-in rods and with glued-in rods forming V-shaped anchors. A methodology for calculating knots and joints on glued rods has been developed. During the design and construction of long-span buildings and structures with glued wooden frames, control tests are conducted. Examples of control tests of the mineral fertilizer warehouses structures are presented. The results of the control tests confirm the correctness of the calculation methodology. Hundreds of buildings and structures with glued wood frames with glued-in rods used in the nodes have been built in Russia.

KEYWORDS: Bending, compression-bending, glued-in rebar, glued-in rod, large-span, rigid joint, test, V-shaped

1 INTRODUCTION

Elements of large-span glue laminated timber structures can have a long length, which causes difficulties for manufacturing and transportation. This is especially true for bent laminated elements of arches, frames, meridional ribs of domes and other structures. There is a need to devide long structures into technological elements with the arrangement of rigid joints performed on the assembly.

The traditional solution is the dowel joints. The assemblies with steel plates in wood kerfs and steel pads on dowels are widely used.

A modern type of joints are steel rods with metric threads or reinforcing bars glued into the wood.

In Russia, a new type of consolidation joints on obliquely glued rods has become widespread. In the laboratory of wooden structures of the Central Research Institute of Building Structures named after V.A. Kucherenko (CNIISK). The institute has developed a system of node joints of wooden structures on glued-in rebars - "TSNIISK System". The founder of the system is S.B. Turkovsky, who is conducting research since 1974 [1].

Based on the results of studies of knotted joints on inclined glued-in rods, the design principles and calculation methods for such joints have been developed.

2 KNOT CONNECTIONS ON GLUED-IN RODS

The basic elements of the CNIISK System are rod elements glued into the wood at an angle to the fibers [2]. The 0° and 90° angles are special cases. In Europe, mainly glued-in rods with metric threads are used [3]. In Russia, mostly periodic profile bars A400 or A500 are used, but bars from other materials - different grades of steel, aluminum alloys, composite reinforcement (carbon fiber, fiberglass, basalt-plastic), etc. can also be used. The main requirement is that the rods have irregularities on the surface: periodic profile (steel or composite reinforcement), threads (e.g. metric), special rifling, etc. The bars are glued with epoxy adhesives.

The first satisfactory results were obtained by S. Turkovsky in 1975 when testing a girder joint on a new type of joints - obliquely bonded reinforcing bars (Fig. 1). Despite the fact that the joint was located in the area of maximum bending moment, the failure occurred outside the joint.

The use of inclined glued-in rods makes it possible to obtain rigid joints equivalent in bearing capacity to a solid section. The use of inclined glued-in rods is widespread in joints stressed by bending or compression with bending.

Compression-curved assemblies include support assemblies of columns rigidly connected with the foundation. The first objects with such assemblies on threaded adhesive screwed rods are the 24 m span warehouse (1979) and the panel production shop (1983) built at the Volokolamsk Experimental Building Structures Plant. Scheme of the support assembly of 6 m high columns is shown in Fig. 2a. The bearing structures of the roof were lenticular glued timber trusses, in which the junction of the upper and lower chords was also

https://doi.org/10.52202/069179-0546

made on glued-in screwed rods for the first time for such trusses.

A tennis court was built in 1983 in the Moscow region. Its main load-bearing structures were a double-hinged frame of 18 m span with glued wooden uprights of variable height (6 - 8) m and a bent-roofed girder.

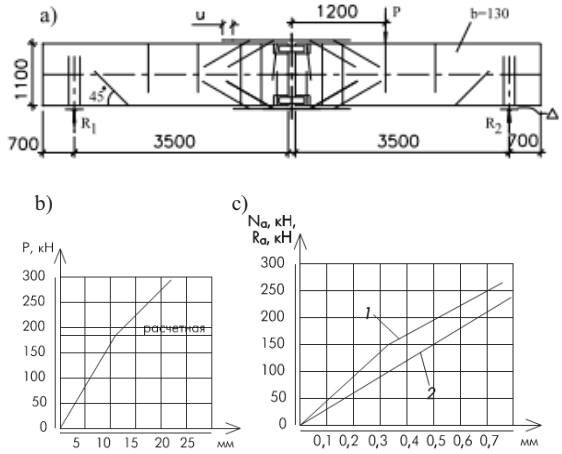

Figure 1: *Bending tests of a beam with a rigid joint: a - test pattern; b - deflections in the middle of the span; c - shear deformations in the joint*

The design of the stiffening of the struts differed from the first two in that the glued-in rebars were used (Fig. 2 b)

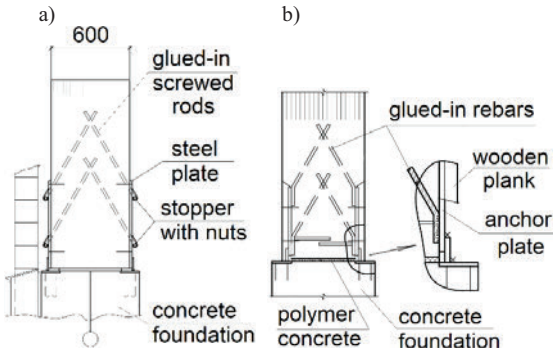

Figure 2: *Stiff pinch-post assemblies in the foundation: a - bonded-rod warehouse assembly (1979); b - bonded-rod tennis court assembly (1983)*

Bendable joints in large-span structures were first used in the construction of the community center of the pioneer camp (now holiday home) "Lipki" in the Moscow region, built in 1985 (Fig. 3).

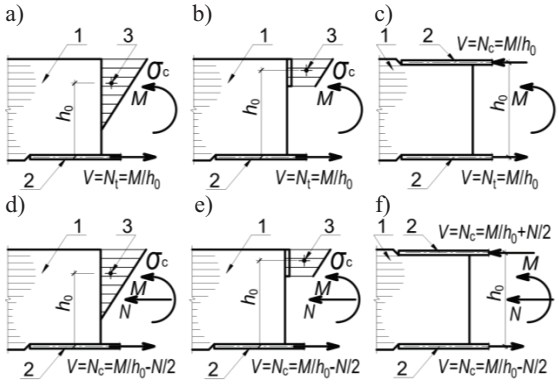
3 DESIGN AND CALCULATION OF RIGID JOINTS

3.1 CALCULATION SCHEMES

The basic principle of a rigid joint is to fasten the embedded plate to the wood member by means of obliquely bonded rods. The bending moment and the longitudinal force cause tension and compression in the joint. The tensile force Nt is taken up by the embedding plate, and the compression force Nc is taken up by the stop at the ends of the wooden elements, either by the stop through the centering gasket or by the embedding plate (Fig. 4). The magnitudes of the forces depend on the shoulder of the internal force pair h_0.



1 - glulam element; 2 - embedded detail; 3 - center of gravity of the compressive stress diagram

Figure 4: *Joint force diagrams: a, b and c - bending members; d, e and f - compression-bending members*

The axial forces in the embedded parts cause shear forces V between the part and the wood, which are taken up by the glued-in rods. In the tensile zone, the

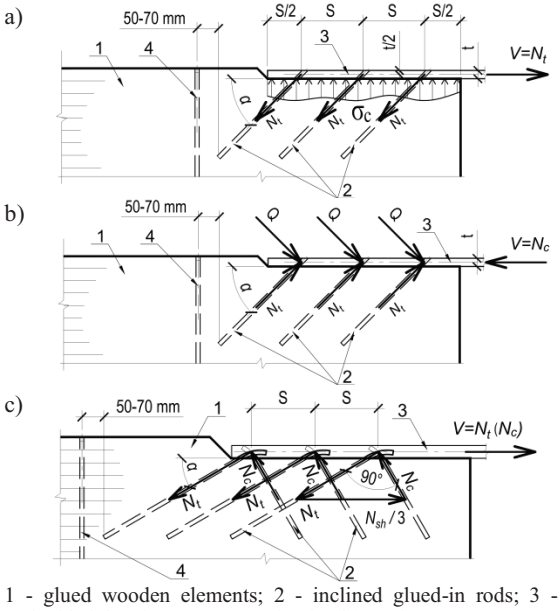
https://doi.org/10.52202/069179-0546

embedded parts are always installed, while in the compressed zone, the structural solutions for the transmission of the compressive forces can be different:
- By the butt-end of wooden elements (Fig.4a and Fig.4d), in this case, if there are no technical possibilities to ensure a tight adjacency, a gap of 30 ± 10 mm is made which is filled with polymer concrete during assembly;
- through the centering gasket (Fig.4b and Fig.4e), which is made of steel or polymer concrete;
- through the embedded part (Fig.4c and Fig.4f).

3.2 JOINTS DESIGN SCHEMES AND THEIR CALCULATION

Two types of structural solutions for rigid joints have been developed (Fig. 5): with unidirectional inclined glued-in rods and with glued-in rods forming V-shaped anchors.

Two types of joint designs have been developed: with unidirectional inclined glued-in rebars and with glued-in rebars forming V-shaped anchors.



1 - glued wooden elements; 2 - inclined glued-in rods; 3 - embedded detail; 4 - transversely glued-in rods

Figure 5: *Types of structural solutions for rigid joints: a - unidirectional inclined glued-in rods in the tensile zone; b - unidirectional inclined glued-in rods in the compressed zone; c - V-shaped anchors*

3.2.1 Joints with unidirectional inclined glued-in rods in the tensile zone

In the tensile zone of a joint with unidirectionally inclined riveted rods, the bending work of the rods is not considered, assuming the formation of a plastic joint at the point where the rod is attached to the embedded plate, which is usually done by welding.

The displacement force in the embedded plate V is decomposed into the tensile force in the rods N_t and the compressive force on the contact between the embedded plate and the wood σ_c (Fig.5a):

$$N_t = V / (n \cdot k_n \cdot \cos\alpha), \quad (1)$$

where:
N_t - pulling force in the inclined glued-in rod;
V - shear force in the embedded part of the joint;
n - number of inclined glued-in rods;
k_n - non-uniformity factor that takes into account the number of glued-in rods;
α - angle of inclination of a glued-in rod to the direction of force in the embedded plate.

$$\sigma_c = N_t \cdot \sin\alpha / (b_{e.d} \cdot S \cdot k_{n.\sigma}), \quad (2)$$

where:
σ_c - the normal buckling stress under the embedded part;
$b_{e.d}$ - width of the embedded plate;
S - step of inclined glued-in rods;
$k_{n.\sigma}$ - nonuniformity coefficient, taking into account the pitch and angle of glued-in rods and the stiffness of the embedded plate.

Based on the results of many years of research, a methodology for calculating the rigid joints of wooden structures on glued-in rods has been developed. It is based on determining the bearing capacity of glued-in rods during pulling out and punching. The main provisions of the calculation procedure are outlined in the Russian Construction Norms and Rules [4,5].

The calculated value of bearing capacity $R_{ax.\alpha.d}$ for pulling out or punching out of a rod glued-in at an angle to the wood fibers should be determined by the formula:

$$R_{ax,\alpha,d} = f_{v,\alpha,d} \cdot \pi \cdot d_1 \cdot l_{ad} \cdot k_v \cdot k_d \le f_{a.d} \cdot A_a, \quad (3)$$

where:
$f_{v.\alpha,d} = f^A_{v.d} \cdot m_{dl} \cdot \Pi m_i$ – design resistance of wood to pulling or punching of the rod glued-in at an angle to the fibers;
$f^A_{v.d}$ – design resistance of wood to pulling out or pressing the core glued-in at the angle of 90° to the fibers, for the loading mode A by SP 64.13330 [4], characterized by linearly increasing load at standard machine tests;
m_{dl} – coefficient of prolonged strength, corresponding to the combination of loading;
Πm_i – product of the coefficients of working conditions mi, considering the angle of slope of the rod to the direction of wood fibers, temperature and humidity conditions of operation;
d_1 – hole diameter;
l_{ad} – calculated length of the rod;
d – diameter of the glued-in rod;
k_v – coefficient taking into account uneven distribution of shear stresses depending on the calculated length of the rod;
k_d – coefficient taking into account the dependence of design resistance on the rod diameter;
A_a – sectional area of the rod;
$f_{a.d}$ – design resistance of the rod material.

It should be noted that the length of the glued-in rods is not only determined by the required load-bearing

https://doi.org/10.52202/069179-0546

capacity. In the wood at the end of a tensile bonded rod, normal tensile stresses occur across the fibers. The shallower the gluing depth in relation to the section height and the greater the angle of the rod to the direction of shear of the embedded detail, the higher the magnitude of the maximum stresses. Thus, if the inclination angle of the glued-in rod is 45°, the gluing depth should be set on the condition that the vertical projection of the rod is not less than 0.4h - cross-sectional height. If the gluing depth is less, to reduce the tensile stresses across the fibers, the rod should be glued-in across the fibers at a distance (50-70) mm along the fibers from the end of the stretched inclined glued-un rod.

3.2.2 Joints with unidirectional inclined glued-in rods in the tensile zone

If the compression forces in the joint are taken by the embedded plate, the shear force in it V acting on one rod is decomposed into the compressive force in the rod N_c and the shear force Q (Fig.3b):

$$V / (n \cdot k_n) = N_c \cdot \cos\alpha + Q \cdot \sin\alpha, \quad (4)$$

Hence:

$$N_c = V \cdot \cos\alpha / (n \cdot k_n), \quad (5)$$

$$Q = V \cdot \sin\alpha / (n \cdot k_n). \quad (6)$$

The bearing capacity of a rod glued-in at an angle to the wood fibers, working for pulling with bending or punching with bending, should be checked by the formula:

$$(N_c / R_{a.d})^2 + Q / F_{v.R.d} \leq 1, \quad (7)$$

where:

$R_{a.d} = f_{a.d} \cdot A_a$ – design bearing capacity of one rod under the condition of tensile strength of the rod material;

$F_{v.R.d}$ – design bearing capacity of the rod in terms of its operation as a dowel in bending at rigid (welded) connection of the glued-in rod with a steel embedded part, MH, it is taken:

$$F_{v.R.d} = 65d^2 \cdot \sqrt{m_{дл}} \cdot \Pi m_i \text{ – for rebars A300;} \quad (8)$$

$$F_{v.R.d} = 85d^2 \cdot \sqrt{m_{дл}} \cdot \Pi m_i \text{ – for rebars A400;} \quad (9)$$

where d is the nominal diameter of the reinforcing bar.

As far as in the rigid joints of bending and compression-bending structures the bearing capacity of unidirectional inclined glued-in bars in the stretched zone is considerably higher than in the compressed zone, the bars are located in the stretched zone, and compression is taken by the frontal stop or through the centering gasket. In structures with a variable arrangement of the compressed and stretched zones, such as arches, the glued-in rods are placed on both sides.

3.2.3 Joints with V-shaped anchors

One of the glued-in rods of the V-shaped anchor, glued-in at an angle α to the direction of the shear force V, works for pulling out (tensioned rod), the second one, glued-in at an angle β, works for pushing through (compressed rod) (Fig. 5c). The forces in the rods are determined from the expression:

$$V / (n \cdot k_u) = N_t \cdot \cos\alpha + N_c \cdot \cos\beta, \quad (10)$$

where N_t and N_c are the pulling and punching forces in obliquely glued-in rods.

Hence:

$$N_t = V / (n \cdot k_n \cdot \cos\alpha \cdot (1 + \mathrm{tg}\alpha / \sin\beta)), \quad (11)$$

$$N_c = V / (n \cdot k_n \cdot \sin\beta \cdot (1/\mathrm{tg}\alpha + 1/\sin\beta)). \quad (12)$$

When α = β, the forces in the tensile and compressed rods are equal:

$$N_t = N_c = V / (n \cdot k_n \cdot (1 + \cos\alpha)), \quad (13)$$

In practice for V-shaped anchors the angle between the glued-in rods is usually taken to be 90°. Then, with the angle of the rod to be pulled out α:

$$N_t = V \cdot \cos\alpha / (n \cdot k_n), \quad (14)$$

$$N_c = V \cdot \sin\alpha / (n \cdot k_n). \quad (15)$$

The design value of the bearing capacity $R_{ax.\alpha.d}$ for the pulling out or punching through of the rod glued-in at an angle to the wood fibers shall be determined according to the formula (3).

V-shaped anchors can be installed in both tensile and compressed zones. However, it is most effective to install them in the tensile zone, especially for compression-curved elements.

4 JOINT CONTROL TESTS

4.1 PURPOSES OF CONTROL TESTS

For large-span structures, control tests of the main assemblies are often required. The rationale for the need to test the knots of laminated timber structures is that:

- structures of unique structures;
- constructions of structures of the 1st responsibility class according to GOST 27751-2014 [6];
- pilot experimental constructions;
- long-span structures with manufacturing defects;
- large-span structures with assembly defects;
- units of critical structures during the mastering of production.

The purposes of control tests of large span laminated timber structures joints are:

- evaluation of the correctness of the adopted design solutions and calculation assumptions;

- determination of the bearing capacity in the absence of the standard calculation methods;
- verification of manufacturability.
- quality control of manufacturing;
- verification of assemblability and quality control on assembly;
- expert evaluation of the causes of structural failures.

An example of testing to determine the bearing capacity of bendable assemblies of critical experimental structures during production development is the above-mentioned test of the rigid girder joint of the boarding house "Lipki" (Fig. 3).

4.2 TESTS OF JOINTS OF LARGE SPAN STRUCTURES

High chemical resistance to various salts aggressive to steel and concrete makes wood competitive in the construction of structures for the storage of such materials. An example of control tests are tests of rigid joints on glued-in rods of the main elements of glued wood frameworks of mineral fertilizer storage facilities and other similar structures.

4.2.1 Warehouse of anti-icing chemicals in Moscow

During the reconstruction of the Moscow Ring Road in 1999, a de-icing agent warehouse was built in Moscow, the frame of which was made in the form of three-jointed bent-beam frames with a span of 60 m - the first long-span structure with compression-curved rigid joints on glued-in rebars (Fig. 6a) [7].

a)

b)

Figure 6: *De-icing agent storage with a span of 60 m: a - installation; b - rigid joint testing*

In order to assess the correctness of the adopted design solutions and design assumptions, control tests were carried out on a fragment of the structure with a rigid joint in the middle of the length (Fig. 6b). The joint was made symmetrical with a frontal stop through epoxy-based polymer concrete. Since the bearing capacity of the joint is determined by the tensile zone, bending tests were performed, with the tensile forces in the joint corresponding to the forces in the tensile zone of the compression-bending joint of the bent frame.

To assess the stress-strain state of the wood in the joint area, electrical strain gauges were glued and mechanical strain and displacement sensors were installed. During the tests, the opening of the joint in the tensile zone, the shear deformations of the embedded plate relative to the wooden element, and the relative deformations along the fibers in the compressed zone were determined.

The tests confirmed the correctness of the adopted design solutions and design assumptions. The failure was caused by wood rupture in the tensile zone outside the joint.

During the tests, an additional task was set to check the effectiveness of the method developed in CNIISK to strengthen glued wooden elements in which shrinkage cracks and delamination of glue joints can appear in the process of tests [8]. In the supporting zone of one of the joined fragment elements in the middle of the section height, an artificial through crack was created with the length of about half the element length. There was performed an inclined reinforcement by reinforcing bars with diameter of 20 mm of class A400 with length of 1000 mm glued-in at an angle of 45° to the fibers. Along the artificial crack, shear gauges were installed.

At the initial stage of tests, approximately up to the normative load, shear was minimal, the structure did not work as a composite element on compliant bonds, but as a monolithic one. The test results confirmed the effectiveness of inclined reinforcement of zones with high levels of tangential stresses and tensile stresses across fibers for strengthening and restoration of wooden structures, primarily the supporting zones of beams.

4.2.2 Potassium salt deposits in Volgograd Region

In the Volgograd region at the mining and beneficiation plant for the extraction and processing of potassium salts two warehouses with frames of glued wooden structures were built (Fig.7).

a)

b)

c)

Figure 7: *87.2 m span warehouse arches: a - frame assembly; b - joint of collapsed arch; c - joint testing*

https://doi.org/10.52202/069179-0546

Structural scheme represents three hinged glued wooden arches with 87.2 m span and 36.7 m height at the ridge. Each half-arch consists of three elements, which at their ends are fitted with embedded parts fixed on inclined glued-in rebars. During installation, the elements are joined into a semi-arch by rigid joints by connecting the embedded parts with M20 bolts made of A4-80 stainless steel.

In 2014, at the beginning of installation of the frame of the first warehouse, two bent wooden girders collapsed as a result of a hurricane. The bolts in the lower rigid joints had sheared off after the half-arcs collapsed. To determine the cause of the collapse, a decision was made to repair one of the rigid joints and conduct a test to confirm sufficient load-bearing capacity. An 8-metre long section with a rigid joint in the middle was cut out of one of the collapsed arches. Restoration of the joint consisted of installing new bolts.

In the first phase, tests were performed for compressive force and bending moment (Fig. 7c). The H and M ratios corresponded to the forces in the arch for the design load combination. During the tests, the shear deformations of the embedded parts relative to the wood, the joint opening width in the tensile zone, and the compression deformations along the fibers in the compressed zone were determined. When the required level of loading was reached, no fracture occurred, the instrumentation showed that the joint was working in the elastic stage.

Since the load-carrying capacity of the joint is determined by the work of the glued-in rods in the tensile zone, it was decided to conduct further tests only in the bending zone, comparing the forces in the glued-in rod located in the tensile zone with the forces in the compression-bending element joint. The bolts were replaced with stronger bolts of class 10.9. The bolts sheared off under a load much greater than the design load.

In the third phase, the bolts were replaced by welding. The failure of the joint occurred from the rupture of the glued-in rebars.

Tests showed sufficient load-bearing capacity and confirmed that the rigid bonds on the bonded bars were not the cause of the collapse.

4.2.3 Potash warehouses in Perm Territory

The main load-bearing structures of the potash production complex warehouses in Perm Krai, built in 2016-2020, are glued wooden triangular arches with a span of 60 m and a height at the ridge of 38.5 m. The 49.3 m long half arches, based on technological and transport limitations, consist of 2 elements along the length with a rigid joint between them on unidirectional obliquely glued-in rebars. Due to the fact that the warehouses of chemical enterprises belong to the constructions of the 1st responsibility class and two companies selected for the manufacture of glued wooden structures of warehouse frameworks had no experience in the manufacture of critical structures with the nodes on the glued-in rebars, the control tests of the rigid joint were required.

A full-scale fragment with a rigid butt-joint in the middle of the span was tested in compression and bending (Fig. 8). The two elements forming the fragment were manufactured at two QDC manufacturing plants. The tensile forces in the joint are taken up through the embedded detail by unidirectional obliquely glued-in rebars. The compression is transmitted by the frontal stop via polymer concrete alignment pads.

In the area of the joint, the test fragment is equipped with electric strain gauges and mechanical strain and displacement sensors to record the stress-strain state of the wood and steel embedded parts, shear strains of the embedded parts, opening of the joint in the tensile zone, deflections of the sample, etc. (Fig. 8b).

Figure 8: *Control tests of a compression-bending rigid joint of an arch with a span of 60 m*

Maximum bending moment in the rigid butt-joint M = 667 kN-m with a longitudinal force N = -532 kN and a shear force Q = 64 kN. The adopted testing scheme allowed to have ratios of internal forces in the butt at any stage of tests, which were proportional to the previously given design values. Loads were applied on the specimen by means of hydraulic jacks in a special stand (Fig.8a). Compressive force N was created by resting it in the end face of a 1500 kN hydraulic jack. The bending moment M was created by two hydraulic jacks of 1000 kN capacity each, with different loads on jacks, resulting in a transverse force Q at the junction.

The tests were conducted in two stages. The first stage of tests was conducted with metal overlays removed in the compressed zone of the joint, which allowed for the exclusion of embedded parts with glued-in rebars in the compressed zone. The second stage was performed with the overlays in place to allow the wood and metal embedded parts with the glued-in rebars to work together in compression.

Each stage consisted of several stages. The first two stages of the tests in both stages were characterized by the work of the specimen in the elastic strain zone. In the first stage, only vertical loads were applied to the specimen, allowing only pure bending to be simulated in the element junction zone. The second stage simulated compression with bending, adding horizontal compressive loads to the vertical loads.

The third stage was conducted only for the second stage of tests and was a continuation of the second stage. At this stage, the specimen was brought to failure.

The maximum loads exceeded the design loads by 1.8 times and the required maximum test loads by 1.18 times. The test results showed that the technical solutions adopted in the design are technological, provide the required load-carrying capacity and confirm the quality of rigid joints in the manufacture of structures.

4.2.4 Mineral fertilizer warehouse of Gomel Chemical Plant

In 2021, a mineral fertilizer warehouse was built at the Gomel chemical plant. The main load-bearing structures were three-armed non-symmetrical triangular arches (Fig. 9a). One half-arch has a slope to the horizon of 45°, the second - 30°. The second half-arch, 33.2 m long, has a rigid joint on inclined glued-in rebars.

The building code of Belarus regulates the compulsory control tests of critical structures. In 2020, in Brest (Belarus), tests were carried out on a fragment of a half-arch with a rigid joint on glued-in rebars (Fig. 9b). The tests were conducted under the scientific supervision of A. Naychuk according to the method developed by A. Pogoreltsev [9]. The tests were conducted in two stages: in compression with bending and in bending. The sample was equipped with measuring instruments (Fig. 9c).

While carrying out the tests, there were determined the regularities of change in the stress-strain state of wood in the area of location of the inclined glued-in rebars, compliance of connection elements, height of the compressed zone (Fig. 9e and 9e), the width of joint opening in the stretched area between the ends of the connected elements (Fig. 9f), depending on the magnitude of applied loads.

It follows from the test results that the height of compression zone of the joint is not a constant value and depends on the suppleness of the embedded parts and the level of tension in the connecting plates. The height of the compressed zone decreases with increasing load.

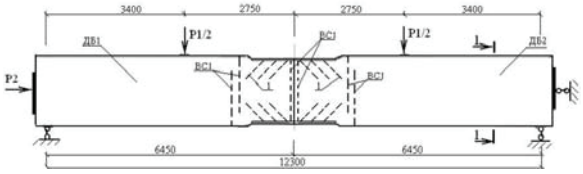
When testing the specimen under the loading scheme of the compression-bending element the carrying capacity of the joint in vertical direction is Rsup,c,90 = 131.5 kN and in horizontal direction - Rsup,c,0 = 124.9 kN, which is more than values of the required carrying capacity.

When testing the prototype according to the bending element loading scheme, the value of actual bearing capacity Rsup,v = 364.9 kN, which is significantly higher than the value of the required bearing capacity.

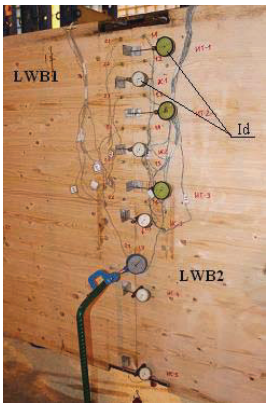
At the same time, numerical studies of the joint operation were performed (Fig. 9g). The obtained data were compared with the test results.

a)

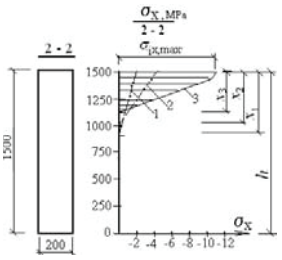
b)



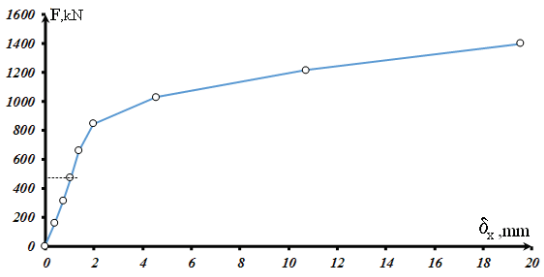
c)



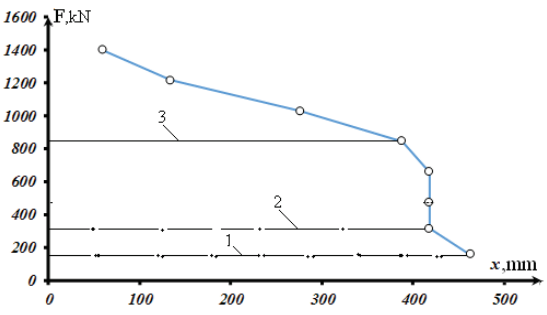
d)



e)

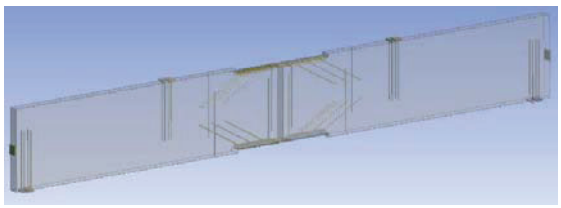


f)



g)

https://doi.org/10.52202/069179-0546



1 - F = 157 kN; 2 - F = 315,3 kN; 3 - F = 843,8 kN

Figure 9: *Fertilizer warehouse: a - installation of arches with a span of 45 m; b - test scheme of a fragment with a rigid joint; c - indicators and strain gauges in the joint zone; e - diagram of normal compressive stresses in section 2-2; f) - dependence of height of compressed zone x on the load value; f) - dependence of width δx of joint opening on the load value; g) - numerical model*

The discrepancy between the data obtained as a result of numerical calculations and tests was most typical for the value of compression zone height, which was 22%. Such a difference is caused by the fact that during the prototype production, a partial adhesive bond between the surfaces of the embedded parts and the wood in the process of gluing of the inclined reinforcing bars took place. This circumstance led to a decrease in the suppleness of the embedded parts and an increase in the height of the compressed zone. In the KE model, the friction coefficient between the surfaces of the embedded parts and the wood was assumed to be zero.

5 CONCLUSIONS

During all the control tests, additional research tasks were solved as part of the glued-in rebar joints research program.

The results of control tests confirm the correctness of the design assumptions laid down in the Russian construction norms and rules [4, 5].

Over the past 25 years in Russia, dozens of buildings with large-span laminated wooden structures using rigid joints on the glued-in rebars have been built: water parks at the Abzakovo ski resort (beams of span 29.8 m), in Ulyanovsk (lenticular trusses of span 32.3 m), in Mytishchi ((lenticular trusses of span 44 m), Rostov-on-Don (lenticular trusses of span 35 m), Saint Petersburg (90 m diameter dome), Novosibirsk (95 m diameter dome); swimming pools in St. Petersburg (lenticular trusses with spans of 45 m and 56 m), Saransk (frames with spans of 40 m and 30 m), Kazan (frames with spans of 54.6 m); sports palaces in Moscow (lenticular trusses with 48 m span and frames with 42 m span), Nefteyugansk (metal and wood lenticular trusses with 42 m span); ice palaces in Moscow (metal and wood lenticular trusses with 50,5 m span), Krasnoyarsk, Irkutsk and Novokuznetsk (sickle-shaped arches with 99,9 m span and many others).

World Conference on Timber Engineering Oslo 2023

MJØSTÅRNET: THE WORLD'S TALLEST TIMBER BUILDING

Harald Liven[1], Rune Abrahamsen[2]

ABSTRACT: Mjøstårnet is an 18-storey mixed-use timber building in Brumunddal, Norway, built by the shore of the lake Mjøsa. The building was completed in March 2019 and has been ratified by CTBUH as the world's tallest all-timber building. Mjøstårnet consists of offices, 72 hotel rooms, 33 apartments with balconies, a restaurant on the ground floor, conference rooms and a rooftop terrace. The architectural pergola extends the building 85,4 m from the ground level.

KEYWORDS: Multi-storey buildings, high rise, assembly, glulam, fire

1 INTRODUCTION

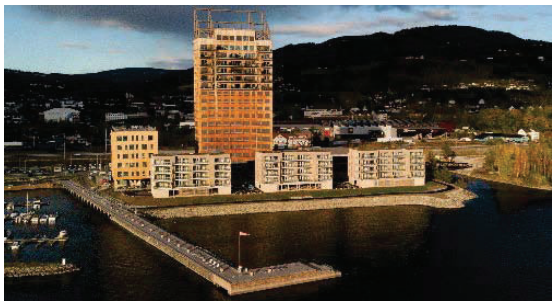

Figure 1: *"Mjøstårnet". View from the lake Mjøsa*

The initiative to build Mjøstårnet comes from investor Arthur Buchardt and the company AB Invest AS. He grew up in Brumunddal and wanted to build the world's tallest timber building placed in his hometown. In that way he wanted to show the world what is possible by using local resources, local suppliers, local competence and sustainable materials. He made the first sketch in February 2015 where he drew the building and its facilities.

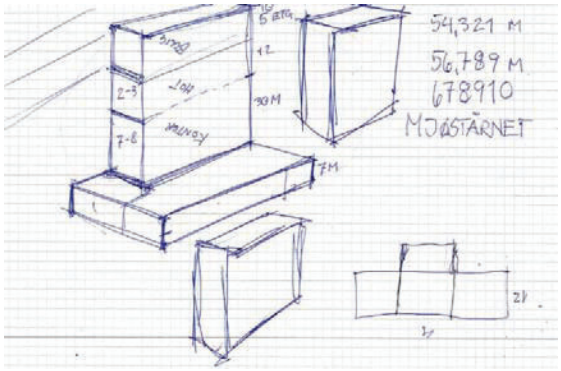

Figure 2*: Sketch from February 2015 © Arthur Buchardt*

Together with Moelven Limtre AS – Norway's largest glulam manufacturer - he continued to develop the project. VOLL architects were engaged as architects and HENT as main contractor. Only four years later, in March 2019, the tallest timber building was completed [6].
Brumunddal is located close to the shore of lake Mjøsa, 140 kilometres north of Norway's capital Oslo.

Figure 3: *Brumunddal located in the central part of Norway*

The completed building has a majority of wooden components originating from nearby sustainable forests. The wooden components comprise glulam structures in the main load bearing, CLT in the elevator and staircase shafts, as well as wooden based floor and façade elements. In total about 4000 m^3 of wooden products were used. To produce this quantity about 16.000 spruce trees were harvested.
The glulam structures as well as floor- and façade elements were produced only 15 kilometres from the site.

2 STRUCTURAL SYSTEM

The structural and dynamic design of the tower was carried out by the Norwegian branch of the design company Sweco in collaboration with Moelven Limtre. The design was performed according to Eurocode 5 [1,2].

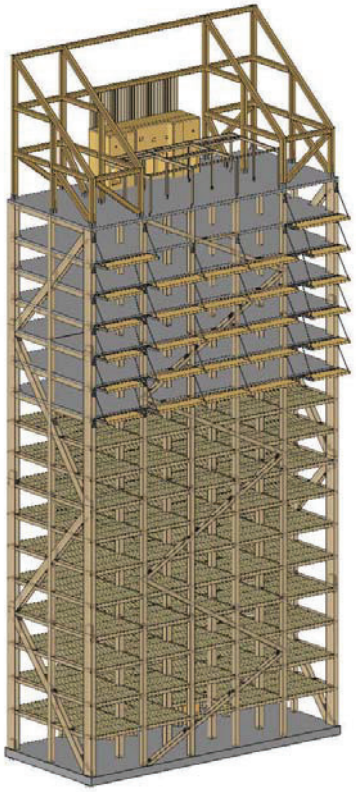

Figure 4: *Structural system*

2.1 The main load bearing

The main load bearing consists of large-scale glulam trusses along the façades as well as internal columns and beams. The footprint of the structure is 16,3 m x 36,9 m measured from the outer corners of the columns.

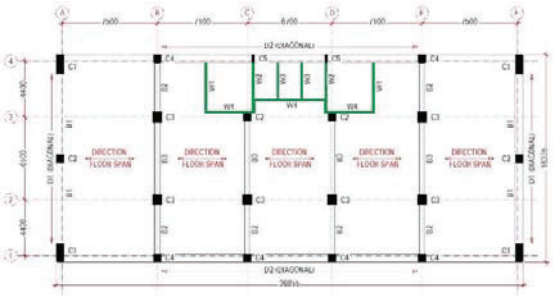

Figure 5*: The axes and main load bearing system*

The 22 columns (C) transfer the vertical load from beams and diagonals to the foundation. The cross-section of the corner columns is 625 mm x 1485 mm. These are the largest elements in the structure. Maximum span for the beams (B) is 6,5 meters and for floor elements 7,1 meters.

The lateral bracing system is quite basic. Four trusses consisting of columns and diagonals (D) are bracing the entire building. There is one truss in each façade and together they give the building the necessary rigidity to handle horizontal deformation and dynamic effects. Focus was placed on keeping the connections as simple as possible. One example is that the diagonals transferring the wind load are connected to separate columns.

Table 1*: Cross-sections of columns, beams, diagonals and walls*

Structure	Width (mm)	Height (mm)
C1	625	1485
C2	625	630
C3 at the bottom C3 at the top	725 625	810 630

D1	625	990
D2	625	495
W1	220	-
W2	180	-
W3	160	-
W4	140	-

When designing tall timber buildings, it is important to verify that relevant comfort criteria are met. Timber buildings are light, and horizontal accelerations induced by wind must be carefully considered. For Mjøstårnet this was one of the governing aspects for the design. The structural damping obtained from the Treet building in Bergen was used for Mjøstårnet. The accelerations in the tower were monitored both during installation and after completion. The dynamic design was solved as a combination of structural stiffness and mass distribution. Tuned mass dampers (TMD's) to further reduce accelerations were not required and are not installed in Mjøstårnet. Four years after the opening there have been no reports of people feeling nauseated or uncomfortable.

2.2 Walls

CLT panels are used for secondary load bearing of three elevators and two staircases, but do not contribute to the building's lateral stability. Thicknesses of CLT walls (W) are listed in *Table 1* and the placement is shown in *figure 5*. All the CLT elements are produced by Stora Enso and installed by the local company Woodcon AS.

2.3 Floor elements

Each floor acts as a nearly rigid diaphragm which distributes the horizontal forces into the façade trusses. From levels 2 to 11 wooden floor elements are used. This is a wooden cassette deck adopted from the Swedish glulam manufacturer Moelven Töreboda, and it is called

https://doi.org/10.52202/069179-0547

Trä8. The digit 8 refers to the span of this element which is up to 8 m.
Glulam joists spaced 600 mm make up the main structures in these elements. As top flange a plate of crossbanded veneers (LVL-C) is used, and as bottom flange a board of solid wood is used. By gluing the flanges to the joists, a static composite is achieved with increased bending and stiffness properties. The top flange cantilevers from the edge beam and transfers the vertical load into the supporting glulam beam. In this way the element can be mounted between the glulam beams, and only the thickness of the LVL-C plate is above the beams. This is an efficient way to minimize the structural height. The total height of the floor element is 439 mm.
A local company, RVT, produced the elements for Moelven Limtre.

***Table 2**: Cross-sections of components in the floor element*

Structure	Width (mm)	Height (mm)
Joist	66	360
LVL-C top flange	31	-
C3 at the bottom	148	48

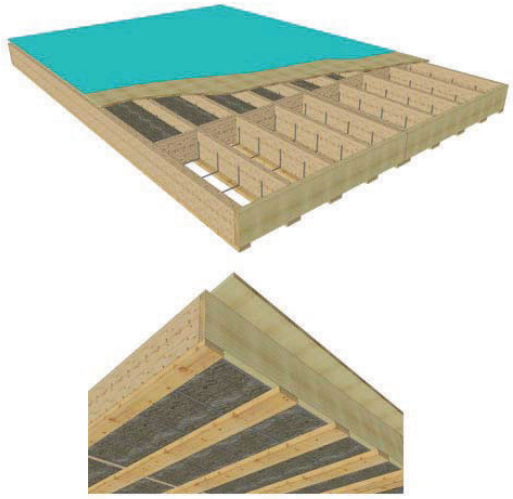

***Figure 6**: Trä8 floor element*

The seven upper floors are 300 mm thick concrete slabs supported by glulam beams. This adds extra weight to the structure which is beneficial for the dynamic behaviour.

2.4 Pergola

The glulam pergola at the very top of the building is not produced with solid rectangular cross-sections. To reduce potential shrinkage cracks on the outer surfaces these glulam parts were produced as hollow sections. The hollow section is composed of four rectangular beams with a width of 90 mm, glued together in each corner. All corners are rounded with a radius of 140 mm to improve aerodynamics.

***Figure 7:** Hollow cross-section in the Pergola*

2.5 Balconies

In the six upper floors, which contain the apartments, balconies are attached to the façade and suspended from the columns with steel bars. CLT panels are used as floor elements. Polyurea coating is used to seal and protect the top of the elements from the weather.

2.6 Connections

Slotted-in steel plates with 12 mm steel dowels are used to transfer the forces between the glulam elements. The distance between the slots is 115 mm and the number of steel plates are two or four. The thickness of the plates is 8 mm or 12 mm. The number and thickness of the steel plates depend on the value of the force transmitted.

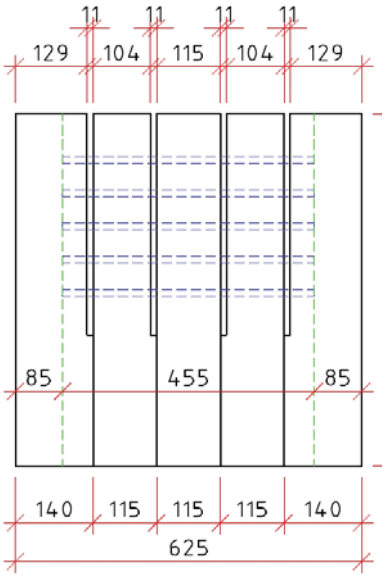

***Figure 8**: Typical cross-section build-up with slotted-in steel plates and dowels.*

Approximately 5000 kN of tension is the highest design force for a connection. It appears in the bottom of each corner when the wind load acts on the longest façade and tries to tilt the building. This requires 4 pcs of 12 mm steel plates and 100 psc of 12 mm steel dowels. All dowels are embedded 85 mm into the wood, which is the same distance as the charring after 120 minutes.

https://doi.org/10.52202/069179-0547

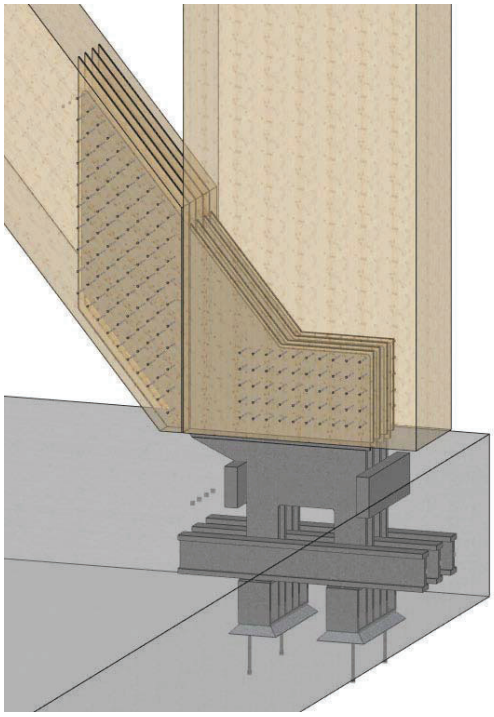

***Figure 9**: Connection at the foundation in each corner.*

3 MATERIALS

A third of the volume of all materials used in the building is wood such as glulam, CLT and solid wood. The percentage of the different materials used to build Mjøstårnet is shown in *Table 3*.

***Table 3**: Volume of materials*

Material	Share %
Wood	34
Insulation	33
Concrete	26
Steel	1
Other materials	6

3.1 The main load bearing

Glulam is used for trusses, beams and columns in the primary load bearing system. For the structural design, glulam strength classes according to EN 14080 [3] are used. Strength class GL30c, combined build-up, is used for all glulam structures accept from the bottom part of the corner columns which is produced as GL30h, homogeneous build-up. Lamellas with strength classes T22 and T15 are used for combined glulam, and only T22 for homogeneous glulam. Spruce is the species used for lamellas.

3.2 Walls

CLT panels is used for elevator shafts and staircases. The strength class of the lamellas is C24 according to EN 338 [4]. Spruce is the species used for these lamellas.

3.3 Floor elements

Timber floor cassettes are used in levels 2-11 and 300 mm thick concrete slabs are used in storeys 12-18. The floor joists are resawn glulam with strength class GL28cs [3]. The characteristic bending strength is 28 MPa and the modulus of elasticity parallel to grain is 12500 MPa. Kerto®-Q panels, produced by Metsä Wood, are used for the top flange and also the edge beam of the elements. Strength class for the bottom flange in solid wood is C24 according to EN 338 [4]. Spruce is the species used for all these components.

3.4 Pergola

GL30c [3] is the strength class used in the pergola structures, and the glulam is Cu-impregnated throughout. Pine is the species used for these lamellas.

3.5 Balconies

CLT is also used as floor elements for the balconies. The strength class of the lamellas used in the panels are C24 according to EN 338 [4]. Spruce is the species used for these lamellas.

3.6 Connections

S355 steel is used in connections together with acid-proof steel dowels with tensile strength f_u=700 MPa.

4 FIRE DESIGN

The fire strategy report for Mjøstårnet states that the main load bearing system must withstand 120 minutes of fire. Secondary load bearing such as floors must withstand 90 minutes. In addition, the structure must withstand a full burnout and prevent a total collapse. This means that after a burnout, the load bearing system will still be in intact and the fire in the structural elements will be put out by itself. The fire design is verified by 90 minutes burnout tests that were performed in 2016 at SP Fire Research AS in Trondheim. The tests prove the fire behaviour of large-scale glulam sections and their connections [5].

***Figure 10**: Burnout test at SP Fire Research AS in Trondheim.*

4.1 Reduction of cross-section

The structural fire design was done by calculating the remaining cross-section after charring according to Eurocode 5 [2]. The charring rate is 0,7 mm/min at every exposed side of the cross-section. This means that 120

https://doi.org/10.52202/069179-0547

minutes of fire gives a charring depth of 84 mm. In addition, a layer of 7 mm with loss of strength must be taken into account. The total reduction of cross-section for every exposed side will be 91 mm for 120 minutes of fire.

4.2 Protection of steel connections

Steel plates and dowels used for connections are embedded deep into the timber. In this way the timber insulates the steel and protects it from fire exposure. All gaps and slots between beams, columns and plates are fitted with an intumescent fire strip. When the heat reaches 150°C this material will start to expand up to twenty times. In this way open gaps and slots will be sealed and the steel inside will be protected. The 90 minutes fire test by SP Fire Research AS [5] proved that the temperature in the steel connections did not reach more than 250°C, which is structurally acceptable.

***Figure 11**: Sealed slots and gaps using intumescent fire strips.*

4.3 Robustness in fire

As for robustness the structure is designed to sustain the loss of the horizontal stiffness of one entire floor. It can also carry the impact load of a timber deck falling down on the floor below.

4.4 Other fire measures

The entire building is sprinklered. In escape stairs, the wall panels are covered with fire gypsum and in all open public areas the wooden surfaces are treated with a fire-retardant paint. The wooden boards used on the façade are heat treated pine, additionally pressure treated with a fire retardant. For every storey in the façade there is also a fire stop device.

5 ASSEMBLY

The assembly of the building was divided into six stages. The main body up to level 18 was built in four steps, were each step comprised four or five storeys. Thereafter came the installation of balconies and in the very end the rooftop pergola.

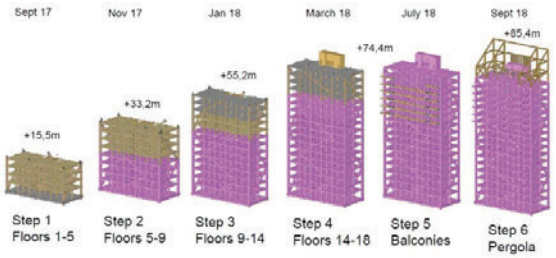

***Figure 12:** Assembly steps*

The first timber element was installed on the 4th of September 2017, and the final beam on the pergola's top was mounted exactly one year later.

***Figure 13:** The last beam installed.*

5.1 Preparation of elements in factory

Every single structural element is processed using Computer Numerical Control (CNC) machines. All cuttings and drillings are done in the factory. It means that the accuracy of the geometry is very high and produced practically with zero tolerances. steel plates were installed into the glulam columns in the factory before being transported to the building site.

***Figure 14**: CNC processing / Block gluing / Installation of steel plates*

5.2 Embedding of base connections

Embedding of the base connections is maybe the most crucial part of the assembly. If the placement of the bases is inaccurate the timber elements will not be possible to assemble correctly, and the geometrical tolerances of the building will be unacceptable. This is particularly important since all the elements arrive the building site precut and predrilled.

https://doi.org/10.52202/069179-0547

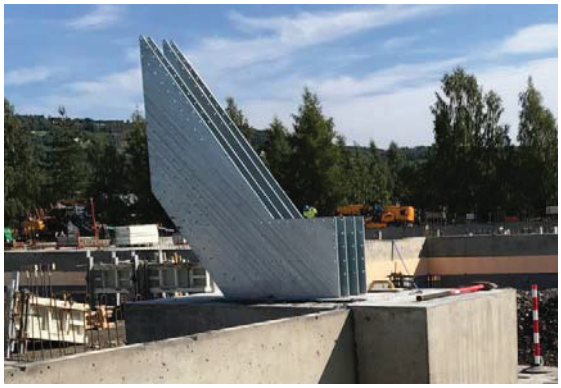

***Figure 15**: Base connection of the corner column and diagonal.*

5.3 Assembly on ground and hoisting of frames

Before the erection started all the glulam structures for the upcoming assembly step were put together into frames on the ground. Then these frames were hoisted into the building and installed. The frame sections were four or five storeys high.

***Figure 16**: Hoisting of frames.*

5.4 Assembly of floor and balcony elements

Both the floor and balcony elements were prefabricated at the factory and hoisted directly on site. There were four lifting hooks on each floor element for lifting the floor elements. A specially designed lifting device was made for the balcony elements. This was done to avoid lifting hooks that potentially would damage the polyurea membrane coating on top of these elements.

***Figure 17**: Hoisting of balconies with tower crane.*

5.5 Assembly in height

The timber skeleton was installed using a tower crane, mobile cranes and lifts. It was not needed to use any kind of scaffolding for the installation of the load bearing structure. The tower crane was operated by the turnkey contractor HENT.

6 CONCLUSIONS

The completed building proves that an 85 meter high glulam building can be built using local competence, local suppliers and local materials. Mjøstårnet is already an iconic landmark in Norway and serves as an inspiration on how to build sustainably in the future. Using the same structural principles, it is possible to double the height.

ACKNOWLEDGEMENTS

The authors would like to thank colleagues and all collaborating parties for their great efforts in this project. Thanks to investor Arthur Buchardt who had the courage, will and opportunity to build Mjøstårnet.

World Conference on Timber Engineering Oslo 2023

THE FIRST MASS TIMBER BUILDING IN BRAZIL

Carlito Calil Neto[1], Alexander Takata[2], Vitor Afonso Neves Silva[3,]

ABSTRACT: The use of new technologies in wood for construction is increasing every year in Brazil. This work aims to demonstrate step by step the entire building system that was used for the construction of the first massive wooden building in Brazil located in one of the main avenues of São Paulo city.

KEYWORDS: First massive timber Brazil, Wood building, Massive Timber, Glued Laminated, Cross Laminated Timber.

1 INTRODUCTION

The mass timber revolution is on the rise, Architects and engineers are working around the world to understand and revolutionize the building industry of how to use wood and create large-scale and sustainable buildings. The move to mass timber is even farther along in North America and Europe. That's because mass timber panels and systems like posts and beams glued under pressure or floor and wall systems nailed together in layers, is not only prized as an innovative building material, superior to steel and concrete in many ways, it is also hoped it will come into its own as a significant part of a climate change solution. In Brazil, this revolution already started with the first mass timber building just have been finished located in the city of São Paulo, Brazil.

Figure 1: *First Timber building in brazil – render*

The four-storey commercial building has a construction system based on the use of CLT (Cross Laminated Timber) panels as floors, walls and slabs. The Glulam (Glued Laminated Timber) panels are used as posts and beams systems. The connections between these elements are made by self-tapping screws developed for this type. application, facilitating and reducing assembly time.

This system has been widely accepted in the European and North American market that besides being able to build single-family residences, it is possible to build multi-floor buildings. Unfortunately, in Brazil this system is not yet as widespread as it could be most of the works are performed in the traditional masonry system with bricks or structured concrete blocks with reinforced concrete columns and beams or steel structures. The choice for the traditional building system is linked to factors such as culture, ease of access to material and especially the wide dissemination of knowledge of the building system that is chosen.

The building owner is DENGO, a Brazilian company that manufacture healthy and sustainable chocolates, and this mass timber building will be a model store for the company. The building has a net area of 1500 m2 and the basement, which holds parking facilities, technical rooms and storage rooms, that has a net area of 564 m2. Rewood is the Brazil's largest glulam manufacturer, and delivers and installs the glulam and CLT. KLH in Austria provides the CLT to Rewood. The architect for the project is the São Paulo based company MFMM. Rewood and Stamade are the responsible for the technical design and design management.

This work aims to demonstrate step by step the entire building system that was used for the construction of the first mass timber building in Brazil located in one of the main avenues of São Paulo.

2 LOCATION

The building site is in an urban and central area of São Paulo, the largest city in Brazil, and is located at Avenida Brigadeiro Faria Lima, one of the main avenues of São Paulo City, see map on Figure 2.

Figure 2: *First wood building in Brazil - outside view*

Figure 2.1: *First wood building in Brazil - outside view*

Brazil has a deficit of 6 million housing units to attend its population, with the projection of a 20 million deficit by 2024. This represents a need for investment of around R$ 76 billion annually to solve the problem. The challenge of sheltering these people clashes with the pressing challenge in addressing in a proper way climate change and the need to reduce greenhouse gas emissions in the recent commitments assumed by the country under its NDC – National determined contributions. Such as many other places around the world, the dominant construction system in Brazilian larger cities is based on two materials: steel and concrete, which are materials thar have been widely used in last century, whose production is based on enormous energy consumption and low concern about GHG emissions.

There are estimates that show that only the production of these two materials accounts for 8% of all humanity's GHG emissions. Also, based on these materials, the construction industry accounts for 47% of the total emissions, the transport sector, 33%, and the primary industry, 19%. Thus, meeting this growing demand for housing, while combating the effects of GHG emissions on climate change, is the challenge posed.

3 WOOD IS THE SOLUTION

Among architects, manufacturers, and environmentalists, many want nothing less than to turn the coming decades of global construction from a giant source of carbon emissions into a giant carbon sink by replacing concrete and steel construction with mass timber. It will avoid the CO2 generated in the production of those building materials and sequester massive amounts of carbon by tying up the wood in buildings.

Wood is the only renewable building material that has grown with sunlight and uses atmospheric CO2 to develop. However, this potential for the use of wood as a smart alternative for GHG emission in the construction industry generally meets the Brazilian tradition in processing timber in the way of keeping the focus on the production of solid high density wood, which has its charm and usefulness. However, to shift the general logic of using wood in the construction industry to upscale its reach and competitiveness for the housing sector it is needed to develop a new industry and a new market for highly processed wood products, such as wood-frame panels or laminated wood panels.

Glulam and or CLT are industrialized products and like any industrialized product the value of its cubic meter is increasingly taken into account the more it is produced. Increasingly wood technology has been well received in the Brazilian market and the engineered wood product has gained shape and knowledge.

The Brazilian market needs to understand that we need a fast and sustainable solution for the next generations and that is why our company Rewood worked hard to build the first timber building in Brazil and to show that it is possible to build large structures with the engineered wood product.

4 STRUCTURAL TIMBER SYSTEM

The main material of the building is wood. Wood is flexible to apply a huge range of building types and applications (structural and aesthetic) and renewable. In addition, engineered wood is innovative, adaptable, and efficient for the uses in construction, therefore, the architects tried to bring out those strengths in design and construction.

https://doi.org/10.52202/069179-0548

The Building has a strong and geometric shape with modern design. The first floor has an opened (wide) rectangular shape and also other floors have rectangular medium spaces. The design objective of the DENGO is to maximize the use of wood in the structural and non-structural application rather than any other material.

The main structural system is made of glued laminated timber (glulam) post and beam grid structure with cross-laminated timber panels (CLT). The CLT is used as slab on glulam beams and glulam columns. The Columns are typically on a 5,4m x 5,4m grid, supporting the CLT floor assemblies. The columns were manufactured continuous with 10 meters length over the three floors with a typical cross-section dimension is 270x270 mm.

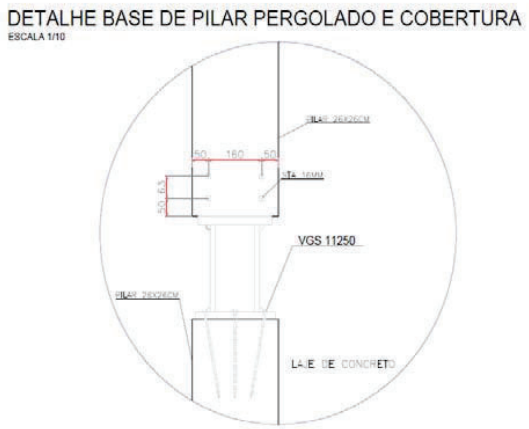

Figure 3: *Connection columns to column*

The 270x320 mm cross-section beams were framed into the column faces using a customized steel connector. The glulam elements are connected by steel plates and dowels. This is a commonly connection used in orther timber structures. Typically, 6 mm steel plates manufactured in Brazil and 12 mm dowels are imported from Rothoblaas in Italy. All the connections were recessed and encapsulated by the surrounding wood material, and is therefore inherently fire resistant.

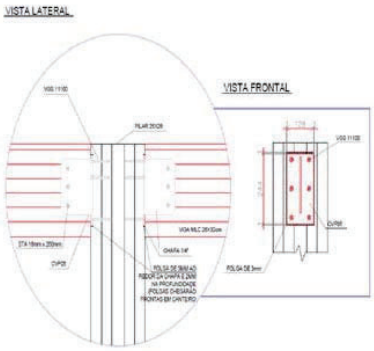

Figure 4: *Detail of connection Columns / Beams steel plate.*

The structural timber is with few exceptions covered behind either glass or metal sheeting. This protects the timber from rain and sun, increases durability and reduces maintenance.

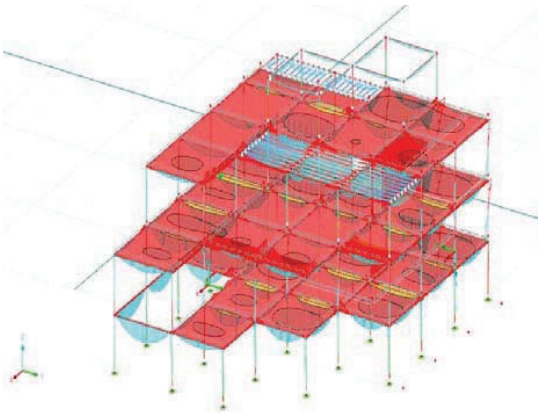

Figure 5: *Global RFEM-model of DENGO*

5 STRUCTURAL FIRE DESIGN

The current Brazilian codes and standards do not adequately address or provide engineering guidance for modern mass timber structures. Base on that, to made the building system we commonly adopt design methods and requirements from regions with well-established mass timber industries, such as those in Europe Eurocode-5.

For a building of this size, Brazilian standards require a 60 min fire-resistance rating on the primary structural frame. This rating is achieved through the charring effect of wood, which provides thermal protection of the competent wood below the char layer. The structural fire design is also performed according to the Eurocode 5. The so-called reduced cross-section method has been used, which determines the effective residual cross-section after charring, A notional charring rate of 38 mm/hr leads to a charring depth of 38 mm after 60 minutes.

Steel connectors are typically designed to rely on wood cover as their protection against fire. A similar concept is used to evaluate the required wood cover thickness to achieve a fire-resistance rating on a steel connector, they are not able to be protected with an adequate wood cover, care must be taken to provide some other means of fire protection. In the typical cases of column base plates and column- to-column connections, the steel is typically protected with a grouted pedestal or by painting the exposed steel surfaces with intumescent paint.

https://doi.org/10.52202/069179-0548

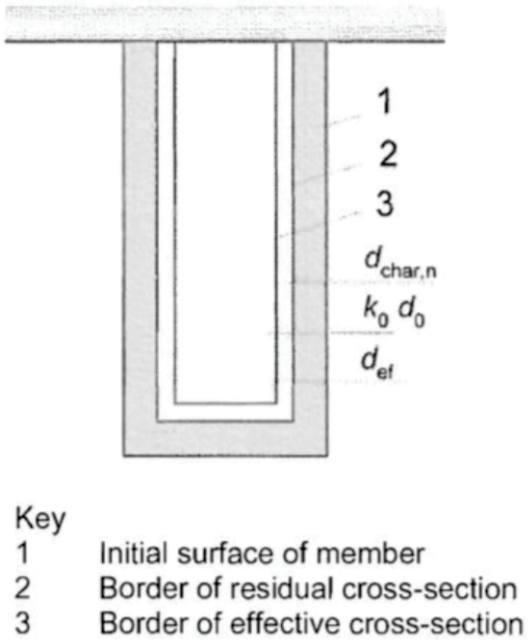

Figure 6: *Definition of residual cross-section and effective cross-section*

6 MATERIALS

All load-bearing structures in the building are wooden. Glulam is used for the columns and beams. Cross-laminated timber (CLT) panels are used for floor/ceiling and internal walls as the wood-frame system.

In the structural model, the properties stated for glulam strength classes GL24h are used. The CLT specifications have bending strength fmk=24 MPa, and properties similar to C24 structural timber. The totally of the glulam is made out Pine of Brazil. Glulam that can be exposed to weathering is made of copper-treated lamellas from Nordic Pine. Structural timber in the building modules and CLT is produced one side from Spruce and the other side is Pine of Brazil.

7 LOADING

The Eurocodes with national annexes for Norway were used to determine the design loads. The wind loading turned out to be the dominating load in the design combinations. The calculated maximum wind speed became V = 45.0 m/s, giving corresponding wind pressure of q = 0,90 kN/m2. The wind load was applied as a transient static load on two sides of the building. The wind load directions considered were 0° e 90°.

Self-weight is set to 5,5 kN/m3 for glulam and CLT, and 25 kN/m3 for the concrete topping. The following loads were applied:

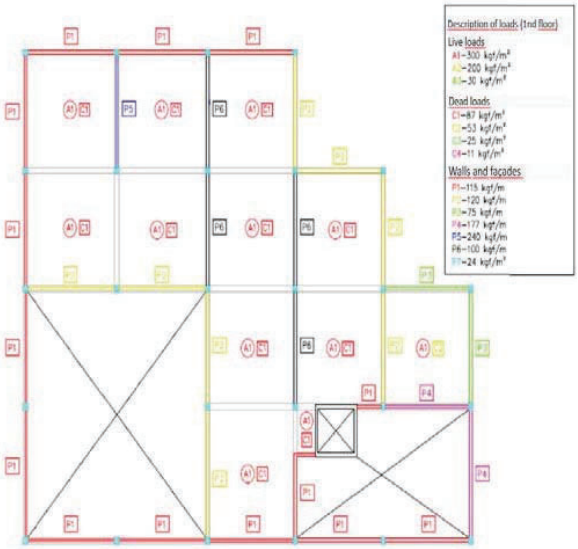

Figure 7: *First floor Loadings*

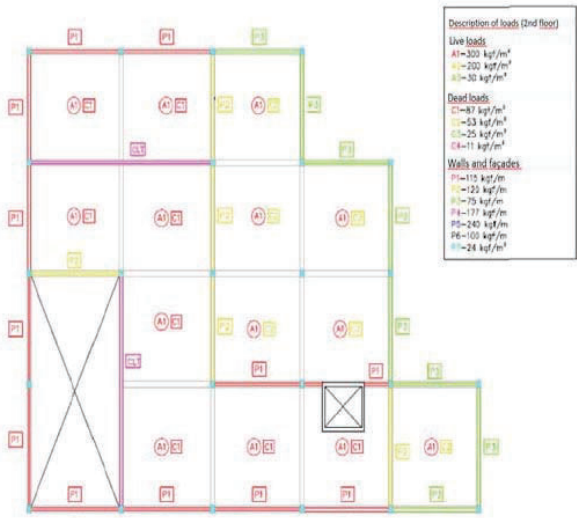

Figure 8: *Second floor Loadings*

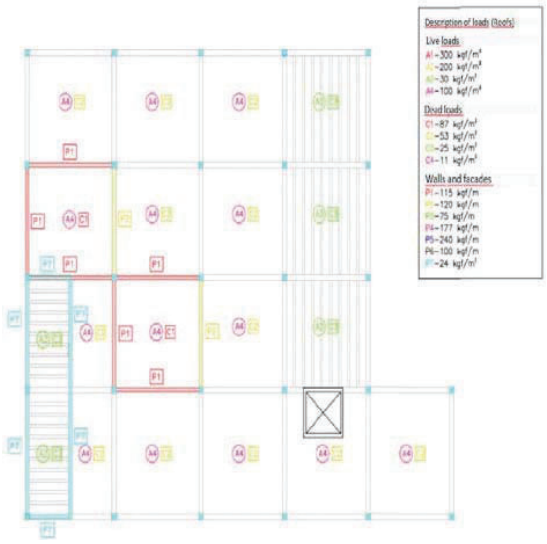

Figure 9: *Third floor Loadings*

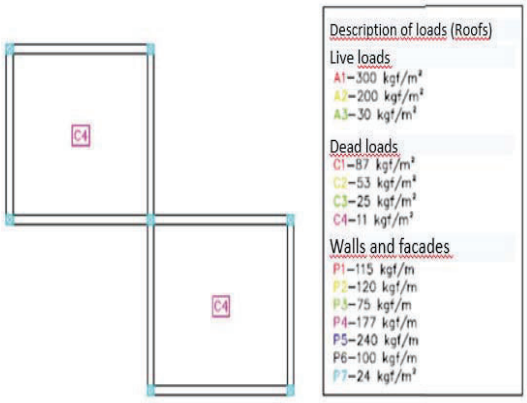

Figure 10: *Roof floor Loadings*

8 ASSEMBLY

The assembly of the building is mostly about installation of prefabricated elements on site. Optimizing the logistics and installation procedures are important to get a smooth building process. Rewood and Pedra Forte use a tower crane as well as a climbing scaffolding system during the building erection.

A step-by-step model ensures that the building can be built correctly. Below is a simplified visualization of the assembly.

The main structure was assembly with 37 days of work. At the moment of this study, the building is already finished September 2020.

Figure 19: *Completed buildng.*

9 CONCLUSIONS

We can conclude that the use of wood for building structures has high potential in the Brazilian market because besides presenting a fast and clean solution it provides volume in the production of engineered wood products. Consequently lowers the value of the product thus allowing a greater opportunity of competitiveness with other materials - it is a renewable and sustainable solution.

10 ACKNOWLEDGEMENT

The dedication of many researchers, engineers and architects is allowing for the refining of traditional techniques, the adoption of new technology and the deployment in the country of an industry focused on the construction in wood.

World Conference on Timber Engineering Oslo 2023

SPOR X – 10-STOREY TIMBER OFFICE BUILDING, DRAMMEN, NORWAY

Katie Overton[1], Gaute Mo[2], Ivana Katavic[3], Manuel Sánchez-Solís[4]

ABSTRACT: SporX is a ten-storey office building in Drammen, Norway. Timber, as the main structural material, was chosen at the start of the project being a readily available local material and to support the ambition for maximum sustainability to achieve a BREAM-NOR Outstanding certification. Another advantage was to minimise building loads at the riverside location with poor ground conditions. Based on an optimal architectural layout SporX makes use of timber elements, both glued-laminated and cross-laminated, for all load-bearing structure above ground floor. Two large central CLT cores, combined with two façade shear walls, act as bracing elements for the 600m^2 floor plate giving a robust timber structural solution designed for R90 fire resistance. The element removal method is used to resist progressive collapse. Timber connections are made using fully threaded, cylindrically headed, wood screws and proprietary concealed connectors. BIM was used by all disciplines for design coordination and to produce a digital twin controlled throughout the construction process. Timber structural elements were fabricated from a LOD400 BIM model developed by Degree of Freedom. Fabrication with strict tolerances allowed for a rapid construction process. Larger element sizes were chosen as having design advantages both for robustness and for connections design.

KEYWORDS: Timber, CLT, cross-laminated, fire, connections, BIM, fabrication, LOD, BREAM_NOR, digital twin

1 INTRODUCTION

Degree of Freedom were responsible for the structural design of SporX, an innovative, ten-storey, timber-framed office building, built on behalf of the property developer Vestaksen Eiendom AS.

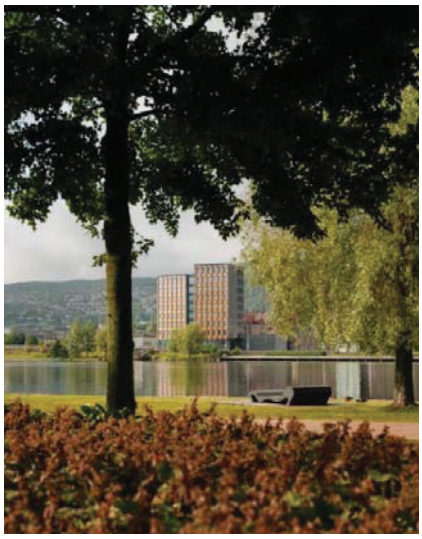

Figure 1: *SporX - Location*

The building, in Drammen, Norway, is adjacent to both the river and the main train station, and was conceived by the architects, Dark, to become the most sustainable office building in the Nordic countries. The use of structural timber as a low-carbon construction material was therefore a fundamental part of the project from the start. This paper describes the advantages of using timber compared to more standard solutions in concrete or steel, for all the main load bearing elements above ground level. Key aspects and challenges related to the design, modelling, fabrication, and construction process are explained. There is a focus on design aspects where special attention was needed including fire design, connection details, horizontal sway, vibrations and progressive collapse.

2 DESIGN PRINCIPLES

2.1 ARCHITECTURAL CONCEPT

The architectural intent was for a sustainable office building and as the building's location has excellent links to public transport only the provision of bicycle parking was needed. Features such as this, combined with the use of timber as the main structural material were key to achieving the BREEAM-NOR Outstanding certification. Harvested responsibly, and in this case locally, timber is arguably one of the best tools both architects and engineers have for reducing greenhouse gas emissions and storing carbon in buildings. Timber, as a construction

[3] Ivana Katavic, Degree of Freedom AS, Oslo, Norway, i.katavic@dofengineers.com
[4] Manuel Sánchez-Solís, Degree of Freedom SLU, Valencia, Spain, m.sanchez@dofengineers.com

https://doi.org/10.52202/069179-0549

material also has inherent benefits for the health and well-being of the building users, for the environment and for the construction process. Advantages include reducing CO2 emissions and construction time whilst maintaining a competitive overall cost.
Architecturally an aesthetically pleasing interior design can be achieved taking advantage of the exposed structure as seen in Figure 2.

Figure 2: *Interior with exposed timber*

The building is divided into nine-storey and ten-storey parts with a two-storey lateral extension, as shown in the architectural section below, and provides approximately 6800m^2 of office space.

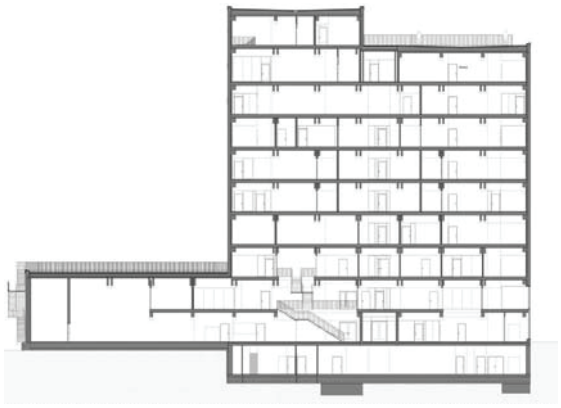

Figure 3: *Architectural section*

2.2 STRUCTURAL CONCEPT

Below the main building is a single storey reinforced concrete basement founded on steel HP piles to bedrock at a depth of approximately 100m. The use of timber was shown to give a 50% cost saving for the foundation design due to the reduced overall building loads.
The architectural requirement for two large cores servicing a relatively small floor plan allowed the original concrete core walls as planned at concept design phase to be substituted by cross laminated timber shear walls. Additional CLT shear walls were introduced on the two side façades to increase the stiffness in the weaker direction. Figure 4 shows a typical floor plan highlighting the location of the shear walls. Glulam timber "columns" are used to reinforce both the corners of the cores and the ends of the shear walls.

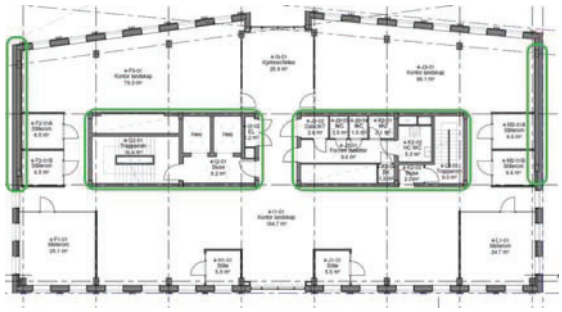

Figure 4: *Architectural floor plan showing shear wall location*

The structural grid is 4.85m with vertical loads transferred via CLT floor slabs to a system of double glulam beams and columns as can be seen during construction in Figure 5. The CLT floor slabs act as diaphragms for the transfer of horizontal actions to the shear walls. At ground level all loads, both horizontal and vertical are transferred to the concrete substructure. This load transfer is one of the key details in timber building design.

Figure 5*: SporX under construction showing the exposed structural frame*

https://doi.org/10.52202/069179-0549

2.3 MATERIALS

2.3.1 Glued laminated timber

GL30c glulam was used for both columns and beams based on standard Nordic production dimensions. Column sizes are typically 355mm by 450mm. In addition, 280mm by 450mm GL30c columns were used to reinforce the ends of the CLT shear walls and facilitate the connection between the timber superstructure and concrete substructure.

Variable depth beams, 190mm wide were adopted to suit both the architectural concept and the integration of openings for services as can be seen in Figure 6.

For the structural design only the beam section over the large openings is considered for calculations, however the timber section adjacent to the holes is reinforced with screws to control possible cracking.

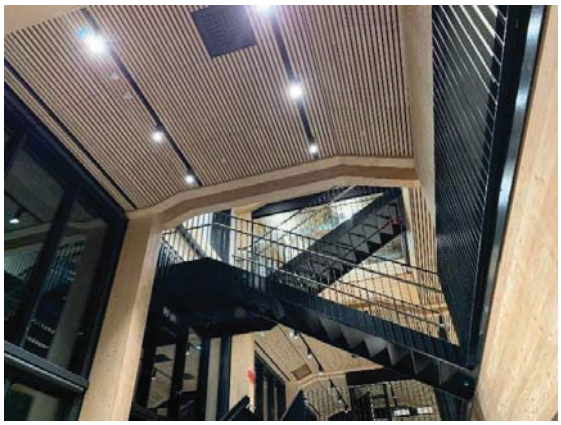

Figure 6: *Double glulam beam & glulam column*

Figure 7: *Opening for services through glulam beam*

2.3.2 Cross laminated timber

Floor slabs are 180mm five-layer cross-laminated timber. Main shear walls are 260mm seven-layer CLT, as shown in Figure 8, with 220mm secondary walls in seven-layer CLT.

Figure 8: *CLT layers in shear walls*

2.3.3 Connectors

The connections between timber elements are by using fully threaded, cylindrically headed timber screws, or by either proprietary or bespoke timber connectors.

2.3.4 Quantities

A summary of the total structural building materials above ground incorporated in the finished building is shown in Table 1.

Table 1: *Material quantities*

Material	Quantity
GL30c glulam	520m3
180(5s) CLT slabs	940m3
260/220(7s) CLT walls	950m3
Timber screws	≈64,000no.
Proprietary brackets	≈64,000no.
Timber nails	≈64,000no.
Steel plates	2,650kg

3 STRUCTURAL DESIGN

3.1 GENERAL

The building is designed in accordance with the relevant Eurocodes to the Norwegian National Annexes [1][2].

No requirement for seismic verifications was established early in the design process by confirming a seismic ground acceleration of 0.2596m/s^2 with NORSAR. The subsequent publication of the 2021 version of the Norwegian National Annex [3] confirmed a value of a_{gR} = 0.25m/s^2 for Drammen Kommune.

For consideration of progressive collapse, the building is classified as consequence class 2b (upper risk group)[4] for an office building less than 15 storeys. The structure allows for the notional removal of columns and beams. Double-storey height columns, triple-storey height CLT walls, continuous façade beams and triple-span CLT floor slabs enhance the structural redundancy and result in a robust overall design. This also minimises the number of connections.

https://doi.org/10.52202/069179-0549

Sway imperfections, based on ϕ equal to 0.005 radians are accounted for by applying Equivalent Horizontal Forces to the structure at each level.

3.2 SERVICEABILITY LIMIT STATE

Timber structures are commonly governed by the Serviceability Limit State, both by vertical and horizontal deflections and vibrations. The design of the 180mm thick CLT floor slabs, spanning 4.85m, was governed by deflection and vibration criteria.

The inclusion of the slip modulus (k_{serv}) for all timber connections was critical for evaluating the overall sway of the structure under horizontal loads. This was particularly relevant for the joints between the panels that formed the CLT shear walls and for the connections between CLT walls and concrete substructure.

The lateral stiffness of the structure is also relevant to checking the effects of the deformed frame geometry and whether a second order linear analysis is needed although EC5 does not give an explicit limit unlike the concrete and steel codes.

3.3 FIRE DESIGN

Well defined and predicable fire behaviour is an intrinsic property of mass timber elements. All the principal structural elements are designed to guarantee a load bearing resistance for 90 minutes in the fire design situation, R90. Generally the structural timber elements are partially or completely exposed to fire as can be seen in Figure 9.

Figure 9: *Timber structure exposed to fire*

Columns have been designed as exposed on all four sides, double beams exposed to fire on one side and all CLT floor slabs exposed to fire on one side only. The CLT shear walls in the cores are designed for fire exposure on both sides, although with a reduced fire duration on the second side based on the separation into fire cells with R60 fire doors.

Timber columns and beams have been designed using the reduced cross section method from NS-EN 1995-1-2 [2]. This method defines a charring depth of 70mm for R90. This char layer insulates the core of the section preventing it heating up. The reduced section maintains its full strength and is verified for the critical fire load combination. In some locations particular elements are considered as redundant in the fire design situation. An example of this is the timber diagonal bracing element in the façade shear wall seen below in the Architectural model.

Figure 10: *Architectural model showing timber diagonal bracing*

Timber-to-timber connections were also verified for R90 fire resistance. Generally this was achieved by providing the calculated depth of timber cover to the concealed connections.

3.4 FINITE ELEMENT MODELLING

A finite element model in SAP2000 of the complete timber structure was used for the verification of both the mass timber elements and for the connections. This model enabled aspects related to the structural design to be considered including:

- Timber as an orthotropic material.

https://doi.org/10.52202/069179-0549

- Orthotropic panel build-up for CLT.
- Connections slip modulus, k_{serv}.
- Nonlinearity.
- Imperfections.
- Fire design situation.

Glulam elements, both beams and columns, were modelled using the frame element of the software. CLT panels, both slabs and walls were modelled using the thick shell element which combines both membrane and plate degrees of freedom.

Timber is an orthotropic material thus modifications of the elastic parameters need to be carried out for both frame and shell elements. To correctly model the shear deformation of the timber frame elements a reduction factor is required for the shear stiffness. For the orthotropic CLT panels, modelled as shell elements, the values for the stiffness matrix were calculated using the software CLT designer created by the Institute for Timber Engineering and Wood Technology of Graz University of Technology (©holz.bau forschungs gmbh).

For the connections between different timber parts links were used with the stiffness for each degree of freedom defined according to the calculated slip modulus for the connection type. For vertical loads, a high stiffness value is defined to ensure that the loads are transferred as expected. Non-linear links were used to model connections in the core walls that are very stiff for compression loads but have a reduced stiffness, or no capacity for the transfer of tension loads.

The concrete substructure is not included in the timber FE model, as shown in Figure 11 and at the base of each column or CLT panel links were used to model the actual connection stiffness and behaviour at the timber-concrete interface.

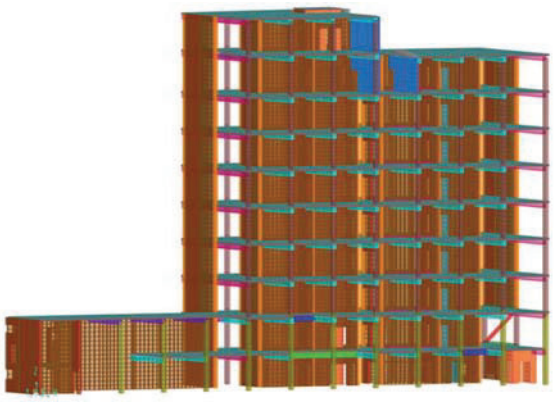

Figure 11: *3D view of FE model*

Degree of Freedom have developed a design tool, compatible with SAP2000, Timber Interactive Modelling and Post-Processing Software (TIMPS) for the purpose of the analysis, design and optimization of timber structures based on the relevant design codes and technical approvals. This tool can provide visual plots of the results for both CLT panel and connection verifications. Selected images are shown below in Figure 12 with the results of both the in-plane shear check and the combined axial load, bending check for a section of the 260mm CLT shear wall.

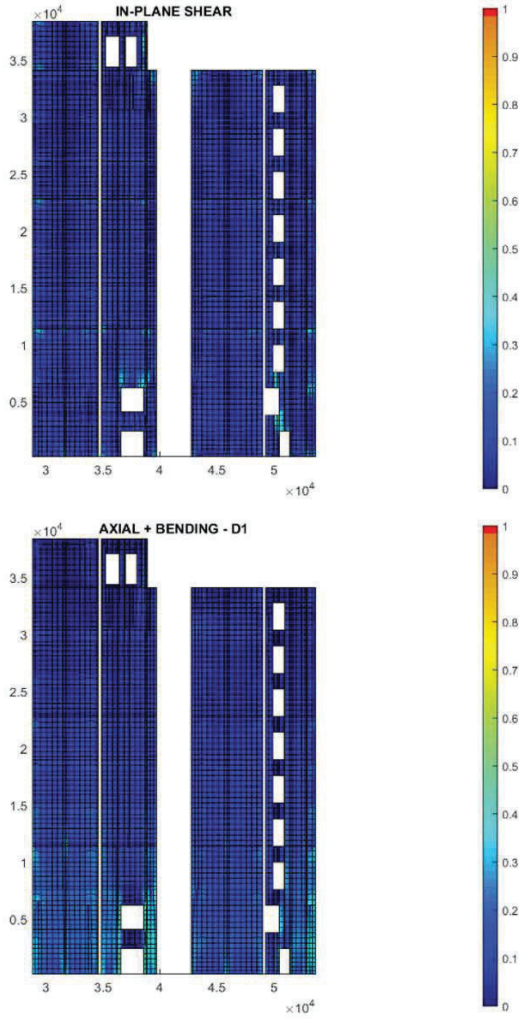

Figure 12: *TIMPS output for CLT verification*

Similarly output for the connections between CLT panels can be plotted. Figure 13 shows the plot for vertical shear forces, an envelope for all ULS load combinations, at the connection between the CLT panel and the glulam column at the corner of the cores.

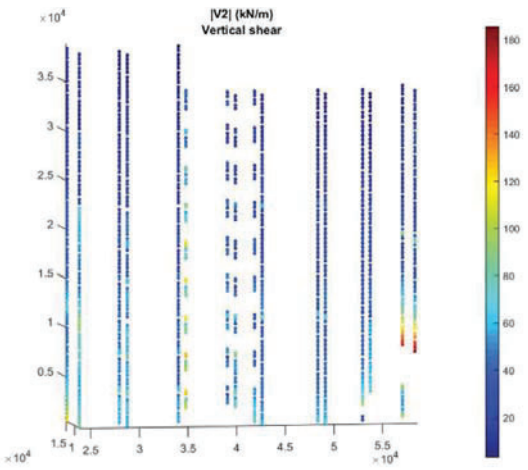

Figure 13: *TIMPS output for connection forces*

3.5 CONNECTIONS

3.5.1 Timber-to-concrete connections

At the base of the CLT shear walls a combination of proprietary steel angle brackets and plates are used to transfer horizontal shear forces to the concrete substructure as seen in Figure 14 and Figure 15.

At the corners of the CLT cores and at the ends of the CLT shear walls a bespoke steel column shoe was designed. This needed to be hidden within the depth of the floor finishes and can be seen in both Figure 14, before floor finishes were installed, and in the construction detail in Figure 16.

Figure 14: *Timber to concrete connection – CLT panel and glulam column*

Figure 15: *Proprietary timber to concrete connector plate*

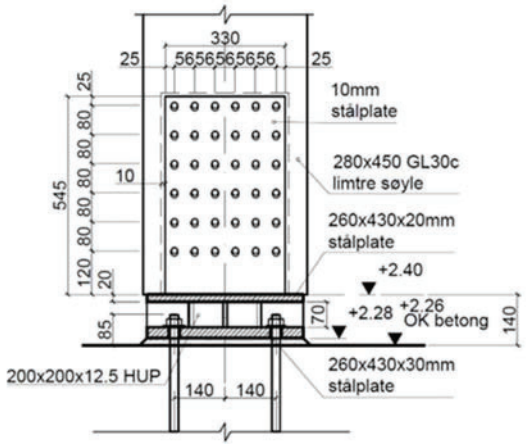

Figure 16: *Construction detail – column shoe*

Careful detailing was required for all timber to concrete connections to allow for different construction tolerances and because of the limited architectural finishes to conceal connections as can be seen in the finished building in

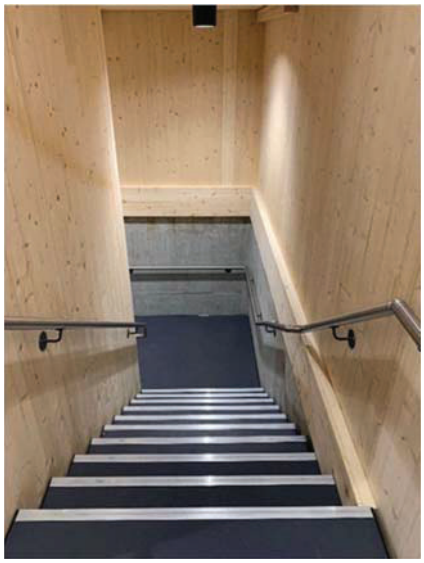

Figure 17: *Timber- concrete interface in finished building*

3.5.1 Timber-to-timber connections

Principal timber-to-timber connections include the double beam to column connections which uses fully threaded timber screws at 45°, WT-T ø8.2x300mm screws from SFS intec. This resulted in a concealed connection with a good load carrying capacity. To facilitate erection the columns are notched to allow for temporary support. The construction detail is shown in Figure 18. Images from both during construction and in the finished building show how timber plugs were used both for aesthetic reasons and to protect the timber screws for the R90 fire design situation.

https://doi.org/10.52202/069179-0549

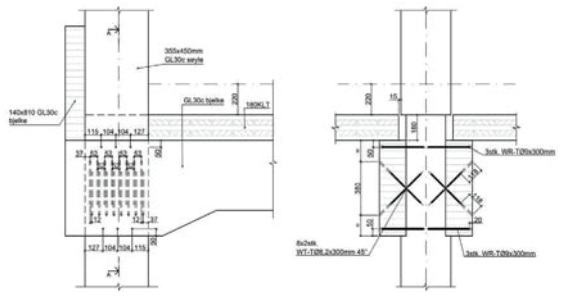

Figure 18: *Timber double beam to column connection*

Figure 19: *Timber beam to column connection – without timber plugs*

Figure 20: *Timber beam to column connection – finished detail*

For timber beam to CLT wall connections both the LOCKT and ALUMAXI concealed connectors from the supplier Rothoblaas were used. This combination of proprietary connector at one end of the beam and screwed connection at the other allowed for erection tolerances.
Between CLT slabs and the CLT core walls proprietary steel angle brackets were detailed to transfer horizontal forces due to wind loads from slab diaphragm to shear walls. Figure 21 shows the typical distribution of angle brackets.

Figure 21: *Steel brackets at CLT slab to CLT shear wall interface*

The connection between CLT panels make use of fully threaded timber screws installed at 45°.

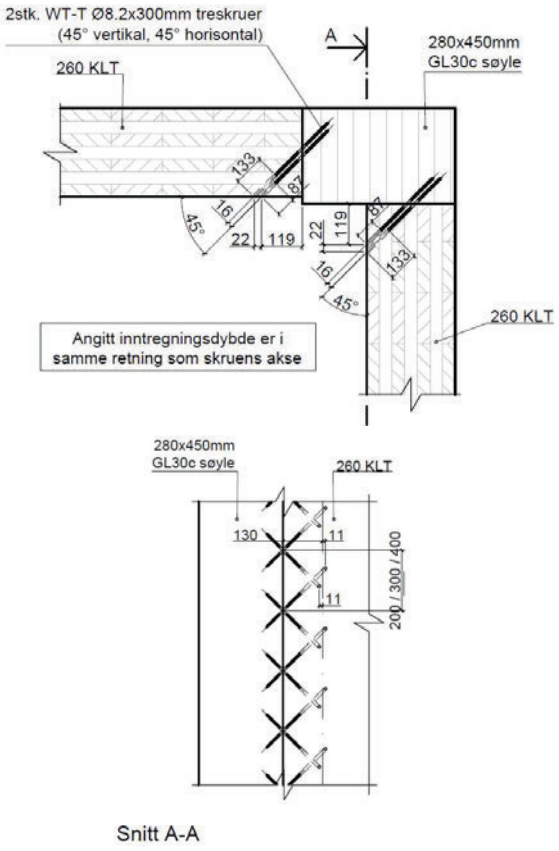

Figure 22: *Timber screws at CLT shear wall to glulam column connection wall interface*

4 BUILDING INFORMATION MODELLING

The project used the most up to date BIM methods during both design and construction. A digital twin was also created and during construction a weekly scan was used to control non-conformances by comparison with the digital twin.

BIM models were developed by all disciplines and coordinated during the design phase. This resulted in a fully integrated LOD350 model at the end of the design phase.

This timber structural model was then advanced to a LOD400 fabrication model on behalf of the contractor. Figure 23 shows the LOD400 timber model as used by the timber supplier for production.

Erection drawings were then produced directly from the BIM model using the software Cadworks.

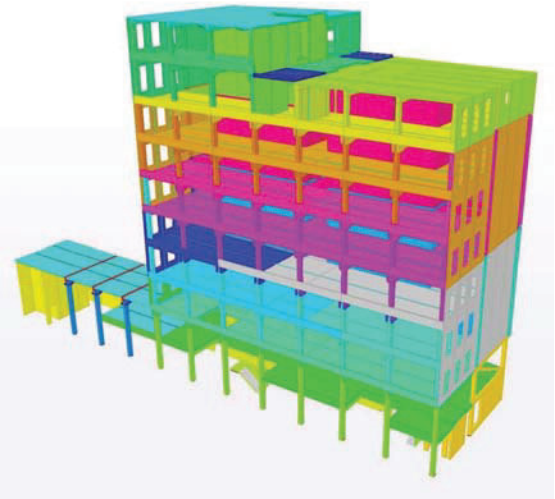

Figure 23: *LOD400 timber production model*

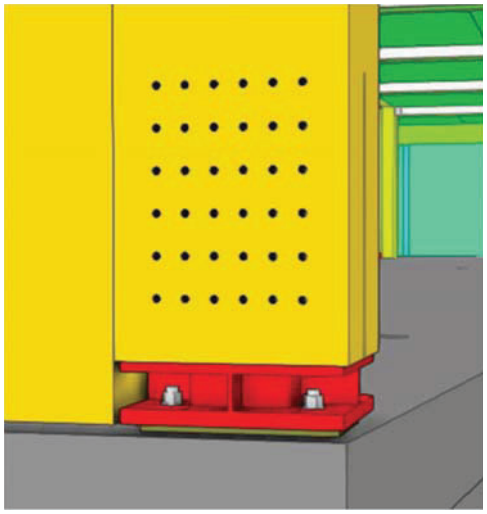

Figure 24: *LOD400 timber production model – connection detail*

Erection drawings were then produced directly from the BIM model using the software Cadworks. An example of the drawings for the 260mm CLT panels that form one of the cores can be seen in Figure 25.

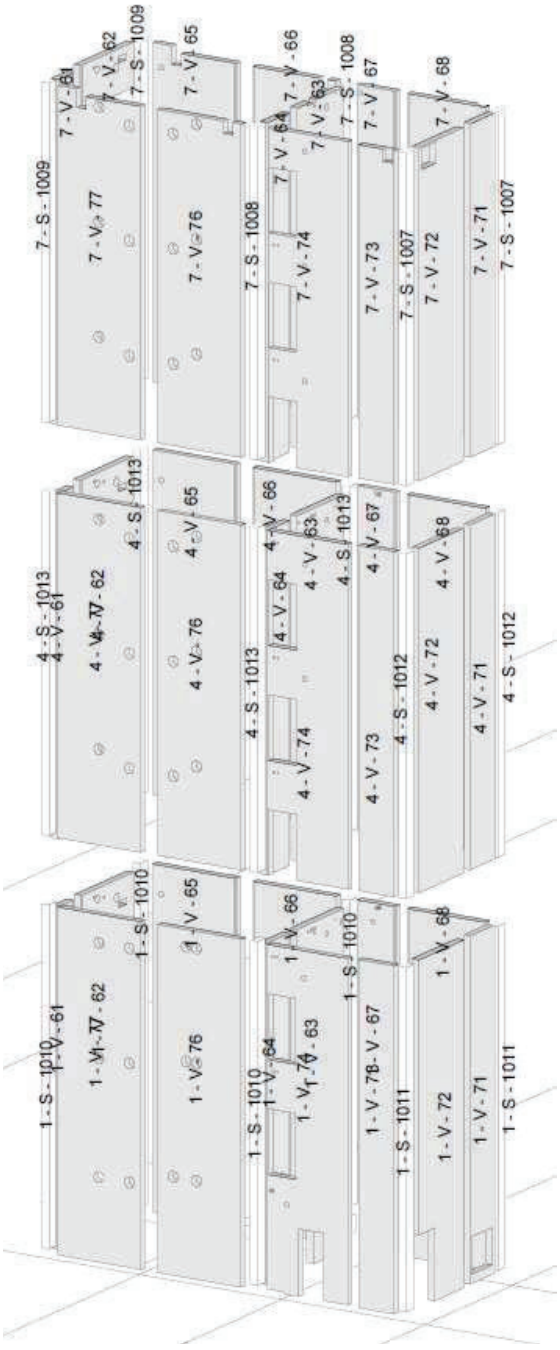

Figure 25: *Timber erection drawing for CLT core*

https://doi.org/10.52202/069179-0549

5 CONSTRUCTION PROCESS

The timber frame was erected over a period of 15 weeks in early 2021 and the building completed in 2022. A key feature of timber construction is the rapid work on site due to the precision of the prefabricated elements. Figure 26 and Figure 27 show the progression of the timber erection from start to finish.

Figure 26: *Start of timber erection*

Figure 27: *Completion of timber erection*

6 CONCLUSIONS

The design of SporX uses a traditional building material, timber, as the load bearing structure for a ten-storey office building. It takes advantage of BIM modelling for the timber elements that can then be prefabricated with strict tolerances for a rapid construction process. The result is an innovative building that makes the best use of a traditional building material with the most up to date construction aids with the use of BIM and precision fabrication.

The result of the architectural and engineering vision of this project can be seen in the images below of the building in its final stages of fit out.

Figure 28: *SporX – finished interior*

Figure 29: *SporX – finished building*

ACKNOWLEDGEMENT

The realisation of this project is thanks to a dedicated design team including the architects, DARK Arkitekter (https://darkarkitekter.no/) The completion of the project has been in collaboration with the main contractor, Betonmast (https://www.betonmast.no/) and the timber fabricator, Splitkon (https://splitkon.no/).

World Conference on Timber Engineering Oslo 2023

Case Study in the Next Generation of Point-Supported CLT Structures

Jamie Pobre Sullivan[1], Carla Dickof[2],Christian Slotboom[3]

ABSTRACT: The new Tall Timber Student Housing tower in Burnaby, British Columbia at the British Columbia Institute of Technology (BCIT) represents a shift forward in tall, hybrid, encapsulated mass timber construction (EMTC). The tower comprises of flat, two-way spanning cross-laminated timber (CLT) floor plates, point-supported on hollow structural steel columns. The structure is encapsulated per the 2018 British Columbia Building Code and uses the latest advances in engineered wood products, prefabrication, and encapsulation strategies for fire resistance. The following case study provides an overview for the next generation of point-supported CLT structures, as encapsulated tall timber buildings, highlighting design challenges and their solutions.

KEYWORDS: Tall Wood Buildings, Mass Timber Encapsulation, Mass Timber, CLT, Point-supported CLT

1 INTRODUCTION

Until recently, timber construction was restricted in height due to limitations in stability and in fire resistance. However, recent advancements in engineered wood products, prefabrication, construction approaches, and codified encapsulation have led to a shift in these restrictions. These advancements include lessons learned in mitigating wood moisture during construction and shipping, and the prevalence of larger high-frequency presses that allow fabrication of wide-format cross laminated timber (CLT) panels beyond the traditional 3.0-metre (10'-0") width. As a result, delivery of mass timber projects has significantly improved. Better understanding of fire resistance in mass timber with use of encapsulation measures, alongside demonstration in precedent projects, has catalysed the use of mass timber in increasingly taller, EMTC-compliant hybrid buildings.

The TallWood House at the University of British Columbia in Vancouver, BC set the precedent for tall timber buildings. With 17 mass timber levels over 1 level of concrete podium above grade, TallWood House achieved a cost competitive alternative to the common concrete student residential tower. The mass timber superstructure comprised of two-way spanning CLT panels supported by glulam timber (GLT) columns; a point-supported CLT system. This flat slab system uses no beams, allowing for unobstructed service distribution. Thus, the need for significant penetrations through supporting structure is minimized, and allows for more compact floor-to-floor heights without sacrificing head room.

Early coordination and construction modelling allowed for an accelerated construction timeline, with the construction of the building completed 2 months ahead of schedule. This success demonstrated what is achievable in tall mass timber structures and that point-supported CLT is cost competitive system for tall-rise, multi-unit residential construction. Stemming from this success, the British Columbia Institute of Technology (BCIT) undertook the development of the Tall Timber Student Housing (BCIT Tall Timber Tower) as the latest tall-timber project incorporating a point-supported CLT floor structure. This project takes advantage of the latest advancements in product fabrication, as well as the new Encapsulated Mass Timber Construction (EMTC) [1] provisions in the National Building Code of Canada (NBCC 2020) [2], which provides a code compliant approach to tall timber using provisions for encapsulated mass timber. Using lessons learned from TallWood House, the BCIT Tall Timber Tower utilizes a wide format panel on hollow structural steel (HSS) columns that aim to further accelerate structural and construction schedule efficiencies. The following case study highlights the Tower's unique design challenges and the proposed solutions implemented to resolve those challenges that aim to make it the next generation in tall, hybrid, ETMC-compliant point-supported CLT structures.

2 CODES AND STANDARDS

BCIT Tall Timber is located in the province of British Columbia in Canada and is governed by the 2018 British Columbia Building Code (BCBC) [3], which was updated in 2019 to include the provisions for EMTC from the 2020 NBCC [2] for tall-rise timber buildings up to 12 storeys.

2.1 Code Compliance and Fire Design

BCBC 2018 Division B [3] classifies encapsulated mass timber construction up to 12 storeys. The Architectural Institute of British Columbia (AIBC) and the Engineers and Geoscientists of British Columbia (EGBC) jointly published the Joint Professional Practice Guidelines for EMTC [1], which include guidelines to the 2019 revisions to the BCBC requirements for minimum member sizes,

[1] Jamie Pobre Sullivan, Associate, Fast+Epp, jpobresullivan@fastepp.com
[2] Carla Dickof, Associate Principal, Fast+Epp, cdickhof@fastepp.com
[3] Christian Slotboom, Graduate Engineer, Fast+Epp, cslotboom@fastepp.com

https://doi.org/10.52202/069179-0550

fire rating requirements (FRR), and minimum thickness and extent of gypsum encapsulation of the wood. Under the 2018 BCBC Division B, EMTC is required to be at least partially encapsulated to ensure fire safety, with the structural system designed to achieve a 2-hour fire resistance rating through any combination of encapsulation and/or char. A typical encapsulated floor assembly that meets this fire resistance rating includes a build up of 38mm (1½") thick concrete topping over a mass timber floor panel and 2 layers of 12.7mm thick Type X gypsum board at the underside, which achieves a maximum 50-minute encapsulation rating; or 60 minutes, if the gypsum layers are directly applied to the CLT per a prescribed spacing according to CSA O86-19 [4]. See Figure 1 below. The remaining 60 or 70 minutes required to achieve a 2-hour fire resistance rating must be achieved through char on the underside of the CLT panel. The concrete topping provides the full 2-hour fire resistance rating at the top side of the floor assembly, as well as providing separation between floors.

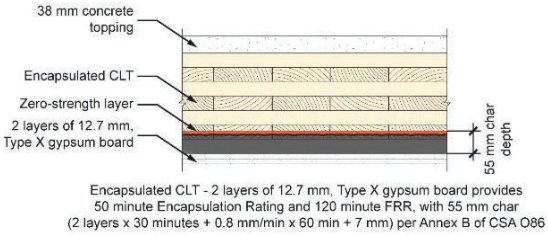

Figure 1: *Encapsulation of CLT from the Joint Professional Practice Guidelines published by AIBC and EGBC [1].*

The HSS columns must also be fire rated or encapsulated, and must meet a mass (M) to perimeter (D) ratio of 75 in conjunction with minimum 31.8mm of Type X gypsum board in order to provide a 2-hour fire resistance rating per Appendix D of the 2018 BCBC Division B. The minimum M/D ratios can control the design of the HSS column, where axial loads may be low.

2.2 Material Standards and Timber Design

The material standards for wood construction in Canada (CSA O86-19) [4] provides prescriptive approaches for the design of timber elements for typical gravity conditions, and for both exposed and encapsulated conditions in fire. Within the CSA wood material standard, guidance is provided on the bending capacity, stiffness, and fire design of CLT panels.

Unlike a post-and-beam system where panels are line-supported, a main consideration for point-supported system design is rolling shear at the column supports, similar to punching shear in a concrete flat slab system. Rolling shear in wood is defined when timber grains "roll over" each other under shear stresses perpendicular to grain. Rolling shear strength is much lower than longitudinal shear strength in timber. Testing shows that panel configuration and confinement at the supports result in added restraint against rolling shear, and thus, effectively increases the assumed rolling shear strength. However, low rolling shear strength values often result in rolling shear being a controlling factor. The punching shear resistance and reinforcing is not addressed in Canadian standards, and thus, research completed in Europe and Canada is used as a baseline for the punching shear evaluation [6,7], similar to the design of TallWood House [5]. Further desktop studies and physical testing [6,7] has also helped to justify values and methods that go beyond the codified CLT design approaches.

To design for resistance against rolling shear, strategies similar to those used for punching shear design in a concrete flat slab are available. This includes using larger supports at column locations to increase shear area, or using inclined fully-threaded screws to reinforce the CLT locally, similar to stud rails in a concrete slab. In general, however, reinforcing is avoided.

3 CASE STUDY OVERVIEW

BCIT Tall Timber Tower is a 22,800 m^2 12-storey building with 11 stories of encapsulated point-supported CLT floors over 1 level of concrete podium above grade and one level of basement below ground. The Tower will house 464 studio units in the upper stories; offices, student lounges, and storage will be contained within the ground and below-grade basement levels. Levels L2 through L6 contains single studio units with a common amenity room at the northwest corner and communal kitchens for residents. Above, at Levels L7 through L12, the same single studio units and common amenity rooms occur as they do in the floors below, but the communal kitchen areas are replaced with accessible studio apartments. See Figure 2 below for a typical architectural layout at the BCIT Tall Timber Tower.

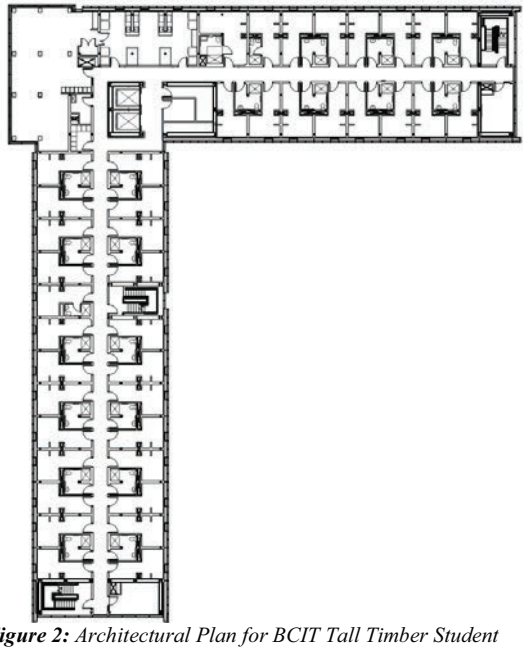

Figure 2: *Architectural Plan for BCIT Tall Timber Student Housing, Courtesy: Perkins&Will*

https://doi.org/10.52202/069179-0550

Given the consistent architectural layout at each floor, the CLT panel sizes are consistent throughout the majority of the typical floor plate. 3.5-metre (11'-6") wide CLT floor panels are supported by HSS columns at the edges and spaced at 4.5 metres across the building width along the length of the panel. The CLT panels are designed for two-way bending with consideration for punching shear, and are designed to develop a 2-hour fire resistance through 1 hour of effective encapsulation and 1-hour char in the panel. The use of steel columns simplifies the column-to-column connection, in comparison to the GLT column-to-column connection used at TallWood House, which minimizes fabrication time and adds speed to steel erection. The smaller HSS sections also allows for columns to occur within suite-to-suite party 152mm (6") deep steel stud walls that align with column grid spacing. This results in the use a of a standard party wall assembly. The lateral resisting system at the BCIT Tall Timber Tower consists of moderately ductile, concentrically braced frames above level L2 and concrete shear walls below level L2 down to the foundation. The braced frames are situated at the egress cores: at the northeast and southwest "bookends", the central elevator and service room core, and the central stair core. Like the typical HSS columns, braced frame columns are encapsulated within the walls, and anchor down into the concrete shear walls that support them with anchor bars continuing down to foundations from level L2. See Figure 3 below for a 3D rendering of the structural framing for the building.

4 KEY DETAILS

The design at BCIT Tall Timber Tower takes advantage of opportunities in wood technology, updated provisions in the building code for encapsulation, and lessons learnt from TallWood House, representing the next generation in point-supported CLT. It optimizes efficient panel design and utilizes added benefits in use of a hybrid design by way of the HSS columns and steel braced frame lateral resisting system. The success of these improvements to TallWood House further underline mass timber's viability in cost and constructability against the more conventional concrete tower residential construction.

4.1 CLT Layup

CLT panels for BCIT Tall Timber Tower consist of 5 total layers of machine stress-rated (MSR) and visually graded lumber interlaced to provide adequate bending resistance and stiffness in two directions. To reduce the number of columns and maximize the CLT span in the strong axis, MSR grade lumber is specified for the primary (outer) layers for increased bending resistance and stiffness. Weak axis bending is significant for point supported CLT, and due to the large panel width, a minimum of No.1/No. 2 visually graded lumber is required in the weak direction. Figure 4 below summarizes the layers used. At the time of design, most North American CLT manufacturers only

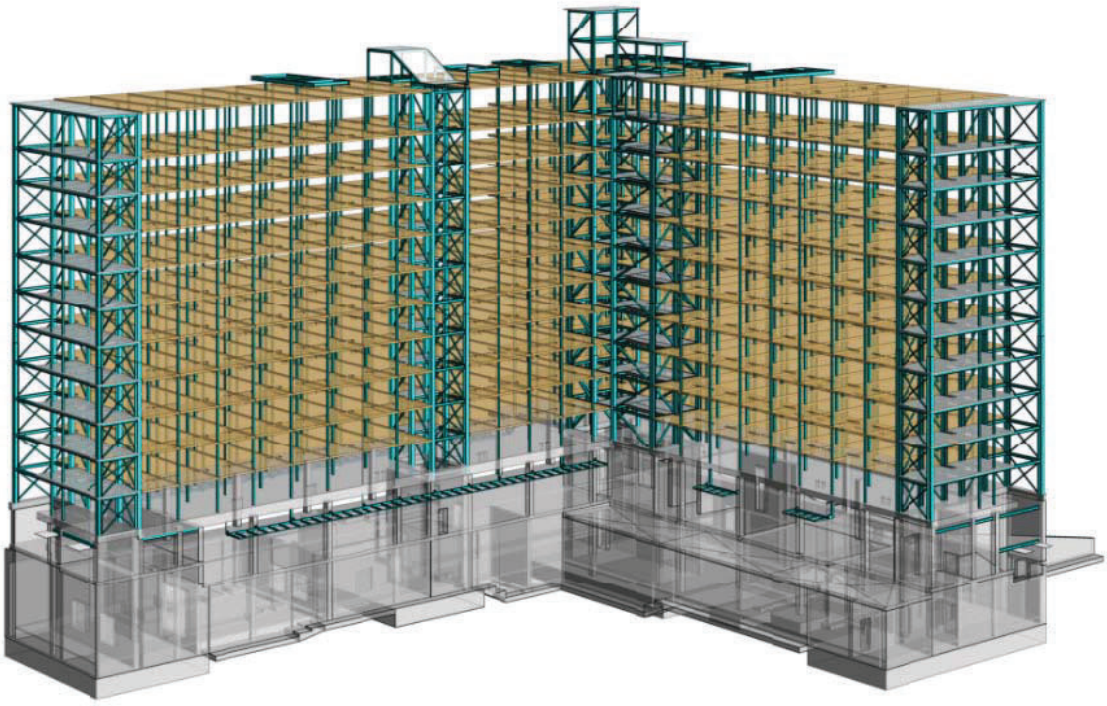

Figure 3: *A 3D rendering of the structural elements for BCIT Tall Timber Student Housing*

https://doi.org/10.52202/069179-0550

provided No.3 laminations in the weak axis, and therefore a custom CLT panel was required.

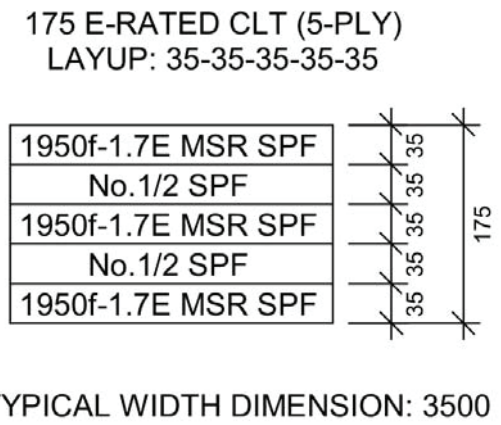

Figure 4: *CLT Panel Layup, BCIT Tall Timber Student Housing*

4.2 CLT Floor Panel Layout

As mentioned previously, the architectural layout lends to an efficient CLT panel layout. Each studio bedroom unit is sized to a maximum 3.5-metre width (see Figure 2), which aligns with the maximum width available for a CLT panel currently available in North America. The depth of the building, governed by the depth of two studio units plus the corridor width, is also sized to be within a maximum CLT panel length. This setup, in which the architectural layout aligns with maximum CLT panel dimensions, means that panel supports can align within suite-to-suite party walls. The CLT panel design is designed to maximize the spacing of HSS supports, in order to further minimize the number of column lines across the building depth. This leads to minimization on overall steel material. The shared washrooms and service risers were located to avoid spatial conflict with columns and reduce openings near column supports. See Figure 5 for the CLT floor panel layout.

More importantly, the architectural layout allows one CLT panel length to be the width of the building, which leads to efficiencies in panel press fabrication and installation. The construction schedule currently shows that each floor level will be erected in one week. At 22,800 m^2, the BCIT Tall Timber Tower is 2x the building area as Tall Wood House, which also erected 1 floor per week during construction. Therefore, BCIT Tall Timber Tower will aim to accelerate construction by a factor of 2 in comparison to that of TallWood House.

Shipping is a primary challenge of utilizing a wide format CLT panel at a maximum length of 12.8 metres. The traditional 2.3- and 3.0-metre wide CLT panel dimensions allow for panels to be shipped within a sea container from Europe or trucked in from outside of the province. Therefore, without a local plant with wide-format press capabilities, the viability of a wide format is limiting. However, the opening of a new CLT plant in the Kootenay Region, an area just east of Metro Vancouver where BCIT Tall Timber Tower is located, made the wide-format CLT panel dimensions viable from a procurement and cost perspective. While this has limited the number of manufacturers that could competitively tender the project, the key stakeholders, specifically BCIT, were willing to take advantage of the benefits of the wide format panels for the project.

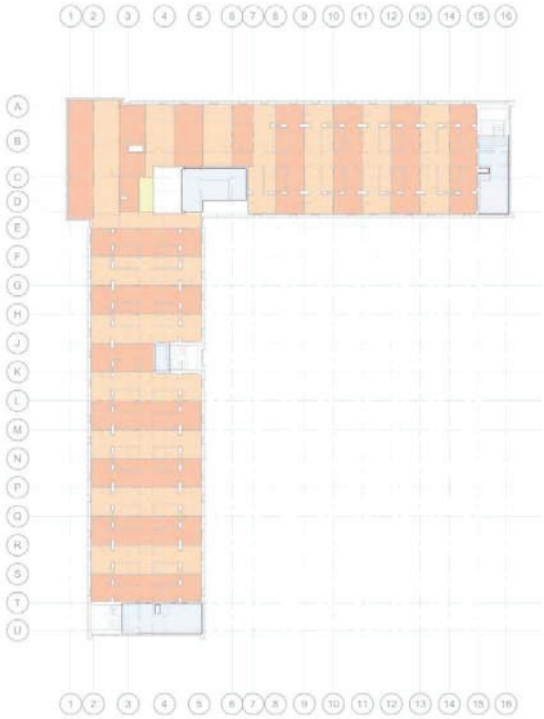

Figure 5: *CLT Panel Layout, BCIT Tall Timber Student Housing*

4.3 HSS Column Supports

HSS columns are sized as 127mm x 127mm square typically, with larger rectangular sizes, as required by increased axial forces at the lower stories. The size limitation is aimed so that the columns can occur within a standard 152mm deep steel stud party wall between units. Columns are then kept to within walls only, at least for the typical residential layouts, and allows for a higher net-to-gross floor space ratio, which is key to maximizing occupiable space, a benefit particularly for developers.

Column lines are then fully encapsulated within the fire-rated demising walls,. and take advantage of the encapsulation already required by BCBC 2018. Added Type X gypsum layers are included to provide the steel column its required fire resistance rating.

Steel columns require a mass to perimeter dimension (M/D) ratio, as required by BCBC 2018 [3], to meet EMTC and fire resistance ratings. Sizing of the HSS column thicknesses, specifically at the smaller plan dimension sizes that were targeted so that the columns can fit within demising walls, is therefore governed by this M/D ratio at the upper stories that contain lower axial

https://doi.org/10.52202/069179-0550

loads. This leads to oversized column weights where not required by structural loading.

To balance this, further analysis and specification of the encapsulation strategy, as shown in Figure 6, were included as part of an alternative solution proposed by GHL Consultants. Within an encapsulated wall, the HSS column perimeter, D, can be considered to only be the sum of column dimensions parallel to the wall length, as long as additional layers of Type X gypsum board are applied to the perpendicular dimensions. This refinement results in a higher M/D ratios for columns, well above the code requirements, which then allows for reduction in column weights, M, where axial loads are low, or at the upper stories.

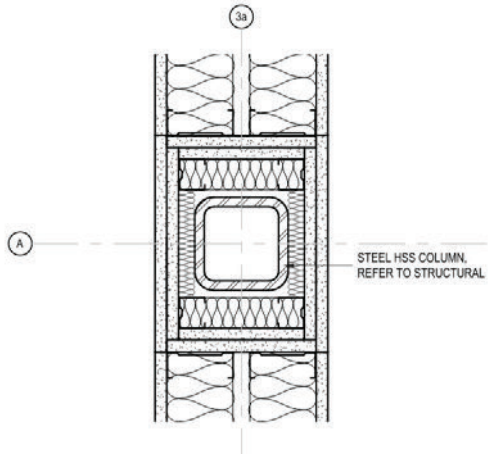

Figure 6: *In-wall Encapsulation of the Steel HSS Columns at BCIT Tall Timber Student Housing, Courtesy: Perkins&Will*

For HSS columns encapsulated outside of walls all four sides of the column are considered for the variable D. These columns are a small percentage of the overall number of columns across the building. Therefore, the cost increase for added weight in these columns is not as significant as the added weight for all of the columns to meet fire resistance requirements.

The lower weight not only reduces material, but also reduces weight and lifting effort required to erect the columns on site. Installation of the glued-laminated columns at TallWood House was celebrated for being so light-weight that 4 installers could lift each column without use of a crane. In the aim to achieve a similar ease of construction, BCIT Tall Timber Tower also anticipates a similar strategy for the column installation by maintaining lighter column weights wherever possible.

4.4 Column-to-Column Connection

The column-to-panel connection comprises of a flat bearing plate that supports the CLT floor and receives the column for the floor above, using a telescopic detail to position and lock in the column above. The 25mm-thick bearing plate is sized to provide vertical stiffness to the connection, as well as sufficient bearing capacity for the CLT panel (See Figure 7). The connection detail accommodates a direct transfer of axial forces between columns and eliminates perpendicular-to-grain bearing issues that might otherwise limit the CLT panel capacity. Shrinkage is a common issue in wood and mass timber buildings, specifically in wood bearing wall and post-and-beam configurations, but this detail also limits the effect of shrinkage and eliminates cumulative shrinkage over the height of the building. Likewise, by using steel column everywhere, including the lateral resisting system, any axial shortening that might be expected in wood columns due to axial load and shrinkage, as well as any differential deformation, is avoided. If wood and steel columns are desired to be used in conjunction on any given floor, shrinkage and any differential deformation is an important consideration.

The detail provides simplicity in design and construction. Once the supporting HSS columns are erected, the CLT panels can be directly dropped in place. Vertical bolts dapped into four corners of the bearing plate are used to position the CLT panel during install with oversized holes through the CLT to allow for tolerance. Then, the HSS column above is lowered into place and bolted to the telescope, and rods through the CLT are then fastened to the CLT with a top plate at the column, providing a nominal panel-to-panel connection. Installation of this detail in the field is simple and provides accuracy, and thus accelerates construction schedule.

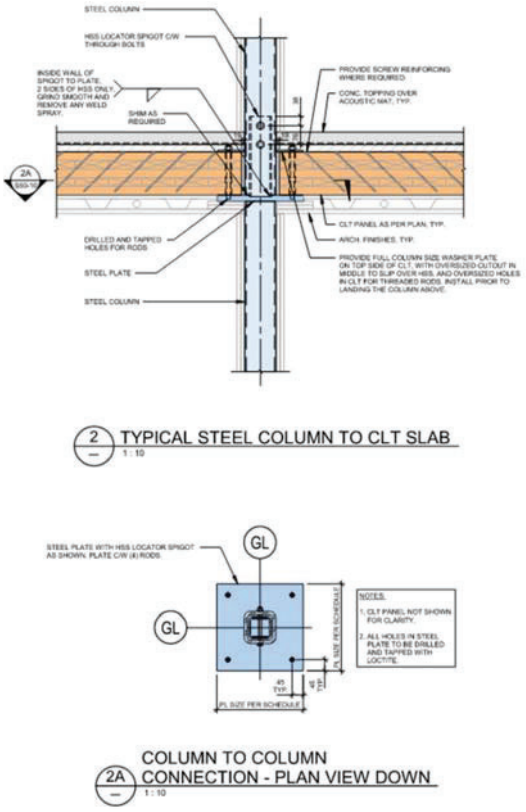

Figure 7: *Structural Column-to-Column Detail for Point-Supported CLT at BCIT Tall Timber Student Housing*

https://doi.org/10.52202/069179-0550

4.5 EMTC Compliant

The CLT floor assembly comprises of a 50mm concrete topping over an acoustic mat, the 175mm thick 5-ply CLT panel, and two layers of 16mm thick Type X gypsum board. The two layers of gypsum are directly attached to the underside of the CLT panel, using provisions listed in CSA 086-19 Annex B [4]. According to the BCBC 2018 Division B [3] provisions and the EMTC Guidelines [1], this assembly is code compliant.

Figure 8 illustrates the gypsum layers where they intersect at the HSS columns and the bearing plate. Careful consideration was given to encapsulation of the steel bearing plate at the HSS columns. Where dapping the bearing plate into the underside of the CLT panels would have eased installation of the encapsulating layers, this would have added considerable time and effort in the shop. Each panel, after pressing, would have been required to be flipped and run through the computer-numerical control (CNC) machine to router the recess for the plate. Additionally, a reduction in CLT panel thickness at the column locations, where shear is highest, would have resulted in added shear reinforcing near the corridors. It was determined that this effort impact plus the addition of screw reinforcing outweighed the install effort of the gypsum layers, and therefore, the following detail was maintained as a result.

Within the single bedroom and studio suites, however, this detail changes slightly to allow for a 25mm deep hat track. This was done to allow for small electrical and communications conduit in a minimal dropped ceiling over the bedroom areas. Despite this slight change, the two layers of 16mm Type X gypsum are still present and are ultimately attached to the CLT, as per CSA O86-19 Annex B. Therefore, the system is still considered to be fully encapsulated under the BCBC 2018 Division B provisions.

Along with the HSS encapsulation strategy as discussed in the previous section, floor assemblies are EMTC compliant

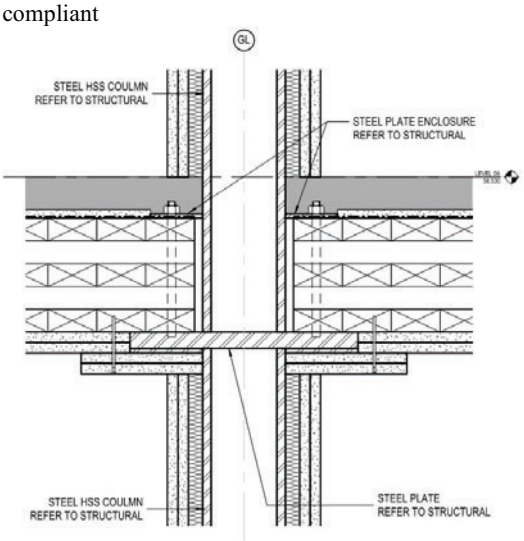

Figure 8: *A Typical CLT floor assembly with encapsulation, Courtesy: Perkins&Will*

4.6 Steel Lateral Resisting System

A moderately ductile, steel concentrically braced frame lateral resisting system is utilized at BCIT Tall Timber Tower, see Figure 9. The steel braced frames occur from the L2 concrete podium slab to the roof level. The is laid out to provide lateral resisting redundancy in both orthogonal directions, while seamlessly integrating the lateral resisting system within cores required for egress.

By placing the braces at the cores, location and frequency of the braced frames limit the mass timber diaphragm span lengths, and therefore diaphragm shear demands. Most importantly, taking advantage of the cores also results in cores that are self-stabilizing during construction, similar to a concrete tower. This significantly reduces the need for temporary bracing of the braced frames during construction.

A steel braced frame lateral resisting system was promoted due to its benefits in construction schedule over a concrete lateral resisting core that extends completely to the roof level. The steel frame is proposed to be completely erected from top of concrete podium at level L2 to the roof before the installation of any CLT floors. The self-stabilizing cores further bolster this strategy. Additionally, up to six levels of the steel frame are proposed to be prefabricated and lifted as one piece, which further limits crane picks and time on site. As a result, this strategy avoids trade overlap and crane sharing, and accelerates construction efficiency.

The concrete shear walls align with the steel braced frames to transfer loads down to foundations below L2. Additional walls added at L1 and at B1 ensure significant added stiffness below the steel braced frame system. The concrete podium lateral resisting shear walls are designed to the capacity of the steel braced frames above. The additional concrete walls further ensure added stiffness below L2 to allow for a two-stage lateral analysis of the structure. Due to the added stiffness of the concrete shear walls in comparison to the steel braced frames above, a two-stage analysis was considered for overall design of the lateral resisting system.

The transition between a concrete shear wall system and a steel braced frame system comes with complications. Balancing a base plate with anchor bolt design that can provide sufficient uplift capacity while still maintaining a reasonable concrete core wall thickness, not greater than 600mm, was a challenge. Another challenge was finding a braced frame layout configuration that allowed for necessary access to the stair and elevator cores. However, the lighter weight of the steel braced frame structure, as well as its capabilities for prefabrication over a concrete jump-forming system to accelerate the construction schedule, far outweigh the benefits of maintaining a consistent concrete core shear wall system from foundation level to roof level.

5 CONCLUSIONS

The use of point-supported CLT offers benefits to construction, architecture, and building services. The latest point-supported CLT projects, such as the BCIT Tall Timber Tower, showcase updated advances in wood products. The introduction of new mass timber suppliers in BC has resulted in cost and procurement viability for wider panels to allow column grid spacing that aligns with architectural layout. Recent research and lessons learned has further developed the point-supported design approach, pushing for use of wider panel sizes and longer spans that maximize panel layout efficiency and construction. Industry acceptance of encapsulation assemblies to resist fire have also progressed, now codified into both Canadian national and provincial building code provisions. Codification particularly has minimized the need for a peer review, as was done with Tallwood, smoothing the path to acceptance of the project overall, and has allowed for partial encapsulation to reduce the number of Type X gypsum layers to achieve sufficient encapsulation resistance.

The design of the BCIT Tall Timber Tower takes full advantage of the technological advancements in wood and fire design. In particular, mass timber panel and steel braced frame prefabrication is utilized in such a way to minimize construction time. While this might increase costs upfront, by requiring pre-planning and more work in the shop for prefabrication, the benefits outweigh the cost in quality control within a more protected environment, and lower construction tolerances in the field, and thus less construction waste. As was observed at TallWood, this upfront cost for prefabrication and the early coordination that it requires, pays dividends in construction.

More importantly, BCIT Tall Timber and the details at which it employs, underline that encapsulated mass timber construction up to 12 storeys is not only achievable, but a true cost competitor to a more typical concrete tower construction. It should also be noted that by going to mass timber construction, it does not mean that the whole system must be purely comprised of mass timber. BCIT Tall Timber capitalizes on a hybrid structure to maximize the timber product that is most effective by volume and weight; in this case, the CLT floor panels. By using details that are intentional to the EMTC provisions, while employing mass timber to its maximum benefit, BCIT Tall Timber Tower is the next generation of tall, hybrid, CLT point-supported structures.

ACKNOWLEDGEMENT

The Authors would like to thank British Columbia Institute of Technology, whose campus at the City of Burnaby will be home to the Tall Timber Student Housing Tower; to Perkins&Will, the Architect of Record; and to GHL Consultants, the building code consultants and fire design engineers for the project.

TALLWOOD 1: LESSONS LEARNED ON COMPLETION OF CANADA'S FIRST 12 STOREY TIMBER-STEEL HYBRID BUILDING

Ornagh Higgins[1], Ilana Danzig[2], Brendan Fitzgerald[3], Jackson Pelling[4], Mehrdad Jahangiri[5]

ABSTRACT: This paper presents the design considerations and construction challenges for the District 56 Tallwood 1 project; a 12 storey mixed-use steel-timber hybrid tower constructed in the South-West region of British Columbia, Canada. The project was completed in 2022 and is located in a region with some of the highest seismic demands in the country. The structural systems made use of pre-fabricated timber and steel components with the goal of decreasing on-site assembly time. This paper describes the structural systems chosen to resist both gravity and lateral loads, design for fire resistance, robustness, and lessons learned during construction.

KEYWORDS: Tall Timber Buildings, Glulam, CLT, Mass Timber, Hybrid, Ductile

1 INTRODUCTION

Tallwood 1 at District 56 is a 12-storey mixed-use residential and commercial mass timber tower located in Langford, BC, Canada. The project is the first of its kind to incorporate the newly adopted British Columbia Building Code (BCBC) [1] provisions for Encapsulated Mass Timber Construction. At the time of completion in 2022, it was also the tallest steel-timber hybrid structure in Canada.

The design takes advantage of prefabricated mass timber panels and pre-assembled steel braced frame components to increase the speed of assembly on site.

Figure 1: *Tallwood 1, completed construction*

This paper will present the solutions chosen for the gravity and lateral systems and discuss the advantages of each. The approach towards fire protection and robustness will be explored as well as challenges faced during construction and lessons learned.

Key Project Info

Location: Langford, Victoria, British Columbia

Height: 41m (12 storeys above ground + 2 levels below ground)

Typical storey height: 3.0 m

Typical floor Area: 1,175 m^2

Total Area: 18,300 m^2

Gravity Super Structure: SPF CLT & Douglas Fir glulam

Lateral structure: Steel Eccentrically Braced Frame (EBF)

Main level & below ground structure: Concrete

Figure 2: *Key project information*

2 STRUCTURAL DESIGN

2.1 GRAVITY FRAMING

The building consists of 11 storeys of mass timber construction with residential occupancy over a one-storey concrete podium with commercial occupancy. There are two levels of underground parking. A concrete transfer structure at L2 accommodates the different column grids between the different structural systems and occupancies.

Gravity framing for the typical residential levels consists of point supported cross-laminated timber panels, spanning in two directions, supported on glue-laminated timber columns. The flat-slab structural system was chosen to minimize the overall floor-to-floor height and to reduce the total number of structural elements to be installed.

The typical residential column grid is 2.95m by 3.60m to accommodate maximum panel widths available from local CLT suppliers. The architectural size and layout of the residential units generally allow for columns to be located within partition walls. Additional glulam beams are used in select locations at larger living rooms or around the elevator openings, where the typical column spacing could not be maintained. The floor plates are identical at all levels with the exception of the penthouse, where longer spans were required to meet the architectural intent.

The typical CLT panel used is a 5 ply panel, 175mm in depth, with two way spanning capabilities. The critical panels are located in the corridor areas where the live load design requirement is 4.8kpa, the design is governed by the minor axis bending moment capacity and deflection. In the major axis the panels are either 2 or 3 span continuous; in the minor axis the panels are single span due to the limit on panel width. Design for bending and one way shear was carried out as per the Canadian standard for Engineering Design in Wood, CSA O86:19 [2]. There is currently no guidance in the Canadian standard on how to calculate punching shear capacity of a CLT panel, however one source of relevant research on this topic can be found in the doctorial thesis by Mestek [3]. The research developed equations to calculate the rolling shear analysis which we then used in our design.

Figure 3: *Installation of CLT on Glulam Columns*

The balconies are also designed for 4.8kpa live load and these panels are exposed from the underside. They are designed for 2hr fire rating without encapsulation and thus are 7 ply panels, 245mm thick.

The penthouse structure consists of 3 residential units, each with custom-designed areas, open spans, and impressive vaulted ceilings. The grid spacing of the columns was increased at this level to achieve the architectural intent. It is constructed from glulam post and beam structure forming a gable roof, with CLT panels primarily spanning in one direction. A combination of custom steel hangers with bearing plates, and pre-engineered concealed connectors are used for the glulam beam connections.

Figure 4: *Penthouse Structural Framing*

2.2 COLUMN TO COLUMN CONNECTION

Due to the standardized panel sizes and grid layout, the glulam columns are generally evenly loaded across the floor plate. This regularity allows standardization of columns sizes and connections. The column sizes are uniform across each floorplate and decrease only 3 times moving up the building. Each of the 3 column sizes uses a variant of the standard column-to-column connection detail.

The column connection contains two elements, see Figure 3; the upper element is a horizontal steel plate screwed to the underside of the column welded to a vertical plate with a slotted hole. The lower element is a horizontal plate screwed to the top of the column welded to a HSS stub. The upper and lower elements are each shop-installed into the glulam columns. During install on-site the vertical steel plate is slotted into the HSS, and a single 19mm dia. pin passes through the HSS and plate to secure the connection. The vertical gravity load is transferred through bearing on the horizontal steel plates and the HSS. The connection is also designed for a tensile force to allow for robustness. This tensile force is resisted through screws in withdrawal installed at an angle into the end grain of the column. The load is then transferred

https://doi.org/10.52202/069179-0551

through the steel components of the connection, and the pin acts in shear and bearing to resist the load.

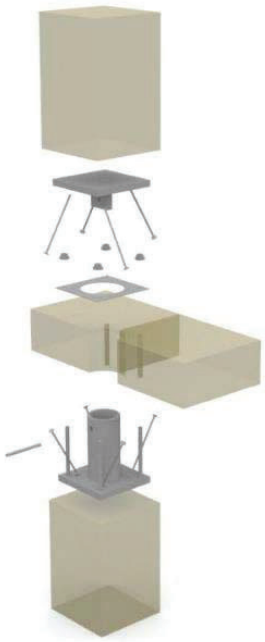

Figure 5: *Column connection detail components*

An important consideration in the detailing of a hybrid mass timber and steel structure is the way in which the different materials behave and playing to the strength of each. One of the benefits of this connection is that it avoids any perpendicular to grain loading of the mass timber elements, which can result in cumulative shrinkage and crushing in excess of what would be manageable from a serviceability limit state. While axial shortening will occur in the glulam columns, with the stress oriented parallel to grain the calculated cumulative deformations are not significant even for 12 storeys. To account for the potential axial shortening, multiple 2mm shim plates were introduced in the glulam column connection. The level of each column could be checked on site and shimmed as appropriate. The result of this approach was an essentially flat floor plate at each level. These shims also helped to reduce the impact of deflections in the concrete transfer slab at Level 2 as it was loaded during erection of the timber structure.

The CLT panels bear directly onto the plates on top of the glulam columns. Threaded anchors provide locating points for the panels during erection and provide temporary lateral support.

Due to the repetitive nature of the floor plate, and the simplicity of the point supported CLT slabs, this column-to-column detail is the primary connector throughout the entire project, with a very limited number of other detail types required. The details that were provided were shop installed where possible, to allow for quick and simple erection on site.

Figure 6: *Glulam column connection – mock up*

2.3 LATERAL FORCE RESISTING SYSTEM

Langford, BC has some of the highest seismic demands in Canada, therefore choosing an appropriate lateral system was one of the key considerations in the design process. Typically for structures of this height in this region we would see ductile concrete shear walls commonly used. These employ a design using a ductility force modification factor, R_d = 3.5, and an overstrength force modification factor R_o = 1.6. The concern with using this system in combination with mass timber was:

1) Concrete construction tolerances are much higher than with mass timber, which could lead to issues with the detailing of connections.
2) Speed of erection on site would be impacted by the time required to construct the concrete core in advance of the timber erection.
3) A single central core would not have been sufficient for the lateral demands, and additional cores or shear walls would be required.

As such, the design team sought out a lateral force resisting system with similar or improved ductility and overstrength, along with a material which allowed for tighter construction tolerances and improved erection times. The system chosen was a highly ductile eccentrically braced steel frame (EBF). This system has similar elastic stiffness when compared to concentrically braced frames, but does not rely on brace buckling to provide ductility. Rather, the stable inelastic response is closer to that of a ductile steel moment frame. The EBF ductility force modification factor, R_d = 4.0, and the overstrength force modification factor R_o = 1.5.

https://doi.org/10.52202/069179-0551

The building's rectangular floor plan necessitated a distribution of frames throughout the building, rather than a single central core, to avoid excessive torsional displacements. This distribution was easily achieved by positioning the frames within walls between units as well around the core.

The steel frames were partially pre-fabricated in multi-storey half-width segments. Each half of the frame was installed and then connected together with a link beam at each level, critical to the performance of the EBF. The goal of this approach to prefabrication was to decrease overall construction time by simplifying on-site assembly, and eliminating most of the site welding.

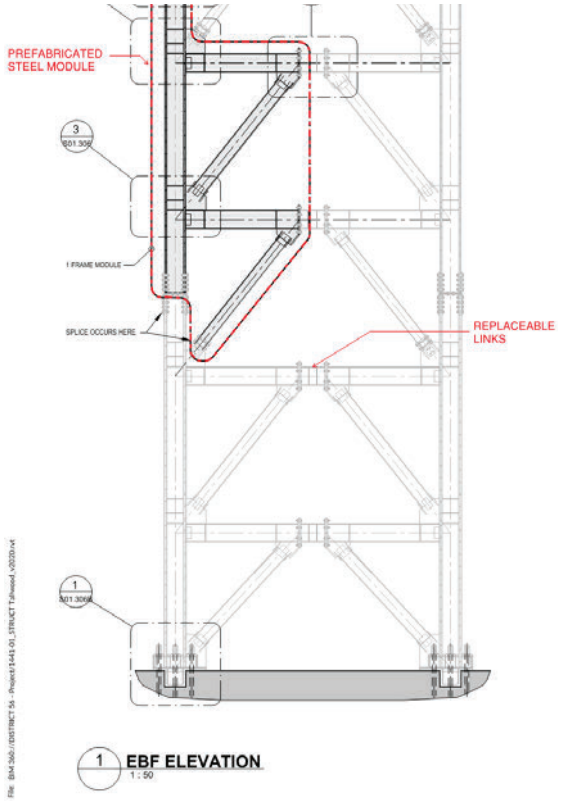

Figure 7: *Lateral force resisting system – EBF*

Capacity design principles in EBF design ensures that inelastic deformations are concentrated in yielding steel links that are capable of repeated cycles of large displacement demand, while remaining stable, and without significant strength degradation. The remaining structural elements are designed to remain elastic at load levels associated with all yielding links having reached their upper limit on capacity.

After a seismic event, yielded links could be replaced to repair the brace frames, increasing the building's resiliency. This repairability has an advantage over more common construction methods such as concrete cores, where the yielded core would likely have to be replaced in its entirety after a major seismic event.

Figure 8: *Installation of EBF modules on site*

Diaphragms consist of CLT panels connected with nailed plywood splines with steel plates and light gauge steel straps providing the chord and collector elements. All timber panels, joint connections, chords, and collectors are capacity protected to ensure they remain elastic. The roof diaphragm's increased complexity due to the geometry resulted in a lengthy design process with a number of bespoke details. A high level of coordination was required between with the CLT supplier and architect during design and construction.

Figure 9: *Roof diaphragm drag strap*

https://doi.org/10.52202/069179-0551

2.4 LATERAL ANALYSIS

Internal forces due to seismic loads were determined from an elastic response spectrum analysis. Three-dimensional dynamic analysis is a requirement of the 2018 BC Building Code due to the building height, seismic hazard, and mass irregularity present with the much heavier L2 level.

Diaphragm storey forces capture higher mode effects and are based on the greatest of: (1) code minimum equivalent static forces based on a percentage of the building's base shear, and (2) forces from the response spectrum analysis scaled up to exceed the probable capacity of the steel braced frames. At all levels, the scaled response spectrum value governs the storey force for this building, and results in an almost constant storey force, and a consistent diaphragm design, over the building height.

Serviceability limit states for drift and accelerations are in accordance with the requirements of the 2018 BC Building Code and 2015 Structural Commentaries [4]. Careful design consideration was given to wind induced accelerations due to the lightweight nature of the building structure relative to concrete buildings of a similar size. Canadian design standards do not provide specific damping values to be used for service level wind analysis in hybrid mass timber buildings, so a lower bound critical damping ratio of 0.01 was assumed, which is consistent with steel framed buildings. Along wind and across wind accelerations are highly influenced by the building's mass, stiffness, and fundamental frequencies in the two principle directions. Tallwood 1, designed for the governing seismic loads, did not require any additional damping or lateral stiffness to minimize response to wind loads.

2.5 FIRE PROTECTION

Changes in the 2020 National Building Code of Canada (NBCC) [5] allow for the construction of timber buildings up to 12 stories tall by introducing a new construction type called Encapsulated Mass Timber Construction (EMTC).

The NBCC is a model code, which is then adopted by the provinces. An amendment to the 2018 BCBC adopted the EMTC provisions in 2020. However, only a select number of local jurisdictions within the province adopted these code provisions. The city of Langford where Tallwood 1 is located was one of 13 local jurisdictions that did.

The EMTC code provisions include details on fire protection requirements during construction, fire rating, minimum member size, allowable occupancies, and square footage limitations. There are also limits on the amount of exposed (unencapsulated) mass timber permitted. Prior to this new construction type, limits on combustible construction of up to 6 stories were permitted, unless an application was made to the Authority Having Jurisdiction (AHJ) proposing an alternative solution demonstrating that the design complies with the objectives of the code, a potentially long and costly process.

Tallwood 1 was the first building in BC to be built to the newly adopted code and the first instance of an EMTC building.

Load bearing columns and floor assemblies are designed for a 2hr fire resistance rating achieved through a combination of encapsulation with 2 layers of 16mm type X gypsum board, which provides 1 hour of fire resistance, and allowance for 1 hour of charring. Char rates, effective cross-sectional properties, and residual member capacities are in accordance with the CSA-O86 standard.

Figure 10: *Mass timber encapsulation progress*

At the penthouse level a significant percentage of the roof structure is exposed so that the timber making up the vaulted ceilings can be visible and celebrated. The design team prepared and submitted an alternative solution application to the AHJ, and the AHJ agreed that a 1-hour fire resistance rating and a higher percentage of exposed wood were acceptable. These exposed elements were designed for 1 hour char as described above.

The steel braces are fire protected through a combination of encapsulation where braces are located within walls, and intumescent paint where braces are exposed across window locations.

2.6 ROBUSTNESS

Structural integrity is a requirement of CSA-O86, stating: *"the general arrangement of the structural system and the interconnection of its members shall provide positive resistance to widespread collapse of the system due to local failure"*

It is important to address integrity when designing high rise mass timber structures since traditional detailing practises do not necessarily provide inherently robust structures. Tallwood 1's integrity design is based on the Eurocode 1 2006 [6]. The tying method is used for the

timber portion of the structure and key element design for the concrete transfer slab. The splines provide the horizontal ties for the CLT floor panels with additional ties provided by the steel diaphragm straps. The columns act as vertical ties with the column-to-column connections being designed for the required tensile force, as previously discussed.

3 CONSTRUCTION

3.1 SHOP DRAWING PROCESS

The shop drawing process for the mass timber elements of the structure was highly detailed and included modelling the slab service penetrations to minimize site drilling. This high level of coordination also allowed the design team to review and comment on all penetrations prior to fabrication.

The timber shop drawings were produced ahead of the steel shop drawings, each using a separate model, preventing proper integration between the timber and steel shop drawings and associated models. Having one complete structural model including both the timber and steel would have helped flag some, if not all, of the tolerance issues we encountered on site between the steel and mass timber components.

3.2 ON SITE ASSEMBLY

Construction of the mass timber structure began in March of 2021 and the structure was topped off in November 2021. The mass timber and structural steel generally came together quite smoothly, in part because steel tolerances tend to be similar to mass timber tolerances. The structure was framed in blocks of 2 to 3 stories, matching the EBF prefabricated module sections. Once the EBF sections were erected and connected together with the links, the mass timber portion of the structure was installed to the same level with no need for temporary lateral support. This sequencing simplified the construction and maximised speed on site, however, due to supply chain challenges related to the wall panels, speed of construction was not as fast as initially anticipated. A code requirement for EMTC states that a maximum of four stories can be constructed without encapsulation, and inability to ship and receive the planned prefabricated external wall panels in time impeded progress on site. Furthermore, there were tolerance issues between the mass timber and steel components, likely due to insufficiently coordinated fabrication models, which required remediation on site and lead to delays. Finally, a highly intricate penthouse structure had a lengthy build, but with stunning results.

Moisture management in timber structures is critical to avoid issues associated with degradation, rot, mould, and visual issues like staining. The bulk of the mass timber construction took place during the drier months, however the climate on Vancouver Island is renowned for its rain and therefore additional measures were required to mitigate the risks associated with moisture. Steps included:

1) Providing protective waterproof covering to glulam beams during construction
2) Sealing joints between the CLT panels once the splines were installed.
3) Removing pooling water from the CLT slabs during heavy rain events
4) Allowing panels that were subject to rain to fully dry before being covered to avoid issues with mould forming.
5) At level 9 the CLT panels had SIGA wetguard applied creating a rainproof layer. An exterior sill plate created a tub effect and 6 drains were installed to manage any surface water. It has become more common to see all CLT floor panels complete with a shop applied membrane. This functions to protect the CLT and provides a dry interior space below so that fit out can progress.
6) At level 12 there were extended delays while the final design of the penthouse was being completed. A torch on waterproof membrane was applied at this level to try mitigate water ingress. There were still localised issues at the column locations where there were openings in the CLT panels. At drag strap locations, where the strap and fasteners stood proud of the slab, repeated impact from walking and moving materials caused the membrane to wear down and allowed moisture to pass through.

3.3 LESSONS LEARNED

Overall, one of mass timber's primary advantages to the cost of a project can be speed of construction, so realizing that speed is critical on a tall wood building. Lessons learned were generally related to items that slowed down construction:

- Although the tolerances of a steel frame are far closer to mass timber than a concrete core, field welds were required at some locations due to misalignments. Introducing more tolerance in the steel to timber details can reduce the need for field welds, along with more stringent coordination between suppliers.
- The importance of simple, repetitive detailing was evident on this project. While the typical panel to column detail was efficient and highly repetitive, the diaphragm connectors were numerous and in the future could be simplified and streamlined to improve fabrication and site installation.
- Due to supply-chain challenges, the non-load bearing external walls were fabricated on-site instead of off-site as originally planned, which slowed down the pace of construction. Offsite prefabricated wall panels are much more ideally

https://doi.org/10.52202/069179-0551

suited to a largely prefabricated mass timber building like this one.

4 CONCLUSIONS

This paper has outlined the main structural design aspects of a completed 12-storey steel-timber hybrid tower. Lessons learned during the design and construction of the project are valuable in advancing more efficient, safe, and cost-effective tall timber buildings in Canada.

ACKNOWLEDGEMENT

Suitability of slim-floor steel-timber composites as intermediate floor constructions - case study based on projects in Finland

Aku Aspila[1], Lauri Lepikonmäki[2], Sami Pajunen[3]

ABSTRACT: The structural engineer provides module divisions and intermediate floor structural thicknesses for the preliminary architectural design. Usually, such data is based on design guidelines provided by manufacturers, national design guides or experiential knowledge from earlier projects. However, there are a few well-known and standardized timber floor systems in Finland, and the knowledge of timber composite structures is still very limited, largely because of the small number of reference cases. Therefore, this study addresses the gap by first presenting general information regarding the slim-floor steel-timber composite (slim-STC) and timber-concrete composite (TCC) systems. Furthermore, this study analyses the implementation of the slim-STC system in the existing office and public buildings in Finland by comparing the vibration behaviour of the slim-STC floor to the selected reference cases. The used six reference cases were selected from Sweco Finland Oy projects and they are representing the typical timber floors and TCC solutions used in office and public buildings in Finland. Based on the analysis, the slim-STC system can provide advantages to the vibration behaviour and the structure could be successfully used in office and public buildings in Finland without complex technical barriers because it has many similarities with the existing floor solutions.

KEYWORDS: Steel-timber composite, Intermediate floor, timber construction

1 INTRODUCTION

New timber-based composite floor structures, such as timber-concrete composite (TCC) and steel-timber composite (STC) floors, have been shown to provide material efficiency and higher load-bearing capabilities by utilizing the best aspects of the used materials (Aspila et al. 2022, Hassanieh et al. 2017a, Heinisuo et al. 2019, Karki and Far 2021, Karki et al. 2021, Loss and Davison 2017, Lukaszewska 2009, Siddika et al. 2021). However, to utilize these new composite structures, information about their capabilities and design methods needs to reach all the stakeholders involved in construction projects. For example, the structural designer should provide module divisions and structural thicknesses for the architects in a relatively early stage of the project to avoid project delays and additional expenses arising from necessary design changes. Usually, such data is based on experience or can be found in design guidelines provided by manufacturers and national regulations. In the project's later phases, the structural design becomes more precise and detailed, and the structural designer needs relevant design rules and calculation tools for validating the selected structural solution. In Finland, the properties of STC and TCC floors are not well-known, and the number of reference cases is still small. Thus, providing information regarding these solutions is more time-consuming and challenging when compared to more traditional floor structures like plain timber or concrete floors.

This study provides information to various parties involved in public and office building projects by first discussing the most important structural design aspects and challenges in intermediate timber or timber composite floor structures when using a beam-column frame system. Secondly, general information about the STC and the TCC systems is presented, based on the literature, so that the advantages and disadvantages of these solutions would be better known. The paper pays special attention to a slim-floor STC floor configuration called the Nordic System. Finally, a comparative analysis is conducted by studying the feasibility of the slim-floor STC solution in selected realized reference cases. The reference cases are provided by Sweco Finland Oy, and they include typical timber floor solutions used in office and public buildings in Finland. The presented information is summarised and the suitability of the slim-floor STC system is discussed for the Finnish public and office building projects.

2 STRUCTURAL DESIGN ASPECTS

2.1 Critical design criteria

The design of timber floor structures consists of two parts - the ultimate limit state (ULS) and the serviceability limit state (SLS) considering structural safety, and user comfortability issues, respectively. The dimensions of timber floors are determined by the SLS design criteria for vibration and maximum deflection especially when using long span (Fink et al. 2018a). The wood material itself has a relatively high stiffness-to-weight ratio, which results in high flexural vibration frequencies. However, the acoustic and fire resistance properties of the wood, as well as the associated regulations require additional structural layers, which in turn inevitably degrade the timber floor vibration properties. Hence, getting the intermediate floor's lowest natural frequency above the threshold value (9 Hz in Finland) sets the most demanding condition for the floor design. Reaching this threshold becomes a harder task if the timber floors are supported by flexural beams affecting the combined vibration.

[3]Sami Pajunen, Tampere University, Finland, sami.pajunen@tuni.fi

https://doi.org/10.52202/069179-0552

In the ULS design, the most critical design criterion is typically the perpendicular compressive strength in the support or load areas. Additionally, in cross-laminated timber (CLT) floors, the rolling shear strength is another key criterion. These strength criteria are such, that exceeding the associated limit value does not lead to an overall collapse of the floor structure, but instead to local damages. Thus, from the structural design perspective, the SLS design criteria for vibration and deflection are the most significant ones. Consequently, the bending stiffness of the floor can be stated as the most important design parameter as it affects both criteria. Bending stiffness can be affected by modifying the following properties: floor supporting structures and boundary conditions, floor material stiffnesses, and floor cross-section shape and dimensions. As the possibilities to modify the abovementioned features in pure timber floors are rather limited, the STC and TCC become very attractive choices for intermediate floor structures.

The current Eurocode 5 (CEN 2005) provides design guidance only for timber floors that consist of glued or mechanically jointed beams and timber decking whereas similar international guidance is not provided for CLT and STC floors. The lack of guidelines for these structures has been identified as a barrier that hinders the mainstreaming and structural understanding of these solutions (Cheraghi-Shirazi et al. 2022, Fink et al. 2018b, Schenk et al. 2022) According to Schenk et al. (2022) "different tools, based on different background theories and with different levels of accuracy may lead to quite diverging results." Considering the TCC floors, additional guidance to the Eurocode 5 was given in 2021 where the ULS design is presented but no further guidance regarding SLS is given (CEN 2021). The SLS deign for TCC is described by Cuerrier-Auclair (2020), Breneman et al. (2021).

2.2 Determining the key structural responses

As justified above, the vibration and deflection properties are the most significant ones when examining the feasibility of the floors to be applied in different construction projects. In what follows only the vibration properties are considered in more depth in terms of the design equations for the floor's lowest natural frequency. The design criterion for the deflection is more straightforward to calculate requiring mainly relevant methods for considering the partial composite action as presented eg. in (Aspila et al. 2022).

The lowest natural frequency of a one-span timber floor supported by rigid supports, for example by walls, can be modelled as a beam and calculated, according to Eurocode 5 as

$$f_0 = \frac{\pi}{2L^2}\sqrt{\frac{EI_L}{m+m_1}} \quad (1)$$

where L is the span length of the slab, EI_l is the bending stiffness along the span length, m is the structural mass per unit length and m_1 is an additional 30 kg/m mass, that considers the live loads according to the Finland's national Annex. In the upcoming Eurocode 5 the m_1 is 10 % of living load (CEN unpublished (updated 2022-05-30)).

Equation (1) assume that the supports underneath the floor slabs are rigid, which is not true in the case of STC floors. Thus, the combined vibration of the floor slab and the supporting steel beam must be both considered. Typically, such a combined vibration problem for a floor slab supported by two flexible beams can be analysed by using the Dunkerley relation as

$$f_{sys} = \sqrt{\frac{1}{\frac{1}{2*f_{0.beam,1}^2}+\frac{1}{2*f_{0.beam,2}^2}+\frac{1}{f_{slab}^2}}} \quad (2)$$

in which the subscript *slab* stands for the floor slab, the frequency of which can be calculated according to Equation (1). The subscripts *beam,1* and *beam,2* denote the steel beams that are supporting the slab. In the calculation of the term $f_{0,\text{beam}}$ for STC structures, the composite action between the timber slab and the steel beam can be taken into account by using eg. the layered beam theory as shown by Aspila et al. (2022). It should be noted that the upcoming Eurocode 5 proposes changes to equation (2) in a form

$$f_{sys} = \sqrt{\frac{1}{\frac{1}{3*f_{0.beam,1}^2}+\frac{1}{3*f_{0.beam,2}^2}+\frac{1}{f_{slab}^2}}} \quad (3)$$

in which the influence of the supporting beam frequencies is reduced.

3 TIMBER-BASED COMPOSITE FLOORS

3.1 The composite action

Timber-based composite structures can provide lightweight structures, quick installation, and low greenhouse emissions as well as increased structural capacity to carry loads and floor spans. Nowadays there exist two main systems for timber-based composite floors, STC and TCC. In STC the composite action is formed with a steel beam by using bolts and screws as shear connectors. In the case of TCC the composite action is formed with a concrete slab by using not only dowel-type shear connectors but also grooving in the timber slabs. The structural behaviour of composite structures is determined by the degree of the composite action, which can be separated into three different stages as shown in Figure *1*.

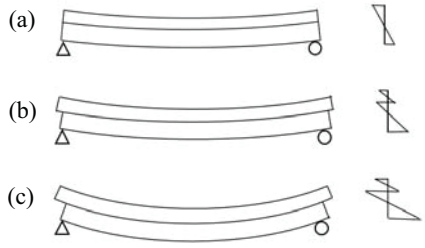

Figure 1. *Deflections and bending stress with different degrees of composite action, (a) full, (b) partial, and (c) no composite action at all.*

The first stage is full composite action where the two parts are acting as one solid block of material and there is no slip between different parts. The second stage is partial composite action in which the flexibility of the

connections causes a slip between the parts. Lastly, if the connection is so weak that it does not carry the shear force at all, the slip is free to occur, and no composite action is formed. Thus, the degree of the composite action is governed by the stiffness and load-carrying capability of the connection.

The effectiveness of the composite action is governed by the distance between the centroids of the beam and slab as depicted in Figure 2. Increasing the distance also increases the effectiveness of the composite action providing that the connectors can carry the increased shear forces between the parts.

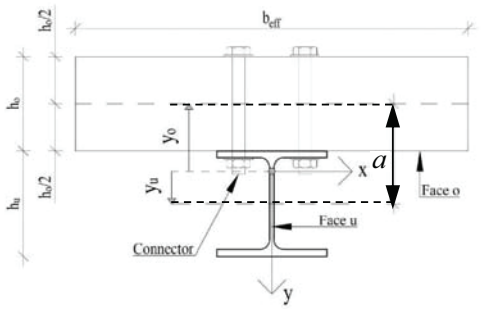

Figure 2. *Cross-section of a traditional STC. The parameter a denotes the distance between part centroids.*

3.2 TIMBER-CONCRETE COMPOSITE FLOORS

The concrete slab has traditionally been used as a reinforcing layer on top of the wooden slab to improve the fire and acoustic properties of the floor. By forming a composite action between timber and concrete parts, structural efficiency, load-bearing capacity, and vibration performance can be substantially increased (Cuerrier-Auclair 2020, Lei Zhang 2022, Siddika et al. 2021). In Finland, TCC structure is typically constructed by using CLT slabs beneath the concrete slab as illustrated in Figure 3. In such a configuration, the CLT slab also provides the casting mould and the support during the construction. The composite action is formed by using screws and grooves.

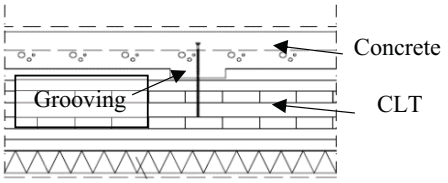

Figure 3. *Typical Finnish CLT-concrete slab has a total height of ca. 200 mm CLT and 100 mm concrete. Due to the fire and the impact of sound insulation regulations, linings might be needed above or below.*

ULS of TCC structures can be analysed by using the Eurocode 5 design guides (CEN 2021). In general, the TCC floors are considered robust structures, in which the only feature requiring further research, is the long-term deflection determination affected by different creep properties of concrete and timber (Breneman et al. 2021).

3.3 STEEL-TIMBER COMPOSITE FLOORS

Steel-timber composite floors differ from the TCC floors substantially since the composite connection is formed now between a slab and a beam, not between two slabs. Depending on the location of the steel beam, the STCs can be divided into two categories. In traditional STC floors the steel beam is located beneath the slab as shown in Figure *2*, whereas, in slim floors, the timber slab is supported by the lower flange of the steel beam as shown in Figure 4. In traditional floors, the efficiency of composite action can be high because the centroids of the beam and the slab are far from each other, as pinpointed in Figure *2*. Typically, such STC structures produce 30%-90% higher load-bearing capacities compared to non-composite constructions (Aspila et al. 2022, Hassanieh et al. 2017b, Karki et al. 2021, Loss and Davison 2017). However, the connections between the steel beam and timber slab must be capable of carrying the developed high shear forces and the connections must be stiff enough to form the desired degree of the composite action. The importance of the connections has led to intense research and development of different connection types such as (Chybinski and Polus 2022, Hassanieh et al. 2017b, Hassanieh et al. 2017c, Loss et al. 2016a, Loss et al. 2016b, Yang et al. 2020).

Field Heinisuo et al. (2019) present the slim-floor STC concept where the possibilities of slim-floor steel-timber composite structures are discussed. The most important benefit of the slim-floor application is the reduced total floor height which in turn creates material savings on the vertical structures and allows the building of more floors with the same building height.

In this paper, the considered slim-floor STC, called as a Nordic system, consists of CLT slabs connected to the welded WQ-beam as presented in Figure 4. In this system, the composite connection is formed by using steel plates on top of the WQ beam and the CLT slab. All the installation regarding the connections can be carried out on top of the platform and the connections can be also easily disassembled. As in all slim-floor configurations, the effectiveness of the composite action is rather small, but based on the results given by Heinisuo et al. (2019), the composite action can reduce the stresses in the steel profile by up to 20%.

https://doi.org/10.52202/069179-0552

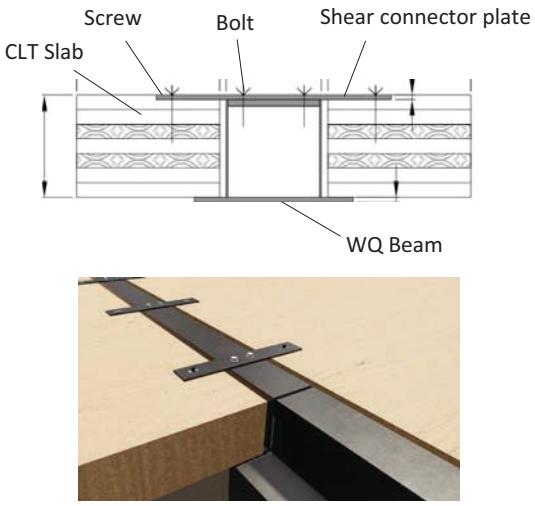

Figure 4. *The considered Nordic system slim-floor. Cross-section (top) and side-view (bottom). The CLT slab and the steel beam are fastened only on top of the profile using the steel plates.*

4 COMPARATIVE ANALYSIS

4.1 Reference cases

The practical feasibility of the Nordic system in the office and public buildings is studied by comparing the key structural responses in realized construction projects. The reference cases are chosen from timber construction projects conducted or participated in by Sweco Finland Oy. A total of two schools and six office building projects with the beam-column system were selected. In the selected reference cases the intermediate floors were built by using TCC, CLT or LVL ribbed-slab systems, see Table 1. Figure 5 illustrates the platforms with modulus divisions.

Table 1. *Reference case data.*

Reference cases						
	Floor			*Primary beam*		
Case	Type	Code	Span (m)	Type	Code	Span (m)
1	TCC	220mm 60-30-40-30-60 100mm C37/45	7,0	GL30c	240x1080	7,0
2	CLT	160mm 40-20-40-20-40	4,0	Delta	D40-500-20	7,0
3	LVL-ripa	H661-5x63x600	8,5	LVL-X	225x590 300x590 (midle)	4,8
4	TCC	220mm 60-30-40-30-60 80mm C30/37	6,0	Delta	D32-400	6,0
5	CLT	280mm 80-40-40-40-80	6,0	LVL-X	2x288x890	6,7
6	TCC	220mm 80-40-40-40-80 80mm C30/37	5,5	WQ22-500	260x20-2x6x200-20x500	5,3

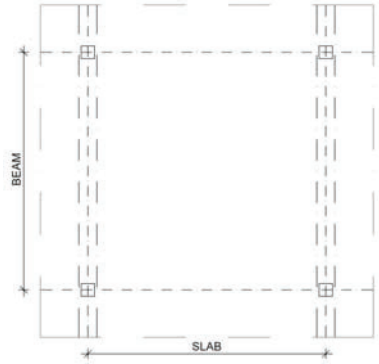

Figure 5. *Platform and modulus divisions of reference cases.*

Table 2 presents the design parameters such as the top and bottom surface masses, self-weight of the structure and living load for the reference cases.

Table 2. *Reference case design parameters.*

Reference cases				
Design parameters				
Case	Top surface mass (kg/m2)	Bottom surface mass (kg/m2)	Selfweight (kN/m2)	Living load (kN/m2)
1	10,0	4,0	3,8	5,0
2	37,0	3,0	0,7	2,5
3	74,0	30,0	0,4	3,0
4	50,0	14,0	3,2	2,5
5	90,0	14,0	1,2	3,8
6	69,0	14,0	3,2	5,0

4.2 Calculation of the Nordic system

The Nordic system is calculated by using the presented data from the reference cases. Span lengths and living loads are taken directly from Table 1 and Table 2. However, for cases 1, 3, 4 and 6 the medium of cases 2 and 5 values were used, see Table 3. For each case, the extra load imposed by the heating, ventilation, and air conditioning (HVAC) was taken also into consideration as a permanent load.

Table 3. *Design loads used to calculate the Nordic system.*

Nordic system				
Design parameters				
Case	Top surface mass (kg/m2)	Bottom surface mass (kg/m2)	HVAC load (kN/m2)	Living load (kN/m2)
1	63,5	8,5	0,5	5,0
2	37,0	3,0	0,5	2,5
3	63,5	8,5	0,5	3,0
4	63,5	8,5	0,5	2,5
5	90,0	14,0	0,5	3,8
6	63,5	8,5	0,5	5,0

The results of the calculation are presented in Table 4 where presented values are obtained by calculating CLT as a beam structure by using Equation (1). In Table 4 the f_1 refers to the lowest natural frequency of the floor

structure that was calculated by using Equation (1) and f_2 refers to the lowest natural frequency of the floor systems that can be calculated by using Equation (2) or (3). Results were obtained by optimizing the CLT and WQ-beam to reach the 9,0 Hz frequency according to the upcoming Eurocode 5.

Table 4. *Nordic system midfloor solution where CLT is calculated as a beam structure.*

Nordic system, CLT as a beam								
	Beam		*floor*		*EC5*		*Upcoming EC5*	
Case	WQ-type	Weight (kg/m)	CLT -type	Weight (kg/m)	f1 (Hz)	f2 (Hz)	f1 (Hz)	f2 (Hz)
1	470x6-360x15-572x13	145,0	320mm 80-40-80-40-80	134,4	9,2	6,7	8,9	7,2
2	330x6-260x15-472x12	106,2	180mm 40-30-40-30-40	75,6	13,8	7,9	14,0	9,1
3	570x8-450x20-662x15	220,2	320mm 80-40-80-40-80	134,4	6,3	6,3	6,3	6,2
4	400x6-370x20-582x15	164,3	300mm 80-40-60-40-80	126,0	10,7	8,4	10,8	9,1
5	570x8-400x20-612x14	201,7	320mm 80-40-80-40-80	134,4	10,6	8,6	10,5	9,0
6	280x6-350x15-562x12	120,5	280mm 80-40-40-40-80	117,6	12,4	8,3	11,9	9,0

4.3 Comparison

The conducted calculation allows comparison between the Nordic system and reference cases as well as between current Eurocode 5 and upcoming Eurocode 5. A comparison between the Nordic system and reference cases is presented in Table 5. Cases 1 and 3 did not reach the boundary limit value of 9 Hz when CLT was calculated as a slab.

Table 5. *Comparing the structural height of the Nordic system to the reference cases when CLT is calculated as a beam structure.*

Comparing Nordic system structural heights to reference cases						
	Reference cases		Nordic system		Comparison	
Case	Floor	Floor+beam	CLT as a beam	CLT+WQ	Floor difference	Floor+slab difference
1	320,0	1400,0	-	-	-	-
2	160,0	400,0	180,0	330,0	-11 %	21 %
3	661,0	1251,0	-	-	-	-
4	300,0	320,0	300,0	400,0	0 %	-20 %
5	280,0	1170,0	320,0	570,0	-13 %	105 %
6	300,0	300,0	280,0	280,0	7 %	7 %

A comparison between the current and the upcoming Eurocode 5 has been shown in Table 6. Upcoming Eurocode 5 provides better values in all cases when examining the lowest natural frequency of the floor system.

Table 6. *Comparing results from Table 4 where the lowest natural frequencies are calculated according to Eurocode 5 and upcoming Eurocode 5.*

Comparing Eurocode 5 and upcoming Eurocode 5		
	CLT as a beam	
Case	f1 (Hz)	f2 (Hz)
1	-3 %	7 %
2	1 %	15 %
3	-2 %	-2 %
4	1 %	8 %
5	-1 %	5 %
6	-4 %	8 %

5 DISCUSSION AND CONCLUSION

This study presents some key design aspects in timber and timber-composite floors in the context of the beam-column structural system. Special attention is paid to a steel-timber composite slim-floor system called the Nordic system. The major objective of the study is to examine the feasibility and effectiveness of the Nordic system in typical practical applications in office and public construction projects in Finland. Based on a selected set of realized construction projects, the results prove that the Nordic system would result in slimmer solutions compared to the adopted current floor types by offering a total build-to-be-disabled floor system. To adopt the full potential of the studied slim-floor system, further research should be carried out to accurately determine the slabs' effective width and formulate an overall structural optimization design task for the whole floor system where the bending stiffness of the CLT in both directions should be taken into consideration.

THE BV2020 SOLUTION – GOING BIG WITH LIGHT TIMBER STRUCTURES

Knut Magnar Sandland[1], Julia Bosnes Tønne[2], Per Gunnar Nordløkken[3]

ABSTRACT:

A growing population world-wide and a strong increasing trend towards more urbanisation calls for changes in the way we develop urban areas and cities. The building sector will play an important role in this development. Better utilization of land with more multi-storey buildings both for residential and commercial use is an important part of the solution. Climate change requires us to take action and substituting building materials with large CO_2 emissions with wood-based solutions which will make a huge positive contribution. Glue-laminated and cross-laminated timber are good alternatives. However, lightweight load bearing timber frame solutions will make an additional contribution to even more sustainable building construction due to less use of raw materials and the possibility to build on weaker ground. The BV2020 solution has the goal to develop concepts that enable mass customized production of prefabricated light timber frame, load bearing elements for buildings up to eight - 8 - storeys for the volume market.

KEY WORDS: tall lightweight timber buildings; wood-based building systems; mass customized production; prefab

1 INTRODUCTION

1.1 BACKGROUND

The challenge of designing tall and safe timber buildings has been a priority for the wood industry and researchers throughout several studies and projects [1]. Even though timber is one of our oldest and most traditional building materials, building codes have limited wide use in higher buildings due to fire safety concerns, amongst other issues [2].

The introduction of function-based regulations instead of material based regulations has played a key role in the use of wood in multi-story buildings with more than four floors. For instance, in Norway the function-based regulations regarding fire risk were introduced in 1997 [3]. This was important for the use of wood in big buildings, and therefore the development of techniques and systems for multi-story wooden buildings is rather new, and it is still a high potential for further development of effective production systems.

Until recently, the attention has mainly been on unique high rise, solid wood, signal-building projects. In later years, an increasing interest has grown also for lightweight timber frame constructions. All these projects have helped to identify and solve many of the fundamental obstacles that follows with an expanded use of timber in high-rise buildings. Now, time has come to realize returns of these findings and to go big, also with respect to volume.

1.2 OBJECTIVES

To really take advantage of the engineering developments that have been made within the timber building industry, one needs to convert all the good work that has been done into complete building concepts that can compete within the volume markets. This is the main goal of the BV2020 project, which paves the way for mass production of prefabricated lightweight timber frame load bearing elements for use in apartment buildings with up to eight storeys. In Figure 1, a typical example of a lightweight timber frame element is shown.

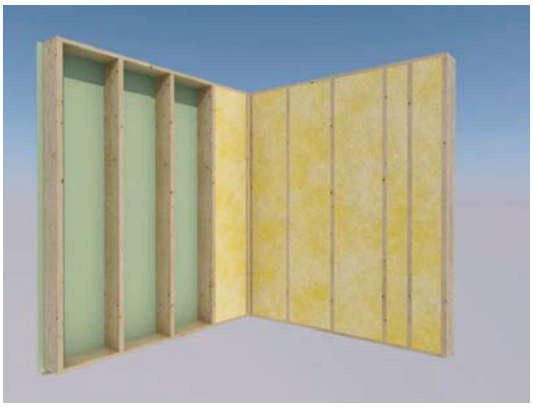

Figure 1: *Example of a typical lightweight timber frame element.*

[1] Knut Magnar Sandland, Project Manager, WoodWorks! Cluster
[2] Julia Bosnes Tønne, Structural Design, Støren Treindustri AS, Norway
[3] Per Gunnar Nordløkken, Technical Manager, Støren Treindustri AS, Norway

https://doi.org/10.52202/069179-0553

The project includes work packages that cover topics such as i) identifying the required material properties for light-weight timber structures, ii) solutions for the overall and detailed design of prefabricated constructions and their connections, iii) optimization and adaptation of the production process, as well as iv) verifying that all relevant aspects of the building as a whole and its solutions meet the required standards.

Støren Treindustri is a member of WoodWorks! Cluster (www.woodworkscluster.no), and the BV2020 project and concept fits well into the main work in the building sector in the cluster, with focus on:

- Transition of Industry 4.0 and Industry 5.0 in the wood based building industry.
- Effective use of digital information in the whole value chain, from raw material to end of life for the buildings.
- Increased industrialization of the building process – more performed in the factory and less at the construction site.
- Sustainability reporting, and the use of it to promote wood as a building material.
- Development of urban building concepts (multi-storey buildings) that are effective to produce, and eliminate the uncertainty among professionals to use wood as a building material for multi-story buildings.

The network in WoodWorks! Cluster exists of R&D organizations and companies covering the whole value chain from forest to building operations, and is used as a resource in the performance of the project work.

2 IMPACT OF BV2020-CONCEPT

The BV2020-concept, by using light framework construction, has potentially several beneficial impacts on the building industry concerning greenhouse gas emissions and cost efficiency. However, this has to be calculated and proven when the concept is fully developed, but in the following sections the most important motives for developing the building concept are discussed.

2.1 Use of wood – the substitution effect concerning greenhouse gas emissions

In the European Union, building construction consumes 40% of materials and 40% of primary energy, and generates 40% of waste annually [4]. The potential to benefit the environment by replacing reinforced concrete structures with timber is illustrated by Skullestad et.al [5], where a 34-84 % reduction in climate change impact has been calculated for 3-21 storey buildings. However, an essential prerequisite when comparing two products is that they can fulfill the same function in a building. In the LCA language, this is referred to as the "functional equivalent of the object". There is a quantification of the technical characteristics and functions required by the object (product). The functional equivalent makes it possible to derive a reference unit used to produce results from calculations (e.g.: per m², per year, per employee, per m² per years).

Comparisons of greenhouse gas calculations should only be made on the basis of the functional characteristics of the objects equivalent. This requires that the functional requirements are described together with the intended use and relevant technical requirements. The functional equivalent of a building or part of a building shall include factors as:

- Building type
- Technical and functional requirements
- Required lifetime
- Total area
- Total heated utility floor space

The BV2020-concept is based on a lightweight construction, and therefore it is not a material intensive construction. This is positive due to greenhouse gas emissions per kg. material. However, the BV2020-construction involves several materials, and in the development of the concept effort to minimize the total greenhouse gas emissions is a priority. Calculations on how the various materials influence the total account of greenhouse gas emissions of the whole building will be important in the BV2020-concept, not limited to parts of the building or single materials.

In [6] it is shown examples of variations in the greenhouse gas emissions dependent on which materials, and the amount of each material, that are used in a wall construction. The difference between the construction systems is rather high, also within the wood construction systems. However, the example of lightweight framework system shows a rather low value in the example. The development to reduce the greenhouse gas emissions is currently very intensive, and therefore it is important to perform dynamic calculations to take this into consideration consecutively. For the BV2020-concept this will be important to optimize the construction due to the total greenhouse gas emission for the whole building.

2.2 Urban nodes

In Norway, residential buildings represent 37 % of the total building mass [7]. Even though multi dwelling buildings constitute a small part of these today, it is evident that the demand for this type of buildings will increase in the years to come. Due to a general population growth, increased urbanisation, and the need to preserve more agricultural area, the call for higher apartment buildings will grow significantly. It is a policy making process in progress in EU to establish urban nodes for effective transport and infrastructure [8]. This development is also reflected in smaller scale, e.g.

establishment of small cities in connection with railway stations.

A compact building mass is cost effective due to infrastructure, and multi-story buildings will be important in this development. It is therefore of great importance that concepts for timber buildings represents a competitive alternative. To exploit the potential of timber as a CO_2-sink, we need to provide the market with competitive timber alternatives within the segments that constitutes the largest volumes. A new normal must be to go big with timber, and the goal for the BV2020-project is to develop a flexible concept and solutions both for construction, fire safety and acoustics that can be manufactured and built in an effective, economical and also environmentally sustainable way, ready to be used. These are on-going activities that will be presented on the WCTE-conference in Oslo 2023.

There will be increasing demands to utilise today's building stock to a much greater extent than has been the case so far. Extensions in the height of existing buildings can therefore be socio-economically advantageous and at the same time contribute to sustainable management of existing buildings. In addition, it will increase the value of existing buildings. In [9] these aspects are described more in detail.

A limitation is what existing buildings can withstand from the extra load from building at top. Some buildings are already planned for this, while most are not. However, due to the relatively low specific gravity, load-bearing structures in light-weight framework constructions of wood will be well suited as a load-bearing system for extensions on existing buildings – and thus it may also be possible on some buildings that were not originally intended for this.

In many existing buildings made of heavier materials such as concrete, masonry and steel, there may be reserve capacity compared to an extension. However, it is an advantage that the extension and load-bearing system do not impose excessive loads on existing buildings. Heavier building systems on extensions may limit the number of additional floors that can be built on. By choosing a "light" extension and lighter load-bearing structures, there are greater opportunities to get more floors and increased usable square meters for the extension.

2.3 Pre-fabrication and industrialisation

For timber constructions to be a truly sustainable and viable alternative, the economic side of it must also be competitive. An effective production process is crucial to attain to be competitive with other building systems. The BV2020-concept is based on prefabrication of elements (Fig. 2), that means fabricate as much as possible in the factory, and then put together on the construction site.

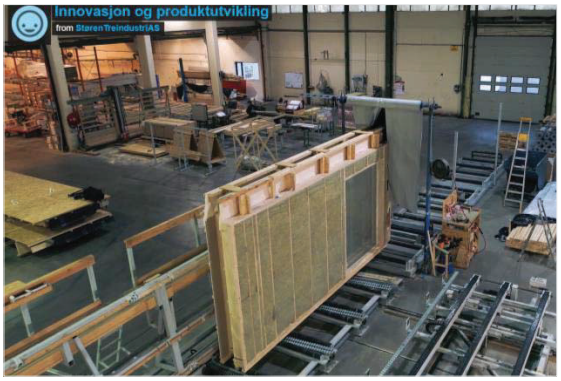

Figure 2: *Production line for elements at Støren Treindustri AS (https://storen-treindustri.no/produkter/).*

There are benefits by performing the building operations in a factory, and are also discussed by [10]:

- Better quality of the wood building product.
- Lower cost compared to performing the operations at the construction site.
- Shorter construction time.
- Independent of weather conditions, which will reduce the risk for humidity in the constructions.
- Reduction of on-site accidents.
- Reduction of waste

A range of variables influence the costs. Even though the direct material costs of wood can be slightly higher than others, the total cost of a finalized mid-rise wood building will often be lower compared to a concrete construction (6 % for eight storey buildings according to [11]). Prefabrication and mass production are key elements to achieve necessary competitiveness of this alternative, and thus even more projects can make the environmentally friendly choice and increase the total use of wood in buildings. This will heavily affect the ability of the building industry to achieve a noticeable reduction in climate change impact, and by doing so, contribute to the crucial global climate goals.

In the life cycle of a building, the operation phase has been dominant concerning energy use and green house gas emissions, but emissions that occur during the operation has declined dramatically over time due to existing substantial energy saving codes or other policies, and thus, the relative contribution of construction stage emissions and impacts becomes more dominant and significant. Therefore, green house gas emissions or impacts in the construction stage must be analysed [12]. The choice of material is the most important at the construction stage concerning green house gas emissions, but also the way of producing the buildings is of importance.

The building industry based on conventional on-site construction approach is by [12] characterized as labor-

https://doi.org/10.52202/069179-0553

intensive, wasteful, and inefficient, and that it is need for more introduction of lean production and prefabrication in the building industry.

In [13] research concerning the development of productivity in industrial wood building sector and conventional building sector has been performed in Sweden. It is the period from 2014-2018 that has been investigated. The results show that the industrial approach has increased the productivity expressed as cost per area of 30 % compared to conventional building processes, and that the lead time for the building process has been reduced by 3,3 months.

Through an Internet survey [14] of hundreds of AEC professionals (Architecture, Engineering, and Construction), data were gathered on the impact of prefabrication and modularization on key industry productivity metrics including project schedules, costs, safety, quality, eliminating waste and creating green buildings. It is reported that some of the most significant productivity findings from prefabrication and modularization users include the following:

- 66 % report that project schedules are decreased – 35 % by four weeks or more.
- 65 % report that project budgets are decreased – 41 % by 6 % or more

Further, [14] report that productivity is the top driver of prefabrication/modularization use among all firms. It is described that time savings and even small cost reductions make a big difference for players in the construction industry, where profit margins are slim due to the labour-intensive and expensive nature of on site construction. In the investigation it is found that 92 % of contractors see productivity as a stronger driver to use prefabrication/modularization, compared to engineers (70 %) and architects (68 %). Competitive advantage (85 %) and generating greater ROI (70 %) (return of investment) are stronger drivers for contractors than they are for architects and engineers [14].

In the research of [12], models and case- studies were performed to calculate the reduction of green house gas emissions when increasing the prefabrication level. It was found that the reduction was 2-5 %, but that it can be even more reduced by higher degree of pre-fabrication.

In the investigation of [14] “green aspects” were not a major driver to prefabrication and modularization adoption. However, when they asked about environmentally aspects, including site waste and amount of materials used, a different story emerged. 76 % of respondents indicated that prefabrication/modular construction reduces site waste – with 44 % indicating that it reduced site waste by 5 % or more. In addition, 62 % of respondents believe that these processes reduce the amount of materials used – with 27 % indicating prefabrication/modularization reduced materials used by 5 % or more [14].

In the development of the BV 2020-concept, and in the WoodWorks! Cluster, the industrialization of the building process has high priority, including the logistic from raw material sources to transport and assembling at the construction site. To optimize the use of raw material and reduction of waste through the whole value chain is important together with high productivity. It is, however, impossible to eliminate the waste totally, but the side streams that the waste represent can be raw material for other types of industry in the region, ant it is on-going activities to study these possibilities.

2.4 Mass customization

To produce buildings effective in an industrial way, it is a challenge to combine it with high variation in the products to meet the customers requirements. Mass customization is, according to [15], a manufacturing paradigm that enables customized and personalized design at a cost near mass production, and that mass customization's ability to lower unit cost, increase quality, and shorten project duration for customized offerings is considered highly relevant for tomorrow's house building industry.

Støren Treindustri has ongoing activities concerning mass customization of the production of buildings up to four floors, and it is possible to adopt it into the BV 2020-concept for buildings up to eight floors.

In [15] it is concluded that a great potential exists for applying mass customization in the house building industry. However, despite its potential, research on mass customization in the house building industry is sparse. In particular, research on developing the solution space and choice navigation tools is limited in this industry.

Several challenges for implementing mass customization in the house building industry have been identified and reported in the literature review of [15]:

- “The requirement for changing the supply chain setup. At the moment, supply chains in the house building industry are structured to fit engineer-to-order building projects and thus lack standards necessary to cope with builders and suppliers of mass-customized offerings.”

- “To align what customers want with the internal capabilities of the company, that is, to define the solution space offered to customers.”

The last bullet point has high priority in the development of the industrial building process in the BV 2020-project and in WoodWorks! Cluster. The variation in the product spectre has to be limited to the limitations in the factories for maintaining high productivity, but at the same time offer more variations where the industrial limitations are lower.

3 FURTHER WORK

To verify the interaction between both technical solutions, fire safety, acoustics, design for efficient manufacturing/ prefabrication, environmentally friendly material use and production and finally a profitable concept for all parts of the value chain, the BV2020 solution must be tested in full scale with a pilot project, preferably an 8 storey residential apartment block.

Furthermore, the concept is also applicable for other building types such as offices, etc., which is also planned for, even though not being part of the initial project description.

For fire safety, the project has developed loadbearing prefabricated floor slab elements of lightweight structural wood with the ability to withstand the complete duration of a fire, including the decay phase, according to Eurocode 1 [16]. This has been possible by taking advantage of products with improved material properties during fire and focus on fire performance in the design of the construction.

With regards to acoustics, the developed concept for the floor elements for spans of approximately 8 meters has shown very good test results both with regards to airborne sound and step sound.

Similar development and tests will be carried out for load bearing walls and transitions. Several other aspects of the concept also need to be managed, ensuring the required flexibility of the entire building.

4 CONCLUSIONS

By substituting building materials with large CO_2 emissions with wood-based solutions, we can make a huge positive contribution to the necessary actions against climate change. The BV2020 solution has the goal to develop concepts that enable mass customized production of prefabricated light timber frame, load bearing elements for buildings up to eight - 8 - storeys for the volume market. The development of the concept is well under way. A concept also for load bearing walls and transitions is under development, and both fire safety and acoustics will be studied this year.

Further development of the design for manufacturing, establishing cost-effective production processes and optimalization of the carbon footprint will be carried out.

Pilot project(s) will hopefully confirm achievement of the projects overall goals and give positive contribution to the reduction of green-house gas emissions.

ACKNOWLEDGEMENT

The BV2020 project is performed together with Veidekke Bygg Trøndelag and InnTre Kjeldstad AS. SINTEF Community is the R&D-partner. The Research Council of Norway and Skogtiltaksfondet have contributed with funding.

THE BENEFITS AND CHALLENGES OF WOOD IN HIGH CORROSIVE SURROUNDINGS

Sigurdur Gunnarsson[1], Tim Skotheimsvik[2]

Summary: The paper addresses the design strategy of designing the joints of large timber structures for corrosive surroundings like swimming hall facilities. It addresses the blind spots of Eurocode 5 and the shows the analytical and practical approach solving both the technical and economical demands of the project both in design- and realization phase.

KEYWORDS: clt, corrosive environments, large structures, WCTE 2023, Oslo, Norway

1 INTRODUCTION

The city of Oslo has a strong environmental policy with an increased use of timber in public buildings as a strategic part to fulfill this policy. The use of timber was therefore a declared the aim of the design for the new main swimming facilities at Tøyen in Oslo.
Swimming halls have high corrosive demands. Timber has obvious advantages regarding corrosive environments in comparison to ferreous materials.
The approach between Eurocode 2 towards reinforcement and Eurocode 5 towards fasteners, have several similarities. Minimal distances between members as well as mechanisms of force-transfer between base material and reinforcement/fastener.

Though the differences are categoric when it comes to corrosions of metals in concrete versus corrosion of metals in timber. The concrete cover is quantitatively defined for the different concrete types and the design of wood only use qualitative terms like ”metal completely covered with wood”. The solution was to contact researchers, producers and institutions in USA, Germany, Italy, and Norway. Applying the fact that corrosion of metals in wood is aqueous [1] and the range of wood moisture content [2] to be expected for the lifetime of the construction, gave the guidelines for both the overall structural design and especially the details.

2 DESIGN PRINCIPLES

The roof structure of the new main swimming facilities at Tøyen in Oslo is designed as hollow wooden beams in a combination of clt and glued laminated timer. The hollow space within the wooded structure in utilized as a technical floor. The basic design idea behind the roof structure, to something more as merely a technical floor, was to use all surfaces as an active part of the structural system. Hence instead of the classical thinking of a lattice structure with a passive cladding and a passive roof slab, inner the lattice was “omitted” and replaced by the visual surfaces as well as the roof slab forming a hollow beam.

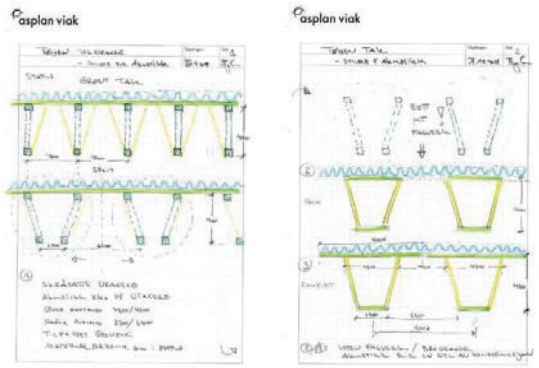

***Figure 1**: Design process – transformation from a spatial additive structure to an integrated solution.*

Additional to the obvious saving in materials by reducing layers also the architectural concept in this way merges completely with the structure.

***Figure 2**: Realisation process: model, mock-up, site.*

The on the top of the structure is a green roof, collecting water which will be used in the bath. The inner surfaces of the structure are for all HVAC and electrical services.

[1] Sigurdur Gunnarsson, Asplan Viak AS, Norway, sigurdur.gunnarsson@asplanviak.no
[2] Tim Skotheimsvik, Asplan Viak AS, Norway, tim.skotheimsvik@asplanviak.no

https://doi.org/10.52202/069179-0554

Holes in the surface serve the acoustics. The form of the structure enhances the use of light.
Combined the task is rather straight forward. A span little over 40 meters with a beam height totaling a little over 4 meters. Put simply, the bearing of the roof is always perpendicular to the direction of swimming, whereas the services inside the roof are parallel to the swimming.

3 SECTION COMPOSITION

The structural target of the design was flexural stiffness, answering both to the economical demands of the client and the available production of the market. A CLT production width of 3.5m was chosen to enable a wider range of bidders even though a few producers can deliver withs of 4 meters and more.
A parametric study was performed to compose the final section. A total of seven different compositions were evaluated regarding amount of material used and the stiffness. To enable a comparison, the values were normalized in the following way: the lightest section was defined as 100% - green line, the softest section was defined as 100% - yellow line. In this way the relative values became visually comparable as shown in the Figure 1.

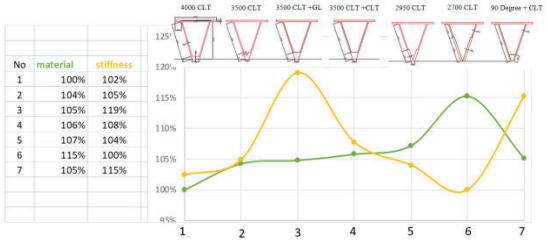

Figure 3: *Comparison of the different compositions for the main beam structure.*

The roof is created of several beam sections spaced out with a cc of 4.5 meters. The roof is completed by placing a smaller plate in between the top of two beam elements where the tolerance of the roof is taken up. The final section for construction is as shown in figure 4.

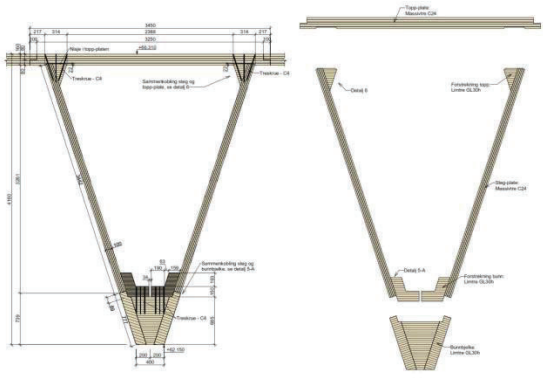

Figure 4: *The final section for construction*

One of the most sensitive points of the functional section "beam + column" is the column foot point. Here an early assessment was made, and a careful material composition and detailing was a successive inter-disciplinary process.

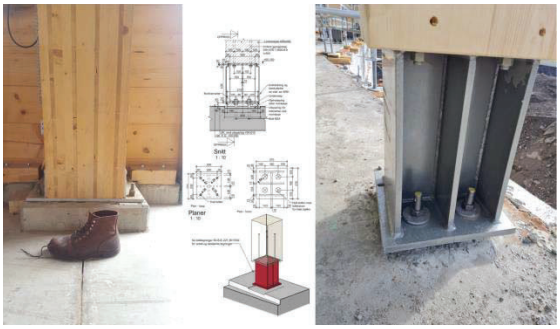

Figure 5: *Column foot point: reference, detailing, site*

4 DESIGNING FOR CORROSIVE ENVIROMENT

It is hard to avoid the use of fully threaded screws when designing large scale spatial timber structures with stiffness as an aim. Unfortunately, the availability fully threaded screws in C5 quality are next to none. Hence the strategy to avoid this problem was twofold: all critical sections being internal and avoiding too high wood humidity. Since the operational humidity and temperature is quite predictable for swimming facilities, it was possible to place the different parts of the construction. This meant designing such that the hygroscopic isotherms had acceptable and non-corrosive values in the zones of maximum forces. This was done in close cooperation with the projects building physic, Fredrik M. Haaland. The following humid zones for order, building and use were defined and placed on the Keylwert-diagram as shown in Figure 2. Thus, it was possible to localize areas non-fitted for connections, but also to verify that other zones had humidity values non-critical in regard to corrosion.

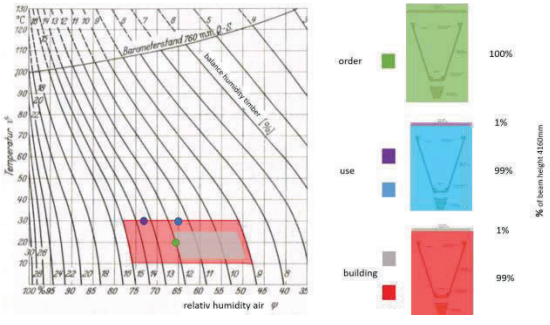

Figure 6: *Humid zones on a Keylwert-diagram.*

https://doi.org/10.52202/069179-0554

In the recent years a strong focus has been set both to assess and to assure the moisture level in wooden constructions. An excellent source used for comparison is “Quality assurance of timber structures” [3] published in Biel 2019. Here different types of buildings, including swimming facilities were evaluated.

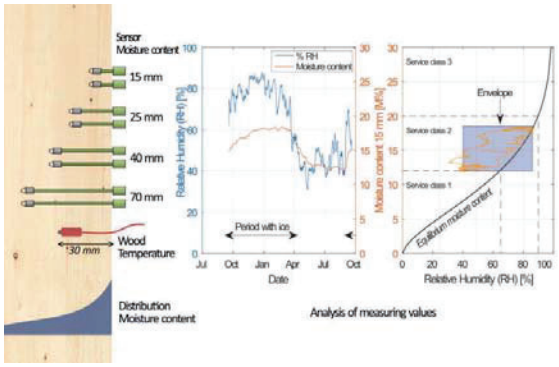

***Figure 7**: Used source for monitoring concept of moisture level [3]*

Due to the large size of the new bath and the different sones of use a monitoring concept reflecting to this was both set out in plan and section of the structure as shown.

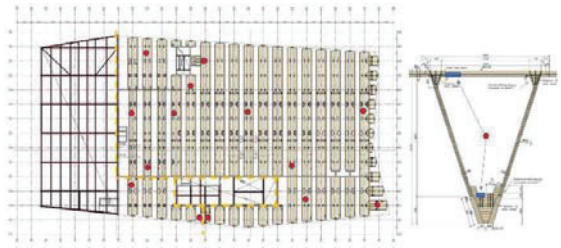

***Figure 8**: Monitoring of moisture in different sones of usage and sectional part of the wood structure.*

5 DESIGNING FOR STIFFNESS

A construction with such large dimensions will always consist of numerous smaller members. Also due to the use for internal services a considerable number of cut-outs must be made. The approach for designing this was straight forward. Starting with a “perfect section” with complete stiffness and no holes gradually increasing flexible boundary conditions and evaluating the influence of material removal. The process of incremented softness is shown in Figure 9 and Figure 10.

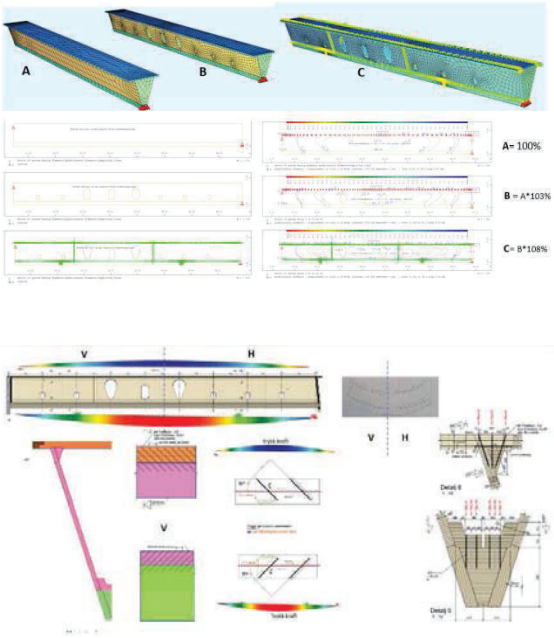

***Figure 9:** The process of incremented softness and link towards detailing in structure*

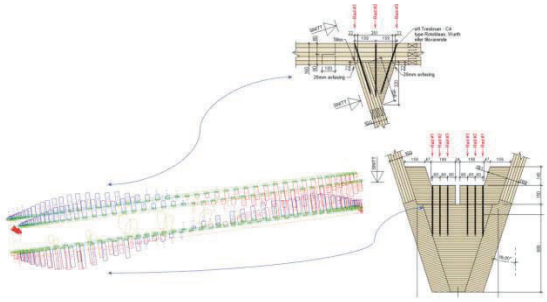

***Figure 10:** Shear flow along the main details of the incremented softness between different elements.*

***Figure 11:** Screws from the top plate ready to be drilled in.*

Resulting spring forces in overall modell as comparative bases for the design of fasteners and checking on deformations.

https://doi.org/10.52202/069179-0554

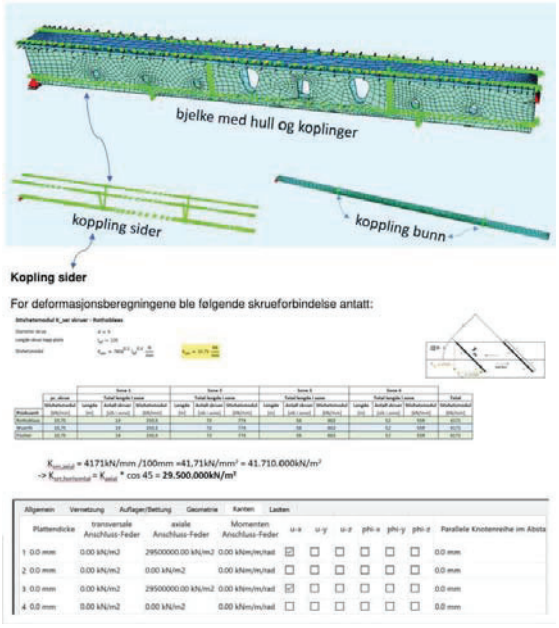

Figure 12: *The process of incremented softness – shell structure modelling principle for a single beam analysis.*

This method of increment made it possible to evaluate the potential of influence quite precisely regarding both forces and deflection. It is important to point out that the use of laminated shell-elements and a complete 3D model of the structure is imperative to assess a reliable result.
One of the most delicate details in the whole project is the connection of the bottom part of the beam. Here a considerable spectrum of solutions was evaluated according to stiffness and feasibility on site.

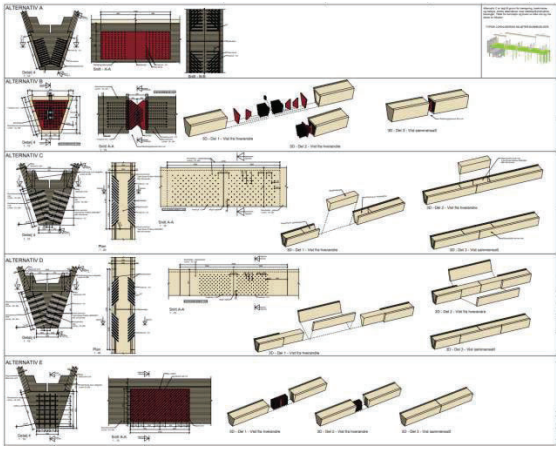

Figure 13: *Variation study of tension detail.*

This was important both due to the high-tension forces, 2.5MN, as well as this is a non-redundant part of a simple-span structure. Before application in the complete model a simple comparative study of stiffness and robustness was executed with the aim to verify the design target.

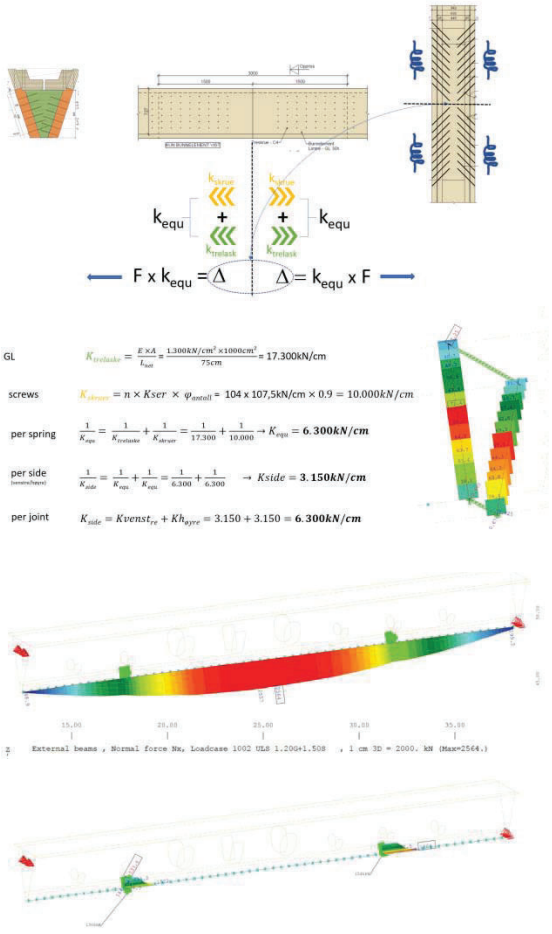

Figure 14: *Tension force distribution – max value 2.5MN, and values at planned site-connections 1.5MN (60%).*

Due to the importance of the on-site tension-connection and the harsh conditions of a swimming hall the following N+1 approach was taken: a combination of a mechanical and glued solution was chosen. In this way both the screws and the glue are independently able to transfer the force at intersection. The design suggested using a 2-component glue solution complying both to the EN 301 as well as low-contact-pressure with allowable thickness around 1.5mm to enable detail-deviations on site. Several rounds were taken with different producers, but the suggested design was clarified in a series of structural-workshops resulting in a 11 step detail description including temperature, humidity, application time shown on the next page in figure 15.

https://doi.org/10.52202/069179-0554

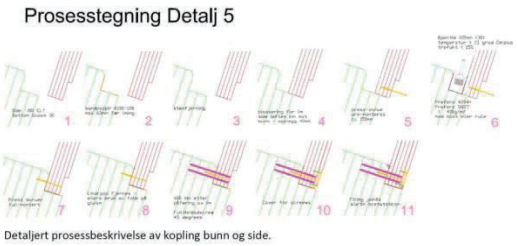

***Figure 15**: 11 step process of an on-site gluing according to EN301 and ETA demands to glue and CLT*

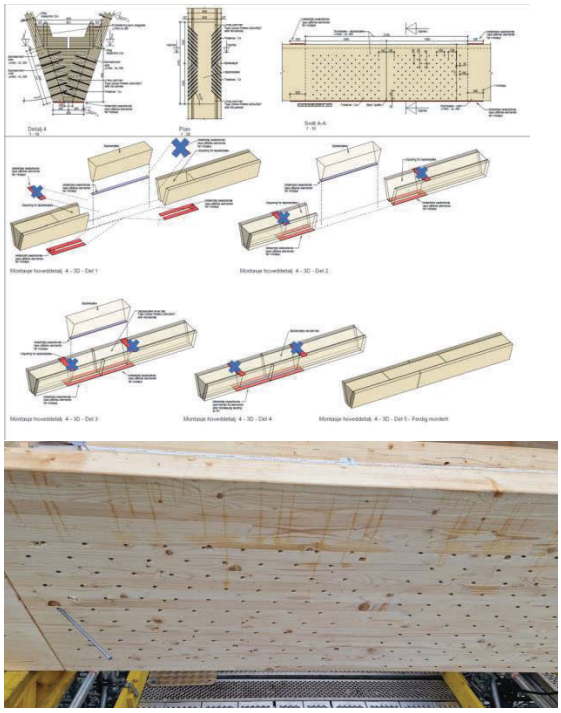
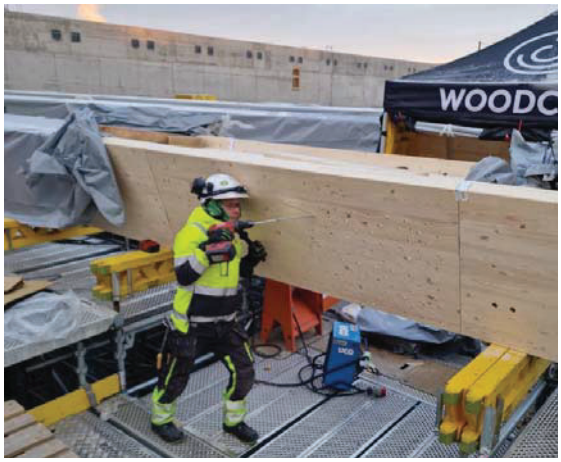
This early working on a high level of detail and practical issues formed the secure basis for a precise description in the tender documents and later a guideline for montage on the site.





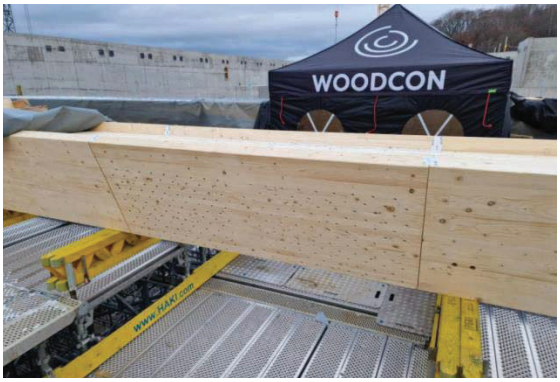


***Figure 16**: Final detailing and realisation on site*

6 CONCLUSION

The New Tøyenbath in Oslo is a project extending boundaries regarding size, functionality and corrosive demands. When compiling such a project this demands the full and continuous focus on details in material, humidity, craftmanship and process of building. While approaching the structural concept and key details of the project a cooperation and open-source approach has been key to developing a contractable and buildable project. Client with a strong vision, early discussions with producers of wood and fasteners. Simple calculations in early phases checking the feasibility of key details and the consequent use of sketches and BIM to navigate between client, producers, and design work. Every project has its delicate points. When realizing a project in C5 environment, success is an incremental process where client, material producers, companies on site and design team will only succeed together.

ACKNOWLEDGEMENT

We would like to thank the client, Oslobygg KF, for their intended aim to push boundaries for larger wood structures in Norway. This project and paper would not be possible without Oslobygg KFs focus on wood structures, continues support and close follow-up throughout the project.

THE NEW CENTRE FOR ADVANCED TIMBER TECHNOLOGY: A LIVING LAB FOR DESIGNERS, INDUSTRY, AND EDUCATION

Gabriele Tamagnone[1], Robert Hairstans[2]

ABSTRACT: To meet the net zero requirements, UK industry will need to change how it operates, relying on more sustainable resources and practices. Within this scheme, the construction industry must move, when possible, from carbon-intensive material to more environmentally-friendly ones (e.g., timber). The general lack of expertise, however, is likely to slow down the transition process. With this in mind, the Centre for Advanced Timber Technology, in Hereford, has been established to form the professionals of the future and to upskill and reskill those willing to learn more about advanced timber practises. Part of this mission is played be the implementation of a living lab approach within the building, through which data will be gathered to inform the curricula and to provide external proof of good or bad practices in timber buildings, which will impact the industry at different levels (e.g., construction practices, design specification or insurance stipulations). This paper analyses the steps taken in this living lab project so far, analysing literature cases, presenting the methodology, and listing the projects involved in the gathering of the data through monitoring of the building.

KEYWORDS: Living lab, Building monitoring, Structural monitoring, Timber education

1 INTRODUCTION

The Centre for Advanced Timber Technology (CATT) at the New Model Institute for Technology and Engineering (NMITE) in Hereford is established to act as Centre of excellence for timber engineering and, more broadly, to deliver high quality teaching in the field of sustainable built environment. In alignment with NMITE's ethos "learning by doing", CATT wants to create learning material underpinned as much as possible by research and first-hand data. This is why the building hosting the Centre is to be a living lab, where features and performances of the building are measured to inform learners, and influence change in the construction industry, raising awareness about timber in constriction and act as test cast to inform how more reliable and durable timber buildings can be built.

1.1 CATT'S MISSION

The declared mission is to establish a centre of timber engineering excellence by:

- Implementing collaborative frameworks;
- Establishing connected ecosystems; and
- Leveraging opportunities.

The first point has been crucial since the beginning, when the Centre was founded in collaboration with Edinburgh Napier University (ENU) as well as external industry stakeholder and representative groups, including Timber Development UK.

The second point has to do with how the research carried out within the Centre can inform and help both inside and outside, and how other experiences of other Centres, Institutions, or research can inform and influence the activities of the CATT. A main asset to this is the implementation of a living lab approach within the building, which will be discussed in later sections.

Figure 1: *Centre for Advanced Timber Technology and Centre for Automated Manufacturing exterior (credits Bond Bryan Architects).*

https://doi.org/10.52202/069179-0555

The third and final point is all about seizing the day, balancing opportunity with feasibility and financial sustainability, yet always with a proactive approach to external discussions and proposals that align with the strategic intent of the centre.

The intent is for the CATT/CAM (Centre for Automated Manufacturing, co-located) building to act as a Living Lab within a portfolio of Living Lab projects working with industry and external stakeholders. This approach will ensure the educational model is actively engaged with industry and informed by live projects and real-world challenges. The delivery of the CATT/CAM building will derive the methodological approach to this. The emphasis will be to collate and codify information during the building delivery and post occupancy phases (including user occupant behaviours) to enrich a Building Information Model (BIM) and correlate it with predicted performance via a feedback loop in accordance with digital twinning approaches and the "Gemini Principles" [1]. Rolling this concept out to other projects will create an ecosystems of assets capable of demonstrating the virtues of utilising advanced timber technologies for built environment delivery when combined with manufacturing techniques, with an emphasis on regenerative design, circularity, socio-economic impact and health and wellbeing [1]-[3]. The aim is to create the necessary condition for a mass validation exercise of predicted performance relative to actual performance considering a range of metrics including, but not limited to, productivity, time/cost certainty, thermal, structural, acoustic, quality assurance, safety (including fire), and environmental impact. Curriculum content will be curated utilising the case study content captured and learning from each project will be through a particular lens or series of lenses tailored to the correct level of educational attainment and necessary learnings of the derived competency framework. The CATT/CAM building will be the HUB of this ecosystem, acting as the showcase given the opportunity to continually test, learn, iterate, and innovate. Further, the co-location of CAM with CATT will result in a symbiosis of timber engineering and advance timber technologies with automated manufacturing and integrated engineering approaches, generating further learning, including the need to consider, for example, the integration of mechanical, electrical, and renewable technologies, utilisation of robotics and interfacing with alternative materials. The CATT/CAM living lab will therefore instil holistic mindsets and collaborative working approaches through the embedded educational model whilst deriving industry solutions and value return to the sector, challenging traditional construction business model and procurement practices.

2 THE CONTEXT

According to the last data, the built environment, when considered as the union between construction industry and building utilisation, is responsible for the 37% of equivalent CO_2 emissions and 34% of global energy consumption, forming the highest portion of human induced climate change [4]. The way we build in the future and how we improve the built environment will have a huge impact on the net zero policies pursued by governments and communities around the world.

Wood, as a natural material, is seen as one of, if not the, main answers of the construction world to global warming contribution. Trees are excellent carbon storers, with 1.83kg of CO_2 stored in each kilogram of wood, on average. Improving the timber industry can result in a better management of woodlands, as wood would become a more and more valuable resource, raising the level of attention to detect wildfires and diseases. However, this is true as long as structures are built to last and materials are procured sustainably, otherwise the carbon stored in the materials is released after too short a period of time, resulting in a counterproductive effort to implement more natural materials, ending in a situation where the use of less sustainable products, but longer lasting, would have produced a more sustainable outcome.

It is, in fact, at least in the UK, the maintenance and durability of timber one of the main causes of concern when a wider implementation of this material in the built environment is discussed. The majority of warranty provider don't see wood as reliable, and to insure the same structure, but built with a more traditional material, such as concrete or steel, can cost up to eight times less when compared to the same made of timber [5]. This fact, together with other misconception around the material, such as the behaviour in case of fire or its reaction to water, have undermined utilisation.

Although it is true many things around timber are misunderstood, it is also true many are the things we still don't know about this material in constructions and its reaction to external actions naturally occurring during erection or in use. Some of the questions that need an answer are, but not limited to:

- How should a building team behave towards timber elements that get wet on-site during construction and how should they assess that those same elements have dried enough to continue with the subsequent construction phases?
- What is the actual difference in sustainability between a timber structure and a more "common" one when everything, from origin of materials to construction and use, is considered?
- Is there a natural decay of mechanical properties of timber elements outdoor or indoor?
- Do systems need to be tweaked, especially air conditioning and heating, when a timber building is considered?
- Do general rules apply adequately to timber constructions with exposed wood?

Numerous are the doubts still surrounding many aspects of these kind of constructions, and many of them need to be addressed to build more sustainably, more reliably, and at lower cost.

Although, things are changing, and CATT acting as a Living Lab has the aim of creating evidence-based information and educational content to this shift towards a more sustainable way to build.

2.1 OBJECTIVES

Goals for CATT acting as a Living Lab can be grouped in four areas:

2.1.1 Durability and Warranty

Timber is regarded as a natural and sustainable material, but being natural can also be a weakness when it comes to durability, due to different issues that may occur during the lifetime of a structure, mainly due to poor detailing and/or lack of knowledge of these materials and products. Consequently, given the scarcity of first-hand data regarding what goes well and what's done wrong, and longevity of timber structure is low-balled by insurance and warranty providers, the latter overprice policies, which in turn renders prohibitive for many customers to build their new project out of wood.
One of the objectives of CATT is to create and gather information on timber structures, both good and bad practice, and to provide useful information for insurance companies to base their judgement on and give prices in line with other materials for timber buildings too. Furthermore, the objective is not only to provide proof timber can be durable, but also to assess when it isn't and what are the countermeasures to be taken to extend the life of wood-based structural and non-structural members.

2.1.2 Sustainability and User experience

Regardless of being natural, with trees sequestering carbon during their growth, the real degree of sustainability of timber constructions is yet to be evaluated precisely. The whole life carbon assessment of these structures is crucial to compare the embodied carbon of these buildings to that of other building materials constructions. Moreover, the durability issue may play a vital role in assessing these figures, with less sustainable, at least at the beginning, materials resulting more environmentally friendly in the long run due to the necessity to maintain and substitute timber decayed elements in inadequately built timber constructions.
In the utilisation of the building, attention must be paid to its serviceability and check if other materials could be better used instead or provide different characteristics to it, not only for its usage, but also for its possible modification of spaces or quality of the experience of the occupants from any point of view.
To summarise, the building must be sustainable before, during, and after, and liveable and functional during.
In this regard, CATT wants to investigate the supply chain of timber constructions, assessing the impact of all elements involved and looking into what differentiate these buildings from others. The aim is also the evaluate users' experience and indoor quality.

2.1.3 Digitisation and Digitalisation

These two topics are at the base of the development of any industry out there. Construction industry will use digital tools, IoT devices, and monitoring campaigns more and more in the years to come. In order to assess the wellbeing of a structure, sensors must be utilised and measurements taken, which then can be used to simulate different scenarios to prepare and act against possible future events before these happen. In the manufacturing and design phases, computer aided and controlled technologies will make production and construction more and more sustainable, with less waste and optimisation both off-site and on-site.
CATT, together with the Centre for Automated Manufacturing, wants to pilot new technologies and partner with industrial stakeholders to develop new ones in order to progress and push the whole timber industry, from seed to building and reuse/recycle, forward.

2.1.4 Outreach and Education

The lack of knowledge in the UK when it comes to wood and timber engineering is palpable, with very few institutions providing specialistic modules in their curricula covering what industry needs to operate in this sector in the best way possible. Many rely on CPDs after graduation or on the experience passed from employee to employee when inserted in the new company. The minority of college or university educated come out work-ready.
CATT is keen to provide education, at any level, for students and professionals wanting to have a career in the field of timber and wood industry and of sustainable built environment. The objective is to deliver up-to-date learning content in different areas, with materials underpinned by research outputs, helping, this way, not only learners, but the whole industry through outreach and dissemination.
Part of these objectives will be pursued using the CATT/CAM building as a living lab, collecting data in different areas directly from it.

3 LIVING LAB

Even if the term "Living lab" has assumed several meanings and has been used in different contexts [6], it is fair to say that the difference between that and a traditional lab is that a living lab doesn't set up tests using a controlled environment, well established boundary conditions, and predetermined loads, actions, or disturbances to see the influence of various aspects on a certain phenomenon.
A living lab takes advantage of ordinary situations, it gathers information from the actual environment to test real life scenarios and see how different approaches work when applied to a situation with unpredictable variables, which are naturally present and constitute the existent operative conditions.
This means a living lab can test a setup with way more external influences than those of a traditional test: usually, in a lab, conditions are established to analyse a specific behaviour when a particular perturbation is applied to the system. In a living lab, nothing, usually, is externally

https://doi.org/10.52202/069179-0555

applied to the system, but naturally occurring events contribute to the variation of settings.
As any test, living labs makes use of sensors and other tools to measure specific quantities. However, as they are bigger in size, greater is the number of sensors too, if compared to a normal test, to be able to get the correct information from the assessed area, which can be a school, a hospital, a factory, or even an entire city. Depending on the characteristics to be evaluated, the desired degree of precision, and the dimensions of the specimen, the capillarity and number of measuring devices could vary from few units to hundreds.
Basically, everything could be transformed into a living lab, depending on the information one wants to extrapolate and from where. Plus, a living lab runs itself: once sensors are placed and the platform starts to collect data, it is just a matter of analysing that data and extract the right information once the sample is wide enough to draw useful conclusions.

4 CATT AS A LIVING LAB PROJECT

4.1 MOTIVATIONS

The main reason behind the Living Lab implementation is to provide the evidence base to support the need to deliver a better, more sustainable built environment. As previously reported, the construction industry and building operations combined are responsible for the biggest slice of carbon emissions and energy consumption in the world, meaning that reversing the trend passes through more sustainable practices in these areas.
This means to adopt sustainable materials and technologies and to build less energivorous buildings. The former means to use natural materials, that, at least, but not only, from a structural point of view, usually means timber. In the UK, however, given the recent policies to reduce the use of flammable materials in construction, the general lack of expertise in timber engineering, and a broad distrust of wood, especially by insurance companies and warranty providers, the spread of timber structures struggles to take off. The insurance question is the one that would benefit the most from living lab approaches within timber buildings: monitoring the actual performance of the structure, especially the load-bearing elements, will give the actual picture of timber durability, providing real data that could change the perception of this material and simultaneously lower the insurance costs, which is the main reason for reconsideration for many costumers willing to have a timber building. The living lab approach will give the opportunity to learn from possible mistakes, inform policy makers, designers, manufacturers, and building companies, and in general will enable the creation of conditions for better, more reliable, and long-lived buildings of this type in the future.
The second aspect, namely, the less energy demanding building piece, can gain from the living lab approach too: the monitoring of the building can challenge the effectiveness of the design solutions adopted, informing the suitability of materials, correct performance of the details, and in general help, once more, to build better timber buildings, with better materials and better details.

4.2 METHODOLOGY

As mentioned, given the lack of skills in the UK and the necessity to change the construction industry, implementing more and more bio-based products in future and retrofitted buildings, CATT's mission is to bridge the gap, providing educational solutions for both professionals and students.
In doing so, the CATT/CAM building, together with other case studies and projects, will be used to create research-based, up-to-date learning content through a living lab approach.
The methods that will be implemented to address the four objectives outlined in 2.1 will be:

4.2.1 Durability and Warranty

The building will be used to test directly the possible issues a timber building can experience, plus measure several properties over time, such as mechanical properties and insulation performance, to give a more complete picture of the construction and its behaviour year after year.
To do this, sensors will be deployed to measure real-time quantities, both inside and outside the building, to compare internal and external conditions and get the best image of the building performance, especially in terms of humidity and moisture, and temperature. Periodic measurements on structural elements will be made to ascertain their properties remain in a suitable range over time [7]-[10]. Measurements like these, or those involving sensors, will be replicated on other buildings to get statistically relevant results and formulate better theses, with attention to the influence of different boundary conditions [11].
In the workshop, laboratory tests may be carried out to simulate different environmental conditions, and outside natural weather could be used in a "controlled" fashion to assess the behaviour of different timber products outside or to evaluate the protection capabilities of different solutions, especially those not yet covered in literature [12], [13].
The major part, if not all, of the data gathered will be used to inform insurance and warranty providers in order for them to understand better the material and related products, and what actually are the things to look more carefully at when stipulating a policy, instead of focusing solely on the fact that the building to be insured is made of timber, and so will eventually rot or burn. Moreover, the proof will be able to inform designers and constructors on non-working details or concepts, moving towards more reliable and durable solutions.

4.2.2 Sustainability and User experience

Life-Cycle Assessment (LCA) and Whole Life Carbon Analysis (WLCA) have already been used successfully to analyse the effective sustainability of timber structures [14]-[18]. However, a shared strategy is still missing, especially to compare timber figures with other materials. CATT's supply chain mapping will be used to do LCA

and WLCA to assist in the establishment of a methodology to assess the actual impact of timber constructions and judge their actual carbon storage capacity when compared to other forms of construction. This exercise will be repeated for other buildings to find a consistent and reliable method to address the issue.
Given the outputs of the first objective, the ability to deliver a more durable timber-built environment will act as an amplifier for sustainability, with less maintenance and replacement needed for timber elements resulting in longer storage of carbon within the buildings.
In addition, relying on the experience gathered from other researches in literature [19], [20], the user experience and comfort will be monitored to address the optimal use of air conditioning and heating system in an environment with exposed wood elements, being wood a hygroscopic material. This part will be covered with direct involvement of occupants with surveys and workshops [21], but other means might be used in the future to analyse other aspects and/or get rid of the human judgement/perception from the equation [22]-[24].

4.2.3 Digitisation and Digitalisation

Information from measuring the building and from the supply chain mapping will be captured within a BIM model, which will be used in the teaching activities, with the different information being used in different contexts to help teaching different topics.
In the future, the digital strategy could then be broadened to include other goals, such as:

- Understand the building from an operational perspective, enabling consumption optimisation [25];
- Have a 3D image of the measurements allowing the visualisation of the conditions and to interrogate whether different measurements are interrelated;
- Run simulations on the building using non-standard scenarios, stress-testing the system.
-

4.2.4 Outreach and Education

Finally, the above will be used, as already mentioned, to inform the outside, namely, all the areas directly or indirectly involved with the timber industry, to push the material forward, help finding better solutions to old and new problems, build more reliable constructions, and develop new technologies. This will be done in partnership with every layer of the sector, from forest to landfill, for CATT to act like glue joining together all these different entities.
More importantly, the data gathered, research undertaken, and knowledge acquired will be used in all the different programmes CATT will deliver to upskill and reskill today's professionals, or to train the future ones [26]. The educational offer will be strongly based on a learning-by-doing approach, with evidence-based content being the backbone of the teaching activities [27].

4.3 LIVING LAB RELATED PROJECTS

4.3.1 Stora Enso partnership

Stora Enso is world leader in the supplying of mass timber products. The company provided the CLT panels for the building, and started a research partnership with the Centre.
48 Wiiste sensors (Figure 2) have been installed in different locations of the building. These sensors are able to monitor the moisture content of the CLT panels at determinate depths using coated screws that work as the pins of a moisture meter. The uncoated part of the screws, namely, the tip, is the measuring part, so that different length screws can measure different parts of the panel. The sensors are all set to measure the moisture content of the inner and outer layer. Furthermore, the sensors allow also the gathering of temperature and humidity data inside the building.
The information collected will be compared to that gathered by a weather station placed on top of the building to assess the correlation between external weather and internal conditions.

Figure 2: *Moisture measuring Wiiste sensors: side (top) and frontal (bottom) view (credits Wiiste Oy).*

4.3.2 Measuring Mass Timber

Together with the architects' firm dRMM, CATT (via ENU) has submitted a proposal to fund a project that will focus on Whole Life Carbon (WLC) and Quality of Life Methods for mass timber buildings. The CATT will act as one of five case studies, and the project itself will use the information gathered with the Supply Chain Mapping (SCM) to contribute to the creation of data bank to demonstrate whole-life value of timber structures. The outline of the advanced proposal is:

- Whole Life Carbon (WLC) assessment: combining the latest industry best practice guidance for assessing

https://doi.org/10.52202/069179-0555

carbon in general and specifically for timber buildings. Defining core input requirements, challenges in data collation and comparing outcomes against business as usual and best practice datasets/benchmarks (e.g., RIBA 2030, LETI)

- Post-Occupancy Evaluation: monitoring relevant essential activity components of the RIBA's POE & BPE Primer, with an emphasis in terms of assessing Quality of Life and user satisfaction. Additional monitoring of internal air quality & thermal comfort to support any qualitative feedback. Comparing outcomes against national and building POE specific datasets.
- Fundamental project information: essential information for each building, to contextualise each case study project's WLC and POE outcomes in terms of their unique circumstances (e.g., date constructed, project build cost, detail on the building's use and client/occupiers, suppliers of mass timber systems, etc.).

4.4 DIGITAL SOLUTIONS

During the construction phase, the companies shared information through a level 2 BIM model to coordinate activities and check whether any modification to the original plan had an impact on any other already schedule undertaking.

The importance of this digital approach is that everyone is sharing the same design space and can know right away what is going on in the other operations, which optimise productivity and increase safety.

From a Living Lab perspective, the digital model can be used to collate data about different aspects of the building: a BIM model can be used not only to plan, but each element within the model can be populated with information regarding several aspects, such as supply chain (e.g., manufacturer, origin of materials, or ubication of production site), performance (e.g., U-value, sound absorption, or structural grade) sustainability (e.g., CO_2 equivalent). This way, a comprehensive tool can be generated and used as a library containing all the information about the building.

The next step is to use the model to create a digital twin. The new model takes advantage of part of the information stored in the BIM model and augment this with information about mechanical, electrical, and plumbing (MEP) systems, such as consumptions and performance. This approach helps to understand if the designed performance is met by the actual building.

The third, and more interesting, step, from a Living Lab perspective, is to use the digital twin to gather data from sensors. This approach allows for the direct estimation of localised performance of the building, enabling immediate action against any possible problem, or the ability to track the evolution of the construction over time, to check performance is maintained throughout. Another advantage of this is the possibility to use up-to-date information to run simulations, both for different from usual scenarios and for different characteristics of the buildings, namely, different materials or MEP systems, to study the building from any desired perspective and address specific problems.

At the present stage, the array of sensors currently deployed is not allowing us to take full advantage of this tool, but, given the goal we set ourselves, the will is to increase the amount of sensors and to expand the current range of monitored characteristics, making the adoption of this technology very likely, if not necessary, in the future.

Furthermore, as previously mentioned, these solutions are of interest for building maintenance and operations, which means not only research and learning activities can be based on this, but also analyses on costs and consumptions can benefit from the digital twin. Therefore, not only the CATT team, but the NMITE's Estate team is interested in this technology and will collaborate on this project too.

5 CONCLUSIONS AND FUTURE STEPS

In this paper, the current operations regarding the implementation of a living lab within the CATT/CAM building of NMITE are presented. The living lab approach is discussed together with the projects that will take advantage of said approach. Finally, digital solutions to be implemented are depicted.

The methodology illustrated is, for now, just a methodology, apart from the moisture in CLT sensors and the supply chain mapping. Nevertheless, the direction shown is clear and the targets set are well-defined and implementable over time with the correct resources secured.

In the future, further measurements and monitoring should be carried out, such as structural health monitoring or thermal performance assessment of the envelope, to not only augment the base knowledge of the building, but also to provide further information on the actual behaviour of such buildings, with an emphasis on durability. The information collated, together with that already gathered, will inform the educational programme providing first hand evidence. The LCA and supply chain mapping will provide evidence of the sustainable procurement approaches taken toward the derivation of a more standardised methodology to evidence the actual sustainability of timber buildings. Digital solutions are also considered as an approach for transparency and visualisation to convey in a more powerful and incisive way concepts regarding timber constructions, capable of assisting with the gathering of data and its interpretation, particularly as the level of sensors and measurements grows and becomes more complex.

QUANTIFYING AND REDUCING EMBODIED CARBON IN THE ACOUSTIC DESIGN OF MASS TIMBER BUILDINGS

James Bligh[1], MIOA, Piltes

ABSTRACT: An adoption of mass timber construction is the construction industry's best shot at reducing its significantly large contribution to global CO_2 emissions and to play its part in slowing down the climate crisis. Acoustic design in mass timber buildings typically relies on mass and facing materials in order to meet design criteria, and can account for a high proportion of the embodied carbon (CO_{2e}) per m² on a build. In order to fit with the ethos of mass timber construction; low embodied carbon, reusable, cradle to cradle materials must be adopted.

This paper presents the findings of a study into the relationship of acoustic performance and CO_{2e}, and proposes alternate approaches that reduce the CO_{2e}/m² of the acoustic design by up to 66% with little to no detriment to acoustic performance. Through single variable analysis in third party laboratory testing, and in situ testing, it has been found to be possible to utilise low CO_2e acoustic systems that reduce the CO_2e/m² in not only the acoustic design, but structural, M&E and architectural disciplines, too.

KEYWORDS: Acoustics, Mass Timber, CLT, Embodied Carbon

1. INTRODUCTION

Mass timber construction (predominantly Cross Laminated Timber [CLT] in Europe), is a method of utilizing sustainably FCS forestry commissioned timber to create building material that is used for structural support, roofs, floors and walls. It has garnered praise from most building design disciplines for its material properties – from structural loading capacity through to its biophilic appeal. Provided reforestation of these FSC supplies keeps up with demand, and in fact accelerates beyond it, the carbon sequestering capability of mass timber construction could lead to a significant reduction in the carbon emissions of the construction industry. To go theoretically further, if adopted on a global scale, mass timber could sequester more carbon than is omitted during the construction program.

Reforestation, increased biodiversity and an increased use of biomass fuels all are secondary beneficial factors to mass timber construction, too. However, the variability in moisture content, density, surface mass and timber species from manufacturer to manufacturer can create uncertainty in the acoustic and structural design of mass timber, leading to overspecification of floor and wall systems. Given these two disciplines have a historical tendency to utilise heavyweight isotropic mass in order to achieve relevant design criteria, the CO_{2e} of acoustic and structural design in mass timber buildings often account for an unnecessarily large proportion of the overall building design.

This paper sets out an observed correlation in acoustic performance and CO_2e/m² in mass timber construction and proposes alternative methods of construction and design approach that greatly reduces the CO_2e/m² of the acoustic design.

2. EMBODIED CARBON AS A METRIC OF SUSTAINABILITY

The lifecycle of a material can be allocated an embodied carbon figure given as CO_{2e}, which is obtained through a review of the CO_2 emissions generated from the entire lifespan of the material. This broadly covers raw material sourcing, manufacturing, transportation and longevity of the material (i.e. does it need replacement/maintenance throughout its life, and can it be demounted, recycled or reused at the end of life). As a result of this, a quantitative metric can and should be placed on any building material being used within a mass timber

[1] James Bligh, Pliteq UK, jbligh@pliteq.com

https://doi.org/10.52202/069179-0556

building – from the structural timber, right the way through to the light switches.

Manufacturers of building materials can opt into obtaining Life Cycle Assessments (LCA) in accordance with ISO 14040:2006 or EPD (Environmental Protection Declaration) in accordance with ISO 14025:2006 in order to provide evidence of the 'sustainability' of their products. However, these assessments are self declarations that are peer reviewed by regulatory bodies, but do not always address secondary ancillary materials required for those products to be used effectively – for example, floating floor isolators requiring heavy mass to obtain sufficient isolation efficiency or ceiling hangers requiring multiple layers of plasterboard. As a result, seemingly low CO_{2e} material products in isolation seem to fit the mass timber ethos, yet require high CO_{2e} materials such as multiple plasterboard linings and wet trades such as concrete and screed in order for them to meet required acoustic performance criteria.

The IPCC 6th Assessment Report offers guidance on how to reduce CO_{2e} emissions in construction, which are broken into 3 leading changes that yield the largest net reduction emission reduction, as **Figure 1** illustrates. The size of the orange circle reflects the size of the contribution of net emission reduction, the intensity of the color within the circle reflects the cost implication of implementing it, assuming material cost, delivery and construction cost:

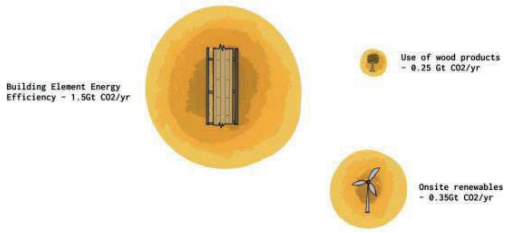

Figure 1: *Contribution to net emission reduction by 2030 (Gt CO_2/yr) – Construction* [1]

The IPCC report goes further, too. It suggests that not only changes to design criteria to aid emission reduction are considered, but also the role building materials play in the net emission reduction of CO_2 are too. **Figure 2** below reflects the data the IPCC report produces, in the same graphical format as Figure 1 follows:

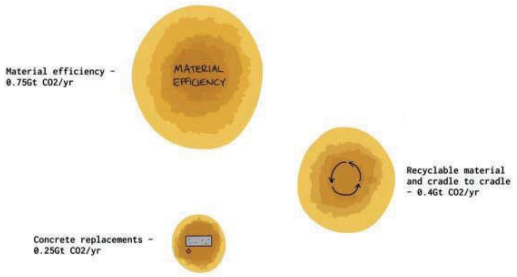

Figure 2: *Contribution to net emission reduction by 2030 (Gt CO_2/yr)- Industry* [2]

As can be seen from **Figure 2**, the efficiency of a building material (whether that be thermal, acoustic, lighting, M&E or other performance based metric) can have a large impact on net emission reduction. This can be interpreted as its ability to perform uniformly across time (low performance creep), as well as its ability to perform with as little secondary ancillary material support as possible, as discussed in the final paragraph of section 2.2**.** If this material was then to be recyclable at the end of its life (or even better demountable and reusable), the net emission reduction of the overall building is vastly improved. Lastly, the use of materials that replace concrete yields a smaller yet still significant impact on reducing emissions. In the context of building materials (i.e. facing layers, poured solutions and foundations), a reduction in the use of concrete still provides a significant chance to reduce net emissions and is largely interchangeable with materials with much lower CO_2 in most building types, but given the manufacturing, shipment and ultimate demolition of concrete accounts for 8% of global CO_2 emissions, a multi-disciplined approach to engineering out concrete where not required and favouring low CO_{2e} material is critical in slowing the climate crisis.

Finally, the benefits of switching to mass timber construction comes with many other quantitative benefits outside of CO_{2e}. Faster construction to meet demand of the housing crisis as urbanization increases worldwide, less site delivery movements, more dynamic thermal reaction, less on-site waste, and its biophilic appeal to name a

few. **Figure 3** illustrates a comparison of two hypothetical 7 storey buildings, one constructed from 100% CLT, the other concrete frame and slab.

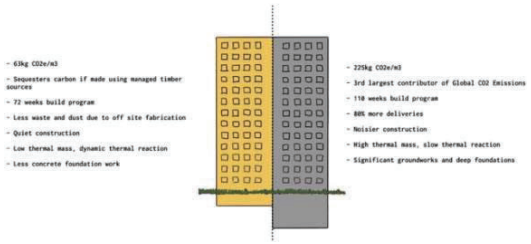

Figure 3: *Comparison of mass timber vs isotopic mass buildings.*

3. RELATIONSHIP OF EMBODIED CARBON AND ACOUSTIC PERFORMANCE

Correlating embodied carbon and acoustic performance is a difficult task to undertake due to the variables associated with design proposals, and the potential positive impacts that seemingly high CO_{2e} building materials may have on the performance of a building. A comparison with the analogy of a plastic wrapped cucumber creating unnecessary plastic waste can be drawn in construction – a plastic wrapped cucumber has a longer shelf life than an unwrapped cucumber, and is resistant to damage in transit. Therefore the plastic significantly reduces food waste - a major contributor of global CO_2 emissions. That said, alternatives to plastic wrap are now available that provide comparative, if not identical wrappage performance.

In the case of mass timber, commonly adopted concrete and screed pours onto the structural mass timber floors, or multiple layers of dense plasterboard wall linings is the plastic. Although these options all provide high thermal mass, good acoustic performance and predictable structural behavior, we must explore low CO_{2e} alternatives to meet comparable or identical performance. **Figures 4** presents an approximate correlation in airborne or impact acoustic performance and embodied carbon of concrete/screeded floor systems that can and are used in mass timber buildings. The estimated CO_{2e} of each system (not including the mass timber) has been obtained through 3rd party LCA.

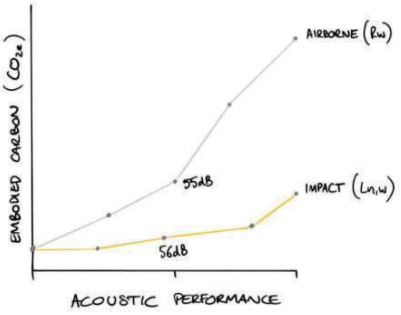

Figure 4: *Correlation of CO2e and acoustic performance in concrete/screeded acoustic floors in mass timber construction.*

Figure 4 provides not only an insight into the relationship between embodied carbon and acoustic performance in the context of floor systems, but also more broadly, the relationship between embodied carbon and general mass loading in mass timber construction. The implications of which have a significant impact on not only structural layouts, but also structural types that having varying CO_{2e} associated with them. **Figure 5** investigates the structural design implications of utilizing high dead loads to obtain high acoustic performance, and the effect on the CO_{2e} associated with that structural type.

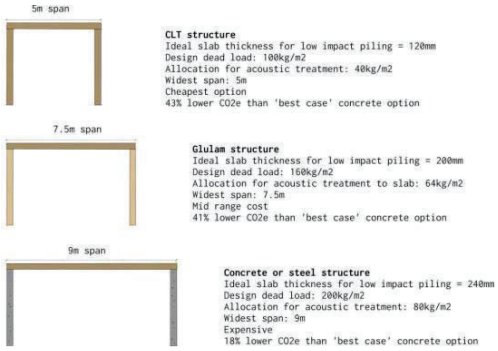

Figure 5: *Structural layout and design dead loads and CO_{2e}*

Figures 4 & 5 demonstrate that the reliance on heavy weight mass to achieve relevant acoustic performance criteria will tend to require heavier duty structural requirements, and subsequently result in higher CO_{2e} of the overall project. Increasing mass timber slab thickness to negate the requirement for heavy weight mass loading yields poor improvements in airborne performance relative to the uptake in cost. The mass law region of mass timber is narrower than

https://doi.org/10.52202/069179-0556

isotopic materials, typically between 125Hz - 2000Hz in mass timber, compared with 63Hz to 2500Hz in isotopic material such as concrete. As a result, doubling the mass of a CLT floor or wall will not provide a 6dB increase in airborne performance. This can be demonstrated through Stora Enso's mass law formula for CLT floor panels as seen below as **Equation 1**, of which estimations compares favorably with almost all laboratory testing of bare CLT panels undertaken to date.

$$Rw = 12.2LOG * (m'CLT) + 15 \qquad (1)$$

where: m,CLT = surface mass of CLT in kg/m^2

Equation 1: *Stora Enso estimation of Rw performance of CLT floor*

4. DESIGN PRINCIPLES TO MAINTAIN ACOUSTIC PERFORMANCE AND REDUCE EMBODIED CARBON

A review of fundamentals of sound insulation design holds the key into looking at reducing embodied carbon in mass timber design. In order to obtain low resonance in a floating floor, and consequently providing good transmission loss values at low frequency on mass timber slabs, mass loading needs to be considered in conjunction with a selected resilient layer, the material properties of which are relative to one another depending on the dynamic stiffness of the resilient layer type, and the density of the mass layer. Resilient materials that have a linear load vs Fn relationship will naturally require more mass per m^2 in order to obtain low Fn, elastomeric materials less so. But both materials requiring mass in order to achieve a Fn that is sufficiently far 'left 'on an airborne sound insulation test, nonetheless. Conversely, ceiling or floor voids provide a much efficient method of lower the Fn of a separating element whilst keeping CO2e low. Airgaps does not cost the earth. The resonance of a floating floor or the resonance of an air stiffness can be calculated as shown below in **Figure 6**.

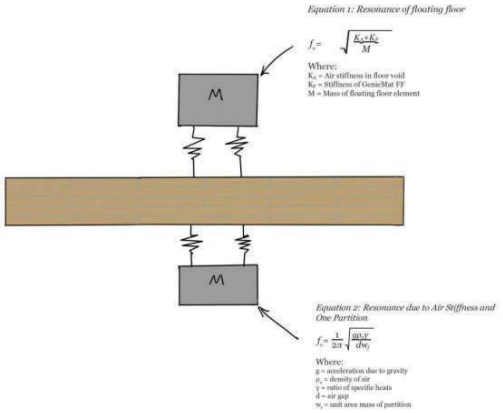

Figure 6: *Resonance calculations of separating elements of a slab.*

Figures 7 & 8 overleaf demonstrate this in effect. A relatively lightweight screed performs similarly to a dry laid, fully demountable boarded system on the same resilient layer, despite drastically different loadings – 82kg/m^2 for the screed, 30kg/m^2 for the dry laid board. It may be theorized that the resonance weakness in sound insulation still lies with the CLT, as the resonance of the floating floor isn't low enough to take this out. An inefficient use of a high CO_{2e} material. If we apply the same thinking to a ceiling void utilizing resilient clips and a sufficiently sized ceiling void (~150mm and above) and a single layer of 15mm plasterboard at 12.8kg/m^2, a much better airborne performance is achieved than the screed, whilst using ~85% less CO_{2e}/m^2.

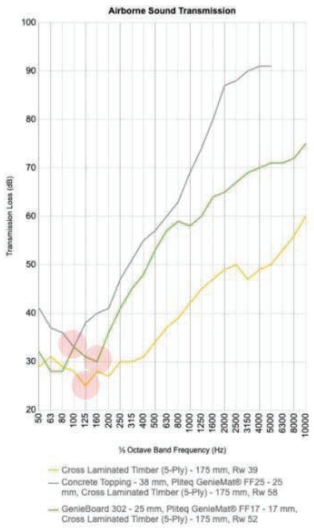

Figure 7: *Airborne and impact performance of differing mass layers on the same resilient layer, on CLT slab*

https://doi.org/10.52202/069179-0556

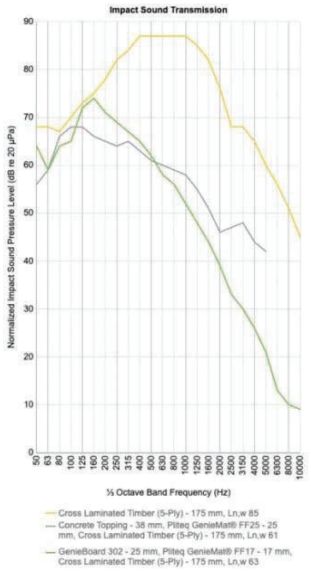

Figure 8: *Airborne and impact performance of differing ceiling void sizes on bare CLT slab*

5. VERIFYING HYPOTHESIS

Building mass timber buildings without using any form of concrete or screed still has many risks outside of acoustics. Insurance for the building is still a significant hurdle for developers as fire regulations are yet to recognize the extensive research into exposed mass timber fire performance. As a result, full encapsulation of the structure with minimum A2:Sfl1 rated material is required in order to obtain insurance for buildings over 7 storeys – materials that are commonly gypsum based. However, this balance of fire performance and the use of high-density material can still work hand in hand with the acoustic design, and obtain high quality acoustic performance. It is possible that we may be at a stage of overdesign of mass timber buildings to compensate for the high fire and acoustic criteria, reflective of current regulatory requirements. A case study of a care home is taken as an example of this. **Figure 9** below illustrates an acoustic system that was devised to provide encapsulation of the structure (direct fix plasterboard) to the soffit, and full class A2:Sfl1 encapsulation of the floors and walls, between each unit. 120 airborne and impact site tests were undertaken on separating floors and walls upon completion to check for compliance with $D_{nT,w} + C_{tr} \geq 45dB$ and $L'_{Tn,w} \leq 62dB$. The average of these site tests are provided, with a data spread of +/- 6dB for airborne performance (largely driven by penetration details or pattressing requirements, and +/- 3dB for impact performance. It is unclear what variables affected the impact performance data spread, but it is theorized that CLT slab spans and room orientations were a contributing factor.

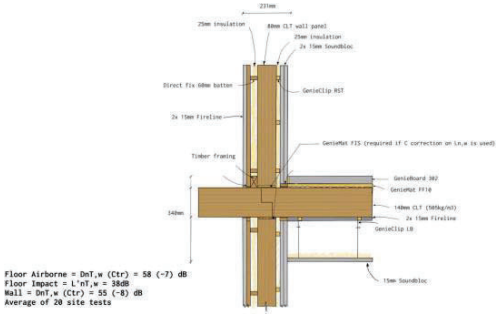

Figure 9: *Full encapsulation CLT detail for residential care home.*

It's estimated that the overdesign of this system led to an 'overspending' of approximately 5.6kg/m^2 of CO_{2e} or, accumulatively, 67.2tons of CO_{2e} across the whole development. If we adopt mass timber for even 20% of the current housing stock requirements, this will lead to an unnecessary 'spend' of approximately 8000 tons of CO_2 per year, at the current housing stock demand construction rate. The residential sector is arguably CLT smallest market currently in the UK, with offices making up most of the demand.

A similar case study was conducted on an office development where 1200m^2 of screed was to be poured on a 140mm CLT slab, with a 5mm virgin polyurethane foam resilient layer separating the two. This system was high in CO_{2e} (approximately 59kg/m^2), non-recyclable and likely to creep in impact performance across the lifespan of the building given the compressibility of the resilient material. An exercise was conducted to review the use of dry laid, demountable and recyclable material in lieu of the poured solution and it was deemed a cost saving system when factoring in the 12 week program saving it provided. **Figure 10** below illustrates the system that was installed.

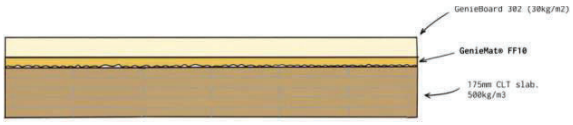

Figure 10: *Dry laid office floor system on CLT to meet BCO Shell and Core (DnT,w 45dB).*

https://doi.org/10.52202/069179-0556

This system provided the structural requisite 0.4kN/m^2 dead load damping to meet minimum floor response factor requirements in conjunction with an installed raised access floor, and achieved an in situ performance of $D_{nT,w}$ 45dB and $L'_{nT,w}$ 50dB before the RAF was installed. The LCA estimated CO_{2e} saving across 1,200m^2 was approximately 34kg/m^2, or 40 tons of CO_{2e} across the development. If this approach would be adopted at current office development construction/refurbishment rates it will save up to 4800 tons of CO_{2e} per year. Providing service/conduit routing within this floor system to negate the requirement for the RAF would provide further significant CO_{2e} savings.

6. CONCLUSIONS

The design of mass timber buildings needs a considerate approach to utilize low embodied carbon materials to achieve relevant criteria for reasons twofold:

- To achieve the 'as little as possible' ethos when considering material use, wastage, cradle to grave material lifecycles in order to reduce embodied carbon in mass timber construction to as low levels as possible.
- To provide high quality mass timber buildings that perform as good or better than currently adopted high CO_{2e} construction (concrete, steel etc) that can be constructed fast, efficiently and to required specification - leading to the furthering of confidence, enthusiasm and trust in mass timber construction and all related engineering disciplines.

Mass Timber construction needs to be considered as a option for most construction projects where viable for the purposes of slowing down the climate crisis, and coordinated engineering approach between all disciplines (but most importantly fire, acoustic and structural) from an as early stage as possible, to ensure the viability of the design from a cost, buildability and cradle to cradle material perspective is ensured. Through third party data and assembly specific testing, this can be done and the elimination of high embodied carbon acoustic materials can be achieved.

7. ACKNOWLEDGEMENT

Thank you to my wife Stefanie for listening to me air my thoughts about mass timber at the dinner table and being disproportionately raging about cement for nearly 2 years, Pliteq for supporting me in my research, and to my immediate Pliteq UK team for laughing at me when I walked into a lamp post whilst enthusiastically talking about CLT, rather than checking if I was ok.

NEW HQ COPENHAGEN
A NEW STANDARD FOR SUSTAINABLE BUILDINGS IN AN INTERNATIONAL CORPORATION

Elias Mohr Wilson[1], Dorthe Keis[2], Mai Marcussen Yoon[3]

ABSTRACT: This paper provides an insight into the process of developing the new headquarters for an international client in Copenhagen. The preliminary analysis leading to the decision to go for a timber construction, as well as the direct and derived effects of using a timber construction in the new headquarters.

KEYWORDS: Headquarter, office building, Copenhagen, Denmark, Arkitema, COWI, timber frame, timber building, hybrid structure, glulam, CLT, LCA, exposed timber, upcycling, recycling.

1 TIMBER HYBRID STRUCTURE AS A DRIVER FOR SUSTAINABILITY

1.1 INTRODUCTION

The client is the Danish branch of a global corporation but wishes to stay anonymous. The client is planning a new headquarters in Ballerup on the edge of Copenhagen.

The client has its current headquarters in an existing building from the 70s in Ballerup, near Copenhagen. Over the past years the needs of the corporation have outgrown the existing facilities, so when the client approached Arkitema/COWI in 2019, the question was how to either accommodate future needs in the existing building, or completely rethink the site and create a headquarters that would be state of the art and show the way forward for future facilities in the global corporation.

Figure 1: *Interior and exterior visualizations of the future building, Arkitema/COWI.*

1.2 PRELIMINARY ANALYSIS AND BACKGROUND

The preliminary analysis showed that the existing buildings would be unfit for the functions needed in the future, and therefore the choice was made to start from scratch. In the early phases, the strategy for the building was laid out. The client's wish to create a futureproof and sustainable new headquarters acted as a main driver.

Sustainability can be interpreted very widely. For their new office building in Ballerup, the client chose to set ambitious goals regarding environmental sustainability.

Giving environmental sustainability highest priority makes good sense. The 2016 illustration of Stockholm Resilience Centre shows this precisely: there is no functional economy without a functional society, and there is no functional society without a functional biosphere.

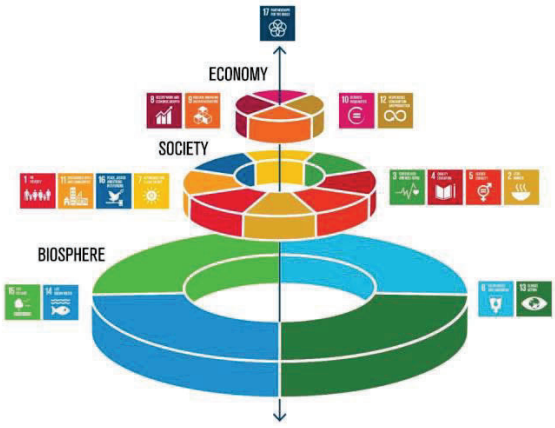

Figure 2*: There is no functional economy without a functional society, and there is no functional society without a functional biosphere. Source: Stockholm Resilience Centre 2016, Contributions to Agenda 2030 - Stockholm Resilience Centre*

Furthermore, this is much in line with the direction of the corporation globally, which aims to conserve natural

[3] Mai Marcussen Yoon, Arkitema, mamyo@arkitema.com

https://doi.org/10.52202/069179-0557

resources and to become CO_2 -neutral by minimizing energy consumption and investing in compensating measures. To the client, minimizing energy consumption is a key element.

Different design strategies for achieving these goals were assessed, and the eventual preferred choice was a timber grid, with timber columns, beams, and slabs, which would allow for maximum flexibility in the future layout while also having a markedly lower CO2 impact on the overall Life Cycle Assessment (LCA) analysis. The lower CO2 impact from the timber structure was a key element in the overall strategy to create the sustainable headquarters for the future.

Due to the early stage of design, a comparative analysis was done on a timber structure vs. a traditional concrete structure, giving the client an overview of the advantages and disadvantages before choosing the method of construction.

The following topics were mentioned as facts regarding timber:

- Timber is a renewable resource.
- Timber is easy to recycle.
- Green energy is used to manufacture the building material, and timber uses considerably less energy than for concrete.
- The timber structure requires no maintenance provided the timber is protected from moisture.
- There is not yet the same tradition in Denmark for using timber as the main structural elements in multi-story office buildings as there is for concrete structures.
- It is not yet routine work for construction companies, architects and engineers in Denmark.
- Using timber as a structural material is in line with the Danish government's recommendation and ambition towards a climate-neutral construction sector.
- It is very good branding for the client to be one of the front runners in Denmark.

Topic	Advantage	Neutral	Dis-advantage
CO_2 emission	+		
Recycling	+		
Energy used on site during construction	+		
Maintenance		-	
Tradition in Denmark, few contractors			÷
Branding	+		
Prefabricated elements		-	
Composite solutions		-	
Shorter grid for columns and higher structural beams and decks			÷
Less foundation required	+		
Time schedule during construction	+		
Construction costs			÷
Planning costs			÷
Limitation of highest floor level			÷

Figure 3: *Advantages/disadvantages for timber construction compared to concrete construction, summarized in note "Timber versus concrete", Arkitema/COWI February 2020*

2 AMBITIONS & FOCUS POINTS

With inspiration from the client's draft for a 'sustainability laboratory', environmental sustainability has the following focus points:

- The GWP (CO_2 -equivalents) should be minimized for the building's whole life cycle by energy efficient design and choice of energy supply.
- LCA should be applied in the early design. No specific limits will be defined before this project. In Bl110 no specific requirements for the use of BIM tools have been defined.
- The clint's "sustainability checklist" applies.

Furthermore, indoor climate is part of the client's project-specific goal about working conditions. No special effort will be made within design regarding "electro smog". For thermal indoor climate and indoor air quality, the requirement is category II according to DS/EN 16798-1:2019.

In alignment with the 'sustainability laboratory'-goals, efforts will be made within the masterplan, building design, renewable energy on site, choice of materials as

https://doi.org/10.52202/069179-0557

well as design of mechanical installations. The stages described correspond to DS/EN 15978:

- Stage 0: The demolition of existing structures (outside system boundary)
- Stage A: Product stage and construction process stage
- Stage B: Use stage (operation and maintenance)
- Stage C: End of Life
- Stage D: Reuse, recovery, and recycling of materials

3 SUSTAINABILITY STRATEGY

A sustainability strategy for the life cycle of the building was decided at the beginning of the outline proposal, and the status was updated at the end of the outline proposal.

3.1 STAGE 0 + A, ENERGY USED ON SITE

This is usually not considered in Danish building projects, even though significant GWP and PE are related to this. The client has decided that within this field no special measures will be carried out.

3.2 STAGE 0 + A, EMBODIED GWP

This is usually not considered in Danish building projects.

Focus is to minimize GWP and PE related to the materials, which are demolished as well as materials used for the new building. Demolished materials should be utilized/recycled in the best possible way.

The GWP and PE of new materials will influence the building design and the choice of materials.

Included: Sensible, qualitative considerations by the general choice of new materials generally and applications of LCA for the selected cases:

- Foundations: Comparison of sand bed or pile foundations
- Construction of floor slabs (3 alternatives)
- External façade cladding (3 alternatives)
- Whole building LCA according to Danish DGNB to provide the client with a benchmark for GWP and PE

3.3 STAGE B, OPERATION AND MAINTENANCE

The building is to meet the (strict) low energy option of the Danish building regulations (for heating, cooling, domestic hot water and auxiliary energy).

The energy demand in operation is to be optimized during design with an eye to the future renewable energy system.

The client will consider all energy demands (GWP and PE) during operation, and not only operation of the building. The client will revise its purchasing policy and implement tough requirements regarding energy demand (GWP and PE) for all equipment.

This is in line with the client's interest for the passive house criteria, which include all equipment, not only the building itself.

The client will apply a commissioning period covering the first 14 months of operation in order to ensure proper operation.

Commissioning covering the first 14 months of operation supplied by COWI/Arkitema.

3.4 STAGE C + D, END OF LIFE AND RECYCLING

The building will basically be designed for long-term usability, in order not to repeat the choices, which led to the planned demolition of the client's buildings dating from 1970-1990.

Included: Design of sensible (in the designer's interpretation) extra space for ducts and in technical rooms. Designing for higher live loads (3.5 rather than 2.5 kN/m²).

But inevitably, possibly for other reasons than its usability, the building will be demolished at some time. This should be accounted for with a "design for disassembly" approach or at least in a way to minimize resources required in demolition and recycling. Demolition is closely connected to the recyclability of the materials and the choice of materials.

Included: minimal, qualitative considerations.

This set of initiatives is in line with the corporation's principles for product development:
"As a matter of principle, we start optimizing products in the development phase, applying the following criteria: energy and material efficiency, emissions education, and repairability.", Client, Sustainability report 2018 spotlights.

4 TIMBER AS ADDED VALUE TO THE OFFICE ENVIRONMENT

4.1 MENTAL HEALTH BENEFITS

Several studies have shown that, as humans, we perceive timber surfaces as more natural and calming compared to other traditional building materials. This added benefit of timber has also become a significant factor in design, and efforts have been taken to ensure as much visible timber in the interior as possible. [1]

4.2 SUSTAINABILITY AS PART OF THE CORPORATE STRATEGY

Utilizing the mental health benefits of timber by exposing the surfaces has several other benefits. The strategy to build and focus on sustainability becomes visible

https://doi.org/10.52202/069179-0557

throughout the building and speaks clearly to the employees and visitors that sustainability is an integrated part the client's identity in the 21st century. This is possible due to the general perception of timber as a natural material.

With the organization of the building around one large multi-story atrium, where all employees and visitors pass through, the strategy is further emphasized by maximizing the amount of exposed wood surfaces in this space. Furthermore, extra steps will be taken by using upcycled wood (offcuts from the wood industry) in the construction of the auditorium podium to save CO2 and improve the overall footprint.

In the vison of the future headquarters, the client had the concept that the use of wood is to be visible and the building material would represent "Nordic Nature".

5 CHALLENGES

5.1 GEOMETRY AND LAYOUT

An appropriate module is 6 x 6 meters. A larger span affects the thickness of the timber required for the constructions, which is not economically viable. A wooden construction requires many pillars, and this can affect floor plans. Therefore, it is important to think about the construction principle from the start.

5.2 BUILDING PARTS

Though timber has been chosen as the main material for the structural frame, concrete still has its place in modern buildings. For example, concrete is required for in foundations, basement and parking facilities and stairwells, since timber is not a viable option.

Another example is if a cantilevering structure is chosen for aesthetic reasons to make the top part of the building ("the cloud") free from the building base. In this area, steel in combination with timber will be necessary to ensure stability and strength.

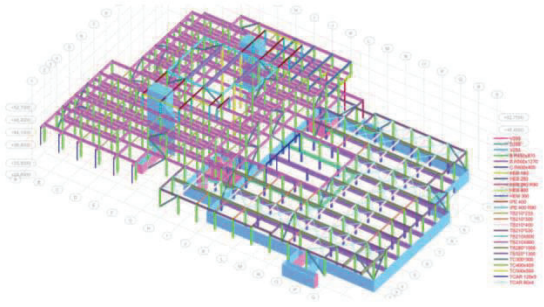

Figure 4: *Structure, Isometry – Building. Outline Proposal, Arkitema/COWI*

Finally, floor-slabs have been designed with a layer of concrete on top of the CLT elements to meet the demands for acoustic dampening between floors in a modern office environment.

At an early stage the client decided not to use wood as the façade cladding, since this would increase maintenance costs, although an exception was made in the courtyard. A panel system of thermo dried FSC-wood lamellas and 100% collected and recycled Green Aluminium offers a distinctive and sustainable façade.

5.3 ACOUSTICS

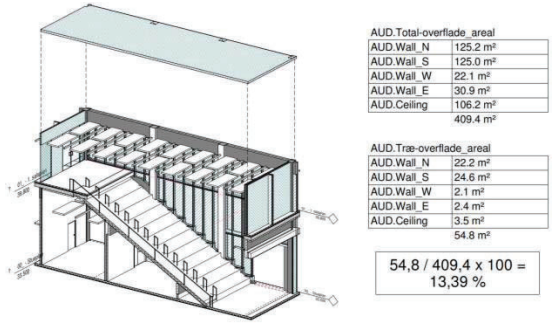
Wood generally has lower sound insulation than concrete. Therefore, noise and vibrations will spread more easily through the construction. The client's headquarters will be a multifunctional building with office, education and noisy workshops. The noisy functions will be located away from noise-sensitive functions. Some workshops will be "box in a box". Floor partitions made of CLT wood with floating concrete floor will create sound insulation due to the increased weight. Due to few reference projects in Denmark, there is some uncertainty in relation to calculation methods. We must learn through measurements of these new buildings. Until then, Arkitema/COWI have learned from, among others, Norwegian projects through COWI Norway and thus obtained evidence for calculations.

5.4 FIRE SAFETY

The project is favoured by the fact that in Denmark the limit for the maximum height has now been raised for wooden buildings from 9.4 m to 12 m. Less documentation is therefore required.

Requirements for the maximum extent of internal exposed wooden surfaces is 20%, and this must be documented.

Constructions are designed for 60 min. fire. The underside of CLT decks need to be covered with mineral wool or plaster boards for fire protection of the wooden surface.



https://doi.org/10.52202/069179-0557

Figure 5: *Quality check/documentation of max 20% exposed wooden surface in the auditorium. Arkitema/COWI*

Great attention must be paid to how installations are routed through a load-bearing wooden construction. It is recommended to plan with longitudinal guides to minimize the number of cross main penetrations. When drilling holes, great attention must be paid to fire sealing and fire joints.

5.5 BUILDING PROCESS

A significant challenge during construction is how to deal with the rain and moisture of the Danish climate. The proposal is to use site-cover weather protection during construction of the building, but this cover comes with the drawback of extra cost compared with traditional construction methods. However, the cover is storm proof and snow proof to Danish standards and offers factory-grade production facilities for the work and therefore gives the possibility to minimize the overall construction time. In the project, it was decided to only cover the taller part of the building. The single-storey part of the building has a steel-trapeze roof, which has interim weather protection.

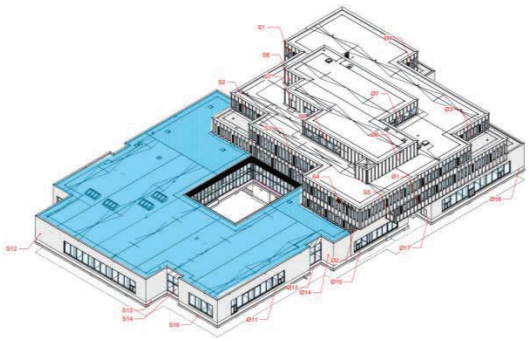


Figure 6: *Lower part of the building with a steel roof solution to minimize use of site-cover. ARKITEMA/COWI*

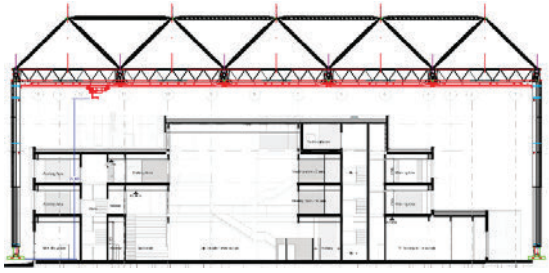

Figure 7: *Site-cover planned as protection for the tallest part of the building. Arkitema/COWI*

6 LIFE CYCLE ASSESSMENT

6.1 ASSESSMENT AS A DESIGN TOOL

Throughout the design process comparative studies have been made on balance aesthetic, functional, financial and sustainability requirements. Life cycle assessment (LCA) was an important design tool in defining building parts and technical solutions:

- The first LCA study compares the GWP and PEtot of a pile foundation and a gravel bed foundation solution. Results of the calculations showed that the gravel bed is the best option in terms of LCA. Based on this, it was decided to use the gravel bed for the project, as there was no significant difference in cost for the two scenarios.

- Lightweight balloon frame exterior walls with slate as façade cladding, was chosen due to good LCA performance.

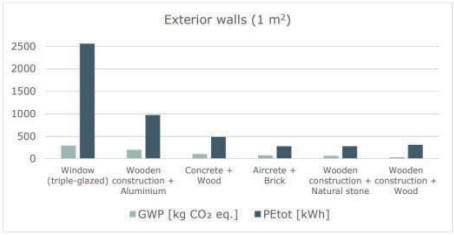

Figure 8: *LCA CALCULATIONS, Outline proposal. Arkitema/COWI, August 2020.*

- Climate sails were chosen in favor of a full-covering climate ceiling, as this solution has significantly lower CO2 emissions

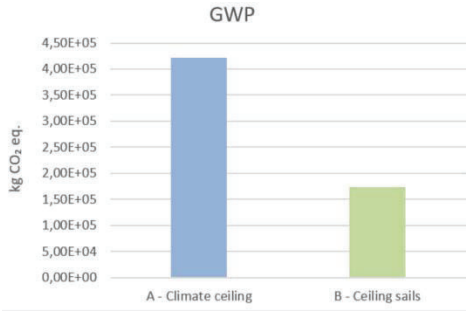

Figure 9: *Integrated design LOG, Arkitema/COWI,*

https://doi.org/10.52202/069179-0557

October 2020.

- 6 relevant types of floor construction were analyzed and the one with the best GWP performance was chosen

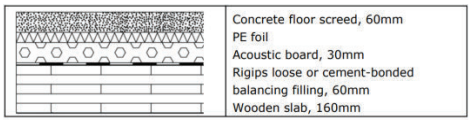

Figure 10: *LCA CALCULATIONS, Outline proposal. Arkitema/COWI, August 2020*

- Acoustic ceilings; Wooden lamellas were chosen due to best GWP performance.

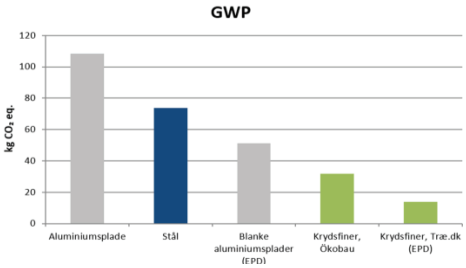

Figure 11: *LCA CALCULATIONS, Outline proposal. Arkitema/COWI, August 2020.*

6.2 ADDITIONAL POTENTIALS

Late in the design process, the client decided to explore additional potentials for sustainability. The following focal points were investigated and incorporated into the final tender project:

- Circular potentials / Reused materials: One aspect, which in the future could be better integrated into the early-stage design process, is the use of recycled/ upcycled building materials. One example is the aforementioned podium stair in the auditorium, which will be built with recycled timber. Other building parts like the choice of carpets have also been chosen with circularity in mind.

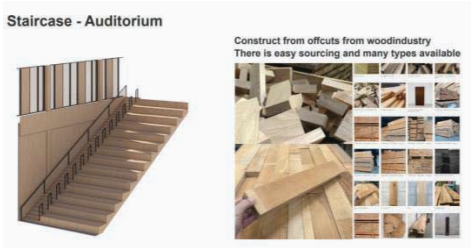

Figure 12: *Circular potentials presentation, Arkitema/COWI, March 2021.*

- Design for disassembly and material loops: Design for disassembly in selected construction details and overview of material loops (facade, floors, interior walls).
- Minimizing harmful substances in building components: Purpose is to protect building workers, building users and the environment in general.
- Reusing rainwater: Rainwater for watering plants, is collected in an underground tank.

6.3 FINAL ASSESSMENT

A life cycle assessment (LCA) was carried out for the full building to have a benchmark for future buildings in the corporation. The assessment describes the full LCA-calculation for the building based on the main project. The results were analyzed with focus on global warming potential (GWP) and total primary energy (PEtot). The additional environmental impact categories were included in the overall results. Generic data were used for all materials except aluminum facades, carpets and wooden floors. Environmental data for wood was also changed to Danish EPD data to represent the Danish market. The method follows the Danish 2020 DGNB manual for new buildings, except for the use of uncertainty factors.

The building has a total GWP of 6,752 tonnes CO_2 eq, which is 9.6 kg CO_2 eq/m²/year over the 50-year calculation period. The results have been compared with the Danish CO_2 requirements from 2023, where the limit is 12 kg CO_2 eq/m²/year. The results show that the slabs, walls, roof, windows/ doors/ curtain walls and solar panels contribute to the largest GWP and PEtot impact. For PEtot especially slabs, beams/ columns and roof have a large impact caused by the wooden constructions. Results have been compared with the Danish DGNB reference office building. Compared with the reference, the client's headquarters in Denmark has a lower environmental impact on all categories. The building would score 56 out of 75 possible DGNB points in the LCA criteria.

https://doi.org/10.52202/069179-0557

6.4 SUSTAINABILITY STRATEGY – STATUS END MAIN PROJECT

By the end of the main project, the following measures will be included in the strategy and design:

- A sustainability manager has been involved in the project since the beginning and will participate in meetings regularly to maintain the focus on sustainable solutions.
- The building will be constructed with timber as a large part of the structure.
- The extent of concrete basement and foundations will be minimized.
- Energy demand for building operation will meet the low energy requirements of the Danish building code.
- Cooling and heating will be supplied by groundwater.
- Demolished materials will be used in the best possible way.
- Sensible, qualitative considerations by the choice of new materials and LCA for selected cases.
- Reused and recycled materials will be used in selected areas (carpets, wooden stair by the auditorium and some lighting fixtures).
- Rainwater will be collected and reused for irrigation of plants and rinsing machines.
- Improved operation and energy efficiency of heating and cooling heat pumps through whole building simulation.
- Indoor climate mostly category II according to DS/EN 16798-1:2019.

The client's project in Ballerup makes a special effort regarding SDG13 by reducing the GWP throughout the life cycle of the building and SDG7 by improving energy efficiency.

A WORKABILITY AND SUSTAINABILITY ASSESSMENT OF MULTI-STOREY EARTHQUAKE-RESISTANT TIMBER BUILDING

Kazuki Tsuda[1], Ahmad Ghazi Aljuhmani[2], Arata Minegishi[3], Yutaka Goto[4], Masaki Maeda[5]

ABSTRACT: Although two-thirds of the area of Japan is covered with forests, the domestic wood resources are not widely used in the construction sector. Due to the complex design process, construction work and high precision needed, most of timber constructions are limited to one or two-storey buildings. This paper aims to clarify the efficiency of a proposed joint system for CLT walls-steel beams hybrid structure. In addition, the workability and the environmental impact of the proposed hybrid system in comparison to other structures were analysed. The proposed joint system showed higher workability and efficiency compared to other conventional joints in Japan. The construction process of a prototype of a module with the proposed system was studied and confirmed its easier and faster work than the conventional system. A 4-storey building was taken as a case study to evaluate the environmental impact of the proposed system. Although the proposed hybrid system showed higher carbon emissions than a conventional CLT alternative, advantage in terms of the environmental impact was confirmed in comparison to a reinforced concrete and a steel structure.

KEYWORDS: Cross-laminated Timber, Hybrid structure, Workability, Life cycle assessment, Sustainability

1 INTRODUCTION

In recent years, a mid-to-high-rise wooden building has been attracting attention from the perspective of a low-carbon building and the effective use of forest resources. In Japan, although 66% of the total land area is covered by forests (Japanese Forestry Agency (JFA)), these renewable resources are not being used to their full potential. Buildings higher than three stories (mid-to-high-rise buildings) are mainly non-wooden structures [1], with a share of only 0.06% for timber buildings.

Cross-laminated Timber (CLT) is considered a promising engineered wood product (EWP) for a structural material of a mid-to-high-rise building with low carbon emissions. CLT has a similar structural performance as reinforced concrete, which means that CLT has the capacity to resist the weight of the building and large earthquakes. Moreover, recent studies [2-5] found the environmental superiority of mid-to-high-rise CLT buildings compared with reinforced concrete buildings.

However, the common structural systems for CLT buildings have challenges regarding reasonable seismic design and workability. For instance, an unreasonable amount of CLT walls (i.e., to compensate for the low strength and stiffness connections) and a large number of complex connections are needed. In order to tackle the structural challenge, CLT-steel hybrid structures can be a possible solution. The effect of the high strength and stiffness of the steel could be effectively used to increase the CLT panel's capacity under lateral loading, thus reducing the number of CLT panels required. The seismic behaviour of the structure using innovative CLT-steel hybrid systems was investigated by several researchers in the past years [6-8]. Fukumoto et al. [9] theoretically investigated the structural performance of steel frames with CLT infill. They found that the use of steel can increase lateral performance by almost 2.0 times compared to the CLT structure.

Nevertheless, such CLT-steel hybrid structures have a difficulty in workability due to a large number of complex connections. Hence, construction companies struggle to deal with the complex construction due to the hybridization. In addition, studies regarding the environmental performance of the hybrid structure are limited.

This paper proposes a novel hybrid structure with CLT and steel beams with steel joints that are designed to have both high efficiency and workability. Moreover, a case

study of a building with the proposed system is also introduced (Figure 1) in order to analyse the environmental performance. The targeted building is 4-storey residential building to promote the mid-rise building. The objectives of this paper are 1- Discussing the efficiency and workability of the proposed joint compared to the conventional connections. 2- Demonstrating the workability of the proposed system. 3- Analysing the environmental performance of the hybrid system in comparison to other common structure systems.

2 PROPOSAL OF A HYBRID STRUCTURAL SYSTEM WITH CLT PANEL AND STEEL BEAM

2.1 Problems of conventional structural systems

In Japan, the ductility of a building is essential to resist earthquakes. Therefore, conventional structural systems are designed to have high ductility. Figure 2 shows the conventional structural systems of CLT panels in Japan. They consist of CLT walls and slabs. The use of CLT slabs caused the reduction of the seismic capacity of the building. When the wall is subjected to lateral force, the wall transfers compression force to the CLT slab perpendicular to the grain, which leads to low rocking resistance.

For the connections of conventional systems, two types of joints are required: tensile joints and shear joints. The tensile joints are installed at the corners of the wall. The common tensile joints are a screw joint with a U-shaped metal bracket and a tensile bolt joint. On the other hand, the shear joints are at the top and bottom of the CLT wall. The common shear joints are a U-shaped and a L-shaped metal connector joint with screws.

These conventional connections have structural challenges. The flexural yielding of screws and the yielding of tensile bolt contribute to the ductility performance of a building. However, although the conventional systems have the desired structural ductility, they do not take advantage of CLT performance to its full potential. For instance, the material's lateral strength of the CLT wall made from Japanese cedar with a thickness of 90 mm (3-ply 3-layer) is reported as 2.31 MPa [10]. Nevertheless, when the tensile bolts are applied as the tensile joints, the strength for designing is 0.40 MPa according to the design guideline of CLT structure [11] This means that the current structural systems utilize only 17 % of the CLT panel performance.

Furthermore, the conventional joint systems have difficulties in material processing and construction workability. The three out of four tensile and shear joint types require Computerized Numerical Control (CNC) processing of the panels for rectangle holes and cut-outs. Making the CNC data and the actual processing in a factory for each CLT panel takes time. Hence, processing CLT wall panels with conventional systems entails higher labour and longer process time.

Regarding the workability of the screw joint, in order to have the necessary structural performance, a large number of screws is required to be installed for 6 joint types. This process takes longer time. As for the tensile bolt joint, anchor bolts are already fixed to the base/floor. Then, the wall is fixed by the anchor inside the pre-drilled holes in the walls. Therefore, high precision for the anchor bolts in the installation is required, which leads to higher labour time and cost.

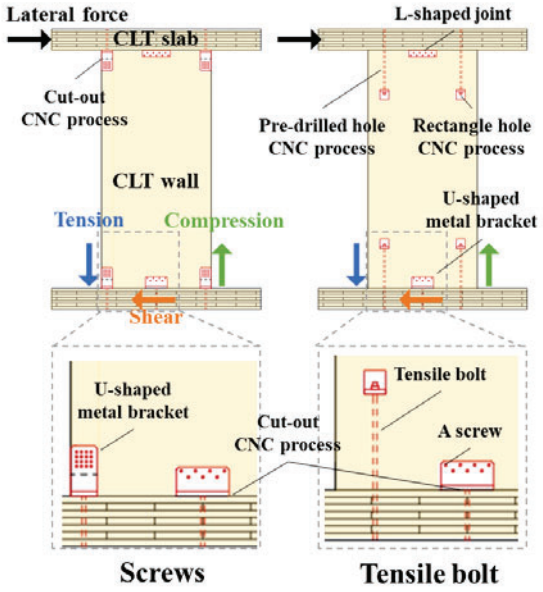

Figure 2: *Conventional structural systems of CLT panels in Japan.*

2.2 Description of a hybrid structural system

To overcome the low efficiency and workability of the conventional systems, a hybrid structure with CLT panels and steel beams is proposed as shown in Figure 3. The use of steel beams increases lateral capacity compared with the use of CLT slabs. Figure 4 shows the differences in the embedment behaviour between the wood slab and the steel beam. The wall transfers compression force parallel to the grain in the main axial layers, which leads to high rocking resistance and better CLT panel performance.

In the joint of the proposed hybrid system configured at the CLT panel corners, steel plates are applied on one side of the CLT panel to connect the panel with steel beams using three bolts in the CLT panel and one bolt in the steel beam. In the proposed structural system, the joint is resisted as the combination of both tension (uplift) and

https://doi.org/10.52202/069179-0558

shear forces which are induced by the lateral force applied on the wall. Therefore, the plate joint requires a smaller number of connectors compared with the conventional joints. Regarding processing, CLT walls can be directly shipped from a production factory to a construction site because carpenters can make bolt holes for the walls on site. Hence, the plate joint system can reduce the cost derived from processing. In addition, the construction of materials by bolts does not require a high construction accuracy as opposed to the tensile bolt connection. This makes the installation of CLT walls easier compared to conventional systems.

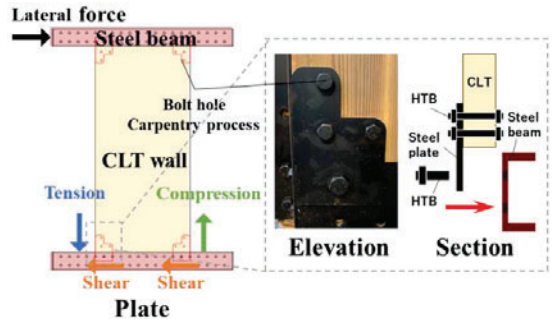

Figure 3: *Details of the hybrid system.*

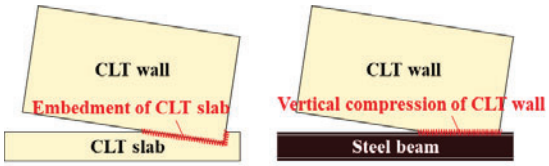

Figure 4: *Embedment difference between a CLT slab and a steel beam.*

3 WORKABILITY PERFORMANCE ANALYSIS

3.1 WORKABILITY COMPARISON

In order to compare the efficiency and workability of the three variations of the joints (two conventional ones and the proposed plate joint), a comparison of the intensity of constructive works of these joints was conducted. The three joints were designed to have the same strength. The design specification and strength of the plate joint were gained from the shear wall tests in a past study [12]. In this study, the joint consisted of three bolts with a diameter of 20 mm (M20), the steel plate with a thickness of 9 mm and the CLT wall with a thickness of 90 mm. The ultimate tensile strength was 66.8 kN. The two conventional joints were designed to have the same strength as the plate joint, based on the design guideline of CLT structure [11]. For the screw joint, the strength of the joint was calculated by multiplying the strength of each screw (5.5 kN) by the number of screws. For the tensile bolt joint, to ensure a ductile failure of the joint, the strength of the joint was calculated based on the yielding capacity of the tensile bolt. In addition to that, the vertical and horizontal edge of the joint (i.e., the distance from the edge of the joint to the edge of the CLT panel) was designed to avoid brittle failure in the CLT wall panel's corner before the tensile bolt yielding.

The specific design and the appearances of the three joints are shown in Figure 5. To have a similar tensile strength with the plate joint, in the case of the screw joint, a U-shaped metal bracket and 12 screws were needed per one corner of the CLT wall, and the thickness of the wall was 90 mm. In the case of the tensile bolt joint, a M20 bolt was needed, and the thickness of the CLT wall was 150 mm to avoid the failure in the CLT wall panel's corner.

As for the screw joint, 48 screws need to be installed per wall for tensile connections, which requires a high workload to drive all necessary screws. The tensile bolt joint required CLT walls whose thickness was 150 mm, which causes a higher production cost. However, in the plate joint, 12 bolts were needed per wall for the connection of the wall and the plate, and the thickness of the wall was 90 mm. In addition, the plate joint required no shear joint. Hence, it was shown that the workability of the plate was better than that of the conventional ones.

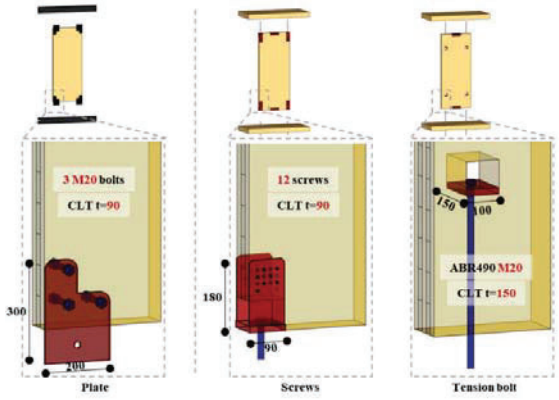

Figure 5: *The specific design and the appearances of each connection that has the same ultimate tensile strength.*

3.2 DEMONSTRATION OF A CLT MODULE WITH THE PROPOSED PLATE JOINT SYSTEM

A module using the proposed structural system with the plate joint was demonstrated to confirm the workability of the proposed joint system. Figure 6 shows a photo and a schematic diagram of the CLT module. The module with a size of 2 m by 4 m in floor plan was constructed for an open-air event in August 2021 in Sendai, Japan. In this event, the module, which housed a small commercial store, contained eight CLT panel walls arranged along the three sides and back of the structure. In Sendai, in the case of the use of local woods, the maximum width of CLT panels is 1.2 m due to the limitation of the production facility of the local manufacturer. Hence, CLT panels with 1 m in width and 2.4 m in length were used as structural walls. The used CLT wall panels were made from Japanese cedar. C-shaped steel section with a 90x200 mm size was used for the beams and the base. For the floor, a wood panel with a thickness of 36 mm was used. For the

https://doi.org/10.52202/069179-0558

roof, a wood panel with a thickness of 200 mm was applied.

Figure 7 shows the process of the construction work with the following steps: (a) Holes with a diameter of 22 mm were drilled through for inserting the M20 bolts. (b) The steel base and beams were assembled on the ground. (c) For the installation of the CLT walls, two CLT wall panels were splined together in advance by convex shear connectors to increase the efficiency of the construction. (d) The CLT walls were put on the steel base and jointed by bolts. (e) The steel beam frame was installed by a crane. (f) The roofs were constructed by the crane. They were fastened with the steel beams by bolts. (g) Carpenters carried wood panels for the floor by hand and put them on the steel base.

As shown in Figure 8, 173 minutes were needed to finish the construction from (b) to (g). The time required to install the eight CLT panels was about 36 minutes. There was an actual CLT building that was built recently with a conventional joint system. According to local construction experts, 18 to 20 panels can be installed in one day (eight hours of construction time). Thus, the demonstration of the single CLT module indicated better workability compared with the conventional joint system.

4 SUSTAINABILITY PERFORMANCE ANALYSIS

4.1 Target buildings

In order to analyse the sustainability performance of the hybrid structure, a life cycle assessment (LCA) was conducted. The analysis quantitatively compared the environmental impacts among four structural systems, including the proposed hybrid system, conventional CLT, reinforced concrete and steel structures. 4-storey prototype residential buildings with total floor area of 1,000 m^2 were designed in Sendai, Japan. As shown in Figure 9, the structure includes a residential space (8x24 m^2) surrounded by a long corridor and balcony.

4.1.1 Functional unit for structural design

The functional unit was defined as the structural performance margin factor equals to 1. The margin factor of 1 means that the building has the minimum structural safety performance that satisfies the Japanese Building Standards Law (JBSL) regarding structural performance.

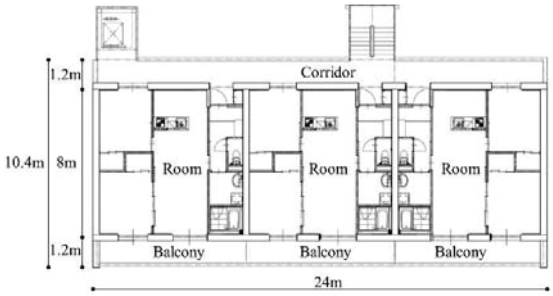

Figure 9: *The image of the floor plan of the 4-storey residential building.*

4.1.2 Building design

In this section, the building design of each scenario is explained. Floor plans and, dimensions and details of structural components were selected to satisfy requirements in JBSL against vertical load and seismic load. Figure 10 shows the floor plans of each building.

The building with the conventional CLT structure (hereinafter CLT building) was designed in the module of 4 m by 8 m. This was because CLT slabs allow spans to be increased up to 4 meters. CLT walls with 1200 mm in width and 210 mm in thickness were used. For the tensile joint, the tensile bolt joint with the diameter of 24 mm was applied. For the floor and the roof, a CLT panel with a thickness of 210 mm was applied according to the design example in the Guidance of Notification of Building Standard Law concerning CLT [13].

Regarding the reinforced concrete structure, two types of structural system are commonly used; moment resisting frame and wall panel structure (hereinafter called "wall type"). In the Japanese design practice, the middle-rise wall type structure is generally selected for residential buildings of reinforced concrete structure. Hence, in this study, the wall type structure was applied for the reinforced concrete structure.

The building with the wall type reinforced concrete structure (hereinafter RC building) was designed in the module of 6 m by 8 m. The floor area is limited up to 60 m^2 in the specification of the JBSL for the wall type structure considering the vibration of slabs. If the module were 8 m by 8 m, an area of one section would have been 64 m^2. Thus, the longitudinal span length was designed as 6 m which gave the same area for four rooms. The RC walls with 1700 mm in width and 250 mm in thickness were used. For the roof and the floor, a reinforced concrete slab with a thickness of 270 mm was applied according to the design example of the guideline for the reinforced concrete [14].

The building with the steel structure (hereinafter S building) was designed in the module of 8 m by 8 m. Steel beams can allow spans to be increased according to the functionality of a building. Therefore, the longitudinal span length was designed as 8 m which gave the same area for three rooms, which can secure larger spaces than the CLT and the RC building. The steel beams with the cross

https://doi.org/10.52202/069179-0558

sections of 440x300 mm and the steel columns with that of 400x400 mm was chosen. For the roof and the floor, a reinforced concrete slab with a thickness of 104 mm was applied according to a catalogue of a deck plate company.

The building with the CLT walls-steel beams hybrid structure (hereinafter CLT+S building) cannot be designed based on the current JBSL. This is because it does not include specifications regarding new hybrid structures. In order to make a reasonable design, the ductility factor was assumed to be between the values of the CLT and S building. As a result, the CLT+S building was designed in the module of 8 m by 8m. Compared to the CLT building, the steel beams allow longer spans. In addition, the needed quantity of CLT walls was decreased from 49 t to 19 t thanks to the hybridization. Compared with the S building, the steel beams could be smaller from the cross sections of 440x300 mm to that of 294x200 mm. This is because the weight of CLT slabs is smaller than that of RC slabs. In addition, putting CLT walls on beams leads to shorter spans that are crucial to bending stress to beams. For the floor and roof, a CLT panel with a thickness of 210 mm was applied according to the design example in the Guidance of Notification of Building Standard Law concerning CLT [13].

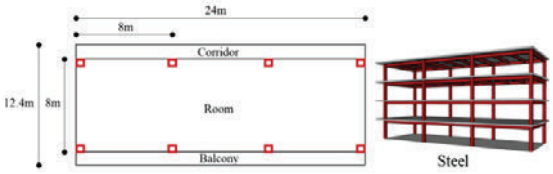
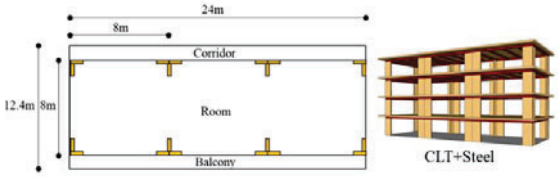
The floor plan and the image of the RC building.



The floor plan and the image of the S building.



The floor plan and the image of the CLT+S building.

Figure 10: *The floor plan and exteriors of each structure (not considering the foundation).*

The plate joint system of the CLT+S building was improved from the previous one (Figure 3) to correspond with the 4-story buildings as shown in Figure 10. An insertion plate was used to fix two CLT wall panels together using four large diameter high-tensile bolts. A bolt diameter of 30 mm was chosen to have larger embedment strength compared to that of 20 mm. The insertion steel plate with a thickness of 22 mm was designed not to fail. Because C-shaped beams are not available in large sizes in Japan, H-shaped steel beams whose flanges were partially removed were used to accommodate the CLT panel.

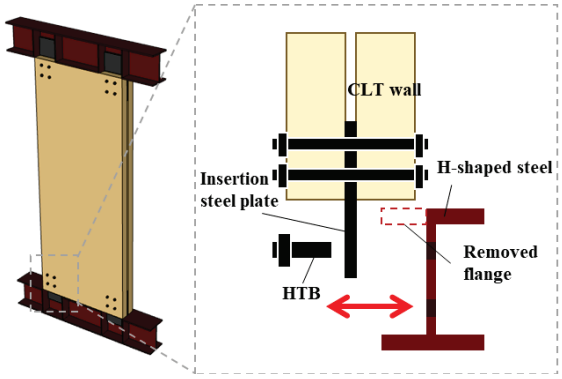


Figure 11: *The specification of CLT walls-steel beams of the hybrid system.*

4.1.3 System boundary in LCA

The life cycle of a building can be divided into material production, transport, construction, use/repair, and demolition/disposal phase. In this study, material production and transport phases were considered in the system boundary to analyse differences by structures. Construction, use/repair, demolition/disposal were excluded for the following reasons. According to [15] and [16], environmental loads during construction are under 1 % of whole emissions. Therefore, ignoring this phase does not make a significant difference. The loads in the use/repair phase are highly dependent on a user of a building. Hence, differences by structures are expected to be small. The data regarding demolition/disposal lacks accuracy because CLT is a new material and most of the buildings with CLT structure are yet to reach their service life.

Wood by-products (wood offcuts and wood shavings) are generated by the pre-cutting of wood laminae and CLT panels. According to an interview with local manufacturing companies, the yield rate from cedar log to wood laminae is almost 50 %. The yield rate from the CLT master panel to the pre-cut panel is approximately 90%. The by-products are used as a heat source for drying cedar lamina, which are the raw material for CLT. It was assumed that the GHG emissions resulting from this drying process are included in the emission intensity value according to Nakano et al. [17].

According to local construction companies, the volume of margin fresh concrete is adjusted to be as small as possible

https://doi.org/10.52202/069179-0558

because the disposal of hardened concrete takes additional money. Hence, the concrete residue was assumed to be negligible.

Steel by-products are generated in a process factory. They are shipped to recycle factory and reuse them into other steel products. In this study, environmental impacts regarding the reuse of the steel by-products were out of the boundary.

4.1.4 Inventory analysis

To evaluate the environmental loads, GHG (Green House Gas) emissions and carbon storage were selected as the impact indicators.

GHG emissions at the material production phase were calculated by multiplying the material weight by the intensities of each material. Table 1 shows the weight of each material. For the intensities of steel and concrete, IDEA version 3.1 (National Institute of Advanced Industrial Science and Technology; Sustainable Management Promotion Organization) [18] was applied. Because it does not contain the intensity data of CLT, it was derived from the work by Nakano et al. [17]. Regarding steel production, the most common manufacturing method in Japan was assumed for each product. Specifically, the blast furnace method was assumed for shaped steel and steel plates, and the electric furnace method was assumed for rebars.

Regarding concrete intensity data, the GHG emissions by production and shipment of cement and aggregate are included in the intensity data of concrete according to IDEA v3.1.

Transport distances of each material were decided by discussing it with local construction companies. The distances of concrete, CLT and steel (including joints, bolts, and rebars) were assumed to be 6.4 km, 50 km, and 192 km respectively. The distances were based on the local market situations around Sendai. The GHG emissions by each return way shipment were calculated by considering the impacts emitted by vehicle with no load from a construction site to a manufacturing factory. Vehicles for concrete, CLT and steel shipment were assumed as the 4-t pomp car, the 10-t track, and the 10-t track respectively. The intensities of the vehicles were applied from IDEA v3.1. Because IDEA v3.1 does not contain the intensity data of the 4-t pomp car, the intensity data of the 4-t track was applied.

Carbon storage was calculated using the following Equation (1) based on "the Guidelines for the Indication of Carbon Storage in Wood Used for Buildings" in Japan [19].

$$C_s = W \times D \times C_f \times \frac{44}{12} \quad (1)$$

where C_s is carbon sequestration of wood used in a building (t), W is the quantity of wood used for building (m^3) (value of air-dried lumber volume), D is the dry density of wood (t/m^3), C_f is carbon content of the wood (-).

Table 1: *Summary of the materials assessed in the study.*

The CLT building

CLT building			
Materials			Quantity [t]
CLT wall		1200x2790x210	4.94x10
CLT lintel		895x2000x210 (X-direction) 895x2290x210 (Y-direction)	2.80x10
Tension bolt		Diameter equals to 24 mm	2.92
U shear plate	L shaped	Thickness equals to 4.5 mm	$3.78x10^{-1}$
	Screw	22 screws per the plate	$8.40x10^{-3}$
L shear plate	L shaped	Thickness equals to 4.5 mm	5.51
	Screw	33 screws per the plate	$2.41x10^{-2}$
Shear plate	Plate	Thickness equals to 6 mm	$5.76x10^{-1}$
	Screw	48 screws per the plate	$6.36x10^{-2}$
CLT slab		Thickness equals to 210 mm	8.68x10

The RC building

Reinforced concrete building			
Materials			Quantity [t]
RC wall	Concrete	1700x2800x250	$3.25x10^2$
	Rebar		$4.83x10^2$
RC beam	Concrete	250x450	3.25x10
	Rebar		4.83
RC slab	Concrete	Thickness equals to 270 mm	$4.76x10^2$
	Rebar		7.07x10

The S building

Steel building			
Materials			Quantity [t]
Column		□-400x400	4.62x10
Girder		H-440x300	3.56x10
Beam		H-350x175	8.54
RC slab	Concrete	Thickness equals to 104 mm	$2.29x10^2$
	Rebar		3.40x10
	Deck plate		1.70x10
Exposed column base			1.54

The CLT+S building

CLT+Steel building		
Materials		Quantity [t]
CLT wall	1200x2706x180	1.93x10
Plate	300x550x22	8.29
HTB	Diameter equals to 30 mm	1.78
Girder	H-294x200	1.75x10
Beam	H-250x125	5.29
CLT slab	Thickness equals to 210 mm	8.67x10

4.2 RESULTS AND DISCUSSION

Figure 12 shows the results of GHG emissions and carbon storage of each building per square meter of the total floor area. GHG emissions of the CLT building, the RC building, the S building and the CLT+S building were 118 kg-CO_{2eq}/m^2, 268 kg-CO_{2eq}/m^2, 308 kg-CO_{2eq}/m^2 and 143 kg-CO_{2eq}/m^2 respectively. Carbon storage of the CLT, CLT+S building were 225 kg-CO_{2eq}/m^2, 156 kg-CO_{2eq}/m^2. The results showed that the CLT+S building emitted higher GHG emissions than the conventional CLT alternative and lower than the RC and S buildings.

Regarding GHG emissions of the CLT+S building and the S building, the emissions by the girder of the CLT+S building (42 kg-CO_{2eq}/m^2) was almost half of that of the S building (83 kg-CO_{2eq}/m^2). The smaller size of steel

beams thanks to putting the CLT walls on the beams significantly reduced GHG emissions.

Regarding the GHG emissions of the CLT+S building and the CLT building, the hybridization reduced the emissions of the CLT wall and the connections (35 kg-CO_{2eq}/m^2) compared with those of the CLT building (64 kg-CO_{2eq}/m^2). However, the additional GHG emission by the steel girders and the beams resulted in larger whole emission of the CLT+S building. From an economical point of view, the current material cost of CLT is very high in Japan. The weight of the CLT walls of the hybrid system (19 t) were one third of that of the CLT building (49 t) thanks to the hybridization. Hence, the reduction of the CLT wall's weight could result in lower production cost.

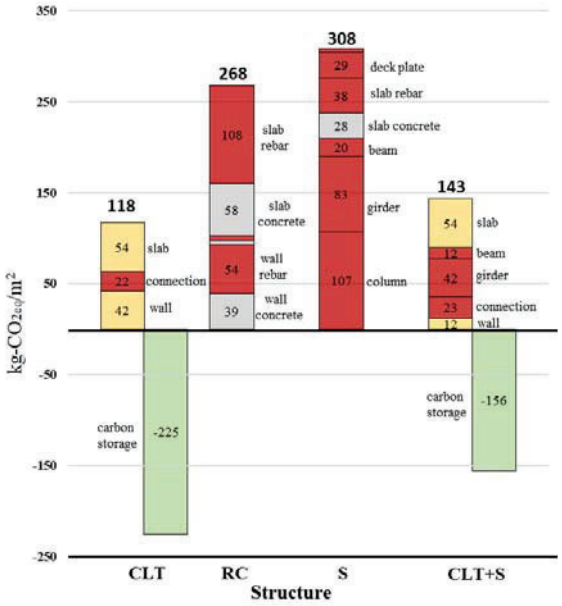

Figure 12: *GHG emissions and carbon storage of each building.*

5 CONCLUSIONS

In this paper, the efficiency and workability of a new hybrid structural system with CLT walls and steel beams with steel plate joints was introduced. Moreover, the environmental impact analysis of 4-storey buildings with four different structural system scenarios was discussed. The conclusions are as follows:

1. To compare the efficiency and workability of the proposed steel plate joint, conventional screw joint and tensile bolt joint, a comparison of the intensity of constructive works of these joints was conducted. It was shown that the workability of the plate joint was better than that of the screw joint and the tensile bolt joint thanks to the reduced construction processes and a lower precision target.
2. A CLT module with the proposed joint system was demonstrated to confirm the workability. The construction of the proposed system was found to be faster and easier than conventional structural systems. This showed the advantage of the workability of the hybrid system and the steel plate joints.
3. To analyse the sustainability performance of the hybrid structure, a LCA study was conducted. The analysis quantitatively compared the environmental impacts of four different structural systems, including the proposed hybrid system, conventional CLT, reinforced concrete and steel structures.
   As a result, the proposed hybrid system showed higher GHG emissions than a conventional CLT alternative and lower than a reinforced concrete and steel alternatives.
4. The weight of the wall panels of the hybrid system were one third of that of the CLT alternative owing to the hybridization. The current material cost of CLT is very high in Japan. Hence, the reduction of the CLT wall's weight could result in lower production cost.

ACKNOWLEDGEMENT

This research was supported by JSPS Kakenhi Grant Number JP19K22001 and JP22H01632, and CLT Building Components Technology Development and Dissemination Project by Japanese Forestry Agency. This fund is gratefully acknowledged. The support of Dr. Naoyuki Matsumoto, Assistant Professor, Tohoku University, and members from Miyagi Prefecture CLT Promotion Council are also appreciated.

COMPUTATIONAL DESIGN DEVELOPMENT OF A WOODEN FAÇADE SYSTEM

Camilla Schlyter[1], Karin Sandberg[2]

ABSTRACT: The implementation of computer design within the building industry has created new possibilities for creating digital tools for users such as architects. There is however a lack of easy to use, efficient digital tools to aid and explore design alternatives for architects when using products within the wood building industry. This paper demonstrates how a modular facade system in wood can be adapted for facade configurations in different contexts by using computational design.

The goal is to develop a digital design tool that is easy to use and provides the architect with a high degree of freedom to create project-unique facades. The design tool is developed with computational design methods for flexible and adaptive design. In parallel, assessment is made that the design solutions can be manufactured smoothly and quickly via digitalization and industrial production. The result of this research shows that the façade system can be customized by using parametric programming methods, and thus enable architects to design facades for different contexts. The design tool was verified with the architect partners concerning usability and manufacturers concerning production.

KEYWORDS: Façade design, Cladding, Heartwood, Parametric design, Adaptable design, Digital design tool

1 INTRODUCTION

Advances in computational design introduces new possibilities for designers, architects, and the wood building industry to collaborate from the initial idea thru the development process to a product ready to manufacture [1,2,3,4]. Previous research has shown that computational design approaches can be used to support the exploration and optimization of design solutions in the building design process [5]. In this paper computational design means a design method using algorithms and parameters to solve design problems by computer processing. Computational design methods support "file-to-factory" processes and interdisciplinary collaborations; it also enables adaptive design towards different contexts and cost-effective manufacturing.

The implementation of computational design within the building industry has its challenges. There is a need to clarify how and when different computational design approaches can be used to support the building design process [5].

There is a lack of easy to use, efficient digital tools to aid and explore design alternatives for architects using products within the wood building industry.

Since the Swedish wood industry is highly digitalized, it can serve as a good foundation for advances in computational design methods.

Parametric design, a software-based programming method, has proven to enable a creative exploration in design development. Data input can be gathered and organized rendering it usable in automated generation of design alternatives. This can be done manually by a user or for instance, using an automated algorithm [6].

Adaptable design is a design paradigm aiming at creating designs and products that can be adapted for different requirements and be influenced by users. An existing design of a product can be adapted to create a new or modified design based on changed requirements. Adaptive design enables manufactures to produce standardized products that are possible for end users to customize [7].

The goal with this project was to develop a digital design tool easy to use for architects when designing an adaptive wood façade system.

This paper demonstrates the use of computational design methods for developing a design tool to enable the façade system to different configurations. Thereby aiding architects in design decisions combined with a freedom to create project-unique facades and manufacturers by

[1] Camilla Schlyter, RISE Research Institutes of Sweden, Sweden, camilla.schlyter@ri.se
[2] Karin Sandberg, RISE Research Institutes of Sweden, Sweden, karin.sandberg@ri.se

https://doi.org/10.52202/069179-0559

assessing that the generated digital data is prepared for use in production so called “file to factory”.

A group of residential buildings in Lombolo, Kiruna Sweden, owned by Kiruna Bostäder AB are used as case to test the digital design tool. Figure 1 shows one of the façades in Lombolo.

Figure 1*: One of the façades today in Lombolo, Kiruna, Sweden. Photo by Karin Sandberg.*

Two case studies using definitions of case study approaches by Yin [8] are presented.

The façade system discussed in this paper was developed in the project “The facade of the city Swift, Stylish, Smart” [9,10] hereafter called the façade project. It consists of an industrial prefabrication of façade elements, corners and connections to windows and doors.

2 MATERIAL AND METHODS

For development of the design tool and the digital workflow a computational design approach was used, which requires information to be digitalized and organized so that it can be used in the automated generation of design alternatives.

The included parameters in the two studies were based on data collected from the façade project [9]. To test the digital design tool, data from the case in Lombolo was used.

The data collected from the façade project consisted of digital models of the façade element and corners. Data collected from the case was boundary information acquired from the configuration of one of the façades by drawings and site visit. Figure. 2 shows examples of collected data.

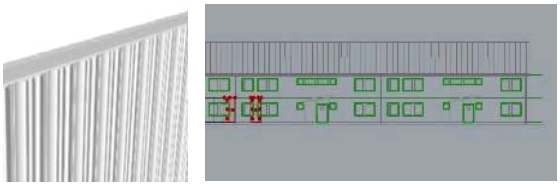

Figure. 2: *To the left - detail of the façade element model, to the right -boundary data from the façade case in Lombolo. Image by Camilla Schlyter.*

The facade system in this case is a facade solution for buildings consisting of a set of components assembled to elements that are fully or partially ready-made and dimensioned regarding adjustment for specific dimensions of buildings, and industrially manufactured. The components of the facade system are joined industrially to facade elements.

The facade system consists of a combination of adaptable elements. The element dimensions are possible to customize for users, such as height, width and surface design but the interfaces between components and assembly components are not possible to customize for users.

2.1 IMPLEMENTATION OF THE TWO STUDIES

2.1.1 Case Study 1

Research question for case study 1: How can an adaptable façade system be explored and optimized using a computational design approach?

The case study was conducted using an explorative approach as described by Yin [8]. The purpose with case study 1 is an exploration of possibilities and functions concerning a digital design tool for enabling design of a and adaptable façade system. Requirements on the digital design tool are: that is easy to use and provides the architect with a high degree of freedom to create project-unique facades within the products design possibilities and limitations. The design tool was developed with computational design methods for ensuring flexible and adaptive design for the user.

In case study 1 a digital design tool was developed to enable the façade system to be easy for the architect to use for different façade configurations. The design tool was developed using parametric design methods. This was done by developing the product´s design rules in parallel with manufacturing processes to assess that the generated data could be used with industrial production techniques. For manufacturers, this means that the façade system can be reused for the development of new designs to save product development time and costs. For architects this means that an adaptable design product gives them the opportunity to design in different ways for different contexts, having the security of using a predefined façade system.

https://doi.org/10.52202/069179-0559

The design tool's function and usability were verified in parallel in workshops together with a reference group of three architects, having different levels of knowledge of computational design from proficient to general user.

2.1.2 Case Study 2

Research question for case study 2: How can a computational design approach be integrated in a digitalized workflow in the value chain of an adaptable façade system?

The case study was conducted using an explorative approach as described by Yin [8]. Case study 2 concerned how the digital information created in case study 1 could travel thru a digital value chain, from design to manufacturing. Ensuring that the design solutions made by the architect can be manufactured smoothly and quickly by industrial production within the boundaries of the façade element design. A prototype of a future digital workflow was developed estimating the required information in the different stages in the design- and manufacturing process. The purpose was gathering knowledge of the requirements of data in the different stages in the value chain so that, in the next step enable a seamless digital workflow without digital information and design intent getting lost thru the value chain.

Moving into fabrication it is important to analyse how to use the "cocktail of software" available. The analysis was managed by using design methods to eliminate data and assess what data is necessary at different points through the whole value chain.

To solve this analysis of available software that allows for information exchange between different systems and tools is required.

For the control files used in industry, transfer of the information is needed from the software architects commonly use such as Autodesk Revit (Revit). In this study Microsoft Excel files (Excel) or Autodesk AutoCad (AutoCad) was used as a middleware between different software. From Excel, for instance, wood cutting lists can be made enabling feeding into the manufacturing machines.

3 RESULTS AND DISCUSSION

3.1 CASE STUDY 1, DEVELOPMENT OF THE DESIGN TOOL

The requirements of the design tool:

- Provide that the facade elements can adapt size wise to different façade contexts.
- Manage different measurements, such as variation of floor level hights and window openings.
- Adapt the size of the façade elements to production, transport and assembly.

Digital models of the facade system were built up using Rhinoceros 3D (Rhino) and Grasshopper software. Thereafter a prototype of the design tool was created using Rhino, Grasshopper, AutoCad and Revit. Revit is commonly used by architects and engineers in Sweden. Dynamo is an extension to Revit and Grasshopper is an extension to Rhino and both Dynamo and Grasshopper enable parametrization. Parametric software such as Rhino thru its extension Grasshopper is seldom used in the wood construction industry, but is interesting since int can provide important digital data concerning customization in the value chain.

What sets computational design approaches apart from more conventional design methods (where the user usually reacts with digital sketches, drawings, or models) is that the user instead interacts with the digital environment and the mechanisms responsible for generating digital representations [10]. The architect can see and interact with the design in real time, adjustments made are visualized immediately.

Using parametric design enabled exploring the structure of relationships between the parameters in the façade system. By using parametric design, it was possible to use algorithms to design boundaries for both, the predefined, standard components (not customizable for users) and the adaptable components (customizable for users).

Case study 1 consisted of four phases:

3.1.1 Phase 1: Inventory of design criteria and design tool

The objective:

- Initial discussion on suitable programming for the design tool prototype.
- Analyse the design criteria, established in previous research, by studying the variability of the components to assess what parts required adaptability towards different contexts and which could remain static.
- Model façade elements and components in Rhino.

Components in the facade system that should be customizable for the user were already established in the previous façade project. After discussions in the project- and reference group it was concluded that the size and adjustment to openings of the facade elements was interesting to explore. The decision was also based on inventory and experience of the façade projects manufacturing processes and aesthetic analyses.

The decision established the boundaries of the case study. Initial analysis of different software was conducted thru a series of meetings within the research group where

https://doi.org/10.52202/069179-0559

possible capacities for automating design procedures, i.e., what the software needed to achieve was discussed. This concerned searching for a method ensuring that the facade elements could be adapted size wise to different façade contexts, including different measurements, floor level heights, and window openings. The initial discussion on suitable programming for the design tool prototype was important, since it created a background for important knowledge for the data collection in the next step. Figure 3 shows ideas for different configurations for the façade elements from the façade project.

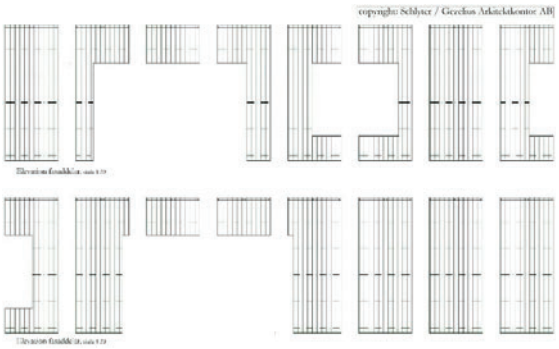

Figure.3: *Exploring the size of the façade elements, from the earlier façade project. Image by Camilla Schlyter.*

The analysis concluded that parametric design was suitable for the façade systems properties, combined with the potential of reducing the amount of time and effort needed to obtain optimized façade solutions for every situation. The hypothesis was that parametrization would enable that the façade system, in a new context, could be created without the need for redesign of the whole system. The façade elements and components were modelled in Rhino to aid in assessing variability, by visualisation. Figure 4 shows evaluation of façade element components that must be considered, such as height, width, thickness, distance to attachment etc.

Figure 4, *Phase 1 resulted in an analyse and overview of the design variability of the components from the project. Image by Camilla Schlyter.*

3.1.2 Phase 2: Systematizing input data

- The objective:
- Study of the components in the facade element in more detail.
- Develop data concerning which components could stay "standard" and which should be able to customize.
- Systemize the input data.

Systematizing the required data resulted in a structured and detailed excel file for identifying data input for digital parameterization. The Excel file was constructed specifically for data input for use in digital parametrisation and aided in establishing a suitable hierarchy, going from system components to data needed for adaptation of the façade elements to the specific case, the building in Lombolo. Summarizing the hierarchy in the Excel file see figure 5.

System level, concerns variables of the components
- Boards, joints, surface, etc.

Existing building
- Façade, plan, width, height, windows etc.
- Floor levels, height etc.

Adaptation of façade element to existing building
- Module, façade system, width, height, littera etc.

Figure 5: *Hierarchy for data input for digital parametrization concerning variables in case, Lombolo. A* ***s****hort summery of the Excel file where information was collected concerning data for digital parameterization.*

The result from managing the large excel file added to the understanding of required additional data input, but also of exactly which data that was essential at a specific level. The data input was discussed with the manufacturer to assess that all required data was accounted for. The Excel file was continually reworked as the study developed.

3.1.3 Phase 3: Test of software

The objective:
- Evaluate programming solutions and software, to ensure that possibilities were not overlooked.
- In Revit the min-max possibilities of the facade element and ways to subdivide the model was tested.

In phase 3 different software and programming solutions to enable the façade system towards different configurations were tested using an iterative approach.

The result from phase 2 was used as background data. Revit, Dynamo, Rhino, Grasshopper and AutoCad software were tested and analyzed see figure 6.

- Revit, with BIM modelling capabilities, is good on documentation and tracking capacities, but lacks parametric features and generation of complex geometry is limited. The Revit structure with families can be a good way of organizing the data in later development when creating an end user interface.
- Dynamo, interesting for next stage in the development in combination with Revit.
- Rhino, lacks BIM modelling capabilities but enables optimization exploration thus making it an ideal platform for design analysis.
- Grasshopper, is an extension of Rhino and has good parametric capacities. Grasshopper enabled the possibility to parametrise the facade system according to the excel sheet and enabled adjustment of the facade system to the case.
- Autocad, contained the component details of the fasade system and was used as a base for modelling in Rhino.

Figure 6: *Test of software with short comments*

Phase 3 resulted in choice of software. The design space of Grasshopper/Rhino proved easy to work with and test solutions valid for the study. Grasshopper/Rhino enabled the possibility to parametrise the facade system according to the excel sheet and adjust the facade system to the case.

3.1.4 Phase 4: Adaptable design

The objective:

- Programming in Grasshopper enabled testing a prototype solution of the design tool. A code for automatic subdivision of facade elements was sketched in Grasshopper, including a "sanity" check.
- Verification of the design tool with a reference group of users, architects.

Phase 4 resulted in a prototype design tool, for adapting the façade elements to different façade configurations using parametrization software. Assessment was made that the façade element details, design criteria, material characteristics, dimensions, material properties can be formulated in program code to provide customized design output, see figure 7, 8.

Figure 7: *Screen shot from Grasshopper, showing boundary lines and a script running on an underlay of a drawing of the residential block in Lombolo. Image by Ola Jaensson and Camilla Schlyter.*

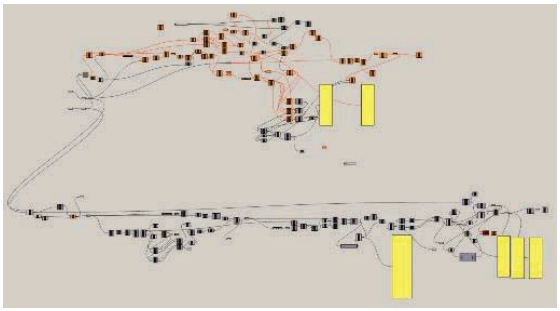

Figure 8: *Screen shot from Grasshopper showing the script. Image by Ola Jaensson and Camilla Schlyter.*

Verification of the design tool with the reference group of architects was done at two occasions. The first meeting was a teams meeting, securing that the chosen variables were valid, in this meeting the manufacturer also attended ensuring that manufacturing data was provided. The second meeting at Equator architects concerned testing the usability of the prototype design tool together with three architects. The architects tested the prototype design tool on the case façade using drawings of a residential building in Lombolo, first applying boundary lines and thereafter creating a façade layout. The result of the test showed that it enabled the architects to create a façade layout quickly once they had set up the boundary lines of the façade. The immediate response was positive and the design of the façade system was much appreciated. The result of the meetings were documented in meeting protocols.

3.1.5 Comments on the results

A master model concept, such as Revit can be used in the future to structure and contain the components and their link inputs, outputs, and processes. BIM software such as Revit can be used as a container to define the façade system, its design variables, constraints, and objectives, and thus support manufacturing.

https://doi.org/10.52202/069179-0559

The software combination of Grasshopper/Rhino worked well in study 1. Revit is suitable for documentation and tracking key information but is not suitable for generating complex geometry nor for analysing real-time simulations, both possible in parametric software. Based on study 1 conclusion was made that further explorations of the "cocktail of software" i.e. middleware is an interesting way to continue the research.

To facilitate information exchange and interoperability for the systems involved in computational design approaches, middleware components can be used as an interface to support information exchange. This could facilitate the integration of existing computer-based methods and tools in BIM-based workflows into computational design approaches.

Important knowledge was gathered concerning how to adjust the programming and data input for the next step. For example, concerning rules on how to cut the individual façade elements when manufacturing the façade system. Figure 9 shows a diagram summarizing the development process of the design tool.

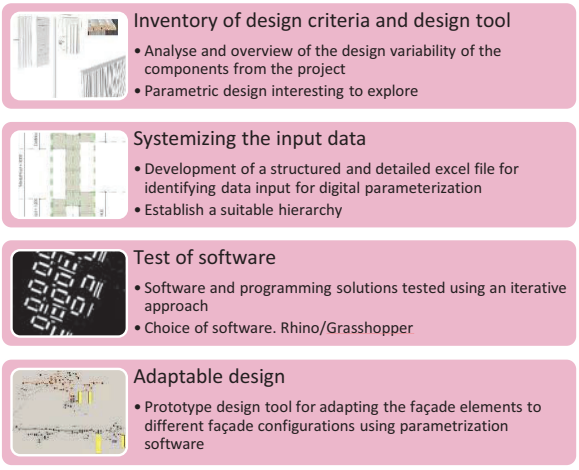

Figure 9: *The digital design tool process*

3.2 CASE STUDY 2, THE FUTURE WORKFLOW

Case study 2 concerns a prototype of a future digital workflow estimating the required information in the different stages in the value chain using the case of adjusting the façade system to a building in Lombolo.

3.2.1 Telling the digital tool what the project is, going from general to specific input

Since the digital tool accepts a generous variety of input, an automatic sanity check was programed enabling the result to be visually communicated to the user. This was done with the purpose of warning when the values or resulting calculated properties seem suboptimal or invalid.

3.2.2 The construction system

Example of system level parameters:

- Wood component dimensions
- Detail dimensions, distances, limits, shapes, and choices
- Standard module width
- Minimum and maximum module height

Proposed next step in the development of the tool: Surface ornamentation type.

3.2.3 The manufacturer

Here, and the properties of the manufacturer's tools, materials and processes are to be defined.

Examples of manufacturer parameters:

- Standard green wood dimensions
- Machines and tools used for a specific construction and design.
- Cost-driving parameters for different machines and treatment methods.
- Preferred output file formats for specific machines such as the g-code, a programming language for CNC (Computer Numerical Control) machines. G-code stands for "Geometric Code". A G-code tells a machine what to do or how to do something for instance, instruct the machine where to move, how fast to move and what path to follow and others etc.

3.2.4 The project parameters

In this level, the specific project is created and defined.
Examples of project parameters:

- Project name
- Geographic location of project (project origin)
- Other administrative data
- Project units
- Number of buildings

3.2.5 The building

In this level specific project data is required.
Examples of building parameters:

- Building names
- Ground contour polylines
- Number of facades
- Number of levels

3.2.6 The buildings façades

Examples of existing facade parameters:

- Elevation contour polylines
- Wall opening contour polylines.

3.2.7 New façade parameters

Examples of new façade parameters:

- Elevation division levels (Z values, the bottom alignment lines of the façade modules)
- Number of modules
- Left and right corner/end module types
- Offset to first façade module.

3.2.8 Dance of adjustments

Dance of adjustments, test of different façade layouts until desired design is achieved. After the design tool has been fed with user input, the façade element generation algorithm calculates necessary directly related parameters and makes a first automatic element division elevation per façade and level.

Figure 10 shows a screenshot from a first automatic element division. This can be adjusted by the user if the division does not comply with the wanted design outcome, but always within the programed boundaries.

Figure 10: *A screenshot from Grasshopper showing a first automatic element division on a façade in Lombolo.*

3.2.9 Outputs

Examples of output and formats:

- Excel module property lists.
- Timber cutting lists.
- Waste prediction
- CO_2 and other resource calculations
- Lists of assembly jig support positions for each module or sub-component.
- Visualization oriented, detailed geometry.
- Metadata-rich BIM geometry.
- Overview elevation drawings with façade modules annotated.
- Annotated construction drawings of individual façade modules.
- Wood shop CNC machinery G-code

4 CONCLUSIONS

The design tool, the result of this research, shows that the façade system can be customized by using parametric programming methods, and enable architects to design facades for different contexts. This has been shown thru analysing the result of the design tool together with architect partners. Assessment has been made that the façade elements details, design criteria, material characteristics, dimensions, materials' properties can be formulated in program code to provide customized design output. Knowledge has been gathered on how to adjust the programming and data input for the next step, the development of a plug in for BIM software such as Revit.

Assessment has been made that the digital information gathered in case study 1 can be used for manufacturing. In case study 2 the digital flow has been hypothetically tested thru the value chain in close collaboration with industry partners. Though the results have to be further confirmed to assure that the façade system will be possible to manufacture smoothly and quickly, best assessed thru physical prototype tests with the industry partners.

An assumption made in the project is that Revit can be interesting for a commercial application in a future by developing an end user interface thru a customized plug in. A plug in is a software component that adds a specific feature to a software that enables customization. The plug in can be infused with diverse input data concerning material properties, keying the specific elements placement in a project and cost et cetera.

Future development can include how numerical data in middleware can be fed into Revit via parametric software to control the parameters of Revit Family components aiming towards a plug in a Revit environment. Thru the Revit family's output, for example, cutting files for the timber industry and control files for manufacturing can be created.

The project shows that the wood building industry can adapt computational design methods when developing adaptable building products. The methodology precented in the paper also provides a possible scaling-up effect applicable to other products. The next step is to further develop the design tool and test it on façade configurations of different design.

ACKNOWLEDGEMENT

Thanks to the strategic program Bioinnovation Construction & Design, IPOS – Innovations in wood-based building materials and products, subproject "The facade of the city Swift, Stylish, Smart". The project is founded equally by Vinnova Sweden's innovation agency, the Swedish Energy Agency, and Formas together with the industry partners. Thanks to E2B2 Swedish Energy Agency concerning the project Climate smart renovation with innovative façade system. A special thanks to Equator Architects in Stockholm for the collaboration with the digital tool, SCA and Hedlunda for industrial input and KBAB.

STUDY CASE: REFURBISHMENT OF THE GARE MARITIME IN BRUSSELS

Charline Lefèvre[1]

ABSTRACT: This paper presents the study case of the Gare Maritime, a former train station in Brussels in Belgium that covers an area of 40.000m² and that has been entirely renovated to welcome under its roof the construction of twelve multilevel pavilions in fully timber structure. Those 4500 m² of twelve new buildings are hosting shops, publics functions and offices and creates a new covered quarter inside the city. This paper introduces first the project, its historical context, its situation and its refurbishment.
Then an explanation of the structural design is given and divided in different parts. A focus is first made over the specific features of the project to explain the challenges of the structure. Then the joints developed on the project are explained explaining the main type of assemblies. Thirdly, all the fire engineering process of the project is described; how the dossier was accepted by the authorities, the simulations and calculations that needed to be done. The last section finally gives information about the mounting process and the upstream preparation that it required. In the next chapter, more can be learned over the innovative technologies that have been implemented on the project to make it completely energy neutral and fossil free before finally concluding and giving some important numbers over the project.

KEYWORDS: Cross-laminated-timber, Glulam, Refurbishment, Collaborative ribbed floor; Thermal analysis.

1 INTRODUCTION

The "Gare Maritime", located on the site of Tour & Taxi in Brussels, is a former railway terminal, built in the early 20th century) by architects Constant Bosman and Henri Vandeveld and engineer Frédéric Bruneel.

Figure 1: *Front facade of the Gare Maritime*

It was once Europe's largest railway terminal but the development of road transport and the gradual removal of European customs barriers reduced activities to the point where this 40,000 m² area (276 by 138 m) was completely abandoned. For many years, it has been vacant and deteriorating. In 2014 a real estate developer bought the site Tour & Taxi and began transforming the storage halls and customs buildings around and to transform step by step the neighbour into a greener quarter.

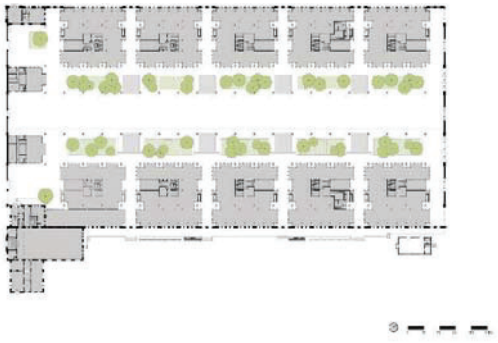

Figure 2: *Ground floor plan*

The former station reaches a maximum height of 23 m. The load bearing structure consists largely of three-hinged frames, made of riveted metallic trusses, covering a 26 meters span. In this magnificent historical hall that has been renovated and reinforced, the Neutelings-Riedijk Architecten's office has inserted twelve four levels pavilions in timber structure with a total of 45.000 m². They will host shops, offices and public functions to make the Gare Maritime a real covered city. The structure of these interior volumes is entirely made of wood. In each of the lateral naves, 5 pavilions fit perfectly into the existing structure, making a total of 10 almost identical pavilions. At the front, 2 additional small pavilions

[1] Charline Lefèvre, Ney & Partners WOW, Belgium, CLE@ney.partners

https://doi.org/10.52202/069179-0560

complete the entrance and the central hall remains an free, covered avenue that can be used for events, sports and arts.

Figure 3: *Elevation*

1.1 RENOVATION PHASE

A first phase of the project was to renovate and reinforce the structure where necessary and to renew the building envelope to contemporary standards. The steel structure was overall in good condition, except for some damaged and corroded elements in the rear façade and under the gutters. One of the important points in the renovation of the structure was to be able to add solar panels on the existing roof. This was possible with a small amount of reinforcement as the structure still had some reserves of strength. Only some elements had to be replaced and there was some strengthening needed on elements that had potential for buckling.

An expertise of the wooden roof frame was also carried out. Some parts were attacked by fungi and had to be completely replaced. However, the expertise and the implementation of a monitoring system to ensure that the wood was properly dried out made it possible to preserve the existing wooden deck as much as possible. The refurbishment focused on a safe structure in accordance with current standards, with maximum respect for the initial project.

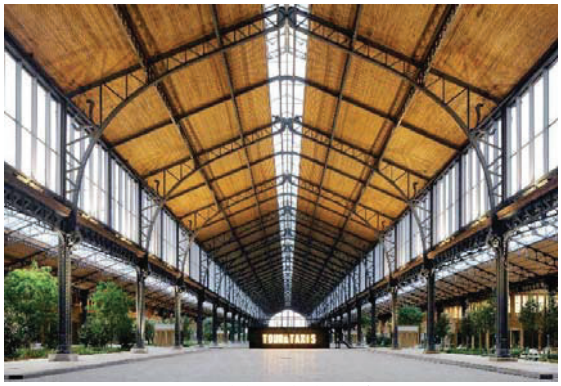

Figure 4: *Interior view of the refurbished naves*

1.2 THE CHOICE OF MATERIAL

At the start of the project, various structural concepts were proposed to the project owner (real-estate developer Extensa) and, for each one, the grid they suit best and their advantages. Those concepts were made of concrete or steel as well as wood.

However, it soon appeared to us that a timber solution was the most adapted proposal in the case of the Gare Maritime and the client was soon convinced too.

First, there was a strong desire from the design team to make the Gare Maritime a pioneering project in line with the existing structure. The aim was therefore to make it an example in terms of sustainability and circularity. The design of a mechanically assembled wooden structure makes it completely removable. Moreover, 1 m^3 of wood on the project represents approximately 1 metric tonne of stored CO2. We can also ensure that the wood is certified and comes from sustainably managed forests. Secondly, the demand was to build these 45,000 m^2 in a really short term. A fully prefabricated structure was the most appropriate way to meet this requirement. Further, it was important to work with relatively light elements. The idea was to limit the impact of the new structure regarding the existing foundation but also to be able to work with small and light machines since the structure is entirely covered, making it impossible to use traditional cranes.
Lastly, since the whole construction site was protected from weather conditions, the situation was ideal for a timber construction.

2 STRUCTURAL DESIGN

One of the challenges for this project was to integrate the 12 new buildings inside the existing historic hall. All the buildings are close to the existing building but remains completely independent of it. The connections between the new and the old building had to consider the thermal expansion of the historic framework. A 7cm gap had to be leaved between the two structures. As a result, there are many cantilevers in each pavilion so that the new structure meets the old one without being fixed to it.

The cores are made of cross laminated timber (CLT) and completed with columns-beams structure and with ribbed floor in glulam and CLT. Walkways and cross stairs connect pavilions to each other's.

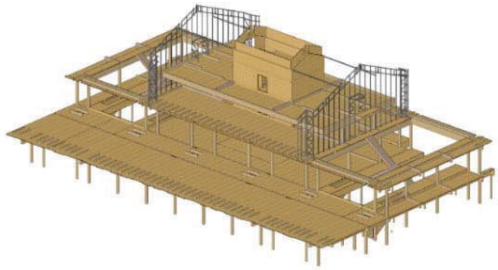

Figure 5: *3D model of one pavilion made with Cadwork [1]*

2.1 SPECIFIC FEATURES

Neutelings Riedijk Architects decided to work with a plan based on a grid of 1.2 by 1.2 m, ideal for the development of offices and perfectly fitting the existing grid of 12 m between the main steel structures. The structure was developed on this concept. All the floors are collaborative screwed ribbed floor composed by a CLT-100 panel that is screwed with glulam ribs every 1.2m. This type of floor

https://doi.org/10.52202/069179-0560

allows to reach bigger spans (up to 8.4 m in this project) while optimizing the volume of wood.

At the beginning, the ribs were supposed to be glued to the CLT panels at the factory but Ney worked with a German timber company (Zublin Timber) on this project and this system would have made transportation from Germany to Brussels very inefficient. The possibility of setting up a workshop to do the gluing on site was considered by the company but the cost was prohibitive. This is why a screwed connection was designed instead.

To solve the cantilevers, the presence of a raised technical floor has been used to implement ribs on the upper side of the CLT. Thanks to this system, users of the buildings have the feeling that only a 10 cm thick CLT slab goes up to the existing structure.

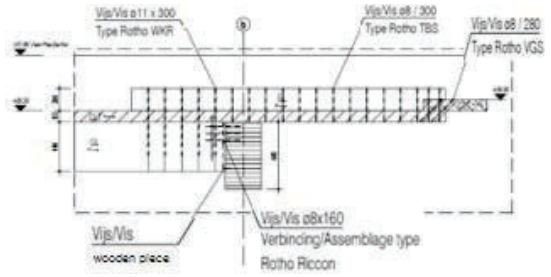

Figure 6: *Reversed collaborative ribbed floor in cantilevers*

To limit the number of holes in the timber elements and to facilitate de mounting, most of the techniques were also integrated under this raised technical floor. But on the ground floor, due to the presence of existing foundation, it was not possible to excavate too much to create a raised floor. An important number of holes had to be made in the ribs to offer flexibility for the future tenants so that they can install techniques in the ceiling. Each hole had to be reinforced by fully threated screws in the ribs.

It was important for the architect to design a structure completely made of wood. To be able to do it, in some areas where we were limited in height and where the stresses were particularly high, spruce LVL (Kerto) and beech LVL (Baubuche) beams have been used for their better mechanical properties. This is the case for the 16.5m long beams that cantilever by 4.8m to support the mezzanine on the third floor and that are made of laminated veneer spruce. The architect chose to clad them to keep the project homogeneous.

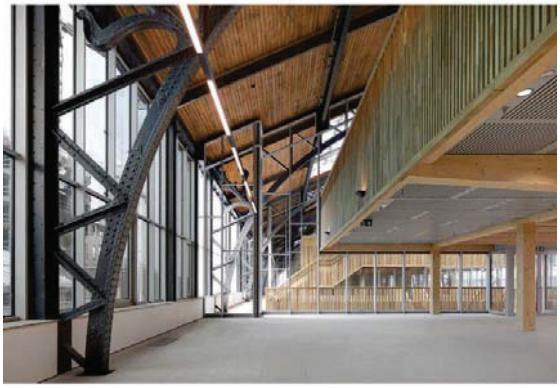

Figure 7: *Mezzanine on cantilevered LVL beams*

2.2 JOINTS

Nearly all joints remain visible on the project. The aesthetics of the connections has therefore been a key point in the design. The ribs on the second and third floors are assembled with concealed connectors using the principle of sliding dovetail joints made with a steel connector.

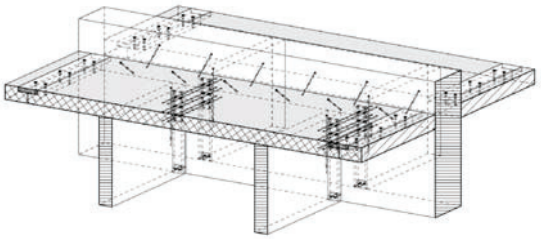

Figure 8: *Ribs connections*

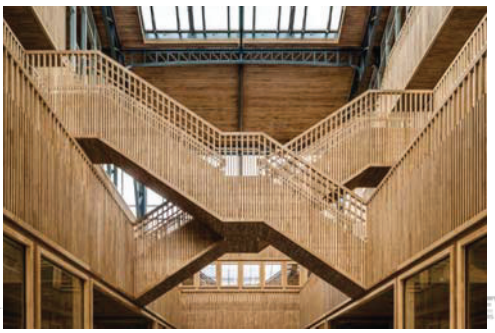
In order to avoid compression problems perpendicular to the grain. Large steel profiles ensure direct load transmission between columns.

For the most heavily loaded beams, an HSK system has been used. These are perforated steel plates (HSK plates) moulded into the wood and glued with epoxy resin ensuring that they remain completely invisible. Those specific joints have also been used the ensure the continuity of the glulam stair stringers.



https://doi.org/10.52202/069179-0560

Figure 9: *Crossing stairs between pavilions using HSK joints*

2.3 FIRE

A big topic on this project was fire safety. It was difficult for the renovation project to comply with existing fire safety Belgian standards and a derogation file had to be drawn up. For example, Belgian fire safety laws require evacuation stairs to be enclosed to protect against fire and smoke while the architect's intention was to work with open staircases.

Thus, several compensatory measures and solutions hade to be integrated in order to be able to execute such a project. Adapting thermal heat scanners used by the US military are used to act as fire detection, crossing stairs between pavilions were designed to act as evacuation stairs, 800 ventilation stacks were added along the existing roof ridge to help with air circulation as well as smoke extraction in case of fire. In addition to those solutions, a modelling of various escape scenarios and simulations of temperature and smoke evolution made by a fire engineering office were necessary to convince the authorities to approve the unconventional solution.

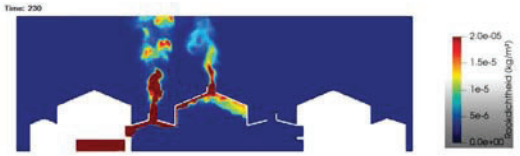


Figure 10: *Simulation of the smoke density*

Concerning the timber structure, an advanced study for fire stability has been performed for this project in collaboration with the University of Liège. Indeed, we were asked to demonstrate that the structure could withstand a longer period of time than originally planned while maintaining the same sections.

When necessary, it was chosen to work with an intumescent transparent paint specially developed for wood. Many products exist on the market to improve the fire reaction of wood but it was not easy to find a paint that improves the fire resistance with technical datas to understand how to calculate the impact of this painting over the timber section during fire. The painting found had valid datas for a floor with a certain load and span. As these assumptions were not met, the project configuration was tested to validate that the values used were still applicable and so a fire test on a real scale mock-up of the floor has been performed in order to validate the complex.

In addition to the fire test, we did further numerical analysis.
A finite element modelling of some joints has been done with the software SAFIR [2] to perform thermal and mechanical analysis and study the behaviour of those joints after a determined time without any protection or with de addition of an intumescent paint.

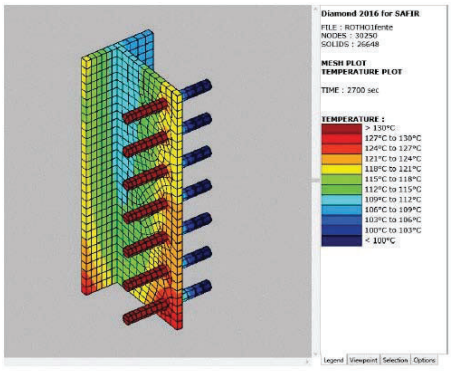

Figure 11: *Thermal analysis of a joint*

In case of fire, the behaviour of the timber depends not only on the temperature of the material but also on the type of solicitation (tension, shear, …). To be able to determine the load bearing capacity of a dowel, we modelled a beam (the dowel) supported by stiffeners whose stiffness varies along the dowel according to the evolution of the mechanical properties of the wood. The stiffener was thus representing the behavior of the wood depending on its temperature.
With the first general model of the joint, we knew the temperature of the wood along the cross section of the beam so we were able to characterize the stiffeners along the dowel. Then we applied at the position of the slotted plate a load that was incremented until the load bearing capacity of the dowel was reached.

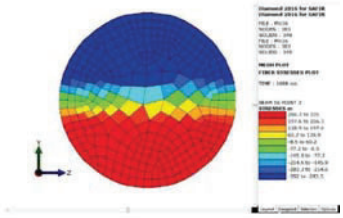

Figure 12: *Mechanical analysis of a dowel in case of fire: stresses in the dowel.*

2.4 MOUNTING

One of the biggest challenge of this project was the great volume of timber alongside the very short programme. The project's extensive scale, the need for precise integration of new elements into the existing structure and the tight deadlines were crucial factors in choosing a BIM process.

Timber construction is undeniably linked to a high degree of prefabrication. The entire structure was then already designed based on a 3D model drawn with software specialized in timber construction. This makes it possible to integrate this BIM process that is conducive to

https://doi.org/10.52202/069179-0560

prefabrication, from the designer to the erector via the supplier, and so on.

The contractors were also required to build a two-storey, full size mock-up on site. This mock-up had to integrate the timber structure, oak siding, steel façade and technical equipment in detail. As part of the project requirements, the contractors were tasked with constructing a full-scale mock-up on site, consisting of a two-storey structure that meticulously incorporated timber elements, steel façade, oak siding and technical equipment.

On one hand, being under cover eliminated any weather dependency during construction. But on the other hands, the new buildings had to be closely integrated into the existing structure – with limited room for manoeuvre. The use of traditional cranes was not possible and the assembly of all the elements and the phasing with the techniques had to be carefully studied.

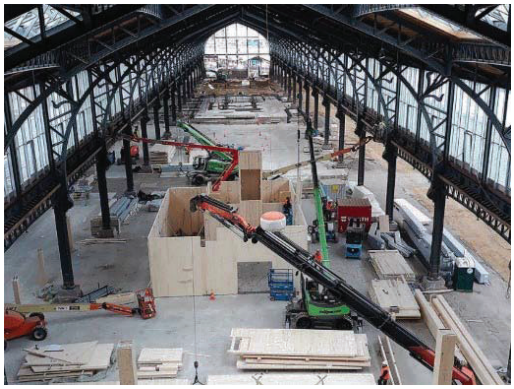

Figure 13: *Construction of the CLT core*

Finally, thanks to the BIM, all the elements were prefabricated, and the construction of the timber structure was extremely fast. It took in average 8 weeks to build 1 pavilion. It means the logistics of delivery and storage of the many pieces had to be tightly managed. The timber structure was fully executed in 10 months, only 14 months after the timber constructor signed the contract.

Figure 14: *Mounting of one pavilion*

3 MODERN AND INNOVATIVE TECHNOLOGIES

The original building has been preserved, including the wood and steel roof, while integrating modern and sustainable technologies for this high energetic performance project. Indeed, the Gare maritime is entirely energy neutral and fossil free.

In addition to CO2 stocked into the volume of wood, sustainability measures have been implemented.

On the roofs a total area of 17 000 m² of solar panels has been installed. The solar technology can also be found in the form of cells integrated into the windows on the south façade of the building. 140-metre deep boreholes were drilled between the pavilions into the bedrock and a subterranean lake system. The then probes are able to provide heating and air conditioning of the space by geothermical energy.and a rainwater recovery system has been installed on the 4 hectares of the roof to maintain the interior gardens and sanitary facilities.

Each pavilion is a highly insulated house underneath the existing envelope. This way, it was not necessary to heat the entire hall. The lateral skylights feature thus triple glazing only in the areas bordering the ten pavilions.
In addition to insulating the offices, Halio's smart tinting glass is used to enhance lighting management of the building. The glass begins tinting within seconds and reaches full tint in less than 3 minutes. It manages not only the intensity of light but also solar heat. Using electrochromic technology, this interactive glazing uses an electrical impulse to switch from total transparency to a dark tint, reducing glare. The glass then transforms into a virtually opaque surface, allowing only 3% of light to pass through. The privacy of the occupants is preserved without cutting them off from the outside environment.

https://doi.org/10.52202/069179-0560

4 CONCLUSIONS

In just three years, the entire 40 000m² of the former railway station underwent a complete renovation, resulting in its transformation into a covered, climate neutral quarter in the heart of Brussels city.

The Gare Maritime now houses a fully wooden structure with a total of 9000 m³ divided into 3000 m³ of glulam and 6000 m³ of CLT. This made the Gare Maritime one of the largest timber projects in Europe when it was inaugurated in September 2020. Since its completion, the project has won several awards, among them in 2020 the Dutch ARC20 Architecture Award, the Belgian Timber Construction Award and the RES Award, and in 2021 the Belgian Building Award, the Europa Nostra Award, the MIPIM Award and the ULI Europe Award for Excellence.

The covered city has now transformed into a bustling hub of various activities, welcoming day workers and visitors. In the evenings and at weekends, the activity continues thanks to its food market and the events held there, such as the world padel tour, which will be held there in 2023 for the second year running.

WIDE-SPAN LVL ROOF STRUCTURE FOR AN INDOOR SWIMMING POOL

Laurent Giampellegrini[1], Samuel Blumer[2], Hendrik Pfeffinger[3]

ABSTRACT: The wide-span roof structure for a new indoor swimming pool in Luxembourg was built as a prefabricated LVL ribbed slab system. The 23.75m span was achieved with PI-elements consisting of slender (75mm) closely spaced and 1100mm deep webs. With the thickness-to-height ratio outside the current standards and a structural behaviour close to the performance limits, the dimensional stability and torsional stiffness of the Kerto Q material was exploited to realise the desired filigree architectural appearance. Given the chloride-laden air of indoor swimming pools, metallic components were limited to a minimum to guarantee a durable and maintenance free structure. The bearing on the reinforced concrete substructure was developed in timber through widely notched supports in the girder webs, exploiting the tension capacity of the cross-layers in the LVL. The webs are connected to the roof plate via hot-dip galvanized dowels to maximise the corrosion resistance. The high and precise degree of prefabrication of the PI-elements in transportable elements enabled a quick and efficient assembly on site.

KEYWORDS: Wide-span, LVL, ribbed slab, dimensional stability, corrosion

1 INTRODUCTION

As part of the redevelopment of a school in Luxembourg City, Cents, the campus was extended to include a sports centre as well as an indoor swimming pool. Embedded in the sloped topography, the school campus designed by Auer Weber Architects, Germany, Stuttgart, creates a new plaza for the local neighbourhood.

Figure 1: *Exterior view of swimming hall within the school campus*

2 STRUCTURAL SYSTEM

The timber roof structure covers the entire 36mx40m plan dimensions of the swimming hall. The indoor space is partitioned on axis 18', at roughly two thirds of its width, into the pool and the general facilities area. The structural system of the roof follows this separation and consists of two simply supported spans. Vertical supports for the timber roof are provided (a) on an intermediary steel beam and the concrete core walls on axis 18' and (b) a concrete ring beam on the outer periphery. The concrete ring beam rests on regularly spaced slender concrete wall elements while the steel beam is supported on the concrete core walls and by additional intermediary steel columns. The lateral stability of the building is achieved through the concrete core and the peripheral concrete wall elements. The top slabs of the timber roof PI-beams are connected to form a diaphragm. On the short span, the roof diaphragm is interrupted to accommodate a skylight.

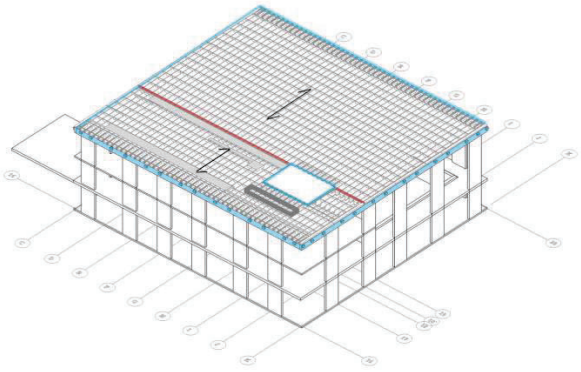

Figure 2: *Axonometry of the indoor swimming hall (blue – concrete ring beam and core, red – steel support)*

[1] Laurent Giampellegrini, PhD, MSc, Director ppa., knippershelbig, Germany, lg@knippershelbig.com
[2] Samuel Blumer, Dipl.-Ing. Dr.techn., sblumer, Austria, samuel.blumer@sblumer.com
[3] Hendrik Pfeffinger, Dipl. Holzbau-Ing. (FH), Projektleitung, Holzbau Amann, Germany, h.pfeffinger@holzbau-amann.de

https://doi.org/10.52202/069179-0561

To achieve the architecturally desired uniform and seamless appearance of the entire roof, the structural elements spanning over the two partitions of the swimming hall roof consist of the same type of PI-beams. The height, spacing and thickness of the ribs and plates is kept the same for both spans, although they differ significantly.

Spanning over a free length of 23.75m over the pool area, the prefabricated PI-beams consist of a pair of slim LVL ribs (Kerto Q) at 800mm centres with a height of 1100mm and a thickness of 75 millimetres. The ribs are structurally connected in shear to the top 69mm LVL slab (Kerto Q) by means of hot-dip galvanised steel dowels. The choice for this type of connector was driven by the required corrosion protection, a topic that is further elaborated in section 4 below. The production limits of the LVL Q-plates were exploited to a maximum as the webs and the top slab are both milled from one continuous plate element. The Q-panels were chosen for their high dimensional and torsional stability considering that the thickness-to-height ratio of the webs exceeds current standards. The webs are additionally restrained by 200mm high transverse bulkheads spaced at 140cm centres along the length of the PI-beams.

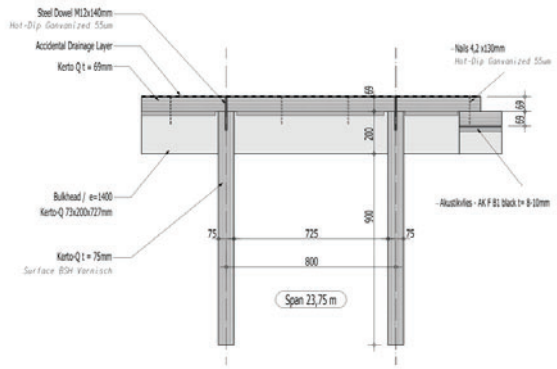

Figure 3: *Section through LVL PI-beams for the 23.75m span*

Figure 4: *Prefabricated PI-beam in the workshop*

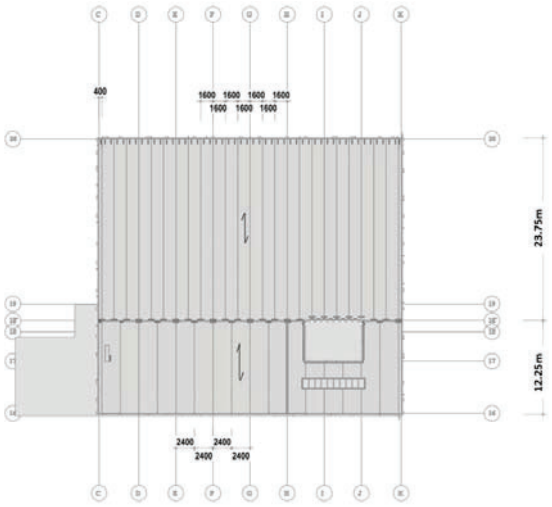

Figure 5: *Plan view of roof*

The LVL ribs are precambered which was achieved via CNC milling of the plates. The precamber was required on the one hand to avoid visual sagging of the beams from the interior view and on the other, to secure the required slope of the roof for drainage. A different precamber was used at the top (180mm) and bottom (120mm) of the ribs.

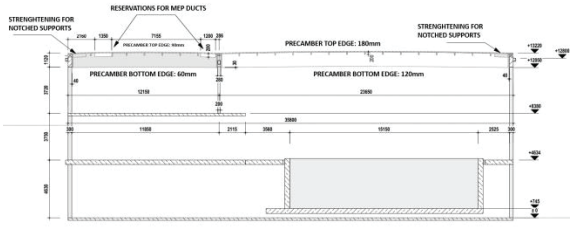

Figure 6: *Section through swimming hall*

The MEP ducts run in the direction of the span so that the number of reservations the roof structure could be kept to a minimum. The lateral distribution of the MEP fixtures was achieved above the general facilities area through reservations made in the smaller span beams at the top of the ribs just below the top plate. An acoustic ceiling with timber lamellas running in the transverse direction closes the space between the ribs. The PI-beams were fully prefabricated in the shop including the accidental drainage layer to allow for a fast and efficient assembly.

https://doi.org/10.52202/069179-0561

3 SPECIAL DETAILS

3.1 SUPPORTS

3.1.1 Introduction

To achieve the desired architectural appearance coupled with the ambition to minimise the use of metallic components, the support of the PI-elements was realised with a deep notch that extends well beyond the usual half-depth limit of the webs. Two main critical points are highlighted in the following figure:

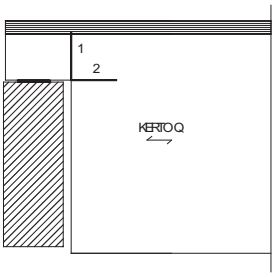

Figure 7: *Support of the single span beam – critical points*

The notches reduce the shear capacity of the beam (1) and raise the risk of tensional failure (2). An alternative solution had been developed by the design engineers.

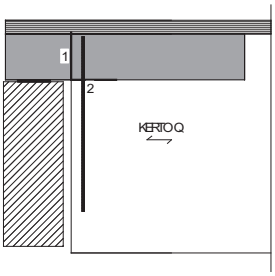

Figure 8: *Thicker beam in upper part (1) and glued in rods (2).*

For this solution, the supports were strengthened on either side of the webs (1) by glued-on LVL plates and strengthened with M14 glued-in rods (2) in the direct vicinity of the support. Additionally, the tensile strength of the cross-layers in the Kerto Q webs was exploited and at the top of the section, the diameter of the glued-in rods was increased via M22/M14 Rampa-sleeves to attain the necessary overall strength.

A verification method of the notch by a reduced shear capacity is given in Eurocode 5 [1].

$$\tau_d = \frac{1.5 \cdot V_d}{h_{notch} \cdot b_{notch}} \leq k_v \cdot f_{v.d} \qquad (1)$$

Whereas k_v represents the reduction factor that considers the geometry of the notch (cf. Formula 6.62 in [1]), the use of formula (1) has to fulfil geometrical parameters according to the Austrian national appendix of Eurocode 5 [3]. The height of the notch has to be bigger than half of the total height of the beam.

$$\frac{h_{notch}}{h_{beam}} \geq 0.5 \qquad (2)$$

In this case, this geometrical requirement is not fulfilled. A finite element model of the entire beam and its support condition has been created to assess the load bearing capacity of the notched support.

3.1.2 Material and methods

One beam with a span of 23.75m has been modelled with the commercial finite element software RFEM 5. The model consists of about 80'000 Triangular surface elements with an edge size of 2.5cm. A detailed stress analysis has been performed on two different models. Model A (MA) consists of a thicker beam in the upper region without glued in rods. Model B (MB) has additionally been reinforced with glued in rods. The linear beam elements of the rods have been connected to the surface elements.

3.1.3 Results

The tension perpendicular to the fibre below the notch is represented in the following table.

Spec.	Reinforcement	σ_y [MPa]
MA	Thicker upper part	4.3 [MPa]
MB	Thicker upper part + rods	2.5 [MPa]

The stress distribution of Model B (MB) is represented in figure 6. The peak vertical stress is located directly below the thicker upper part of the beam. The thickening was pulled down a little on the front side.

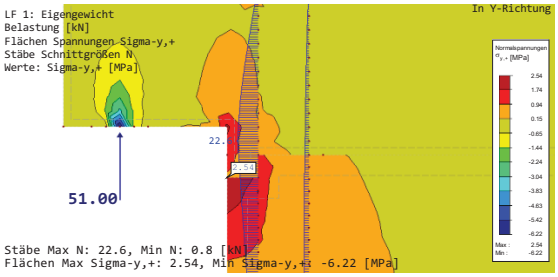

Figure 9: *Traction perpendicular to the fibre σ_y= 2.54 [MPa]*

Due to the higher resistance of Kerto Q, cracking can be prevented.

$$f_{t.90.edge.Rd} = \frac{k_{mod} \cdot f_{t.90.edge.Rk}}{\gamma_M} = 3MPa \qquad (3)$$

Where k_{mod}=0.6 is the reduction factor for permanent loading, $f_{t.90.edge.Rk}$=6 MPa the tensile stress perpendicular to the grain according to the declaration of product of Kerto Q and γ_M=1.2 the material safety factor for LVL timber defined in [1] and [2]. The final solution is presented in the following figure:

https://doi.org/10.52202/069179-0561

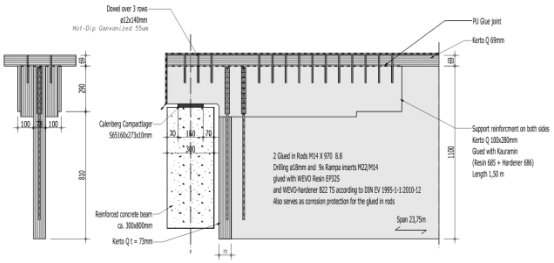

Figure 10: *Final technical solution of the support*

3.1.4 Discussion and conclusion

A detailed stress check was performed for the notched support. The use of Kerto Q reduces the risk of cracking perpendicular to the grain. Additional glued-in bars and thickening of the beams above the bearing area made it possible to solve this geometrically demanding support system. In addition, steel could be avoided. Before such special solutions are worked out, an attempt should be made to achieve direct beam support without notching. However, this is not always possible due to the given boundary conditions.

Figure 11: *Finished notched support of the PI-beams on the concrete ring.*

3.2 PI – Beam

The webs of the PI-girder were statically connected to the slab by steel dowels. The connectors are distributed along the entire beam length and concentrated near the support points (see Figure 12). Without the use of glue, a partially rigid connection is created between the web and the roof panel.

The spring stiffnesses of the anchors can be calculated according to Eurocode 5 [1]. However, they may vary slightly depending on production and tolerances of the holes in the panels. Therefore, the verifications were carried out with half and double spring stiffnesses.

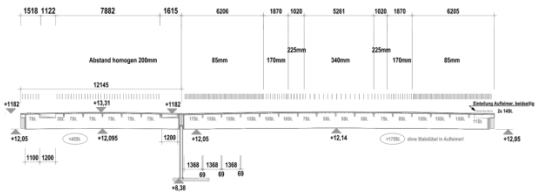

Figure 12: *Arrangement of shear dowels along the beams*

4 CORROSION PROTECTION OF METALLC FASTENERS

A major challenge was the corrosion protection of the metallic fasteners and to get the approval by the local checking authorities.

4.1 SWIMMING POOL ATMOSPHERE

The risk for corrosion of metallic components rises with increasing water vapour in the air. Since the air in an indoor swimming pool is always to some extent humid due to the water evaporation, this environment presents an increased risk for corrosion. Through adequate ventilation and air conditioning measures, a water content of 14g/kg dry air should be an upper bound [5], which for typical indoor pool air temperatures of around 30°C corresponds to approximately 50% relative air humidity. This corresponds to approximately double the amount of humidity present in the atmosphere of typical western European cities. This environment gives rise to a wood equilibrium moisture content between 7-9 M.-% [5] and thus, according to [1], the LVL timber can be classified into the service class 1.

In addition to the air humidity, the presence of salts in the water, in particular chloride salts, contribute to metallic corrosion. The pool is operated with tap water and has a typical average chloride content of around 55mg per litre. Through convection, sodium chloride salts in aerosols are transported through the air and can deposit onto metallic surfaces to amplify the corrosion process. Also, chlorine is usually added to the pool water for disinfection purposes. Free chlorine is typically dosed to a concentration of around 0.3mg per litre and reacts with water to form hydrochloric and hypochlorous acid. The latter, with its high oxidation potential, is the disinfectant active ingredient. Excess chlorine can evaporate as chlorine gas into the ambient air and transform into hydrochloric acid in electrolyte films on metallic surfaces in the presence of water, for example due to condensation.

4.2 CODE REQUIREMENTS

The minimum corrosion protection requirements for metallic fasteners in the Eurocodes [1] is given in Section 4, Table 4.1, reproduced below.

https://doi.org/10.52202/069179-0561

Table 1: *Examples of minimum specifications for material protection against corrosion for fasteners from Table 4.1 in [1]*

Fastener	Service Class[b]		
	1	2	3
Nails and screws with $d \leq 4$ mm	None	Fe/Zn 12c[a]	Fe/Zn 25c[a]
Bolts, dowels, nails and screws with $d > 4$ mm	None	None	Fe/Zn 25c[a]
Staples	Fe/Zn 12c[a]	Fe/Zn 12c[a]	Stainless steel
Punched metal plate fasteners and steel plates up to 3 mm thickness	Fe/Zn 12c[a]	Fe/Zn 12c[a]	Stainless steel
Steel plates from 3 mm up to 5 mm in thickness	None	Fe/Zn 12c[a]	Fe/Zn 25c[a]
Steel plates over 5 mm thickness	None	None	Fe/Zn 25c[a]
[a] If hot dip zinc coating is used, Fe/Zn 12c should be replaced by Z275 and Fe/Zn 25c by Z350 in accordance with EN 10147			
[b] For especially corrosive conditions consideration should be given to heavier hot dip coatings or stainless steel.			

It can be seen from this table, that for service class 1, there are no specific corrosion protection requirements for nails, screw, dowels, and steel plates. However, the nature and severity of the corrosive environment and whether the steel is completely exposed to the atmosphere or within and protected by the timber is not addressed.

The German national annexe [2] states in Section 4, that for moderate, severe, or very severe corrosive environments (corrosion categories C3, C4, C5 according to DIN EN ISO 12944-2:1998-07 [7]), the minimum specifications for material protection against corrosion can be taken from the DIN SPEC 1052-100 [4]. In DIN EN ISO 12944-2:1998-07 [7], swimming pools are classified under the category C4 which is a highly corrosive environment. Consequently, according to the DIN SPEC 1052-100 [4] a minimum average zinc coating of 55µm for screws, nails and steel plates is required. Although in the latter document, the corrosive environment is considered, no distinction is made between fasteners directly exposed to the atmosphere and those within and protected by the timber.

This distinction is made in [6], where the minimum requirements for corrosion protection for metallic fasteners in timber as a function of the equilibrium moisture content are given. The relevant table from [6] is reproduced below.

Table 2: *Classes for corrosion resistant materials and zinc coatings for fasteners in the timber — Minimum requirements. Table 1 from [6]*

Timber class	T1	T2	T3	T4	T5
Moisture content	$\omega < 10\ \%$[a]	$10\ \% \leq \omega \leq 16\ \%$[a]	$16 < \omega \leq 20\ \%$[a]		Permanent $\omega > 20\ \%$
Treatment/acidity of timber	–	–	Untreated and pH > 4	Treated[b] or pH ≤ 4	–
Minimum zinc thickness on carbon steel	–[c]	10 µm	20 µm	55 µm	n/a
Stainless steel grade	–	–	K2	K2 / K3[d]	K3
[a] Short periods with higher moisture content may be disregarded.					
[b] Treatment containing copper or salts (e.g. chlorides) and fire retardants that may influence corrosion rate.					
[c] The appearance may change without a protective coating.					
[d] Class of stainless steel depends on the type of treatment applied to the timber.					

It can be seen that for an equilibrium moisture content below 10%, no particular protection is required. This is very much in line with the conclusions of the specialist approval [5] that was undertaken for this project. In the latter study, it was concluded that the low concentration of chloride aerosols that get into the atmosphere from the tap water operated swimming pool and deposit onto the timber surface would not pose any considerable corrosion risk for the fasteners embedded in the timber elements. This is to be attributed to the low humidity present in the timber (7-9%) on the one hand, and on the other, the phenolic resin used to glue the veneers in the LVL plates that forms an impenetrable barrier.

5 ASSEMBLY

To ensure a quick erection of the visible timber construction on site, the contractor, Holzbau Amann, decided to preassemble the roof into elements in the workshop. To do so, the maximum width for transportation by truck and the maximum preassembly grade were to be considered.

The initial schedule intended a preassembly for both types of elements, with lengths 12,20m and 23,75m, with a width of 2,40m with each element consisting of 3 LVL ribs. Due to production limitations with the supplier of the LVL boards from Finland it was not possible to manufacture the LVL boards with a thickness of 69mm into 23,75m x 2,40m elements. Hence the roof elements were preassembled with dimensions 23,75m x 1,60m, consisting of 2 LVL webs only.

The fabrication of the roof elements in the contractor's workshop started by milling the LVL beams of 23,75m and 12,20m length on a CNC-machine. On the underside of each beam, the precamber according to the results of the structural analysis was milled. Additionally, on top of each beam the roof pitch was milled by the CNC-machine, giving the roof its final shape.

Figure 13*: Production of the PI-elements in the factory*

The threaded rods for the strengthening of the supports were glued in the LVL beams in the workshop under controlled ambient conditions. Lateral strips of LVL were glued to both sides of the beams to absorb the shear forces near the notched supports.

Furthermore, a protective coating was applied to protect the wood from grime and effects of the weather during transportation and assembly.

https://doi.org/10.52202/069179-0561

After connecting the ribs to the LVL roof boards with hot-dip galvanized steel dowels (55µm), 2 preassembled roof elements were loaded on the truck. Each truck, moving from Southern Germany to the site in Luxembourg, was accompanied by an escort vehicle.

***Figure 14**: Two roof elements loaded on the truck*

Arriving on site, the preassembled roof elements, already covered with a sheet acting as a secondary water protection layer, were lifted from the trucks and directly assembled on the concrete structure.

***Figure 15**: Delivery via a side street in Luxembourg*

***Figure 16**: A prefabricated 23,75m roof element on the crane*

To ensure the assembly of the timber roof without constraint forces, the contractor responsible for the concrete structure had been preliminary advised of the required precision and the admissible tolerances of his works. The concrete works were verified by a surveyor and deviations were to be corrected by the concrete contractor if needed. Thus, the timber roof could be assembled quickly without any difficulties.

***Figure 17**: Assembly of the roof with individual LVL PI-Panels*

On one edge of the roof, the LVL beams rest on the concrete ring wall, on the other edge on a fire-proof coated steel profile. Above the steel profile, in between the LVL beams, LVL planks were installed vertically to realize the continuation of the fire barrier.

***Figure 18**: Support points*

To protect the wood elements from the weather the waterproofing was installed in parallel to the assembly of the timber roof. Due to the milled pitch on the upper side of the LVL beams, the final roof pitch was in place right away.

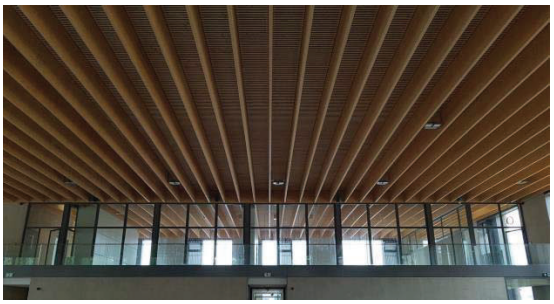

***Figure 19**: Finished Roof underside view*

The ensemble of air ducts and cable lines were projected in the design phase. Cutouts and slots in the LVL beams were realized in the workshop, making sure they were placed in structurally stress-free zones of the beams.

https://doi.org/10.52202/069179-0561

***Figure 20**: Roof underside with acoustic ceiling and LVL-Panels in visual quality*

6 CONCLUSIONS

To meet the architectural requirements and to provide a visually simple and durable structural design, various technical challenges had to be overcome and special solutions had to be developed beyond the limits of the current regulations and standards. The solutions developed exploit the material and size limits of the LVL panels and the details were designed with a minimum of metallic components given the stringent corrosion protection requirements. A high degree of prefabrication allowed for a fast and minimally disruptive assembly on site. The result is a sophisticated ribbed-slab roof structure, milled and assembled in a quality close to joinery.

DESIGN OF A TALL MASS TIMBER TOWER FOR OCCUPANT COMFORT UNDER WIND-INDUCED ACCELERATIONS

Laurent Giampellegrini[1], Anthony Rety[2], Guillaume Caussarieu[3], Tim Sleik[4], Lucia Theurer[5], Johannes Pohl[6], Tobias Wacker[7]

ABSTRACT: The current trend of increasing the height limits of timber buildings makes wind-induced accelerations for occupant comfort an important design parameter. This article presents the two-step process used for the design of a 51m tall mass timber tower located in Sweden. The lateral stiffness of the tower is provided through a CLT inner core and a braced glulam post-and-beam system along its outer periphery. The structural scheme, the dynamics of high-rise timber structures, the 3D modelling assumptions to capture the global stiffness with suitable accuracy as well as the analytical state-of-the-art methods used to determine the wind-induced accelerations in the along-wind, across-wind and torsional direction at the top of the tower are presented. Through a parameter study, the sensitivity of the structure to changes in connection stiffnesses and mass distribution is assessed. Given the uncertainty inherent to the analytical methods, the calculations are validated in a second step against the acceleration response obtained from wind tunnel testing. The differences between the analytical and experimental approaches are compared and the key parameters are discussed.

KEYWORDS: Tall Mass Timber Building, Wind-induced Accelerations, Occupant Comfort, Parameter Study, Design process, 3D Modelling, Wind Tunnel Testing

1 INTRODUCTION

For the *Embassy of Sharing* project in Malmö, Sweden, a total of seven buildings are in planning. The *Fyrtornet* is the first of these buildings and with a height of 51m, will be Malmö's first and Sweden's tallest office building in mass timber. This 11-story building, a landmark for progressive and sustainable construction built entirely in timber above ground, consists of offices with public functions on the two lower floors. The wooden structure is visible from the outside through the glazed facades. The structure is expected to be completed in 2023.

Figure 1: *Architectural rendering of the Fyrtornet Tower*

2 STRUCTURAL SYSTEM

2.1 OVERVIEW

The gravity system consists of CLT slabs that span from the timber core across an intermediary and an outer post-and-beam system in glued laminated timber. The only exception is at the 11th floor, where a concrete slab is used to add mass to control the wind-induced vibration levels. The lateral bracing of the building is achieved via the combined action of an inner CLT core and the outermost braced post-and-beam structure. To accommodate the sloped geometry of the two glazed facades facing south and east, a horizontal transfer is introduced at the 6th level. Vertical transfers occur on the 2nd and 8th floor.

2.2 STRUCTURAL LAYOUT

The following sections and plan views from the building show the structural layout of the CLT slabs, the CLT core and the post-and-beam structure in glued laminated timber. The columns are spaced on a regular 4.8m grid in both directions. The main structural elements are located between gridlines A1-A6 and B1-B6. Within these gridlines, all columns and diagonals are directly supported on the reinforced concrete foundations. Between gridlines

A6-A7 and B6-B7, the vertical loads from the upper levels are brought to the foundation through cantilevering beams on the first floor, supported by inclined columns. This design feature allows for a protected pedestrian area. Due to the sloped geometry of the south and east facades, the floors decrease in surface as higher levels are reached. On every third floor starting from level 2, there is an accessible terrace just behind the glass facade. The next 2 levels are then identical but without any terrace.

Figure 2: *Axonometric overview of timber structure*

The CLT slabs span over two bays, except around the CLT core where they are simply supported. The top faces of the slabs are either flush or laid on top of the glued laminated timber beams. This provides the required space for the main ventilation ducts coming from and running around the CLT core. On the first floor, due to the library usage, 7-ply CLT slabs with a thickness of 240mm are used. The slabs on all the upper floors are 5-ply with a thickness of 180mm. The inner core is built-up from 125cm wide and 280mm to 320mm thick CLT panels.

To accommodate the geometry of the sloped facades, the diagonal bracing, which contributes to the overall lateral stability of the building and provides the necessary torsional stability around the CLT core, is shifted from axes A6/B6 to A5/B5 respectively. To ensure structural continuity of the horizontal load transfer across the height of the building, the horizontal loads are transferred from the bracing on axes A5/B5 above level 6 to the shifted bracing on axes A6/B6 and the CLT core on axes A4/B4 on the lower levels through the CLT slabs, which form a diaphragm at each level. The vertical loads are directly transferred through the columns located on gridlines A2/B5, A4/B5, A5/B2, and A5/B4.

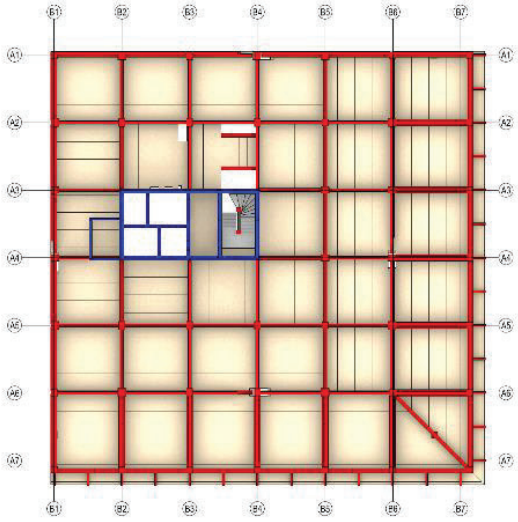

Figure 3: *Level 1 plan view (View from below - Core in blue, beams and columns in red)*

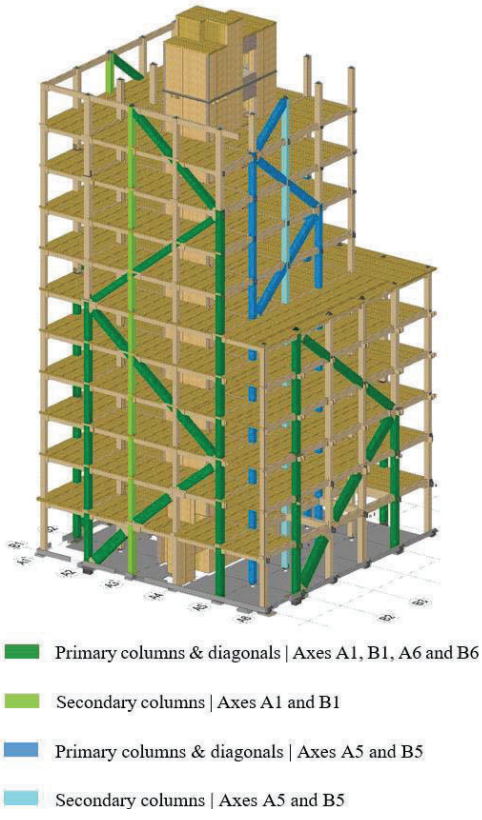

Figure 4: Axonometric view of the glued laminated bracing system

On axes A1 and B1, the glazed facade is vertical so that the bracing system is continuous across the height of the building. To reduce the amount of steel connections, the primary columns are, in general, continuous over 2 to 3

https://doi.org/10.52202/069179-0562

levels. Secondary columns span, in general, from one level to the next.

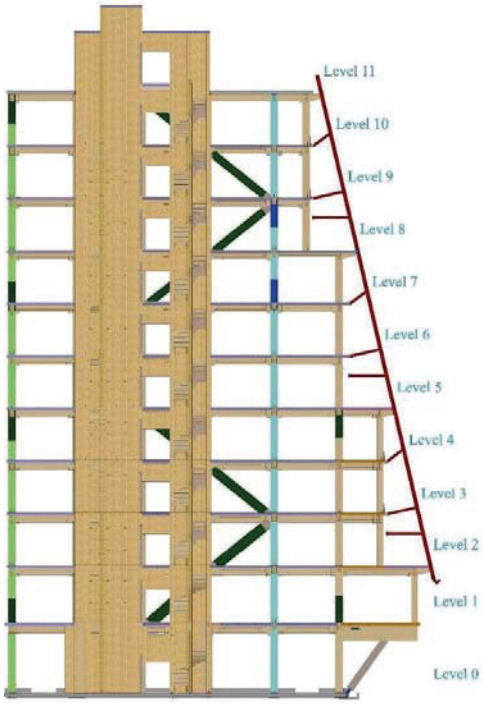

Figure 5: *East-West section of the Fyrtornet Tower*

The cross sections of the bracing diagonals (GL28h) are 560x920mm on the first floor and reduce to 560x600mm on the top floor. The main columns of the bracing system have a constant cross-section of 560x560mm and 440x560mm for the shifted bracing beams from level 6 onwards while the secondary columns are 440x560mm wide. These columns and diagonals are defined as "key elements" according to the Swedish national annex to the Eurocode 1-7 and are therefore designed with an additional safety coefficient of 1.3.

The sloped glazed facades start from the 2nd floor and extend through the entire height of the building. The design of the facade was outside the design scope but a close exchange with the facade designers was necessary to assess the weight distribution on the building and to coordinate the geometry for the assessment of the wind induced loads.

2.3 CONNECTION DESIGN

The bracing diagonals located on the ground floor must sustain a characteristic load of approximately 4000kN. The joints are realized with a dowel-type connection with multiple shear planes. The design of these connections is based on Eurocode 5 [1] and the related Swedish national annex as well as the recommendations given in reference [2]. The connection between the timber elements and the foundation follows the same principle and is achieved through a multiple shear plane connection (4 slotted-in steel plates) with dowel-type fasteners. The large cross-section sizes were achieved by block gluing three beams together.

Figure 6: *Connection design (Cadwork 3D) and bracing glulam beam in the factory.*

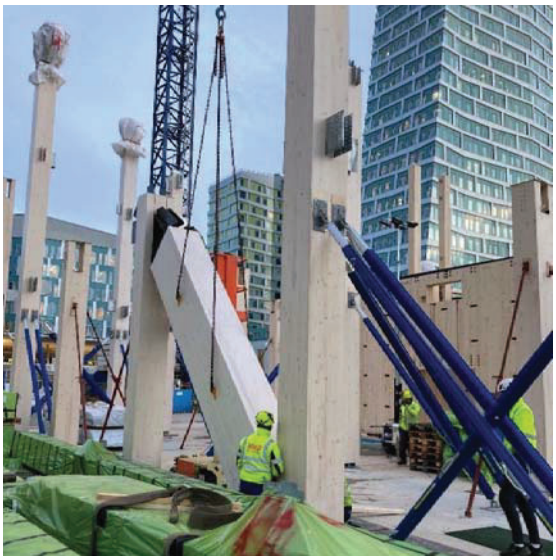

Figure 7: *Bracing beam during installation*

The slab-to-slab connections are realized with a rabbet and a screwed 27mm, 3-ply coverboard. On level 6, these connections are replaced by nailed perforated steel plates to transfer the horizontal loads coming from the shifted bracing diagonals. The 125cm wide CLT core-wall panels are joined with a steel slot connector fixed with inclined auxiliary screws that tighten the panels against each other. This design allows for a very stiff connection and therefore generates a near-monolithic behaviour.

3 DESIGN FOR VIBRATION

3.1 APPROACH

At an early design stage, wind-induced comfort at the top of the tower was recognised as an important design driver. To assess the influence of various design decisions early in the process, a set of analytical tools based on the relevant construction codes and state-of-the-art literature were developed to allow for a quick assessment of the wind-induced accelerations at the top of the tower and to provide feedback to the design team. Once the calculations from these initial calculations showed satisfactory results, the accelerations were subsequently checked in a second step with the input from the data generated from a wind tunnel test. Sufficient time was

https://doi.org/10.52202/069179-0562

allowed to make final adjustments to the structure if needed and to steer the dynamic properties in the right direction in order to meet the required comfort criteria.

3.2 COMFORT CRITERIA

For high-rise buildings, and in particular for tall mass timber buildings such as the Fyrtornet tower, which have a low mass compared to their traditional concrete or steel counterparts, it is important to assess if the horizontal accelerations on the top occupied floors under (turbulent) wind action might be disagreeable or even unacceptable. The perception of acceleration levels is dependent on many factors and is to some extent subjective. Furthermore, the planned usage of the building must be considered. For residential buildings, more restrictive acceleration criteria apply than for office buildings.

Of interest are, in general, the peak accelerations expected to occur only a few times over the lifetime of the building, (for instance during a windstorm) as opposed to the root-mean-square values which are also sometimes used. The common criteria for the perception of acceleration relates the acceleration levels to the frequency of occurrence. Following the generally accepted criteria for high-rise buildings given in [3], the wind-induced horizontal peak accelerations should not exceed the values given in table 1 below.

Table 1: *Generally acceptable 10-year peak accelerations depending on the usage of the building [8]*

Planned usage	Generally acceptable accelerations
Office	2.0 – 2.5 %-g
Hotel	1.5 – 2.0 %-g
Residential	1.0 – 1.5 (to 1.8) %-g

g denotes gravitational acceleration

Extensive examinations indicate that the people's sensitivity to motion becomes less as the frequency of motion (eigenfrequency of the building) decreases. This dependency is not fully reflected in the criteria mentioned above. The criteria in [3] were developed primarily for tall buildings which tend to have natural frequencies in the range of about 0.15 Hz to 0.30 Hz. Following the criterion of the International Organisation Standardization (ISO 10137:2007) [4], the dependence of the frequency is considered in the range of interest between 0.06 Hz and 1 Hz. The published criteria are based on a one-year wind and the peak accelerations of the considered building should not exceed the evaluation curves given in ISO 10137: 2007 – Annex D [4], reproduced below for convenience.

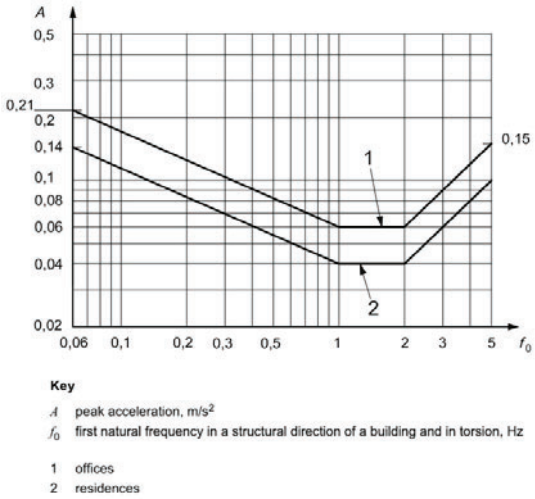

Figure 8: *ISO 10137: 2007 – Annex D: Evaluation curves for wind-induced vibrations in buildings in the horizontal direction for a 1-year return period.*

The acceleration limits in [4] need to be satisfied for peak accelerations resulting from a 1-year return period wind in the along-wind, across-wind, and torsional direction. In many cases, however, the fundamental translational and torsional modes are not independent, and the superposition of these modes will result in higher accelerations than from each mode alone. Although there is little information in the technical literature on how to address the combined acceleration from different modes of vibration, this was considered in both the analytical and wind tunnel assessment. This is described in more detail in subsequent sections.

Finally, it is important to note that the threshold of vibration perception is around 0.5%g. In other words, even if the limiting acceleration criteria above are met, wind induced accelerations will be felt by the occupants under strong winds, but the levels are limited such that with a high likelihood, they do not cause discomfort.

3.3 3D FE MODEL AND KEY PARAMETERS

The creation of a reliable global FE model was critical to properly assess the wind-induced accelerations, which strongly depend on the natural frequencies and mass distribution of the building.

3.3.1 Workflow

Two important criteria for the modelling were the geometrical accuracy and a precise representation of the structural system. For the former, the procedure consisted of extracting the geometry as well as the relevant structural attributes from the 3D Cadwork construction model provided by Binderholz. Centerlines of the structural elements, material grades and cross-sections were retrieved and referenced in the modelling Software Rhinoceros 3D from Robert McNeel & Associates and its visual programming interface Grasshopper. The finite-element model was then created using the Grasshopper

https://doi.org/10.52202/069179-0562

interface to the finite-element software SOFiSTiK AG This workflow allowed for a precise and seamless translation from a "Solid" 3D geometry to the needed line and surface geometry. Furthermore, relying on a semi-automated process greatly improved the speed and flexibility of the information transfer while reducing the risk of errors.

3.3.2 Connection stiffness

To capture the natural frequencies and associated vibration modes of the building with sufficient accuracy, it is important to consider the loss of stiffness generated by the mechanical connections (a) between the 1.25m wide CLT panels in core walls (b) between the CLT panels that make up the floor diaphragms and (c) the diagonals in the peripheral bracing elements. The connections between the post-and-beam elements were considered ideally articulated.

The approach chosen was to generate equivalent material properties with reduced shear stiffnesses (G-modulus) rather than representing the detailed plate discretization in the global model. To estimate the equivalent material properties, sub-models were generated, and the key behavioural parameters extensively studied. For the walls (
Figure 9), the actual panel partition was considered together with the connector stiffness. In addition, the stiffness of the hold-down bracket and the bottom shear connector were also integrated in the model to accurately capture the wall behaviour. An iterative procedure was then undertaken to obtain the same lateral and rotational displacements between the detailed wall model and the simplified one based on equivalent material properties. For the floors (
Figure 10), the full discretization of the constitutive panels and the associated spline connector stiffness was modelled and evaluated to determine the equivalent material properties. A similar strategy was implemented to capture the stiffness behaviour from floor to floor where the hold-down and shear brackets were modelled as continuous springs rather than discrete elements while maintaining the overall wall in-plane rotational behaviour.

This approach had the advantage to greatly simplify the global modelling while maintaining the overall behaviour sufficiently accurate. This proved to be an effective strategy to perform fast and reliable parameter studies.

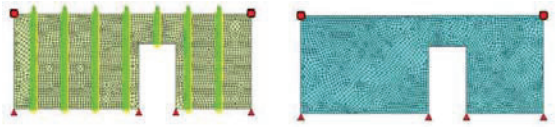

Figure 9: *Walls sub FE-models used to tune the equivalent shear stiffness (G-Modulus)*

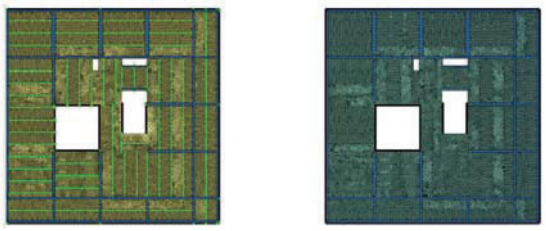

Figure 10: *Floor sub FE-models used to tune the equivalent shear stiffness (G-Modulus)*

To assess the effect of the basement and the foundation on the overall stiffness, the soil and anchorage stiffness provided by the local engineers responsible for the foundation design were considered at an early stage in the model. Considering that the connections had a high stiffness coupled with the fact that the soil stiffness is, in general, significantly higher under dynamic loads (increased by factor of around 4 to 6 compared to its stiffness under static loads [5]), the differences in natural frequencies compared to an idealized rigid support proved to be insignificant.

3.3.3 Analytical assessment of vibrations

The methods given in the Eurocodes and its national annexes are restricted to the calculation of the wind-induced accelerations in the along-wind direction. Furthermore, these methods are approximations that cover only simple geometries, and the effect of the surrounding buildings is not considered leading to uncertainties in, for instance, the force coefficients and peak factors. Moreover, as pointed out in the comparative study in [6], the methods according to the EKS 11, BFS 2019:1 [7] yield a significantly higher accelerations than those presented in EN 1991-1-4 [8]. The Eurocode framework does not provide methods to calculate the across-wind accelerations nor those arising from torsional modes. Furthermore, no guidance is given to account for the superposition of these components. To be able to steer the design into the right direction and assess the effect on the wind-induced vibrations early in the design, the approach described below was adopted.

To calculate the accelerations in the along-wind direction, the method in EN 1991-1-4 [8] was used according to the framework set-out in Annexe B. This method has also been employed in recent studies [6][9][10][11] to assess the wind-induced acceleration of tall mass timber buildings to meet the ISO 10137:2007 [4] comfort standards. In particular, based on the comparative studies in [6], the input parameters according to the EKS 11, BFS 2019:1 [7] were used for the reasons already mentioned above. The wind-induced accelerations in the across-wind direction were calculated according to the Canadian National Code NBCC [12], with the basic wind input data brought back into the Eurocode framework. The accelerations from the torsional modes were calculated according to the principles given in [13]. Also, the superposition of all three components as a square-root-of-sum-of-squares, with an overall reduction factor of 0.8 according to [13] was assessed to account for the fact that

the peaks of all three components are unlikely to occur simultaneously.

3.3.4 Parameter study

To assess the effect of the connection stiffness and mass distribution over the height of the building on the wind-induced vibrations of the tower and use this as an input to inform the structural design, a parameter study was undertaken. For each set of parameters, the wind induced accelerations at the last occupied floor of the tower were computed following the method outlined in the analytical assessment given in the previous section i.e., the accelerations from the first three modes of vibration (along-wind, across-wind and torsion) as well as their superposition. The sensitivity of the vibration response to the various parameters could be determined and changes made where they are the most effective.

The wind-induced accelerations based on the modal parameters obtained from the global finite element model were computed by considering the variation of the following parameters: a) Inter-panel shear connection between wall elements b) Inter-panel shear connection between floor elements c) Tie-down anchors level to level d) Horizontal shear connection level to level e) Tie down anchors level to basement f) Horizontal shear connection level to basement g) Damping and h) Mass distribution over the height of the building.

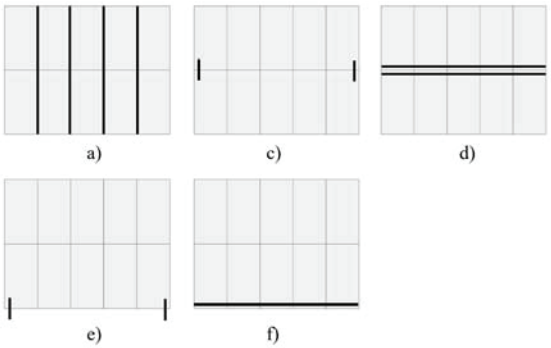

Figure 11: *Schematic illustration of the different parameters at the walls between two levels.*

For a constant damping value, it was found that the mass distribution and the shear connection between the CLT-panels in the core walls (Figure 11 - a) were the driving parameters. The stiffness of the tie-downs (Figure 11 - d, f) and the horizontal shear connection (Figure 11 - e, g) had only a marginal effect on the calculated accelerations. The reason was that under the 1-year and 10-year return period winds, the CLT core walls remained largely in compression. In general, it was found that a variation of the connection stiffnesses of around 20% from the base design values would not lead to a significant increase in acceleration levels. This was also the case for the connection stiffness of the bracing elements. To satisfy the ULS requirements, these connections inherently exhibited a very high stiffness.

While increasing the mass in the top third of the building decreases the natural frequencies, wind-induced peak accelerations could efficiently be decreased by this measure. This effect has been used to influence the floor build-ups in the top floors and to set out the thickness of the concrete slab on the last level to meet the required comfort criteria.

Figure 12 below shows the robustness of the calculated acceleration levels with the changes in stiffness and mass parameters towards the end of the design stage. While the acceleration levels from each individual mode were met with sufficient margin, the superposition tended to exceed the criteria given in ISO 10137:2007 [4]. However, given the uncertainties inherent in this computation and the lack of guidance available, it was chosen to give the modal parameters of the structure (see Figure 13) to the wind engineers and assess the accelerations via wind tunnel testing on this basis.

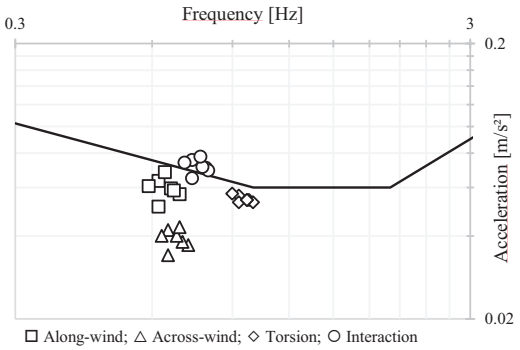

Figure 12: *Summary of the parameter study near design completion showing the first three natural frequencies (translational and torsional modes) and the resulting acceleration as well as the acceleration limit for office buildings according to [4]*

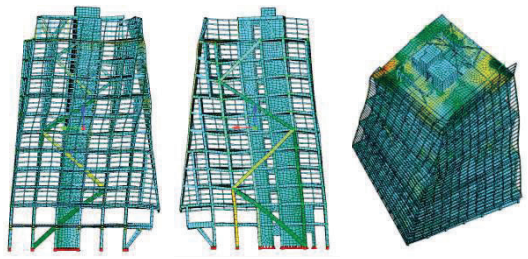

Figure 13: *First lateral mode-shape (0.72Hz), second lateral mode-shape (0.73Hz) and third torsional mode-shape (0.97Hz) from the finite-element model.*

3.3.5 Damping

The damping of a structure, expressed either as the logarithmic decrement δ or as the damping ratio ζ (% of critical damping), is a key parameter in determining the dynamic response of a structure subjected to dynamic loads. Yet, as opposed to stiffness and mass, it cannot be directly calculated, and the designer must rely on values that are code-based or given in state-of-the-art literature for similar types of structures.

https://doi.org/10.52202/069179-0562

EN 1991-1-4 [8] provides a table in appendix F with damping values for various types of structures depending on type, material and connections used. However, the damping values given cover primarily different types of structures made from steel and reinforced concrete. For timber structures, only a single reference is given in this table, namely that for timber bridges with the damping expected to be in the range from δ =0.06 to δ =0.12. The ISO 10137 [4], from the which the acceleration limits are taken for the one-year return period wind, gives damping values of ζ =0.01% for steel frame buildings and ζ =0.02% for concrete frame buildings. Timber buildings are not covered.

The major contributors to overall damping are (i) material damping (ii) structural damping and (iii) damping due to friction from relative movement of non-structural elements (e.g., screed and cladding). In addition, aerodynamic damping i.e., energy dissipation as the building moves through the air may also be considered according to EN 1991-1-4 [8] but was omitted here on the conservative side.

Due to the fact that (a) the Fyrtornet tower consists of a CLT core and slab diaphragms made up from 1.25m wide panels connected with a significant number of dissipative connectors (b) on the periphery, bracing is provided by a braced post-and-beam system, joined with dowel-type connections across multiple shear planes (c) each floor has at least 4cm of floating screed and (d) the building is closed with a timber façade system, it is expected that the overall damping of the tower will be significant. Most studies that address the issue of wind-induced vibrations tend to take damping ratios in the vicinity of 2% of critical, see for instance [6][9][10][11]. Damping ratios from measured examples show a significant scatter: minimum values tend to be around 1.3% while high damping ratios around 3%-4% and values in excess of 5% have been reported [14][15][16]. The large scatter can be attributed to the type of lateral resistance system and its connections, the inclusion of façades and other non-structural elements during measurements as well as the amplitude of the vibration levels. Measurements in [17] showed that for large vibration amplitudes, defined as > 0.05m/s² i.e., in the perceptible range but still below the ISO 10137 limits, the damping ranged from 2.5%-3.5%, depending on the mode. In [15][16], damping values across different structures with different lateral bracing systems are listed, also with measurements after non-structural elements have been included. For post-and-beam systems with a CLT core, the measured damping ranges between 2-3% [16]. In the conclusion of [16], the following recommendations based on the pool of measurements taken are given: for a post-and-beam structure a damping ratio of 1.9% may be used while for a CLT structure, a damping ratio of 2-2.5% may be used. For hybrid structures, damping values are in the range between 2-3% of critical.

Based on the above literature research, while staying within the limits given in EN 1991-1-4, a damping of

1.9% of critical or δ=0.12

was chosen for the 1-year and 10-year wind criterion given that the lateral bracing system of the Fyrtornet consist of both a braced post- and-beam system and a CLT core and diaphragm system.

4 WIND TUNNEL TESTING

To eliminate the uncertainties and unknowns outlined in the analytical assessment, the wind-induced accelerations at the last occupied level of the tower were computed with the wind tunnel generated data.

4.1 WIND TUNNEL SET-UP

For the pressure measurements, a rigid model of the tower in a scale of 1:200 was constructed. The tests were carried out in two configurations: (1) the Fyrtornet tower as a stand-alone solitary building without any additional surrounding buildings and (2) in a configuration including all significant existing and proposed future buildings in the near vicinity within a radius of approximately 200 metres. Surroundings beyond the immediate neighbourhood of the building are simulated by appropriate roughness elements on the tunnel floor in order to provide an accurate simulation of the wind speed profile and turbulence of the approaching wind. The facades of the tower were equipped with about 150 pressure taps and the time-series were recorded simultaneously by means of high-response differential pressure transducers.

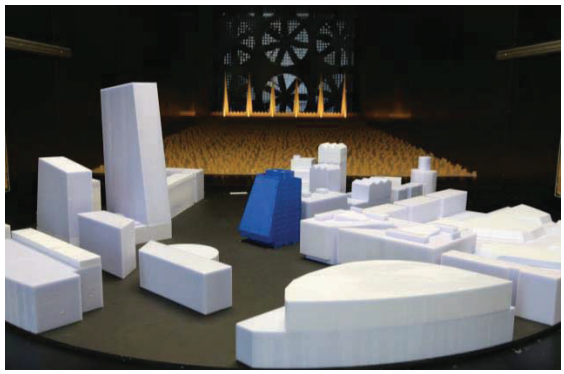

Figure 14: *Wind tunnel test set-up with local environment*

4.2 CALCUATED ACCELERATIONS

As a basis for the wind-induced vibration calculation based on the wind-tunnel measurements on the rigid model, a simplified linear analytical model was established that correctly represents the mass distribution and modal properties of the tower as established in the more complex 3D finite-element model.

The main steps for the computation of the dynamic response of the tower can be summarized as follows: (1) calculation of the generalized force-time series based on the measured pressure time-series and the mode shape information, (2) Fourier transformation of the generalized force-time series and multiplication with the mechanical

admittance function for the respective mode shapes. This results in the complex generalized deformation spectrum. On this basis, the deformation and acceleration time-series are computed. (3) Extreme value analysis of the acceleration time-series.

For the vibration response calculation, a logarithmic damping decrement of $\delta = 0.12$ was assumed to be representative for 10-year and 1-year winds. The predicted peak accelerations in the upper floors of the tower are:

$$a_{10a,peak}\,(\delta=0.12) = 2.40\%\text{- g}$$

for the 10-years-wind and

$$a_{1a,peak}\,(\delta=0.12) = 0.70\%\text{-g}$$

for the 1-year-wind.

These accelerations occur on the outer corner range of the last occupied floor level (Level 20; 39.6 m above ground) and include the contribution of the along wind, crosswind, and radial accelerations. The values represent the maximum peak accelerations of all investigated wind directions and constellations. Considering the natural frequencies of the building, both the 10-year and the 1-year accelerations are within the acceptable limits for an office building according to the comfort criteria described above.

It is important to note that, although the wind tunnel analysis seems to validate the code-based analytical calculations, the reasons for the reasonably good match are not obvious. In fact, the general wind climate on site proved to be less onerous than the wind speeds given in the code. On the other hand, the peak acceleration values given above arise predominantly from one direction in which the presence of one of the tall buildings next to the Fyrtornet plays a significant role.

5 SITE ASSMEBLY

The assembly sequence starts with the CLT core. Walls are pre-assembled on the floor and are then installed as one monolithic element. Once the core over the height of one storey is assembled, the glulam structural elements are installed: first all the columns, which are temporarily propped, then the bracing and finally the horizontal beams.

In the next step, the CLT slabs are installed and act as a temporary water protection. A moisture protective, diffusion open, membrane is already applied to the slabs in the factory and only some minor rework on-site is required. Keeping timber as dry as possible during assembly is one of the key elements to ensure a good quality to the building. This sequence of steps is then repeated for each storey.

The timber structure assembly started in November 2022 and is planned be completed by June 2023.

Figure 15: *On site situation the 6th of December 2022. Picture taken from south-east.*

Figure 16: *On site situation the 21st of February. Picture taken from south-west. Timber structure levels 1 to 4 is completed.*

6 CONCLUSIONS

The two-step approach taken to assess the wind-induced accelerations for comfort on the Fyrtornet tower proved to be a reliable and necessary strategy.

In the first step, the analytical assessment of the acceleration at the last occupied floor of the tower based on methods given in codes and state-of-the-art literature, coupled with a parameter study on the influence of the connections stiffnesses and mass distribution on the accelerations allowed to steer the structural design in the right direction. However, the code-based methods that are available to date do not provide comprehensive guidance on how to compute the wind-induced vibrations for the across-wind and torsional modes and no information is given on how the response from individual modes is superposed. Also, recommendations for damping values applicable for tall mass timber buildings are not existent in the current European codes so that an extensive literature research of the current state-of-the-art must be undertaken. Additional research in this field is needed.

https://doi.org/10.52202/069179-0562

Given that analytical methods ultimately remain idealisations for simple geometries and cannot fully account for the effects of the wind effects from adjacent buildings, it is recommended to assess the wind-induced vibrations in second step through wind-tunnel based methods in order to yield a reliable and yet efficient structural design.

BUILDING INFORMATION MODELING OF A TIMBER BRIDGE – A CASE STUDY

Alvdis Hardeng[1]

ABSTRACT: The development of using BIM models as the sole documentation in road projects has come a long way, but in Norway the development has come particularly far. A BIM model gives the user a good overall picture with access to any information needed. One of the biggest advantages of BIM is that the design basis is more elaborated and with higher level of details. The reduction in change orders on site is noticeable.

This case study shows how a BIM model can be used, from calculation and modeling to structural review, productions and procurements, assembly and useability after construction. Tande Bridge is chosen as an example of this process as it one of the first timber bridges to be built based solely on BIM models and was a success. A BIM model of a timber bridge includes large glulam beams, concrete abutments and steel joints with essential detail. We can therefore conclude that we have a well-functioning system for BIM models in a bridge life span that can be used on every kind of construction and material. Even greater success will come with more standardization and development of software.

KEYWORDS: Timber Bridge, Building Information Modeling (BIM), Model-based Design, Drawingless Design, Model Maturity Index (MMI).

1 INTRODUCTION

Norway has a long history of timber bridges. The breakthrough came with the Olympics in Lillehammer in 1994. A new method for connections was developed (slotted steel plates with dowels) and creosote impregnation guaranteed a life span of 100 years. This was the beginning of making larger road bridges in glulam. In recent years, many overpasses have been built in glulam, especially in the eastern part of Norway. Medium-sized timber bridges with a pre-stressed timber deck are competitive with other materials, especially when there is limited construction time and deck hight is needed.

The design basis has historically been 2D drawings. The change from 2D drawings to 3D models was done in a few years' time around 2016 in Norway. At first Building Information Modeling (BIM) models were used as the basis for creating 2D drawings, whereas we now use the same BIM models throughout the whole project. The development has come a long way, and in Norway the development of drawingless projects has come the furthest [1]. This paper shows how BIM can be used as sole documentation for the whole life cycle of a timber bridge. From calculation and modeling to structural review, productions and procurements, assembly and ultimately archiving and maintenance.

BIM models offer a much better visualization than 2D drawings, but it is important to find the right platforms to disseminate the knowledge. One of the biggest advantages of BIM is that the design basis is more elaborated with a higher level of detail. A 3D model can also make clash controls easy in the early stages of the bridge design, which leads to a reduction of the number of changes on site.

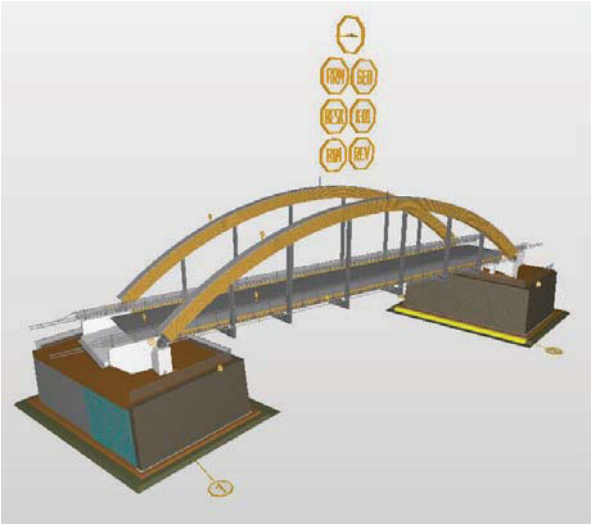

Figure 1: *BIM model of Tande Bridge*

[1] Alvdis Hardeng, Sweco Norge AS, Norway, alvdis.hardeng@sweco.no

https://doi.org/10.52202/069179-0563

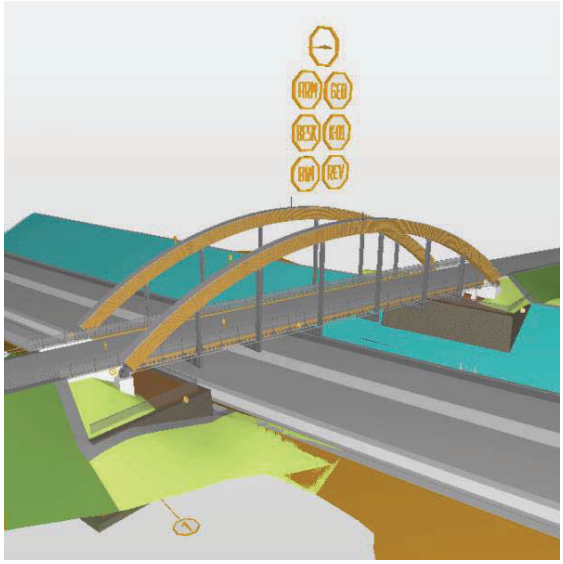

Figure 2: *BIM model of Tande Bridge with road geometry and landscape*

A BIM model consists of several files. Typically, there will be separate files for each discipline, which provides the user with a clear overview and easy access to relevant information. Figure 1 shows the BIM model of Tande Bridge. In Figure 2 road geometry and landscape design have also been added. To ensure that the BIM model file will not be too big, the road geometry and landscape are customized and only showing what's relevant to the specific bridge. The «coins» (shown over the bridge in Figure 1 and Figure 2) have been developed by Sweco as a practical way of gathering links to useful documents such as the "overview drawing", the design report, the geotechnical report etc. Typically, the documents you will need throughout the life span of the bridge.

To make a good BIM model it is necessary to know who will use it and what they will use it for, for example structural review, procurement, or assembly etc. It is also of great importance what kind of information is needed in the various phases. There is a lot of information inside a model and without good filters in the software, it is difficult to sort and utilize the information. Material, dimension, object name and construction part are examples of topics the BIM model should filter on. An accurate and structured BIM model is necessary to avoid that the user will not experience an overflow of information.

As a tool to ensure good information flow, the BIM manual was introduced. This is a document that always follow the BIM model. The BIM manual describes how the model's structured, the level of detailing used in this particular model, how object information is sorted, how to filter in the model, a review of how model maturity index (MMI) is used, and other relevant information are important topics that are reviewed in the BIM manual. The MMI number describes the level of maturity through number codes. It is not possible to determine whether a construction part has been subject to structural review by simply looking at the object in the model. The MMI level is therefore utilized to link the maturity with the object to explain which phase it is in and if you could use the information for preliminary design, clash controls or procurement. The use of MMI is primarily for the design, structural review and construction phases.

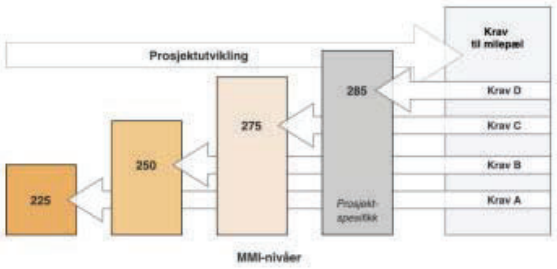

Figure 3: *Conceptual sketch showing the MMI level increasing during the project development and linked to requirements [2].*

Figure 3 shows how the level of MMI increases through the project development and how it is linked to requirements that constitute a milestone. It is possible to have different levels of MMI on different objects in the same model. The total level of MMI for a model always refers to the lowest MMI level. To get a good overview it is possible to sort on the different levels of MMI in every BIM model.

A timber bridge consists of glulam beams, concrete abutments and steel details and generally has a lot of different components from small steel connections to large glulam beams. It is important to choose the right level of detailing on each component. If you can manage the life cycle of a timber bridge solely based on BIM models, you can manage every type of construction and material. Tande Bridge is chosen as an example of this process. Tande Bridge is one of the first timber bridges built solely based on BIM models. Tande Bridge was designed in 2018 and built in 2020. The bridge is a two-way 80km/h road south of Lillehammer, crossing the E6 highway. It has an arch span of 48,5 meters connected with tension bars. The glulam arch is connected at the top with a steel joint.

2 TANDE BRIDGE – FROM DESIGN TO MAINTENANCE

2.1 STRUCTURAL DESIGN

The development of BIM models has come furthest in the planning phase. The priority in this phase is to optimize the structural design and make it even more efficient. In Norway, many of the large road projects are Engineering, Procurement and Construction (EPC) contracts. This has resulted in a reduction of time to complete the structural design, and the need for streamlining and optimizing the design period is noticeable. The introduction of parametric design into modelling is particularly favourable when working with preliminary design. The need for detailing is superior, and the focus is finding a buildable solution for the right price. The use of

https://doi.org/10.52202/069179-0563

parametric design enables quick changes and gives a good overview over the geometry with a detail level sufficient for the design phase. Pre-made script for all the typical bridge solutions makes it easy to choose the right bridge solution fast. As it is easy to add road geometry, landscape, traction pipes etc., showstoppers are quickly discovered, and a solid bridge solution can be established.

It is important to consider what level of detailing a BIM model needs. Objects must have enough details to be useful for a good understanding of the model and in a clash control. At the same time, unnecessary details can make the model hard to use, as the files become too large. An example is screws. Screws come predefined in every modelling program, with everything from head to thread modelled visually. However, you still need to describe the object with information such as material, surface treatment etc. in the model before the object can be used for procurement and construction. This means that a better-looking screw will make the file heavier without providing much benefit. For design purposes you would achieve equal result with a cylinder of the same diameter and description as the screw which would not make the file heavier. Considering the number of screws in a bridge construction, it can be favourable to make a simplified screw duplicate as shown in Figure 4.

Figure 4: *Simplified screw duplicate used at Tande Bridge*

All price-bearing elements must be modelled. The focus on Tande Bridge were the glulam beams with steel details, necessary detailing of the steel details, the abutments and to sort every component into phases. The holes in the steel are especially important and can be difficult to model. It is important to ensure that the hole stays a hole for the whole process from modelling and to procurement.

Object information is added in the design software before the IFC export (a PDF file for BIM models). Object information is called user-defined attribute (UDA). The UDAs are important information that should be easily accessed, such as material quality, placement priority, links to drawings etc. The information should be short and descriptive. A high-quality BIM model includes useful attributes to objects in the model. The key is understanding what information is needed in the different phases.

The detail level needed for the UDA differs from phase to phase. For a preliminary design, there is less need for detailed attributes compared to a building project where the attributes should be adjusted to procurement. The input in the UDA enables the possibility to classification. Figure 5 shows the UDA for the glulam beams on Tande bridge. Everything from dimension to surface treatment and MMI level are described.

Figure 5: *Extract from the UDA for a glulam beam*

The setup for UDA shown in Figure 5 follows guidelines given by the Norwegian Public Road Administration in addition to the needs of the glulam subcontractor and the contractor. Every set of attributes is linked to an element to ensure that the necessary amount of information for every phase is provided in the model.

Figure 6 and Figure 7 show how it is possible to filter and sort in the BIM model. In Figure 6 all glulam arcs are shown, and in Figure 7 all element with the material "GL30C" are shown.

https://doi.org/10.52202/069179-0563

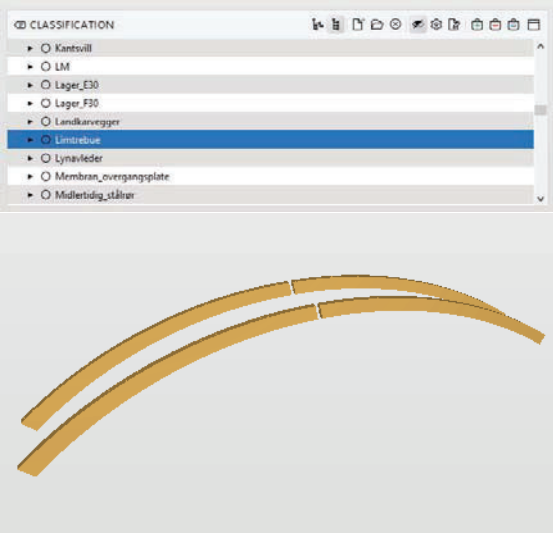

Figure 6: *The BIM model when sorting on glulam arc*

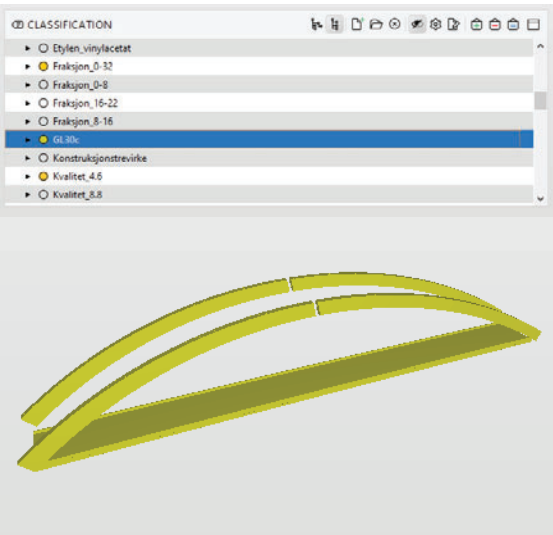

Figure 7: *The BIM model when sorting on "GL30c"*

Even if we have a BIM model, we still make the "overview drawing". The drawing gives an overall view of the construction and should provide the necessary information without having to look up the design report or look at the model. When modelling a bridge, a cost-benefit assessment should be made. How do you show what is needed without doing a needless amount of work that will also make the file unnecessary big? Therefore, drawings showing the principle of backfilling around the bridge and maintenance drawings with tables to be filled out after the bridge opening are still being made.

2.2 STRUCTURAL REVIEW

When working with a 3D model, collisions will immediately be apparent. Discovering collisions at an early stage gives a far more effective opportunity to address the issues than fixing collisions when discovered in the late stage of structural design or on site. This advantage is significant for economic reasons and decreases time delays for the contractor. In the first phase after model completion, the models are used for interdisciplinary control and afterwards for third-party control. With a greater degree of standardization, more checks can also be done automatically and that will help improve quality and save time.

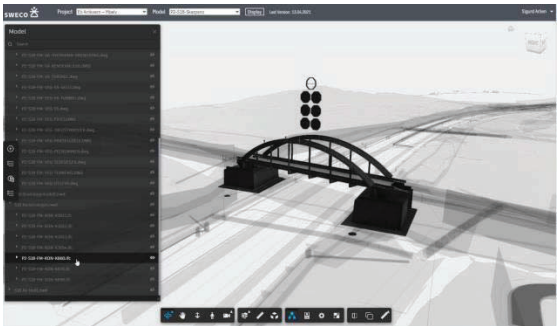

Figure 8: *Tande Bridge in the online model viewer for the road project*

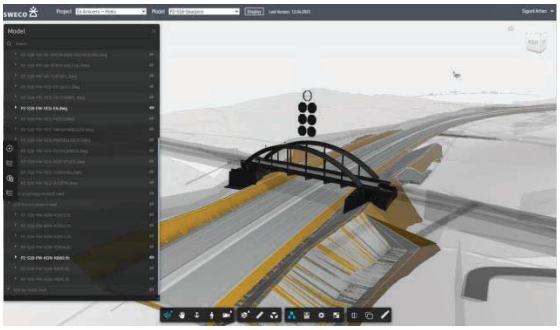

Figure 9: *Tande Bridge with road geometry in the online model viewer for the road project*

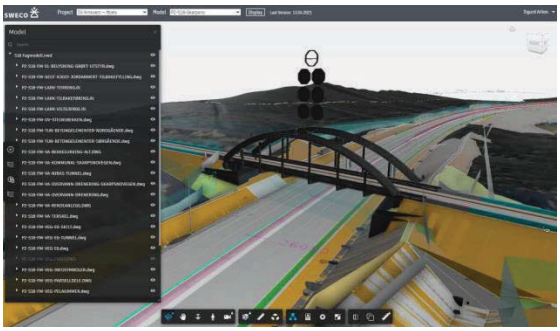

Figure 10: *Tande Bridge with all the different models visible in the online model viewer for the road project*

Having a good solution for showcasing all the different models are important. This is particularly useful when you have several bridges with models not only from the civil engineer, but also from road engineer, landscape architect etc. It should be easy to navigate and to turn on and off

https://doi.org/10.52202/069179-0563

each model. Figure 8, 9 and 10 show Tande Bridge in the online model viewer used in the road project. Figure 8 highlights the bridge alone, while Figure 9 also includes the road geometry is highlighted. In Figure 10 all the different models are visible.

The BIM model is also used for structural review. This is an efficient method where it is possible to perform the structural review and add comments directly in the model. The comments are saved in a separate file where it is possible to add answers. The file is then sent back and forth until every comment is sufficiently addresses. Figure 11 shows a screenshot of the structural review of Tande Bridge. The different comments are listed at the bottom with supplementary comments on the left and a visual display top right.

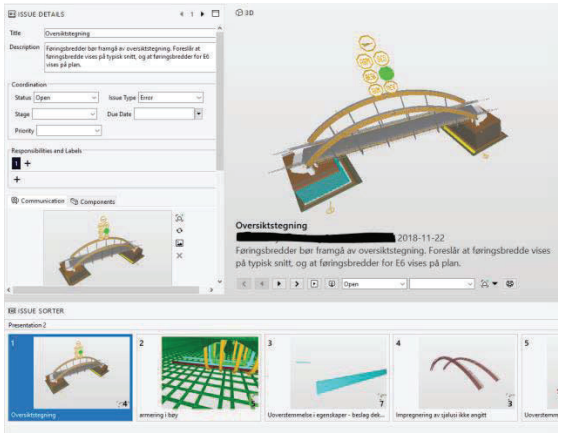

Figure 11: *Screenshot of the structural review of Tande Bridge*

It is recommended to use the BIM manual to inform the person performing the different reviews. A good, standardized model with a good setup of filters, this will ensure that the structural review can be done in an effective way.

2.3 GLULAM SUBCONTRACTOR

The biggest advantage for the glulam subcontractor is how quickly they get a good overview with a BIM model and how easily the model can be updated when changes occur.

Figure 12: *Extract from the UDAs for the glulam deck*

Figure 12 shows how the glulam deck is described in the attributes, sufficient for procurements. The attributes include surface treatment, radius on the deck, material etc. The attributes also show the status of the model and the corresponding date, as well as the level of MMI for the specific element (here: 400 and ready for procurement).

The import of the BIM model into the supplier's software normally works adequately, but there may be some bugs and the import can be time consuming. The glulam subcontractor produces the glulam with a CNC machine. CNC machines are used to computerize production machines in various types of industry. It is particularly the holes in the glulam that make transfer to the CNC machine challenging. When the model is exported to IFC format, it is important to check that each hole remains a hole and does not transform into splines. Work is continuously being done to address this challenge. A good import depends on an accurate and thorough model, since the IFC format is less accurate than the precision of the CNC machine. A very detailed BIM model is not necessarily sufficient for the supplier. It can make the model too heavy without any benefits. Improved software with good filters and a more standardized setup for models, which considers the needs of the suppliers, are important.

2.4 CONSTRUCTION

Looking at hourly consumption, it is on the construction site that the BIM model is used the most. However, this is also where available software is least developed. Software must be optimized to present views and information from BIM models in an easy and efficient way. All information in the BIM model is connected to a component. Thus, a single file can provide all the information needed to build the bridge.

The glulam beams on Tande Bridge were transported to the construction site pre-assembled. Smaller elements

https://doi.org/10.52202/069179-0563

were prepared at the factory and then transported to the construction site by night. The abutments where already built on each side of the highway. The traffic was redirected, and the assembly could take place during a weekend. Figure 13 shows the assembly of the glulam arcs.

Figure 13: *The glulam arches are assembled on the construction site. Picture taken by Sweco*

Using the BIM models sequenced information for the assembly will be an advantage. The contractor can then go through the construction period to check any time-critical elements and perform space-saving measures.

However, the use of tablets and other digital tools can be difficult on site, especially due to weather conditions. An example is the challenges of using touch screens in rainy weather.

Revisions done in the model must be marked and described carefully, as it is not possible to highlight the revisions as it is for drawings. When updating a model, the change must be described sufficiently including the revision mark and date. That way it is possible to filter the model regarding the updates as shown in figure 14.

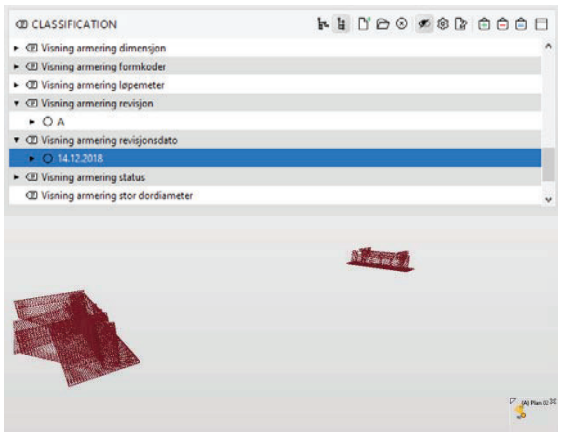

Figure 14: *The BIM model showing a revision made at a certain date*

The history of 3D models on construction sites is not long, so it is important to constantly get feedback from contractors and to incorporate the feedback into the model. A good project includes the contractors' needs from the beginning. Even though there is a requirement that all cost-bearing elements must be included in the model, the needs of the contractors should be given more emphasis.

2.5 USEABILITY OF BIM MODELS AFTER CONSTRUCTION

There is little experience with using BIM models in the operation and maintenance phase. Experience will come with time as main inspections are carried out every five years on bridges in use. As in all other projects, it is important that the BIM model is updated with any changes along the way. The existing national archive system is not adapted for handling BIM models. Currently, everything is just stored together and then it is practical that the BIM model comes in a single file.

On the road project where Tande Bridge is situated, the contractors made a digital display of the entire project which contained all BIM models. All information was connected to a component. It is then possible to extract parts of the database by sorting on object information. This ensures that only the information needed will be provided, thus avoiding information overload.

Figure 15 shows Tande Bridge in the summer of 2022.

Figure 15: *Tande Bridge open and in use. Picture taken by Sweco*

3 CONCLUSION AND FUTURE WORKS

Tande Bridge as a BIM model was a success. This shows that we have a well-functioning system for BIM models that can be used on any type of bridge and any kind of material, and that we can use one BIM model for the whole process. The industry will become more automatized and the need for digital information will increase. The key to even greater success is more standardization in every phase.

As with all projects made with BIM models the collisions are discovered sooner rather than later and often in a phase where it easier and cheaper to correct them. At the moment, the software developed for each phase is not at a stage where we can take full advantage of all opportunities. Since the models are full of information, it must be easy to sort relevant information. We need a

https://doi.org/10.52202/069179-0563

better structure for information and how to sort it into different phases. If not, it is very easy to get information overload.

The advantages of increased quality and a more efficient workflow will give financial gains and increase the impetus for working solely with BIM models. Hopefully, this will also be an incentive for the development of software. Further collaboration on standardization will be time-consuming and involve some trial and error, but it will be necessary to move the process forward. The collection of best practice from every phase to ensure that the needs of different actors are met, should also be considered in future work on standardization.

ACKNOWLEDGEMENT

I would like to thank my colleagues at Sweco and the many contributors in the E6 Arnkvern – Moelv road project for a great and ground-breaking collaboration. I also want to thank Sweco for facilitating work on this paper, as well as the great interlocutors at Sweco who have given me useful feedback on the text.

NLT DEVELOPMENT FOR BRAZILIAN MARKET – TESTS AND USE

Carlito Calil Neto[1], Alexander Takata[2], Vitor Afonso Neves Silva[3]

ABSTRACT: NLT is an old method of construction with a range of modern opportunity to create compelling architecture. Used in many historic applications, it is enjoying renewed interest as we rediscover the many benefits of mass timber and advance wood technology and manufacturing. Lightweight, low-carbon, and very compatible with high-performance buildings, innovation with NLT is inspiring new opportunities for large- and small-scale buildings across sectors and around the world. The use of new technologies in wood for construction is increasing every year in Brazil. This work aims to demonstrate the development and construction of the first NLT structure in São Paulo city.

KEYWORDS: NLT, Brazil,

1 INTRODUCTION

Part of the family of mass timber products, Nail-laminated timber (NLT) is mechanically laminated to create a solid structural element. NLT is created by placing dimension lumber on edge and fastening the individual laminations together with nails. Typically used as floors and roofs, NLT can also be used for walls, elevator shafts, and stair shafts. Plywood/OSB added to one face can provide in-plane shear capacity, allowing the product to be used as a shear wall or diaphragm.

The mass timber product range available in North America includes Glued-laminated Timber (GLT), Cross-laminated Timber (CLT) and Nail-laminated Timber (NLT). While this wide range of products affords many options for specific design applications, each has different design challenges, performance characteristics, and construction advantages.

Among architects, manufacturers, and environmentalists, many want nothing less than to turn the coming decades of global construction from a giant source of carbon emissions into a giant carbon sink by replacing concrete and steel construction with mass timber. It will avoid the CO2 generated in the production of those building materials and sequester massive amounts of carbon by tying up the wood in buildings.

Wood is the only renewable building material that has grown with sunlight and uses atmospheric CO2 to develop. However, this potential for the use of wood as a smart alternative for GHG emission in the construction industry generally meets the Brazilian tradition in processing timber in the way of keeping the focus on the production of solid high density wood, which has its charm and usefulness. However, to shift the general logic of using wood in the construction industry to upscale its reach and competitiveness for the housing sector it is needed to develop a new industry and a new market for highly processed wood products, such as wood-frame panels or laminated wood panels.

NLT is significant in the range of available mass timber options given the relative ease of fabrication and access to material; NLT requires no necessarily unique manufacturing facility and can be fabricated with local dimension lumber for use in applications across sectors and structure types. While products like GLT and CLT have modern publications and resources aimed at assisting designers and builders with specification, detailing, and installation, NLT resources are dated and focus on prescriptive rather than engineered applications.

In this work, test methods and results were performed at LaMEM (Wood and Timber Structures Laboratory), São Carlos Engineering School, São Paulo University, in Brazil. It was delivered 2 different NLT plates with dimensions of 91 x 1500 x 2600 millimeters. The element is made up of 34 lamellae of Pinus taeda, each measuring 44x80x2600 mm, nailed together by two distinct arrangements of ring nails measuring 35 mm in length and 3 mm in diameter. This set is coupled to an OSB APA Structural board 11.1x1200x2600 mm using nails of the same model as the previous one.

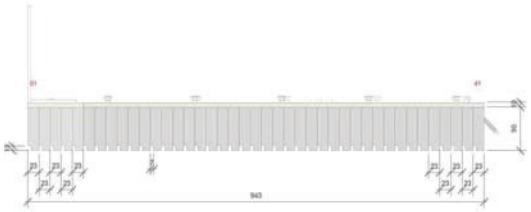

Figure 1: *test scheme NLT plate*

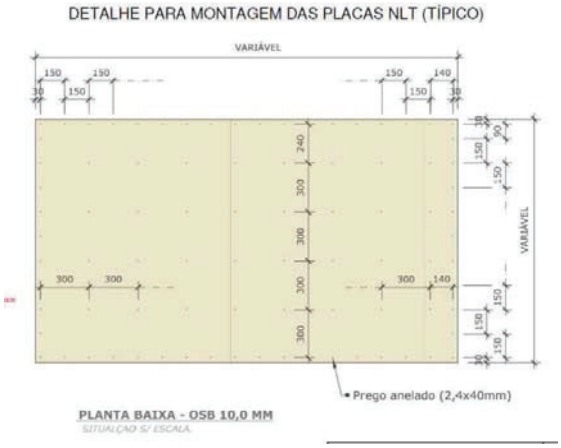

Figure 2: *test scheme NLT plate / OSB*

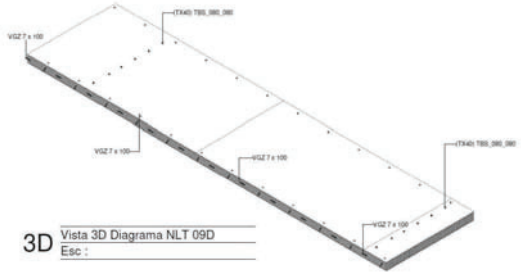

Figure 3: *test scheme NLT plate / OSB*

The NLT 1 board has 1 nail every 270 millimeters that alternates the height with respect to the section, as shown in Figure 1. The NLT 2 board has 2 nails every 270 millimeters, spaced 30 millimeters apart and 25 millimeters apart with in relation to the section limits.

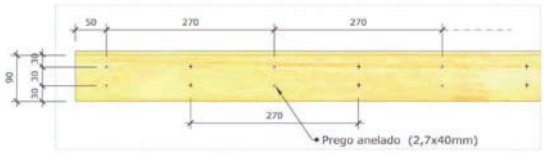

Figure 4: *test scheme Nail - NLT plate*

2 METHODS

The board tests were performed according to PEREIRA (2014) which is based on ASTM PRG 320 and whose scheme is illustrated in Figure 1.

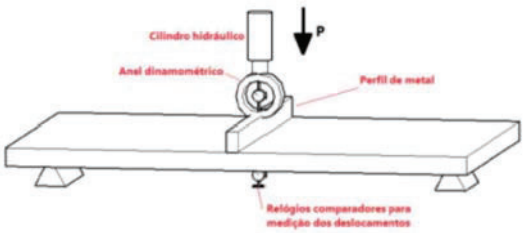

Figure 5: *test scheme*

This procedure was carried out by positioning the NLT plate, with the direction of the pine lamellae oriented towards the span, on two supports composed of metallic tubes positioned 100 mm from the edges of the plate. Then, a steel profile beam I was positioned on the central axis of the plate and the hydraulic cylinder was adjusted so that its center coincides with the center of the face of the NLT element. Finally, 3 strain gauges are positioned on the underside of the plate, along the axis of the metal beam. One of them is aligned with the axis of the hydraulic cylinder and the other two are equidistant in the middle of the distance between the center of the plate and its edge.

Figure 6: *NLT board assembly*

https://doi.org/10.52202/069179-0564

Figure 7: *Detail of the positioning of the strain gauges*

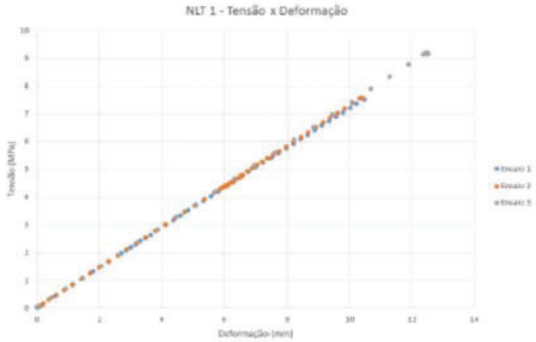
The procedure adopted was to apply the load gradually until the limit of l/300 was reached, with the value of the span being measured by the distance between the supports of the plate. Thus, the load was applied until the limit of 8 millimeters was reached. The load was then relieved and the procedure was repeated two more times, and in each process the applied force and the respective displacements were recorded by the software.

Finally, the load was increased until the NLT element ruptured, and the critical values were recorded. The figures below illustrate the rupture of both NLT plates, which was caused by traction on the lower fibers of the pine lamellae.

Figure 8: *NLT panel rupture details*

3 RESULTS

Based on the results obtained for certain forces and displacements, it was possible to generate 3 stress x strain curves for each plate. It can be observed that as the tests were performed up to a strain of 8 millimeters, there was no material flow in none of the 3 analyzes of each NLT plate, which corroborates the linear arrangement of the graphs presented, having elastic behavior in this interval.



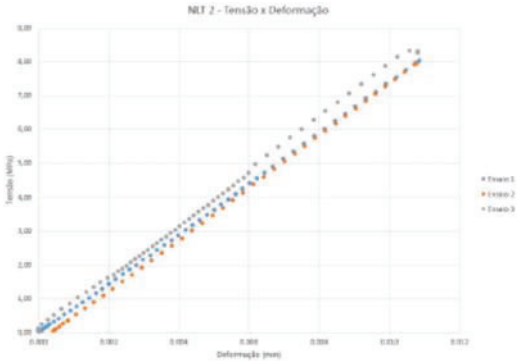


Figure 9: *Tension x Deformation curve of the NLT plate*

Next, the summary table of the performed assay is presented, containing the average of the MOE of the 3 assays performed for each NLT plate.

Table 1: *Margin settings*

NLT plate 1				
Test	Desity	Rupture	MOR (kfg)	MOR (kgf)
1	570,5	9327	8614	34
2			8725	
3			8824	
NLT plate 2				
Test	Desity	Rupture	MOR (kfg)	MOR (kgf)
1	580,1	9081	8839	33
2			9170	
3			9173	

The results obtained were imputed in the RFEM calculation program for the structural calculation of the architectural proposal. The project was designed by the architectural studio MK27.

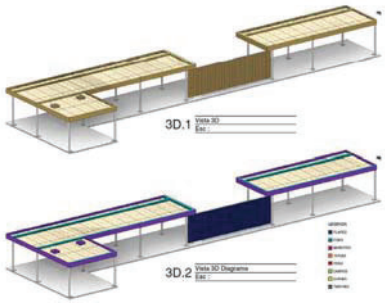

Figure 10: *architectural proposal*

https://doi.org/10.52202/069179-0564

Figure 11: *layout structure*

The big difference in using NLT in this project was that instead of the boards being placed on top of the beams, they were actually used hanging.

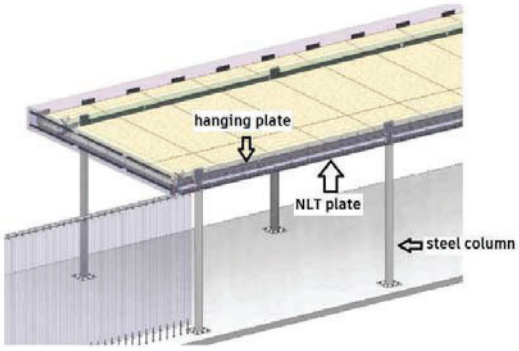

Figure 12: *structural detail*

https://doi.org/10.52202/069179-0564

4 CONCLUSIONS

The NLT product, despite being very old technology, still demonstrates very interesting physical and mechanical characteristics for today's projects and when well designed and used, its cost benefit and beauty stands out among the products used today in the Brazilian market.

World Conference on Timber Engineering Oslo 2023

A SURVEY OF THE DESIGN OF TIMBER-CONCRETE HYBRID BUILDINGS IN SWEDEN

Carl Larsson[1], Michael Dorn[2]

ABSTRACT: There is a growing interest in timber buildings in Sweden and increased availability of Glulam (GLT) and particularly Cross Laminated Timber (CLT) products. Timber buildings, though, often have difficulties in fulfilling the performance requirements of a building project. The use of concrete elements in addition to timber elements in the load-bearing structure is a widespread solution, introducing timber-concrete hybrid buildings. The study presents responses from interviews regarding ten different timber-concrete hybrid building projects in Sweden with a load-bearing structure above the foundation level in both timber and concrete. Four main types of timber-concrete hybrids were found: a CLT structure on top of a concrete structure, a post-beam system in GLT with CLT slabs and concrete walls, a post-beam system in GLT with concrete hollow core slabs, and a timber structure with some slabs in concrete. The results show that timber-concrete hybrid buildings are flexible and suitable for various construction types. The reasons for using concrete in timber construction were primarily to increase self-weight, obtain longer span lengths, and overcome shear wall capacity issues. There is still a lack of competence in the design of structural timber projects, and at most, five different structural designers were involved in the load-bearing design of a single building. This highlights issues regarding project management of the design process within timber-concrete hybrid buildings.

KEYWORDS: Timber-concrete hybrid, CLT building systems, Timber building systems, Structural management

1 INTRODUCTION

The use of timber in modern, large-scale building projects in Sweden is low compared to concrete. In recent years, though, there has been a growing interest from the construction industry, from architects and from developers to use timber as the primary material in the load-bearing structure of buildings [1]. It is well known that an increased share of timber products like sawn timber, glulam timber (GLT), and cross-laminated timber (CLT) in buildings is beneficial from an environmental perspective. For example, the load-bearing structure is identified to significantly impact the carbon footprint during the construction phase [2].

Timber-concrete hybrid buildings use both materials in the load-bearing system and are a possibility widely used to increase the use of timber overall. Plenty of timber-concrete hybrid structures are operating, including showcase examples like the 18-story Brock Commons in Vancouver, the 24-story HoHo Tower in Vienna, and the 10-story Banyan Warf in London. However, the research in this area is limited compared to other hybrid structures, where several topics have been studied regarding structural systems, connectors, and modeling.

This study aims to give real-life examples of how timber and concrete are combined in hybrid structures today in the Swedish construction industry without going into technical solutions or the performance of these buildings. In addition, the study focuses on the structural design phase, where many decisions are made, e.g., the requirements of the building, how the building will be built, and which structural materials will be used. The study is based on interviews with structural designers, contractors, and developers involved in these projects.

The following research questions are addressed:

1. How are timber and concrete combined in a typical Swedish project? What is the reason for this?
2. How do structural designers work in the late design phase of a timber-concrete hybrid project?

2 METHODS

The study applies a qualitative research methodology based on interviews with primarily structural designers involved in the late design phase in the construction process of building projects in Sweden. In several of the studied projects, complementary interviews were held with other people involved in the respective project, such as developers and contractors. The qualitative method was chosen because it allows the researcher to secure vivid and accurate accounts based on the interviewee's personal experience in building projects [3].

Ten different projects were identified as they were recently completed or under production in early 2020.

[1] Carl Larsson, Linnaeus University, Sweden carl.larsson@lnu.se
[2] Michael Dorn, Linnaeus University, Sweden michael.dorn@lnu.se

https://doi.org/10.52202/069179-0565

Interviews regarding these projects were performed, at least two for each project. In total, 17 people were interviewed, eleven structural designers, one developer, and five contractors. Several respondents have worked on more than one project; in these cases, interviews were held separately for each project. Of the structural designers, there were six timber element designers and five concrete element designers. The concrete element designers acted in some projects also as the main designer. Most of the interviews were held in Swedish, except with two of the timber element designers who were located outside Sweden.

The questionnaire contained nine questions and is presented in Table 1. The test interviews were analyzed to verify that the questionnaire gives responses that fulfill the overall research questions of this study.

Table 1: *Questionnaire of the interviews.*

	Question
1	What are the name and the background of the project?
2	What was the reason for mixing the use of concrete and timber?
3	How has the structural design been divided into different involved contractors or designers?
4	Which designer has been responsible for the collaboration of the structural designers?
5	Which designer was responsible for the total stability of the structure?
6	When did the project agree that the structure had enough stability and which analysis was to be performed?
7	Which project partner was responsible for the robustness criteria of the structure, and which method was used for these criteria?
8	Which structural data were shared between the different structural designers involved, and what software was used?
9	Lessons learned from your point of view in these types of projects?

2.1 Data analysis

Grounded Analysis [4] was performed as a data analysis method for the open-ended questions. It allows the data collection and analysis to proceed simultaneously, allowing the researcher to obtain a complete picture of the respondents' views on their building projects. The Grounded Analysis is commonly used in Management Research [5] and was performed using the suggested methodology by Easterby-Smith & Thorpe [6].

The answers' consistency was controlled by performing interviews with at least two stakeholders for each project. This is also the reason why only ten building projects were included in the final analysis, out of 16 suitable projects identified initially.

3 RESULTS

3.1 Projects

Two Swedish mid-size cities have focused on construction with timber, where political processes were created to foster new developments; Växjö in the Southern and Skellefteå in the Northern part of Sweden, respectively. A relatively large number of the studied project are therefore located in these two towns, see Figure 1. The purpose of the buildings was categorized as schools, residential buildings, offices, and others.

From a structural point of view, four different system types of the timber-concrete hybrid were found in the ten projects identified, shown in Figure 2. The categories and building types do not necessarily coincide.

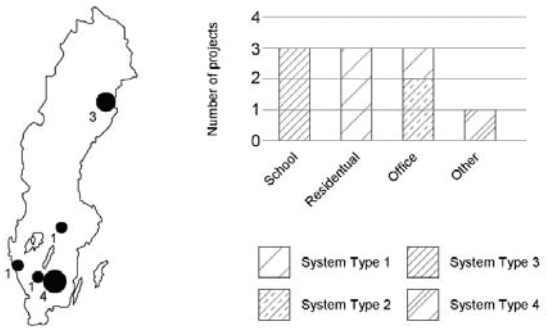

Figure 1: *Project locations and purposes of the buildings in the studied projects*

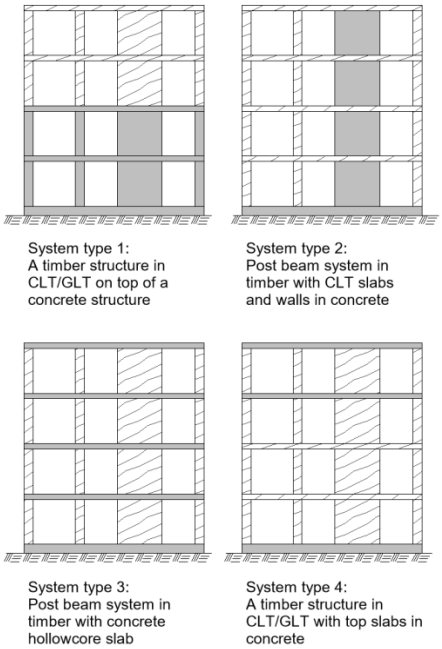

Figure 2: *System types of the load-bearing structure*

https://doi.org/10.52202/069179-0565

3.2 Reasons for choosing a timber-concrete hybrid

The reasons for using timber structural elements in a project are shown in Figure 3. The respondents mentioned the following reasons:

- Architectural competition: The use of timber resulted from an architect competition where timber construction was part of the winning entry.
- Property developer's demands: The property developer required a timber structure.
- Municipality demands: The municipality demanded a timber structure, e.g., enforced in a land allocation process.

The following reasons for using concrete elements over timber elements in the projects were mentioned by the respondents:

- Economy: Timber solutions were too expensive; replacing some structural elements with concrete elements was more economical.
- Experience: Concrete was used on critical structural elements due to a lack of experience and/or knowledge of designing with timber.
- Span width: The use of timber was not feasible due to limited span widths with timber structures. These limitations include dynamics and limited height issues.
- Shear wall capacity: Concrete walls were used due to the increased shear capacity of the wall but also, i.e., for connectors.
- Self-weight: Concrete elements were used to increase self-weight to handle the uplift forces of the structure.

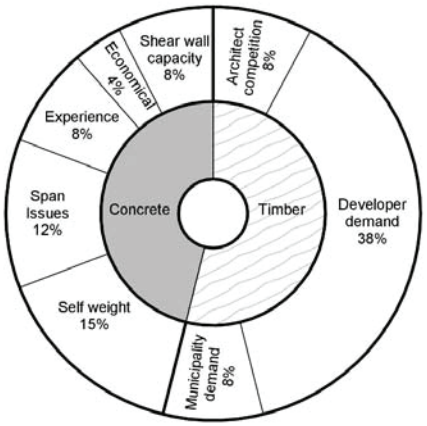

Figure 3: *Reasons for a specific load-bearing structure. One mention by a respondent equals 4% of the figure*

3.3 Project management in structural design

For this study, a *designer* is defined as the company represented as a structural designer within the building project, not the number of individuals working as structural designers.

The total number of structural designers in the projects differs between 2 to 5, with a mean of 3.3 structural designers involved. As seen in Figure 4, no correlation is seen between the number of designers and the contract worth. All respondents highlight that each designer is responsible for their field of expertise and the respective structural elements. Typically, the following structural designers were involved:

- Main designer
- Timber element designer
- Concrete element designer
- Additional designers (e.g., truss, roof, or steel constructions)

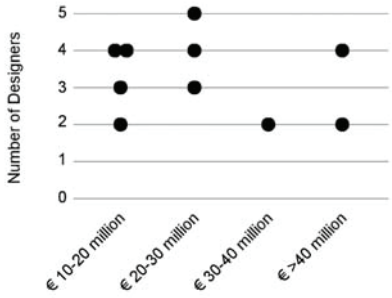

Figure 4: *Contract worth and the number of designers within the projects*

A project's main designer was responsible for collaboration between the partners and the overall coarse calculation checks of other designers' work. In nine of the projects, a specific designer was assigned as the main designer. In one of the projects, there was a contradictive response from the respondents who had this role.

In the nine projects with a designated main designer, the main designer was also responsible for the foundation design. In addition, there is a wide range of tasks related to the role, spanning from the design of precast concrete and steel trusses to details of the building envelope. For a load takedown and stability analysis of the complete building, the main designer had a unified model for calculation in one project. As for the other nine projects, the timber element designer was responsible for these calculations.

Figure 5 shows the type and complexity of calculations performed, mainly 3d Finite Element (FE) analysis and 2-dimensional calculations. The number of included structural elements in the calculational models also varies. The results show that the designers made two different main assumptions for calculations when not including all elements: the first is that the designer simplifies these elements to fictitious beam or shell elements with properties considered suitable, e.g., rigid elements; the second is to view such elements as (fixed) boundary conditions in the calculational model.

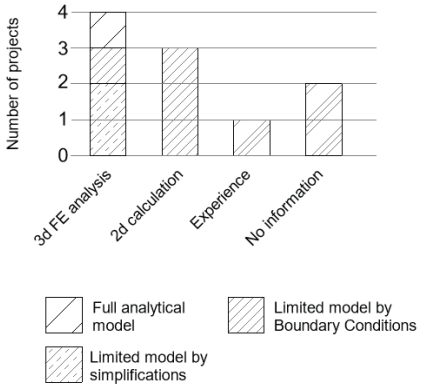

Figure 5: *Type of global calculations performed on timber-concrete hybrid structures*

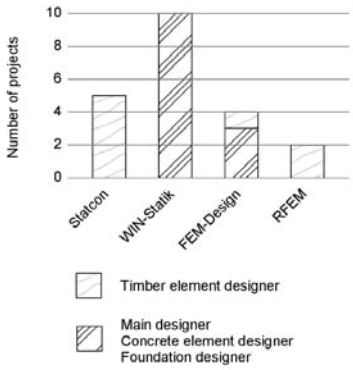

Figure 6: *Type of calculation software used by the designers*

In addition, the findings from the interviews conclude that the criteria of the requirements for horizontal stability differ. Of the ten investigated projects, answers were given for only six. The type of stability criteria within these projects was:

- Maximum load-bearing capacity for a defined truss member.
- Horizontal displacement criteria for the overall building height or story height.
- Comfort criteria such as accelerations due to wind load.
- "Engineering knowledge" (no calculation, stability was considered obvious).

According to all respondents, information on characteristic or design loads, reaction forces, and section forces are exchanged between the designers in the design process. In addition, complementary information in terms of sketches, drawings, or documents was exchanged, explaining these loads. In none of the studied projects, the designers shared their entire structural model for calculation with the other designers. However, three respondents mention that the documentation of calculations is available when their designing task is complete.

All respondents use more than one type of software. The software used in these projects is listed in Figure 6. In general, the timber element designers used the software RFEM by Dlubal [7] for 2D and 3D FE-analysis and design and Statcon by Elecosoft [8] for 2-dimensional element design. The foundation and concrete designers use the WIN-Statik package [9] for 2-dimensional design and FEM-Design [10] for 3-dimensional FE-analysis and design, both by StruSoft.

4 DISCUSSION

4.1 Projects

The study shows four major types of timber-concrete hybrid structures among the studied projects. Previous research primarily discusses timber-concrete hybrids using a post-beam system in GLT with CLT slabs with concrete walls [11] [12] (System type 2 in this study) or systems used for high-rise buildings [13] (System type 4 in this study. This study shows two alternative timber-concrete hybrids, a CLT structure on top of a concrete structure and a post-beam system in GLT with concrete hollow core slabs.

The result shows that it is manageable to replace traditional structural elements with timber structural elements in various ways and still fulfill all requirements of a modern building in Sweden. The findings also show that the use of the building has a significant impact on the structural elements that are in concrete or timber, as seen in Figure 1.

The selection of the projects does not reflect the overall construction industry in Sweden, as the project locations and the number of projects do not match the overall building permits in Sweden [14]. Contact to the project partners was primarily done within the SBUF network, the Development Fund of the Swedish Construction Industry.

However, a voluntary database for timber projects in Sweden, Woodprint Sweden, shows that a majority of these timber projects are located in the cities of Växjö and Skellefteå [15]. This confirms that the selection of projects in this study is representative of seven of the studied projects located in these cities. The municipalities of both these cities have strategies for increasing the number of timber buildings [16] [17], which explains the high number of projects within these cities. It also confirms that the number of timber projects is closely related to political decisions and public actions [18].

https://doi.org/10.52202/069179-0565

4.2 Reasons for a load-bearing structure in both timber and concrete

The main reason for the use of timber in the main structure was the property developer's demand. It is added that in seven projects, municipalities or other public organizations acted as property developers. As confirmed under the project discussion, the rising number of timber projects is due to political decisions and public action. The respondents in this study make the same conclusions, stating that property developers and municipalities are highly represented as key figures for decision-making in favor of a timber structure. Municipalities are both landowners and/or developers in several projects, implying that Sweden's public and political role in timber building is crucial.

Reasons for choosing concrete instead of timber for some elements (apart from the foundation) are mainly due to economic or structural issues. The respondents do not point to other known problems with timber construction, such as acoustic and fire demands. This was also seen in another study where the Swedish architects' perception of using timber as the construction material was investigated [19]. The authors concluded that acoustic and fire demands came in fourth place after issues regarding uncertainties and lack of control over the decision to use timber as the structural material. Altogether, this implies that previously known problems with timber materials in load-bearing constructions are manageable within a modern Swedish building project.

In only one project, the respondents answered that lack of experience in timber design was a reason for choosing concrete. However, one of the interviewed contractors responded that it was difficult to find timber designers in Sweden, and two of the timber designers in this study were located outside Sweden. On the one hand, this suggests that there are structural designers available who are confident in designing CLT components despite the lack of standard regulations such as Eurocodes and the National Annexes. Nevertheless, there still is a lack of experience and knowledge in timber design by Swedish designers, but also by architects and developers who need broader knowledge in the early stage of project development [19].

With most respondents working as structural engineers, developers, and contractors, key personnel in the decision progress, such as architects, are underrepresented in this study. Conclusions, therefore, might not cover the wide range of variables in the decision-making process in a modern construction project due to the limited number of respondents.

4.3 Project management in structural design

As the interviews have shown, designers usually work in well-defined fields within their area of expertise. In particular, the results clearly show that the project's main designer is not the designer responsible for the load takedown and stability analysis of the entire building. The timber element designer mainly performed these calculations.

Although a high number of structural engineers characterizes the investigated projects, no correlation was found between the number of involved designers and the different types of construction, nor the worth of the construction contract for the projects. However, the high number of structural designers is not unique to timber-concrete hybrid buildings. In Sweden, the topic of the number of designers included in construction projects has been discussed at least since the progressive collapse of a three-story building in Ystad in 2012. In a report by The Swedish Accident Investigation Authority [20], the high number of involved structural designers and issues regarding this resulted in revised construction rules. In 2015 [21] and 2018 [22], additional requirements were added, demanding adequate collaboration between different structural designers.

Still, it is noteworthy that in one of the ten projects studied, different answers were given regarding who was the main designer, showing that the different roles of structural designers still can be somewhat unclear and understood differently between various stakeholders within a project. Another topic is the variation of the types of analysis performed for the design calculations in these projects. The results conclude other findings regarding practicing designers where both Fröderberg [23] and Klasson [24] conclude that there is a large variety of design approaches and results.

As for the investigated timber-concrete hybrid projects, several different calculational approaches and design criteria for horizontal stability were used. Combining these results with the findings in this study regarding additional designers in timber-concrete hybrids highlights topics of risk management and project management of the involved designers in these projects.

Results from the interviews are unambiguous in that it is the specifying of load actions on and between separate structural elements that are shared among the designers. No shared models are used between the different designers. It is also clear that the structural designers did not want other designers' structural components within their own structural model for calculation if it was not considered absolutely necessary. Therefore, other designers' elements are either neglected or simplified with stiff elements or by boundary conditions.

Altogether, this leads to a well-working workflow with clear boundaries between the designers. It is also relatively easy to follow which designers are responsible for designing each element. However, one may argue that there is a risk with a fractioned structural model for calculations. The total systems' stiffness and compliance of, e.g., connections, is not considered in such models. Consequently, this will have an effect on the load takedown calculations and the design of the building, and, ultimately, the safety beta index for the structure as a whole.

As computer-aided structural calculations play a vital role for practicing structural engineers, the responses are of

great interest, especially due to the increased number of designers in timber-concrete hybrids. It is noted that the different types of calculation software used by the respondents cannot automatically share their files and models in between.
Other widely used software within the building industry, such as software drawings and modeling, geometric design, or BIM software, have a better basis for collaboration. For example, these fields have several common standards, such as Industry Foundation Classes (IFC) [25], that allow for an automated exchange between designers. This type of standard is missing for structural design software.
The practice of exchanging loads and sectional forces is obviously the most practical way of working. It might explain why the respondents in this study seldom model the complete building for analysis, only the parts that they are responsible for.

5 CONCLUSIONS

This interview study provides a brief and general overview of the state of timber-concrete hybrid buildings in Sweden. While clearly not exhaustive, some overall trends are seen, and the following conclusions are drawn:

- More structural designers are involved in timber-concrete hybrid projects than in regular building projects.
- Collaborative design and project management are identified as key aspects of a successful timber-concrete hybrid project.
- The responsibility for performing statical calculations differs, and it is seldom that the main designer has a statical model for the entire building.

The findings conclude that in the structural design phase of the project, topics regarding collaboration are of great importance. This is prior to topics such as connectors, acoustic, and fire, topics that are usually common in timber buildings. These findings are of great importance for research as they highlight the importance of performing studies on full-scale structures and not only on single components, especially since several regulations are performance-based for the building and not material-specific for a single structural member.
The increased number of involved designers might affect the structural safety of a building. The large variety of design approaches gives different design loads for the single structural element. Fröderberg [23] concluded that the different design approaches done by practicing designers lowered the level of safety of the building significantly. As the safety factors in the current Eurocode framework are calibrated to a specific level of safety in buildings [26], the design approaches and assumptions made by the different designers involved in timber-concrete hybrid projects are of utter importance. Once again, this highlights the collaborative design topics discussed in this study.
In addition, the presented work highlights the importance of knowledge in timber engineering for designers in such projects, even if the main work within a project is within, e.g., prefab concrete elements. The knowledge of the needs and restrictions of other materials' elements must be considered.
In the long run, unified calculation and design models need to be introduced because these models should allow for better results since the building's overall behavior is reflected.
It is in the industry's best interest to quickly establish a well-functioning ecosystem for timber construction. The concrete industry, both in the prefab and the in-situ versions, can be a role model with its standards and how far it has come.

ACKNOWLEDGEMENT

The authors would like to thank all interview partners for their participation. The research is funded by the Swedish construction industry's organization for research and development (SBUF, project number 13721 "Building systems in CLT and other materials") and Skanska Sverige AB. The research work is part of the project "Improving the competitive advantage of CLT-based building systems through engineering design and reduced carbon footprint" with support from the Knowledge Foundation (KKS, project number 20190026).

World Conference on Timber Engineering Oslo 2023

CASE STUDY: A 10-STOREY TIMBER BRACED FRAME AND CLT STRUCTURE IN VANCOUVER, BC

Carla Dickof[1], Robert Jackson[2], Jenna Kim[3], Ashkan Hashemi[4]

ABSTRACT: This paper outlines the structural design approach used for the Keith Drive Office Building project, a 10-storey mass timber building in Vancouver, British Columbia, Canada. The office building includes exposed timber throughout most of the building, including timber brace frames along the perimeter, and cross laminated timber (CLT) shearwalls at the interior near the elevator and stair cores for seismic and wind forces. The project deployed resilient slip friction joint (RSFJ) dampers as energy dissipative devices on both the timber braced frames and CLT shearwalls. Non-linear time history analysis (NLTHA) was completed to evaluate the performance of the building. Detailed modelling and calibration of 2D shell elements was undertaken to ensure a reasonable understanding of the impact of the semi-rigid CLT diaphragm.

KEYWORDS: Mass Timber, Tall Timber, Tectonus, non-linear time history analysis, CLT shear wall, timber brace

1 INTRODUCTION

The Keith Drive Office Building is a 10-storey mass timber structure and construction began in the fall of 2022 in Vancouver, British Columbia, Canada. The 43-meter-tall structure is comprised of nine floors of mass timber construction over a concrete podium and four levels of below-grade concrete parking. The timber gravity structure consists of 9-ply cross laminated timber floor panels supported on dropped perimeter glulam beams and flush interior steel beams. The Seismic Force Resisting System (SRFS) consists of perimeter timber braced frames and interior balloon framed CLT shearwalls. See Figure 1 and 2 for building renderings.

Figure 1: *Keith Drive Rendering*

2 DESIGN

The project intent was to create a mass timber building. The project was awarded significant external funding through the Green Construction in Wood Program from NRCAN allowing it to push the boundaries of timber engineering and design in Canada, the project design quickly headed in a direction of a 'pure' mass timber superstructure complete with a timber lateral system. . Exposing the timber to view wherever possible was a key goal for the architect and owner, providing a unique experience for occupants.

The extent of exposed timber in both the gravity and lateral system exceed code prescribed limitations, requiring the project team to work closely with the city to address all concerns. Alternative solutions were provided to address the various issues; the approach for the structural alternate solution included peer review and non-linear time history analysis.

The base of the structural system consists of four levels of below grade concrete parkade and one level of concrete podium to accommodate the sloped site. The timber superstructure springs from the second floor concrete transfer slab as shown in Figure 2. From Level 2 to Level 10 CLT floors are supported on dropped perimeter glulam beams and interior flush steel beams. Interior perimeter timber braced frames and interior balloon framed CLT shearwalls provide the SFRS.

2.1 GRAVITY SYSTEM

The gravity system is comprised of 9-ply, 315mm thick CLT panel with a non-structural concrete topping spanning between glulam perimeter beams and flush steel interior beams. The interior steel beams are comprised of an HSS with an extended bottom plate welded to the underside, acting as a seat for the CLT; this flush framing system allows for unobstructed mechanical distribution and reduces overall building height. Both steel and glulam beams are supported by glulam columns carried down to the concrete podium at Level 2.

The building requires a 2-hour fire rating requirement (FRR) for all structural gravity members. The timber gravity framing achieved its FRR via char design as per the O86-19 Annex B design method [1]. The steel beam achieves the required FRR by way of drywall encapsulation at the underside, matching the aesthetic of other service chases adjacent.

The central area of the building accomodates a dropped ceiling to allow the mechanical, electrical and plumbing (MEP) to be routed as required, with the flush steel supports avoiding any conflicts. Beyond this central zone, the CLT soffit is exposed throughout, with all MEP routing passing within planned spline zones in the CLT floor as shown in Figure 3. 3-ply, 105 mm thick CLT panels act as splines connecting the 9-ply panels.

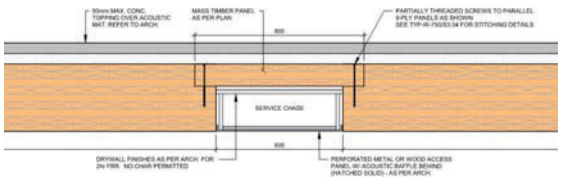

Figure 3: *3-ply CLT spline for MEP routing*

The 9-ply, 315mm panels are fully exposed with double outer layers at the top and bottom to accomdoate a 2-hour FRR over the 8.2m span, while also increasing panel stiffness for deflection and vibration response. Similarly, the supporting glulam columns and perimiter beams are all designed to achieve a 2-hour FRR through char without encapsulation. The 3-ply, 105mm CLT splines are fire protected with type X gypsum board. The flush steel beams are similarly encapsulated to protect the steel withough intumsecent paint or fire spray.

The column-to-column connection, shown in Figure 4, is configured to provide direct load transfer between the vertical elements rather than transfering forces through the beams or the floor plans. The beam-to-column connections at the perimeter make use of Knapp megant form fitted connectors at all locations, embeded to be protected from char, and the interior steel beams bear directly on the column-to-column end connecitons. Glulam columns will arrive on-site with a steel connecting plate and Hollow Square Sections (HSS) stubs fastened to the end-grain with glued-in rods. The glulam column above will have a similar connection with smaller diameter HSS stubs. Stubs are connected using glued in threaded rods bolted to the stub, which allow for simple installation and a tension connection in the extreme event where a column below is eliminated, according to progressive collapse principles. CLT floor panels will be notched around the HSS sections and bear directly on the column below.

2.2 LATERAL SYSTEM

The lateral system consists of perimeter timber braced frames and interior CLT shear walls. The perimeter timber braced frames mimic the architectural expression of the honeycomb on the building's façade. The interior CLT shearwalls are placed near elevator or stair cores to accommodate the large open floor plan desired by the architect and owner to provide flexibility around the egress stair shafts for more interior glazing. Refer to figure 6. To achieve energy dissipation without damaging the structural members or connections, Resilient Slip Friction Joints (RSFJ's) are provided at each brace (one end), and at the ends of the CLT shearwalls, as hold-downs., allowing energy dissipation without damage to the structural system as shown in Figures 7 and 8.

Both timber braced frames and CLT shearwall SFRSs are codified systems in the most recent version of National Building Code of Canada (NBCC 2020), with defined ductility and overstrength values and height limits [2]; however, the prescribed height limits are significantly less than the actual building and the ductility and overstrength values associated with the codified systems are not relevant for a system with RSFJ's.

Therefore, to support the SFRS design, an NLTHA was completed, alongside an onerous third-party peer review in accordance with NBCC Structural Commentary J [2]. Iterative NLTHA was used to optimize the RSFJ design for the 2% in 50-year design earthquake. NLTHA was also implemented at 130%, and 150% of the design earthquake to review the collapse risk for an earthquake exceeding the design earthquake. Linear dynamic analysis was performed at service level earthquake (40% in 50-year) to ensure the RSFJs remain in the initial linear portion of the hysteresis for low level earthquakes.

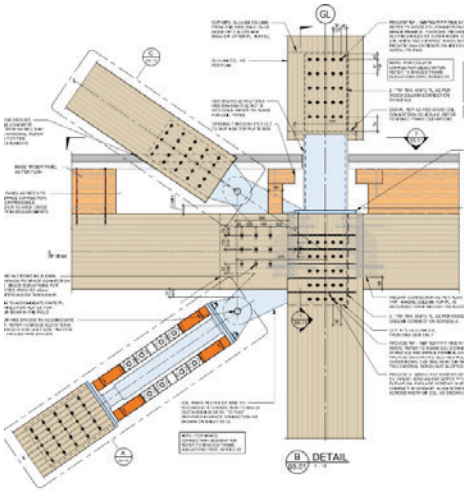

Figure 7: *Timber Braced Frame Connections*

2.3 NLTHA APPROACH

Fifteen ground motion sets, scaled to the design earthquake level (2% in 50-year) were used with each set including two horizontal and one vertical acceleration records. The two horizontal records were implimented in

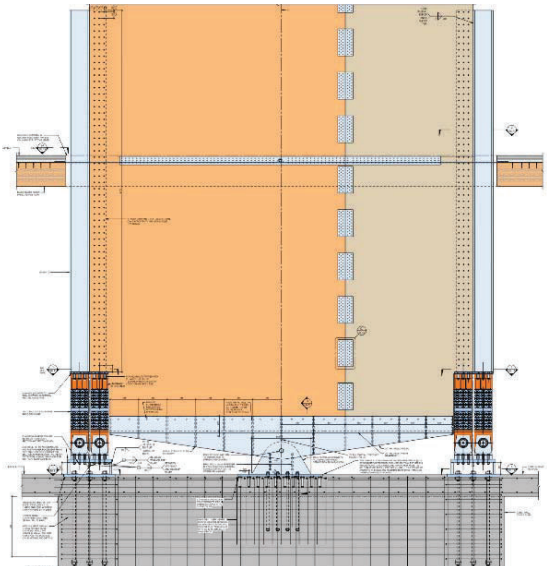

Figure 8: *CLT Shearwall Base Connection*

https://doi.org/10.52202/069179-0566

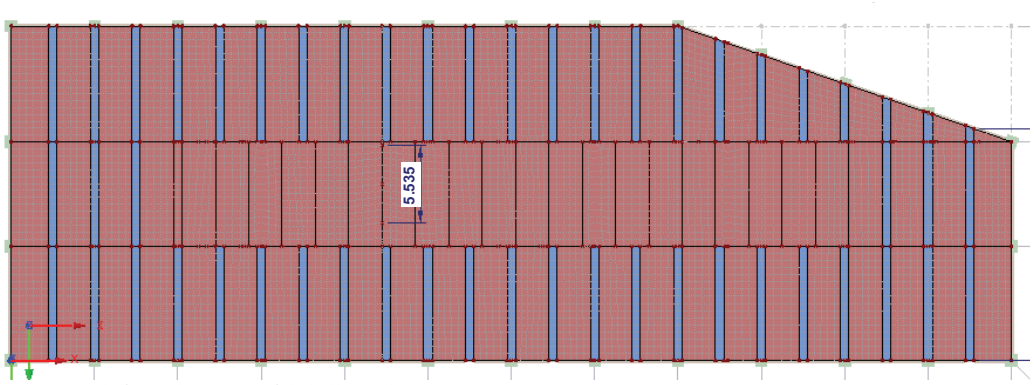

Figure 9: *Detailed Diaphragm Model shell type layout*

two orientations, rotated by 90 degrees, resulting in total of thirty time history load cases. The average responses for the top five records are considered for the acceptance criteria. The maximum response for the top record was also reviewed; while some devices exceeded the ultimate force (F_{ult}) and ultimate displacement (Δ_{ult}) limits, they were within the secondary fuse response, not exceeding the stop force (1.25 F_{ult}) and stop displacement (1.5 Δ_{ult}) limits.

Additional NLTHA was conducted using ground motions scaled to 130% and 150% of the design earthquake level to assess the structure's stability at higher hazard levels. For the 130% of the design earthquake level ground motions, the force and deformation demand of the RSFJ devices remained primarily below the stop force (1.25 F_{ult}) and stop displacement (1.5 Δ_{ult}) for the average of the top five responses. For the 150% of the design earthquake level ground motions, the force demand of the RSFJ devices remained below the stop displacement (1.5 Δ_{ult}) but the force demands were 10% ~ 30% above the stop force (1.25 F_{ult}) for the average of the top five responses. Force demand-to-capacity ratios remained consistent throughout all RSFJ devices in braced frames, suggesting the structure is not likely to develop a soft story failure mechanism or force concentration.

The braced frames were modelled with glulam beam, glulam brace, glulam column and non-linear friction spring damper type links representing RSFJ device. These non-linear springs were active in axial direction and fixed in all other degrees of freedom.

The CLT shearwalls were modelled as 3 panels of 245 mm thick shell elements connected using rigid links representing spline plates. Non-linear friction spring damper type links were modelled at each end of the CLT shearwall bottom on Level 2 representing hold-downs. These non-linear springs were active in axial direction and fixed in all other degrees of freedom. At the centre of the bottom of the CLT shearwall on Level 2, a stiff frame element was modelled representing the shear connection to the concrete structure below. This frame element was released in rotation about the axis perpendicular to the face of the shearwall to represent the true-pin condition. This connection allows the shearwall to rotate about its center and transfer shear forces to concrete wall below.

The CLT shearwall shell element's stiffness properties were calibrated against CLT shearwall modelled in RFEM RF-Laminate.

2.4 DIAPHRGAM CONSIDERATIONS

CLT diaphragms are complex and provide significantly stiffer behaviour than that associated with a flexible diaphragm given the large format stiff billets used throughout. Despite the relatively high stiffness of the panels, the stiffness of the diaphragm is much lower than that of the individual panels due to the flexible nailed or screwed connections between panels. These discrete connection locations between panels result semi-rigid behaviour. Evaluating the rigidity of CLT diaphragms is directly related to the panel sizes, the number of joints, and the stiffness of the joints between panels, as well as the chord and drag connection stiffnesses.

Understanding and representing the diaphragm behaviour in the NLTHA model was a critical component of ensuring a realistic building response in the model. The shared behaviour of the CLT splines, connections to the steel and timber beams and drag connection into the lateral elements is critical due to the comparatively high stiffness of the CLT panels and low stiffness of the connections between elements. Detailed diaphragm models can be developed to include all the elements, but that represent a large computation burden. If implemented in a larger NLTHA they would significantly slow the model processing. To resolve this problem a detailed diaphragm model was developed for a for a single floor to study the diaphragm behaviour and calibrate a simple shell element, which is adjusted to match the load distribution and deformation coincident with the detailed model, via membrane stiffness modifiers. That simple shell element was then implemented in the larger NLTHA model to simplify analysis.

The detailed diaphragm model is composed of a series of shell elements representing each individual panel with properties associated with the panel types described in the structural drawings as shown in figure 9. Drag and chord elements are also incorporated into the detailed diaphragm model. The joints between the panels, drags, and chord elements are represented with linear line springs with stiffnesses representative of the connection

type. Both 3ply 105V panels, and 9ply 315V XL panels with layups based on APA product approvals are implemented in the model. The layout of the individual shell elements and the panel implementation is shown in the light blue panels represent 3 ply CLT panels, and the red panels represent 9 ply CLT panels. The layup for each panel type has been defined using RF-Laminate
The linear springs are designed based on the stiffness properties of the screwed connection between CLT panels and steel drags to CLT panels based on screwed connection stiffness as provided Eurocode 5 (EN 1995-1-1:2004+A1) as described in clause 7.

$$\text{Wood-wood Stiffness} = \rho_m^{1.5} d/23$$

$$\text{steel-wood Stiffness} = 2(\rho_m^{1.5} d/23)$$

The stiffness is generally applied in both the x and y directions are shown in Figure 10. These correspond to the axes in the plane of the CLT floor panel at the spline, drag, and chord connections.

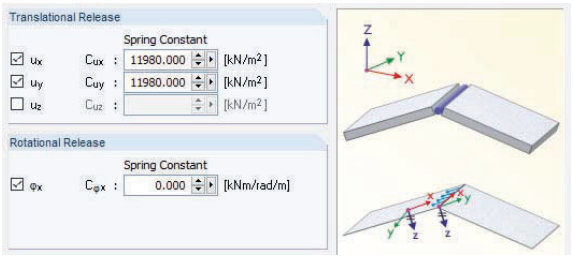

Figure 10: *line spring axes*

The simplified diaphragm model is comprised of a single shell element tuned to represent the combined properties of the complex model as discussed above. The shell element is defined with orthotropic properties modified as needed to allow the load distribution to match that found from the detailed shell element. Additionally, the bending properties in the weak direction of the individual panels (X-direction in the drawings) has been reduced to near zero. This is a conservative simplification to ensure that the shell element does not resist significant weak axis moment, as minimal moment would be transferred across CLT- CLT splines joints. Property modifiers for weak axis bending and torsion for the shell are thus reduced to near zero.
An iterative process was implemented to bring the force distribution for each lateral element to within 5% of the detailed diaphragm model for a unit applied area load. To verify the behaviour, the reactions of each LFRS elements were compared for both the complex and the simplified shell diaphragm model. For all cases the variation in load distribution was within 5% or less. A summary of the variation in LFRS shear is provided in Table 1.

Table 1: *Variation in reaction SFRSs*

	LFRS Location	Variance
Y-dir.	Brace @ GL 2	4.80%
	Brace @ GL 14	3.80%
	Wall @ GL 5	2.00%
	Wall @ GL 6.5	2.05%
	Wall @ GL 9	2.50%
	Wall @ 10.5	0.50%
X-dir.	Braces @ GL D	0.2-0.9%
	Braces @ GL A	0.2-1.0%
	Braces @ GL 15	1.5-2.3%

2.5 BEAM-TO-COLUMN CONNECTIONS

The glulam beam-to-column connections required a 2-hour FRR. To achieve this with exposed members, Knapp Megant form fitting connectors are specified with sufficient timber encapsulation to provide the necessary FRR. Inter-storey drift tolerance of these connections was investigated with testing was undertaken to show the inter-storey drift tolerance and established rotation stiffness and strength of the joint.
Perimeter glulam beams connected using Knapp Megant concealed hangers were the connection of primary study, as the direct bearing connection of the flush steel beams at the columns should not pose a problem. The drift capacity of these hangers was not explicitly available from the supplier or fabricator but it is critical to the behaviour of the system. To better understand the behaviour of the hangers, testing was completed to determine the rotational capacity of the hanger under the design loads of the system and localized drift studies and sensitivity studies were completed to assess the behaviour of the frames [5].

2.6 THE RESILIENT SLIP FRICTION JOINT DEVICES

The Resilient Slip Friction Joint (RSFJ) is a friction device that dissipates the seismic energy through friction while providing re-centring force. Friction dissipation occurs via sliding movement of clamped plates. An RSFJ device consists of 2 outer plates and 2 centre plates with elongated holes, which are grooved and clamped together with high strength bolts and disc springs (refer to Figure 13).

https://doi.org/10.52202/069179-0566

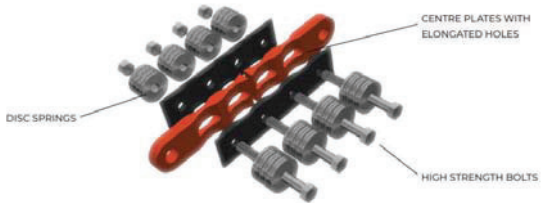

Figure 11: *The RSFJ components*

When the applied force overcomes the frictional resistance between the sloped bearing surfaces, the centre slotted plates start to slide, and energy is dissipated through friction during cycles of sliding. During unloading, the reversing force induced by the elastically compacted disc springs is larger than the friction force acting between the facing surfaces, providing self-centring characteristics

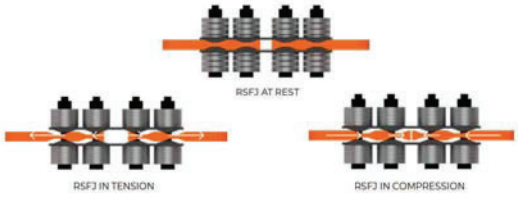

Figure 12: *RSFJ cyclic loading behaviour*

The hysteretic shape of the response of this type of RSFJ device is a flag shape common for friction based dampers. Each point in the hysteresis is a uniquely defined parameters (F_{slip}, F_{ult} , $F_{restoring}$, $F_{residual}$ and Δ_{ult}) as shown in Figure 15. The number of tapered friction planes and associated bolts/spring washers is flexible, allowing for a 'tunable' connection in both force and displacement.

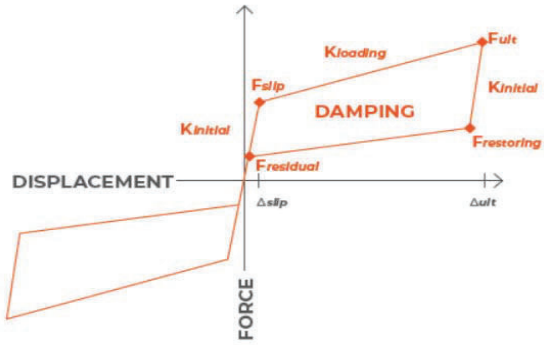

Figure 13: *Typical RSFJ Hysteresis*

The flag shape of the hysteresis can be tuned as needed to meet the design requirements to achieve the desired load-slip response up the F_{slip}, and F_{ult}. This is achieved by changing variables like the number or angled of the ridges in the plate, and/or the number of bolts and disc springs at each bolt. The behaviour and performance of the RSFJ has been extensively evaluated via joint component tests and large-scale experiments. With testing showing that the performance of the RSFJ is stable and that the theoretically predicted hysteretic behaviour (see Fig. 3(a)) matches well with test results [3]. This technology has been studied and tested for different configurations and applications. Experimentally tested full-scale rocking Cross Laminated Timber (CLT) and Laminated Veneer Lumber (LVL) walls with RSFJ hold-own connections. The mass timber lateral systems showed repeatable and damage free performance without any strength or stiffness degradation. The damage observed in the timber elements or connections was insignificant and negligible given that all non-fuse members were capacity-protected [3] [4]

The RSFJs also have 25% additional capacity beyond the F_{ult} provided in resulting from bolt bending in the RSFJ bolts. This additional capacity prevents failure after the ultimate strength is reached but will no longer represent a self-centering system without damage.

The RSFJs strength and deformation capacities were chosen through multiple iterations of Non-Linear Time History Analysis. the final hysteretic flag shapes for each device are shown in Figures 14 for the braces. The hold-downs are consistent across all 4 walls as shown in Figure 15.

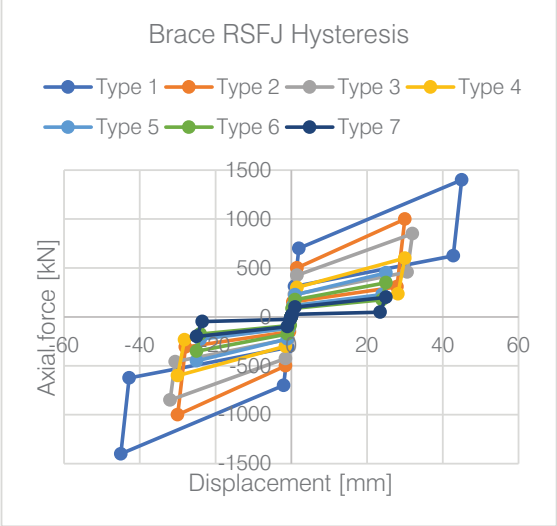

Figure 14: *Hystersis for brace RSFJs at various plan and storey locationas*

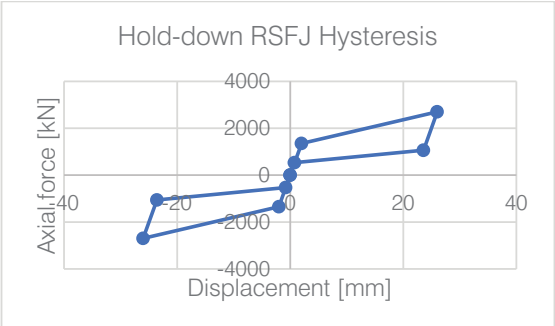

Figure 15: Hysteresis for CLT wall RSFJ hold-downs

Each RSFJ is tested (Figure 16) to ensure that it achieves the specified hysteretic forms as shown in figure 14 and

15. This testing ensures that the ultimate and slip strengths and deformations match the specified values and also is critical in minimizing the overstrength required for capacity protected elements as there is little variability prior to the yield in the bolts.

Figure 16: *Testing of RSFJ for brace at upper level of Keith Drive project*

To achieve the varied ultimate strengths and hysteretic forms shown the RSFJs are tuned with a varying number of spring discs and angle of the saw-tooth plates as previously described. At the CLT walls, the system is stable without the presence of the RSFJ due to the base connection and the connections to the diaphragms at each level, allowing the RSFJs to fastened directly to the CLT panels without additional components for stability as shown in Figure 8. At the braces, the RSFJs interrupt the length of the brace; to avoid issues with instability in the brace member under compression, two RSFJ devices are paired with central elongating tubes called Anti-Buckling Tubes (ABTs) to address this issue, without compromising the hysteretic behaviour (Figure 16).

Figure 17: *Brace RSFJ for upper-level braces at the Keith Drive Office Building*

These assemblies are then bolted to highly coordinated end plates that are either connected in to braces frame nodes at the beam to column connections, or into the ends of timber braces as shown in Figure 18.

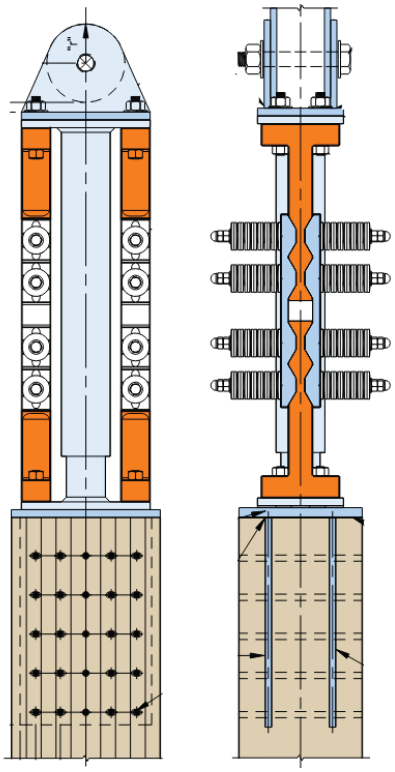

Figure 18: Brace connection of RSFJ and ABTs

2.7 CAPACITY DESIGN

Capacity design principles are applied based on the overstrength of the RSFJ devices, overstrength of the RSFJs is applied to the ultimate strength (F_{ult}) of the RSFJs within the SFRS element in the system. This direct overstrength is applied to: Timber Brace members and their connections to both the RSFJ and the frame, beam members and their connections in braces based, CLT shearwall panels, CLT shearwall base-shear connections, RSFJ hold-down connections the Shearwall, and all other connections between CLT panels in the shearwall. A the CLT shearwalls, because the RSFJs were able to be tuned within a few percent of the ultimate RSFJ strength, the overstrength factor could be applied directly to the NLTHA results.

The glulam column and glulam column-to-column connection design loads have been determined based on the maximum of the probable capacity of the RSFJ devices and the NLTHA results increased by the RSFJ overstrength. As the likelihood of each device within a brace frame simultaneously reaching its probable capacity is low, a Square Root Sum of Square (SRSS) approach is applied to all the columns and column-to-column connections in the brace frames (i.e.. components subject

https://doi.org/10.52202/069179-0566

to determine the tension/compression design forces in the brace frame columns. The column design loads are determined by combining the SSRS overturning earthquake with appropriate dead, live, and snow loads. The diaphragm panels and connections are also capacity protected. The design loads for the diaphragms are based on the capacity of the braced frames and CLT shearwalls, at that level, such that the 'fuse' remains the RSFJ, rather than the diaphragm fasteners themselves.

3 CONCLUSIONS

The innovative timber braced frame and tall CLT shearwall system proposed for this project significantly exceeds prescriptive approaches for timber systems in the NBCC. With the implimentation of self-centering, zero damage dissipative RSFJ devices, this building will achieve a high level of performance and will represent a first-of-its-kind timber lateral system in a seismic zone for a tall timber building in North America. By performing detailed NLTHA modeling including the non-linear link elements to represent the dissipative RSFJs and linear elements to test drift tolerance of the gravity structure, and accurate shell elements representing the true behaviour of the semi-rigid diaphragm, the overal behaviour of the system has been tuned through performance based design

To achieve a realistic distribution of loads between SFRS elements, a detailed diaphragm model was developed with the development of a simplified, calibrated, shell element to simplify the NLTHA model and analysis.

The building is currently under construction, targeting concrete completion up to level 2 by December 2023, and timber superstructure completion by end of summer 2024

ACKNOWLEDGEMENT

The authors gratefully acknowledge the involvement of the architect, DIALOG, as well as Tectonus Resilient Seismic Solutions. The project was supported by Natural Resources Canada (NRCAN) through the Green Construction through Wood (GCWood) Program.

HUT – INDOOR CLIMBING CENTRE, SKIEN, NORWAY

Katie Overton[1], Gaute Mo[2], Fernando Ibañez[3], Sondre Dolsvåg[4]

ABSTRACT: HUT, Høyt Under Taket, is an indoor climbing centre in Skien, Norway designed by Degree of Freedom in collaboration with the architect Snøhetta. The building combines a single-storey climbing hall, with a maximum clear height of 14.6m, and a three-storey annex. The architectural concept is based on a variable series of 12.5m wide timber portals forming the signature element of this building, the climbing hall. All structural members above ground level are timber, principally cross-laminated timber (CLT). CLT is also used both for the climbing hall façades and for the load bearing walls of the three-storey annex building. Glued-laminated timbers are used as framing elements in the glazed façades at either end of the climbing hall, as part of the CLT rib slabs, and as long span beams supporting the annex roof. Structural analysis has been performed using a finite element model that models the CLT panels as shells and uses link elements to model the connection stiffnesses. Timber-to timber connections are principally realized using timber screws. All timber elements have been fabricated using a LOD400 BIM model fully coordinated with all other disciplines during the design process.

KEYWORDS: Timber, cross-laminated, glued-laminated, CLT rib slab, screws, connections, BIM, portal.

1 INTRODUCTION

HUT Skien is a signature building for the indoor activity centre Høyt Under Taket (High under the Roof), located in Skien, Norway. The load bearing structure is 100% timber above ground level. The project was developed in close collaboration with Snøhetta, Betonmast and Degree of Freedom.

Figure 1: *HUT Skien – Finished building*

From the start there was a high level of ambition regarding sustainability and innovation in timber construction.

This paper is a case study describing how the architectural concept has been translated into a structural frame that reflects the original architectural vision.
The timber structure was erected early in 2022 and the building was opened to the public in late 2022. The finished building can be seen in Figure 1.

2 ARCHITECTURAL CONCEPT

The building is designed to be a landmark, of high architectural quality that provides a unique experience whilst being functional, climate smart and cost-effective.
The building, named 'Portal' at its inception, was conceived by the architects as a low threshold entrance portal to provide access to indoor climbing for all skill levels. The result is a 1,500 m^2 climbing centre with a focus on activity and inclusion for the local community.
The aim was to have a recognizable profile, with internal activity visible from the outside through large glass façades. These large glass surfaces bring natural light into the building and provide extra airiness and connection to nature complemented by the extensive use of exposed timber surfaces throughout.
The architectural identity was based on the concept of a cave, similar to the image in Figure 2, a portal to a world which one would want to explore further. In a cave the distinction between wall and ceiling is blurred, replicated here in the timber structural form. Timber was chosen early in the concept design phase as the main material for both structural and architectural purposes.

Figure 2: *Architectural inspiration*

A key feature of the building are the frames, or portals, with a changing geometry as you move through the space. The starting architectural geometry is shown in Figure 3. At concept design phase the construction of these portals as cross-laminated, CLT, elements was proposed and evaluated to ensure that an adequate lateral stiffness could be achieved.

Figure 3: *Portal concept geometry*

An architectural aim was to leave the structural timber exposed as much as possible as seen in Figure 4.

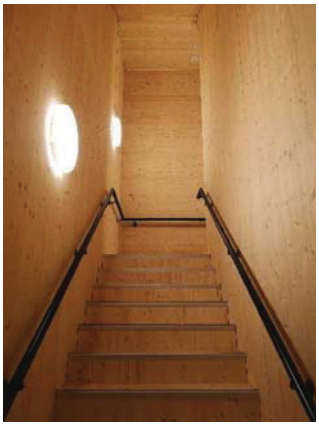

Figure 4: *Exposed timber structure in staircase*

Timber was also chosen as the main cladding material. There is no vapor barrier/plastic used in the external walls, which allows the timber's hygroscopic properties to naturally help regulate humidity, improving the indoor climate. Externally the structure is clad in a dark timber façade as both a protective outer layer and visually to highlight the building's bright interior.

Figure 5: *Building exterior with dark timber cladding*

3 STRUCTURAL SYSTEM

3.1 DESCRIPTION

The building is divided into two parts, the climbing hall and the annex each with a different structural system.
The climbing hall has a series of CLT portals as vertical load bearing elements Portals are spaced at 6m centres generally, and with a single 9m end span. Portal height steps from 11m up to 14.5m. The portals are clad with CLT panels to provide out of plane stability with the portals having an in-plane stiffness to act as moment frames.

Figure 6: *Climbing Hall structure*

The portals support the roof which is a combination of CLT slabs and CLT rib slabs. The rib slab is used for the single span where portals are separated 9m. Figure 6 shows an overview of the climbing frame structure once erected on site.

The climbing hall also includes a mezzanine floor at one end which spans 12.5m across the full width of the hall using CLT rib slabs.

Figure 7: *Soffit view of mezzanine rib slab*

The glazed façades at either end of the climbing hall have vertical and horizontal glulam members for additional restraint as seen in Figure 8.

Figure 8: *View of glazed façade from mezzanine*

The annex building has a combination of CLT walls and glulam columns as vertical load bearing elements. Floor slabs are standard CLT slabs with glulam beams used at roof level where larger open spaces were required. A view of the finished annex structure can be seen in Figure 9.

Figure 9: *View of annex from mezzanine*

The timber superstructure is anchored to the concrete substructure with a combination of both proprietary and bespoke steel brackets.

3.2 MATERIALS

Different thicknesses and build-up of CLT slabs are used in the building ranging from three-layer 100mm CLT panels as part of the roof CLT rib slab to seven-layer 240mm thick CLT panels for the tallest portal frames.
Glulam elements are typically GL24h but with GL28h for the ribs of the CLT rib slab.
The building contains 62m^3 of glulam elements and 627m^3 of CLT panels in total, of which 130m^3 are in the portal frames.

3.3 DESIGN

The building is designed for R30 fire resistance, and all elements have been designed using the reduced cross section method from NS-EN 1995-1-2 [1]. In general all timber elements are exposed with no additional protection provided.
The slip modulus, k_{serv}, for all connections has been considered in the design based on NS-EN 1995-1-1 [2]. The connection stiffness is of particular importance when calculating the overall horizontal sway of the timber portal frames. The slip modulus of both CLT-to-CLT panel connections and CLT to concrete connections was allowed for in the detailed design.
For the long span mezzanine floor the governing criteria for the design of the CLT slab were vibration limits.

3.4 FINITE ELEMENT MODEL

Structural analysis was carried out using a full 3D finite element model in SAP2000, shown in Figure 10. This model allowed for both ULS and SLS design of the CLT panels, and for the design of the connections.

https://doi.org/10.52202/069179-0567

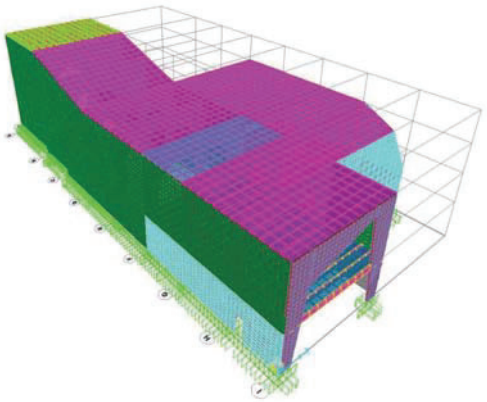

Figure 10: *3D view of FE model*

.

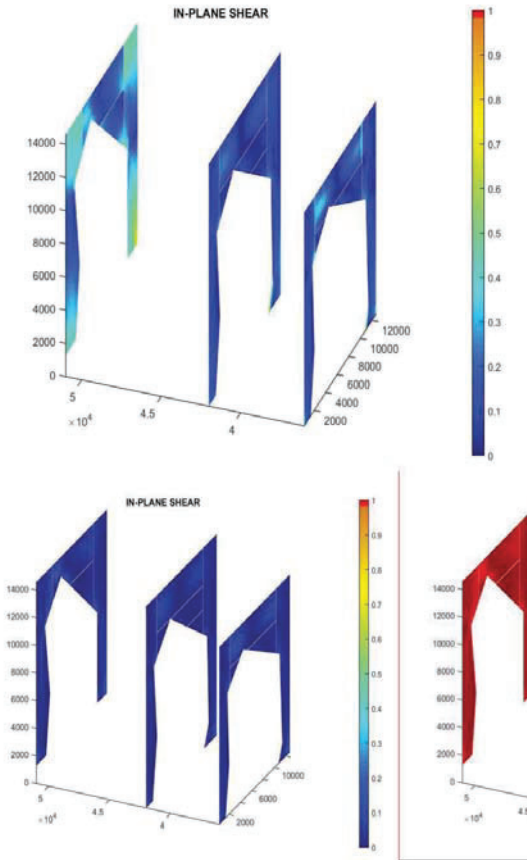

Figure 11: *ULS and Fire design verifications for 240mm CLT portals*

For the orthotropic CLT panels the values for the stiffness matrix were calculated using the software CLT designer created by the Institute for Timber Engineering and Wood Technology of Graz University of Technology (©holz.bau forschungs gmbh). All CLT models were modelled as shell elements with link elements modelling the joints. The stiffness for each degree of freedom was defined based on the calculated slip modulus for the connection type.

Verifications for the CLT panels were carried out for the Ultimate Limit State, the Serviceability Limit State and the fire design situation. An example is shown in Figure 11 for the 240mm thick portal frames demonstrating the check for in-plane shear. For the same 240mm thick CLT portal frames the horizontal displacement for the envelope of characteristic SLS load combinations is shown in Figure 12.

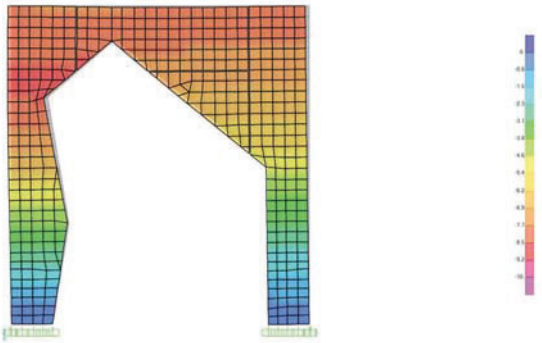

Figure 12: *SLS verifications for 240mm CLT portal*

3.5 CONNECTIONS

The two main types of connections to be resolved for this project were the timber-to-concrete connections and the connections between the different parts of the CLT portal frames.

Timber-to-concrete connections, dependent on location, were required to resist in-plane horizontal loads, out-of-plane horizontal loads, and in some locations uplift. Due to the extent of exposed timber structure in this building alternative solutions had to be found to give a concealed connection. A combination of proprietary angle brackets, see Figure 13, and bespoke, dowelled, steel plate connections were used.

Figure 13: *Proprietary angle bracket to base of portal frame*

https://doi.org/10.52202/069179-0567

Figure 14: View of timber concrete interface details

Where a concealed connection was required architecturally a dowelled connection with an central steel plate was used as shown in the detail in Figure 15. The central steel plate is 8mm thick and the connection has 39no. 12nn diameter steel dowels. For this detail the steel baseplate was cast in-situ with the ground floor slab to a detail by the concrete designer. The central steel plate was subsequently welded in the correct position on site before installing the portal frame.

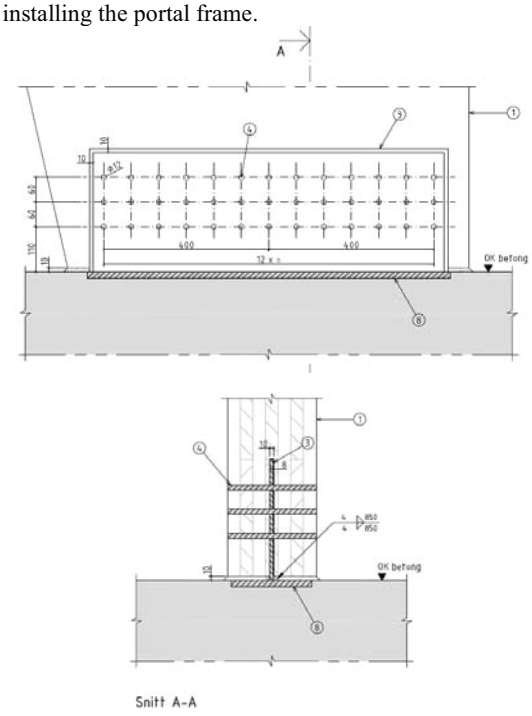

Figure 15: Concealed doweled connection for portal frame

Timber-to-timber connections for the portal frames were realized using fully threaded, cylindrically headed, timber screws installed at 45°, 9mm VGZ screws from Rotho Blaas. The detail is shown in Figure 16. Crossed screw connections, with screws at 45°, give the most robust connection detail for the critical CLT panel to CLT panel connections. The position of these screws can be seen in Figure 17, during construction, prior to the final timber plugs being installed.

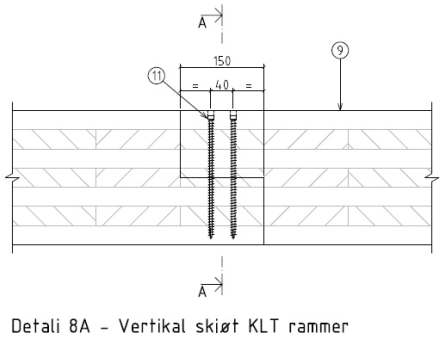

Figure 16: *CLT portal frame connection – screws at 45°*

Figure 17: *Screwed connection between portal frame panels*

In the finished building these divisions between CLT panels are barely visible as seen in Figure 18.

Figure 18: *Portal frame joints*

4 BIM

From the initial concept phase through to the construction phase information was shared and coordinated between disciplines using BIM. Degree of Freedom produced the LOD400 model in Tekla (Figure 19) as the basis for the timber fabrication model.

Included in the BIM model were all the different steel brackets needed at the timber-to-concrete interface. This use of the BIM model allowed for full coordination with the concrete designer, coordination with the Architects to

https://doi.org/10.52202/069179-0567

check visibility, in addition to providing the complete information to the timber supplier for fabrication.

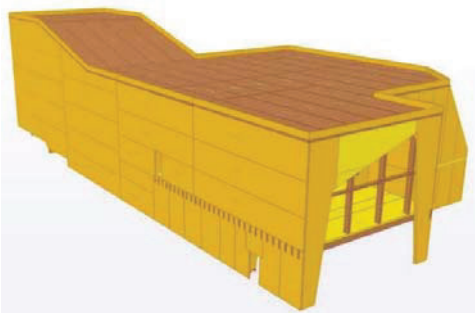

Figure 19: *Overview of BIM model*

An example of the detail of the LOD400 BIM model is shown below in Figure 20 for the 240mm CLT portal with steel brackets at the portal base.

Figure 20: *240mm CLT portal in LOD400 BIM*

The erection drawings were then produced in Tekla directly from the BIM model.

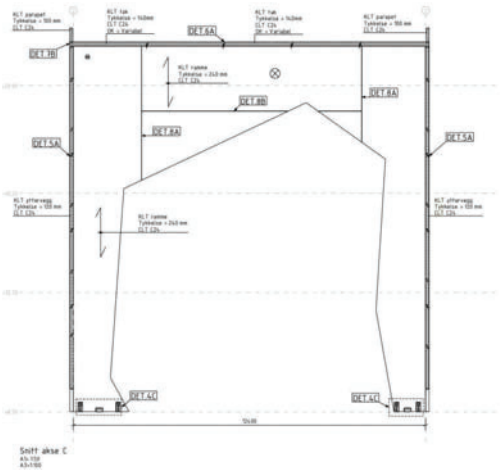

Figure 21: *Portal frame erection drawing*

5 CONSTRUCTION

A combination of LOD400 production models for off-site fabrication, and the site-handling of lighter timber parts, facilitated a rapid erection process on site, despite the adverse weather conditions of the Norwegian winter. Total time for timber erection was five weeks. The use of timber elements also led to less environmental impact on and around the construction site with a reduced number of deliveries and a faster and cleaner construction method with significantly less noise.

Figure 22: *HUT under construction – climbing hall*

Figure 23: *HUT under construction – annex building*

The location of all steel brackets on the erection drawings, produced directly from the BIM model, facilitated their installation on site as shown in Figure 24.

Figure 24: *Installation of steel brackets between timber and concrete*

https://doi.org/10.52202/069179-0567

6 CONCLUSIONS

This project successfully demonstrates how timber has been used to realise the original architectural vision whilst providing both a cost-effective design and a rapid site erection procedure. The load bearing structure has become multi-functional as it also forms part of the building finishes. The use of timber has given a solid, durable, natural and sustainable solution to this singular building as can be seen below in the finished building both without fittings and its final use as a climbing centre.

World Conference on Timber Engineering Oslo 2023

ECONOMIC COMPARISON OF MASS TIMBER AND CONCRETE CONSTRUCTION IN THE NORDIC REGION

Julie Swartz Andersen[1], Yutaka Goto[2], Michael Englund[3], Henning Johansen[4], Ketil Armann Hansen[5], Alexander Hollberg[6], Daniela Grotenfelt[7]

ABSTRACT: The timber sector has been growing strongly in various regions of the world. Yet, the construction industry is still far from being sustainable. One barrier is the economic concern in planning and construction works of timber constructions. This study aims to provide insights on the cost performance of Cross Laminated Timber (CLT) constructions for stakeholders to make an informed decision. It analysed the production cost of multi-story residential buildings with CLT in comparison to concrete in Norway and Sweden. The production cost data of various construction projects with either CLT or concrete was collected and analysed. Interviews with stakeholders were conducted to complement the interpretation of the cost data. The result showed that each project had its individual conditions in the economic background and requirements by client, and thus it was difficult to formulate a general tendency on the cost performance. The variability of the cost was larger and the average production cost was higher in CLT cases. Yet, there are high incentives of contractors and clients for a more sustainable alternative in general. The incentive is also reinforced by the general experience of contractors that the construction cost is better optimized as the contractor gains more experiences.

KEYWORDS: Construction cost, LCC, mass timber, CLT, Nordic region, residential building, comparison to concrete

1 INTRODUCTION

1.1 Background

The construction sector is the source for approximately 37% of the global greenhouse gas emissions [1]. When considering the application of technologies with greenhouse gas (GHG) emission reduction potentials, one must consider its economic aspect as well in order to practically succeed in reducing the GHG emissions. In the practices of construction projects in the current market, decisions are very often made based on the priority on the economic performance among all viable technical alternatives. This is because construction projects must satisfy numbers of legislative requirements for safety, comfort, energy efficiency, etc., and this incurs already a large cost in general even in the case of solution with the lowest possible cost.

In fact, there is an increasing number of applications of more costly solutions with a higher initial investment in the construction industry. This is especially the case when those technologies directly concern the energy efficiency of the buildings, such as thicker insulation, heat exchanger, better-insulating window, etc. This trend is driven by both environmental and economic views. While the solution may be more environmentally, the saving of energy over a certain period can compensate the higher initial investment. This payback time analysis is key to promote those energy efficiency measure in many cases. However, in the case of embodied carbon emissions of construction materials, there is no tangible payback time for different levels of investment unless some substantial carbon tax rules would be introduced in the market. The current market situation does not economically favour a less carbon intensive material unless it is less costly than other common materials.

In order to reduce the climate impact of the industry, the use of timber is seen to be an efficient alternative to conventional materials [2]. The Nordic construction market has seen a major development of the timber construction sector in the past decades especially in Norway, Sweden and Finland. The major drivers of this significant growth are; (1) there are large areas of productive forest and thus there are sufficient resources for the local market, (2) there are well-experienced wood-processing and timber construction companies since timber construction has been very common for smaller buildings, and (3) there is the growing consciousness of environmental sustainability and timber is seen as a more favourable option for its carbon neutrality, renewability and circularity. This advancement of the timber

https://doi.org/10.52202/069179-0568

construction industry is primarily supported by research and developments in structural and fire safety technologies. Among various technologies, cross laminated timber (CLT) has been a major contributor of the expansion of the technical possibilities especially in structural capacity [3].

Yet, the construction industry is still far from being sustainable in terms of the use of renewable resources among other sustainability concerns. Although there have been innovative solutions for CLT constructions to overcome technical challenges in structure, moisture, fire and acoustics, the economic aspect is still a barrier for the further expansion of the timber industry is the economic uncertainty. There is a common concern that timber structures tend to become more costly in planning and construction works compared to other alternatives such as concrete structures.

1.2 Objective and limitation

This study aimed to analyse construction cost of timber buildings and to discuss the advantages, disadvantages and potential of cost optimization in comparison to concrete alternatives. The objectives of the study were (1) a systemic literature review on the construction cost of timber structures, (2) the quantitative data collection and comparison of production cost of various residential construction projects in CLT and concrete in Norway and Sweden, (3) qualitative data collection on the view of stakeholders on the production cost of CLT/concrete constructions, and (4) analysis of the cost structure in order to highlight the economic advantages and disadvantages of CLT structure.

The investigation was limited to the cost of the design and construction stage (A1-A5 module, according to [4]) until the project is handed over to the occupants. Only the actual construction cost was investigated, and the sales price and other sales- associated factors of the apartments is not included. The rest of the life cycle was disregarded in this study. [5, 6] show that if a timber construction is fully protected against weather, the lifespan of the construction will be the same as for a conventional concrete construction. Thus, it was assumed that the maintenance cost for the load bearing frame was zero in both CLT and concrete cases during a calculation period of 50 years. The operational cost for heating etc., was assumed to be the same between CLT and concrete cases with the same energy performance and appliances installations. The demolition phase was excluded as CLT constructions are still new in the market and there is little practical experience in the demolition of CLT apartments.

2 Methodology

2.1 Literature study

The aim of the literature study was to investigate the state-of-the-art research of the cost of timber projects. By examining previous studies about the topic, their results can serve as reference for the results of present study's case study analyses and interviews. As a literature study uses second- hand data and case studies deliver first-hand data, the study opens for a wider perspective of results for the study.

2.2 Construction cost of case studies

A case study represents the actual problems and benefits which might occur during the design stage and construction stage of a project. By using case study as first-hand data it enables to examine the data more deeply in a specific context, which is for multi-story residential buildings in the Nordic countries for this study. This specifies the results of the study to actors in the construction industry in the Nordic countries and creates a more detailed insight into the subject of interest for these actors.

However, case study research has its limitations. The results based on a case study are only as good as the data is and the method is as well criticized for generalizing results based on limited number of cases. Yet, case study is useful to explain a process and the result of the studied subject by using both the quantitative and qualitative data for real-life projects. Hence, case study is chosen as the primary method for this study. These case studies are examined during qualitative interviews and quantitative data analyses.

Before choosing the case buildings and collecting data, limitations were set in order to obtain data with sufficient quality and comparability.

The types of case studies were limited to multi-story residential buildings constructed in CLT and conventional concrete and steel in Sweden and Norway. The building should have at least three stories in some parts of the building and a maximum of eight stories. For the timber building the primary loadbearing system should be constructed in CLT. Furthermore, it was prioritized to use case buildings which were built by contractors who have built such types of buildings before. This was for minimizing additional cost as a result of developing new construction methods and larger beginner mistakes. It was identified in previous studies that cost might increase when the contractor is doing a CLT project for the first time [7, 8].

All contractors and building owners who responded to the request for the data collection were asked to provide the construction data in the same cost group structure to ensure comparability. The construction cost data was collected in accordance with the cost structure model in the Norwegian Standard (NS) 3451 "Bygningsdelstabell (Building component table)" [9]. Table 1 shows the structure of the cost items and how the data was delivered. If the contractors or building owners were not able to deliver the cost data according to the standard, they were asked to deliver the total cost sum of the project. It was decided to include these projects with limited level of detail in order to increase the amount of case buildings. However, these projects were excluded from the comparison of each cost group and only used for comparison of the total cost.

https://doi.org/10.52202/069179-0568

2.3 Stakeholder interview

Qualitative analyses have been performed as interviews of developers and entrepreneurs of the case project and of other stakeholders within the building industry. The interviews can collect insights into behaviours and thoughts which quantitative data cannot. It can as well explain the reason for the data to occur in a specific way. The interviews were performed as semi-structured interviews with the ability to be flexible from the planned questions and to be creative with more questions, which come throughout the interview. The planned questions were provided to the interviewees from Denmark, Sweden and Norway in writing in advance. In some cases, response was collected in writing, which was complemented by an oral interview to ask further questions afterwards. This method was useful for the project since the people interviewed were able to speak of their experiences. Table 2 shows the interviewed stakeholders.

3 CASE STUDY BUILDINGS

This chapter describes the 9 case buildings (6 projects in Norway and 3 projects in Sweden) for the analyses in the study.

3.1 Bergheim bo- og aktivitetssenter (CLT 1)

Bergheim bo- og aktivitetssenter (CLT 1) is a care home for 96 residents located in Halden in the south of Norway. The gross total area (GTA) of the building is 11,700 m^2, with no underground parking. The building is distributed on three storeys. The upper two storeys were constructed in CLT and the ground floor in concrete. The building is shaped in a horseshoe form with a yard in the middle. The rendering and the completed project are shown in Figure 1. The building was constructed in the period from October 2017 to February 2019 by a turnkey contractor, Solid Entreprenør. The building owner is Halden municipality. The municipality specifically demanded a massive timber building for the care home, and thus the project was planned to be a timber building from the beginning. The supplier of the CLT was Binderholz in Austria.

Figure 1: *Bergheim bo- og aktivitetssenter project (CLT 1) constructed with CLT in Hadlen, Norway*

3.2 Solhøy (CLT 2)

Solhøy (CLT 2) is a care home for 67 residents located in Vestby in the south of Norway. Solhøy has four storeys. The basement is constructed in concrete and steel, and the above three storeys are constructed in CLT. The building has a GTA of 11,536 m^2 including parking basement, with an average apartment size of 33.5 m^2. The construction of the building started the January 2021 and is planned to end in December 2022. The project has a turnkey contractor with a fixed price for the total cost of the building. The contractor is Solid Entreprenør, which is the same company for CLT 1. The building owner is Vestby municipality, who demanded a building constructed in massive timber from the beginning. The supplier for the CLT panel is Splitkon, located in Norway. Figure 2 shows the rendering and the status of the construction in March 2022.

Figure 2: *Solhøy project (CLT 2) constructed with CLT in Vestby, Norway*

3.3 St. Olavsvej 18 (CLT 3)

St. Olavsvej 18 (CLT 3) is an apartment building in five storeys including the basement, located in Kristiansand in the south of Norway. The GTA of the building is 1,657 m^2 including 550 m^2 parking basement and 28 apartments of average 45 m^2. The basement is constructed in concrete and the upper storeys are constructed in CLT. The construction started in 2021. Similar to CLT 2 project, this project also has a turnkey contractor, VEF Entreprenør, with a fixed price of the project. Figure 3 shows how the building's rendering and the state under construction.

https://doi.org/10.52202/069179-0568

Figure 3: *St. Olavsvei 18 project (CLT 3) constructed with CLT in Kristiansand, Norway*

3.4 Ski BB1 Magasinparken (Concrete 1)

Ski BB1 Magasinparken (Concrete 1) is an apartment complex, consisting of 7 buildings with 183 apartments in total, and is located in Ski in the south of Norway. The building is owned by Solon Bolig AS Solon Eiendom, and was built by Solid Entreprenør, which as well constructed CLT 1 and 2. The average apartment size is 79 m^2 and the GTA of the project is 24,805 m^2, including 7,800 m^2 parking basement. The number of storeys varies for each building. Three of the buildings have four storeys, three other buildings have five storeys and one building has eight storeys. In addition, each building has a basement. The buildings are constructed in concrete slabs and steel columns. The foundation was made as pile foundation, which often has a higher cost. The project was constructed from March 2019 to September 2020. Figure 4 shows some pictures of the buildings.

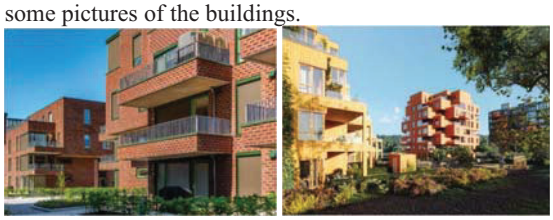

Figure 4: *Ski BB1 Magasinparken project (Concrete 1) built with concrete in Ski, Norway*

3.5 Trelasttomta (Concrete 2)

The project Trelasttomta consists of four apartment buildings varying from four to seven storeys and one shared basement underneath all the four buildings. The project is owned by Ekornud Eindom AS and is located in Myrvoll in the southern part of Norway. Architect of the buildings are Nuno Architects and is constructed by Solid entrepreneurs as the turnkey contractor, from January 2019 to December 2020. The total gross area for all four buildings is 9,950 m^2 including 2,250 m^2 parking basement and consists of 72 apartments with an average size of 63.2 m^2. The buildings are mainly constructed in concrete and steel, with concrete slabs and loadbearing system in steel. Figure 5 shows some renderings.

Figure 5: *Trelasttomta (Concrete 2) constructed in concrete in Myrvoll, Norway*

3.6 Fagertun Panorama (Concrete 3)

Fagertun Panorama consists of four apartment buildings with two or three storeys and a basement, which are made in concrete. The GTA of the project is 3,359 m^2 including 1,216 m^2 parking basement with 21 apartments with an average size of 91 m^2. The owner is Dovreveien 3 AS, and buildings are located in Lillesand in the south of Norway. VEF Entreprenør was the turnkey contractors of the project and constructed the building from November 2019 to October 2021. The buildings were constructed as conventional apartment buildings of Norway with steel columns and concrete slabs. Figure 6 shows the project after construction completion.

Figure 6: *Fagertun Panorama (Concrete 3) constructed in concrete in Lillesand, Norway*

3.7 Fagertun Panorama (CLT 4)

Arken consists of three buildings with total of 85 rental apartments and has a GTA of 8,327 m^2 with above ground parking only. The project was built in Växjö in the southern part of Sweden. From the beginning it was required to be constructed as a wooden construction, with environmentally friendly materials and low energy consumption. In fact, the project was planned as a part of the regional Energy Plan with a requirement of yearly energy consumptions of 55 kWh per unit heated floor area. However, this project has lower U-values for the building envelope with thicker insulation compared with buildings built according to the minimum requirement by the Swedish regulation. The buildings consist of apartments with one to five rooms, with an average apartment size of 65,3 m^2. The buildings were constructed with a CLT frame, with slabs, outer walls, load bearing inner walls, joist, balconies, elevator shafts, beams and columns in CLT and glue laminated timber from Martinssons in the north of Sweden. The buildings were constructed by a local contractor in Växjö, Värends Entreprenad. Figure 7 shows the project after the construction completion.

Figure 7: *Arken (CLT 4) constructed in CLT in Växjö, Sweden*

https://doi.org/10.52202/069179-0568

3.8 Björkdungen 5 (CLT 5)

Björkdungen 5, located in Bengtsfors in the south-west of Sweden, is a four-storey apartment building with a dentist office placed on the ground floor of the building. The basement and the ground floor were made from concrete, including the elevator shaft. The load bearing structure in the two storeys above was made from CLT, including half of the facade walls. The other half of the facades was made from Sven Johansson Bygg (SJB bygg) own light weight system in wood. The inner load bearing walls of the smaller top floor was from CLT. The facade walls were made from their own light weight system. The elevator shaft was made from CLT in the three top levels. The CLT was delivered from the mill of Stora Enso in central Sweden

The building is owned by Bengtsforshus AB, which is the municipal housing company in Bengtsfors. The building was built by SJB bygg as the turnkey contractor with a construction time of 15 months, from March 2020 to August 2021. This project was the first CLT building built by SJB Bygg. The GTA of the project is 1,536 m^2 including 375 m^2 for the dentist office, a basement of 166 m^2 and 11 apartments with a size of 55-76 m^2. Figure 8 shows the building Björkdungen 5 under construction and as a finished building.

Figure 8: *Björkdungen 5 (CLT 5) constructed in CLT in Bengtsfors, Sweden*

3.9 Tingstorget (Concrete 4)

Tingstorget, located in Botkyrka in the south-east of Sweden, consists of 729 apartments distributed in 14 buildings varying from rowhouses in 3 storeys to multi-storey buildings with 6-8 storeys. The GTA of the whole project is 43,007 m^2 including 3,964 m^2 parking basement. Tingstorget has a load-bearing system in concrete, load bearing inner walls, elevator shaft, staircase and joist constructed in steel and massive concrete. The exterior wall is made of concrete sandwich elements. The roofs are constructed with prefabricated timber elements and is covered with steel roofing plates. The contractor team was a combination between a turnkey contractor, Titania, and an executive contractor. The turnkey contractor was responsible for the framework construction and roof, and the executive contractor was responsible for the rest of the work with in- house employees as well as external consultants which might have contributed to a slightly higher cost. The total construction time was 3 years, from August 2016 to 2019. Figure 9 shows the Tingstorget buildings after the construction completion.

Figure 9: *Tingstorget (Concrete 3) constructed in concrete in Botkyrka, Sweden*

4 RESULT

4.1 Literature study

The period for the design and construction stage (project period) has a great impact on the total construction cost of a building, hence it has been examined in different comparative studies of traditional concrete/steel buildings and timber buildings. Table 3 shows the results of project period and cost for five different studies (M.F. Lagurda-Mallo et al. (2016) [10], R.E. Smith et al. (2017) [8], Center for Sustainable Architecture with Wood (2016) [7], Østnor (2018) [11], and Halseth (2019) [12]), comparing concrete/steel and timber buildings.

Table 3: *Comparisons of time and cost of timber building compared to concrete/steel alternative in five different studies.*

Articles	Construction time of timber buildings compared to concrete/steel building [+/- % time]	Project period of timber buildings compared to concrete/steel building [+/- % time]	Cost of timber buildings compared to concrete/steel building [+/- % time]
M.F. Lagurda-Mallo et al. (2016)	-61.1%	N/A	-21.7%
R. E. Smith et al. (2017)	N/A	-20%	-4.2%
Centre for Sustainable Architecture with wood (2016)	+20%	N/A	+4%
Østnor (2018)	-42%	N/A	+60%
Halseth (2019)	-40%	N/A	+13%

The results in Table 3 show a varying result of the project period and cost, but most of the examined studies have a shorter construction time for the timber building. The only study with a longer construction time for the timber building was in [7]. The reason for this study having a longer construction time was that the timber building was constructed as a prefabricated timber frame structure, which was stated to have a longer construction time compared to panel system in concrete. Meanwhile, the other studies, which all showed a shorter construction time in the timber case, compared CLT with concrete. Furthermore, the timber frame construction in [7] was supposed to receive 5 Star grading of the Australian sustainable building certificate, Green Star [13], which was not the case for the compared concrete building. The certification system required more documentation and additional tasks, thus the process extended the construction time additionally.

One of the reasons for higher cost in three of the examined studies was due to the higher material prices for timber compared to concrete [7, 11, 12]. Another reason is that the cases in those studies (with CLT or prefabricated timber frames) were pilot projects, which resulted in more working hours for the design team to create solutions for e.g., acoustic and fire.

The Swedish company, ETC, who develops, finances and built timber buildings, describes how they have developed

construction and design methods and thereby decrease the cost. After building three buildings they have seen that their second building was 9% less expensive in labor costs. The third building was 10% less in labor costs than the second building. They observed this despite of the fact that during this time the labor costs in general had risen substantially [14]. It shows an example of the cost reduction potential in learnings from the experiences for further process optimization.

4.2 Construction cost of case studies

The cost data for the Norwegian and the Swedish case buildings was analysed separately since the market's general economic structure and technical and legislative construction standards are not the same for the two countries.

In order to normalize the influence of the inflation and to show the magnitude of difference in the two markets, the cost data of each project was converted to euro and index regulated to prices of 2021 by the construction cost index regulation for residential buildings [15]. By converting the prices to 2021 euros it enables for comparison between the project and for future similar projects. Furthermore, all prices are presented without VAT (value added tax) and without the cost of land purchase and landscaping.

The results of the analysis of cost data are based on the raw data which was supplied by the contractors and developers. Results are strictly based on those inputs with no subjective correction of those raw data.

4.2.1 Norwegian cases

The cases CLT 1-3 and Concrete 1-3 are Norwegian buildings, and they were analysed and compared to each other in the same analysis. The collected data is divided into the cost group structure according to [9], which is presented in Table 4 and the total construction cost of the Norwegian projects are illustrated in Figure 10. Common cost (Cost element 01 in Table 4) includes dismantling and setup of construction site, cranes, barracks and operation of construction site, insurance, collateral and guarantees. General cost (Cost element 08) includes engineering and the client's administration, project management, constructions management, special consultants (legal, financial, etc). The landscaping cost was excluded in these results since the cost of landscaping is not relevant for the cost of the building in terms of the selection of the construction materials.

Table 4 and Figure 10 shows that all the Norwegian concrete project has a lower construction cost compared with the CLT building. Thereby this is a clear tendency for the analysed Norwegian project, that it is more costly to construct CLT buildings compared with CLT buildings. However, Table 4 shows that the cost of each project can vary for each cost group. When looking into the cost group, common cost, it shows that the cost for CLT 2 was more than twice higher than for the other projects. Furthermore, the general cost is three times higher for CLT 1 and CLT 2 than for Concrete 1, Concrete 2 and Concrete 3. This might show, together with the literature study (Section 4.1) that there is a tendency that the CLT buildings have higher cost in the design stage than concrete buildings. However, the general cost for CLT 3 is not shown explicitly but is included implicitly among the other cost groups. This is a typical example of the cost calculation practice that even though the cost is divided according to the same standard [9], the calculators of each project can objectively allocate the cost figures to different cost groups. Due to this, the figures of each cost group must only carefully be compared directly and cannot be compared without knowing the background of the numbers.

Table 4: *Results of Norwegian case projects divided into the cost group structure according to NS 3451*

Cost elements		CLT 1	CLT 2	CLT 3	Concrete 1	Concrete 2	Concrete 3
		EUR/m^2(GTA) (2021)					
01	Common costs	251	679	232	309	190	161
02	Building	1302	1561	1573	1232	1105	865
021	Site preparation	16	0	0	0	1	0
021	Ground and founda	140	219	384	195	129	119
022	Load-bearing syster	20	34	139	15	-	59
023	External walls	167	335	244	186	152	289
024	Internal walls	424	389	277	281	251	61
025	Slabs	223	284	177	300	393	180
026	Roof	103	116	52	38	43	56
027	Fixed furniture	147	144	97	88	73	36
028	Stairs. balconies.	18	24	167	111	52	60
029	Structural relief work - Plumbing	45	16	8	18	11	2
029	Structural relief work - Electrical	0	0	28	-	-	4
03	Plumbing and HVAC installations	350	360	350	226	211	123
04	El-instrations	182	264	141	139	117	52
05	IT and automatio	-	-	-	-	-	-
06	Other installation	18	27	257	17	24	151
Building cost (01-06)		2104	2891	2553	1922	1646	1353
08	General cost	200	163	-	69	65	22
Construction cost (01-0		**2303**	**3054**	**2553**	**1991**	**1711**	**1374**

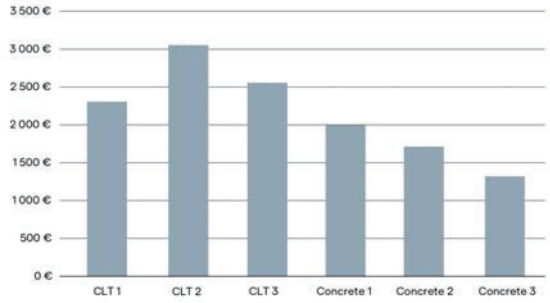

Figure 10: *Total construction cost per GTA for the Norwegian projects*

In the investigation on the cost of CLT buildings compared to concrete buildings, it is necessary to exclude the cost of building parts which are not directly related to building being a CLT or a concrete building. Such building parts are the fixed furniture and installations. The costs of these groups are more dependent on if e.g., the building needs more ventilation according to its particular usage or has many small apartment units (care homes) where each unit has its own bathroom and kitchen. This increases the cost of these groups but is not related to it

https://doi.org/10.52202/069179-0568

being a CLT or concrete building. Therefore, the cost of fixed furniture and other installations are excluded in Figure 11.
The cost of six cases presented in Figure 11 illustrates that the cost of the concrete buildings is still lower than the CLT building. However, the cost difference between all three CLT buildings and the concrete buildings have become lower but cost still varies within the CLT cases and the concrete cases. However, the largest variation was observed for CLT 2. According to the additional questions asked to the contractor of case CLT 2, it was commented that one of the reasons for the case CLT 2 to have a higher cost was that there is a large underground work for the basement constructed in concrete. For this basement, which includes parking areas, technical installation rooms and other functions beneath the whole building, it was required more blasting and other works which were costly. However, this shows that a higher cost of a CLT project do not necessarily need to be a result of the building being constructed in CLT but might be because of other conditions which affects the total cost more.

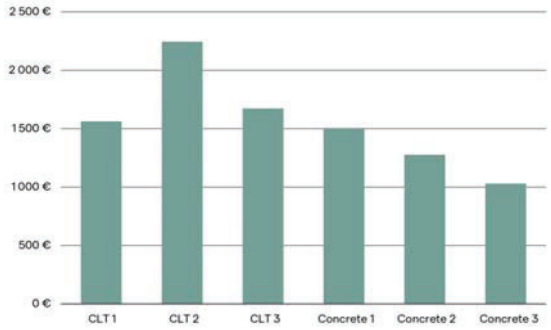

Figure 11: *Cost per GTA for the Norwegian cases, excluding fixed inventory and installations*

Furthermore, it is relevant to investigate the cost of the cases without common cost, and general cost, and thereby only looking at the cost of the materials and labour cost during the construction. This investigation is shown in Figure 12 where the cost of site preparation, ground conditions, load-bearing system, external walls, internal walls, slabs, roofs and stairs and balconies is evaluated separately.

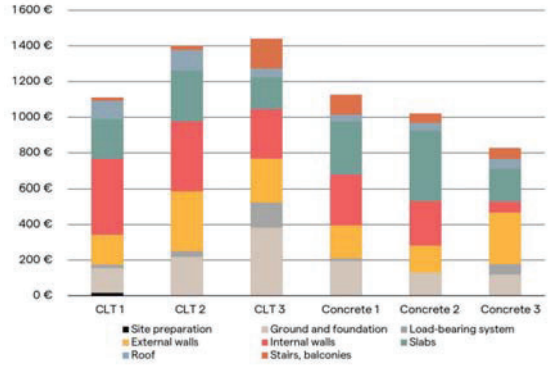

Figure 12: *Cost of the building parts including materials and labour cost of the Norwegian cases*

The results of the cost of the building parts show that the variation within the CLT buildings changed from case CLT 2 having the highest cost to case CLT 3 having a slightly higher cost per GTA. As mentioned earlier, the cost group general cost was not shown explicitly in CLT 3, thus this cost might be included in cost of the building parts shown in Figure 12. Therefore, it cannot be concluded that the building parts are the most expensive for case CLT 3 compared to the other cases.
Through the analysis of the Norwegian cases, it can be concluded that cost varies within the CLT projects and the concrete projects. But there is a tendency that the concrete building has a lower construction cost compared to CLT buildings.

4.2.2 Swedish cases

For the data collection of Swedish case buildings, there was a limited willingness to share cost data from the stakeholders' side. Also, for the ones who contributed with the data, the breakdown of the cost groups was not possible to provide with the level of details as the Norwegian cases. Thus, it was only possible to receive the total cost for three projects, two CLT projects and one concrete project. Table 5 and Figure 13 shows the total cost per GTA for the three Swedish case buildings and the percentage difference from the highest cost per GTA of the three buildings.

Table 5: *Results of total cost per GTA for the Swedish cases*

	CLT 4	CLT 5	Concrete 4
Total cost per GTA (EUR/m^2)	1970	1915	2232
Percentage difference from maximum	-11.7%	-14.2%	0%

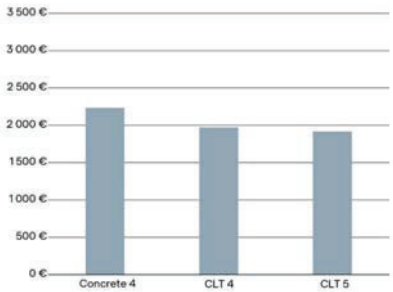

Figure 13: *Total cost per GTA for the Swedish cases*

The results show that the two Swedish CLT case buildings has a respectively 11.7% and 14.2% lower cost than the concrete building. As mentioned above, the results of the Swedish projects are not divided into the same cost group structure. Therefore, it cannot be concluded which cost groups had the highest and lowest cost for each project. However, the contractor of Concrete 4 is different than the projects CLT 4 and CLT 5. Concrete 4 have had a combination of a turnkey contractor and an executive contractor, whereas CLT 4 and CLT 5 only have had a turnkey contractor. This might cause some cost

differences. Furthermore, Concrete 4 consists of 14 building whereas CLT 4 consists of three buildings and CLT 5 only consists of one building. It can be assumed that the cost per GTA for the same total floor area becomes higher with increased length of building envelope (more windows, more insulations etc.). Thus, the cost per GTA for Concrete 4 might show somewhat higher number compared to a regular concrete building with just one volume.

Through the questions to the contractor for Concrete 4, Titania, they described that the cost of the final building ran over budget due to complication with the ground and foundations work. This as well might be one of the reasons for the higher cost for case building Concrete 4. Furthermore, Titania stated that if they had a more optimized logistic solution and a lower construction rate, they would probably have been able to save 5-10% of the total cost.

The case building CLT 5, which has the lowest cost per GTA of the Swedish project, can as well be defined as a hybrid building between concrete and CLT. The ground floor and the slab above the ground floor was constructed in concrete. The 1st and 2nd floor are mostly constructed with CLT. The contractor SJB bygg stated that the entire building would have been cheaper if the building was constructed in only concrete and steel or with a timber frame structure. This statement should however be seen in the context that SJB bygg are used to work with concrete and steel and timber frames, but not with CLT. Furthermore, they stated that if they are doing a similar project again the project time would be approx. 10-20% shorter, which should be reflected as a lower cost for the next time.

Moreover, the results illustrated in Figure 13 show that the CLT projects have a low variety for the Swedish project, whereas the earlier mentioned Norwegian projects has a larger cost variation between the CLT projects. Since we know the cost of only two Swedish CLT projects, it cannot be concluded that this shows a general tendency for Swedish projects, and this can be studied further in an additional study where more case studies are available. Even though the cost data of Swedish projects are limited in this study, the results of the Swedish projects still show that CLT buildings do not necessarily have a higher cost than concrete buildings. For a deeper analysis and investigation more project and cost data divided into a cost group structure are needed.

4.3 Stakeholder interview

The results of the interviews from the building industry and the case studies were analyzed in order to recognize tendencies in the costs and methods to construct in CLT and concrete.

4.3.1 Materia cost

The Danish contractor and the one of the Norwegian contractors (see Table 2), who both have constructed concrete building and CLT buildings, stated that it has been more expensive to build CLT buildings compared to concrete buildings up until June 2022 when the project has concluded. They both pointed out that the material cost has been higher in the CLT project, compared to the material cost for a concrete project. The higher material cost has been a result of fewer suppliers and a long transportation. However, the Danish company stated that more suppliers are coming to the Nordic countries and therefore transportation prices have decreased in the last three years. Furthermore, the Norwegian company pointed out that due to the fire regulations in Norway large amounts of fire gypsum boards are needed and it increases the material cost of CLT buildings. In addition, a building of 8 stories constructed in CLT in Norway would need a sprinkler system, which is not the case for a concrete and steel building in Norway. Thereby the material cost for a CLT building may increase further for a building of this height, by adding additional gypsum boards.

However, the weight of a timber building is lower than a concrete building, thus less material is needed for the foundation. This means that in areas with challenging ground conditions, the cost of the foundation can be reduced because of a lighter building.

The contractors and owners of the CLT cases stated that those case studies were planned as timber constructions from the beginning, and thus there was no solid cost comparison to other alternatives. Yet, as stated in section 4.2.2. according to the contractor, SBJ Bygg, CLT 5 projects would have become less costly if other conventional materials than CLT would have been used.

4.3.2 Time and logistics

Through the interviews with the Swedish municipality, one Norwegian contractor and the Danish contractor, they have all pointed out that construction time of CLT building have potential to be shorter than concrete buildings. The Norwegian company has had experience of shorten the construction time by two months by constructing a CLT building compared to a similar building constructed in cast-in concrete and steel.

It was also pointed out that in order to shorten construction time, then the logistics is important to optimize. For the Norwegian company, it was important that the CLT elements and materials arrived as planned every week, so that all the workers were able to do their job and follow the time schedule.

On the first CLT project that the Danish company carried out, they optimized the cost for deliverance of CLT elements by loading the trucks to the maximum, and thereby decrease the numbers deliveries. However, they found huge logistic challenges by handling all CLT elements before they needed them. It demanded to handle the elements 2, 3 and 4 times and every time with a risk for scratches and marks on the elements. Furthermore, the risk of moisture in the elements as a consequence of unstable Danish weather conditions and no weather protection on the site. From this experience they have learned to demand the CLT elements in the order they needed it for the assembly of the building, and thereby streamline the processes.

In addition, the interviews pointed out that CLT buildings constructed by an architect, engineer and contractor who

https://doi.org/10.52202/069179-0568

experienced a CLT project for the first time, have a higher project cost. The Swedish municipality stated that in the beginning their CLT projects, they had a 20-30% higher project cost than concrete alternatives. As more CLT projects were built in the municipality by various local contractors, the cost difference decreased to 10% between CLT and concrete, where CLT is still higher. During the pandemic period the construction cost was heavily influenced by it.

In addition, the Norwegian contractor stated that the shorter construction time is beneficial for the developer of the project, since the occupancies can move into the apartments earlier and start paying rent, which means that the developer will save interest rate for the earlier incoming money.

In the case of the Swedish municipality, in 2013 they launched the policy that more than 50% of the newly built municipal buildings would be timber construction (including hybrid construction where timber is the primary material) by 2020. Their goal was not only reached but succeeded with an average of 70%. From the city planning viewpoint, the municipality appreciates buildings that are more prefabricated and faster to build as the disruption in the town is shorter. While there are several materials and ways to prefabricate, CLT shows a high advantage for high level of prefabrication.

4.3.3 Weather protection

For the construction work of either a CLT building or a concrete building the weather is an important factor in the construction cost. Concrete must dry before the interior finish work can start, and if the humidity is high, it is more difficult to dry the concrete and might need heating equipment to dry the concrete. Timber constructions is built by an organic material and therefor is important to keep the material dry in order not to be infected by fungus or mold. Therefore, it has been investigated throughout the interviews and in the case studies what have been experienced in relation to weather protections. Through the questions for the case study buildings, it showed that none of the studied cases in Norway and Sweden used a tent to cover the construction for protection against rain. For the case CLT 3 VEF Entreprenør had to dry the construction with heated air, however they only did it for a very limited time. For case Concrete 3, VEF Entreprenør as well used heating to dry the concrete before closing the construction, but in a larger scale compared to case CLT 3.

During the project Maskinparken 3, whose cost data was not a part for this study, its construction company did not use weather protection during the construction. They explained that due to the cold and dry weather in Trondheim they had no need for using a tent or drying, other than natural aeration. According to their experience, when they had snow, they could easily remove it and afterwards let the construction dry. Furthermore, they experienced that if they had snow or rain during a weekend, only a small amount of water had penetrated the construction. The construction was then easy to dry before closing it by gypsum boards and insulation. However, they stated that they had a great awareness of the risk of moisture during the entire construction period.

In addition to the risk of rain, they also had to be aware of the wind. When they had to hoist the large wall and deck elements it was important that the wind was weak. If it was too windy then they were not able to control the large elements with the crane.

In the case of the Danish contractor, they have bad experiences by constructing a CLT building in Denmark without using a tent or other weather protection. They stated that in Denmark they have other weather conditions than Norway, which might occur as a higher risk to build a CLT construction without a tent in Denmark than in Norway.

In the case of the Swedish municipality, two out of ten recent timber buildings were built under a tent, and others were exposed. Meanwhile, they stated that they have experience to save money by using a tent as a result of continuously dry work conditions, which does not incur waste of time by waiting for the construction to dry after accidental wetting.

5 DISCUSSION

5.1 Sensitivity and uncertainties

Throughout the process of data collection, it was clear that the project and results would be limited by the number of cases studies. Many of the companies who were contacted and asked to contribute to the project, did not had time or wanted to participate in the project. The limited number of cases resulted in a limited data base for the project, and therefore creates some uncertainties throughout the project. The uncertainties have been identified and are listed below.

Identified uncertainties:

- Representativeness of the collected data set
- Cost differences which are derived from different types of buildings (care homes, family apartments, apartment buildings with service facilities)
- Influence of the timing of the project in relation to the general economy and labour market
- Influence of different locations within each country
- Influence of different construction methods
- Influence of the variation of the contractor team
- Influence of the pandemic since 2020

The uncertainty of the representativeness of the data can cause a large sensitivity for the assessment since each project constitute to a large impact of average result. Nevertheless, the results of the cases examined in the project still show that a timber building does not necessarily need to be more expensive. In addition, the interviews and literature studies showed that there are other advantages and disadvantages in the construction methods for timber buildings, which cannot directly be seen in the total cost, such as the construction time.

Not all the case projects are built in the same year. Even though the costs have been index regulated for the price development of the construction industry, the numbers can still be affected by the time the building was built. For instance, there could be advancements in the construction

techniques in 2021 compared to those in 2016. Moreover, the prices for different materials develop differently. Thereby, the comparison of projects built during different time periods might cause an uncertainty for such an economic analysis. This must always be considered when project cost is compared.

In our study, the costs were only compared with other project within the same country. This was done in such a way since each country has its own market with different material prices different labour cost, different definitions of floor areas etc. However, there are also different prices within the countries. A project constructed in the northern part of Sweden most likely has a different price in the southern part of Sweden. This is as well an uncertainty in the project.

The global pandemic of corona virus caused a substantial impact on the global economy, and the construction sector have been also heavily affected in many regards such as labour cost, material cost, transportation cost, logistic, real estate price etc. The influence of the pandemic on the construction cost might become more apparent in the near future.

6 CONCLUSIONS

The results found throughout the analysis reflect the cost of cases of CLT buildings and concrete/steel buildings in Sweden and Norway, as well as information from interviews of stakeholders. The results showed tendencies of how the cost have been at the time where the buildings were designed and build. The market develops continuously, especially within more projects with a stronger focus on sustainability. Therefore, it is important not to apply the conclusions of the case studies as an exact forecast for future buildings but must be used as an indicator of the costs and what to be aware of due to cost of timber and concrete buildings in the Nordic countries.

The following are the main findings of the study:

- There is a tendency that the CLT buildings has a higher construction cost compared with the concrete buildings for the Norwegian case buildings.
- The cost of a CLT building does not necessarily need to become higher compared to a concrete building. It depends on the type of project and how it is executed.
- The more experience one has with CLT buildings, from cost calculation to designing and constructing, the more likely the building becomes more cost efficient.
- The material cost is often higher for CLT buildings compared with concrete buildings.
- The prefabrication of CLT modules most often result in a shorter construction time as well as better working conditions in the factory and on site.
- The logistics of a CLT building is different than for a concrete building and most be considered carefully to lower the cost.
- CLT buildings are lighter than concrete ones and in many cases that presents an advantage on foundation costs.
- None of the cases studies used a tent as weather protection, but it is stated that it possible to save money when applying a tent, due to a more continuously workflow.

ACKNOWLEDGEMENT

COWI Foundation is acknowledged for its financing for the project execution. The construction companies and the other stakeholders are greatly acknowledged for their contribution with the data and to the interviews.

THE RELATIONS IN THE PLANAR AND SECTIONAL SCALES AND KAN COMPOSITION OF TRADITIONAL KOREAN ARCHITECTURE

Sangyeon Park[1], BongHee Jeon[2*]

ABSTRACT: In traditional architecture of East Asia, a distinct feature is the clustering of multiple buildings to form a single-unit. Therefore, the expansion of a single-unit building has not been given as much consideration as in Western architecture. This study aims to examine the planar and sectional scales in the Kan composition of traditional Korean architecture and to identify the limitations of scale expansion. Although previous studies have focused on the characteristics of the plan and section, this study is the first to conduct a comprehensive survey of all nationally designated cultural properties and derive statistical significance. The typical plan configuration consists of three bays for both the front and side, which emphasizes the facade. However, a plan with a side of five bays is relatively uncommon, and there are no examples of buildings in Korea exceeding five bays. This can be attributed to the structural characteristics of East Asian wooden architecture, where expansion to the side is difficult and the desire for depth and height is not prominent. In contrast, China and Japan have buildings with a side length of six and seven bays, respectively, allowing for a more expandable limit of scale.
KEYWORDS: traditional Korean wooden buildings, Kan Composition, scale of Kan, limitations of scale expansion

1 INTRODUCTION

Traditional wooden architecture in East Asia is comprised into three main components: the foundation, body, and roof. These three parts are constructed into a single building through the joining method of the structural members. This study focuses on the planning and scale of the body section. In the process of constructing wooden architecture, the initial consideration is to establish a floor plan, which subsequently informs the creation of a section plan and elevation plan. The floor plan plays a crucial role in determining the overall size of the building. [1]

In traditional East Asian architecture, the floor plan is divided into units called "Kan" (bay). Kan is a term with a wide range of meanings, including length, width, the width between columns, or the unit area where four columns are placed. [2] This is due to the development of East Asian architecture based on the post and lintel structure. The length of one Kan, or the distance between columns, must be determined on the floor plan [1]. A standard Kan is approximately 8ja (about 2.4m), but the size may vary depending on the dimensions of other wooden components such as purlins and the distance between the body and the bracket set (gongpo) that connects the body and the roof. [2]

In traditional wooden architecture, a single building is constructed using a combination of bays. Therefore, the number of Kans is a vital measure in determining the size of the architecture [1]. The single building is composed of the Purlin-Direction, which makes up the façade, and the Beam-Direction, which makes up the side. The arrangement of bays is achieved by combining the number of bays in the Purlin-Direction and the Beam-Direction. This study aims to examine the scale of the façade, side, and height, based on the configuration of the bays, and to understand the characteristics and relationship between the plan and section in Korean traditional wooden-structure buildings. Although some studies have investigated the characteristics of the plan and section in the past, this study is significant as it conducts a comprehensive survey of representative cultural assets throughout the country and statistically processes them, thereby providing a more accurate understanding of the characteristics of Korean traditional architecture.

In traditional architecture across Korea and other parts of East Asia, it is common for individual buildings to be clustered together, leading to less emphasis being placed on the expansion of a single building's scale when compared to Western architecture. The objective of this study is to investigate the extent of the expansion of scale achieved in traditional Korean architecture. The evolution of Korean architecture has moved towards dispersing functions across multiple buildings to form clusters. As a result, the depth of space cannot be fully appreciated from the entry point of a single building or house (chae) alone. Since the chae is composed of several kan and differentiates, [3] the investigation of kan is crucial for understanding traditional Korean space. Similarly, the scale of individual buildings in traditional Chinese architecture is also limited in terms of expansion due to

[1] Sangyeon Park, Seoul National University, Republic of Korea, syhee55@snu.ac.kr

https://doi.org/10.52202/069179-0569

the fact that its units are based on a cluster composed of "number".[4]

2 METHODS

The Korean government manages a total of 489 buildings constructed using the traditional-timber structure that are of historical or archaeological significance. Among these buildings, 238 excluding residential buildings and clusters of multiple buildings have been selected and classified into categories based on their function, which includes Buddhist temples, Confucian schools, royal halls (palace), pavilions, shrines, government-managed buildings, residential buildings, and others. The exclusion of residential buildings was due to their high frequency of practical use, resulting in a wide range of styles that do not preserve traditional forms. This study aims to investigate the characteristics and limitations of the floor plan and height of the 238 buildings, including the number of bays, scale, relationship between the core bay (jeongkan) and side bay (hyeopkan), and external and internal heights, as well as to classify them by their function. In traditional Korean architecture, the function of a building plays a crucial role. During the traditional era, buildings were differentiated based on their formality and scale depending on one's social class, [2] which applied not only to residential buildings but also to public buildings such as temples and schools. Previous studies have suggested that the internal spatial structures were modified according to the building's function, not only in terms of scale but also in terms of the arrangement of internal columns to create appropriate spaces. [5]

Upon classifying the floor plans according to their architectural type, the findings revealed that Buddhist temples comprised approximately 45% of the total number of buildings, followed by Confucian schools at 20%, palaces at 10%, pavilions at 11%, shrines at 7%, government-managed buildings at 6%, and others at 1%. These results suggest that Buddhist-related facilities represent a significant portion of the traditional timber-structured buildings in Korea, comprising almost half of the total number of structures examined

3 SCALE OF KOREAN WOODEN TRADITIONAL ARCHITURE

3.1 Composition of Kan

Upon examination of the layout of 238 buildings, it was determined that 92.0% (219 buildings) of the structures adhered to a rectangular shape with perpendicular columns. In analyzing the size of the kan (bay) within these structures, a 3x3 structure with Purin-Direction 3-bay type (front) and Beam-Direction 3-bay type (side) was identified as the most frequent, accounting for 26.0% (57 buildings) of the surveyed structures. The subsequent most common layout was a 3-bay front and 2-bay side structure, which constituted 18.3% (40 buildings). A layout with a 5-bay front and 3-bay side was found in 15.5% (34 buildings), whereas a 5-bay front and 4-bay side layout was present in 8.2% (17 buildings). Structures with a 5-bay front and 2-bay side were discovered in 4.1% (9 buildings). The remaining bay configurations were scarce, with only 1-3 structures per configuration. In summary, the layout with 3 bays along the front was the most commonly found in the survey. [6]

In a prior study, the predominant occurrence of a 3-unit front width (Purin-Direction 3kan) and 3-unit side width (Beam-Direction 3kan) in traditional Korean architecture was attributed to several factors. First, the front width of 3 units was determined to be the minimum unit capable of achieving centrality and serving as the entrance facade of the building [5]. Thus, having centrality was deemed significant. Second, a survey of buildings in 219-dong found that all structures, with the exception of two, had a front width that was either longer or equal to the side width. In the two buildings with a greater side width, the

https://doi.org/10.52202/069179-0569

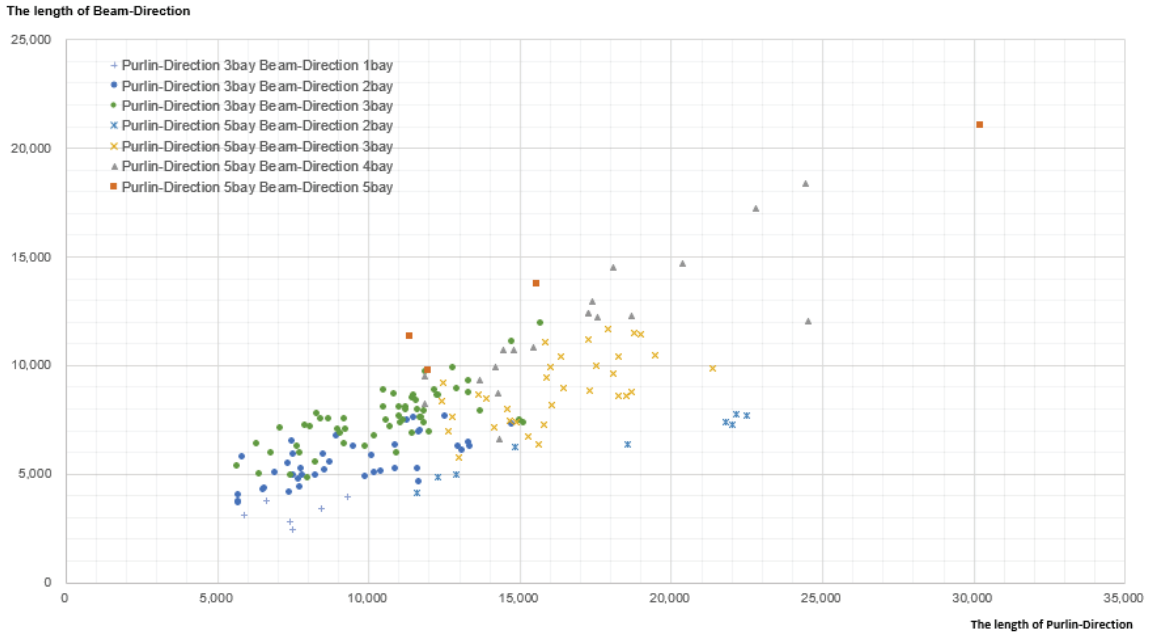

Figure 1 : Kan composition and the length

front-to-side ratio was 0.94 and 0.99, signifying no significant variance in side width. Furthermore, when comparing the widths of the core and side bays in 110 buildings with a front width of 3 units, it was found that the widths of the core and side bay were almost equal in 46% of the cases.[6] In a 3-unit configuration, the core bay (jeongkan) refers to the middle bay, while the side bays (hyeopkan) are located on either side.

In addition, it has been established through previous research that the 3-bay façade represents a fundamental structure in traditional wooden architecture not only in Korea but also across East Asia [5]. The recognition of this structural element has been preserved through generations and continues to be employed in contemporary design. For instance, the Korean pavilion at the Montreal Expo '67 was designed with the intention of linking tradition and modernity through the use of this architectural feature [8]. Notably, this fundamental structure has remained steadfast in its traditional essence.

In Chinese architecture, the importance of frontality has also been widely recognized. This can be observed in the design of the great hall (大殿) at the Foguang Temple (佛光寺) during the Tang Dynasty, where the core bay (當心間) was enlarged by widening the gap between the columns relative to the other bays [4].

In traditional East Asian architecture, the standardized wooden structures require joints that restrict the expansion of space in the beam direction due to the size of the wooden components. As a result, the scale and structure of buildings are limited. The longitudinal direction, on the other hand, represents 44% (94 buildings) of the total, with the majority consisting of three bays. The maximum number of bays found in the longitudinal direction is five, with nine buildings exhibiting five bays on the side. All of these are classified as the highest level of Korea's traditional cultural heritage classification system, as national treasures or treasures, indicating their high hierarchy and scale.

3.2 Scale of Kan

Research was conducted on the relationship between the length of the purin-direction and the beam-direction in various bay configurations, including 3X1 Bay(purin-direction 3bay and the beam- direction 1bay), 3X2 Bay, 3X3 Bay, 5X2 Bay, 5X3 Bay, 5X4 Bay, and 5X5 Bay. The most commonly utilized floor plan, the 3X3 Bay configuration, exhibited a purin-direction length ranging from 5.6m to 15.7m (with a median value of 11.2m) and a beam-direction length ranging from 4.8m to 11.9m (with a median value of 7.5m). It was observed that for small-scale planning, the kan were combined in 3X2 Bay due to the shorter length in both directions compared to the 3X3 Bay configuration. For even smaller-scale planning, while the number of cases was limited, it was found that the 3X1 Bay configuration was combined.

In cases where there was a demand to expand beyond the 3X3 Bay configuration, it was observed that the 5X3 Bay configuration was commonly utilized. For the 5X3 Bay configuration, the purin-direction length ranged from 12.4m to 21.4m (with a median value of 15.9m) and the beam-direction length ranged from 5.8m to 11.7m (with a median value of 8.8m). As the front bays expand in size, it is expected that the overall scale of the structure will increase. However, it is noteworthy that even with only 3 bays in the side, the resulting structure can still possess a significant length.

In matters for significant increase in scale, 5X4 Bay was adopted. Even compared to 5X3 Bay, which had the same 5 cells in the front, it is evident that a rapid expansion of the scale was achieved in both the purin and beam directions. The purin-direction length ranges from 11.9m to 24.5m (with a median of 17.3m) and the beam-direction

https://doi.org/10.52202/069179-0569

length ranges from 8.3m to 18.4m (with a median of 12.1m).

The 5X2 Bay floor plan exhibited a variety of front length distributions, while the 5X5 Bay floor plan had a unique combination of longitudinal and latitudinal lengths similar to the Geunjeongjeon Hall in Gyeongbokgung Palace. However, compared to floor plans with 3 or 4 bays in the side, no significant expansion of the scale was observed.

3.3 Distribution of Heights by Kan Composition and Building Function

The height of buildings has been classified into three categories and measured accordingly. Initially, the height perceived from the outside of the building, which includes both the body and roof, was determined. The measurement criteria were based on the distance from the stylobate (gidan) to the roof ridge (yongmaru). Subsequently, the interior height of the building was measured, taking into account whether a ceiling was present or not. In cases where no ceiling was present, the height was quantified from the floor to the top purlin, which is typically perceived as the maximum height of the building. Conversely, where a ceiling was present, the height was measured from the floor to the ceiling, which is assumed to be the element that people perceive as the maximum height of the building and detect the sense of space. In cases where multiple ceilings are present, the height was determined based on the highest ceiling.

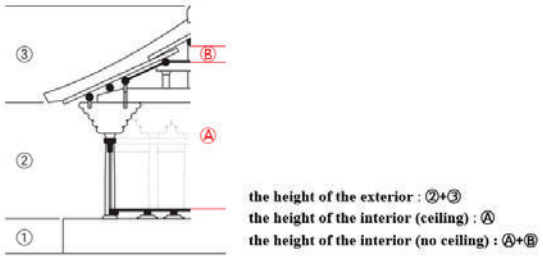

Figure 2. Standard for determining the height of a building.

The relationship between the height of the building and the use of the building was examined. The numerical values were analyzed using the median. For the height outside the building, the values were recorded in the order of shrine, Confucian academies, Buddhist temples, palaces, and governmental buildings. In terms of internal height, in cases where there was no ceiling, ancestral shrine buildings (3,666mm) and school buildings (4,753mm) exhibited a height of approximately 4 meters, while government buildings (5,411mm), Buddhist buildings (6,425mm), and residential buildings for noble families (6,898mm) showed a height of 6m. The palace recorded the highest value of 8 meters. For cases where there was a ceiling, the internal height was recorded as follows in descending order: residential buildings for noble families (3,034mm), school buildings (4,132mm), ancestral shrine buildings (4,452mm), the palace (4,978m), Buddhist buildings (5,635mm), and government buildings (6,788mm).

The median of the palace, which had the highest recorded values for outside height and inside height without a ceiling, was unexpectedly smaller than anticipated. This can be attributed to the significant difference between the minimum (4,413mm) and maximum (8,483mm) values. Among various types, palace buildings recorded the highest value for inside height with a ceiling, with the Deoksugung Junghwajeon (8,483mm) being the maximum recorded value. Conversely, the Sunwonjeon, a shrine building dedicated to ancestral worship located within the Changdeokgung Palace compound, has been recorded to have the minimum interior height. Despite being classified as a palace, its use as a sacrificial space within the palace accounts for its limited vertical elevation. Notably, shrine buildings tend to exhibit comparatively lower height values when classified by function.[9]

The composition of the kan and the distribution of heights by building function suggest that higher-ranked palaces and Buddhist buildings tend to have taller structures. Specifically, in the case of purin-direction 3 kan, Buddhist buildings displayed the highest heights irrespective of the type of beam-direction. For the most prevalent form of 3x3 kan, the heights of Buddhist buildings ranged from 9.2m to 20m, with an average height of 15 meters. Meanwhile, in the case of purin-direction 5 kan, both Buddhist and palace buildings demonstrated higher values for height compared to other building types. For a 5x4 kan, which is typically employed for large-scale expansion, the increase in height was significantly greater compared to a 3x3 kan. The average height of Buddhist buildings was 18.8m, whereas the average height of palaces was 17.7m. This represents an increase of approximately 3-4m in comparison to the 15m average height of a 3x3 Buddhist building.

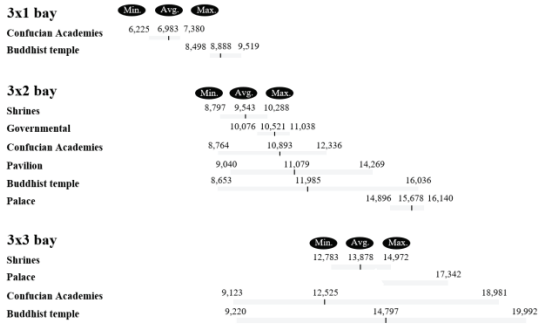

Figure 3: Height Distribution by Building Function with purin-direction 3 kan

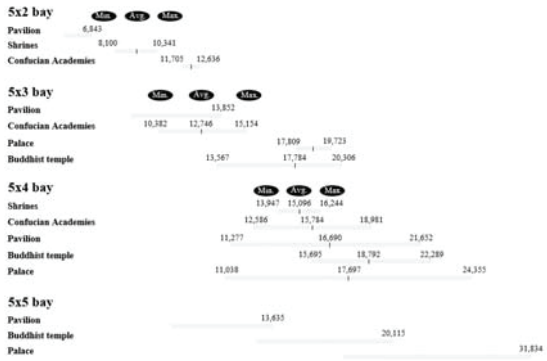

Figure 4. Height Distribution by Building Function with purin-direction 5 kan

https://doi.org/10.52202/069179-0569

We analyzed the relationship between composition and scale of kan and heights as a key element of the floor plan and section plan in traditional wooden architecture.

Considering the characteristic of purin-direction kan with a strong symbolic meaning and the side bay with a strong structural meaning, [5] the relationship between the height and purin-direction kan, height and beam-direction kan were analyzed respectively.

Upon data analysis, in the case of purin-direction kan, when the scale increases from 3 to 5 kans, the median showed a difference of about 3.8-6.6m. However, the difference in height is narrower, ranging from 3.8-4.7m.

In contrast, for beam-direction kan, an increase in size from 2 to 3 kans resulted in a difference of 2.2-3.6m, and when increased from 3 to 4 kans, the numerical difference was recorded to be 1.9-3.3m, indicating that the range of numerical values was not significantly large. Thus, it can be concluded that while purin-direction kan exhibits greater flexibility in scale expansion, there are limitations to the expansion of height and beam-direction kan.

4 Limitations of Planar Structures and Expansion

4.1 Scale and expansion of plan

Traditional East Asian architecture employs standardized wooden structures, which allows for expansion in the purlin direction by connecting wooden pieces. However, expansion in the direction is limited due to the standard size of wooden beams, resulting in limitations on the structure and size of the building. In Korean traditional architecture, expansion in purin-direction(front) can extend up to 19 kan, while expansion in the beam-direction(side) is limited to a maximum of 5 kan.

The existence of large-scale expansion in the front direction in Korean architecture may be attributed to the pursuit of frontality, despite its cluster-like characteristics. Moreover, expansion may occur for functional reasons when a large space is required even for a single building. An example of such expansion can be seen in the Jeongjeon building at the Jongmyo Shrine, a national treasure that exhibits an overwhelming front length of 70m and side length of 14m with 19 kan in the front and 4 kan in the side. This large space was created to accommodate the functional space required for the addition of royal funeral tablets.

Figure 5. the façade of Jongmyo

On the other hand, the expansion of buildings in the side direction is limited to a maximum of 5 kan, resulting in a total of 9 buildings in Korean traditional architecture with such a design feature. Of these, the buildings with five bays on the front are the Bulguksa Temple Daeungjeon Hall in Gyeongju(cultural assets designated as treasures), the Kangnung Gyeongpodae Pavilion (Treasure), and the Geunjeongjeon Hall in Gyeongbok Palace (National Treasure). The buildings with seven bays on the front are the Gyeonghoeru Pavilion in Gyeongbok Palace (National Treasure) and the Gakhwangjeon Hall in Gu-rye Hwaeomsa Temple (National Treasure), both of which are main halls in Buddhist temples. Next, the buildings with five bays on the side and nine bays on the front are the Sebyeonggwan Guest House in Tongyeong (National Treasure), and the buildings with eleven bays on the front are the Huwonjeong Hall in Changdeok Palace (Treasure). Finally, one building has fifteen bays on the front, which is Guest House in Yeosu (National Treasure).

The lateral span of the beams in the beam-direction, consisting of five kan, is characterized by a broad distribution ranging from a minimum of 9.8m at Gangneung Gwanryongnu Pavilion to a maximum of 28.2m at Gyeonghoeru Pavilion in Gyeongbokgung Palace, with an average length of 16m. The column-beam construction method exhibits a structural limitation in terms of extending the length of the beams. Furthermore, the employment of wooden beams is subject to constraints on the maximum length, as even the most massive trees fail to exceed 20m in length. Typically, the beam spans in the beam direction do not surpass 10m, with a majority of structures being limited to lengths of 5-6m. [10]

4.2 Scale and expansion of height

When examining the utilization of large-scale buildings, it can be deduced that practical necessities, such as the requirement to accommodate numerous individuals and the inclusion of guest quarters, prompted the construction of sizable structures rather than a desire for scaling up a singular building. The dimensions and elevation of the lateral bays are contingent upon the number of rafters and the limitations of the beams. The purlin framework, referred to as ryangga, was analyzed to ascertain the height of the edifice based on the dimensions of the ryangga. Concerning the external height of the building, the average height of 3 ryang was 7,955m, 5 ryang was 14,170mm, 7 ryang was 17,907mm, and 9 ryang was 18,675mm, illustrating a correlation between an increasing height and an expanding size of the ryangga. Nevertheless, it was observed that the height discrepancy between 7 ryang and 9 ryang was merely around 0.8m, which is an insignificant difference. In the case of buildings without an interior ceiling, the height also increased proportionate to the dimensions of the ryangga, and the gap in height between 7 ryang (8,439mm) and 9 ryang (9,447mm) was approximately 1m, but the disparity between 5 ryang (6,474mm) and 7 ryang was approximately 2m, signifying an increase in the magnitude of the difference. The height of structures with an internal ceiling followed the same pattern. In conclusion, a substantial association between the size and height of the ryangga is apparent, and the relatively minimal height difference between 7 ryang and 9 ryang suggests that the dimensions of the ryangga were not a

https://doi.org/10.52202/069179-0569

significant consideration when designing the furniture structure.

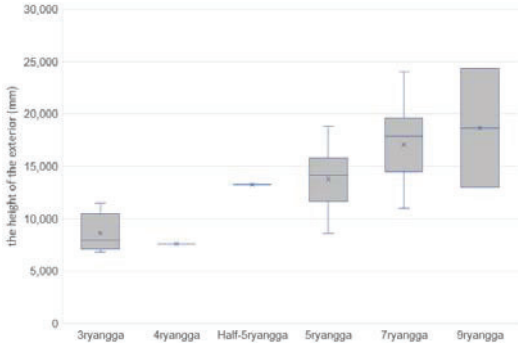

Figure 6. The relationship between the ryangga structure and height

Regarding the limitations of column components, the expansion of building height is also subject to such constraints. When assessing building height across different historical periods, the median height was found to be highest during the late Chosun era, measuring 13,947mm, followed by the Goryeo period at 13,234mm. During the Chosun period, building height tended to increase progressively from the early to the middle to the late period. The difference in height between the middle (13,843mm) and late (13,947mm) periods of the Chosun era was minimal, whereas the transition from the early period (11,008mm) to the middle period resulted in a substantial increase in height. Over time, the column component played a critical role in determining building height, and efforts to raise height through bracket sets (gongpo) became evident. An analysis was conducted on the trend in the height of columns and bracket sets (gongpo) over time. When examining the median height trend of the interior height of buildings without ceilings, there was no notable change in the absolute height of the column. However, the height of bracket sets (gongpo) component exhibited an increasing trend during the late Chosun period.

Concerning the interior height of buildings with ceilings, the column height displayed a declining trend during the late Joseon period, while the height of bracket sets (gongpo) component showed an upward trend as the Chosun era progressed from the early to the middle to the late period. In conclusion, it can be deduced that, as the Chosun period advanced into the later periods, the adjustment of bracket sets (gongpo) for height became a more significant consideration than column height.

5 CONCLUSION

Traditional Korean wooden architecture permits unrestricted expansion along the purlin-direction, enabling buildings to extend up to 19 kan (approximately 32 meters) in length. However, the expansion in the beam-direction is constrained to a maximum of 5 kan (approximately 8.5-23 meters) due to the structural limitations of the side walls. Many traditional Korean cultural properties reflect this maximum length of 5 kan. Similarly, the height is also restricted to around 19 meters due to the length of the column and their connection with the side walls. While attempts were made to increase the height to some extent as time progressed, owing to the addition of columns and bracket sets, it can be surmised that there was limited interest in expansion, as evidenced by the minor differences in height between the 7 and 9 kan structures.

In traditional Korean wooden architecture, similar to Chinese and Japanese architecture, there were clear limitations on the scale of buildings, particularly in terms of lateral expansion, with a maximum length of 5 kan. In China, traditional architecture never expanded beyond a certain point and remained at a consistent level, with the maximum front length in Tang-era architecture being only 11-13 kan and depth limited to 5-6 kan. The Taehwajeon of the Qing palace is the largest surviving single-story wooden structure with a front length of 11 kan and depth of 5 kan [4]. In Japan, there was a period when lateral kan counting was not present, indicating a lack of concept for depth in ancient Japanese architecture [7]. Unlike China and Korea, which recognized maximum lengths of 6 and 5 kan, respectively, Japanese architecture shows many examples of traditional buildings with a maximum lateral length of 7 kan, including the Kondo of Todai-ji Temple. This can be attributed to not only differences in recognition, but also differences in the sophisticated wooden structures required to achieve larger scales and heights in the three East Asian countries. A detailed comparison of these differences requires further research.

COMPARATIVE RESEARCH OF SINGLE-FAMILY HOUSING CONSTRUCTION SYSTEMS BY CONSTRUCTION COST USING STRUCTURAL WOOD AND OTHER MATERIALITY

Carlos Kahler[1], Janina Gysling[2], Daniel Soto[3], Wilson Mejías[4], Francisco Jiménez[5], Carolina Molina[6]

ABSTRACT:

The wood construction massification in Chile has been considered in the last years as a strategic axis in forestry, and environmental policies, considering that this is a forestry country, the remarkable environmental contribution potential the use of this material has, and the necessity of reducing the housing deficit.

In order to evaluate the development feasibility of a massive housing wood construction, with higher quality standards than the ones traditionally used, a comparative analysis is conducted in terms of construction costs based on 4 constructive systems: wood framing, post and beam construction system, galvanized steel, and confined masonry.

The wood frame system is presented as the most competitive mainly due the wall, and roofing final cost, but also in the carcass work final cost; it is also more competitive in the construction final cost, but here the gasps are reduced. All evaluated systems have budgets that may be eligible for state subsidies.

Among the keys to improve competitivity in wood construction is the diversification of lengths, and dimensions in structural products supply. In relation to the post and beam system, traditionally associated to higher value, and size, it is concluded that is possible to develop delimited footage projects, with low cost, which also allows a greater use of the system advantages in terms of the possibility to modify the house internal distribution.

KEYWORDS: wood construction; construction system costs; lumber dimensions.

1 INTRODUCTION

In Chile, the authorized area of new housing constructions that used wood as a predominant structural material reached only 12.9% of the authorized housing area at national level in 2019 [1]. This participation of wood is in contrast with others wood-producing countries, where the participation of this material exceeds 80%, as in case of United States, Canada, Finland, and others [2].

The wood participation in the Metropolitan region housing construction, which is where the present research is focused on, reached in 2019 only 1.3% of the authorized area in the housing building permits [1].

In recent market researches carried out by INFOR [3], several construction materials demanding actors recognize the value of wood in terms of thermic, and acoustic insulation, seismic performance, and construction, and products costs. But they also claim a low valuation in durability, fire resistance, structural features, and clients' perception.

To promote wood housing construction, especially in those regions far from forest resources, a lack of wood construction culture, and where this kind of houses are perceived as a low-cost option, but with poor quality, it is necessary to promote proper construction systems, based on structural graded timber products. On the other hand, it is necessary to clear up doubts in terms of feasibility of the use of quality structural timber, with accessible construction costs for mass population, which in great proportion make use of state subsidies.

Currently, an important opportunity is being presented to promote wood construction massively in Chile, since the Ministry of Housing, and Town Planning has applied a Housing Emergency Plan, which aims to resolve during the 2022-2025 period, at least 40% of the current housing deficit, calculated in 643.000 dwellings. This means that the goal of this period is 260.000 dwellings, from which 135.590 corresponds to new works, and 124.410 are under construction [4]. In this plan, is expected that wood starts to play a fundamental roll as a structural material. Due to the short deadlines established, it is suggested that a great part of this wood housing demand to be develop through industrialized construction. However, companies that work with these systems are recently created, and with limited capacity, so the challenge should be approached by working together with traditional construction onsite, and industrialized construction. The present research focus on the background related to the former type of construction, with the aim to incorporate in this process the small, and medium size construction companies, as well as the small, and medium size sawmill industry.

This research is approached with the purpose of evaluate costs structures, feasibility in choosing massive construction alternatives in accordance with Chile being a forestry country, and with the challenges the climate crisis brings.

The analysis is based on recent research carried out by the Area of Information, and Forest Economics' professionals, in coordination with an architecture company with a vast experience in volume calculation, and in average value, single-family housing construction projects, using different materials [5].

2 MATERIALS AND METHODS

The construction costs of four construction systems are evaluated, these systems use different predominant structural materials: wood frame (in two models, with different dimensions), wooden post-beam, steel frame, and confined masonry. These construction systems are defined hereunder.

a) Wood frame system: a frame is a constructive disposition based on the use of linear structural members, combined in different positions to build structural elements [6].

A partition is a vertical frame constituted by two posts located at short distances (between 0.30, and 1.0m) jointed by their edges with horizontal, or inclined members.

The most frequently used framing systems, since they are more cost effective, are characterized by the supporting function of the majority of their partitions that jointed together constitute the whole system, these are simple systems with butt, and nailed joints.

In the present research, two models of this construction system have been considered: framing with 2x4 members, and 2x6 members framing.

b) Post-beam system: it is constituted by horizontal, vertical, and inclined members connected one to another. They transmit the static, and dynamic loads from beams to posts (pillars), and then to foundations. It is characterized by using big dimensional, and/or laminated timber, allowing greater distances between posts.

The constant technologic development in construction materials has allow this construction system to be highlighted by its architectural features, in accordance with the modern architecture concepts. However, it is important to note that this type of solutions is not applicable in dwellings with state subsidy, basically because of its high cost. [7].

c) Steel frame: this construction system follows the same concept as the frame system aforementioned, since for its execution, linear structural members are needed, which are combined in different positions to build structural elements.

This construction system consists in light steel profiles that provide horizontal, and vertical structural solutions, partition walls, and roofing structures.

d) Confined masonry system: This construction system is constituted by reinforced concrete elements, posts, beams, and chains which completely frame brick walls. This may be executed with handmade bricks or industrialized bricks, and different materials like a clay, or aerate concrete blocks, among others. Mortar is used in brick laying.

In the first methodological phase, a general architectural model is defined upon which this research is based on, allowing a cost comparative analysis for all of the construction systems to be developed. The architectural model considers a construction area of 80 m², which represents the average declared values in building permits in 2019 [8]

The base model presents the following architectural planning:

- Living-dining. Useful area: 27 m^2
- Kitchen. Useful area: 8.06 m^2
- Room 1. Useful area: 11.53 m^2
- Room 2. Useful area: 9.05 m^2
- Room 3. Useful area: 8.25 m^2
- Bathroom. Useful area: 4.34 m^2
- Hallway. Useful area: 3.42 m^2

It should be noted that the indicated useful areas, which in total amounts to 71.65 m², are referential, since dimensions can change depending on walls thickness in each construction system.

As a part of the model's design definition, it was decided to consider a spread footing, and concrete ground in all cases. While it is true that the majority of the evaluated systems in this research can be executed with isolated footing, and flooring frame, it is also true that the

foundation system, and the selected concrete base represents the country's predominant preference, basically due to cultural reasons [8]. This decision can go in detriment of systems that do not require them, but the finishing standards make this definition advisable.

As dwelling location, the commune of Santiago, in the Metropolitan region, has been considered. This region is by far the main housing demand center in Chile, representing 43% of the authorized dwellings in 2019, and 45% of the new works area. However, it has a low wood construction participation at national level, representing only 3.6% of number of dwellings, and 4.6% of the authorized housing area that uses wood as a predominant structural material in walls [9]

In a second phase, and counting on the base design, a particular structural, and architectural design was developed for each alternative, considering the features of each construction system, and trying at the same that they all share, where possible, the same useful footage, window dimensioning, and finishing materials. The suggested designs are in compliance with standards required by *La Ordenanza General de Urbanismo y Construcción* (OGUC) in relation to inhabitability, and safety.[10]

In the volume calculation process, the amounts of projected materials for each model in the corresponding unit of measure are quantified. The budgetary process continues with the development of a Unit Price Analysis (APU) for each model, where each item is identified and quantified, considering for that purpose the market value prices, and recognized suppliers in the construction industry. The APU analyses incorporate all the variables included in the execution of every item, like cost of materials put in work, workforce costs, and performance, tools, equipment, operational costs, and contractor's utilities. With APUs results, budget itemized tables were created for each model, whose final sum determines the construction direct cost, which includes general expenses, utilities, and taxes.

3 RESULTS

3.1 TECHNICAL SPECIFICATIONS OF SUGGESTED MODELS

According to the research objectives, the differences in design of the five construction models suggested are concentrated in carcass stage, and in particular, in the structure of exterior, and interior walls. To identify the cost gaps among structural materiality, foundation proposals, quality roofing, and finishings, and equivalent designs were formulated.

a) Carcass specifications

Vertical structures of walls, and partitions proposals

In case of the wood framing models suggested, vertical partition is assembled out of 2x4" sized impregnated pine posts (IPV) for the first model, and 2x6" with C16 structural grading (according to European norm) or similar for the second model. The distance between 2x4" posts is 40 cm, and 60 cm in case of 2x6", in both cases dimensions are the same for inferior, superior, and stick framing sills, and bridging. The members are dried to a moister content of 15%. The members length are 3.2 meters for 2.4" dimensions, and 4.8 meters in case of 2x6".

In the wooden post- beam model, structural posts should be laminated of 115x115 mm in members of 2.7 meters long. The anchoring will be executed with dawer inserts in stem wall, and lateral metallic connectors. It contemplates the use of structural double tee pine beams of 2x6" with C16 structural grading or similar, dried in chambers to a moisture content of 15%. Structural, and non-structural vertical partitioning uses pine IPV 2x4". The anchoring in the concrete ground is executed with expansion bolts, and posts, and beams with drywall screws.

The design suggested to the steel framing profiles model considers the use of vertical partition (perimeter, and structural) conformed by structural studs of 90x38x12x0.85 mm type. In case of inferior, and superior sills, a channel profile of 92x30x0.85 mm is used. Capping beams are considered for partitioning bearing the load from roofing, which are conformed by two studs, and a channel profile of the same type aforementioned. All the structural, and/or perimeter partitioning should be coated in the outer side with OSB panels of 11.1 mm thick.

The model suggested for confined masonry considers the use of reinforced-concrete pillars. The ironwork has 4 ribbed steel bars of 9.2, or 10 mm long, with 4 ribs every 20 cm. It will be used reinforce concrete bridging and beams with the same dimension as stem wall, as well as its ironwork. The partitioning walls will used pine framework IPV of 2x4" in all its elements.

Foundation proposals

For all framing models, a reinforced-concrete spread footing system is proposed in their perimeter axis. The stem walls correspond to reinforced-concrete chains of 15x30 cm. The stick framing beams considers the same dimension, and ironwork.

In case of confined masonry, a reinforced-concrete spread footing foundation is proposed in its perimetral axis, as well as in interior structural axis. This aspect is presented as a significant difference with the aforementioned models. The vertical structure load suggests foundations to transmit the load to the floor in all of its extent. Stem walls corresponds to the same stem wall proposed in the previous reinforced-concrete pillars of 15x30 cm.

For all proposed models, it is considered for concrete ground sub-bases the use of aggregates in different sizes compacted in layers. In the different models, it is proposed

https://doi.org/10.52202/069179-0570

the construction of a reinforced-concrete ground of 9 cm thick.

Roofing structures proposals

For the three models based on wood as a structural material, as well as to confined masonry model, it has been considered a roofing structure formed by 1x4", and 2x4" IPV sized pine trusses. Above them, dry pine rafters of 1x4". It is proposed the use of a base cover in OSB of 11.1 mm, and a steel roofing sheet of the product called "PV6 zincalum"

The model based on galvanized steel profile structures presents a roofing structure conformed by trusses set up with studs of 90x38x12x0.85 mm, in case of superior, and inferior webs, and king post, and stud profiles of 60x38x0.85 mm in case of diagonals. Above them, rafters made with structural omega profiles of 38x35x0.85 mm. In a similar way of the rest of models, a OSB cover base of 11.1 mm thick, and a PV6 zincalum steel sheet covering is suggested.

b) Finishing specifications

As flooring finishings in all models, it is suggested the use of porcelanato floor of 60x60 cm in all surfaces, and baseboards of the same material, in all spaces except for the bathroom. For all models it is proposed the use of PVC (Polyvinil chloride) thermal panels in windows.

As interior walls coating for models based on wood, and steel structures, it has been considered the use of gypsum wall board of 15 mm, and moisture resistant gypsum board for dry, and humid areas respectively. For the confined masonry model, it is contemplated in interior walls the use of stucco, and refining in dry zones, and for bathrooms only stucco as substrate for coating.

For interior walls it is used an insulation product: a mat-like polyester fiber, or technical equivalent in compliance with the corresponding Chilean norm. This type of insulation is suggested for all models.

It is proposed the use of EIFS (Exterior Insulation, and Finishing System) exterior cladding. For its installation, OSB boards from the vertical structure will be provided with waterproof coating, then polyester plates of 30 mm thick are assembled using a special elastomeric sticky paste. For finishing, it is considered the placement of a glass-fiber mesh in continuous strips using the same paste used to assemble polystyrene plates. Special granulated painting will be applied. It should be noted that this solution is presented as a finishing after the coating, erasing thermal bridges that could be present in partitions, and/or walls. [11]

In case of confined masonry model, the EIFS exterior cladding is suggested. The application of this system is similar to previous cases, but the waterproofing of OSB panels is replaced by adhesive bonding previous to polystyrene placement.

3.2 COST ESTIMATION AND GAPS

In the design proposals for different models, it was decided to develop medium-high standard solutions, in finishings, installations, and other carcass work elements such as roofing, and its base. Nevertheless, the budgets obtained can be perfectly eligible for state subsidy.

The results present final budgets ranging from US$636.4/m², to US$672.2/m², for 2x4" wood framing model, and the wooden post-beam model respectively. This represents a gap of 5.6% (Figure 1).

This result was expected since the post-beam system is frequently associated to high-standard solutions. What is remarkable is there is no significant differences in terms of costs, but it does represent important architectural advantages in terms of interior design modification, in respect of distribution, and area dimensions.

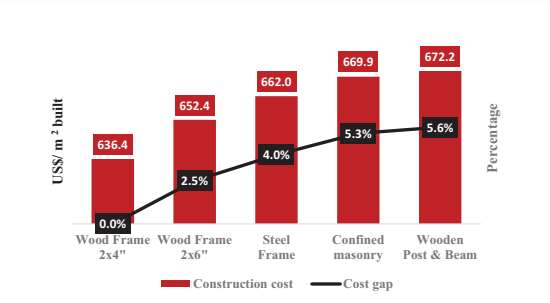

Figure 1: Final cost of construction per square meter built by model, and costs gaps.

Another interesting result is the margin difference of 2.5% between the two frame work alternatives, being the 2x6" framing the most expensive alternative. In 2x6" framing cost, the unit cost of the member used is three times superior to the 2x4" impregnated pine. The dimensions found in the market play an important roll in lowering differences in prices. The length of the 2x6" (4.8 m) allows a better use, generating scraps of only 30 cm, while in case of 2x4" member, (3.2 m) it generates scraps of 95 cm. To the better-use factor of 2x6" members, it is added the lower number of members required, due to its greater dimensions, and more distance within the frame, at the same time improving the performance in construction since there are less unions to be used.

Given the marginal cost difference of the 2x6" framing, in relation to the 2x4" framing, the evaluation of both models can be seen more as an appreciation, and comparison of these structures. Considering that the appreciation corresponds to a subjective valuation, it is assumed that clients tends to prefer more stable, and robust constructive solutions, therefore the 2x6 framing solution becomes more attractive since it presents partitioning of 18cm, which are similar to masonry walls with stucco in both faces.

The galvanized steel alternative also presents advantages in offers in terms of dimensions, with a variety of products in the market of 2.4;2.5;3.0; and 6.0 meters long.

Both wood frame models are presented as the most competitive in budget, in relation to other models using different materiality as in case of steel framing, and confined masonry. The latter is the only one who is not qualified as a dry construction, which increases execution deadlines, and project delivery.

When analyzing the cost structure of main items for each system, it is possible to verify that, due to the high, and homogenous finishings standards proposed for different projects, the cost for this concept is very similar to carcass work's, even surpassing it in case of the three models that use framing whether in wood, as well as in steels profile.

In short, big gaps among models occurs in structural cost related to carcass work. Thus, in construction of wall structures, gaps reach a maximum record of 49.8% between 2x4" wood framing model, and the wooden post-beam model, and a minimum record of 11.6% between the same 2x4" framing model, and the steel framing model. However, the maximum gap drops to 32.1% when considering the wall, and roofing as a whole, and it attenuates in 13.3% when considering the whole carcass phase. It should be highlighted that when comparing the wall structure costs, the steel framing has less costs than the 2x6" wood framing, advantage it loses when adding roofing structures, where reinforce steel has the highest cost from all the other models (Figure 2).

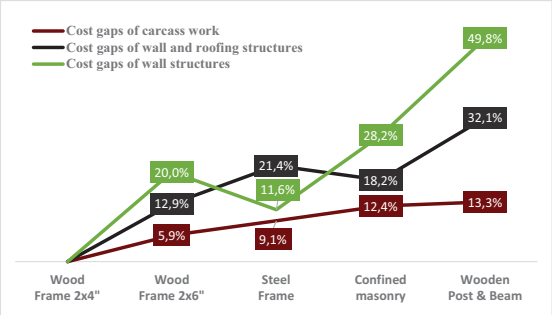

***Figure 2**: Cost gaps by construction system, and project's key phases*

4 CONCLUSIONS

It is concluded that wood framing systems are competitive in relation to the use of systems based on other materials.

The estimated budgets for three wood construction models revels that it is possible to move to better standard housing projects than to the traditional ones, with prices that may be eligible for state subsidy.

This research has proved that the initial impact when comparing the unit values of analyzed wood members (2x4", and 2x6") is mitigated with design, greater use of members in works, and operational performance improvements. It is evident that a more diverse supply of products in terms of length, and dimensions, would increase wood construction competitivity.

On the other hand, the research demonstrates that is perfectly possible to incorporate other wood construction systems that may be eligible for state subsidy, and that provides greater opportunities than conventional systems. This is the case of post-beam construction system, which is traditionally associated to higher value, and size dwellings. It emerges that is feasible to develop a delimited footage project, with low cost, additionally enabling a greater use of the structural, and constructive advantages of the system in terms of interior distribution modification. It is also an attractive system for clients, and is appreciated by architects due to the possibilities it offers in terms of space, natural lighting -since it allows big openings-, and also because of the visible presence of wood in greater dimensions.

ACKNOWLEDGEMENT

The present research have been carry out under the framework of the project entitled: *"Fortalecimiento de las Capacidades Tecnológicas del Instituto Forestal (INFOR), para el desarrollo de la Industria Secundaria de la Madera, a través de bienes públicos, orientados al sector de la construcción"*. The project was funded by *la Corporación de Fomento a la Producción* (CORFO).

World Conference on Timber Engineering Oslo 2023

CASE STUDY ON A LARGE-SCALE TIMBER ACADEMIC BUILDING DESIGNED TO ADDRESS CURRENT INDUSTRY CHALLENGES

Javier Fierro [1], Herry Chen [2], Tyler Hull[3], Andrea Atkins[4], Daniel Lacroix[5]

ABSTRACT: The need for more sustainable construction has led to the desire to increase the use of wood materials in our buildings. However, challenges in terms of larger column grids, future design flexibility, and fire resistance have occurred in institutional, commercial, and industrial building types that have hindered mass timber's adoption. This study reviews these challenges and provides insight into the design of a mass timber academic building as a viable design solution. The building creates open-concept and future flexible spaces by taking advantage of several novel structural solutions, while achieving fire resistance requirements. The structural solutions include the long span hollowcore mass timber floor panels for large amenity areas, two flat plate "service towers", and a combination of timber braced frames and CLT shear walls for the lateral system, in order to meet the challenges faced.

KEYWORDS: Academic building, hollowcore mass timber, flat plate, design challenges, design precedents

1 INTRODUCTION

1.1 BACKGROUND

The Intergovernmental Panel on Climate Change has emphasized that global warming needs to be limited in order to avoid the worst effects of climate change and prevent long-lasting changes to our planet [1]. One approach to tackle this global issue is the way in which we build our structures. As per the United Nations Global Status Report 2017, the buildings and construction industry accounted for 39% of global energy-related CO_2 emissions, with 11% embodied in the construction processes and materials [2]. This, combined with the wider availability of mass timber products, has led to a desire to use more sustainable materials, such as wood, in our buildings.

Still, challenges remain in some building types that are hindering mass timber's adoption, in particular, in high-end residential as well as institutional, commercial, and industrial (ICI) buildings[3,4]. Key features of these building types that are challenging and limiting the use of mass timber include:

1. Larger column grids – these buildings often require large, open floor plan spaces;
2. Future design flexibility – the use of these spaces often changes over the building's lifetime;
3. Fire resistance – codes often require non-combustible materials and/or increased fire resistance ratings in these spaces.

1.2 LITERATURE REVIEW

Currently, a limited number of mass timber projects have been able to solve the design challenges faced in ICI and high-end residential structures. These solutions have often involved the use of novel structural systems pioneered or innovated to overcome a specific challenge on a project. Despite the additional analysis and engineering required at the time, these novel systems now serve as precedents to those looking to build ICI and high-end residential structures using mass timber as opposed to conventional materials such as concrete or steel. To illustrate the potential and capabilities of mass timber in ICI and high-end residential structures, a handful of these projects and their innovative solutions are presented.

The four-storey Edward J. Ray Hall at Oregon State University uses a post-and-beam system to meet the owners' requirements for adaptability and the large open classroom spaces [5]. To optimize the CLT thickness, while maintaining the required 9m clear span, the main grid has columns spaced at 3.05m, with glulam beams spanning 9.75m over the classrooms. A 3.05m wide grid with shallower beams is run down the middle of the building to act as a service corridor. This allows services to access any of the spaces between the deeper 9.75m-long beams without having to drill holes through beams, or jog beneath them. The underside of the wood slab is left fully exposed while a 100mm concrete topping is used for lateral design and to limit floor vibration [5]. The post-

and-beam system used in the Oregon State project is depicted in Figure 1.

The four-storey John W. Olver Design Building at the University of Massachusetts (UMass) also consists of a post-and-beam glulam system; however, the slab spans are longer (i.e., up to 8m distance over the open spaces) [6]. The latter was achieved by using a timber-concrete composite (TCC) floor supported by shallower beams spanning the shorter distance between columns.

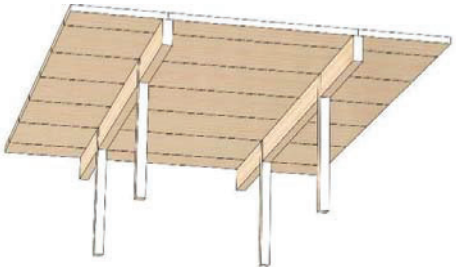

Figure 1. *Post-and-beam system* [7]

Brock Commons, which is located at the University of British Columbia, uses a flat plate system to frame an 18-storey (53m) hybrid mass timber and concrete student residence (Figure 2). The structure includes CLT floor panels that are point-supported on glulam columns; eliminating the use of beams which is highly efficient in framing tall buildings with a smaller, regular grid. The column grid of 4m x 2.85m was chosen to match the maximum available CLT panel size as each panel had to be supported in the corners by columns [8]. Eliminating the dropped beams maximized the future adaptability; however, the column grids are limited by the largest available width of CLT panels, as well as the two-way spanning capabilities of the CLT slabs.

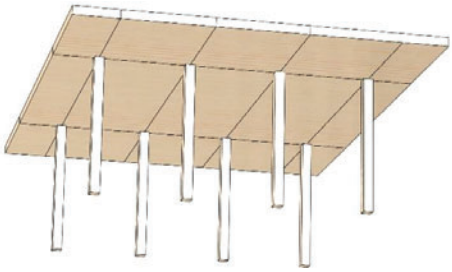

Figure 2. *Flat plate system* [7]

The Limberlost project at George Brown College, also known as The Arbour, uses an advanced structural system aiming to eliminate the use of deep glulam beams. Large flat beams consisting of 2.4m wide TCC slabs are used to support thinner CLT slabs spanning in the opposite direction in a similar fashion to systems employed in concrete parking garages. These wide beams require large "wall-column" supports, of similar width, to prevent the slabs from toppling due to unbalanced loads [9]. This system is shown in Figure 3. Here the wide flat beams consist of a 7-ply (245mm) CLT slab with 150mm of concrete compositely connected to span 9.2m over the open areas to provide flexibility for space planning [9].

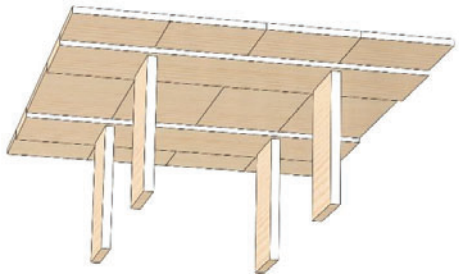

Figure 3. *Wide flat beam system* [7]

With regards to lateral systems, a number of approaches are observed in these projects. Brock Commons and the Oregon State project make use of concrete shear walls for the lateral load resisting system [5,10]. This was attributed to the lack of perimeter beams in the gravity systems, the ongoing development of code guidance on the use of mass timber lateral systems, and the relative familiarity of concrete shear wall systems. The Limberlost project uses steel braced frames, and again, this choice was attributed to the developing code provisions and lack of precedents using mass timber lateral systems as well as the designers' familiarity with steel braced frames. The UMass project was one of the first to make use of a mass timber lateral system. This system incorporates a combination of CLT shear walls and glulam braces [11]. The combination works well together due to their similar relative stiffnesses, and the ability to use shear walls in the vertical circulation core areas while braces are used around the perimeter to allow for openings [11]. In terms of tall structures, the 51m Mjøstårnet building in Norway showcases the use of glulam braced frame trusses along the exterior of the structure to resist wind-dominant lateral loads, thereby eliminating the need for shear walls [12]. With a growing list of building precedents using mass timber lateral systems, as well as ever-growing knowledge and code guidance around these systems, more projects are able to employ mass timber lateral systems including the Origine building in Quebec, Canada, the Candlewood Suites in Alabama, USA, and the Fast and Epp Home Office building in Vancouver, Canada [13–15].

1.3 OBJECTIVES

This case study focuses on a review of the main challenges faced by using mass timber in ICI and high-end residential building types, as well as provides an overview of a large-scale mass timber academic building design in the context of an international design contest. The building design was completed as part of Rothoblaas Build the (Im)possible design challenge, where it was selected as the winner in the academic category [16]. The design approach, along with design solutions to the identified three main challenges, is discussed with the intention of providing architects, engineers, and decision-makers with novel solutions to the design of mass timber ICI and high-end residential buildings, adding to the growing precedent list of these types of buildings.

https://doi.org/10.52202/069179-0571

2 CHALLENGES TO MASS TIMBER IN ICI BUILDINGS

2.1 LARGER COLUMN GRIDS

ICI and high-end residential building types often require large, open floor plan spaces that can challenge the efficient use of mass timber building products. For example, commercial office space frequently demands at least a 9m (~30ft) column grid [17], which is challenging to efficiently achieve using conventional mass timber slab products such as CLT or nail laminated timber (NLT) on glulam beams (e.g., Figure 4). This is primarily due to strict serviceability limits and poor vibration performance limiting the achievable slab spans [3]. To overcome these shortcomings, a common solution consists of using a concrete topping on top of the wood, thereby contributing to a greater slab depth as well as increased total weight of the building. While a beam and purlin system can be implemented to limit the spans of slab products, this leads to deep purlins which can negatively impact the clear floor-to-ceiling height and the ease of running services, as well as causing more "beam shadowing" [7]. For these reasons, a flat slab post and beam system is preferable, if an efficient structural system allows for the long slab spans. Furthermore, in the principal girder span direction, large column grids can also lead to deeper beams that can affect the overall floor-to-floor height and impact the running of building services.

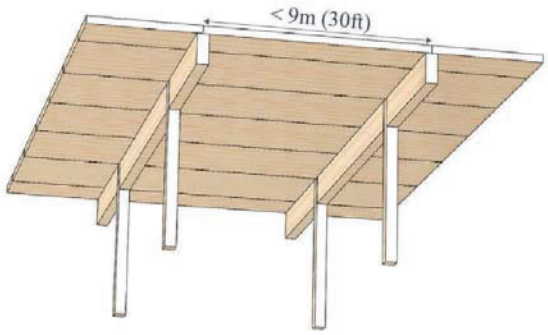

Figure 4. *Flat slab post and beam system [6]*

2.2 FUTURE DESIGN FLEXIBILITY

ICI buildings generally have a longer design life which means that the building, or individual spaces, will likely change occupancy over the lifespan of the building. The need for future-flexible spaces is thus tremendously important in these types of buildings. When combined with larger column grids to create more open-flexible spaces, this often requires limitations on the number of large load-bearing walls and deep beams. An open floor plate thus allows for building services and partition walls to be placed almost anywhere within the space (Figure 5). Therefore, selecting a structural system that allows future flexibility in design plays a key role in the design of ICI buildings.

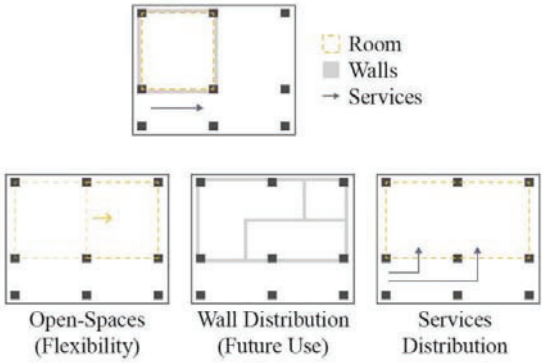

Figure 5. *Design flexibility in ICI buildings*

2.3 FIRE RESISTANCE

Structural members that are exposed to view are not uncommon in ICI buildings, as leaving structural elements exposed often optimizes costs by limiting the number of finishes. Mass timber also has the added aesthetic and biophilic benefits associated with natural materials [18], which often means mass timber building owners want the structure left exposed. However, wood is a combustible material and if desired to be left exposed requires compliance with prescriptive design code provisions, engineering analysis using known charring rates, or more time-consuming "alternative solution" pathways to justify the structure's fire resistance. These extra steps can hinder mass timber's use as prescriptive design codes typically limit how much wood-based materials can be exposed, often varying from jurisdiction to jurisdiction. These exposure restrictions limit the aesthetic and biophilic benefits of using wood-based materials. It is possible to expose nearly all of the mass timber in a structure using the reduced cross-section method (i.e., charring) in the Canadian *Engineering design in wood* standard (CSA 086) [19], as shown in Figure 6. However, this approach can be much more complex and time consuming than simply achieving the required fire resistance through encapsulation of the timber structure in non-combustible materials.

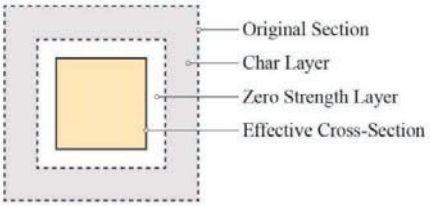

Figure 6. *Effective cross-section for fire design (CSA 086)*

3 CASE STUDY OF ALL-WOOD MASS TIMBER ACADEMIC BUILDING

3.1 OVERVIEW OF DESIGN APPROACH

The proposed design solution is a 7-storey state-of-the-art Mass Timber Engineering Building (MTEB), as shown in Figure 7, that is proposed for the University of Waterloo main campus in Waterloo, Ontario, Canada.

https://doi.org/10.52202/069179-0571

Figure 7. *Exterior render of METB*

The MTEB aims to provide academic and research spaces to nurture research in timber and sustainable construction at the University of Waterloo, promote the adoption of mass timber in ICI buildings and confront the changing climate with innovative new solutions. The building creates 28 000m^2 of multifunctional and future-flexible spaces by taking advantage of several novel structural solutions (Figure 8Figure 7).

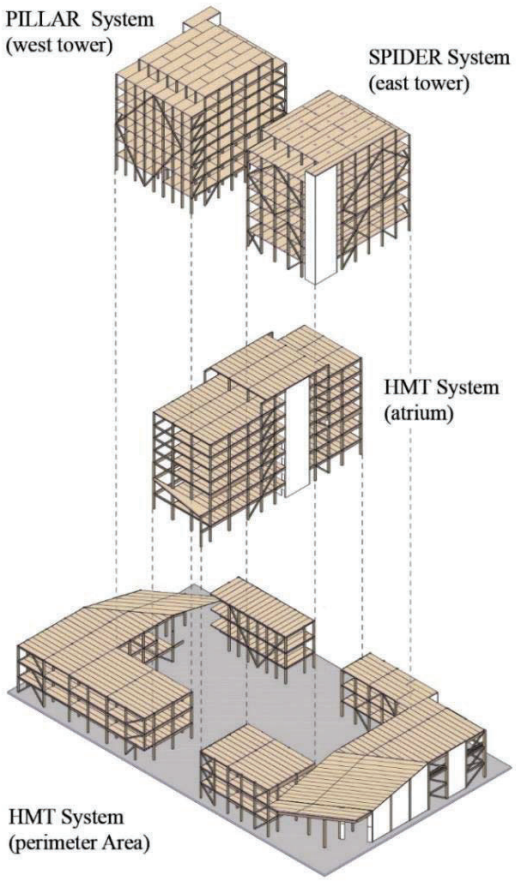

Figure 8. The *MTEB structural system*

Hollowcore mass timber (HMT) panels [20] are used at the perimeter areas and to connect the two towers through a multilevel atrium. Large open space areas, with clear spans ranging from 7-15m are created with the HMT panels. The perimeter structure accommodates lecture halls, workshops, testing laboratories, classrooms, computer laboratories, and a library. The atrium provides a connection between the two towers at each level of the structure and creates gathering areas, event spaces, and access points at the ground level.

Rothoblaas' SPIDER and PILLAR connectors [21] are used to create a flat plate structure in the two towers adjacent to the atrium. The flat plate system, traditionally only achievable with reinforced concrete, takes advantage of the two-way spanning capabilities of CLT to create spaces with tremendous flexibility, where building services do not conflict with beams or load-bearing walls, and partition walls can be placed as desired. For this reason, the towers accommodate spaces that can be distributed in a smaller and consistently repeating grid (5m x 5m and 3.5m x 5m) for small laboratories, meeting rooms, office spaces, etc. The system also allows the two flat plate regions to act as "service towers" bringing services from the centre of the building into the perimeter zone without conflict.

The lateral system uses a combination of braced timber frames, supplemented by CLT shear walls that are used for the elevator and stair cores. The Waterloo lateral design loads are wind-governed, allowing for braced timber frames to be selected for their material efficiency compared to a shear wall system, and to free up the perimeter of the structure of large load-bearing walls, allowing for windows and other openings in the current and future layouts of the space.

The design of the structural system aims to serve the growing demand for space with a flexible design to serve multiple functions, with adaptability considerations for future use. The building form is the result of an optimization of the HMT, flat plate, and bracing systems to obtain an efficient structural design.

3.2 GRAVITY SYSTEM

The structural gravity framing was designed as per the Ontario Building Code (OBC) 2012 [22]. The loading consists of the structure's self weight, superimposed dead loads, live loads, as well as snow and rain loads (Table 1).

Table 1. *Loading summary*

Dead Loads		
HMT Panel (420-740mm)	1.10-1.50	kPa
CLT Panel	0.8	kPa
Live Loads		
Lecture Hall/Mechanical	3.6	kPa
Library*	7.2	kPa
Corridor/Gathering Areas	4.8	kPa
Flexible Space	4.8	kPa
Labs/Other Spaces	2.4	kPa
Snow + Rain Load		
Base	2.0	kPa

*50% considered as long-term loading

Table 2 provides information regarding the material properties for the main structural members from the CSA

https://doi.org/10.52202/069179-0571

086 to provide designers a reference against other international wood design codes.

Table 2. *Material information* [19]

Beams and Slabs			
Material	Grade	F_b (MPa)	E (MPa)
Glulam	SPF 20f-E	25.6	10,300
CLT	E1	28.2	11,700
Columns			
Material	Grade	Fc (MPa)	E (MPa)
Glulam	SPF 12c	25.2	9,700

3.2.1 Hollowcore Mass Timber (HMT) System

The requirements for long-span spaces at the perimeter of the building and atrium area are met using an HMT system. This is a one-way floor system with a fully assembled depth varying from 420mm to 740mm for the 7m to 15m spans achieved. The HMT panel utilizes 3-ply CLT panels for the top and bottom flanges, with glulam beams acting as web members as shown in Figure 9.

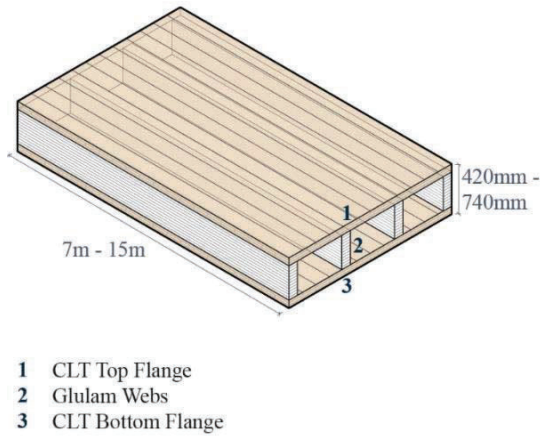

Figure 9. *Hollowcore mass timber panel*

The CLT and glulam can be fastened together using mechanical or adhesive shear connectors in order to provide a partially- or fully-composite section. For this project, the HMT panels utilize shop-glued connections for the bottom flanges and Rothoblaas HD sharp plates for the top flanges (Figure 10a). This allows for the ribbed sections to be interlaced during long-distance shipping, thereby decreasing the amount of "void air" shipped as shown in Figure 10b. The top flanges are attached using sharp plates on site where some services and acoustic treatments can be installed in the void space of the panels (Figure 10c). For shorter shipping distances, the top flanges can also be shop-glued to limit the work required on site. The shear connections play an important role in the degree of composite action achieved between the flanges and the webs. As such, the glued connection and HD sharp plates were deemed optimal as both were able to provide near-fully composite shear transfer.

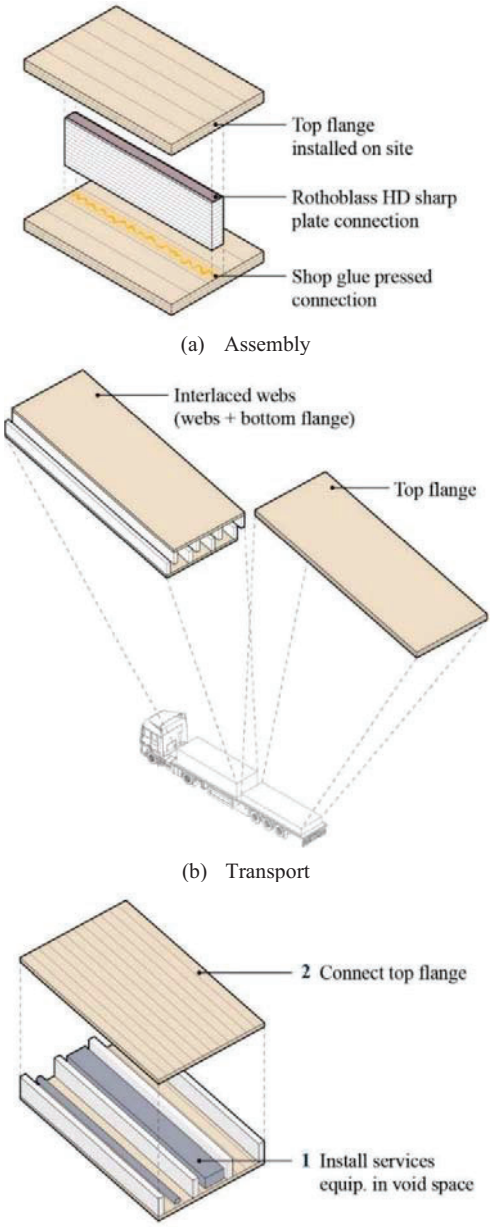

Figure 10. *HMT construction sequence*

The HTM panels are supported by a post-and-beam glulam structure by face-mounting the glulam webs to main beams or columns using flush hangers. Beams typically span seven meters in order to have a depth that is similar to the HMT panel depth, providing relatively continuous headroom clearance. Building services are integrated within a raised access floor system to maximize the overhead visibility of exposed mass timber slabs providing biophilic benefits. A cement board layer is installed between the mass timber slabs and raised floor to meet concealed space requirements and aid with acoustics. The post-and-beam structure using the HMT panels is shown in Figure 11.

3.2.2 Mass Timber Flat Plate Floor System

The seven-storey central towers are designed to engage the two-way spanning capabilities of CLT panels by point-supporting them on glulam columns using the Rothoblaas SPIDER and PILLAR connectors [21]. The flat-plate system eliminates beams which reduces the structural depth, thereby creating a clear ceiling space that allows for easy distribution of building services in addition to the possibility of installing large exterior windows. However, flat plate systems create areas of high shear and bending stresses, as well as compression perpendicular-to-grain, at the support locations. This can lead to high rolling shear stresses in the CLT panel [23]; similar to the punching shear behaviour seen in flat plate concrete structures. The east and west towers use the SPIDER and PILLAR connectors, respectively, to provide adequate reinforcement for punching shear stresses and to bypass compression perpendicular-to-grain caused by bearing on the CLT slabs.

Rothoblaas SPIDER System

For the east tower, a 5m x 5m column grid is created using a 220mm 7-ply CLT, with dimensions of 3m x 15m (width x length), for panels centred over the columns, and 2m x 15m for intermediate panels connected to the column bands using a metal plate and epoxy moment connection as seen in Figure 12.

The SPIDER connector consists of three main components: a cylinder and bottom plate fixed to the column below, the top plate attached to the column above, and the coupling disk and cone to engage the six arms connected to the panel to the steel core (Figure 13) [24]. For aesthetic and fire resistance purposes, the bottom plate is concealed by grooving the column below and the segment of the connector above the CLT panel can be covered with the finished floor.

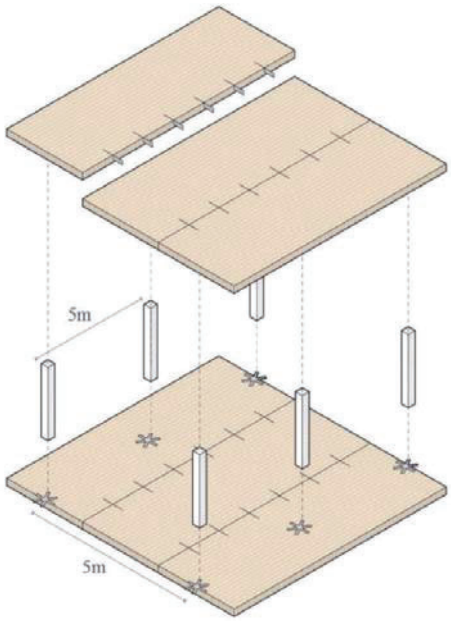

Figure 12. *5m x 5m flat plate grid with spider connector*

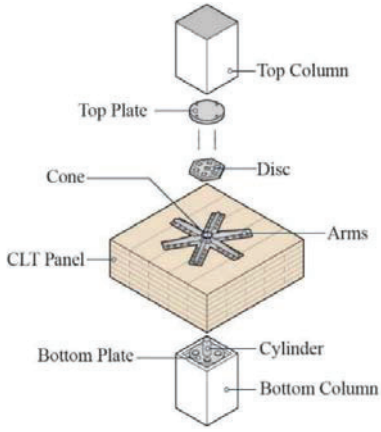

Figure 13. *SPIDER connector components*

To connect the glulam columns to the CLT, the connector (1) transfers the axial load from the column above to the column below through the steel core, (2) resists rolling shear with 45-degree fully-threaded screw reinforcement in its arms, and (3) reduces the concentrated stress at the column below by transferring the slab loads directly to the steel core (Figure 14). Further information can be found in the extensive research performed by Maurer and Maderebner [23] on the mechanical methods and numerical simulations of the SPIDER system to provide engineers with an insightful understanding of the structural response of the connector.

Due to the imposed limit on the width of CLT panels to around 3.5m during transportation, for column grids greater than 3.5m, a moment connection is necessary between CLT panels. In the design, these connections are placed 1.5m from the centre line of the column (Figure 10) to avoid the zones of maximum bending and shear stresses over the column, and the large bending stresses

found at midspan. The manufacturer recommended that the moment connection consist of steel plates that are epoxy-glued into vertical grooves in the top of the CLT panel [24]. The grooves are cut deep enough to ensure positive and negative bending strength while leaving enough wood material beneath to protect the connection from the fire below. Moment connections between panels can also be created using other systems such as TS3's high performance glued butt-joint [25] or metal tension straps.

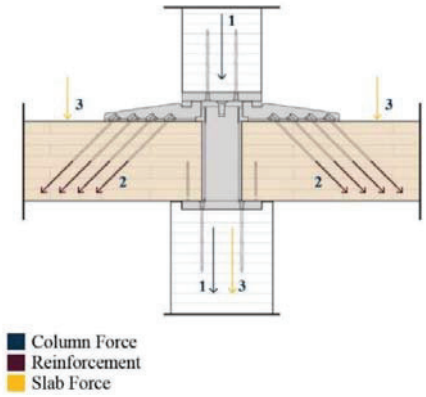

Figure 14. *SPIDER connector mechanics*

Rothoblaas PILLAR System

For the west tower, a 3.5m x 5m column grid is created using a 200mm 7-ply CLT panel with dimensions of 3.5m x 10m (width x length) that are edge- and corner-supported by the PILLAR system (Figure 15).

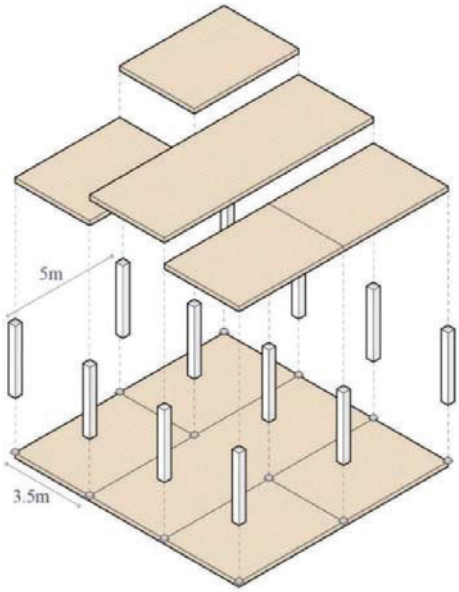

Figure 15. *3.5m x 5m flat plate grid with PILLAR connector*

This connector is a simpler alternative for the smaller column spacing of the west tower, where stresses at the columns are lower. The PILLAR connector also has three main components; the cylinder, bottom plate, and top plate (Figure 16) [24].

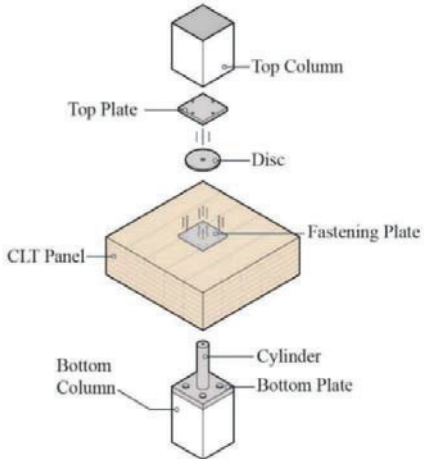

Figure 16. *PILLAR connector components*

The mechanics of the PILLAR connector are similar to that of the SPIDER connector; however, the absence of the arms diminishes the rolling shear and punching shear resistance. The rolling shear and bending resistance, as well as the bearing resistance, are provided by the CLT panel itself, and therefore this limits the maximum column spacing due to the absence of additional reinforcement seen in the SPIDER connector (Figure 17).

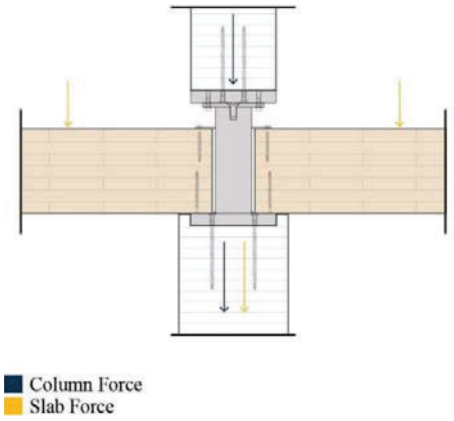

Figure 17. *PILLAR connector mechanics*

3.3 LATERAL SYSTEM

Mass timber buildings are fortunate in having a lower overall weight, and thus reduced seismic demands, but are more susceptible to vibrations induced by wind or occupant loading. Currently, design provisions in the CSA O86 [19] focus solely on the use of CLT as shear walls in platform construction for mass timber lateral load resisting systems (LLRS). Despite not being included in CSA O86 [19], code provisions for braced timber frames (BTFs) are provided for use in low- to mid-rise buildings [26]. The lack of guidance for the design and detailing of BTFs and their connection on the overall system ductility and stiffness has contributed to the limited use on projects. However, ongoing research has contributed to design guides being developed and future iteration of the wood design code to incorporate BTF design [27]. Many

https://doi.org/10.52202/069179-0571

international design codes are similarly limiting with explicit guidance lacking, or novel guidance having recently been added as a result of on-going research efforts [28]. With limited explicit guidance, or designers lacking the most current knowledge base, many opt to fall back to more familiar steel bracing and concrete shear wall LLRS in lieu of pursuing more complex, and possibly 'alternative solution'-based paths with mass timber LLRS. With the goal of demonstrating the viability of mass timber LLRS, the design of the MTEB makes use of CLT shear walls and BTFs. However, these systems can easily be substituted with concrete shear walls (e.g., Brock Commons) or steel braced frames (e.g.., Limberlost).

3.3.1 Braced Timber Frames

Despite including provisions on the design of panel-based LLRS (e.g., CLT and light frame shear walls), the current CSA O86 [19] does not provide explicit guidance for BTFs. However, it is a generally accepted practice that connections can be designed for highly ductile yielding failure modes in order to achieve moderately ductile performance for seismic design [29]. This has allowed BTFs to be successfully deployed in several past projects, such as the Mjorstarnet [12].

In Waterloo, a city located in a low seismic hazard zone, the proposed LLRS for the MTEB consists of braced frames fastened to beams and columns by two internal knife plates and 7.5mm SBD self-drilling dowels (Figure 18). The BTFs are located around the perimeter of the building in order to counteract wind-induced vibration and are left exposed to contribute to the architectural expression of the entire building.

Figure 18. *Lateral brace system*

3.3.2 Shear Walls

Similar to BTFs, CLT shear walls heavily rely on the yielding of connections to dissipate energy [29]. The high relative stiffness of CLT can prove to be an efficient LLRS in low- to mid-rise buildings if careful attention is given to achieve the necessary detailing required by code for "rocking" to occur [29]. This mechanism is heavily reliant on a combination of elastic and plastic connectors acting upon wall segments of appropriate aspect ratio, a challenging feat in high-rise timber construction. Given that the MTEB already employs a CLT-based gravity system for the elevator and stair cores, these walls can be effectively utilized as shear walls to counteract the governing wind loads, all while using the same CLT suppliers and trades.

The CSA O86 [19], like many other international standards, includes discussion on the design and detailing of platform-type CLT shear walls. However, design provisions for balloon-framed CLT shear walls (e.g., John W. Olver Building, UMass) are still under development, and often require alternative approval and reference material outside the design codes [29]. The Canadian CLT Handbook is a prominent reference that provides guidance on the design of CLT balloon-framed LLRS [30].

3.4 FIRE DESIGN

An acceptable level of fire performance of mass timber structures can be achieved through the encapsulation of some or all wood elements. While straight-forward in achieving the desired fire performance rating, full encapsulation of the structural elements in fire resistant finishes, such as gypsum drywall, severely discounts the biophilic benefits of using timber. It was desired to expose a large portion of the mass timber structure in the MTEB, including nearly 100% of ceilings to maximize these benefits for the greater university community. This was done through calculations of the charring and residual cross-section of mass timber elements, including around connections. While the acceptable code solutions in many jurisdictions lag behind the level of exposure and design solutions prosed for the MTEB, the goal was to design to the approved requirements for the 2024 International Building Code (IBC) in the United States as an easier justification for the alternative solution being proposed. The 2024 IBC has been approved to allow mass timber buildings up to 12 storeys to fully exposed ceilings and exposed up to 40% of walls and columns based on testing from the Research Institute of Sweden [24].

Overall, the main fire performance solutions of the MTEB include; 1. Beams and columns designed to have residual capacity after 2 hours of charring to support the required loading, 2. The bottom flange of the HMT panels insulate the webs and top flange which have sufficient capacity as a ribbed panel given that the HMT panels are governed by vibration, rather than strength as in a fire scenario, and 3. The concealed space under the raised access floor contains a non-combustible cement board layer to meet code requirements for concealed spaces.

https://doi.org/10.52202/069179-0571

4 ADDITIONAL CONSIDERATIONS

Other considerations regarding the design of the MTEB include the sustainability, building envelope opportunities, and benefits of mass timber structures.

4.1 NON-STRUCTURAL BENEFITS

4.1.1 Sustainability

The MTEB is a sustainable timber building that depicts the possibilities of mass timber innovative systems to serve multipurpose academic buildings. Wood as a building material, when harvested from sustainably managed forests, has a smaller carbon footprint than traditional construction materials. Wood also has the added benefit of absorbing and storing carbon over its life, storing approximately one tonne of carbon per $1m^3$ of wood building product [31]. As a result, mass timber structures can play a crucial role in reducing a building's material and construction environmental impact and in achieving a design team's green building goals. From the carbon analysis of the MTEB it was found that when compared to an equivalent steel or concrete building, the MTEB would contribute an estimated four times less carbon emissions in terms of building materials for the primary structure (Fig. 19). Foundations were not designed for the MTEB case study and therefore were excluded from the analysis. However, it should be noted that mass timber structures are often much lighter, thus requiring smaller foundations than their concrete or steel alternatives thereby resulting in less carbon emissions. Overall, it is estimated the MTEB would also store 9800 tonnes of carbon in the wood structural materials [32]. This analysis further validates the fundamental need for the use of mass timber in net-zero carbon construction of ICI buildings.

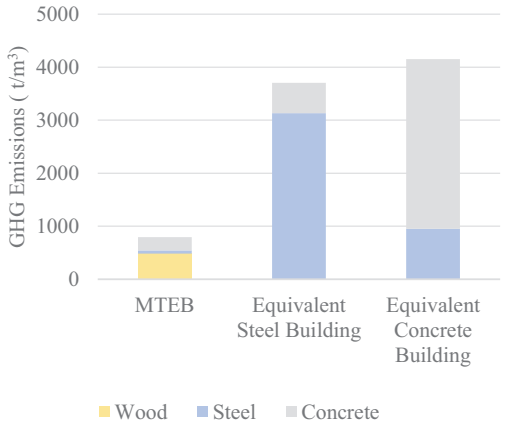

Fig. 19: *Carbon impact of the MTEB and alternative designs*

4.1.2 Occupant Impact

Wood buildings have also shown learning and happiness benefits in their occupants, a phenomenon known as biophilia. Studies have found that students benefit from being surrounded by natural materials. Demattè et al. [18] stated that wooden environments make users feel comfortable, generate a greater level of positive feelings, and even encourage sensory stimuli. Determan et al. [33] found that biophilic learning spaces result in students with higher academic performance and reduced stress levels. The biophilic appeal of wood spaces can also lead to increased design longevity, reducing long-term costs of upgrades, renovations, and re-designs.

4.1.3 Construction Efficiency

Projects that use mass panel systems are completed faster and more efficiently. Brock Commons Tallwood House, an 18-story student residence at the University of British Columbia, took just 2.5 months for timber erection [10] – four months faster than a comparable reinforced concrete building. Prefabrication also leads to fewer site errors, remedial work, and material waste. At one-fifth the density of concrete, wood projects have smaller foundation requirements, thereby decreasing project costs. All this translates to less time on site, fewer disruptions on campus, and long-term beneficial space for the campus community.

5 CONCLUSIONS

This paper outlines challenges facing the adoption of mass timber in institutional, commercial, industrial, and high-end residential buildings including; larger column grids, future design flexibility, and fire resistance. Design strategies previously used to overcome them are presented, along with a detailed description of those implemented in this case study, in order to give designers an additional precedent exhibiting the capabilities of mass timber for types of structures typically reserved for concrete and steel. The project has shown:

- The importance of selecting efficient structural systems based on the needs of the intended building use early in the project;
- Mass timber composite panels, specifically hollowcore mass timber panels, can be an efficient system for achieving the long spans in a simple post-and-beam system;
- Flat plate systems are viable with mass timber products, including column grids larger than the typical maximum panel width of 3.5m;
- With a focus on future design flexibility, mass timber can be designed to accommodate future use changes of these building types;
- In wind-governed lateral system design, the use of CLT shear walls as vertical circulation cores, in combination with glulam braced frames in perimeter walls provides an efficient structural and architectural solution.

EUPHORBIA: MASS TIMBER STADIUM

Alexandros Kitriniaris[1], Sotiris Monachogios[2], Zannis Konteas[3]

ABSTRACT: The key concepts of material efficiency, lifespan, design for manufacture and assembly (DFMA), design for flexibility of use and design for disassembly and reuse, are currently at the forefront of mass timber development. The role that timber must play in decarbonising the construction industry is of vital importance, replacing the more conventional building methods building established in the last century, mainly using concrete and metal; materials and ways of building that are widely blamed for excessive amounts of carbon dioxide emissions. These topics are at the centre of our architecture philosophy, both in research and practice. In this spirit, we present "Euphorbia," a mass timber stadium in Galatsi, Athens, designed by KAAF – Kitriniaris Associates Architecture Firm in collaboration with timber engineers and consultants.

KEYWORDS: Mass Timber, Energy Performance Design, Sustainability, Material Ecology, DfMA, BIM

1 INTRODUCTION

Use of mass timber has been put forward as one solution for the construction industry to address its contribution to climate change. It has the potential to transform the industry, but its potential impact on design remains to be seen. Even though mono-materiality comes to the foreground, mass timber design is still connected with standardized manufacturing processes lacking aesthetic expression as an equivalent form of architecture quality.

On this point, throughout our case study it is essential to interconnect architecture, engineering, science, art, culture, and aesthetics under the umbrella of a holistic transdisciplinary target focused on mass timber design and construction. To this end, the paper analyzes three main topics. The first is related to the mass timber performance research methodology applied to the mass timber stadium; the second, to the mass timber design and fabrication techniques; the third, to the quantitative analysis of the project. This in turn, is related to the calculation of the number of trees to be used for the construction of the project, the total CO2 stored in the building mass, and the number of projects that could be constructed per forest growth in Greece.

2 MASS TIMBER PERFORMANCE

One of the first major efforts to reduce the consumption of energy and consequent emissions in the built environment has been the introduction of energy efficiency through several incentives, policies, and norms. The large release of carbon in recent centuries can, to a great extent, be attributed to urban life. Our cities are growing. Currently urban areas consume some 67 to 76 % of all primary energy and cause 71 to 76 % of greenhouse gas emissions. [1]

Figure 1: *Exterior Perspective from the pedestrian corridor*

2.1 GOVERNMENTAL POLICIES

As awareness increases and governments and regulatory bodies around the world begin to understand the need to regulate embodied carbon, the industry is having to quickly establish consistent methods to measure and quantify the impact of the materials they use to build, and to benchmark what 'low carbon' should mean to meet environmental targets.

With improvements in thermal fabric and operational energy having historically been the target of sustainability agendas, the significance of embodied carbon has increased and is subsequently moving to the forefront of political agendas. Building with wood not only provides embodied carbon benefits through the substitution of familiar, highly carbon intensive conventional building materials such as steel and concrete, but wood also stores biogenic carbon absorbed during the life of the trees.

https://doi.org/10.52202/069179-0572

2.2 CARBON SEQUESTRATION

The use of mass timber construction has the potential to counterbalance short-term declines in the carbon stock of forests [2]. As they regrow, they will renew their place in the carbon cycle, absorbing carbon dioxide. In general terms, as global temperatures rise, increasing the effects of climate change on forests, the relocation of carbon from the forest to the urban environment may counterbalance these effects, along with those caused by dwindling land-based carbon sinks.

The carbon sequestered in a tree has already been absorbed from the atmosphere. The benefit of sustainability and responsible construction is to protect wood so as not to release carbon back into the atmosphere [3]. So, the benefit is that as long as it comes from a sustainable forest, those trees are allowed to regrow. This is one of the reasons for building with wood and not leaving trees unprotected from fire and decay. But this concept has a duration of 60-70 years. The longer the lifespan of the structure, the less risk is involved. The answer to these questions is that the right balance must be found. We really need to focus on upfront carbon to see the implications that may be caused at the end of a project's life.

2.3 LIFE-CYCLE ASSESSMENT

The construction sector is responsible for over 35% of the EU's total waste generation and accounts for about 50% of all extracted resources and an estimated 5-12% of total GHG emissions. Passive design minimized energy demand as well as using energy from renewable sources. Now industries focus on how to balance the embodied carbon within the building either through offsetting – the scheme of being able to plant trees - or by sequestering carbon within the building. Material choices minimize embodied carbon and sequestered carbon as off-setting. So, we should focus on making the building fully sustainable.

Through this process an understanding of the direct relationship between the lifespan of building components and materials and their overall embodied carbon impact has been established, that means we must consider not only the immediate carbon cost, but also the maintenance requirements, how these can be minimised, and the lifespan extended. [4]

2.4 MATERIAL ECOLOGY

For timber components which store carbon, lifespan is even more significant. The longer these components and elements are utilised within a building, where they are protected from damage and decay that would re-release their stored carbon, the greater their contribution to the new 'carbon store' within the built environment, which can act as an urban forest. [5]

Nowadays, traceability of the materials and the embodied energy are critical aspects of the design process to inform the value chains and distribute the material catalogues throughout each project life cycle from certified forests with responsible management of manufacturing, assembly, and reuse. Mass timber components should last longer than 60 years, which is the equivalent of the time needed for a tree to grow, mature and be logged for construction purposes. The lifespan of the timber components is 30-300 years, of the envelope 60 years, of the interior 15 years, and of systems 10 years. In our case study, it is important to examine the following:

Materials

• Choice of materials and their attributes
• The distance between the site of manufacture and the construction site
• Ergonomic application

Their lifespan and plans for recycling them

Construction

• Airtightness of the building shell
• Controlled ventilation with heat reclamation
• Internal air quality

The total energy footprint in relation to the environment
Collection and reuse of rainwater
Use of solar and wind power

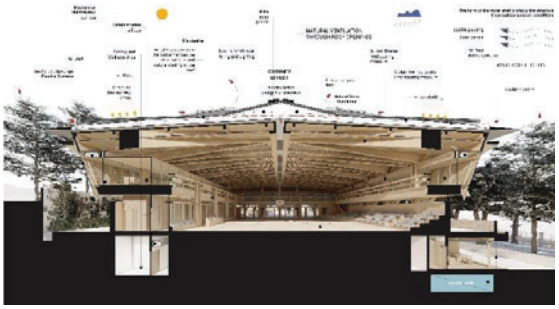

Figure 2: *Perspective Section of the Mass Timber Stadium*

3 MASS TIMBER DESIGN

Design for disassembly (DfD), is related to the component's lifespan so if components last long enough, they are more likely to achieve net-zero KgCO2e/m2. To this end, and given that there are different levels of demountability, it is necessary to translate our concept in relation to the full disassembly or reassembly potential of the structure in a different location, or the partial reuse of parts of the project's components such as glazing, timber panels, CLT decks, GluLam components, and metal connectors. Components must be easily identifiable with quantitative and qualitative data available for future uses (eg. through digital twins) and clear documentation of the method of deconstruction is important. The BIM model gives digital insight of the building to all its stages. In our case, building as a material catalog in this huge dataset is critical to understand which material is used and to review the quality of each component.

After stone, wood is the most ancient reusable construction material of natural origins, yet the shared global concerns of our time are leading to renewed architectural norms. Since the dawn of industrialisation through to today, even though

architecture is constantly becoming more complex, the building industry does not seem to make effective use of contemporary computational fabrication technologies. New questions regarding the manufacturing processes have been addressed, while at the same time a new way of architectural tectonic has emerged by shifting the paradigm from digital design manufacturing to evolutionary robotic manufacturing of natural forms.

3.1 CONCEPT

The main architectural concept of the project is related to a plant called Galatsida, a *Euphorbia* genus. It is believed that Galatsi area in Attica was named for the Galatsida plant which is abundant in the area. The name comes from the milky juice secreted by the shoots and leaves of *euphorbia. Euphorbia* is a large genus of plants in the *Euphorbiaceae* family, represented in Greece by more than 40 species. A special feature of euphorbias is their cup-shaped inflorescence, which is why it is called "kyanthos" from the ancient Greek word for cup. The mass timber stadium is located inside the premises of the "Veikos Grove" in Galatsi and has a total gross buildable area of 3.000 sqm.

The purpose of the design, according to the Municipality initiative, is to create an iconic, sustainable, passive-design stadium made of ecological and biobased materials such as wood, which will promote the principles of recyclability, reusability, energy performance, traceability, and material ecology through athletic values, by accommodating local basketball games, training and gymnastics facilities, and administration offices.

On the ground floor is the sports area and the central entrance for spectators and athletes. Spectator stands are in the northwest wing, numbering 200 seats, and there are separate restrooms for spectators. The stands communicate with the upper level through two linear staircases, allowing more standing spectators. The southeast wing hosts the reception, the athlete and referee changing rooms, and the two central stairways that connect the ground floor with the basement and the upper floor. Also on the upper floor are the administrative offices which overlook the playing field, while the remaining wings on this level can host additional sporting activities. The basement includes additional changing areas, the central space of the gymnasium, storerooms and engineering facilities. In the northwest wing the basement becomes the ground floor as it is at pedestrian street level. This area is reserved for the sports associations. The case study has controlled air flow, is watertight, the internal air quality is excellent, while part of the necessary energy production uses BIPV.

Special attention is given to the correct application of the connection between elements of different materials to avoid thermal bridges, through automated control of air conditioning and temperature in the building interior according to maximum and minimum public use of the space.

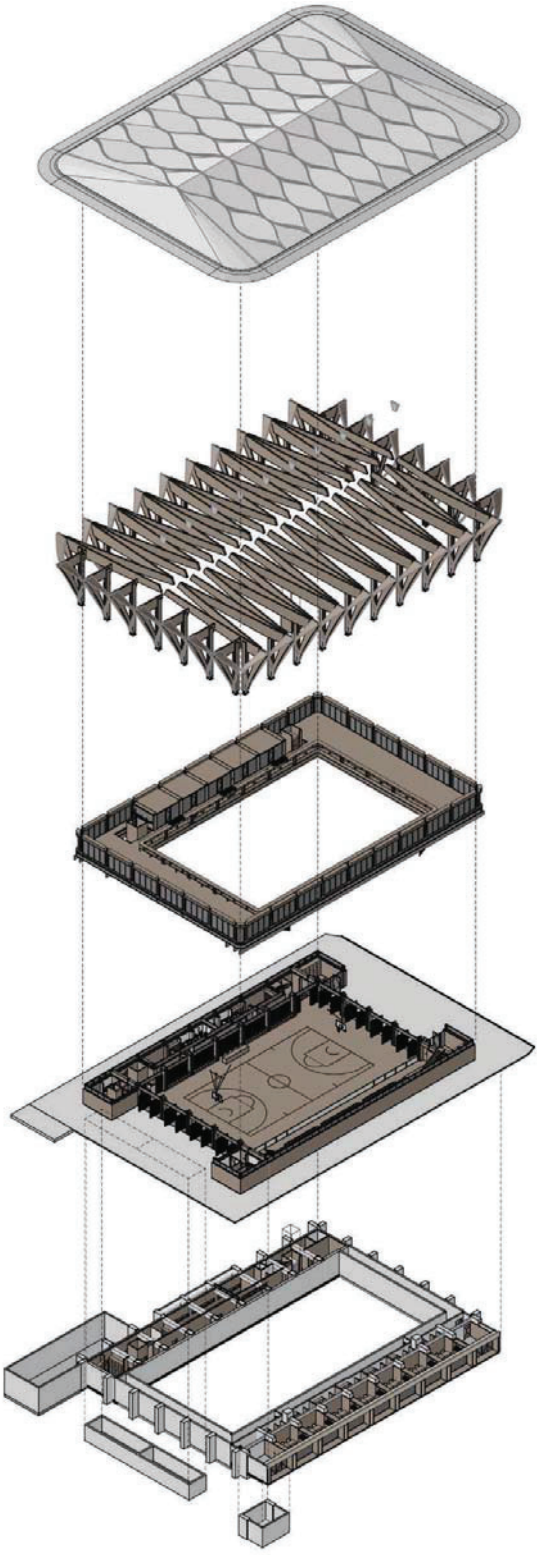

Figure 3: *Axonometric Exploded Analysis Diagram*

https://doi.org/10.52202/069179-0572

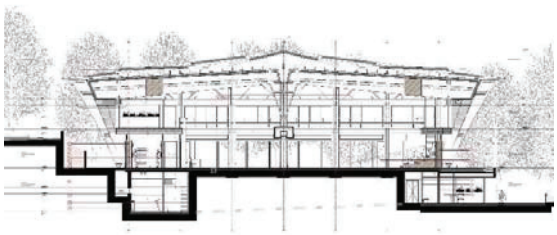

Figure 4: *Cross Section of the Mass Timber Stadium*

Rainwater is collected in a special tank from the tiled surfaces of the surrounding area and the roof. Using special filters and recirculation, it is reused in the changing rooms and restrooms. Part of it is reused for irrigating the surrounding Grove, while there is a second tank for fire safety.

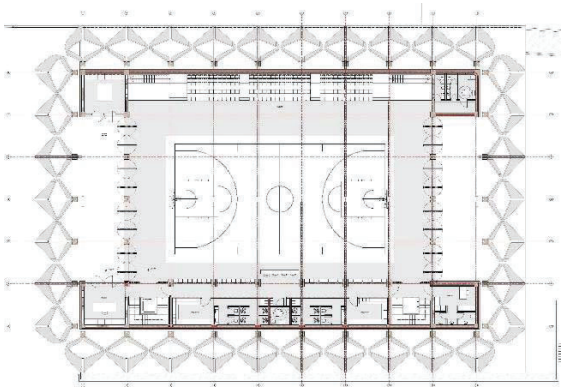

Figure 5: *Main Plan of the Mass Timber Stadium*

3.2 TIMBER LOAD BEARING STRUCTURE

The mass timber stadium is designed so that the Load Bearing Structure consists of:

- Wooden elements for the sections above the final gymnasium level, and specifically, glued timber (GluLam, GL32 category), non-glued timber (plywood) and cross-laminated timber (CLT). Supplementary metal elements are used when judged necessary, mostly as connecting elements but also for rigidity. These elements relate to the ground floor, the upper level, and the roof.
- Reinforced concrete for the sections beneath the ground, and more specifically beneath the final gymnasium level, partially extending into view at the pedestrian street level under the gymnasium. The foundations of the building and all the underground sections are constructed of reinforced concrete. These elements are in the first and second basements.

The load bearing system of the gymnasium is organised on a 5 metre rectangular grid, with seven repetitions on the one axis, and ten on the other, with general dimensions of 45 m in length and 30 m in width.

The foundation is strengthened around the perimeter of the building, since the load bearing elements are arranged around it, while internally a grid is formed from strap beams parallel to the smaller dimension of the building. These beams receive the horizontal loads exerted on the columns supports, while transverse beams are used mostly for the lateral stiffening of the first strap beams. On these beams lies the ground floor slab made of reinforced concrete.

3.2.1 BUILDING SHELL

The **shell** of the structure consists of 10 identical isostatic frames, bridging a 30-metre span. They are symmetrical and consist of beams and columns as shown in the drawings, functioning as a three-pin arch, since they include three joints within their plane: one joint at the support of each column and one at the top, where the two beams are connected. Each three-pin frame consists of the following:

1. **Two twin vertical columns,** 20 by 60 cm cross-section, 8.40 metres high.
2. **Two main beams** between the twin columns, slightly inclined. The main beams are approximately 18 metres long, 20 cm wide, and variable in height from 1.65 metres at the point of connection with the twin column, to 1.05 metres at their other end.
3. **Two deviating beams,** of the same dimensions as the main beams above, only deviating horizontally comparing to them, symmetrically arranged on either side of the twins columns. These beams connect to one another at the middle axis of the gymnasium, at half the distance across the 5-metre grid, at 2.5 metres.
4. **An inclined column** between the two twin ones, sloping outwards. Its external side is curved, resulting a variable cross-section. The base of this column starts from a cross section of 20 by 60 cm and ends at the top, under the roof, at 20 centimeters by 96 cm. A UPN 140 stainless steel element is added alongside this inclined column so as to stand in for the static function and allow easy replacement of the timber member.
5. **Two curvilinear V-shaped members** emanating from either side of the inclined column and extending to the top of it, at face level, with the flare of the geometry occurring approximately at mid-height. The inner stems of two arrays in a row connect in the middle, at half the distance of the 5 meter grid, at 2.5 meters.
   The 3 aforementioned elements (1, 4 and 5) have a common starting point in a metal joint at the base of the building on the ground floor.
6. **Horizontal beams** between the twin columns, extending towards the interior of the gymnasium, on which the CLT plates of the mezzanine rest. Their cross-sections are 20 by 80 centimetres with a length of 7 metres for the

three sides of the gymnasium, except for the beams that support the loft above the spectator stands, which have a cross-section of 20 by 35 centimetres and a length of 3.5 meters.

The use of a large number of beams: 1 main beam and 2 inclined beams, each 5 meters long and with a large cross-section, allows their flexural-torsional buckling to remain non-critical and thus they do not require flexural-torsional security against wind, snow, and earthquake loads. However, it is necessary to ensure against flexural buckling, and for this reason a dense mesh of blinds is placed around the middle of the static height of the beams which also has an architectural function related to the acoustics and lighting of the sports area.

The shell is completed on the upper surfaces with composite frames of wood and plywood with thermal insulation within, which are built into the ground and bolted to the upper seat of the main and diagonal beams.

The small facades of the building are shaped in a similar way to the large ones, with vertical and inclined columns and diagonal elements. More specifically, on the two narrow sides of 30 metres, the load-bearing body consists of 7 groups, each arranged on the 5 metre framework. Each of these groups consists of the elements described previously. More specifically: a twin vertical post (1), an inclined post (4), two curved V-shaped members (5) and horizontal beams with cross-sections of 20 by 80 cm and 7 metres long (6). Instead of the main beam (2) at full length, there are shorter beams that extend until they touch the outer main beams of the long sides, 20 cm wide, about 1.5 metres high and 3.85 metres long.

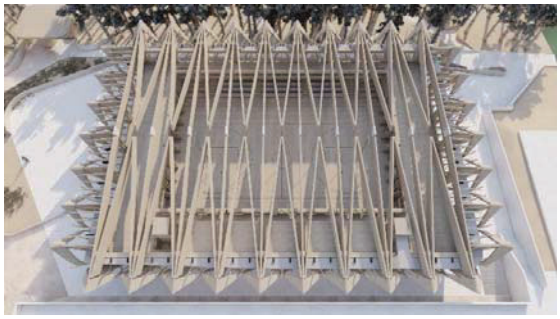

Figure 6: *Main Structural System of the Mass Timber Stadium*

The out-of-plane stiffness of the beams is achieved by the frames formed by the vertical posts and a grid at their upper level. This network is formed at the upper end of the twin vertical posts (member 1), there is a system of double, parallel GluLam wooden beams, and two more inclined ones, which runs throughout the gymnasium and provides rigidity at the face level.

3.2.2 BUILDING CORE

All areas of the internal are made of CLT and GluLam. All floors are made of CLT, and so are the walls, whereas vertical members of GluLam in conjuction with steel members are used as columns between openings.

Higher than the ground floor spectator stand, a 35-meter-long and 3-meter-wide loft is formed. Its floor is again made of CLT, like all other areas, only this floor is partly suspended by the main beams of the roof, and partly supported by the aforementioned 20 by 35 cm GluLam beams.

On the outer side of the corridor in the changing room area there are twin columns 20 by 60 centimetres cross-section and 4.8 metres high, between which the horizontal beams (member 6) of the changing room side terminate. On them lie the CLT plates and office spaces of the upper level. A corresponding function is served by the twin columns on the two narrow sides, with the CLT plate resting on the horizontal beam system on each of these sides. The stairwells on the changing room side, as well as the lift core, are made of CLT slabs and walls respectively.

Figure 7: *Interior Perspective of the Basketball Court*

3.2.3 ROOF

The roof is made of a metal frame and fiberglass panels on curved surfaces which, with an appropriate slope, channel the rainwater into special channels which end in the perimeter gutters. The choice of fiberglass material has a double meaning. On the one hand, it is a material with great resistance to weather conditions, and on the other, it helps to reduce the burden of additional loads on the construction. The metal frame is placed on the underlying wooden cross-beam and plywood cladding, the outer surface of which is protected externally by a vapor barrier and water resistant membrane. The construction consists of numbered pieces which will be fabricated off-site with CNC machines, and will be transported and assembled on-site.

4 FOREST GROWTH

Forests cover 31 percent of the planet. Approximately half of this forest area is reasonably intact, and more than one third is primary forest. The net loss of forest area has decreased significantly since 1990, but deforestation and forest degradation continue at alarming rates resulting in significant loss of biodiversity. The world is not on track to meet the target of the United Nations Strategic Plan for Forests to increase forest area by 3 percent worldwide by 2030 [6]. Urban and built-up areas are equal to 1% of the total land area of the world. As forests are vulnerable to wildfires and decay it is important to secure forests from

https://doi.org/10.52202/069179-0572

releasing carbon back into the atmosphere. Apart from world forest management plans that have already been implemented and increased in the last decade, the other way to secure carbon from being released is to store it in buildings.

4.1 WORLD FOREST AREA

The world forest area is equal to 4 billion hectares. In the last 30 years, world forest losses demonstrate an absolute change of -177 million hectares, or a relative change of -4 percent. The number of trees in the world are equal to 3 trillion trees with an average of 22,500 trees per square kilometer and 422 trees per capita. The report shows that the over the last 30 years, -35 million hectares of primary forest were lost, a relative change of -3 percent. A planted forest gained +105 million hectares, a relative change of +56 percent, while the naturally regenerated forests have lost approximately -200 million hectares, a relative change of -8 percent. [7]

4.2 EUROPEAN FOREST COVER

By considering the increase of forest growth in Europe in the last 30 years, between 1990 (208 million hectares) to 2020 (227 million hectares), we notice that there is an annual change of +0.3 percent, with a forest growth of 19 million hectares, equal to 650 thousand hectares of forest growth per year, while the forest area in Europe per capita equates to 0.33 people. [8]

4.3 FOREST COVER IN GREECE

Forest area in Greece was reported at 30.27 percent in 2020, according to the UN F.AO & the World Bank collection of development indicators, compiled from officially recognized sources. In 2020, forest area for Greece was 39,018 sq. km (3.9 million hectares). Forest area of Greece increased from 36,304 sq. km (3.6 million hectares) in 2001 to 39,018 sq. km in 2020 growing at an average annual rate of +0.38 percent. [9]

4.4 QUANTITATIVE ANALYSIS

With the aim of linking mass timber construction to the forest growth in Greece, we calculate that 1,825 mature trees (by taking into account a mature tree with a height of 30m and a trunk diameter of 0.75m) required for the construction of the mass timber stadium, 2,500 tn of CO2 on building mass (by taking into account that 1 tree absorbs 1tn CO2 and releases 727 kg O2 per cubic meter of growth), while 1.7 projects per hour or 40.7 projects per day or 14,872 projects per year could be constructed per forest growth in Greece. The total wood product calculated for the mass timber stadium equals to 2,500 m3 including off-cuts.

5 CONCLUSIONS

Through the analysis of the case study, the following points have been evaluated:

- understand mass timber structural solutions for larger scale, big span spaces, as well as how these systems deal with the performance aspects and the occupant benefits of exposed timber surfaces within these buildings.
- consider building longevity as well as flexibility for future change of use and adaptation at the design stage.
- focus on key aspects which influence the ability to disassemble a building into components that can be re-used at end of life, as opposed to demolition.
- highlight how the significance of building and component lifespan on the embodied carbon of buildings is critical for consideration of sequestered carbon within LCA analysis of biobased products such as wood.
- calculate the number of trees per project as well as the number of projects per forest growth per year as a quantitative analysis of a mass timber building.

ACKNOWLEDGEMENT

PLASTIC DESIGN OF BESPOKE INTERLOCKING TIMBER-TO-TIMBER CONNECTIONS FOR ROBOTIC ASSEMBLY

Davide Tanadini[1], Giulia Boller[2], Pok Yin Victor Leung[3], Pierluigi D'Acunto[4]

ABSTRACT: *CantiBox* is a robotically assembled pavilion composed of linear timber elements. The interweaving logic of the structure makes it possible to use exclusively interlocking timber-to-timber connections during the automatic assembly. The design of the connections is based on the static method of limit analysis, which allows adjusting the geometry of each joint according to the internal force distribution.

KEYWORDS: Spatial timber structure, Interlocking timber-to-timber joints, Robotic assembly, Limit analysis

1 INTRODUCTION

In recent years, the timber industry has increasingly promoted the introduction of digital technologies in the manufacturing and construction processes. Thanks to the major developments in Computer Numerical Control (CNC) machines, the production of complex and customized timber geometries is no longer a major challenge. Moreover, much scientific research has been carried out in the field of robotic assembly of timber structures made of plates and linear elements [1] [2] [3].
In this context, the *CantiBox* project demonstrates two novel contributions for jointed timber structures: (a) the application of the static method of limit analysis for designing interlocking timber-to-timber connections, which allows the adjustment of individual joint geometries based on real-time performance assessment; (b) the use of distributed mechanical tools operated by a robotic arm to achieve a fully automatic assembly process. Both contributions complete a critical knowledge gap that enables bespoke design and construction of spatial timber structures. Their flexibility to accommodate custom designs is enabled by the interweaving logic used to create a reciprocal network.

2 LIMIT ANALYSIS

2.1 INTERLOCKING TIMBER-TO-TIMBER CONNECTIONS

An approach based on the static method of limit analysis (e.g. lower bound theorem of the theory of plasticity) is well suited to the analysis and design of any structural timber element. Indeed, it is not restricted to a specific structural typology, scale or material [4] [5]. In the context of this project, the static method is adopted to address the analysis and design of interlocking timber-to-timber connections.

Figure 1: *The Cantibox project leverages innovative approaches to structural design and robotic assembly to enable the development of a customized spatial timber structure (©Ali Zigeli 2022).*

Timber-to-timber connections are particularly favourable for robotic assembly. Compared to other connections that require metal fasteners, an interlocking timber-to-timber connection is advantageous because it is composed of a smaller number of elements (i.e. a minimum of two) and thus requires fewer actions by the robotic arm (i.e. a minimum of one insertion). Therefore, this type of connection is highly suitable to be integrated into a digital automated process.
Digital fabrication makes it possible to achieve great freedom in terms of geometry. Since manufacturing complex interlocking timber-to-timber connections is no longer an obstacle due to recent developments in digital fabrication, their adoption is mainly limited by the difficulties in structural analysis. However, applying the

static method of limit analysis to timber provides a new possible approach to the analysis and design of interlocking timber-to-timber connections. The illustrative representation of the state of internal forces in the form of strut-and-ties, or stress fields, makes the interactions between force and geometry explicit. It represents, therefore, the basis for the development of efficient connections.

2.2 PLASTIC DESIGN OF CONNECTIONS

The objective of plastic design is to analyze the connection, determine its load-carrying capacity by assessing the collapse load with reasonable accuracy and inform the design by optimizing its geometry. In an interlocking connection, the capacity is expressed as a function of two parameters: the contact surface A_i and its strength $f_{y,i}$. The former controls the flow of forces between timber elements, while the latter controls the flow of forces within an element. Given these two parameters, it is then possible to evaluate and adjust the capacity of the connection. The contact surface indicates the area available for force transfer. The contact surface strength indicates the maximum stress that a surface can withstand. In general, the larger the contact surface and/or the more efficient the internal force flow, the greater the connection capacity.

$$\text{Connection capacity} = f\left(A_i, f_{y,i}\right)$$

$\rightarrow F_{Rd,i} = A_{F,i} \cdot f_{y,i}$

$\rightarrow M_{Rd,i} = A_{M,i} \cdot f_{y,i} \cdot h_i$

A_i : Contact surface
$f_{y,i}$: Contact surface strength
h_i : Lever's arm

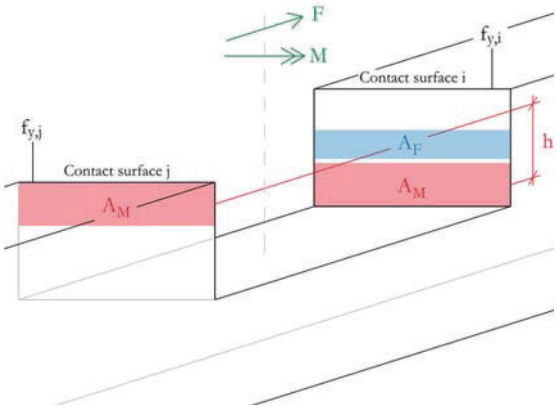

Figure 2: *Schematic representation of the redistribution of forces in an interlocking connection.*

2.2.1 Transfer of forces between timber elements

In the case of interlocking timber-to-timber connections, the forces between elements are transmitted through contact surfaces. Unlike other types of connection, here, only compressive forces are transferred. Being timber anisotropic, the positioning of the connection with respect to the grain's orientation is decisive.

Different strategies can be adopted to meet the material requirements [5]. In this project, three strategies are employed: (a) the tension forces are transmitted by designing connection geometries that transform tension into compression; (b) large contact surfaces enable the transmission of higher forces; (c) the transmission of different kinds of stresses required contact surfaces oriented in multiple directions.

2.2.2 Flow of internal forces in timber elements

The compressive forces transmitted via contact surfaces are considered a starting point for analyzing internal forces. The limit analysis allows the visualization of the internal state of equilibrium, represented in the form of stress fields (continuous case) or strut-and-ties (discrete case). This representation is helpful for the analysis and especially for the design of interlocking timber-to-timber connections. Stress discontinuities may be present in the equilibrium state of the internal forces, in line with the plastic theory.

By comparing connections with different geometries, it can be observed that their structural capacity differs, although the joints have the same dimension of the contact surface over which the force is introduced [5]. In fact, some connections may favour a more efficient internal force flow than others (e.g. less force redirection or more effective exploitation of anisotropy). Therefore, it is necessary to conduct a quantitative analysis of the internal force flow to determine the capacity.

This analysis can be performed by means of stress fields, strut-and-tie models, force diagrams and yield conditions, as shown in Figure 3.

Stress fields and related strut-and-tie models, which show the resultants of the underlying stress field, represent the equilibrium condition of the internal force flow. They also provide visual information on internal forces, which is very useful in qualitative analysis. Given the geometry, the applied external forces and the boundary conditions, the compression force must be redirected towards the support. The force diagram represents the equilibrium of the forces acting in the strut-und-tie models using a closed cycle of vectors (i.e. force polygon) at each node, allowing for computing the magnitude of the forces. The compatibility of the internal stress states with the material properties is verified through yield conditions. In the yield conditions diagram, the individual stress states, one for each element of the strut-and-ties, are displayed. If the stress states lie within the curve of the yield conditions, the latter are respected. The yield conditions are represented by the uniaxial strength formula (i.e. Hankinson [6]) of the Swiss code 265 [7].

The possibility to model the internal forces, combined with the understanding of the material behaviour, allows for identifying possible critical situations and, consequently, improving the efficiency of the connection by manipulating the geometry or the internal forces model.

https://doi.org/10.52202/069179-0573

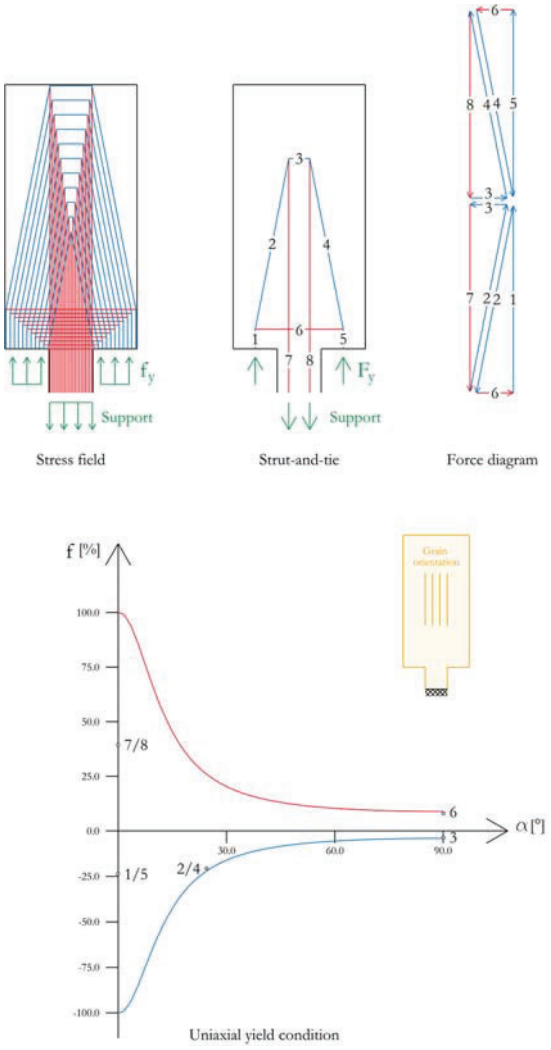

Figure 3: *A parallelepiped timber element is tested. The element presents two notches through which the external load is transferred. Tension forces are shown in red, compression forces in blue and external forces in green. The analysis allows the understanding of the flow of internal forces and the assessment of the collapse load.*

2.2.3 Algorithm for the definition of contact surfaces

An algorithm is responsible for the plastic allocation of contact surfaces. Having defined as input the available contact surfaces A_i and the respective strength $f_{y,i}$, it determines which surface to activate for a given load. This process can also be performed manually, but in the case of combined loads, it becomes quickly tedious. The algorithm follows the principles below:

No overlapping between contact surfaces:

$$A_{Force} \bigcap A_{Bending} = \emptyset$$

Axial forces equilibrium:

$$F + \int_{(+)} f_y \, dA_{Force} - \int_{(-)} f_y \, dA_{Force} = 0$$

Bending forces equilibrium:

$$M + \int_{(+)} f_y \cdot h \, dA_{Bending} - \int_{(-)} f_y \cdot h \, dA_{Bending} = 0$$

(+) positive side (-) negative side

The graphical representation of the result of the algorithm is shown in Figure 4.

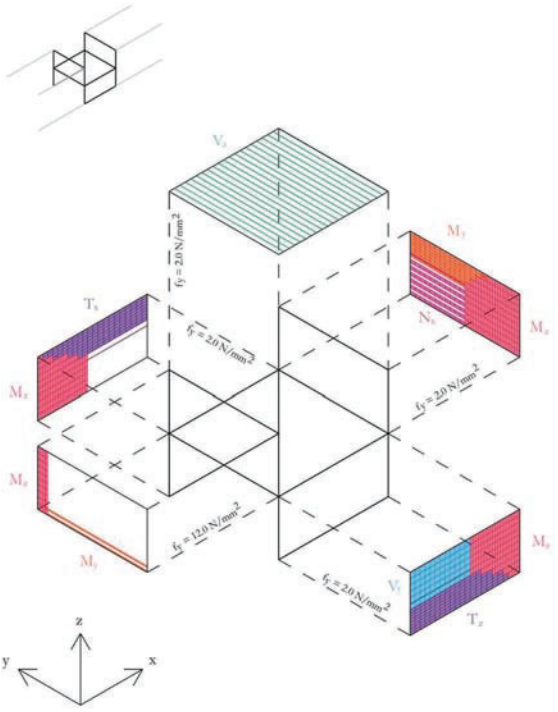

Figure 4: *The algorithm is responsible for distributing the contact surfaces required for efficient force transfer between timber elements.*

3 PAVILION DESIGN

The *CantiBox* pavilion features a complex three-dimensional reciprocal structural system based on geometrically optimized and customized interlocking timber-to-timber connections.

3.1 STRUCTURAL CONCEPT

A reciprocal structure is composed of a minimum of three elements that support each other so that each element is supported either by another element or by the ground [8].

https://doi.org/10.52202/069179-0573

In this structural system, each element is essential, and the failure of a single element leads to a chain reaction that results in the collapse of the entire structure. This structural principle has been known for a long time, and its use is widespread [9].
Besides three-dimensional structures such as vaults or bridges, reciprocal systems are also used to obtain planar geometries. The adoption of reciprocal structures for the formation of ceilings is well known. Villard de Honnecourt, Sebastiano Serlio, and John Wallis provide relevant examples of this technique. In this case, the reciprocal system is called planar grillage [9]. Indeed, the planar structure composed of short timber elements forms the ceiling connecting the vertical structural elements of a building.

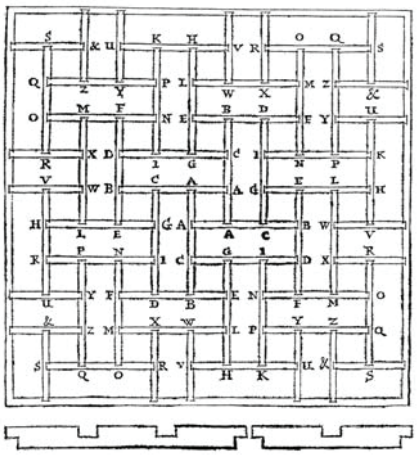

Figure 5: *Sketches of the planar grillage developed by Wallis [10]. The reciprocal structure allows long distances to be covered using multiple short elements that support each other.*

In the *CantiBox*, a planar grillage is used as a basic structural module. From a structural point of view, it acts like a Vierendeel truss. The reciprocal planar grillage module presents three horizontal and three vertical elements, as shown in Figure 6. The elements are interwoven, with connections oriented in opposite directions. Only once the last component is assembled, the reciprocal system is closed, the structure can be considered stable, and the disassembly is prevented. Furthermore, the assembly of the grillage complies with the automatic robotic assembly process developed for this project, which does not allow any triangulation in the structure. Connecting several reciprocal planar grillages together allows the development of spatial structures using only interlocking timber-to-timber half-lap connections.
In the design of the *CantiBox*, strict rules must be considered, which are dictated by the planar nature of the grillage module, by the use of square timber elements, and by the assembly process, which allows only planar connections (i.e. the plane of the reciprocal planar grillage module must be shared by two faces of the beam to which it is to be connected). Therefore, the design presents box-like structures where each face consists of a reciprocal planar grillage module.

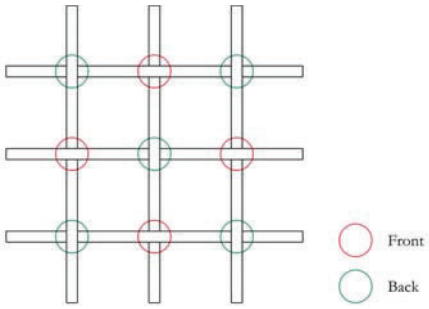

Figure 6: *Schematic representation of a reciprocal planar grillage module used in the CantiBox pavilion. In a real scenario, the assembly of this type of reciprocal structure is impossible without relying on the elastic flexibility of the elements. The interwoven composition prevents disassembly by presenting an alternating orientation of the connections. In the CantiBox pavilion, the last element to be assembled - the key element - exhibits a different orientation of the connections that allow it to be assembled without compromising the reciprocal system.*

3.2 GLOBAL DESIGN

CantiBox consists of three independent units: two lateral boxes connected to the ground and a cantilevering central box supported by the other units, as shown in Figure 7. The boxes are connected via shared horizontal planes. Each unit is composed of 20 linear timber elements of solid spruce with a cross-section of 10 by 10 cm, which are automatically assembled via robotic fabrication. The six linear timber elements of each face of the boxes are interconnected through bespoke half-lap joints arranged in the plane to generate a reciprocal system. Of these six elements, four present connections facing two opposite directions (e.g. two inward and one outward). This characteristic allows assembling each face with an interweaving pattern that ensures the correct automatic positioning of the elements within the face using a robotic arm. The sixth linear element of each face - the key element - has three connections pointing in the same direction to allow assembly by a robot. For this reason, one connection of the key element is ensured by a metal fastener that prevents disassembly [11].
For the evaluation of the global structural behaviour of the *CantiBox*, Finite Element Analysis (FEA) is used. In the analysis, each joint is regarded as a rigid connection. Since the project is built in the open air, the following external forces are considered according to the Swiss codes 260 [12] and 261 [13]: self-weight of the structure and wind load. The wind load acts in different directions. For each element, the most unfavourable direction is considered. In the definition of the support conditions, translational movement is blocked in all directions while rotational movement is allowed. The construction detail of the supports is characterized by a steel blade penetrating a notch in the timber, which is then fixed with a steel pin. The capacity of linear timber elements to resist

https://doi.org/10.52202/069179-0573

axial forces, shear forces and bending moments is determined according to Swiss code 265 [7].

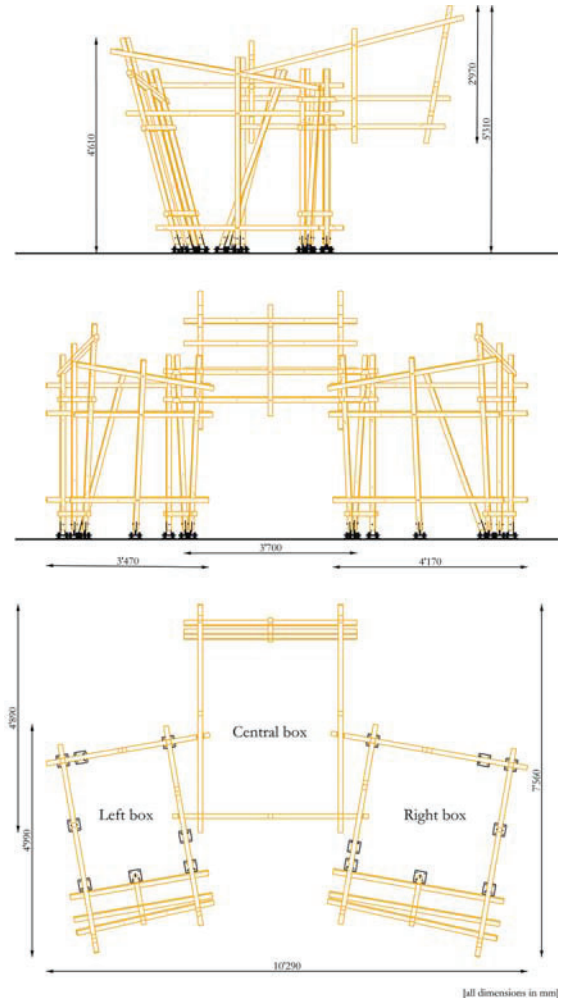

Figure 7: *The structure occupies an area in plan of 10.3 by 7.6 m and reaches a maximum height of 5.3 m.*

3.3 CONNECTION DESIGN

3.3.1 Half-lap connections

Among the many types of interlocking timber-to-timber connections, half-lap connections are adopted since these connections best meet the requirements of automatic robotic assembly. The prototypical half-lap connection is produced through a subtractive process in which half of the cross-section in each of the two elements to be connected is removed. From a static point of view, half-lap connections allow both axial forces and bending moments to be transferred. In addition, this single typology enables great flexibility in the geometry of the structure since a wide range of angles can be achieved on several planes.

3.3.2 Structural capacity of the connections

Based on plastic theory, the static method of limit analysis is adopted to determine the capacity of the interlocking timber-to-timber connections and their design (Section 2.2). The structural capacity of a connection depends on the geometry and the boundary conditions of the connected elements. Here, it is conservatively assumed that the connection has a fixed end on the left side and a free end on the right side.

Contact surfaces

In the half-lap connection, five contact surfaces are identified. These allow axial forces to be transferred in each direction except that of insertion, as shown in Figure 8. The transfer of bending moments occurs by combining in pairs the contact surfaces used for transferring axial forces (Figure 9). A bending moment can be transferred by activating multiple combinations of contact surfaces. From this first analysis, the importance of the extension of the beam beyond the connection that constitutes the free ends becomes apparent. This part activates an extra contact surface to transfer axial forces and bending moments.

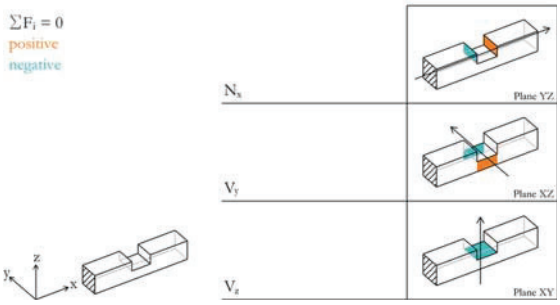

Figure 8: *Contact surfaces activated for the transfer of axial forces. Positive load transfer requires a positive surface.*

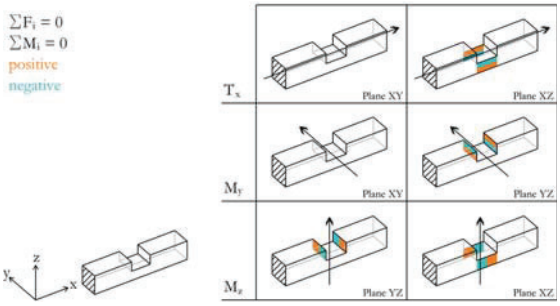

Figure 9: *The coupling of contact surfaces responsible for transferring axial forces ensures the transfer of bending moments.*

Strength of the contact surface

The internal force flow analysis aims to determine the maximum stress applicable to a contact surface. Therefore, this value represents the strength provided by

https://doi.org/10.52202/069179-0573

the internal force flow system. It may be different for each contact surface.
As a reference, Figure 10 shows a more in-depth view of the force flow for several activated contact surfaces. A complete internal force flow analysis based on stress fields, strut-and-tie models, force diagrams and yield conditions is performed according to 2.2.2.

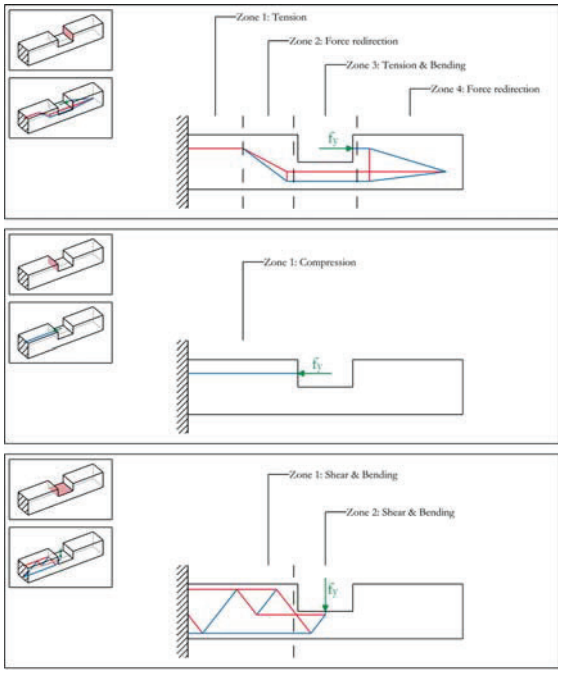

Figure 10: *Several typologies of internal force flow developing in the XZ plane are illustrated. Tension forces are shown in red, compression forces in blue and external forces in green.*

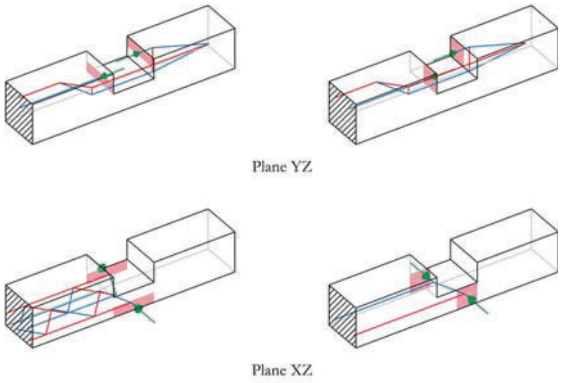

Figure 11: *The transfer of a bending moment occurs by activating two contact surfaces in the same plane. This results in a double flow of internal forces that must be controlled. For example, in the case of contact surfaces activated in the YZ plane, the single flow of forces develops on the XZ plane. Since the flow of forces is double, they can interact. Consequently, an analysis in the XY plane may be necessary as well.*

While in the case of single-activated contact surfaces, the development of internal forces develops in one plane, in the case of simultaneous activation of multiple contact surfaces, multiple flows of internal forces can develop. This happens with bending moment transfer, which occurs by activating a minimum of two contact surfaces, as shown in Figure 11. In this case, the interaction between multiple internal force flows, occurring in planes different from that of the single force flow, can cause changes in the strength of a contact surface.

3.3.3 Parametrization

As each connection is subjected to different loads, it is possible to modify the contact surfaces required for load transfer by varying the geometry of the joints. The prototypical half-lap joint connection is customized whenever necessary to adapt its capacity to internal stresses. In the *CantiBox* project, the prototypical half-lap connection is modified via four parameters (i.e. x, y, z^+, and z^-), as shown in Figure 12 and Figure 13. In this case, the increase in the capacity of the connection is achieved through an increase in the contact surface, while the associated strength is assumed unchanged.

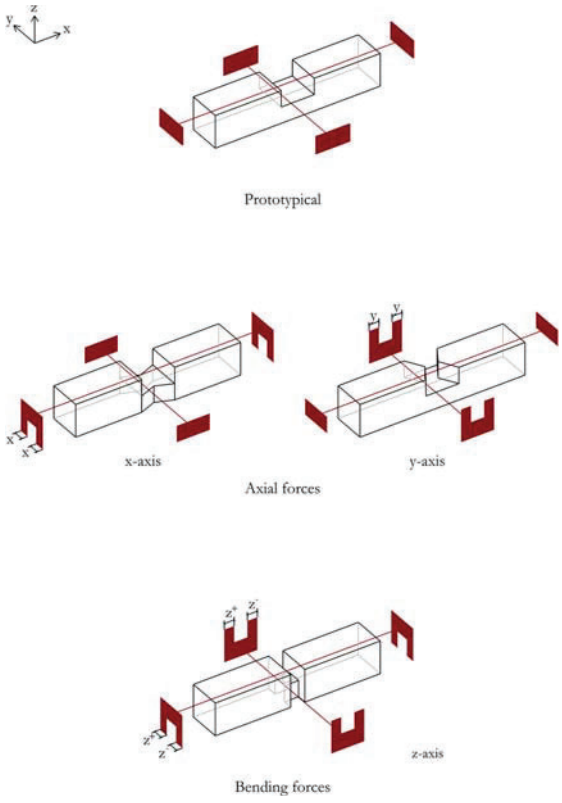

Figure 12: *The geometry modification occurs through four parameters. This allows the capacity of the prototypical half-lap connection to be changed by manipulating the size of the contact surface used to transfer the forces. As contact surface is considered the projection of the connection geometry plane perpendicular to the axes in which the acting loads are determined.*

https://doi.org/10.52202/069179-0573

The capacity to transfer axial forces is governed by the parameters x and y for the respective axes. Parameters z^+ and z^- govern the bending moment capacity in the z-axis for positive and negative moments, respectively. The parameters are considered independent, which means, for example, that the parameter x only influences the transfer of axial forces in the x-axis, not the bending moment in the z-axis.

The connection design process is parameterized and integrated into an algorithm that is automatically able, given the forces to be transferred and the strength of the contact surfaces, to define the geometry of the connection. The algorithm defines the geometry by a control polyline governed by the four parameters described earlier. Geometrical changes take five steps up to a maximum value for a single parameter of 10 mm. The limit is set because geometric changes involve a subtractive process that, if uncontrolled, could change the flow of internal forces and, thus, the strength of individual contact surfaces.

The digital interface developed for this project is shown in Figure 14. It allows the plastic redistribution of forces to be monitored and provides valuable information for fabrication. Concerning fabrication, acute angles are avoided. In addition, there is a real-time three-dimensional visualization of the connection generated by the algorithm. The final design showcases bespoke connections according to the different load conditions, as shown in Figure 15.

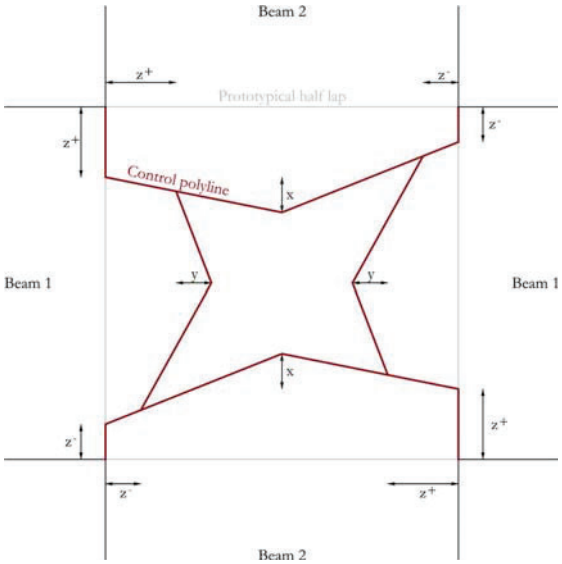

Figure 13: *A polyline defines the three-dimensional geometry of the half-lap connection.*

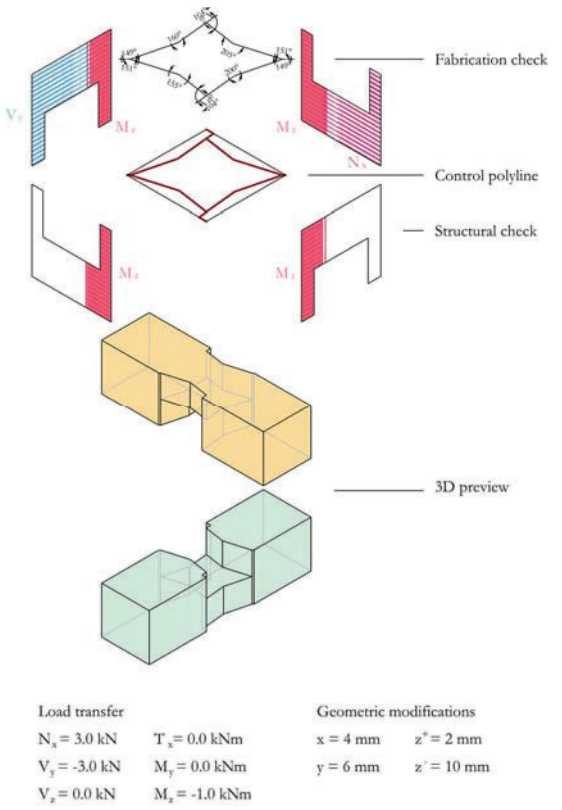

Figure 14: *The digital interface developed for designing and analyzing the connection integrates geometry, fabrication and structural feedback. The parametric space for customization is carefully designed so joints can be machinable by commonly available automatic joinery machines and assembled by our robotic tools.*

Figure 15: *CNC machines foster the design of bespoke geometry for the connections. All the half-lap connections – prototypical and bespoke - are machined with a Hundegger Robot Drive automatic joinery machine (©GKR 2022).*

https://doi.org/10.52202/069179-0573

3.4 ASSEMBLY

The structure is constructed through a fully automatic process [14], which involves using a set of custom-built, remote-controlled, distributed robotic clamps (Figure 16) and screwdrivers (Figure 17). Each of the three units is constructed spatially in an automatic process (Figure 18) instead of planar sub-assemblies. Robotic clamps are used for joints that do not require fasteners. Robotic screwdrivers, which can be loaded with a left-in fastener, are used for the key elements. Those operate in collaboration with an industrial robotic arm to assemble the timber structure spatially. This assembly method is explicitly developed for half-lap connections and allows for overcoming several problems traditionally experienced in the assembly of interlocking timber-to-timber connections, such as:

- The clamp provides a guide that reduces misalignment problems when inserting a new beam into an existing structure.
- Since the clamps are controlled remotely and each clamp is independent, several clamps can be used simultaneously. This allows the simultaneous insertion of a new beam in multiple connections.
- The clamp introduces a large but localized force, which the robotic arm cannot do. This exceeds the resistance given by friction during insertion, as the connections are tight-fit.

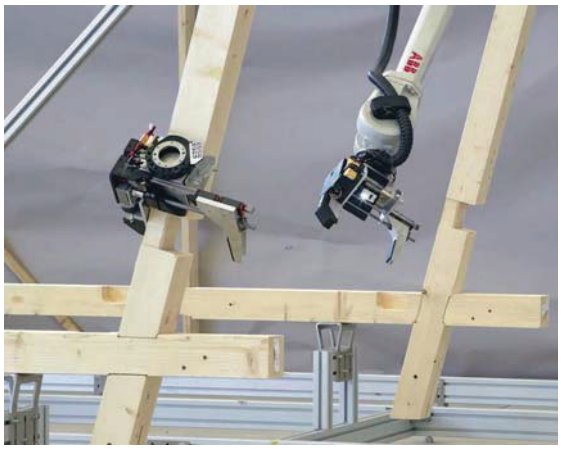

Figure 16: *The robotic arm positions two robotic clamps to insert a new timber element in the structure (©GKR 2022).*

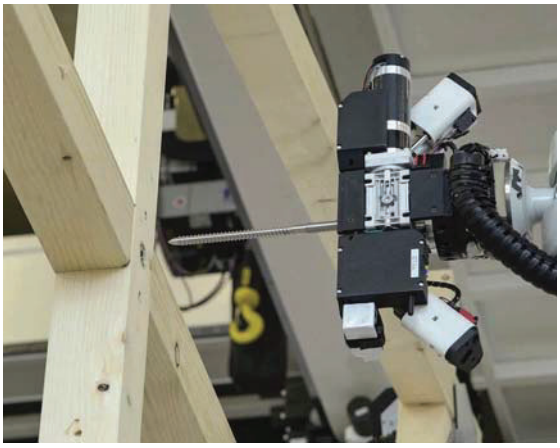

Figure 17: *A key timber element is assembled by a robotic screwdriver loaded with a left-in fastener (©GKR 2022).*

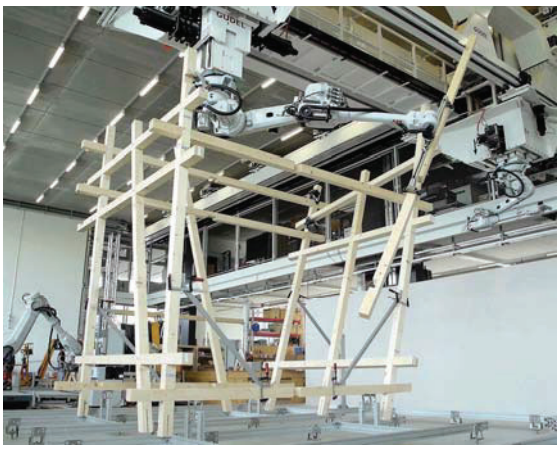

Figure 18: *One of the timber units during construction, with the robotic arm positioning a timber element following the assembly sequence (©GKR 2022).*

The assembly sequence of one face of the box is shown in Figure 19. The interweaving logic of the face allows the use of interlocking timber-to-timber connections during the automatic assembly. Only the last assembled element - the key element - requires a non-structural screw to close the reciprocal system and prevent the system from disassembly.

Figure 19: *The interweaving logic used during the assembly allows the number of metal fasteners to be limited to one per face.*

4 CONCLUSIONS

This paper discusses the design and fabrication of the *CantiBox*, a robotically assembled structure composed of linear timber elements and customized interlocking timber-to-timber connections. The project is made possible by the interweaving logic used in its assembly. Special attention is given to the method developed for analyzing and designing the interlocking timber-to-timber connections, which is based on the lower bound theorem of the theory of plasticity. This novel application of limit analysis to timber allows for informing the design and assessing the collapse load. The proposed static method for limit analysis uses stress fields, strut-and-tie models, force diagrams and yield conditions. Furthermore, it facilitates understanding the relationships between geometry and structural performance, thus allowing to customize each connection according to the specific load conditions. The development of a bespoke assembly set-up allows the structure to be automatically assembled in its final three-dimensional configurations.

CASE STUDY: TERMINUS – NEW FRONTIERS IN HYBRID MASS TIMBER SEISMIC DESIGN

Brendan Fitzgerald[1], Ilana Danzig[2], Mehrdad Jahangiri[3], Ornagh Higgins[4], Jackson Pelling[5]

ABSTRACT: Terminus is a recently completed 5-storey mass timber commercial building in one of the highest seismic regions in Canada. The seismic demand and the exposed timber drove ASPECT Structural Engineers to undertake a thorough investigation to select a lateral load resisting system that would complement the building's mass timber superstructure, maximize use of timber, and provide a high level of ductility. The selected system involved the novel integration of steel buckling restrained brace frames within a timber post and beam frame. During design and construction ASPECT worked closely with the builder and the mass timber supplier to ensure that all elements of the lateral system were detailed carefully and that all components fit together seamlessly during installation.

KEYWORDS: Mass Timber, Seismic, Innovation, BRB, Hybrid

1 INTRODUCTION

Terminus is a 5-storey mass timber commercial building designed and constructed by a project team consisting of ASPECT Structural Engineers, Jack James Architecture, Design Build Services (DBS), and Structurlam. Located in one of North America's highest seismic regions on Vancouver Island, BC, Terminus' lateral design warranted a lengthy investigation of various systems. Vancouver Island's code-based seismic design parameters are some of the most demanding in North America. According to the Structural Engineers Association of British Columbia, the West Coast of Canada is one of the few locations in the world where all three major categories of tectonic plate boundaries occur: convergent, divergent, and transform. Over the past 70 years these plate boundaries have accounted for more than 100 recorded earthquakes of magnitude 5 or greater [1]. The investigation undertook by the project team involved a selection of different lateral systems that would simultaneously satisfy the onerous seismic loads of the region and meet the client's desire for an aesthetically interesting structure – one that would complement the building's mass timber superstructure.

Terminus' gravity load resisting system is composed of four levels of glulam columns and beams sitting atop a concrete podium and underground parking structure. The diaphragm at each timber level comprises one-way spanning CLT panels, all of which are connected with plywood splines and a matrix of steel plate drag straps fastened to the top of the panels. ASPECT and DBS worked closely in sizing all gravity members and designing all gravity connections to satisfy the building's loading demands and one hour fire rating. The time and effort that went into detailing Terminus' timber components and connections helped motivate the project team in choosing a lateral system that would celebrate the beautiful exposed west coast timber in the building.

Figure 1: *Terminus, Finished Building*

The Buckling Restrained Brace (BRB) timber hybrid system that was ultimately chosen was decidedly best suited to satisfy these requirements, and allowed for a well-integrated, ductile, and highly architectural lateral load resisting system.

2 LATERAL SCHEMES AND SELECTED SYSTEM

As developer, designer, builder, and eventually, occupant for the project, DBS was committed to a mass timber structure that was highly architectural, safe, and celebrated the best of what timber can be. Coupled with their desire to furnish themselves and future tenants with a beautiful and robust building, DBS' stake in the project bolstered their willingness to explore various state-of-the-art options for the building's lateral force resisting system. Working together ASPECT and DBS identified cost, aesthetics, ductility, post-earthquake repairability, and precedence as the guiding criteria that would be used to make their selection. ASPECT undertook an investigation of potential candidates for the lateral system, and with DBS' help they shortlisted four options that were determined to best meet the associated parameters. The proposed systems are summarized below, including a list of advantages and disadvantages associated with each option:

2.1 Glulam Brace Frames with Quaketek Friction Dampers

This proprietary system manufactured by Quaketek (a Canadian based seismic protection technology company) is a steel Seismic Friction Damper that is installed at the brace/column interface within a glulam braced frame. The dampers are fuses, dissipating energy induced by the earthquake via friction. The dampers respond symmetrically throughout their cycle (in compression and tension), offering energy dissipation through a range of building motions [2].

The advantages offered by this system include:
-High ductility and offers substantial energy dissipation, which accordingly reduces forces on the other elements in the brace frame.
-Post-earthquake reusability (they can also be easily replaced if necessary).
-Quaketek offers in-house testing to suit a project's specific needs (helps to streamline the design process).

The disadvantages associated with this system include:
-It is not currently codified in Canada (although some research has shown that this system performs similarly to buckling restrained braces, which are an available option in the Canadian Code) [3].
-This product requires additional moment frames for optimal performance, including self-centring, which comes at a high cost in a mass timber building.

2.2 Glulam Brace Frames with Tectonus Resilient Slip Friction Joints (RSFJ)

The RSFJ is manufactured by New Zealand based company Tectonus Resilient Seismic Solutions. This system can be installed at the brace/column interface within a glulam brace frame, and it works by dissipating energy via slip friction as its tightly clamped grooved components move across each other. During a seismic event, the RSFJ will slip and re-centre cyclically before any of the other brace components yield [4].

The advantages offered by this system include:
-High ductility and offers substantial energy dissipation, which accordingly reduces forces on the other elements in the brace frame and other building elements such as the foundations and diaphragms.
-Self-centring capability, which helps to limit residual drifts and associated repair costs post-earthquake.
-Replaceable after an earthquake.
-All RSFJs are tested to suit a project's specific needs.

The disadvantages associated with this system include:
-It is not currently codified in Canada (although to-date there are some recent Canadian projects that have successfully employed this system) [3].
-This system presents higher associated costs relative to the other solutions listed herein.

2.3 Moderately Ductile Glulam Brace Frames (R_D = 2.0, R_O = 1.5)

This codified system features a glulam frame complete with glulam brace members connected to the columns and beams with detailed steel components designed to yield, dissipating energy during an earthquake.

The advantages offered by this system include:
-It is currently codified in Canada (although the code does not provide design guidance) [3].
-Not a proprietary system, so it would be easy to source and detail the component materials and parts. It is also a system that is relatively popular as a mass timber lateral scheme, so there are precedent projects that would offer design guidance.

The disadvantages associated with this system include:
-Lower ductility and energy dissipation than other options, which would increase the cost of the other frame components, and other building elements such as the foundations and diaphragms.
-It is not self-centring, and it is not easily replaced or repaired following an earthquake. This implication could result in substantial post-earthquake costs and could potentially require demolishing the building.

2.4 Steel Buckling Restrained Braces (BRB) in a Timber Frame (R_D = 4.0, R_O = 1.2)

A BRB is a steel section (highlighted in red and blue in Figure 2, below) that is encased in a concrete sleeve (shown in grey in figure 2, below), thus restrained from buckling. The centre of the steel section is slender and designed to yield in both tension and compression during an earthquake [5]. Incorporating a BRB in a timber frame is a unique approach that allows designers the opportunity to preserve the timber structure (incorporating only a limited amount of steel), whilst achieving an impressive level of ductility. Within the BRB braced frame, columns and beams are timber, and the diagonal brace elements are steel encased in concrete.

https://doi.org/10.52202/069179-0574

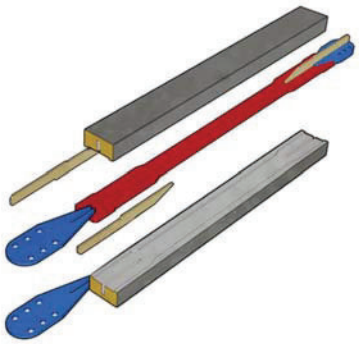

Figure 2: *BRB Cross-Section*

The advantages offered by this system include:
-It is currently codified in Canada (as an all-steel system) [3].
-Comparatively low costs (especially relative to the level of ductility that it achieves).
-High ductility and offers substantial energy dissipation, which accordingly reduces forces on the other elements in the brace frame and other building elements such as the foundations and diaphragms.
-Does not require backup moment resisting frames (as is the case with other lateral systems, such as the Quaketeck dampers).

The disadvantages associated with this system include:
-It is not self-centring. This implication could result in substantial post-earthquake costs and could potentially require demolishing the building.
-There are no precedents for using BRBs in a timber frame.

Following much deliberation between ASPECT, DBS, and Jack James, the timber-BRB hybrid was selected for Terminus' lateral system. Despite the lack of precedence for this type of system (steel BRBs are codified in Canada as an all-steel system, but no other project in North America has featured buckling restrained braces within a timber frame), the project team agreed that the high ductility and the low associated costs would be appropriate for the high seismic loads and the project budget. Furthermore, the opportunity to integrate the steel braces within the timber superstructure meant that DBS' design preference to maximize the amount of timber on the project would be fulfilled.

3 DETAILING OF STEEL/TIMBER CONNECTIONS

Following a linear dynamic analysis of the structure, ASPECT established brace loads, and worked with CoreBrace (the BRB designer and supplier) to finalize the brace dimensions. To optimize geometry and aesthetics, ASPECT and DBS elected to position the braces in a chevron orientation, spanning from floor to ceiling. Framed within glulam columns and beams, the BRBs are the only primary steel elements in the building. Evident in figure 3 below, the integration of the steel braces within the building's timber gravity elements presented the unique opportunity to showcase its mass timber with only minimal additional lateral steel (or concrete) components. CoreBrace's BRB design features a ductile steel plate core enclosed within an outer steel casing, a grout fill, and a proprietary debonding interface material. The ends of the ductile steel plate core are connected to steel lug plates extending out beyond the ends of the outer casing, complete with a bolt hole pattern for connection to the timber columns and beams.

Figure 3: *Newly Installed Braces*

The Canadian engineering steel design standard [3], requires suppliers to perform qualification tests on proprietary buckling restrained braces to demonstrate that design resistances can be developed without buckling the braces under deformations of 2x the design storey drift. CoreBrace performed these tests in-house and used the results to ascertain tensile and compressive strength design factors that were necessary to approximate the design overstrength factors for the brace connections. In compression, the overstrength factor is calculated as the product of three design parameters: ω (a strain hardening adjustment factor equal to approximately 1.4), β (a friction adjustment factor ranging from approximately 1.2 to 1.4), and Ry (the probably yield stress material factor equal to 1.1). In tension the overstrength factor is calculated similarly, without the inclusion of β. The resulting overstrength factors for the braces in compression and tension respectively are 2.1 and 1.6. Accordingly, all the timber connections and timber elements within the frame were designed to the probable capacities of the braces, including the overstrength factors noted above.

As shown in the following figures (4 and 5), ASPECT designed the typical brace connections using steel knife plates projecting from the ends of the braces, complete with multiple rows of stainless steel tight fit pins fastening the plates to the timber frame elements. All these connections were designed in accordance with the Canadian Engineering Wood Design Standard [6].

https://doi.org/10.52202/069179-0574

Figure 4: *Painted Brace Apex Connection*

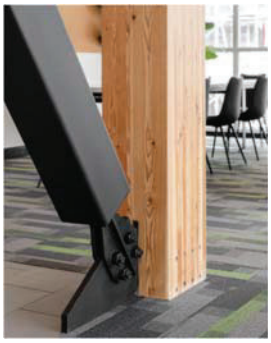

Figure 5: *Painted Brace-Column Connection*

Figures 6 and 7 show typical details for the brace apex and brace column connections. The brace-column connection features a 25mm thick steel knife plates fastened to the column with large groups of 16mm diameter tight fit pins. The plates project from the base of the columns to receive the end of the braces where they are fastened with 28mm diameter heavy hex bolts. The brace apex connection features a V-shaped 25mm thick steel knife plate that projects through a slot in the bottom of the beam and extends up to the top of CLT where it connects with a steel drag element running along the top of the floor. The steel drag strut eliminates the need to utilize the beam as a tie member, which greatly reducing the number and complexity of connections in the system. Whereas conventional chevron brace frames typically require large beams to resolve net vertical forces resulting when one brace buckles in compression and the other yields in tension, BRB's allow designers to avoid this design challenge as the compression capacity and the tension capacity are much closer. Accordingly, the glulam beam was simply designed to resist the comparatively small vertical reaction at the brace apex resulting from the brace action. As shown in figure 6, the beam is top flush with the floor panels. Shifting the beam upwards facilitated higher ductility in the braces by increasing their length, reducing the amount of steel required at the connections. Self-tapping screws installed through the depth of the beam serve to reinforce it against perpendicular to grain splitting, and screws installed through its width effectively clamp the beam and knife plate.

With deformation compatibility in mind, the intersections between the braces and the timber frame elements were detailed to accommodate sufficient rotation such that they could be idealized (as much as possible) as pinned connections. Horizontally slotted holes in the steel knife plates and the use of small diameter stainless steel tight fit pins help to prevent the connections from attracting moment and protect the timber elements from brittle failures. Researchers at the University of Canterbury performed a test program with a glulam frame BRB mock up comprising tight fit pin connections similar to those designed by ASPECT on this project. Their study investigated the cyclic performance of this type of system, and it demonstrated that the tight fit pins connecting the braces to the timber frame elements provided a decent amount of auxiliary ductility to the system while also carrying adequate strength to ensure the primary ductility mechanism would occur in the braces [7]. Additional ductility in a structure that is susceptible to significant earthquake effects is an invaluable benefit that can set the highest performing structures apart in a seismic event.

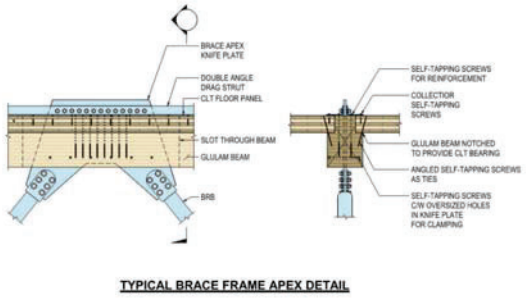

Figure 6: *Brace Apex Detail*

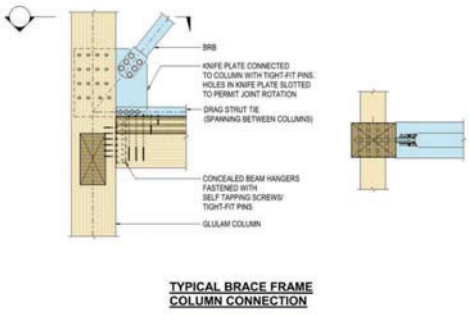

Figure 7: *Brace-Column Detail*

4 FABRICATION AND ERECTION OF TIMBER STRUCTURE

Following the design process, ASPECT worked closely with Structurlam (the timber supplier) for modelling, fabrication, and shop installation of the lateral system components and connections. A steady supply of detail sketches delivered by ASPECT coupled with frequent coordination meetings between the two teams aided Structurlam as they modelled the structure and prepared a

https://doi.org/10.52202/069179-0574

comprehensive shop drawing package. Despite the difficulties associated with having to navigate most of the design process during the early months of the Covid Pandemic, the help of remote meetings and a cohesive coordination schedule assisted the project team in successfully delivering construction drawings on time from their temporary home offices. The coordination between ASPECT and Structurlam aided to ensure accuracy in the fabricated components, and it helped to expedite and ease the installation process.

Structurlam assembled the largest and most critical lateral system connections in their shop. An example of this is observed in figure 8, where the large pre-installed column/brace knife plates located at the tops of the columns can be seen awaiting installation of the braces for the storey above. The pre-installation of the most complex components (notably the tight fit pin column-brace connections) saved a significant amount of onsite installation time and ensured that each of these critical connections was installed in a controlled environment by individuals with abundant mass timber experience.

Figure 8: *Brace Installation*

Tight fit connections demand very strict tolerances in both the steel and timber, and routinely this type of connection has shown to be quite difficult to install in-situ. Being installed in the shop meant that the exposed column faces housing the tight fit pin connections would not be subject to hammer blows by contractors with less experience during installation. To further alleviate the difficulty of installing some of the complex connections onsite, as shown in figure 9 below, the columns were fabricated and installed continuous over the building's first three storeys. Reducing the number of column splices also helped to provide as direct a load-path as possible, which was ultimately a huge benefit due to the high axial forces present in the columns towards the base of the structure.

Figure 9: *Continuous Column Installation*

Despite concerns about inclement weather and moisture management leading into the installation process, DBS's experience in mass timber construction ensured that due care was taken to protect the timber elements and all the crucial lateral system connections from damaging water ingress. Thanks to a carefully planned and executed moisture management strategy (one which included frequent squeegeeing, temporary rainwater leaders, coverings for the vital steel components, and an aggressive installation process) DBS was able to meet their erection goals even though installation occurred during a particularly rainy Pacific Northwest Winter (DBS' team had to deal with a combination of intense rains, snow, and driving winds throughout the mass timber installation process). Terminus' superstructure (including all gravity and lateral system elements) was assembled and erected over a span of roughly 2.5 months (this included 3 occupiable levels of mass timber and the roof, each of which comprise close to 1250m^2).

5 CONCLUSION

Several factors threatened to dampen progress on this building throughout design and construction, including the seismic demands of the region, the complexity of the lateral system connections, low tolerances in the system, a tight construction schedule, and the threat of inclement weather. Despite all these complications, the combination of collaboration, motivation, and experience displayed by the project team ultimately propelled this beautiful mass timber structure and its innovative lateral system to a timely completion. Opened in May 2021, Terminus' beautiful timber structure houses several new tenants, including DBS' entire design office. As the first of its kind in North America, the timber-BRB hybrid lateral system serves as a benchmark for success and innovation in modern mass timber.

HARDWOOD GLULAM IN COMPLEX STRUCTURES: DESIGN AND CONSTRUCTION OF THE MACA MUSEUM IN URUGUAY

Vanesa Baño[1], Leandro Domenech[2], Carlos Mazzey[3], Thomas Vieillard[4], Jean-Bernard Journot[4]

ABSTRACT: This work presents the process of structural design, fabrication, and construction of the MACA museum in Uruguay, with a focus on the use of hardwood species. The main room of MACA museum (1600 m^2) is a 3D complex structure made of Red Grandis (*Eucalyptus grandis*) glulam. The structure was designed by 19 bi-hinged frames, made up of inclined columns of 15 m of maximum height and curved beams of variable cross-section up to 27 m long. Given that Uruguay's first forest plantations date in the '90s, there is not yet a structural timber industry. The first timber standards were approved in 2018, and even Europe lacks a harmonized standard for the manufacturing of hardwood glulam. This paper presents the state of the art in hardwoods glulam and focuses on the difficulties and opportunities associated with the use of a hardwood species. In addition, it contemplates the importance of coordinated work between the academy and the industry (architects, structural engineers, and constructors) in the development of the design, manufacturing, and construction of the complex hardwood glulam structure of the MACA museum.

KEYWORDS: *Eucalyptus grandis*, hardwood, glulam, timber industry, structural design, construction, New European Bauhaus

1 INTRODUCTION

1.1 SOLID TIMBER OF HARDWOOD SPECIES WORLDWIDE

By 2030, the global production of coniferous (softwood) sawn wood is expected to increase at an annual rate of 1.8% [1]. Approximately 50% of this timber will be used for construction purposes as a substitute for steel, concrete, and masonry. The other 50% is destined for other uses of solid timber, such as packaging, furniture, or carpentry. In an analysis of the volume production of softwoods and hardwoods worldwide, according to data obtained from FAOSTAT, all the continents, except Asia, produce a higher volume of softwood species (Fig. 1).

This higher use of softwoods can be also observed in Europe, where while the production of coniferous sawn wood maintained an increasing trend over the years, the production of hardwood (non-coniferous) remained constant. Fig. 2 shows the graph of solid wood volume production from 2000 to 2020, generated from the FAOSTAT database.

In addition, the growing interest in sustainable low-carbon biobased materials for construction implies that the trend in demand for mass timber (glued laminated timber -GLT or glulam- and cross-laminated timber -CLT-, among others), continues increasing worldwide, mostly focused on softwood species [1].

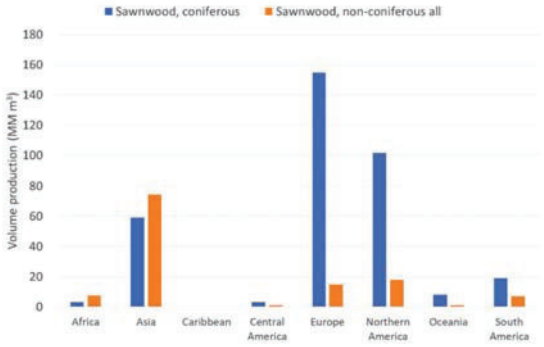

Figure 1: *Sawnwood volume production per continent (data obtained from FAOSTAT, 2022)*

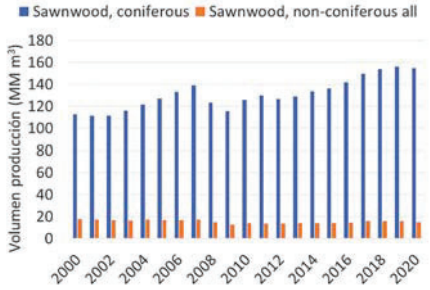

Figure 2: *Sawnwood volume production between 2000 and 2020 in Europe (data obtained from FAOSTAT, 2022)*

https://doi.org/10.52202/069179-0575

Under this panorama of increasing coniferous´demand for construction, is when the possibility of considering hardwood for structural use arises. Traditionally, hardwood prices were higher than those of softwoods due to, among other factors, the higher energy consumption in drying. However, softwood sawnwood prices have increased considerably in the last few years. As an example, in the US the prices increased more than double from 2010 to 2018, to nearly quadruple by September 2020, decreasing again to values close to those of 2010 at the end of 2020 [2].

1.2 OVERVIEW OF THE HARDWOODS GLULAM IN EUROPE

According to the European standard prEN 1912:2021 [3] data, most European countries have national softwood timber visually graded for structural use, and only five countries (GE, FR, BE, ES, and IT) have graded hardwood sawn wood (ash, beech, poplar, Southern blue gum, shining gum, and sweet chestnut), as shown in Fig. 3. Although this shows the current reduced interest in hardwoods for structural use, the number of species and countries has increased slightly since the previous version of 2012 [4].

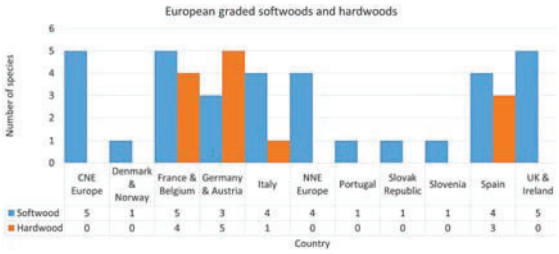

Figure 3: *Softwood and hardwood species visually graded for structural use in Europe (data obtained from* [3]*)*

Current European standards for engineered wood products (EWPs), such as GLT [5], CLT [6], or laminated veneer lumber (LVL) [7] are focused on softwood species, and harmonized European standards for hardwood species are not yet developed. The draft of the European standard about hardwood GLT is under development since 2014 [8], but there is not yet a consensus on the manufacturing requirements which contemplate the variability of the hardwood species. Therefore, it´s not possible to obtain the CE marking via the harmonized European standards, which is mandatory under the Construction Products Regulation (EU 305/2011) [9]. The European Technical Assessment (ETA), which is the basis for a Declaration of Performance (DoP), offers a voluntary route for the manufacturers to obtain the CE marking for hardwood glulam and other novelty products. In the absence of EN standards, European Assessment Documents (EADs) are the technical specifications developed by the European Organisation for Technical Assessment (EOTA) as the basis for the ETA certifications. The ETA for hardwood glulam can be obtained from the EADs for hardwood glulam production number 130010-01-0304 [10] and 130320-00-0304 [10], depending on the species.

Although there are several manufacturers in Europe able to produce hardwood glulam, only four (one in Germany, one in Austria, and two in Spain) obtained the CE marking throughout the ETA certification, according to the EOTA database [11]. Other alternatives are to go to the market using the report of the experimental test results from an external laboratory, and under the responsibility of the manufacturer, as presented in this paper.

1.3 EUCALYPTUS GLULAM IN SOUTH AMERICA

In the South American context, glulam production is mainly concentrated in Chile, with some industries in Argentina and Brazil, and a factory under construction in Uruguay. However, only Brazil has been manufacturing hardwood glulam beams for structural use for years. The company ITA began eucalyptus glulam production in 2008 and built some long-span structures, such as the Haras Polana with a cantilever of 12 m or the Iporanga Convention Center with a span of 14 m [12], Fig 4. However, the lack of standards and marketing strategies has slowed down the development of the glulam industry in the country, although the recent development of standards and the interest of new companies to produce glulam will probably increase the current production capacity by tenfold [13].

Figure 4: *Eucalyptus glulam structures in Brazil* [12]

1.4 FOREST AND TIMBER INDUSTRY IN URUGUAY

During the 90s, Uruguay's forestry sector experienced significant growth and currently, there is 845,000 ha of planted forests. *Eucalyptus spp*. covers 71% of the planted area, with approximately 600.000 ha, from which 42% corresponds to *Eucalyptus grandis* and *Eucalyptus saligna.* and 17% to Southern blue gum (*Eucalyptus globulus)*. *Pine spp*. covers 18% of the planted area, most of them of Loblolly and Slash pine (*Pinus taeda* and *Pinus elliottii)* [14]. The annual production of *E. grandis* is 11.2 million m^3 of roundwood, which is primarily used by the pulp industry and energy sector. The trees used for this purpose are typically between 10 and 12 years old. Approximately 1.2 million m^3 from the annual average supply are intended for mechanical transformation, with trees between 18 and 24 years old [15]. With growth rates of $30 m^3 ha^{-1} yr^-$, *E. grandis* becomes a promising raw material for glulam production in Uruguay.

https://doi.org/10.52202/069179-0575

Since timber is not a traditional construction material in Uruguay, the standards focused on structural timber are very recent. The first standards of timber grading for eucalyptus [16] and pine [17] were approved in 2018, while the standard with the requirements for glulam production [18] was approved in 2019, even though there is not yet a local manufacturing industry for structural products. However, the Uruguayan company *Urufor* has a large tradition in manufacturing laminated Red Grandis (a genetically improved variety of *Eucalyptus grandis*) products for non-structural use, but aesthetics and carpentry use, mainly for exportation. Regarding the national pine industry, the first manufacturing company of glulam and CLT is currently under construction, and it will start to produce in 2023 (*Arboreal*). According to the Uruguayan Technical Standard UNIT 1262 [16], mechanical properties of *E. grandis* sawn wood visually graded are $f_{m,k}$=21.4 N/mm^2, $E_{0,m}$=11960 N/mm^2 and ρ_k=386 Kg/m^3, which could be assigned to a strength class C20 of the European standard EN 338 [19]. Under the lack of a national structural code for designing timber structures in Uruguay, Eurocode 5 [20] [21] has been adopted as the reference code.

1.5 OBJECTIVE

This paper focuses on the importance of coordinated efforts between academia and industry (including architects, structural engineers, and constructors) in the design, manufacturing, and construction of complex and aesthetically pleasing hardwood glulam structures. Specifically, it examines the Atchugarry Museum of Contemporary Art (MACA), which features beams with spans of up to 27 meters and is aligned with the criteria of the New European Bauhaus (NEB).

2 CASE STUDY: MACA

2.1 ARCHITECTURAL DESIGN

MACA museum is situated in Maldonado, Uruguay, and was devised by the sculptor Pablo Atchugarry, throughout the Pablo Atchugarry Foundation. The main building, destined for the sculptures showroom, consists of a 3D curved structure with a floor area of 1600 m^2, designed by Carlos Ott Architect (Fig. 5). It was initially thought to be solved with a steel structure, but it turned to be a timber structure (Fig. 6) after a positive technical feasibility study carried out by some of the authors through the Faculty of Engineering of Universidad de la República.

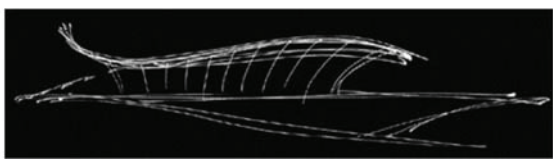

Figure 5: *Architectural sketch of MACA (Source: Carlos Ott)*

Figure 6: *3D rendering of MACA (Source: Carlos Ott)*

This study was focused on the pre-dimensioning of the frames, estimation of wood volume, analysis of the potential glulam suppliers, possibilities of transportation to Uruguay, and construction logistics.

2.2 STRUCTURAL DESIGN

The continuation of the engineering work from the feasibility study developed at the University was made through the creation of a timber engineering study named *Oak Ingeniería*, which was responsible for converting the architectural design into a timber structure, respecting the three-dimensional shape of the envelope.

The initial structural design was solved by 19 bi-hinged frames, made up of inclined columns of 15 m of maximum height and curved beams of variable cross-section up to 27 m long. It was initially designed with softwood glulam of strength class GL24h and the frames were composed of double columns connected to the curved beams by mechanical fasteners (Fig. 7). The design was made looking for a simple solution that could be provided by as many international companies as possible during the tendering process, and which implied a softwood wood volume of 237 m^3. The international tendering was won by the French company *Simonin SAS* with an initial solution using spruce glulam.

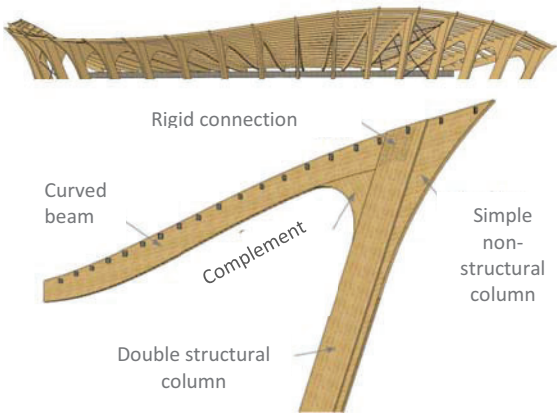

Figure 7: *BIM model of the preliminary softwood structural solution*

https://doi.org/10.52202/069179-0575

2.3 MATERIALS AND GLULAM MANUFACTURING

Since MACA was intended to become an iconic structure and building for the country, the involved actors proposed the option to use local wood for its construction, with the aim to give a local character to the design. Red Grandis was selected for the structure, mainly because of its aesthetics and color, which differ from the most common softwood species used in structures. The tradition and expertise of the company *Urufor* sawing, sorting, and drying this species was key for the selection. 350 m^3 of dried Red Grandis boards (Fig. 7a) of 25/28 mm of thickness were provided by *Urufor* and sent to the *Simonin* facilities in France for glulam manufacturing (Fig. 7b).

(a) (b)

Figure 7: *Red Grandis boards and glulam at Simonin facilities*

The initial environmental cost of this business model was accepted thinking that this iconic building would contribute of promoting the use of local wood for structural purposes. Also, it would allow evaluating of a potential future hardwood-based timber industry, which could provide local structural glulam in a more environmentally friendly solution.

The manufacturing of hardwood glulam implies the reduction in the thickness of the lamellas with the aim to ease the drying process and saving costs. The thickness of the lamellas after the board planning resulted in 20/23 mm in the case of Red Grandis, much lower than the common thickness in softwood, which usually varies between 35 and 45 mm for curved and straight beams, respectively. The increase in drying time of *E. grandis* of 25 mm of thickness versus *Pinus taeda* of 40 mm of thickness corresponds to a factor of 4.25 [22]. In addition, the reduced thickness implies that the number of glue lines increased by 1.6 in the case of lamellas of 25 mm of thickness than that of 40 mm and, therefore, a higher amount of adhesive is required. Both factors have a direct incidence on the hardwood glulam cost.

Under the lack of a specific standard for glulam production, the manufacturing process followed the requirements of standard EN 14080. The initial type testing and the factory production control were made through an agreement with the industrial technical centre *FCBA* to ensure the mechanical properties and the gluing quality. In addition, an internal delamination control according to method C of EN 14080 was made.

The characteristic values of the mechanical properties of the boards and the bending strength of the finger joint ($f_{m,j,k}$) were obtained from experimental tests, resulting in three hardwood strength classes depending of the visual quality: D18 ($f_{m,j,k}$=22 N/mm^2), D20 ($f_{m,j,k}$=36 N/mm^2), and D24 ($f_{m,j,k}$=30 N/mm^2). The values were like those declared for sweet chestnut or Poplar nigra (D24 and D18) and for the lower visual qualities of beech (D18, D24) from France [3]. Glulam beams were manufactured using a Melamine Urea Formaldehyde (MUF) adhesive for hardwood species and results from the initial type testing on full-scale glulam beams resulted in the strength classes named GLD20h (ρ_k= 475 Kg/m^3), GLD24h (ρ_k= 485 Kg/m^3), and GLD28h (ρ_k= 530 Kg/m^3) for the lamellas of strength classes D18, D20, and D24, respectively. The obtained hardwood strength classes were like those of softwood species in terms of bending strength and modulus of elasticity, but with higher values of density.

As a comparison, densities resulted in values 1.3 higher than those of softwood for GL24h and GL28h. These results also showed the increase in the density of Red Grandis, the *Eucalyptus grandis* genetically improved by *Urufor*, with respect to that declared in the Uruguayan standard UNIT 1262 [16].

2.4 STRUCTURAL REDESIGN

The change from a softwood to a hardwood species during the tendering implied a revision of the initial structural design. Not only the cross-section of the members had to be modified, but also the configuration of the frame with the aim to reduce the total wood volume and, in this way, to partially compensate for the higher costs of hardwood versus softwood glulam. The double columns that braced the beams were substituted by simple columns joined by a high resistance connexion of glued bars that support the corresponding bending moment. This connection was solved with the Resix system, patented by *Simonin,* which benefited from the higher timber density of Red Grandis with respect to the softwood species. With the aim to facilitate the transportation of the glulam beams from France to Uruguay, with a total span of up to 27 m, they were manufactured in two parts, joined *in situ* generating a rigid connection with this *Resix* system. Each of the 19 bi-hinged frames consisted of the connection of seven glulam pieces, as shown in Fig. 8, with parts 1, 2, and 3 constituting the main structure of the portal frame. The columns were divided into two parts with the aim to separate the parts located in the interior from those in contact with the weather environment. The objective was that the exterior part of the columns could be repaired or replaced easily in the case of damage due to weather exposure, without affecting the structure of the bi-hinged frame. Fig. 9 shows the final configuration of the frames and the detail of the rigid Resix connection.

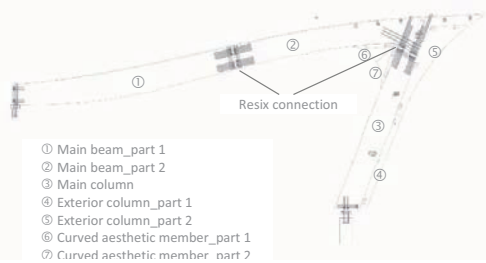

Figure 8: *Scheme of one of the bi-hinged frames*

Figure 9: *Final design of the frames and rigid Resix connection*

The BIM model was modified according to this final design and all the notches were designed to be manufactured by a computer numerical control machine (CNC), which was the key to the successful building process over 10,000 km away from the manufacturing company. Fig. 10 shows the machining of the main beams for the Resix connection and the location of the purlins.

Figure 10: *CNC machining in the beams and purlins*

2.3. CONSTRUCTION PROCESS

The timber structure was erected by *Simonin France* in collaboration with the Uruguayan building company *Atchugarry Arquitectura y Construcción*, which served for the local training in timber construction. With a total of 196 m^3 of Red Grandis glulam (48 m^3 for the purlins, 68 m^3 for the columns, and 80 m^3 for the beams), the construction process started in October 2020 and the MACA Museum was inaugurated in January 2022.

The complex 3D design of the building implied that each glulam piece is different from the other, resulting in a total of 322 purlins, each one with a unique cross-section, length, and angle of insertion on the beams, which also implied the design of unique steel fasteners for each member. Different stages of the construction process are shown in Fig. 11.

Figure 11: *MACA construction process*

https://doi.org/10.52202/069179-0575

During the construction process, black stains were observed on the hardwood timber structure associated with the rains that occurred during the installation of the steel structure for the envelope. It was caused by the contact between the natural wood tannins of the Eucalyptus diluted in water with the oxidized iron contained in steel filings, a problem that doesn´t occurs with softwood species. After different tests developed in the frame of a Master Engineering thesis [23], they were removed by applying oxalic acid, as shown in Fig. 12.

Figure 12. *Steel structure for supporting the envelope and experimental tests with oxalic acid to remove the stains* [23].

Fig. 13 shows images of MACA museum once finished.

Figure 13: *Images during the construction process of MACA*

3 ALIGNMENTS WITH THE NEB VALUES

The design and construction of the sculptures hall of the MACA museum were aligned with some of the New European Bauhaus (NEB) values, launched in 2021 by the European Commission.

1) Together

According to Pablo Atchugarry, owner and developer of the museum, the intention of MACA, located in a 40-hectare greenery field, which is also an international sculpture park, is "to be a bridge for local and international art, an open and free museum where the art can be available all the year". To reach his objective, a collaborative design work process between the owner and the architect in the first stage of the project conception, and then with the academy, engineers, providers, manufacturers, and constructors, made it possible for MACA to become a reality.

2) Sustainable

During the collaborative design work process, the building´s structure was converted from steel to wood. With a total structural wood volume of 197 m^3, the content of biogenic carbon, which was calculated according to EN 16449, was 148 tn. This calculation doesn´t consider the influence of transportation, which would affect the result because the wood made a round trip between Uruguay and France due to the lack of national glulam manufacturers, as had been the case of steel, usually imported from China because of the lack of national steel industry. *Eucalyptus grandis* provided by Urufor comes from sustainable forest management, certified by FSC [24].

3) Beautiful

The 3D building's shape and the aesthetics of Red grandis wood made the MACA museum cited by several international institutions and magazines as a monument to timber architecture or highlighted its aesthetics [25] [26] [27] [28] [29]. In addition, it was selected as one of the best museums of 2022 worldwide by the Conde Nast Traveller magazine [30].

4 CONCLUSIONS

This paper presents the design, fabrication, and construction of the MACA museum's structure, with a focus on the challenges and opportunities that arise when using a hardwood species. The successful implementation of the project was only possible due to the collaborative efforts of all stakeholders from the outset. The architectural and engineering design was developed through an iterative process between the owner, architects, and engineers, with close collaboration with the wood supplier and the manufacturing company. The outcome was a flawless building process, with only one purlin requiring modification due to a human error in the digital order of the CNC machine.

The final redesign with Red Grandis, with values of density 1.3 higher than that of a GL24h from softwoods, resulted in a reduction of 41 m^3 in total wood volume with respect to the initial solution in spruce. However, the

https://doi.org/10.52202/069179-0575

increased cost of this hardwood glulam with respect to a softwood (4.25 times the drying time and 1.6 the amount of adhesive), coupled with transportation costs for manufacturing in another continent, didn´t offset the volume savings. Nonetheless, the choice of Red Grandis, a sustainable and local raw material, resulted in an aesthetically pleasing building, where the wood's natural color and curved building´s structure highlight a unique design in South America, as a result of a collaborating design, complying with the NEB values.

ACKNOWLEDGEMENT

The writing and presentation of this work in the WCTE were made in the frame of the European research project Horizon 2020: BASAJAUN No. 862942, funded by the European Union.

CASE STUDY – THE USE OF ROBOTICS IN THE CONSTRUCTION OF TIMBER STRUCTURES USING WESTERN AUSTRALIA'S LARGEST MASS ENGINEERED TIMBER BUILDING AS A TEST BED

Ralph Belperio[1] Pratik Shrestha[2]

ABSTRACT: In 2023, Murdoch University in Australia opened a new teaching facility, called Boola Katitjin. The focal point of this building is the use of Mass Engineered Timber (MET). Boola Katitjin is the largest timber building in Western Australia (WA). Due to their modular and prefabricated nature, MET buildings provide a fertile testing ground for deploying robotics in construction. This paper presents the research that was undertaken to explore the use of robotics in the construction of a MET building to improve the productivity of timber construction. It also presents the findings of the successful deployment of the robot on Boola Katitjin, in a collaboration between Aurecon, University of Technology, Sydney & Murdoch University – bringing an opportunity for academia to collaborate with industry. The findings demonstrated that by using robots to install screw fixings into CLT panels, approximately 15-20% saving in the timber installation construction programme could be realised, compared with using humans to install the screw fixings into CLT. Furthermore, our results show that a robot can install screw fixings at a faster rate (on average) than a human, and with greater accuracies. Finally, this paper presents the challenges faced and assumptions made.

KEYWORDS: Mass Engineered Timber; Robotics; Innovation; Automation, Academia & Industry Collaboration

1 INTRODUCTION

In a world first, Murdoch University (MU), in partnership with Aurecon & University of Technology, Sydney (UTS) deployed robots on a live construction site to construct part of Murdoch's Mass Engineered Timber Building, Boola Katitjin. This tripartite partnership created an academia & industry collaboration to investigate the use of robotics to improve construction productivity.

2 SYNOPSIS

Boola Katitjin is Murdoch University's (MU) new teaching and learning facility, opened in February 2023. Using mass engineered timber (MET), it is the largest mass timber building in Western Australia (WA).

MET buildings can be exemplar in sustainable, circular design by using local renewable materials, designing out waste through modular design and construction, and reducing the carbon footprint of materials using timber, which sequesters carbon. However, due to their relative niche status in Australia, the price of MET buildings often remains a barrier.

In engineering Boola Katitjin, Aurecon challenged traditional mindsets around financial viability through:

• Deep engagement with the timber industry, including a WA Timber Forum to identify risks, challenges and opportunities with timber supply and construction

• Incorporating a world-first robotics technology trial to provide a proof of concept to increase construction efficiency and safety and reduce cost.

The deployment of robotics on Boola Katitjin was led by Aurecon, leveraging an Aurecon Design Academy [1] research thesis on robotics in timber construction, in partnership with the University of Technology, Sydney (UTS). The modular and prefabricated nature of MET buildings provides a fertile testing ground for deploying robotics. Seizing this opportunity, the client, Murdoch University and contractor, Multiplex, were supportive of using the construction of Boola Katitjin as a testbed and exemplar for this emerging innovative technology.

3 INNOVATIONS

3.1 ACADEMIA/INDUSTRY COLLABORATION

The commitment to deploy robotics resulted from a brainstorming session between MU and Aurecon where we explored the challenges the construction industry is currently facing around safety and productivity.

During the workshop, a blue-sky question emerged "Wouldn't it be cool if robots built Boola Katitjin?". This simple question turned into an opportunity to embed academic research into Boola Katitjin around deployment of robotics. This idea gained further traction with the inclusion of UTS, creating a tripartite partnership.

Together, Aurecon, UTS and MU created an academia/industry collaboration project to investigate the use of robotics in construction to advance innovation and improve productivity and safety, through the robotic installation of up to 100 screws (300-400 mm long) into the timber slabs. There are 200,000 – 300,000 screw

fixings in total on the Boola Katitjin project. The proof of concept concluded with the successful deployment of the robot – Quenda-bot - on a live construction site in May 2022. This research predicts that it is possible to achieve time savings of 15-20 per cent of the construction schedule once the technology is fully developed and deployed.

3.2 DISRUPTING THE CONSTRUCTION INDUSTRY

This innovation not only has the potential to improve construction productivity and safety on a larger scale, but also contributes to the decarbonisation of the construction industry, with the potential to improve efficiency to embed timber as a preferred material of choice. There are great opportunities for this innovation to be replicated on future timber construction sites and change the way in which we design and construct buildings, to increase speed of construction and reduce embodied carbon. Ultimately, this innovation has the potential to significantly disrupt the construction industry – historically a laggard when it comes to innovation and automation.

Despite being one of the oldest and largest global industries, the sector remains resistant to change, preferring to use historically prevalent materials and construction techniques.

3.3 SUSTAINABILTY AND COST REDUCTION

Building and construction are responsible for 40 per cent of global carbon emissions. Timber building systems can help reduce these emissions. Not only is timber renewable, but it also has a lower embodied carbon footprint than traditional materials, while lending itself to modular design and construction techniques that cut waste and enable reuse of elements, improving the circularity of the construction. When sustainably sourced and manufactured, timber can play an important role in a regenerative economy. Yet it remains more costly in practice. This project aimed to demonstrate cost savings through supply chain collaboration and technological innovation. If cost-effectiveness can be improved to the point where building in timber is cheaper than traditional alternatives, we expect the flood gates to open in terms of uptake of timber as a structural material of choice.

3.4 IMPROVING SAFETY

On Boola Katitjin, there are approximately 200,000 – 300,000 screw fixings. The traditional method of installation is for a construction worker to use a battery-powered impact driver to install these individually, in a crouched position. Being crouched in the same position, while exerting downwards force on the screw, causes back/leg and ergonomic issues.

Aurecon conducted a stakeholder interview with the site team, which uncovered that worker fatigue and morale was a major concern, which the site team had to mitigate by giving the operators more regular breaks every 45 minutes. The introduction of robotics has the potential to largely eliminate these related health and safety concerns. The robot can autonomously install screw fixings throughout the day and night, potentially eliminating robot/human interactions. This will enable construction workers to undertake higher value tasks, assisting with physical and mental health and skill development.

By coupling automation and MET, timber buildings will become safer to build, more efficient, and less costly, enabling the construction industry to move towards a more sustainable and innovative future.

3.5 SUPPLY CHAIN COLLABORATION

As MET is a relatively new material in the Australian context, engagement with the timber industry was conducted via industry workshops, hosted by Aurecon, to identify risks, challenges and opportunities with timber construction and support the timber industry to emerge and scale up.

With exemplar projects such as Boola Katitjin, we remain hopeful that the industry will continue to scale to embrace the opportunities created by the existence and promotion of projects such as Boola Katitjin.

4 PROOF OF CONCEPT TRIAL

4.1 QUENDA-BOT TRIAL

There are 200,000 – 300,000 screw fixings in total on the Boola Katitjin project. The proof of concept concluded with the successful deployment of the robot on a live construction site in May 2022, installing around 100 screws. This research predicts that once the technology is fully developed, it will be possible to save 15-20 per cent of the construction schedule.

The challenges around the robotics technology trial were considerable, which were solved through creating a digital twin and using 3D simulations.

Figure 1: *Quenda-bot on site at Boola Katitjin*

4.1.1 Creating a digital twin

The robot is equipped with a LIDAR (Light Detection and Ranging) navigation system for autonomous travel. However, while the robot could navigate around a place, it needed to still understand where it was globally.

As the civil and structural consultant engineers on the project, Aurecon already had a BIM model (REVIT) of Boola Katitjin. Aurecon and UTS devised a workflow whereby the UTS team exported Aurecon's BIM model and inserted it into their robotics software - Gazebo. This created a digital twin of the building, to allow the robot to understand where in space it was and where it was in the building relative to grid references. Once the robot understands where it is from a global perspective, it then switches to an onboard navigation system to pinpoint where to install the screws.

This workflow has redefined the term 'digital twin'. Historically, we have always considered digital twinning from a construction/built environment/infrastructure perspective. We have now created a new workflow where the digital twin is relatable to robotics, opening a new offering to two industries. Based on this workflow and navigation system methodology, the robot was then able to install the screw fixings to within +/-5mm accuracy, which is acceptable and, in many cases, exceeds the accuracy of manually installed screws.

4.1.2 3D simulations

Pandemic restrictions limited usual lab experimentation practices, hence numerous complex 3D simulations were used to prototype virtually and learn. The robot 3D simulation tests are conducted inside the Gazebo software, which allows the simulation of robots in complex indoor and outdoor environments. This was a fast way to prototype virtually. We were able to trial new and different elements, fail fast in a virtual environment, learn, reset and move on. Following the successful completion of the simulations and virtual prototyping, the robot was then built and tested in a physical lab environment, prior to the successful deployment on site.

4.2 Outcomes of the innovative application of the technology

The objectives of this project were to create a sustainable, circular building and to enable projects of this type to flourish across the Asia Pacific region, by demonstrating economic viability, safety, and sustainability.

5 FUTURE OPPORTUNITIES

5.1 THE OPPORTUNITY

MET building systems can help reduce carbon emissions, of which the building and construction sector contributes 40 per cent. It also lends itself to modular design and construction techniques that cut waste and enable reuse of elements in the future. When sustainably sourced and manufactured, timber can play an important role in a regenerative economy. By enabling the efficient and safer construction of timber structures, the aspiration is to make timber the building material of choice. This will contribute to a "step change" in the decarbonisation of the construction industry.

5.2 THE CHALLENGE

MET construction remains costly in practice. This project provided a testbed to research innovations that seek to drive greater efficiencies through supply chain collaboration and technological innovation. If timber construction can achieve greater efficiency to be directly cost competitive to concrete and steel, volumes would increase, further reducing the cost of timber construction. Another challenge will be the ability of the supply chain to meet demand without diminishing supply volumes to traditional markets such as stick built housing. Once cost competitiveness is achieved, then we believe that the focus of the timber industry will shift to meeting the demand in a sustainable way.

6 OUTCOMES

The research commenced with industry engagement to identify risks, challenges and opportunities, and concluded with the successful deployment of the robot – Quenda-bot - on a live construction site, through the collaboration of Aurecon, UTS, Murdoch University and Multiplex. The following outcomes were achieved:

- The robot successfully installed 100 screws as a world-first proof of concept.
- The research predicts a saving of 15-20 per cent off the timber construction schedule if the robotics are suitable developed and deployed fully on site.
- Further gains in productivity and safety could be realised via a 24-hour construction site.
- Worker safety can also be improved through the removal of rote and repetitive tasks, enabling a greater focus on higher value tasks and skills development.
- This research is highly replicable and scalable and is ready to be deployed onto future projects.

6.1 OVERVIEW OF FUTURE APPLICATIONS

Timber remains the only truly sustainable mainstream building material yet has not reached its full potential for commercial applications in the region due to cost and supply chain challenges.

The objective of the Boola Katitjin robotics project was to demonstrate that MET buildings, which also lend themselves to modular design and construction, are economically viable, safe, and sustainable – contributing to a regenerative economy. This in turn reduces waste and increases the potential for future reuse of some elements.

Aurecon has amassed an enviable track record in successful timber design over the past 40 years, including Australia's tallest commercial timber building, 25 King St, one of Australia's tallest residential timber buildings, Monterey Apartments, both located in Brisbane and one of the world's largest timber buildings, Nanyang Technological University Academic Building South in Singapore.

Boola Katitjin is the largest mass timber building in Western Australia. Through the successful design and construction of these and future timber buildings, Aurecon aims to consolidate our reputation as the 'designers of choice' for MET and low carbon buildings of all typologies.

Following the successful deployment of the robot in May 2022, which demonstrated potential savings of 15-20 per cent off the timber construction schedule, the project team have been working on the next stage of robot development. Future developments include improvements to the robot to enable it to install screw fixings more autonomously and at a faster rate.

The project team is currently working on sourcing funding and have identified potential future timber projects on which the robot could be deployed at scale. The aspiration

of the next project is for the robot to do an entire floor plate without any human intervention.
This innovation not only improves construction productivity and safety, but also contributes to the decarbonisation and circularity of the construction industry.
Ultimately, this replicable and scalable research has the potential to disrupt the construction industry for more sustainable outcomes.

6.2 MEDIA COVERAGE

The project generated significant interest from local media outlets, resulting in elevated profile for the project and interest in the emerging technology from various parties:

FINANCIAL REVIEW

Murdoch Uni pilots robot construction

Michael Bleby

The newest worker fixing screws in the framing of Murdoch University's Building 360 is not doing it in hi-vis jackets, or even with eye protection.

Rather, it is on wheels and has a six-axis arm, in a world-first operation to use a robot to install screw fixings – the industrial-sized screws that secure the timber framing to the wooden floor – in a further step down the road to manufacturing-like processes in construction.

It is only a pilot at this stage, testing the safe use of the University of Technology Sydney-designed robot on a live site. It will only place between 50 and 100 out of a total 200,000-300,000 screw fixings on the four-storey structure that will be WA's largest engineered timber building.

But the productivity gains were potentially huge, said Tim Spies, Aurecon's built environment managing director and a consultant to the project.

"On a typical 18-month schedule for a building of this scale and configuration, it would be possible to save between 15-20 per cent of the timber construction schedule," he said. "This could represent a saving of between 4-8 weeks on the overall build."

Further gains could come from the work robots could provide during night work, he said. Humans could "drop in" the timber slabs during the day, and the robot work throughout the night installing screws.

Multiplex is the construction contractor on the building with a $145 million budget. Practical completion is due in November.

UTS Robotics Institute and the project leader, Dikai Liu, said intelligent robots were changing construction.

"Construction sites are varied, complex and changing – and that can be a real challenge for a robot to navigate and conduct operations," Professor Liu said. "What we have been able to design is an intelligent robot that can focus on an important task even amidst this disruptive environment."

Mass Engineered Timber buildings offer a good testing ground for robotics in construction. Installing screw fixings into CLT slabs is typically the most repetitive task in any timber project.

Figure 4: *The Australian Financial Review article*

We were informed that Rory Campbell from 7 News Perth would attend site briefly during the trial. Such was the enthusiasm for Quenda-bot that he and the 7 News team ended up remaining on site for 3 hours during the trial, resulting in coverage on multiple media platforms.

The project also generated significant interest in engineering circles, including an article in the Innovation section of Create, Engineers Australia's magazine and website [2].

Meet the robot helping to build Western Australia's largest mass-engineered timber building

by Jonathan Bradley — July 26, 2022 in Innovation 3 min read 0

Figure 6: *Engineers Australia coverage*

https://doi.org/10.52202/069179-0576

7 CONCLUSIONS

International design, engineering and advisory company Aurecon has introduced robotics technology into the construction of Murdoch University's new Boola Katitjin building in a world-first trial, in collaboration with major partners Murdoch University (MU) and University of Technology, Sydney (UTS).

Boola Katitjin is Western Australia's largest mass-engineered-timber (MET) building. MET buildings can be exemplar in sustainable, circular design by using local renewable materials, designing out waste through modular design and construction, and reducing the carbon footprint of materials using timber, which sequesters carbon. However, due to their relative infancy in Australia and New Zealand (ANZ), the price of MET buildings can be perceived as a barrier.

The objectives of the research project were to create a sustainable, circular building and to enable projects of this type to flourish across Australia and New Zealand, by demonstrating economic viability, safety, and sustainability. Conceptualised by Aurecon as part of an Aurecon Design Academy [1] thesis project and delivered as an industry/academia collaboration between Aurecon, University of Technology, Sydney (UTS) researchers, Murdoch University and Multiplex, the aim was to demonstrate that robots could deliver cumbersome screw fixings - a repetitive and time-consuming task that causes fatigue and injury in workers.

The robot – "Quenda-bot" – was successfully deployed on the 'live' Boola Katitjin construction site in May 2022, demonstrating how automation could improve worker safety and construction efficiency, with potential savings of 15-20 per cent from the timber construction schedule.

There are around 200,000 to 300,000 screw fixings on the Boola Katitjin construction site. The proof-of-concept trial successfully installed around 100 screw fixings.

Following the successful deployment of the robot, the project team have been working on the next stage of development. The future application is for the robot to be refined to enable it to install screw fixings at a faster rate. The project team is currently working on sourcing funding and have identified potential future timber projects on which the robot could be deployed at scale. An aspiration for the next project is for the robot to screw fix an entire floor plate without any human intervention.

Ultimately, this research has the potential to disrupt the construction industry for more sustainable outcomes

ACKNOWLEDGEMENTS

The Authors would like to acknowledge the support and tireless efforts of the following parties in making this work possible:

- Murdoch University – for having the vision to build WA's largest Mass Engineered Timber building, and entrusting Aurecon to conceptualise and deliver that game-changing building for them. Also, to allow Aurecon to assist them in developing a process for achieving a world-first innovation, using their project as a testbed. We will forever be thankful for the support and trust they put in us to deliver.
- University of Technology, Sydney – Robotics Institute, and particularly the leadership of the quintessential gentleman Professor Dikai Liu, and his team led capably on site by Professor Shoudong Huang. Without access to the eminent skills and capability contained in that Institute, and their innate willingness and ability to collaborate, the outcomes presented here would not have been possible.

VALIDATING MOISTURE-SAFE ENERGY EFFICIENT CLT ASSEMBLIES IN HOT AND HUMID CLIMATES USING EXPERIMENTAL TESTING

Marcus Strang[1], Paola Leardini[1], Maryam Shirmohammadi[2]

ABSTRACT: Climate specific cross-laminated timber (CLT) construction detailing to manage moisture risks in subtropical and tropical regions of Australia is validated through experimental testing, statistical analysis, and computational hygrothermal modelling. Three projects in Australia are monitored: a CLT micro-unit built in a subtropical climate, a small CLT structure assembled inside a controlled double climatic chamber simulating a tropical environment, and an existing residential building located in a tropical climate. Several parameters are altered in the experiment design to understand the most reliable assemblies for CLT buildings in hot and humid climates that can sufficiently control the moisture risks. The findings suggest that the hygrothermal modelling guidance from ASHRAE 160 pertaining to construction unprotected from stormwater accurately represents CLT assemblies in hot and humid climates. The importance of adhering weather resistant membranes (WRB) to both the external face and edge grains of the CLT panels is revealed. In tropical climates, the positioning of internal insulation and WRB with increased vapour resistance are also shown to be beneficial, while ventilated cavities and drainage layers behind the cladding is critical for rain protection.

KEYWORDS: CLT, Hot and humid climates, Moisture, Construction wetting, Field monitoring, Energy efficiency.

1 INTRODUCTION

CLT construction and highly energy efficient buildings were originally developed and adopted in temperate and cold climates, where the vapour transfers predominantly from the inside to the outside. Instead, buildings in tropical and subtropical climates face different conditions, where cooling-dominated interior zones exert a vapour pressure in the direction of the interior for much of the year, due to high ambient relative humidity (RH) and temperatures. In addition, buildings constructed with CLT envelopes that are located in tropical climates have enhanced susceptibility to biotic deterioration [1] due to ambient temperatures and RH being within a range that is optimal for biotic growth to occur. As the market for energy efficient CLT buildings expands into these climates, performance testing and subsequent design adaptation is required. This is especially concerning in Australia, where the building industry has been slowly transitioning towards energy efficient buildings with increased levels of airtightness and thermal protection, adopting modern construction materials and practices that may exacerbate moisture risks. [2]. Therefore, this study focuses on experimental testing — including design and results — to validate simulation results and, thus, the proposed moisture safe solutions in subtropical and tropical regions.

2 METHODOLOGY

Three projects in Australia were subjected to a monitoring campaign aimed to validate results of previous hygrothermal simulation. A CLT micro-unit has been designed and built at the Salisbury research facility of Queensland Department of Agriculture and Fisheries (DAF) and exposed to the hot and humid subtropical climate of Brisbane, as shown in Figure 1. A small CLT structure, employing the same assemblies of the micro-unit, has been placed inside a controlled double climatic chamber to simulate exposure to a tropical environment, as shown in Figure 2. Lastly, an existing CLT residential building located in tropical Cairns was also instrumented, as shown in Figure 3.

Figure 1: *The CLT micro-unit's shown before cladding is installed (left) and after installation (right)*

https://doi.org/10.52202/069179-0577

Figure 2: *The arrangement of the internal and external insulation of the small structure within the double climatic chambers is shown before the seal is completed between the two climatic chambers*

Figure 3: *Construction of a CLT residential project in Cairns, depicting the steel framing and ground floor CLT panels with scaffolding and the weather resistant membrane visible*

The monitoring campaign of the three projects included the installation of moisture content (MC) sensors within the CLT panels. This was done to demonstrate the impact of different parameters and investigate the moisture performance and hygroscopic characteristics of the CLT structures over two phases. The first phase of the study monitored changes in MC of CLT panels through exposure to hot and humid climates during the 'construction' period, while the second phase investigated the change in vapour flow through the CLT assemblies once construction was complete and the building space was conditioned. The experiments allow the evaluation of specific parameters, including the influence of weather resistant membranes (WRB), location of the insulation layer (internal/external), and exposure of unprotected walls to high humidity and high temperature during construction, to verify moisture-safe assemblies developed in earlier studies using hygrothermal simulation for these same hot and humid climates [3]. The different parameters investigated in this study are shown in Figure 4.

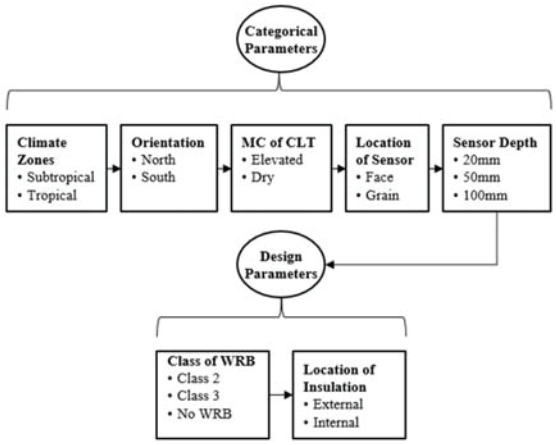

Figure 4: *Parameters evaluated within the two experimental tests*

The MC measurements were processed and inputted into calibrated hygrothermal simulation models to evaluate these parameters over the construction and operational phases. This was done to support the identification of the most appropriate CLT assemblies for hot and humid climates to avoid moisture risks.

2.1 CONSTRUCTION OF THE CLT MONITORING PROJECTS

The purpose of the three experiments was to cover specific climatic conditions for assessing long-term construction risks for CLT assemblies in hot and humid Australian climate.

2.1.1 CLT MICRO-UNIT EXPERIMENT

The CLT micro-unit was constructed to understand the impact of membrane vapour permeability on MC of the CLT panels during construction. For this reason, the two types of WRBs (a Class 2 and Class 3 product) were adhered to the external surface of the CLT panel on the north and south orientations. To assess the worst-case orientations, due to solar-driven inward diffusion effect on the north orientation and wind-driven rain and minimal drying potential effect on the south orientation. While the east and west oriented CLT panels were left exposed as reference cases. The CLT envelope was left exposed for 6 months during Brisbane's hot and humid summer season, as shown in Figure 5. This was expected to provide conservative results in terms of moisture risk, as a typical summer season in Brisbane was associated with the highest precipitation and RH for the year, which was a key consideration for this research. The duration of the experiment was decided to reflect worse-case delays during the construction phase of large-scale CLT buildings, for instance, due to procurement issues of the windows, concrete structure, or steel framing.

https://doi.org/10.52202/069179-0577

Figure 5: *The CLT micro-unit during the 'construction' period. The location of the sensor arrays on the interior CLT surface, the 2 WRB types, as well as the exposed CLT surfaces, edge grains, and rough door opening are visible*

The protected 'operational' phase commenced with the installation of the door, insulation panels, eave over the door, wall cladding, and roofing sheets flashed for rainfall drainage. A small, decentralised ventilation system with heat recovery and a small split system were also installed internally and activated during the 'operational' phase.

2.1.2 CLIMATIC CHAMBER EXPERIMENT

The climatic chamber experiment was developed to understand how CLT assemblies dry-out in tropical climates after construction wetting. This was done by changing certain parameters in the assembly, including the insulation layer location, vapour permeability of the WRB, and initial MC of the CLT panels. The configuration of the internal and external insulation, as well as the 2 types of WRBs with different vapour permeabilities can be seen in Figure 6.

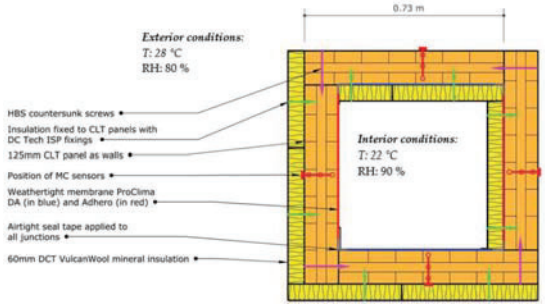

Figure 6: *The position of the insulation, different WRB types, and MC sensors in the double climatic chamber experiment*

To assess the influence of the initial MC of the CLT, 4 CLT panels were installed 'dry', while 4 CLT panels were 'wetted', letting them soak with a 10 mm layer of water sitting on their surface to represent two wetting events on-site, of 4 days and 7 days respectively, with a 10-day gap. All 8 CLT panels were then assembled in the double climatic chamber, as shown in Figure 7. The CLT assemblies were then subjected to 'exterior' condition of 28 °C and RH of 80 % for two months — a typical monsoon season in Cairns or Darwin. Insulation was then added, and the 'interior' condition was set to 22 °C and RH of 90 % for an additional two months, to represent an actively cooled building with a very high internal humidity loads, such as a kitchen or bathroom zone with an inadequate ventilation strategy.

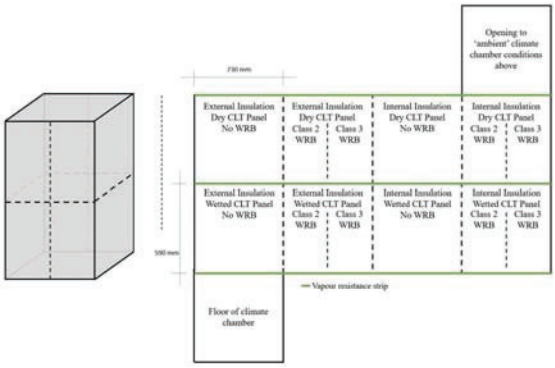

Figure 7: *Unfolded configuration of the CLT panels installed in the double climatic chamber*

2.1.3 RESIDENTIAL CLT BUILDING

A detached three-bedroom residential CLT building located in Cairns, comprising 180 m^2 of conditioned space was monitored over its construction period. No monitoring during occupation of the building took place. The project was instrumented to understand the moisture risks inherent with 'real-world' CLT buildings construction and the challenges of building with CLT in locations exposed to monsoon weather patterns. Only the north and south orientations were instrumented with MC sensors, as shown in Figure 8. As these were the worst-case orientations, due to solar-driven inward diffusion effect on the north orientation and wind-driven rain and minimal drying potential effect on the south orientation.

Figure 8: *Each red dots depicts the locations of two MC sensor arrays for the tropical residential construction (plan view)*

https://doi.org/10.52202/069179-0577

2.2 INSTALLATION OF THE WIRELESS SENSING SYSTEM

The monitoring of the MC within all three projects was achieved with small, wireless, pin-type electric resistance moisture meters from OmniSense LLC (sensor S-11) [4]. The sensors have a sampling frequency of 6 minutes, a temperature error of ±2 °C, and a RH error of ±5 %. Installation of the MC sensors involved covering the MC probes (18-8 stainless steel mounting screws) with heat-shrink tubing to electrically isolate the screw shaft, while the screw head and tip were left exposed by 20 mm, to enable an electrical connection through the timber back to the electric circuit, and then embedded into the CLT panels as shown in Figure 17. The insulated probes were installed as arrays at three depths — 20 mm from the internal CLT panel surface, at the centre of the panel (50 mm from the internal surface), and 20 mm from the external panel surface (100 mm from the internal surface). An array of sensors was installed for each unique combination of assembly design parameters in each experiment, leading to the installation of 45 sensors in the CLT micro unit, 48 sensors in the double climatic chamber, and 18 sensors in the residential CLT project.

Figure 9: *A MC sensor with heat-shrink tubing and 20 mm exposed screw tip (left), then embedded in to the CLT wall (right) in the residential CLT building in Cairns*

2.3 CALIBRATION AND VALIDATION OF HYGROTHERMAL SIMULATIONS

Calibrated hygrothermal simulations require that the initial and boundary conditions represent the real conditions of the experiment as closely as possible. The monitored data of the external and internal boundary conditions, and the initial MC within the CLT panels were used for this purpose. The hygrothermal material properties were assigned from the material library within WUFI, which is the hygrothermal simulation tool utilised within this study. The dataset from the WUFI material library contains all the relevant hygrothermal properties to allow realistic simulation of the assembly layers used in the experiments.

2.3.1 BOUNDARY CONDITIONS FOR CALIBRATION

In the case of the CLT micro-unit and residential CLT building, the exterior boundary conditions were downloaded from a local weather station. While the exterior boundary conditions of the climatic chamber experiment and the interior boundary conditions for all three experiments were generated by RH and temperature sensors located in the plastic housing of the MC sensors. The temperature and RH values for the interior and exterior boundary conditions were processed and then formatted for use in WUFI. The boundary conditions are shown in Figure 10, Figure 11, and Figure 12 for the CLT micro-unit, double climatic chamber, and residential building, respectively.

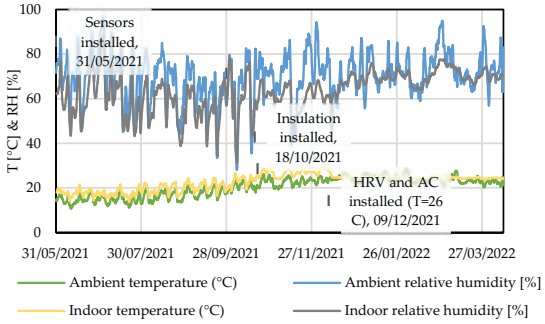

Figure 10: *The internal and ambient conditions from the naturally exposed prototype CLT micro-unit experiment in Salisbury. Data presented in a 24-hour moving average for visual clarity*

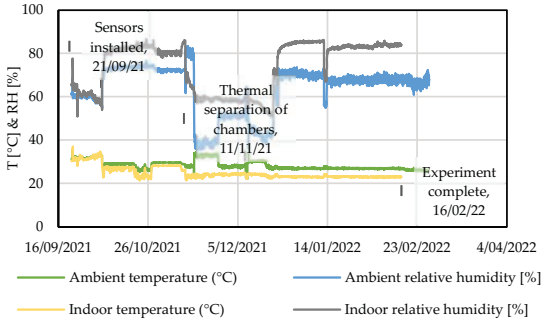

Figure 11: *The internal and ambient conditions from the double climatic chamber experiment simulating tropical conditions*

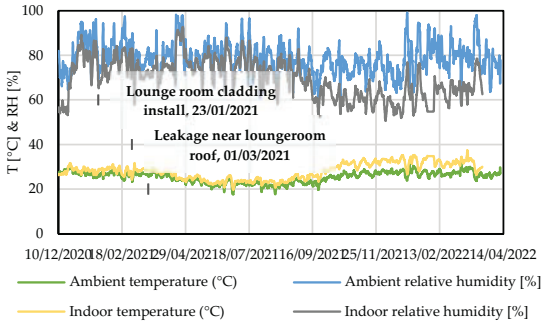

Figure 12: *The internal and ambient conditions from the tropical CLT residential building in Cairns. Data presented in a 24-hour moving average for visual clarity*

For the CLT micro-unit experiment, the air change rate in the 35 mm ventilated air gap behind the cladding was tested using an Almemo 2690 Ahlborn hand-held anemometer device [5]. Recordings were taken multiples times per day, over the course of two days, and the average air change rate was calculated as 54 ac/h. This appears to be a reasonable air change rate for fully ventilated fibre cement cladding, as air change rates of around 50 ac/h have previously been suggested in the literature [6], [7]. This air change rate was used as a boundary condition in both the hygrothermal models representing the CLT micro-unit and CLT residential building.

The initial MC settings used in the calibrated simulations were approximated by taking the average MC from the first 5 hours of MC monitoring for each sensor. This initial MC from each sensor was converted to a water content and assigned across the thickness of the three lamellae respectively. An example of the initial MC assignments can be seen for the CLT micro-unit, where Figure 13 depicts the 'construction' phase and Figure 14 depicts the 'operational' phase. These figures depict the 125 mm thick CLT panels which consist of 3 lamellae of radiata pine adhered together. Where in contrast to European CLT, it should also be noted that the edge gap of Australian CLT is not adhered.

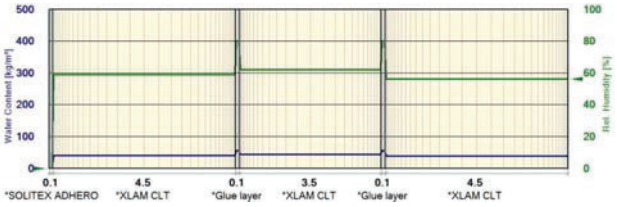

Figure 13: *Screenshot taken from WUFI of the cross-section of the CLT micro-unit wall assembly [cm] representing the 'construction' phase, where the initial MC assigned to the three lamellae is calibrated from the monitored data*

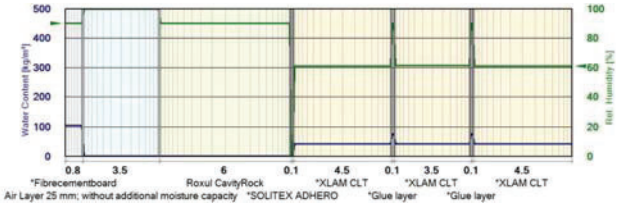

Figure 14: *Screenshot taken from WUFI of the cross-section of the CLT micro-unit wall assembly [cm] representing the 'operation' phase, where the initial MC assigned to the three lamellae are set to be consistent with the MC from the end of the 'construction' phase simulation.*

2.3.2 VALIDATION OF THE CALIBRATED HYGROTHERMAL SIMULATIONS

To validate the calibrated simulation data, hourly MC values were extracted from a 1 mm slice of CLT at the 20 mm, 50 mm, and 100 mm depths from the internal surface of the CLT panel to represent the positions of the MC sensors. The MC data from the sensors was cleaned by removing any null values and values lower than 8 % MC, which represented a loss of connection of the sensor probe with timber. Linear regression statistics packages were utilised in the statistical software R-studio and R to establish if a significant correlation exists between the simulated MC data and the monitored data. This was done by fitting the data to a regression model. The root mean squared error (RMSE) was used to quantify an error of deviation in the predictive quality from the simulations, as shown in Equation 1. While, the Pearson's product-moment correlation method was used to verify if sufficient correlation exists between the calibrated WUFI simulations and the monitored MC readings, as shown in Equation 2.

$$\mathrm{RMSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(y_i - f(x_i)\right)^2}$$

Equation 1: *Root mean squared error (RMSE) to measure average residual MC error [8]*

$$r = \frac{\sum(x_i - \bar{x}) \cdot (y_i - \bar{y})}{\sqrt{\sum(x_i - \bar{x}) \cdot (y_i - \bar{y})}}$$

Equation 2: *Pearson's correlation coefficient (r) [9]. Where 0 is equivalent to no relationship and 1.0 is equivalent to a perfect relationship*

If RMSE values were computed to be less than the average error of the OmniSense sensors, then the hygrothermal simulation was deemed to be validated. The variable error of a OmniSense sensor can be calculated by comparing the MC of radiata pine samples using the OmniSense sensors against the oven-drying gravimetric method. The variable error range of the OmniSense sensors can be defined by the equation given in Figure 15, and was thus used for the purpose of validating the WUFI simulations.

https://doi.org/10.52202/069179-0577

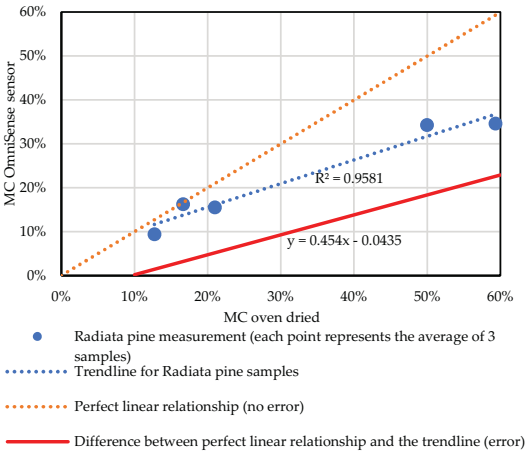

Figure 15: *Variable MC measurement error given for OmniSense sensors [10]. The coefficient of determination (R^2) is shown for the radiata pine samples, while an equation is given for the variable error*

3 RESULTS AND FINDINGS

Results from the monitoring campaigns of the three CLT projects in representative Australian subtropical and tropical climates are used to support notable observations about the monitored data relating to moisture risks within the CLT assemblies.

3.1.1 MONITORING OF THE CLT MICRO-UNIT

The monitoring data from some of the sensors in the CLT micro-unit shows that the sensor embedded in the assembly without a WRB has consistently higher MC, as shown in Figure 16; a maximum of 21.7 %, compared to the assembly with a WRB that records a maximum MC of only 13.1 %. MC of the assembly without a WRB remained higher even after the cladding was installed; showing that the assembly was never able to achieve a dry-out condition by returning to a MC equivalent to that of the assembly with a WRB over the monitored period.

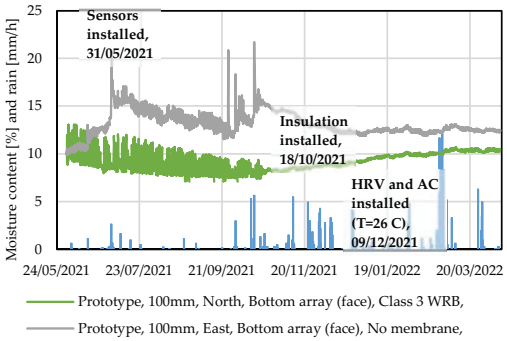

Figure 16: *Comparison between MC of an unprotected and protected CLT panel. Rainfall (mm/h) indicated by the blue vertical lines*

Table 1 statistically compares the CLT micro-unit predictive simulation results against the monitored results. The importance of installing a WRB can, again, been seen, as the assembly without a WRB had excessively high MC. It was also notable that Class 2 assemblies appeared to perform more poorly than Class 3. This was likely because the Class 2 WRB was not a pressure-adhered product; instead, it was stapled to the exterior surface of the CLT and then the staples were sealed with proprietary tape. It was noted that on windy days, air convection passed the Class 2 WRB, as movement of the membrane could be seen. This confirms the importance of using an adhered WRB product to avoid MC peaks during construction wetting. It should also be noted that the calibrated simulations for all assemblies returned maximum mould growth index (MGI) values that did not exceed the critical threshold of 3, which is given by ASHRAE 160 [11]. This means that, although peaks in MC may have occurred during construction, the long-term moisture safety was still ensured in subtropical climates.

Table 1: *D = embedment depth of sensor (mm). O = orientation of assembly. C = class of WRB. MC = maximum monitored MC (%), values greater than 18 % are highlighted in pink to indicate excessive moisture. R = RMSE (%), values highlighted in pink where the value exceeds the arithmetic mean sensor error. E = arithmetic mean sensor error (%). P = Pearson's correlation coefficient, values lower than 0.3 are highlighted in pink to indicate a weak relationship. MGI = maximum simulated MGI for the assembly*

3.1.2 MONITORING OF THE CLIMATIC CHAMBER

The monitoring data from the sensors in the double climatic chamber experiment shows that positioning vapour-open insulation internally is beneficial in maintaining a lower MC in comparison to externally positioned insulation (see Figure 17), departing from the construction method in cold and temperate climates with external insulation. However, Figure 18 demonstrates the importance of avoiding construction wetting for long-term moisture durability, for both external and internal insulation assemblies. As when wetted, the assemblies do not achieve dry-out equilibrium and continue to increase in MC over the duration of the experiment.

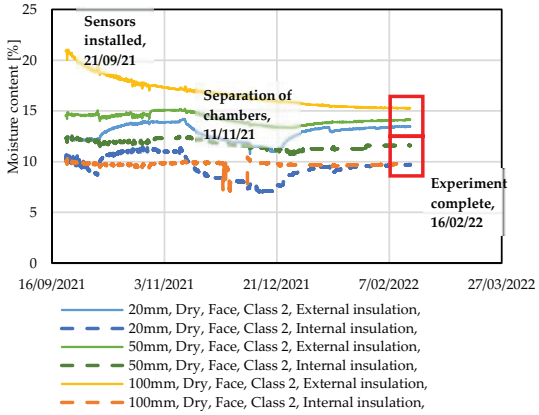

Figure 17: *Red rectangles highlight a comparison between the insulation position, external and internal*

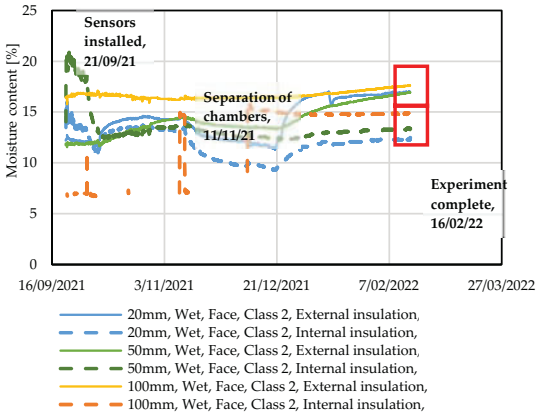

Figure 18: *Red rectangles highlight a comparison between the effect of construction wetting in tropical climate (dry and wetted panels)*

Table 2 summarise the CLT micro-unit monitoring results. It reveals that for dry assemblies, Class 3 WRB was most appropriate for assemblies with external insulation, while a Class 2 WRB was most appropriate for internal insulation. This is because a Class 2 WRB resists vapour from diffusing into the assembly. However, if the CLT panel is wetted, then the Class 3 WRB was most suitable to allow sufficient drying-out capacity. Predictive simulations were statistically compared against a few of the monitored results; this was because the 'ambient' boundary conditions of the climatic chamber experiment could not be correctly defined, as the air in the chamber was inadequately mixed. However, the MGI values for these assemblies did not indicate any mould growth over the duration of the experiment.

Table 2: *D = embedment depth of sensor (mm). L = location of insulation, external (e) or internal (i). C = class of WRB. I = initial state of CLT, wetted (w) or dry (d). 3.1.3 MONITORING OF THE RESIDENTIAL CLT BUILDING

The monitoring data from the sensors in the CLT residential building shows the moisture risks due to leaks in roof cladding over the north-east wall orientation, causing high MC. Figure 19 shows a MC range of 17.5–28.2 % for a sensor in the north-east orientation, compared to the equivalent sensor in the south-west assembly that was not exposed to the roof leak, with a lower MC range of 8.7–17.8 %.Table 3 statistically compares the CLT micro-unit predictive simulation results against the monitored results. This shows a general trend for sensors installed near the CLT floor panel, which had a greater predisposition for higher MC ranges. This was likely due to the window frame rough openings during construction, which allowed stormwater to pass inside of the construction and be absorbed into the CLT floor panel end-grain. However, the MGI values for these assemblies were shown to be less than the critical threshold over the duration of the experiment.

3.1.4 LIMITATIONS OF THE STATISTICAL RESULTS FOR THE CALIBRATED MODELS

Generally, the statistical results of the monitored data and calibrated simulations indicate a strong measure of closeness from the Pearson's correlation coefficients. However, the RMSE values are generally larger than the mean sensor error, which means that calibration is not validated for the respective sensor. Only 30 % of the calibrated simulations achieved both the accepted values for Pearson's correlation and RMSE values, and thus can be deemed validated. While this shows that calibration is possible, it also shows that more accurate knowledge of boundary conditions and a higher quality representation of the microclimate may align the other simulations with the monitored data. A notable observation was that the sensors embedded closest to the external surface had the worst correlation to the measured MC values. Therefore, the weather data collected at nearby weather stations may insufficiently represent the 'microclimate' around the projects for adequate calibration.

In the case of the CLT residential building, failure to sufficiently calibrate the models was due to leaks occurring during the construction phase. This was because the exact nature of the stormwater's flow, speed, and path could not be adequately represented by a simple ratio of driving rain applied to a position within the assembly. However, this failure to calibration for leaks was also

interesting because they appear to validate guidance from ASHRAE 160, which recommends assigning an initial MC of two times the equilibrium MC at a RH of 80 % across the entire assembly when construction sites were not protected from stormwater. Following this guidance would have led to an initial MC of 30 %, which accurately represents the peak MC due to the leak. This suggests that for projects where defects such as water intrusion past the roofing may occur during construction (practically all projects), this 'unprotected' modelling guidance should be used to assess long-term moisture risks. Additionally, this guidance avoids overly complex procedures, such as 3D hygrothermal modelling or quantifying the exact amount of water leaking through an envelope defect. However, it should be noted that this same modelling approach is not capable of replicating the exact nature of the stormwater's flow and thus, it cannot be used to calibrate simulations.

Calibration of the hygrothermal simulations for the climatic chamber experiment was also problematic because the sources of heating, cooling, and humidification were all localised on one side of the chamber, with insufficient blending of the air volume, which led to non-homogenous conditions within the climatic chambers. To resolve this issue in future experiments, internal fans or diffusers should be installed in each chamber to distribute and disperse the conditioned air evenly around the monitored space.

4 CONCLUSIONS

Results from the monitoring campaigns of three CLT construction projects are used to draw conclusions about moisture risks in hot and humid Australian climates.

A notable observation about the monitored data relating to moisture risks within the CLT assemblies is that, in hot and humid climates, external insulation is appropriate — which is supported by simulation results. However, in tropical climates, positioning of insulation on the internal CLT face, and airtight and vapour resistant membranes positioned behind the cladding are shown to be beneficial. Good interior ventilation strategies as well as ventilated cavities and drainage layers behind the cladding are also highly advantageous for improved moisture safety. These results also show that adhered WRBs are critical for moisture safety.

The simulations revealed a faster drying sequence in the monitored data as compared to WUFI simulations. In addition, regardless of the difficulty in calibrating the hygrothermal simulations with the monitored data, the simulations showed a low MGI, and thus moisture safety in the CLT assemblies. This corresponded with the monitored data, which showed that despite elevated MC during the 'construction' stage, the MC dropped to safe levels during the 'operational' stage. The simulation results also confirm that the guidance about simulation settings and initial conditions given by hygrothermal standard ASHRAE 160 are appropriate for CLT assemblies in hot and humid climates.

Future work would use the simulated MGI values from the calibrated simulated MC values to produce a maximum initial MC to maintain moisture safety for the various CLT assemblies in hot and humid climates. Additional details and discussions about these monitoring campaigns can be found in the PhD thesis by the primary author.

ACKNOWLEDGEMENT

This research was conducted by the Australian Research Council Research Hub for Advanced Solutions to Transform Tall Timber Buildings (project number IH150100030), with funding from the Australian Government and Department of Agriculture and Fisheries.

Donations of construction materials and components were used to build the experiments. A decentralised energy recovery ventilation unit, Lunos NeXXt ERV system donated by LAROS Technologies. Weather resistance barriers, Solitex Adhero and DA airtight vapour check product, tapes, and grommets donated by Pro Clima Australia. PHI-certified 2.4 by 2.4 m French-style double door opening with double glazing and motorised exterior Zipscreen blinds donated by Logikhaus. 2 kW split type Alira air conditioner heat pump donated by Daikin. Zinc coated steel self-tapping wood screws, WB4 90 plate, and acoustic sealants donated by Rothoblaas. 15 sheets of Tectiva 8 mm fibre cement cladding donated by EQUITONE. 6 untreated radiata pine CLT panels of 125 mm thickness donated by XLam. NVELOPE NV9 aluminium sub-frame profiles along, fixing, and joint trims, 60 mm, and 80 mm Vulcanwool rigid mineral wool insulation batts donated by DCTech.

LOAD LEVELS AND CRITICAL DESIGN ISSUES IN A MULTI-STOREY RESIDENTIAL TIMBER BUILDING BUILT UP BY PREFABRICATED VOLUMETRIC ELEMENTS

Johan Vessby[1], Tomas Forsberg[2], Marie Johansson[3], Rajan Maharjan[4]

ABSTRACT: The use of structural timber in residential buildings has increased considerably in Sweden during the last decade. Concomitantly, there has been an emphasis on augmenting the level of prefabrication for such structures. A simultaneous need for education imparted in universities exists, and this paper contributes to this need by outlining a design example of a residential timber building with simple geometry using prefabricated volumetric elements. The serviceability limit state as well as the ultimate limit state have been defined and studied for some critical design situations. The results indicate, for example, that the degree of utilisation in the studied building system for compression perpendicular to the bottom rail in the first storey and buckling of the studs are in the same range - 91 % to 97 % - for the walls separating apartments.

KEYWORDS: Design, Education, Prefabrication, Volumetric structure, Module

1 INTRODUCTION

The number of residential buildings with structural timber in their load-bearing frames, has increased considerably in Sweden over time. The primary reason for this is the increase in the population of urban regions in the country, which has led to a rise in demand for housing stock. Another driver, which has been influencing this trend, is the need to truncate the life-cycle greenhouse gas footprint of buildings, and timber-based structures perform well in this regard [1].

A noticeable trend in the last few years is the practice of increasing the level of prefabrication of the building modules. Some advantages of this practice are the increased speed in which the building can be assembled on-site, see Figure 1, the controlled climate in which the modules are produced and not the least the improvement in working environments for labourers at different stages of the construction.

The rapidity with which developments are happening in this sector warrants and motivates the design of new academic course modules in the universities, which both students and professionals opting for competence enhancement opportunities, can avail of [2]. The primary aims of this paper are:

- to present a typical timber structure produced by volumetric modules,
- to calculate a selection of critical design loads acting on the structure and,

Figure 1: *Example of installation of a prefabricated timber module in a four-storey building.*

- to discuss some of the challenging design issues related to such a building according to current harmonized design codes [3-5].

The dual motives are to make these results the foundation on which a new academic course can be designed and to facilitate the evolution of numerical models [6, 7], the results from which can be related to load levels obtained.

2 OBJECT DESCRIPTION

The building studied in the case study is a four-storey building designed using prefabricated volumetric elements, so called "modules", using a light-weigth stud-and-rail system. The building is designed using 10 volumetric elements in width and four volumetric elements in height. The total length, width and height dimensions of the building are 40, 10.5 and 15.5 m respectively and the exterior corridor is 1.5 m wide.
The prefabricated volumetric elements are approximately 4.0 m wide (in the A direction, Figure 2), 9.0 m long (in the B direction, Figure 2) and 3.0 m in height. The long wall elements of the volumetric elements are made of 45 · 95 mm sawn timber with a centre-to-centre distance of typically 600 mm. The bottom rail and top rail is made up of sawn timber with a dimension of 45 · 95 mm. On the inside of the studs, sheets are screwed to the studs giving horizontal stability. The sheet material can be OSB, plywood and/or gypsum wallboards depending on manufacturer. The load bearing part of the gable (short walls) of the volumetric elements is made up of 45 · 170 mm studs with sheet material on the inside screwed to the studs. The floor and ceiling are made up of sawn timber orientated in the short direction of the module with a board glued and screwed to the sawn boards. In the studied version module the floor and ceiling elements are screwed to the inside of the wall elements to minimise the amount of timber loaded perpendicular to the grain.
The northern and eastern facades of the complete building studied are shown in Figure 3 (*a, b*) together with a section of the building (*c*). The direction north, east etc. is used in this paper to ease the understanding of directions.
The roof trusses with a 28° inclination on the top chord to a horizontal axis are oriented with their span in a north-south direction so that self-weight and the snow load, contribute to the total load, only along the edges A_4-B_4 and E_4-F_4, respectively, for each single volume on the top floor respectively, see Figure 4. The northern and southern walls (the shorter walls of the single volume) are exterior walls requiring a greater degree of insulation, vis-à-vis the eastern and western walls (the longer walls of the single volume) for a typical volume inside the building. Owing to the requirement of extra insulation and the fact that the load attributed to the snow will act primarily on those walls, almost a doubling of the height of the cross-sections of their studs, vis-à-vis those in the interior eastern and western walls, is called for. As depicted in Figure 4, the cross-section (width · height) of the latter is typically 45 mm · 95 mm.

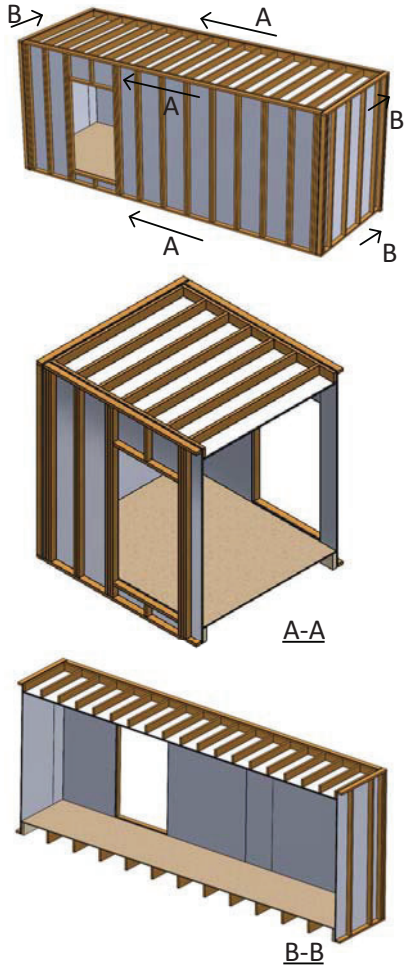

Figure 2: *Illustration of a typical module used for assembling residential buildings.*

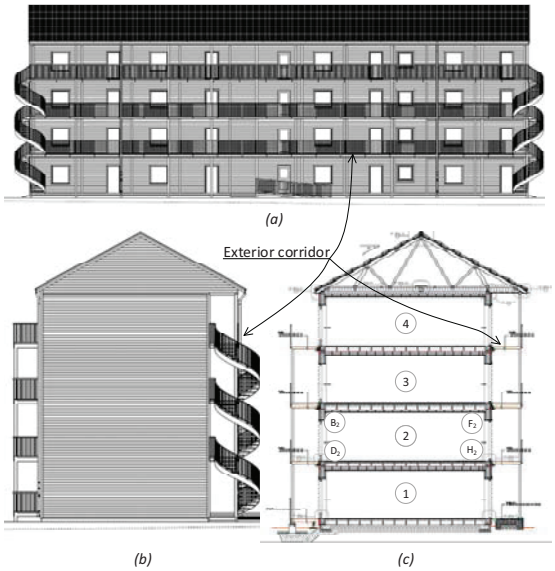

Figure 3: *Illustrations of the studied building: (a) northern façade (b) eastern façade and (c) section of the building.*

https://doi.org/10.52202/069179-0578

The eastern and western walls of the lowest storey are subjected to all the imposed loads in the building by virtue of the orientation of the joists in the flooring for each module. Along the northern façade of the building there is an exterior corridor linking the different apartments on each floor.

How the prefabricated volumetric elements are attached to each other, is a critical design issue, which is complicated by conflicting design requirements. Designing for structural stability calls for strong tie-downs, while designing for good acoustics entails a decrease in number of mechanical connections is desired to reduce the level and transmission of structure-borne noise. In this study, an extreme case devoid of any mechanical connections securing the elements to one another will be considered. The critical issue with load transfer among self-bearing modules will not be discussed.

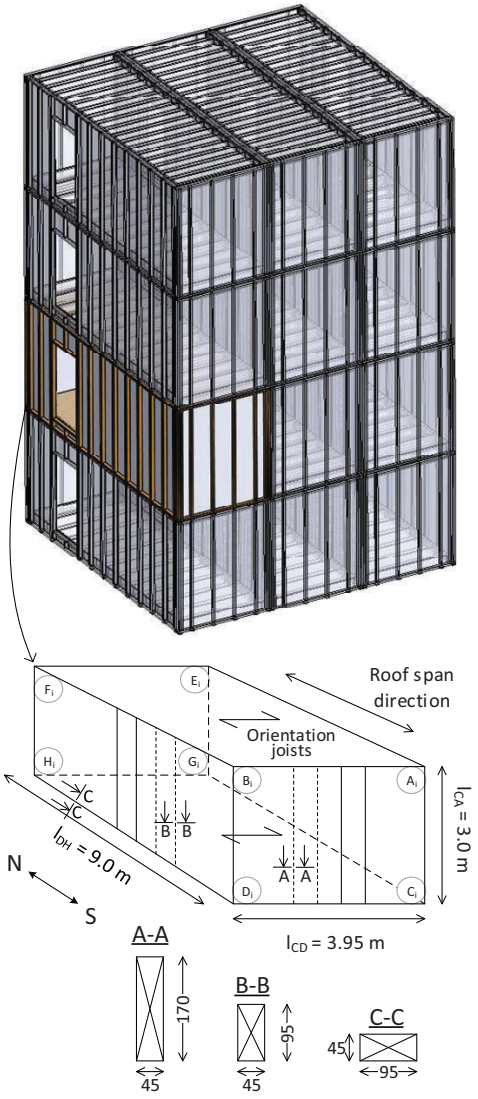

Figure 4: *Example of simplified volumetric element for storey i in the studied structure. Geometrical dimensions as well as the direction of the compass are indicated.*

3 LOAD COMBINATIONS

Design loads acting on a building are calculated in ultimate limit state (ULS) and in serviceability limit state (SLS). For the design cases selected and studied herein the self-weight of the various structural components are unfavourable and thus the load combination for the ULS designed is obtained as

$$E_d = \gamma_d \cdot 0.89 \cdot 1.35 G_k + \gamma_d 1.5 Q_{k,1} + \gamma_d 1.5 \sum_{i>1} \psi_{0,i} Q_{k,i} \quad (1)$$

where E_d is the design load, G_k the self-weight, $Q_{k,1}$ the leading variable action and $Q_{k,i}$ accompanying variable actions acting on the structure being reduced by the reduction factor $\psi_{0,i}$ due to the improbability of simultaneous maximum occurrence of accompanying variable actions. The partial safety factor γ_d is a safety factor defined in the Swedish national annex depending on safety class dependent of the risk of consequences of a failure [5].

In the SLS the characteristic, frequent and quasi-permanent load combinations will be used and they are formulated as

$$E_d = G_k + Q_{k,1} + \sum_{i>1} \psi_{0,i}\, \mathrm{Q_{k,i}} \quad (2)$$

$$E_d = G_k + \psi_{1,1} Q_{k,1} + \sum_{i>1} \psi_{2,i}\, \mathrm{Q_{k,i}} \quad (3)$$

and

$$E_d = G_k + \sum_{i\geq 1} \psi_{2,i} \mathrm{Q_{k,i}} \quad (4)$$

where $\psi_{2,i}\mathrm{Q_{k,i}}$ equates to the average value over a period of time. The characteristic combination (2) is used for calculating the load levels for irreversible permanent actions such as fracture, the frequent combination (3) is used for reversible actions such as vibrations and finally the quasi-permanent combination (4) is used for long term effects, e.g. creep.

The permanent action is considered for the building as a whole. The total self-weight for a single volumetric element of the type used in the studied building ranges between $G_{k,vol}$ = 80 and 90 kN. Permanent loads caused by floor and walls are considered to be distributed loads. The walls range from g_k = 0.35 kN/m^2 for interior load bearing walls to g_k = 0.54 kN/m^2 for exterior load bearing walls and the self-weight of the floor is set to g_k = 1.02 kN/m^2.

Beside the permanent action three variable actions add to the total loading of the building; snow load, wind load and imposed load.

The residential building used as an example is assumed to be located in the city of Karlstad (Sweden), where the characteristic snow load is s_k = 2.5 kN/m^2 for the horizontal projection of the area (less than half of extreme values common in some regions of Sweden, reaching 5.5 kN/m^2). The reference wind speed at height z = 16 m for the studied object is v_b = 23 m/s which in terrain category III corresponds to a wind pressure

https://doi.org/10.52202/069179-0578

q_p = 0.61 kN/m^2 (less than half of the maximum wind load of 1.29 kN/m^2 in terrain category 0, in coastal regions; and 64% more than the minimum value of 0.37 kN/m^2 in terrain category IV).
The third substantial variable load is the imposed load (q_k). For a residential building, where the floor area is used as living space, it is a category A load, and thus q_k = 2.0 kN/m^2. The imposed loads for the exterior corridors for each floor on the northern façade of the building, and the attic, are set to 3.5 kN/m^2 and 0.5 kN/m^2 respectively. The total imposed load can be multiplied by the reduction factor α_n which in turn is calculated as

$$\alpha_n = \frac{2 + (n-2)\psi_0}{n} \quad (5)$$

where n denotes the number of storeys in the same load category (>2) above the loaded structural parts, and ψ_0 is a reduction factor.
The horizontal force caused by the initial inclination of interacting structural parts should be considered in the design of the shear walls within one storey. In the structure analysed in this paper, this has been done by calculating a total inclination of such parts consisting of one systematic part, and one random part, so that the total angle $\alpha_{m.d}$ can be determined as

$$\alpha_{m.d} = 0.003 + \frac{0.012}{\sqrt{n_{part}}} \quad (6)$$

Service class 1 is used for all structural parts within the prefabricated volumetric elements, and structural timber of quality C24 is assumed. The partial safety factor is set to γ_d = 1.0.

4 SELECTED CRITICAL DESIGN CASES

A comprehensive structural design of the building studied, necessitates several calculations. Some of them, being standard and conventional in nature, are not interesting in the context of this paper. Others which are interesting are scrutinized in greater details in this section. The three selected design cases which are related to critical issues the building industry encounters, are illustrated in Figure 4 and discussed thereafter, and degrees of utilisation are determined for them.

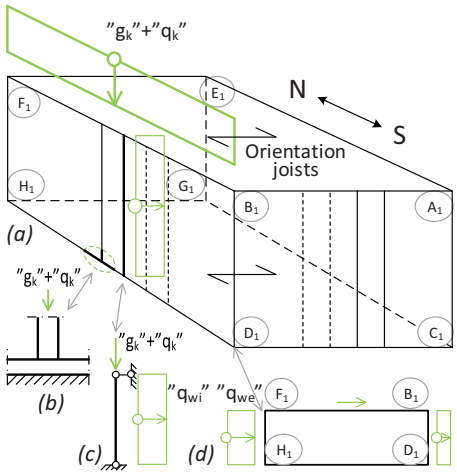

Figure 5: *Illustration of selected design cases a) overview of module in storey 1, b) load perpendicular to the fibres, c) buckling of stud and d) wind load on the structure.*

4.1 Vertical loading in ULS

The design vertical load in the eastern and western walls of the module, see Figure 4, is calculated by including self-weight and the imposed load in the ULS design, equation (1). The combination can be used to calculate the design load for local compression perpendicular to the bottom rail, see Figure 5 (b), and for obtaining the vertical design load in studs in the internal wall which are used in combination with the internal wind load to design for buckling, see Figure 5(c). For the local compression perpendicular to the grains, the design load calculated to N_{Ec90d} = 17.5 kN with the imposed action being the leading action. The centre-to-centre distance (cc) of the studs is assumed to be equal to 400 mm. The most critical load in the analysis of buckling of the stud is the one with imposed load as the leading action, and the internal wind load as the accompanying variable action. For that design case, N_{Ec90d} = 14.1 kN and $q_{w.int}$ = 0.033 kN/m.
In a typical stud in the exterior (northern or southern) wall of the module where a load consisting of snow (leading action), self-weight and imposed loading from the floor- and ceiling elements, and the exterior corridor, is acting, the design load is $N_{Ec90d.N}$ = 31.9 kN but due to the smaller cross section in the eastern and western walls focus is put on those walls in the following.
An important detail in the design of compression perpendicular to the fibres is the addition in the EKS11 [5] that allows for assigning the material coefficients γ_M = 1.0 and k_{mod} = 1.0 under specified circumstances. These circumstances are [5] that the "*sole consequence*" of the pressure perpendicular to the grain is *"increased deformations that have no significant impact on the system´s stability and mechanical resistance"*. Cases where this may be applicable include the *"indentation of joists into a sill beam and waling of low buildings*.". Finally, it is also stated that *"where deformations have significant effect on function (e.g. in tall buildings), the recommended partial factors in"* EC5 should be utilized. This implies a necessity for defining whether the building is a tall building or not, *a priori*, which is often

challenging. Compared to a situation with $\gamma_M = 1.3$ and $k_{mod} = 0.8$, the reduction in the design material parameter is substantial, 62%, when $\gamma_M = k_{mod} = 1.0$.

4.2 Vertical loading in SLS

Vertical loading leads to instantaneous and time dependent vertical displacements [8]. In a design situation this is particularly interesting, if the elevator shaft is made of another material (concrete, for instance), or if the load bearing structure for the exterior corridor is made of steel, for example, see Figure 3. In such cases, relatively large differences in vertical displacements may be seen; and this may lead to a series of undesired effects.

According to EC5, the loads for design of the long-term effects should be calculated using Equation (4). Quasi-permanent value ($\psi_2 Q_k$) is used for the variable loads so that the load levels are reduced to the long-term average. The variable action to be included in the load case derives purely from the imposed load. The design load on a stud in wall D_1-H_1 at the first storey is calculated to $E_d = 7.9$ kN. Methods are presented in EC5 to take account of the short term (elastic) and long term (creep) effects in the timber material. In addition, the reduction of the moisture content of the timber, from around $mc_{init} = 13\%$ on average, to $mc_{avg_longterm} = 9\%$ in the long-term results in a reduction in the nominal dimensions of the members, and contributes considerably thereby to the total displacement. Note that only "direct" effects of the *mc* decrease is included here. In the calculations performed herein the total vertical displacement is the sum of the contributions from elastic, time dependent effects, and the shrinkage owing to the change in the moisture content. As far as the physical structure is concerned, deviations from the nominal dimensions such as small length deviations or saw-cuts not perfectly perpendicular to the length direction of the timber member are very likely to play a key role, at least during the initial phase after the installation is completed. However, these effects being difficult to quantify, have not been included in this analysis.

The deformation limit is not defined in EC 5 for example, but should be specified at a project level. For a building assembled using prefabricated modules, a suggested total vertical displacement span of 15 mm < $v_{lim} \leq 20$ mm is recommended. This is based on a rule of thumb that the angle for the exterior corridor should be a minimum of 1:100 so that the floor of the corridor is always inclined away from the building facilitating possible flow of rain water (and meltwater) outwards. The typical width of a corridor lies in the range of 1.5 to 2 metres. For the case-study building with an approximate height $h_{tot} = 15$ m this correlates to $v_{lim.longterm} = h_{tot}/(750 \text{ to } 1000) = 15 – 20$ mm.

4.3 Wind load acting on the northern façade (SLS and ULS)

One of the most challenging loads to design for in prefabricated modules with a load bearing timber structure braced with sheathings mechanically attached to the frame members is the lateral load caused by wind. In the current study, only the effects of the load acting on the northern wall (and suction on the southern) will be analysed. Thus, only the shear walls parallel to F_1-B_1- D_1-H_1 see Figure 5(d), will be subjected to the wind load and therefore analysed. Each "tower" of modules is assumed to stand separate. It follows that 50% of the load on the area B-A-C-D enters along the line A-C, and the other half acts along B-D. The horizontal elements in the ceiling and the flooring are assumed to be stiff, continuous and securely attached to the walls.

In addition to the wind load, the initial inclination of the studs, see equation (6), combined with the acting imposed load and self-weight, contribute to the total horizontal load for any given module. Challenges in ULS arise if the modules are designed with large openings in the walls used as shear walls. Such analyses, however, are straight forward and the load effect can easily be compared with resistance (using method A in EC5).

For the current building, the design horizontal load acting on and in parallel with the eastern wall in the first storey, is $H_{d.w.ULS} = 30.9$ kN of which the contribution due to inclined members is only $H_{d.i.ULS} = 1.4$ kN.

In SLS, there are uncertainties related to the task of manually calculating the horizontal displacement for each storey, as well as for the building as a whole. A recommendation has been given [9] and is formulated as

$$u \approx 4.5 \frac{sH_{d.SLS}}{bk} + \frac{H_{d.SLS}h}{G_k bt} \qquad (7)$$

where s is the fastener spacing, $H_{d.SLS}$ is the design force (no account of inclined members), b, h and t are the width, height and thickness of the sheet respectively, and G_k is its shear modulus. The largest uncertainty relates to the slip modulus k. Due to the relatively high horizontal load ($H_{d.SLS.char} = 19.7$ kN) in characteristic combination, see equation (2), the secant slip modulus used is that calculated as $k = K_u = 2/3 \cdot K_{ser}$. For the screw with $d = 3.9$ mm in combination with a plywood sheathing material the secant modulus is calculated to $k = 922$ kN/m which is a relatively high value.

The design criteria for the horizontal displacement is the next issue the designer of the building is faced with. Limitations of that displacement are project-specific, though general recommendations suggest that they must be limited – for the building on the whole, as well as for each storey – to $h/500$ [10,11] where h is the total height of the building (when calculated for the building as a whole) or the height of each storey (when calculated for that purpose).

5 RESULTS AND DISCUSSION

The selected critical design cases were:

1. Vertical loading in ULS,
2. Vertical loading in SLS,
3. Wind load acting on the northern façade (SLS and ULS).

As it turns out, the degree of utilisation is relatively high for all the three cases, and they are accounted for, in the sub-sections which follow.

https://doi.org/10.52202/069179-0578

5.1 Vertical loading in ULS

The degree of utilisation for local compression under each stud along the bottom rail – between points H_1-D_1 and G_1-C_1, is calculated to be 91 %. The corresponding degrees of utilisation for the second, third and fourth storeys are 73 %, 54 % and 32 % respectively. It must be recalled that this applies for the assumed situation with no openings in the long walls on the eastern and western sides of the module.

For the design situation with buckling in the studs around the strong axis, the degree of utilization has been tabulated in Table 1 for two different centre-to-centre distances.

Table 1: *Load levels and degree of utilisation within parenthesis.*

Storey:	1	2	3	4
Local comp., cc 400 mm [kN,(%)]	17.5 (91)	13.9 (73)	10.4 (54)	6.2 (32)
Buckling, cc 400 mm [kN,(%)]	14.1 (97)	10.5 (73)	6.7 (48)	2.5 (20)
Buckling, cc 600 mm [kN,(%)]	21.2 (144)	15.7 (108)	10.1 (70)	3.7 (28)

5.2 Vertical loading in SLS

The storey-wise long-term cumulative vertical displacement is tabulated in Table 2. The total vertical long-term displacement for the top storey thus is calculated to $v_{lim.longterm}$ = 13.7 mm. This corresponds to a value less than the suggested limit of 15 - 20 mm, and thereby the use of $k_{mod} = \gamma_M = 1.0$ for the ULS design of the local compression in section "Vertical loading in ULS" could be adopted here if the suggested methodology is followed. However, since the suggested method is still not common practice the conventional values for k_{mod} and γ_M are used for the design in ULS in the current example. Had the displacement $v_{lim.longterm}$ been greater than the suggested limit, the partial coefficients in the ULS should be set to their actual "ordinary" values.

In Figure 6 the vertical displacements over the building height are illustrated with the long-term component (including immediate elastic displacement), the shrinkage caused by variation in moisture content and the total vertical displacement. Note the considerable contribution of the regions including timber compressed perpendicular to the fibers. It is also worth noticing that the effect of shrinkage due to change in moisture content from 13% to 9% is larger than the effect of the external load acting under long term.

Table 2: *Components contributing to the total vertical long-term displacement for each storey.*

Storey:	1	2	3	4
Elastic [mm]	1.43	1.06	0.68	0.31
Long term [mm]	0.59	0.44	0.30	0.15
Shrinkage [mm]	2.17	2.17	2.17	2.17
Total [mm]	4.19	3.67	3.15	2.63

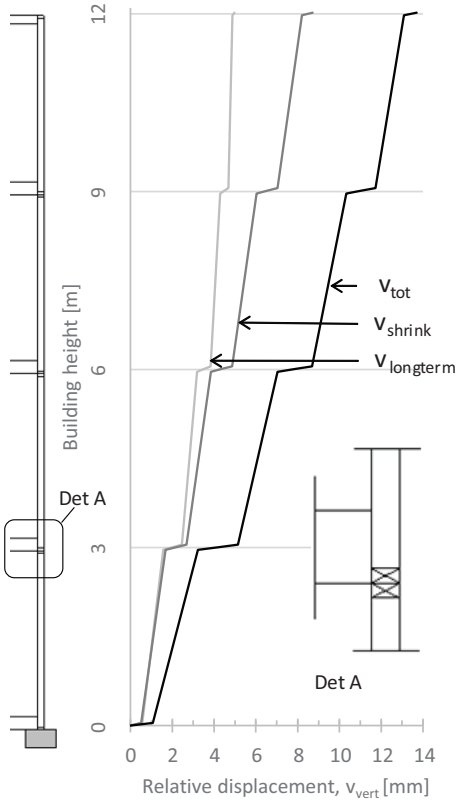

Figure 6: *Relative vertical displacement over the height of the building caused by immediate, long term and shrinkage.*

5.3 Wind load acting on the northern façade (SLS and ULS)

For the first storey, the total horizontal load to be accounted for during the design of the shear walls in ULS, and with wind as the leading action is $H_{d,w}$ = 30.9 kN, which includes both wind load and the horizontal component caused by the initial inclination of the studs, and the vertical load from all the storeys above. Under the assumption of an even load distribution across the top rail, this would correspond to a total load of 3.7 kN/m. The corresponding loads for the 2nd, 3rd and 4th storeys, are tabulated in Table 3. If the SLS is considered, the design loads for characteristic and frequent load combinations are very different from each other. For example, for the first storey, the characteristic combination, Equation (2), gives five times higher load levels compared to the frequent combination, Equation (3). There are reports of repeated cracking of the plasterboard for such buildings, commencing from the interior corners of the doors or window openings. If such cracks are to be regarded as "permanent damage", the horizontal load to be used when calculating the action causing these cracks should be taken from the characteristic load combination. If they instead are regarded as "temporary disturbances" since they normally are not even visible, the load used (frequent combination) for the design is only a fraction of the other. This issue calls for further investigation in future research. For the purpose of this study, conservatively, the

characteristic combination 6.14 is used for calculation of the action in SLS.
The horizontal displacement for each storey is calculated using Equation (7) and used load levels are shown in Table 3, the degree of utilisation shown within parentheses. This gives a total horizontal displacement u_{tot} = 7.0 mm (30%).

Table 3: *Horizontal load ULS and SLS. Degree of utilisation is shown within parentheses.*

Storey:	1	2	3	4
ULS [kN, (%)]	30.9 (100)	23.5 (76)	16.0 (52)	8.5 (27)
SLS, Characteristic [kN, (%)]	19.7 (46)	14.9 (35)	10.2 (24)	5.5 (13)
SLS, Frequent [kN, (%)]	3.9 (9)	3.0 (7)	2.0 (5)	1.1 (3)

6 CONCLUSIONS

In this paper, some critical design issues are identified, selected for further analysis and discussed with respect to load levels and degree of utilisation for a four-storey building using prefabricated volume elements. For the four-storey residential building studied, the degree of utilisation is 97% for the design case with buckling of individual studs in the first storey, and 91% for loading perpendicular to the rail at the same storey, in both cases in the eastern and western walls. It is concluded that this high degree of utilisation indicates the necessity for special attention since minor changes in the design might lead to overutilization.
For the building studied, the calculated maximum long term relative vertical displacement is $v_{lim.longterm}$ = 13.7 mm. In addition to elastic and time-dependent effects the displacement is calculated based on a 4% reduction in moisture content in the timber material. It must be noted that these reductions may be much higher from time to time. Since the design criteria must be project-specific, and very limited guidelines exist, it is, for this building, suggested to limit the displacement based on a minimal inclination of an external corridor with typical width. This results in a limitation being 15 - 20 mm corresponding to h/(750;1000), for the case-study building. It is suggested to assume "no significant impact" for the ULS design as long as this calculated displacement does not exceed h/750 including effects of short- and long term as well as shrinkage. It is concluded that relatively large vertical displacements occur, that limits are set on project basis and that selection of partial coefficients largely influences the analysis in ULS.
The horizontal displacement caused by wind loading for instance, may initiate the formation and propagation of cracks at (and from) the vicinity of the "inner" corners in door openings. Such crack-initiations may occur for low levels of loading, and may not always be visually observed. However, they should be considered as causing permanent damage to the structure. In the current study, the load levels obtained in the characteristic combination (corresponding to permanent damage) is used for obtaining those loads serving as input data for the calculation of horizontal displacement. Also note that there might be other causes for cracks occurring, such as differential vertical displacement.
The use of prefabricated modules in light-weight timber systems is a building system that is common in the Nordic countries as well as in North America. It is, however, a subject rarely covered in the education for structural engineers today. As the building system is frequently utilized it is important that it is also covered in the curriculum for future students and the case study in the current paper is one way to cover the subject. The example include some of the critical aspects when designing buildings using modules such as:

- load paths in both vertical and horizontal directions,
- design calculations for selected elements in ULS and
- critical design calculations for SLS.

7 FURTHER WORK

The current work has proven that there is a high degree of utilisation for some of the selected load cases in the design of residential buildings. Regarding local compression perpendicular to the grain as well as relative vertical displacement, the utilisation may be reduced considerably if the rails are imparted greater stiffness and strength. Waste material from CLT-production is of particular interest in this respect, and will be investigated further in the future.
It will also be interesting to further scrutinise the criteria for long-term vertical displacements and cracking caused by the wind load. These issues are becoming increasingly important due to the tendency to construct taller buildings.
As a closing note, it must be mentioned that in spite of the prevailing tradition in Sweden to design timber buildings, the general design knowledge and the comprehension of the challenges associated with buildings constructed using prefabricated elements, leaves a lot to be desired. Load transfer among modules, effects of accidental loads, uplift due to wind load, and other issues related to modules with large openings have to be studied in greater detail in the future.
The example can also be further developed as a design example in education by including parts as design of the floor elements in ULS and SLS as well as horizontal stability and design of connections e.g. between volumes.

ACKNOWLEDGEMENT

The research is financially supported by several wood construction companies in Sweden and by the strategic innovation programme Smart Built Environment (2020-00224). The authors acknowledge that support with great gratitude.

ARBORETUM, THE LARGEST EVER WOOD OFFICE CAMPUS IN EUROPE: TECHNICAL, ORGANIZATIONAL, AND SUSTAINABILITY CHALLENGES : AN EXAMPLE OF LOW CARBON PROJECT FAR BEYOND THE ALIGNMENT WITH THE EUROPEAN TAXONOMY

Laurent Petit[1], Renaud Blondeau-Patissier[2]

ABSTRACT: this article describes the design and construction of the Arboretum office campus, near Paris, which represents the largest complex built in CLT solid wood; through this experience, the developer shares their convictions: the resolute hunt for carbon emissions, which needs science based tools to measure the efficiency of the design and monitor possible improvements; the sobriety of design, which consists in getting rid of all materials that are not absolutely essential, and giving some of them a double function, structural and decorative, without any addition of other materials; the aesthetic interest of structural wood, which, if it can be left visible, provides unparalleled comfort. The article also describes specific test campaigns, regarding the efficiency of sprinkler or water mist on constructions entirely made of apparent wood.

KEYWORDS: Arboretum, Visible Mass Timber, Sobriety, Low Carbon Building Initiative, LCBI, European Taxonomy, BBCA

1 INTRODUCTION

Arboretum, the largest wooden structure office complex ever built in Europe, will be completed in autumn 2023.

This project, developed by WO_2 on behalf of the ICAWOOD investment fund, is located on the banks of the Seine river in Nanterre, 15 minutes away from Paris and includes 5 buildings with a wooden structure totalling 118,000 m² as well as two refurbished industrial buildings for 8,000 m².

WO_2 is a developer created in 2014 with the main objective of reducing the carbon footprint of construction. WO_2 is currently developing 370,000 m² of office buildings and mixed-use projects. When the company was created, little attention was paid to controlling emissions related to building materials; Many efforts had been made throughout Europe to reduce energy consumption: the hunt for kWh/m² had already begun, but there was still little interest in the materials themselves, although traditional materials are very emissive. WO_2 naturally turned to biosourced materials by associating them with a very broad approach of sobriety and control of quantities.

The Arboretum project is the best example of this approach: it responds to several challenges:

- A considerable reduction in carbon emissions (-47% compared to traditional construction, namely concrete post and beams, hollow core slabs), measured according to the BBCA ("Bâtiment Bas Carbone") association method [1]. This methodology has been recently revised in order to be used in all European countries. This initiative known as "Low Carbon Building Initiative – LCBI", is further presented in 2.3.
- The use of timber, as the main structural material, at a never seen before scale: This needed very efficient supply logistics, enabling the wooden structure, representing 28,000 m³ of CLT and Glulam, to have been erected in 15 months. The job required delivering around eight 50m³ loads of precision-packed wood materials from Stora Enso mills every week.
- Very high energy sobriety, the buildings consuming only 61 kWh/year /m², in accordance with the new French 2020 regulations, one of the most demanding in the world.

In short, Arboretum demonstrates the very latest in what is possible with industrial processes to reduce the embodied emissions from buildings by utilizing wood. Efficient construction employing prefabricated CLT has never been taken to this scale before. This instills fresh thinking and optimism for a future with a low-carbon architecture for all.

2 THE HUNT FOR CARBON EMISSIONS

2.1 UNDERSTAND, MEASURE, ACT

In many European countries, authorities encourage economic players to reduce their CO_2 emissions. It is up

[1] Laurent Petit, Technical Director, WO_2, l.petit@wo2.com
[2] Renaud Blondeau-Patissier, Stora Enso, Wood Product – Building Solutions Research Manager, renaud.blondeau@storaenso.com

https://doi.org/10.52202/069179-0579

to developers and real estate companies to comply with the new Corporate Sustainability Reporting Directive, by revising their business model with the aim of reducing their emissions and aligning themselves with the objectives of the European Taxonomy.
For corporations, the point is to create a new culture of carbon calculation, which must now even supplant economic criteria alone.
This requires understanding where CO_2 emissions come from and making LCA a major decision criterion. WO_2 has therefore based its emissions reduction strategy on:

- The sobriety of design,
- Low-emitting materials
- The detailed ACV calculation, as exhaustively as possible.

2.2 2015, THE FIRST STEPS OF COMPLETE LCA WITH BBCA LABEL

BBCA pioneered the first carbon calculation method for a complete building; the methodology can be summarized in several stages, which can also be found in the European Level(s) methodology:

- Breakdown of the building into 14 construction lots: the entire building is assessed. It is relatively easy to assess construction materials, the manufacturing processes of which are well described in the EPDs (Environmental Product Declarations), but it is still difficult to precisely measure the embodied carbon of technical equipment (which includes many materials, electronic components, and require complex industrial processes). Despite this difficulty, and the vagaries that still exist in the calculation of the building's technical equipment, it was deemed essential to have a complete assessment. Carbon savings must be made wherever possible, and not only by substituting emissive materials with biobased materials.

  In this, the BBCA Label differs from many environmental labels, which consider carbon emissions as one parameter among others without requiring a performance on complete emissions.
- Definition of a reference surface: to make the projects comparable with each other, the calculation of the ratio of embodied carbon per m² requires great transparency in the choice of the denominator, namely the reference surface.
- Finally, the heart of the evaluation process lies in knowing the impacts of each component: the EPDs are the key to the quality of the evaluation; about 7000 EPDs are available on the INIES (French government initiative) database. This revolutionizes the way projects are designed, since in addition to the technical properties of the materials (fire resistance, mechanical resistance, thermal conductivity, etc.), their aesthetic appearance, their cost, they are selected according to their embodied carbon. This new design approach is just emerging among most architects and design offices. It is therefore the role of the developer to foster this new approach in the design team. Nice challenge!

2.3 FURTHER DEVELOPMENT OF BBCA LABEL : LOW CARBON BUILDING INITIATIVE (LCBI)

The number of buildings assessed in LCA is still very limited in Europe; differences in approach are noted between EU countries, which lead to significant differences in results. Although the LCA is based on European standards (EN 15804+A2 and 15978), some LCA modules are not systematically taken into account in all countries; and the evaluation of buildings is most often uncomplete, limited to the envelope.
This makes a pan-European view of property company portfolios relatively confusing. Different European real estate players have therefore come together to adopt a common methodology [2], which can be applied in several countries. This is based on:

- A breakdown of the buildings by allotments (according to the Level(s) Standard of the EU)
- A complete analysis of the building, if necessary, if the assessment is partial, supplementing it with fixed data
- The use of EPDs for materials and equipment that web platforms are able to recalculate according to the country of use, or production (depending on the energy mix of each country).
- This new LCBI Label, which should be available after a calibration phase at the end of 2023, will make it possible to certify the compliance of a building with the European Taxonomy, and will make available figures that can be used in the SBTi strategies of real estate companies.

2.4 DESIGN SOBRIETY

Sobriety is not penance! But this can be achieved by removing unnecessary architectural features, while paying attention to what is meaningful to users.
In the case of the Arboretum project, wide terraces on each level provide fantastic comfort to people, making the building desirable and therefore sustainable. Each occupant can benefit from direct access to the park, via stairs that combine the dual function of escape routes and pleasure stairs.

Figure 1: *"enjoyable stairs" to replace dull lifts – dec 2022 © Raffin*

Wood (CLT and glulam) was used both for the structure and for the decoration: rather than designing banal structures, of poor aesthetics, which are then hidden by decorative materials, as it is often the case, the designers of the project have chosen to leave the timber structures exposed.

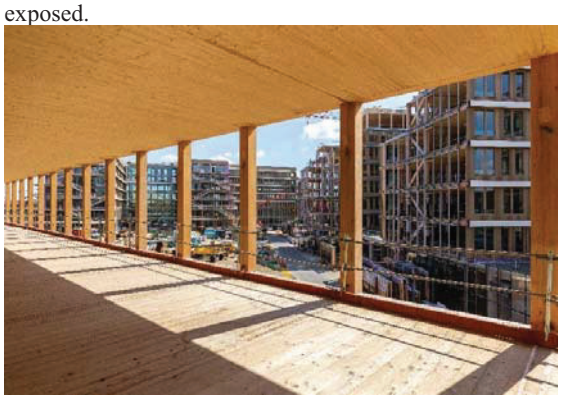

Figure 2: *Erection of CLT slabs meant to remain visible in the project © Raffin*

This is yet another challenge for the design team, which requires excellent collaboration between the engineers who design the structure that must remain visible and the architects.

Figure 3: *Mock-up of the office floor, with visible CLT ceiling © WO_2*

Great attention has been paid to the exposed wood: all the assemblies have been designed so as to remain invisible: in addition to aesthetics, this gives the connecting metal elements a degree of protection against fire. Complete tests had to be carried out to size the sprinkler system. These tests are described in section 4.
Finally, a very meticulous site organization was put in place to ensure flawless installation of the wooden elements that must remain visible.
WO_2 is convinced of the qualities of a wood environment, both for comfort and aesthetics, and quality of life in general.

Figure 4*: View of the construction site (Aug. 2022) – © Raffin*

2.5 LOW EMISSION MATERIALS

Significant reduction of CO_2 emissions has been achieved by replacing most of the concrete with wood and reusing materials from former industrial building. Each part of the building had its own "CO_2 budget", carefully monitored by engineers, in order to challenge the selection and optimise the choice of materials. The project used the INIES database, a government initiative, assessing more than 7000 building components.

2.6 ENERGY SOBRIETY

The project uses heat pumps to heat or cool the building using groundwater as the energy source or sink. Combined with excellent insulation, limited need for

https://doi.org/10.52202/069179-0579

artificial lightning, the project will require only 61 kWh/year /m².
The renewable energy source of geothermal energy is transformed into electricity that powers the heat pumps. The energy-related CO_2 emissions are therefore very low, i.e. 3.9 $kgCO_2eq/m^2$/year; for comparison, the emissions generally observed in European office buildings, according to CRREM data, are 51.4 $kgCO_2eq/m^2$/year (average AT, BE, DK, FR, DE, IT, ES, UK).

2.7 FULL CALCULATION OF LCA

The project was awarded the highest distinction from "Association Bâtiment Bas Carbone" (BBCA). This CO_2 focused certification is the first ever to assess emissions from building materials as well as over the 50 year life cycle for energy. The full LCA amounts to 673 $kgCO_2/m^2$, **ie -47 % compared to a panel of recently designed projects.**
This matches the 2028 cap of CO_2 emissions set by the new French regulation (Environmental Regulations RE 2020): For the first time a cap has been set, requiring to assess emission when filing a building permit. Construction of a building exceeding this cap is not allowed.

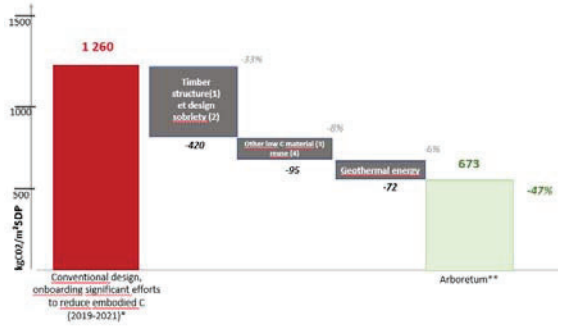

Figure 5: *breakdown of CO_2 savings for Arboretum*

* Benchmark LCA – Artelia 2021 – GHG BBCA v3.1 comparison of 6 concrete buildings located in the Paris region, designed between 2019 and 2021.

** Source: BBCA v3.1 calculation, Artelia 2021

(1) Wooden structure: Storage effect (142 $kgCO_2e/m^2$), superstructure substitution effect (129 $kgCO_2e/m^2$) and wooden facades (33 $kgCO_2e/m^2$)
(2) Sobriety: reduction of car parks, no false ceiling, wooden frame wall on the facade instead of curtain walls (single or double skin) in a conventional design
(3) Low-carbon materials: Recycled carpet, CEM III type concrete
(4) Reuse: Crushed concrete, aggregates

3 BENEFITS OF CLT

3.1 PERFECT LOGISTICS

Thanks to a disciplined and efficient design process the CTL supplier (Stora Enso), was provided with precise manufacturing drawings. The erection of the building superstructure, completed in 15 months, was as fast as expected.

3.2 PRESERVATION OF THE QUALITIES OF THE CLT DURING THE WORKS

It proved impossible to fully protect the 9-hectare site from bad weather as it is sometimes done in Nordic countries. The contractor, French company MATHIS, therefore developed specific tools in order to:
- Guarantee a perfect erection of CLT panels, with extreme care, without any scratches and fully controlled adjustment tolerances;
- Protect the open connexions from moisture
- And if needed, an efficient procedure to clear the stains which might affect the CLT ensuring a perfect finish.

4 FURTHER TESTS: FIRE PROTECTION

The design of Arboretum, whose timber structures are widely visible, required the development of a fire protection system using water spray. WO_2 brought together the various manufacturers to test the two available technologies:

- On one side, the traditional sprinkler (described by the European standard EN 12845)
- On the other hand, the water mist technology (according to the EN 14972 standard): this technology, although less widespread in buildings, has many advantages: the mode of action is different from the traditional sprinkler: rather than drowning the start of a fire by spraying water at a pressure of about 3 bars, it is a matter of instantaneous vaporization of micro-droplets diffused at a pressure of 80 bars, to absorb a large quantity of heat and lower the temperature of the room. The propagation of the fire is then controlled, and it becomes possible for the firemen to intervene. The amount of water sprayed is less than that of a traditional sprinkler system, and it is the preferred technology for all sensitive premises, such as historical buildings, museums, luxury hotels, where water damage can be more important than fire outbreaks.

From the point of view of the building owner, this technology also has the advantage of requiring very small diameter pipes (from 12 to 32 mm), in crimped stainless steel, which is a guarantee of durability.
WO_2 therefore had a test campaign carried out by the EFECTIS laboratory, accompanied by the LISI

https://doi.org/10.52202/069179-0579

engineering office, which allowed each of the concepts to be fine-tuned (choice of nozzles, spacing, flow rate, etc.) in order to verify their effectiveness.

4.1 TEST MODEL

A 300 m² test mock-up was built at the EFECTIS test site in St Yan (FR); it includes CLT and Glulam structures identical to the real building: exposed ceiling (height 3.10 m) along the facades; glulam columns and beams; central part of the mock-up with a false ceiling.

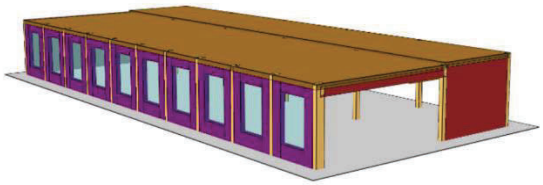

Figure 6: *mock-up*

The model was equipped with side wall nozzles (in green) and hanging nozzles located under the false ceiling (in red) or protecting the space of the technical airducts (in blue).

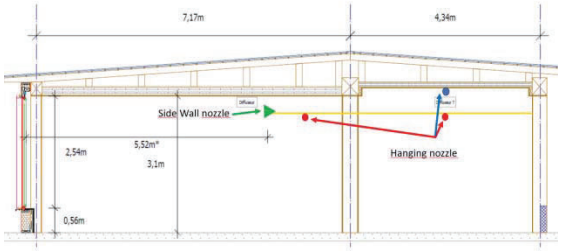

Figure 7: *cross section of the mock-up*

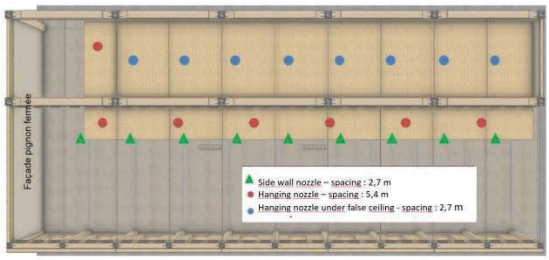

Figure 8: *plan view of the nozzles*

Different locations of fire starts were tested: at the foot of a facade post (figure 9), and at the end of an office floor (figure 10): each fire start being located at the farthest location from the nozzles and at the foot of a glulam post. The purpose of the test was to verify that the rapidity of action of the sprinkler system or water mist allowed to counter the ignition of the wooden structures. Indeed, there are many test reports in the technical literature attesting to the effectiveness of these systems for furniture fires in non-combustible rooms, but few demonstrating their effectiveness in the event of flashover of a solid wood structure, particularly the ceiling.

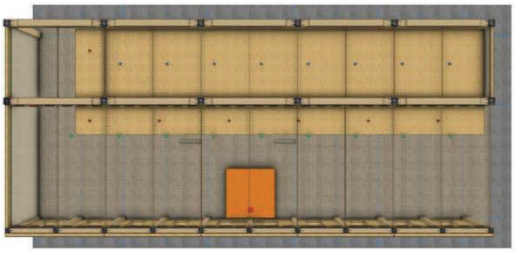

Figure 9: *the orange square shows the fire start, at the foot of a post*

Figure 10: *fire start at the end of the office floor*

4.2 CONDUCT OF THE TESTS

The fire starts were carried out with relatively high start-up kinetics (1 MW in 5 minutes), in order to stress the structures even before the nozzles were triggered.
4 fire start locations were tested for each extinguishing technology. In all configurations, fire control was observed, demonstrating the effectiveness of the extinguishing systems in the case of exposed timber structures, including the ceiling.

Figure 11*: fire start at the end of the office floor*

Photo 12 shows the activation of the nozzles, after the fire has started; photo 13 shows very limited damage to the ceiling after activation of the water mist system.
In conclusion, the tests carried out have allowed the design of the systems to be finalized, and offer a wide choice of technologies (traditional sprinkler, high or low pressure water mist) likely to meet the need for protection of a largely exposed timber structure.

https://doi.org/10.52202/069179-0579

***Figure 12**: activation of water mist*

***Figure 13**: limited damage to the ceiling structure*

5 CONCLUSIONS

The critical need for decarbonisation increases the value of biobased materials.

The Arboretum project demonstrates the ability to significantly decrease carbon emissions. As the largest development of its type, it has been a laboratory of solutions which have shown their relevance.

World Conference on Timber Engineering Oslo 2023

CLEAR THE STAGE FOR TIMBER CONSTRUCTIONS

Jonas Schmidt[1]

ABSTRACT: The Globe Theater is currently under construction in Coburg, an ensemble of four buildings connected by intermediate structures. The center of the building complex is formed by a striking round building in timber hybrid construction. The three adjoining buildings are designed as two-story timber buildings in skeleton construction. Initially, the Globe Theater will serve as an interim venue for the Landestheater, which is undergoing fundamental renovation. In the long term, the new building will be used for various purposes. The circular theater structure, which is predominantly made of wood as a building material, involves many engineering challenges. In structural design, these included the "subtensioned system" of the ceiling over the open area, the "compression-tension ring system" that mutually supports the roof structure, the cantilevered wood-concrete composite ceiling, and the trusses that span the stage. In the fire protection planning, the challenge lay in the detailed design as well as the integration of the technical systems into the building structure. In the process, details were developed that are outside the rules and regulations. This article explains these special features. However, the Globe Theater is not only special in its construction. Among other things, the design also has the special feature that it was created by two students from Coburg University of Applied Sciences. The implementation of a student design into reality is something very special.

KEYWORDS: Structural timber engineering, hybrid structures, structural fire protection, vibrations

1 INTRODUCTION

The idea for the circular shape of the theater building came from Coburg architecture students Isabel Stengel and Anders Macht. The design is based on the Elizabethan Globe Theatre in London. This picked up on Coburg's connection to the British royal family, which came originated from the marriage of Prince Albert to Queen Victoria in 1840.

The main building has a diameter of 36 m and a height of 18 m. The basement is designed as a water-impermeable reinforced concrete structure. The high-value building component is assigned to service class A and additionally protected against groundwater by means of fresh concrete composite foil.

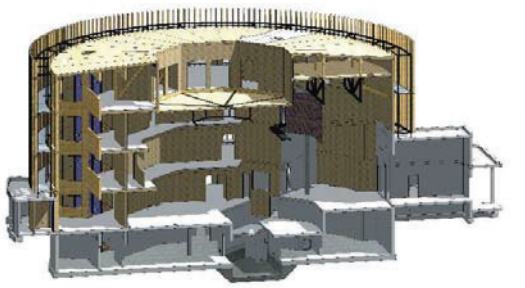

Figure 1: *Cross section through the main building*

The 18 m high wooden building consists of four floors and has a gross floor area of about 5,100 m^2. The first floor houses the revolving stage and the auditorium as well as the height-adjustable orchestra pit. In the entrance area is the foyer, which is open across all floors up to the roof. The foyer is flanked on both sides by representative staircases made of solid wood.

Figure 2: *Foyer area*

The first and second floors contain the galleries. The third floor contains preparation rooms and an interior open-air area (Figs. 1 and 3).

[1] Jonas Schmidt, Dr.-Ing., Ingenieurgruppe Knörnschild & Kollegen, Germany, js@ig-knoernschild.de

https://doi.org/10.52202/069179-0580

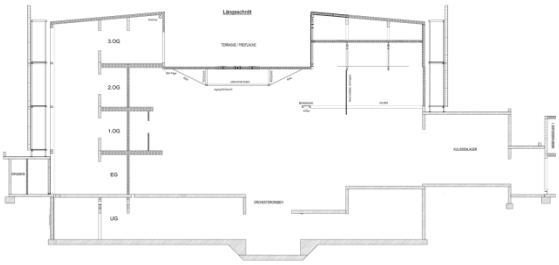

Figure 3: *Cross section through the main building*

In addition to the main building, there are three subsidiary buildings as a wooden structure (Fig. 4) with a total gross floor area of about 1,750 m^2. These buildings are connected to the main building via the stage storage area and are also connected with each other via an open arcade.

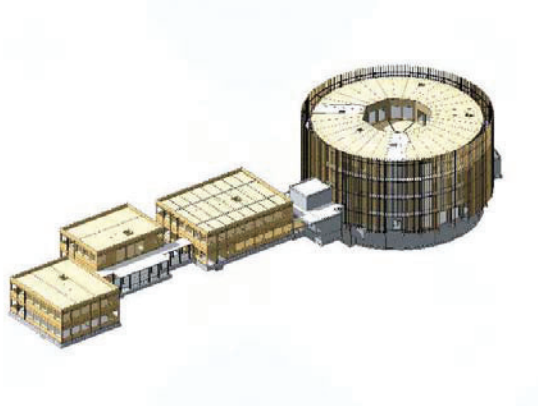

Figure 4:*: Main building with outbuildings and connecting corridor*

Figure 5:*: Aerial photo with main building in foreground*

2 STRUCTURE

2.1 Overview of the structure

The basement and two stairwells as well as the scenery storage are made of reinforced concrete. The four-story main building is largely made of wood from the first floor to the attic. The exterior and interior walls as well as the roof are made of cross-laminated timber and the slabs are a wood-concrete composite construction. Above the auditorium, there is an accessible open space on the 3rd floor (Figs. 3 and 7). This is designed as a subtensioned system. The polygonal structure of the top floor is mutually supported on the inner side by a steel compression-tension ring system. Above the stage are three steel trusses that support the floor above and the lacing floor. The structure is braced by the two reinforced concrete stairwells and the cross-laminated timber walls.

Figure 6: *State of construction of the main building*

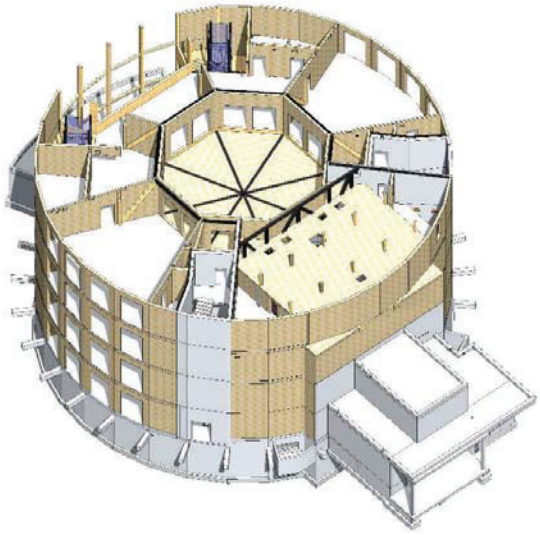

Figure 7: *Illustration upper floor*

2.2 Subtensioned system

The roof structure above the auditorium is designed as an subtensioned system (Fig. 9). For this purpose, eight steel girders are arranged in a star shape and infilled with triangular cross-laminated timber elements. The steel girders are supported by eight air columns, which are connected by a tension ring (octagon) and attached to the steel girders by inclined tension rods. Thus the tensile forces are short-circuited in the steel girder (compression element). In order to dispense with shoring, the star-shaped roof structure was pre-assembled on the construction side and lifted into place. To reduce the weight, not all the cross-laminated timber elements were installed, only the amount necessary for holding the steel girders with respect to bending torsional buckling. The

https://doi.org/10.52202/069179-0580

remaining cross laminated timber (CLT) elements were subsequently lifted into place.

***Figure 8:**: Lifting of the subtensioned system*

Since the subtensioned ceiling is fixed below the compression ring structure of the roof, a mounting joint of the steel girders close to the support had to be provided for reasons of space. The subtensioned system is supported by the large truss spanning the gap between the stairwells and, in the remaining area, by vertical steel tension elements attached to the compression ring.

***Figure 9:**: Suspended System above the spectators*

2.3 Compression-tension ring system

The vertical load is mainly carried by the outer walls (outer ring) and the parallel inner walls (inner ring) (Fig. 3). The inwardly cantilevered ceilings serve as spectator galleries on the first and second floors and as usable space for preparation rooms on the third floor. Further, on the third floor, the subtensioned ceiling above the auditorium is suspended from the compression ring and further derived into the wooden compression struts.

Since the polygonal three-story wooden structure on the 3rd floor cantilevers inward and receives additional loads from the suspended, subtensioned ceiling, the structure requires horizontal support from the compression ring. The steel compression ring runs underneath the roof and supports the roof structure. The compressive forces are transmitted via the compression struts from the roof level to the ceiling level and there to the tension ring (Fig. 10). The tension ring consists of a steel plate that is milled into the CLT slab and installed below the concrete slab of the wood-concrete composite floor. The vertical component of the compression strut is transferred into the interior wall below. A steel detail was developed for the footing (Fig. 17) to transfer the loads through the slab. When the tension or compression ring is closed, the horizontal forces in the ring cancel each other out. In the Globe, however, these are interrupted in the area of the platforms, so that the forces are transferred into the reinforced concrete stairwells.

***Figure 10:**: compression ring and compression strut at the 3rd floor*

https://doi.org/10.52202/069179-0580

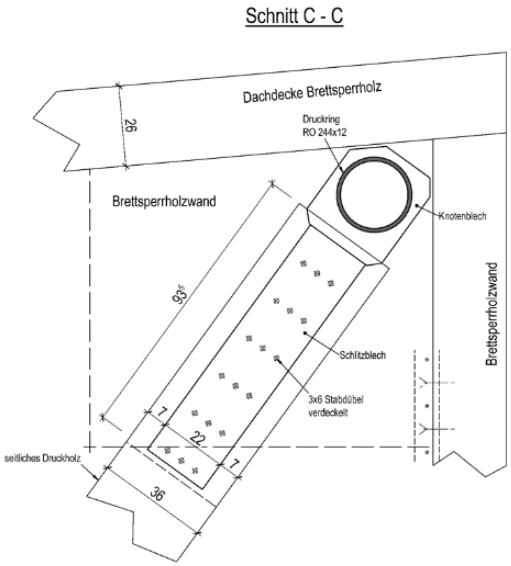

***Figure 11:**: Detail tension-compression ring: compression strut*

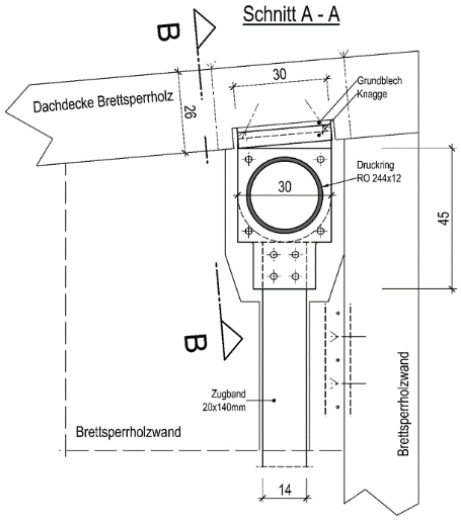

***Figure 12:** Detail tension-compression ring: tension rod that hangs up the open-air area to the compression ring*

2.4 Wood-concrete composite deck

Another special feature is the wood-concrete composite floor. Since this has cantilevered areas, the simplified assumption that the tensile forces are absorbed in the wood and the compressive forces in the concrete is deviated from. In the area of the supporting moment, it is the other way round. The tensile forces occur in the concrete, which must be reinforced accordingly. The wood-concrete composite floor was modeled as a framework model according to Kneidl/Hartmann. The cross laminated timber element was considered as the lower chord, the concrete slab as the upper chord and the connecting elements for coupling the two chords. The connecting elements was modeled with compliant bond to obtain the internal forces and deformations as close to reality as possible. For economic design, the slab was divided into sections to adjust the spacing of the connecting elements to the shear force line. In particular, the length of the upper tension zone had to be taken into account depending on the load combinations. The cracked concrete in the support area was taken into account by modifying the stiffnesses. The concrete slabs are precast elements and were bolted to the cross-laminated timber slabs on site.

***Figure 13:** Cantilevered ceiling elements in the as-built condition*

Thus, the penetration of moisture into the wood was reduced, the ceiling was immediately loadable and the construction process could be continued steadily.

***Figure 14:** Screwing the concrete slab at the construction site*

2.5 Truss girder

Above the stage, steel lattice girders were used to span the stage area without supports. In addition to the technical equipment above the stage, the lattice girders also support part of the open-air area on the 3rd floor.

https://doi.org/10.52202/069179-0580

3 CONSTRUCTION AND DETAILS

3.1 Connection of compression strut to tension ring

The compression strut, which transmits the compressive forces from the compression ring, meets the tension ring and the wall below in the area of the ceiling above the 2nd floor. The horizontal component of the compressive force must be transferred to the tension ring. There is a steel part developed for this purpose, which is the base of the compression strut and at the same time connected to the tension ring (Fig. 18). The connection must allow horizontal slip parallel to the compression strut so that the tension ring is activated and the horizontal force is not transferred into the ceiling. At the same time, however, the joint must transfer horizontal differential forces into the ceiling. These arise in the tension ring due to asymmetrical loading of the sub-tensioned ceiling structure.

Figure 17: *Detail of the base of the compression strut on the tension ring – tension ring and steel connector*

Figure 18: *Detail of the base of the compression strut on the tension ring – including wooden column*

3.2 Connection of foyer column to concrete ceiling

The foyer column must absorb tensile and compressive forces. To be able to absorb the tensile forces, threaded rods were glued into the wooden column. The threaded rods were attached to a steel profile that was designed and dimensioned for this joint. The anchoring in the reinforced concrete slab was done by welded reinforcement.

https://doi.org/10.52202/069179-0580

Figure 19: *Detail of the base of the foyer column with special steel part and glued-in threaded rods*

3.3 Joint of beam to foyer support

The beam that spans along the foyer serves as a support for the ceilings. Since the ceilings in the auditorium cantilever, lifting forces also occur here. To be more effective in terms of assembly, the beam was connected to the foyer support using fully threaded bolts. For this purpose, protection against the effects of fire had to be provided by covering. In order to avoid increasing the cross-sections as much as possible, gypsum fiberboards were milled into the joint area and these in turn were joined with wood materials.

Figure 20: *Interceptor beam with cut-out for capping on the left side*

4 CONSTRUCTIVE FIRE PROTECTION

Fire protection was a particular challenge for this special wooden building. While the model timber construction guideline was used for the ancillary buildings, most of the details had to be developed individually for the round main building with regard to the fire resistance criteria. Most of the structural components are rated for a fire resistance duration of 90 minutes. The wooden components are dimensioned by taking into account the fire. The steel components as well as connecting elements of the joint are also largely manufactured with sufficient timber covering or capping.
In order to keep the component cross-sections as slim as possible, some connections are provided with cut-outs, installed in the gypsum boards and then covered again with three-layer wooden-boards. Exposed steel parts are provided with a fire protection coating.

5 VIBRATIONS

Since visitors to theater performances also sit quietly in the stands and thus on the cantilever, low-intensity vibrations can also be felt. People react differently to the vibration behavior of structures. When used as a theater, special attention was paid to this. Human-induced vibrations caused by foot traffic were reduced to a minimum by the wood-concrete composite ceiling, so that during quiet performances there is no risk of visitors feeling uncomfortable due to building vibrations. Furthermore, the vibration behavior due to the excitation "bouncing" was also investigated. This load situation can also be absorbed by the selected slab system. For evaluation, the natural frequency and the deformation under static load were considered on both the two-dimensional system and the three-dimensional system. The natural frequency of the ceiling is about 9.4 Hertz, which is above the human excitable range and above the Eurocode 1 limit of 8 Hertz. In addition, the limit deformations under a load of 2 kN on the cantilever were also considered, and the limit values are complied with.

6 FACADE

The circular theater building received a closed formwork of vertical boards as a facade cladding. To "hide" the maintenance aisles in front of it, the building is enclosed by a second facade in the form of glulam slats with varying spacing. Where there are foyer areas and thus large window areas, the distances are larger, in the area of closed walls they are smaller. Sheet metal covers on the slat heads and air-flushed connections ensure that water cannot penetrate anywhere or dry out again properly. The wood was given a pre-greying coating. The wooden slats have been designed in a way that damaged wood can be replaced.

Figure 21: *Facade*

7 CONCLUSIONS

The round Globe Theater, built predominantly in wood, consists of a sophisticated timber construction. The building material wood was focused on from the beginning for reasons of sustainability. The approach to only use wood from the region was not implemented in the value chain due to the logistical effort. Nevertheless, the implementation in wood is a success for timber construction.

For the ceilings, a wood-concrete composite ceiling was used, particularly because of the vibration requirements. Prefabricated reinforced concrete elements were used, which were screwed onto the cross-laminated timber panels at the construction site. Although the precast reinforced concrete elements consisted of a tapered geometry, the assembly on the construction site worked very well. This is also a very good variant for the future in the prefabrication of hybrid structures.

Fire protection is always a major challenge in timber structures. The planners of the fire protection, the structural design, the technical building equipment as well as the inspectors have to work together very well.

In fire protection planning, the challenge lay in the detailed design of the demanding supporting structure and the integration of the technical systems into the building structure. In the process, details were developed that are outside of the rules and regulations.

TRANSFORMATION OF RECLAIMED MATERIALS FROM BARN BUILDINGS – DESIGN OF A NEW TIMBER BUILDING FRAME

Terje Planke[1], Kristine Nore[2], Victoria Rygh Nordhagen[3], André Bockelie[4], Dimitrios Kraniotis[5]

ABSTRACT: Norsk Folkemuseum, the Norwegian Museum of Cultural History, plans to build a centre for traditional wood crafts and building customs, *TradLab TRE*. TradLab will be built as a modern and traditional building with the reuse of the materials of old barns. A desire to use these materials for the load-bearing system and in the new buildings demands careful dismantling of the barn building. The Norwegian Museum of Cultural History requires the design and execution of special solutions by the design team and executors. The goal is to integrate as much old timber as possible in the new building and to add new timber where it is needed. The project also wants to reuse cladding and find more ways to use the material in the new buildings, such as in the floor surface or climate walls. By using the craftmanship skills to integrate the traditional knowledge into the design of the building, the overall goal is to investigate the actual efficiency of tradition.

KEYWORDS: Reuse of timber, Problems of legality, barn, digital mapping, demonstration project, standardisation.

1 INTRODUCTION

TradLab will increase interest in and strengthen the practice of traditional crafts inside and outside the museum. Through exploration and training, the museum will attract both established expert environments at (international) level and new, broad target groups in the museum's catchment area [1]. TradLab will be the preferred place to cultivate the sustainability of tradition.
In the sub-project TradLab TRE, the focus will be on continuing and disseminating knowledge about material quality and wood crafts related to handicrafts, building customs and building protection. The primary goal is to erect a new building at *Østlandstunet* in the centre of the openair museum, which is well adapted to conduct training in manual wood crafts and building customs. The reuse of (reclaimed materials of) barns is a mission of the SirkLåve project within the bigger SirkTRE-project [2]. In a resource-efficient circular economy perspective, the ideal practice of reuse is to keep the structure of building in the existing location. The next level, when the barn's use life is ended, is the reuse of the area, preferably with the materials from the old barn. This was the main execution of new barns during the raise of the "unit-barn" which led to almost 10 000 barns raised between 1820 and 1920 in Norway. In this period, the reclaimed wood from earlier logged barn buildings was used to build the new, larger structure, leading to more built area. However, the functionality of these barns has been reduced because of the introduction of threshers and tractors in general.

2 METHOD

Norsk Folkemuseum was able to receive materials from old barns which did not serve society anymore and would be demolished, see Fig. 1 and 2. The goal is to use as much as possible of the materials for the load-bearing system and climate wall in the new buildings. This demands a sufficiently careful, and efficient dismantling of the barn building. The museum also wants to reuse cladding and find more ways to use the material in the new buildings.

Figure 1. The first old barn from Sande.

2.1 EXISTING BUILDING – OLD BARNS

The project started with documenting an old wooden barn located in Vestfold, Norway, see Fig.1. This old construction has been housing multiple functions throughout the last hundred years and has gone through several structural changes in that time. The barn is supported by a wooden structure consisting roughly of

[1] Terje Planke, NTNU Norwegian University of Science and Technology, Norway & Norsk Folkemuseum, ORCID 0000-0001-9561-5419
[2] Kristine Nore, NTNU Norwegian University of Science and Technology, Norway Omtre AS, Norway, kristine.nore@omtre.no ORCID 0000-0003-0008-9853
[3] Victoria Rygh Nordhagen, Omtre AS, Norway, victoria@omtre.no
[4] André Bockelie, Resirqel AS, andre@resirqel.no
[5] Dimitris Kraniotis, Oslo Metropolitan University (OsloMet), Oslo, Norway, dimkra@oslomet.no

https://doi.org/10.52202/069179-0581

155 × 155 mm timber (columns, beams, truss). There is a simple truss design supporting the roof. As for many traditional buildings, it is the total building system, with the dependency between different building parts that gives the full load capacity of the barn structure. The building represents a tradition of great strength with a minimum of wooden structure. In addition, only a small amount of iron parts was used, which supports easy reuse. The existing building has been documented through traditional means and by a full scan.

The chosen building for reuse was suddenly not available, due to external causes. The museum chose to look for other possible objects and was offered the spare parts from the large barn from the Nedre Sem farm in Asker that was to be taken down. This project is a "FutureBuilt" project where they are reusing much of the old construction [3], see Fig. 2.

Figure 2. The second old barn from Nedre Sem in Asker.

2.2 BUILDINGS IN TRADLAB

The new construction project consists mainly of two buildings, see Fig. 3. TradLab TRE is placed in a building environment consisting of many old wooden buildings. The two buildings are placed next to each other. The first building is given a traditional construction based on reuse of the 155 × 155 mm^2 beams, see Fig. 4.

Figure 3. Traditional structure to be built for a new purpose. Drawing by Olav Vidvei.

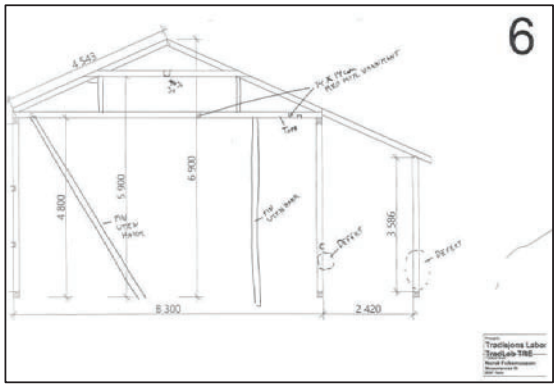

Figure 4. The documentation of section #6 of the old barn. Drawing by Magnus Wammen and Olav Vidvei, Norsk Folkemuseum.

Traditional building

This building will house a workshop for researching and teaching traditional wood techniques. It also includes public areas for exhibitions of woodworking technologies. The museum wants the building to express craftsmanship and display traditional ways of making wooden constructions. At the same time, it must fulfil modern demands required by a new building, as a workplace for traditional craftsmen.

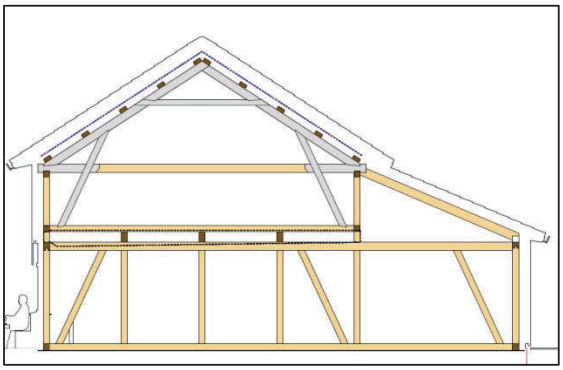

Figure 5. Traditional structure to be built for a new purpose. Drawing by Olav Vidvei, Norsk Folkemuseum.

The open building

The other building will be a two-storey building for outdoor work and outdoor exhibitions about "Norwegian Wood". This building also functions as a means for general availability to the main building by connecting the first floor to the terrain. This building construction is named "grindbygg", which could be translated with timber framing with "post and beam", see Fig. 5. This open structure is extremely material-efficient, made from local wood, with a minimal effort for manufacturing the logs into beams.

2.3 CONCEPTS CONSIDERED

Two main concepts have been considered in the startup of the project: *reuse in the same way* and *reuse in a new way.* The objective was regardless to find the best use of the

https://doi.org/10.52202/069179-0581

existing barn, thereby ending up in between the two ideal types.

Reuse in the same way

This method of reuse is about taking down the existing building and use the reclaimed timber in nearly or the same way it stood before, see Fig. 6. This has been used extensively in Norway with wooden/timber buildings traditionally. The museum has moved and reused many buildings "as is". The museum has recorded that many of the log buildings and the "post and beam" buildings have been moved, also before the museum collected them. The challenge in doing it now lies in new demands and regulations. The fact that it will have a different use (a public building and a two-storey building) also entails challenges.

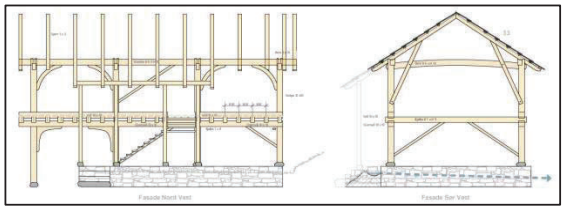

Figure 6. The grindbygg, as an open building without insulation nor wall-cladding.

Reuse in a new way

Reuse in a new way is at the other end of the scale of reuse. This method is about finding new ways of using the reclaimed old building parts in new buildings. This can be as simple as using a beam as a column. Finding new uses for what has been load bearing constructions in the climate wall, interior, non-load bearing constructions (internal walls e.g., or combine elements to form a load-bearing element. The need for design must follow Eurocode 5 [4].

Combination new and old

This envelops finding new ways to use old building elements and adding parts of new structures where necessary. Using old wood for a cordwood masonry wall or stack wall will ensure a near to 100% use of the old timber frame elements.

2.4 SCANNING AND MODELLING OF THE OLD BARN

One important step is the diagnosis, which means collecting data and information for careful dismantling and design choices [5]. The scanning of the barn in Vestfold was done with a Leica BLK360 imaging laser scanner, resulting in dome pictures. The point cloud (Fig. 7) was used as reference to create a BIM model. The point cloud of the barn contains of 480 820 205 points from 22 scans linked together. The scans have all been done on about the same level 1,3 meter above the ground. The overall error of the point cloud was 3mm and have an average overlap of 58%. The model is based on the point cloud where the framework is modelled with an accuracy of ±2,5mm. Information about position, damage, load impact and variation in dimension are included in the BIM model.

The barn was also measured manually, taking out the relevant dimensions of reusable elements.

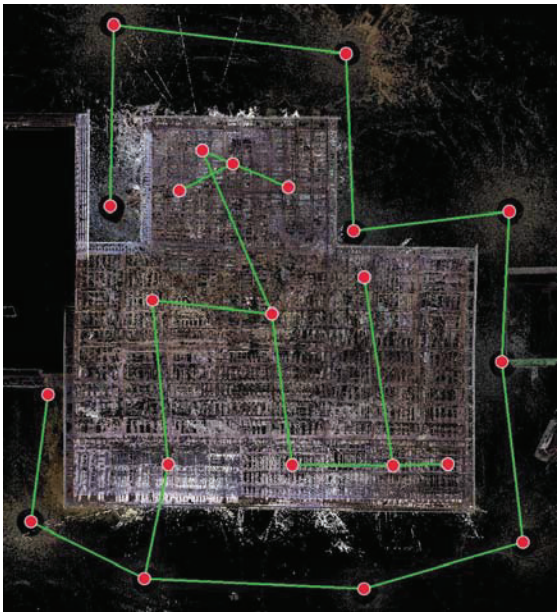

Figure 7. Sitemap of the scans.

Figure 8. 3D representation of point cloud.

3 RESULTS

In this project we ended up using the principles and dimensions of the old barns and reshaping it for our new purposes. The design of the new building was thereby closely related to the dimensions and quality of the old, reusable parts. The old posts (155×155 mm) and beams are sorted out for reuse as posts and ground sills. The quality of each post must be assessed. This is done when dismantling the old barn, and further in the process of pre-cut all the parts before shaping the joints.

The craftspeople who will do the joinery and raise the building, are certified for controlling and sorting constructive timbers into classes like C20, C30 by visual means [6], and are now establishing a procedure to certify constructive timber for C40 for traditional constructions.

The main challenge in the design process is to make the building according to tradition, while supporting the building technical requirements in the Norwegian

building regulations TEK17 [7], since the project is moving besides or outside the pre-accepted solutions within the standard. The goal is to use as little constructive timber as possible to reduce the footprint.
The solution chosen in this project, for reusing as much as possible of the original timber is to use the old parts in the vertical standing and horizontal elements with little forces, for the parts with most tension. To maximize the reuse, all the shorter fragments of the posts is to be used as *kubb*, or bricks in between the posts. This way, all parts longer than the thickness of the construction, will be used as the inner part of the outer climate structure.

3.1 MAPPING OF DAMAGES

Figure 9 is also a screenshot from a dome picture showing damage, drying cracks, and cut-outs. The dome pictures make it easier to identify the quality of the timber. Figure 10 shows the same area but as a point cloud from about the same spot.

Figure 9. Screenshot from a dome picture of the barn showing damage.

Figure 10. Screenshot from the point cloud of the barn showing damage.

Fig. 11 and 12 display a screenshot of TruSlicer in Cyclone REGISTER 360 BLK edition of the point cloud from above showing point around columns, walls, and some items. In the TruSlicer mode it is possible to slide through the point cloud and find damage and measure them like in Figure 13.

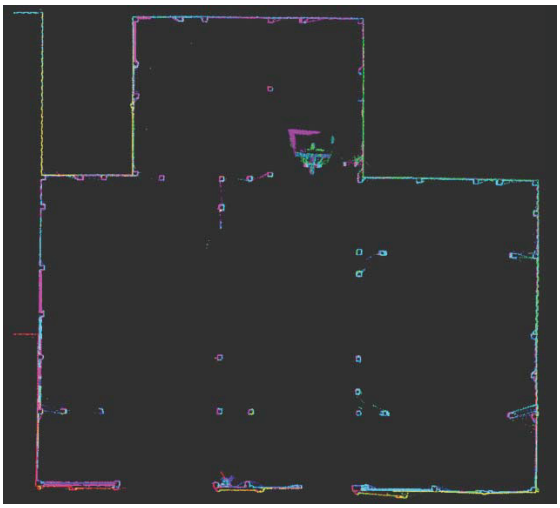

Figure 11. Screenshot of floor plan view of the barn.

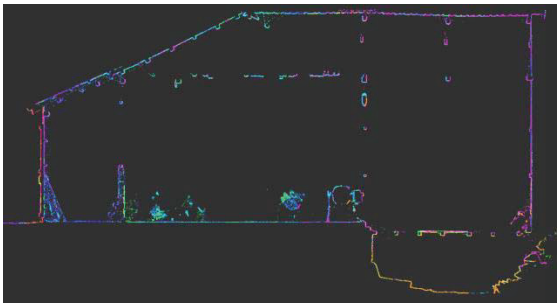

Figure 12. Screenshot of a section of the point cloud.

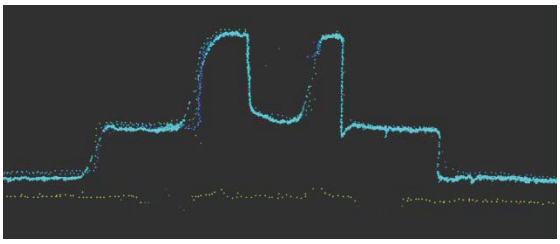

Figure 13. Damage shown in TruSlicer.

3.2 Natural materials - beneficial for ventilation

When it is not painted, the wood has a great hygroscopic quality to support a wanted indoor climate. The wooden bricks will be mortared with local clay. Wood and clay are hygroscopic. The beneficial effect is called hygrothermal mass, a moisture buffer effect which increase human comfort and reduce the need of energy for comfort reasons, and thus energy needs of the building. Hence, the properties of clay and wood fit well with passive

https://doi.org/10.52202/069179-0581

ventilation. The effect of these choices will be studied after the building is raised. A minimum and natural source of ventilation will be chosen in the first period, when starting the use of the building.

4 DISCUSSION AND CONCLUDING REMARKS

Reduce – the need for a new building?
This project already had a good decision for the barn mapped in Sande. When the farmer saw the value of his old building, he decided not to replace it with a new building. From a circular economy perspective, not building and prolonging the service time of the construction can be the best option. However, an additional critical question must be raised [8]. Is the service time extension beneficial, healthy, and safe for the user and/or society?

Reuse of material - in the same way
How much of an existing construction is fit for reuse in the same way? Since it was not possible to copy the shape of the old building, it was impossible to reuse the parts just as they were. In Norway, existing standards for testing or assessing the load bearing capabilities are available. By visual assessment of the class or quality, the loadbearing parts are sorted out. This documentation enables further use.
Architectural challenges exist. The architecture is closely designed based on the dimensions of the old parts. The architect is basing the structure on dialogue with the craftspeople and the solutions are further discussed with the engineers to have sufficient capacity.
Which jointing techniques are preferred? Old notches in the reused materials are placed in the places with least stress and static problems. The joints are "bladed" with 1/3 and 2/3 felling and wooden pegs, to ensure easier disassembly and reuse in the future.

Reuse in a new way
The new use of the timber structure is different from the use in the old barns. During the design, three questions arose which are related to the diagnosis methods, and the domains of architecture and building physics:

1. How much of the existing construction is fit for reuse in a new way?
2. How can we adapt and match the architectural needs, structural demands, and material properties of reclaimed wood?
3. Do traditional timber structures (when using old building parts in walls, or using traditional techniques) used in new constructions provide satisfactory building physical properties?

For the TradLab TRE project, it turned out that the main delivery of structural reclaimed timber will come from Sem Gård in Asker. The TradLab will need more timber parts, preferably reclaimed wood of constructions that do not serve society anymore.

Combination new and old
By using the craftmanship skills to integrate the traditional knowledge into the design of the building, the overall goal was to investigate the actual efficiency of tradition. The prospected way of using old beams combined with new ones and in addition using the small parts for *kubb* led to a very high degree of reuse. The building system is also linked to a former technique. A desire for the future is that the TradLab TRE will inspire future generations to use old building techniques, customised for the future needs. Cooperation with traditional craftsmen in circular construction projects brings in inherited properties and intangible cultural heritage that can create multiple value for society. Mapping of the basis is the way to learn old structural techniques and to provide a material bank for planning the next use of this valuable resource. The potential use of reclaimed wood is emerging in the construction sector and should be explored more in future practice and research.

ACKNOWLEDGEMENT

The authors acknowledge the Norwegian Research Council, Innovation Norway and Siva, the actors behind the program Green Platform and the public financing of SirkTRE (project nr. 328731).

DESIGN OF THE ROADMAP FOR THE CONSTRUCTION OF WOODEN SOCIAL HOUSING IN URUGUAY.

Juan José Ugarte[1], Andres Sierra[2], Keren Codriansky[3], Marcia Croci[4], Carolina Pérez-Gomar[5], Virginia Campodónico[6]

ABSTRACT: The government of Uruguay, aware of the new forest heritage present in its territory, has decided to promote the production of social housing in wood [1]. From a strategic planning process based on the "Delta Model" methodology [2] and the participation of all the different actors, represented by: the academic sector, government agencies, the productive and industrial sector, professional organizations, and users, it was possible to agree on a set of 10 actions that allow a qualitative and quantitative leap in this matter [3].

Thus, progress was made in the definition of priorities and actions for the development of pertinent public policies, such as: improvement of regulations, standards, and characterization of national wood; design of training programs for technical and professional skills; compliance with challenges of technological progress of small companies; and the implementation of a dissemination program at the national level. In addition, a crucial aspect has been the activation of the demand, from the execution by the public sector of calls for the construction of social housing in wood (in extension and height) and the creation of economic or fiscal incentives to develop this type of houses.

KEYWORDS: Strategic planning, public policies, promotion programs, wooden houses.

1 INTRODUCTION

1.1 DIAGNOSIS AND CONSULTING

Various studies diagnosed the gaps and challenges that the wood products sector faces today in Uruguay [4], as well as the regulations to increase the participation of this type of building in its public policies and the construction industry [5].

Figure 1: *Forest plantation in Uruguay. Source: SPF.*

Within the framework of this Administration, the Uruguayan Ministry of Housing and Territorial Planning (MVOT) has established various programs that make it possible to achieve a housing solution for large sectors of the population. Within them, it has been proposed to promote the use of wood of national origin in constructive solutions tending to increase the supply of public housing, reducing execution times and construction costs.

To carry out this challenge, the MVOT, with the support of the Inter-American Development Bank (IDB), decided to manage an international consultancy to support the preparation of this "Roadmap" which would allow prioritizing and coordinating the actions necessary to achieve this goal.

1.2 WOODEN CONSTRUCTION AROUND THE WORLD

According to the World Bank, there will be a need for 300 million housing units by 2030 [6], and how different countries address this deficit will be fundamental to guaranteeing global sustainable development.

[5] Carolina Pérez-Gomar, Ministry of Housing and Territorial Planning of Uruguay, cperez@mvot.gub.uy
[6] Virginia Campodónico, Ministry of Housing and Territorial Planning of Uruguay, vcampodonico@mvot.gub.uy

https://doi.org/10.52202/069179-0582

In this sense, two factors have positioned wood as the optimal construction material for the 21st century: productivity and environmental impact.

Regarding productivity, during the last decades, the wood industry has evolved thanks to the development of the industrialization of the production of engineered wood elements, the creation of more efficient construction systems, and the prefabrication of parts and components, which have resulted in the massification of its use in construction.

Regarding the environmental impact, wood "sequesters carbon," a process that takes place from the afforestation stage when the trees absorb carbon dioxide in their photosynthesis process and stores it inside for years. When trees are treated to produce wood, carbon remains stored inside for the entire useful life of the element.

1.3 WOODEN CONSTRUCTION IN URUGUAY

Although Uruguay is not a country with a long history of wood construction, the forestry industry has great national relevance, contributing to 4% of the national GDP, translating into more than 2,100 million dollars; this arises from the implementation of the Forestry Law in Uruguay in 1987, at which time the production of the national forestry industry began to grow exponentially, registering an increase from about 200 thousand hectares in the 1990s to about 1 million hectares in 2020, encouraging the use of wood for both construction and carpentry. In addition, the sector generates around 18,000 jobs, which rises to more than 25,000 jobs when considering the indirect and induced effects [7].

Figure 2: *Morgavi Woods sawmill. Source: Morgavi Woods.*

Regarding the construction industry in Uruguay, there is a record of at least 14 low-income housing projects in wood, totaling more than 260 units built in the last decades. These are framed in individual initiatives of specific departmental governments, some in agreements with other state agencies or institutions.

In this line, the Government of Uruguay, through the MVOT, ensures in its Five-Year Housing Plan 2020-2024 that in this period, it must offer 105,545 housing solutions, which include construction of new homes, relocations, repairs, neighborhood improvement, among others. Furthermore, in the same document, the MVOT states as one of its objectives is "To promote the use of wood of national origin in constructive solutions aimed at increasing the supply of public housing, reducing execution times and construction costs" [8].

In this line, the government has implemented a series of initiatives to promote the use of wood in construction, among them, the creation of the Honorary Wood Commission (CHM) according to the National Budget Law 2020-2024; a collaborative table, made up of actors from the private, public, academic and professional sectors that seeks to develop a plan to promote the use of Uruguayan forest resources.

2 CO-CONSTRUCTION OF THE ROADMAP

2.1 METHODOLOGY

For the definition of the "baseline" and the identification of barriers and challenges to achieving this objective, those surveyed by the Honorary Wood Commission were considered:

Table 1: *Challenges defined by the Honorary Wood Commission*.

Nº	Challenge
1	Updating of laws, rules, and regulations.
2	Building capacity of professionals, technicians, and workers.
3	Research and development of construction elements and systems.
4	Technology transfer to the MSME sector.
5	Supply of structural Wood.
6	Overcoming cultural and market barriers.
7	Structure multi-stakeholder governance models.

As a methodology to carry out this strategic planning work, this project was inspired by the "Delta Model" conceived by MIT professor Arnoldo Hax and already used during other projects, together with one of the authors of this article [9] [10], and establishes the following five strategic tasks:

Table 2: *Five strategic tasks*.

Nº	Task
1	Constituent segmentation and value proposition.
2	Existing and desired capabilities.
3	Define Mission-Vision for Roadmap.
4	Roadmap Agenda: Axes, actions, and goals.
5	Management of the agenda: Indicators and metrics.

Following this model, a critical step was the segmentation of the different "constituents or stakeholders," for which we worked based on five large reference groups, all of them linked in some way to the theme of building wooden houses:

The public sector, represented by the ministries of Housing (MVOT), Agriculture (MGAP), Industries (MIEM), Environment (MA), and Economy (MEF), together with the respective agencies and directorates; the private sector, represented by the world of forestry, wood processing, and industrialized construction; the academic sector, coming from the university faculties of architecture, engineering, chemistry, among others, the technical careers and the LATU and LATITUD laboratories; the technical-professional sector, represented by the associations of architects, engineers, developers, and technicians; and the civil society sector, represented by social workers who have participated in this type of project and neighbors who live in wooden houses.

During the process, the following activities were carried out:

Table 3: *Process Activities*

Nº	Activity
1	Review and comparison of documentation
2	Systematic documentation and benchmark
3	Collaboration with Technical Committees
4	Structured interviews with stakeholders
5	Departmental visits
6	Advisory to the MVOT
7	Cooperation in the definition of public policies.
8	Development of a Roadmap or Map of Actions
9	Review and dissemination

Some of the most relevant processes are described below.

2.2 LOCAL DIAGNOSIS

In Uruguay, to promote the wood industry in general, and thus enabling the use of the material for both construction and carpentry, among other actions, the MVOT creates the Office of Construction Advice, Planning, and Development in wood, whose objectives are:

Table 4: *Objectives of the Wood Office*

Nº	Objective
1	Promote the use of Uruguayan wood for construction.
2	Promote research and standardization of construction systems and technologies in wood to define quality standards.
3	Prepare technical documents for the use and acceptance of wood in construction.
4	Participate in the process of granting the “CIR” (registration certificate) for construction technologies in wood.

Uruguay's national housing policies are implemented by the Public Housing System (SPV), an organization headed by the National Housing Directorate (DINAVI) of the MVOT, which is made up of various institutions, such as the Honorary Commission for the Eradication of Unhealthy Rural Housing (MEVIR), the National Housing Agency (ANV), the Social Welfare Bank (BPS) and the Mortgage Bank of Uruguay (BHU), from where various housing programs are developed to provide access to housing promoted by the Ministry.

There are currently some social housing projects in wood, such as Barrio Progreso (nine houses) and Barrio Manduví (forty-five houses), located in Rivera; the T15 project (twenty-three homes), situated in Tacuarembó.

Figure 3: *Barrio Manduví Houses (forty-five houses), located in Rivera.*

In addition, there are other detonating works, in engineered wood, such as the Wanderlust Hotel (1805m2 in GLULAM and CLT) in José Ignacio, the Anastacio Inn (1200m2 in CLT), and the Atchugarry Museum of Contemporary Art (5000m2 in Eucalyptus Grandis GLULAM).

Figure 4: *Wanderlust Hotel (1805m2 in GLULAM and CLT) located in José Ignacio.*

https://doi.org/10.52202/069179-0582

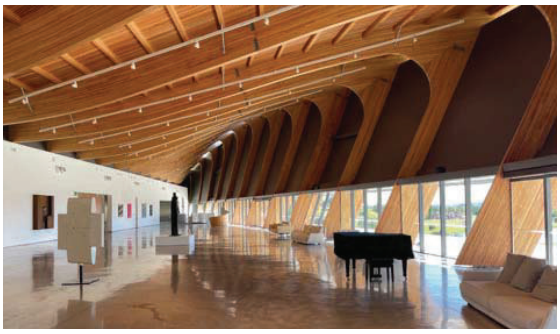

Figure 5: *Atchugarry Museum of Contemporary Art (5000m2 in Eucalyptus Grandis GLULAM).*

A series of organizations and associations that bring together companies and institutions with similar objectives related to the forestry sector in Uruguay were also identified, the most critical being: The Honorary Wood Commission (CHM: made up of representatives of the MGAP, MIEM, MVOT, MA, Congress of Mayors, LATU, UdelaR, and Private Universities); The Timber Development Network (REDEMA: in charge of the project to Strengthen the Timber Industry in the Northern Region, with Emphasis on the Competitiveness of MSMEs); The Association of Entrepreneurs of Wood and Related Products (ADEMA: which represents all its associates in defense of the interests of MSMEs, both in sawmilling and carpentry) and the Association of Wood and Related Industrialists of Uruguay (ADIMAU, which brings together furniture manufacturers).

Some limitations and needs revealed were the following:

Table 5: *Limitations and needs revealed*

Nº	Limitations and needs
1	Regulatory limitations related to the Horizontal Property regime.
2	Limitations to incorporating non-traditional construction solutions.
3	Restrictions related to the action of fire loads and fire regulations.
4	Need for infrastructure and equipment for laboratory tests and to verify the performance of construction systems with wood.
5	Necessity to develop a conformity assessment and certification system for wooden houses.

2.3 INTERNATIONAL BENCHMARK

In addition to the local diagnosis, an International Benchmark study was carried out, which allowed drawing a baseline on the "state of the art" in areas related to wood construction through the experiences of other countries which have a history of using wood for the construction of collective housing, but they are different in their level of progress, internal characteristics, and development.

Chile: Where the Wood Agenda of the Ministry of Housing and Urbanism (MINVU) was created in 2012 around five strategic axes: regulations, quality, constructive solutions, training and dissemination, and triggering projects. Axes have been critical to developing a roadmap that has advanced in terms of wood construction thanks to continuous collaborative work.

Figure 6: *Ecosustainable neighbourhood in Chañaral, Chile.*

Figure 7: *Experimental Tower with 6 floors. Peñuelas, Chile.*

Canada: With a public agenda for wooden construction (2010 - 2030) led by Natural Resources Canada (NRCan), where since 2010, the programs have sought to develop two different axes of wooden construction: construction at height and construction at massive wood. They proposed a multivariate challenge, including developing new materials, new manufacturing and assembly processes, new building codes, and new design approaches, among others.

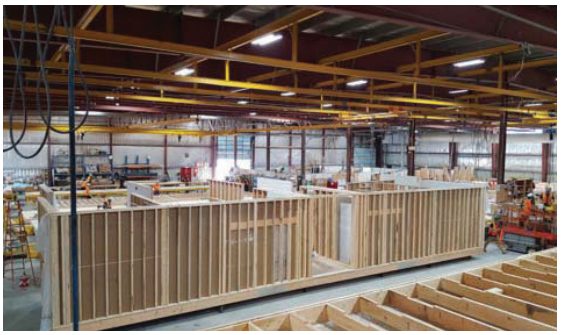

Figure 8: *Prefabricated plant for wooden structures: Metric Modular. Source: www.naturallywood.com*

Finland: where there is the Wood Construction Program (2016-2025), a joint venture of the Finnish government coordinated by the Ministry of the Environment, aimed at increasing the use of wood in urban development, public buildings, and large constructions such as bridges or sheds. The program also aims to diversify and expand the different applications of wood by developing the most significant possible added value to this material.

Figure 9: *Houses in Sipoo. Source: https://www.a-kruunu.fi*

Thus, the result was a comparative documentation of three countries that have faced similar challenges at different times, considering their particular institutions and existing capacities. It was also possible to know each country's historical line of development and the ambitious goals for the coming years aimed at increasing the construction of social housing in wood in those latitudes.

2.4 DEPARTMENTAL VISITS

The political-territorial ordering of Uruguay follows a regional logic, being organized into 19 departments. In this way, the administrative functions are distributed in two levels: The National Government and the Departmental Government. Furthermore, the Municipalities of each department are organized differently from each other to meet the needs and particularities of each of them.

The participation of departmental governments in general, and of forestry departments in particular, was considered essential for creating and developing the Roadmap.

In this line, more in-depth departmental work was carried out with the municipalities with the highest incidence of forestry, which are Tacuarembó and Rivera, considering them possible pilot departments for the development of the construction of social housing in wood. In addition, field visits and face-to-face interviews were conducted with authorities, professionals, business academics, workers, and users, and facilities, industries, and projects were visited. Thus, it sought to obtain a vision from the territories on the opportunities, barriers, and challenges that implementing an agenda for promoting low-income housing in Maderas would present, in addition to inviting them to participate actively in its performance.

Figure 10: *Guided tour by the owner of the Nortimber sawmill, located in Rivera.*

Figure 11: *Visit to the Arboreal plant, located in Tacuarembó.*

Figure 12: *Conversation with the owner of one of the houses in the T15 project, located in Tacuarembó.*

2.5 INTERVIEWS WITH STAKEHOLDERS

A series of structured interviews were carried out online via the Zoom platform, which allowed for conversations with 75 stakeholders in the sector, organized into five reference groups:

Table 6: *Five reference groups*

Nº	Reference groups
1	Public sector.
2	Business sector.
3	Academic sector.
4	Professional colleges.
5	Users.

https://doi.org/10.52202/069179-0582

The objective of these meetings was to understand the position of the actor interviewed in the production chain of the forestry sector and/or in the construction processes, considering the existing barriers to development in the current context, the possible lines of action for the future of the interviewed, and the appropriate external actions that would influence these lines of action.

It was considered that the "one-on-one" meeting methodology would be more suitable for the participants compared to more massive modalities such as the focus group, so that they have the space to express their points of view without restrictions, and thus gather the greatest amount of information possible and reliable.

Figure 13: *Diagram (cloud) of sectors and constituent actors of the Roadmap.*

For each interview, a detailed minute of the conversation was made, leaving a formal record. Firstly, one hundred and eight actions proposed by the seventy-five participating leading actors from the forestry and construction sectors were obtained. Many of these actions were repeated and/or aimed at similar themes, for which reason an analysis and processing of the proposals was carried out, after which the number was reduced to a total of sixty-two actions that were classified systematically in seven thematic axes.

2.6 PRIORITIES OF THE WORKING COMMITTEE

The sixty-two proposals for action obtained from the structured interview process were ordered around the following seven axes:

1. Laws, norms, and regulations for building in wood: Actions linked to innovating in the legal, normative, and regulatory bodies for building with wood, both nationally and departmentally, such as fire protection, horizontal property, structural performance, hygrothermal comfort, protection, and durability, among others.

2. Capacity building of professionals, technicians, and workers for the evaluation, design, and execution of wood projects: Actions aimed at strengthening professional and technical capacities, both in the public and private spheres, for building with wood in areas such as engineering, architecture, construction, economy, industries, administration, and assemblies.

3. Research and development in elements and construction systems in wood: Actions aimed at strengthening the scientific and innovation bases linked to building with wood (materials and techniques) concerning advanced human capital, laboratory infrastructure, and other resources.

4. Transfer of technological capabilities to the SME sector of industrialized building with wood: Actions aimed at strengthening the scientific and innovation bases linked to building with wood (materials and systems) concerning advanced human capital, laboratory infrastructure, and other resources.

5. Supply of structural wood to the industrial processing chain, emphasizing SMEs: Actions aimed at strengthening the supply chain of certified structural wood, of national origin, to wood SMEs, guaranteeing a wide range of products sustainably over time.

6. Overcoming cultural and market barriers for wooden buildings: Actions aimed at overcoming the cultural and market gaps around wooden structures, which allow prejudices to be reduced and to recognize their environmental, economic, and quality advantages.

7. Governance structure for the promotion of low-income housing with wood: Actions aimed at strengthening the participation of multi-stakeholders in the development of the roadmap, integrating the network of initiatives currently under development (national and departmental), involving international experience in its management to accelerate in a guaranteed way the obtaining of good results.

3 ANALYSIS OF THE RESULTS

3.1 INTERNATIONAL BENCHMARK WORKSHOP

For the design of the Roadmap, it was considered of great value to share the information collected in the study with the actors involved and other interested parties. To this end, the International Benchmark Workshop was held on April 6, 2022, in a hybrid format, with a face-to-face attendance of 70 people, in addition to 499 connections in an online form.

The workshop had the participation of 9 Uruguayan speakers, who delved into the different topics in the base case of Uruguay, and five international speakers who presented the cases of Chile, Canada, and Finland.

The day was organized around five thematic blocks within which three experts presented, to then move on to a

question space led by a moderator. They talked about Uruguayan programs and regulations, the benchmark with Chile, Finland, and Canada, the wood industry in Uruguay, and academic capacities and national laboratories. With this, it was possible to draw a baseline and identify the leading local challenges to overcome the gaps to effectively promote social housing in wood.

Figure 14: *Exhibitors of the Block nº1 of the International Benchmark Workshop.*

Figure 15: *Participation of the Minister of Housing and Territorial Planning of Uruguay, during the International Benchmark Workshop.*

3.2 10 (+1) PRIORITIZED ACTIONS

As a result of the previously described structured interviews with the different actors involved in the forestry and construction industry, a series of actions grouped into seven thematic axes were defined, then discussed and prioritized by a select Working Committee to prioritize them. in order of importance and urgency.

A selection of the actors previously interviewed worked in a committee around three tables, placing different representatives of the five reference groups in each, thus achieving a broad and non-sectoral vision of the proposals for action.

Figure 16: *Working Committee Tables.*

Figure 17: *Presentation by one Working Committee Table.*

Figure 18: *Space for questions during Workshop.*

Each table discussed and voted on at least 2 of the seven axes, defining each of their assistants which actions were first (3 points), second (2 points), or third priority (1 point) for the development of this Roadmap.

This collaborative process resulted in a list of 10 priority actions to promote the construction of affordable housing in wood, which were defined as primary lines of action for the development of the Roadmap. These actions had a high transversal adherence averaging 87.9%, varying between 100% and 74%.

Thus, the ten prioritized actions (plus one that which was considered a necessary cross-section), accompanied by a communication process and a governance plan, were the following:

https://doi.org/10.52202/069179-0582

Table 7: *Prioritized actions after voting and % of consensus.*

Nº	Prioritized action	%
1	Create or update the national and local regulations for wood construction, such as: the national fire decree, the horizontal property law, wood durability and others.	100%
2	Develop and carry-out several wood projects: high- rise and block housing units and public buildings to stimulate demand.	96%
3	Complete the description of local wood to support the updating of the legislation and the certification of production standards (including resistance and protection, among others).	94%
4	Generate and implement collaborative training program at all levels (professionals, technical staff and workers) in the private and public sectors.	93%
5	Encourage the development of building solution suitable for the local wood and its required performance standards (structures, fire, acoustic, thermal, etc.) through access to public CIR (registration certificate), or similar.	91%
6	Develop an investment and support program for woodworking SMEs to improve the competitiveness and productivity, including training activities and partnership.	89%
7	Create and implement an effective communication strategy for the different audiences: users, developers, professionals, general public (at national and departmental level).	85%
8	Generate incentives for private developers so that they choose wood for their buildings (exemptions, contributions, financial or insurance costs).	81%
9	Promote trade in forestry products, ensuring a constant quality supply for SMEs, sawmills and component production.	76%
10	Generate guidelines for the design, specifications, construction, and use (maintenance) of timber buildings (wood framing and engineering) for the different target audiences.	74%
C.	CROSS-SECTION. Generate a governance structure involving all Roadmap stakeholders, working together with other proposals currently under development.	N/A

Each of these actions is associated with the priority axes of the working committee described above and has specific tasks, internal groups, external advisers, complementary initiatives, and a metric with particular goals for six months, two years, and four years. For example, among the most relevant:

Table 8: *Examples of specific actions and metrics.*

Action	Specific task	Term
Action 1	Approval of new fire resistance laws and regulations.	Two years
Action 2	Architecture competitions and the start of works.	Two years
Action 2	Constructed works of isolated housing complexes, a collective housing building, and a social equipment building.	Four years
Action 4	Training and specialization program.	Four years
Action 7	Communication Strategy.	Two years
Action 8	Economic Incentive Instruments.	Four years
Action 10	Publication of Wood Design Guides.	Two years

3.3 INTERNAL GROUPS AND EXTERNAL ADVISORS

For the correct development of the Roadmap and each of the ten prioritized actions, internal groups were defined in charge of meeting the specific objectives that each of them poses. These groups were determined based on their relationship with the topic to be dealt with and the existing capacities they can offer to face the challenges.

The five reference groups were included, maintaining the intersectoral methodology of the project. In addition, it was considered, for specific lines of action, to work with external advisors specialized in the issues to be dealt with, but simultaneously, with a broader perspective than internal groups directly related to these.

Each group has members committed to a dedication of 4 hours per week (nucleus), 1.5 hours per week (committee), and 1.5 hours per month (assembly).

4 CONCLUSIONS

4.1 MULTI-SECTOR PARTICIPATION

The success of the Roadmap for promoting low-income wooden housing in Uruguay is subject to joint multisectoral participation in its creation, development, and implementation. For this reason, including the experiences and points of view of actors from all areas of the forestry and the construction sector was essential for analyzing the current national context prior to its co-construction.

Figure 19: *Release of the "Roadmap for the construction of wooden social housing in Uruguay".*

4.2 ONGOING ACTIVITIES

Technical Cooperation with Japan is currently under development through the efforts of the Inter-American Development Bank (IDB), which offers an investment of USD 750,000 to support the MVOT and other relevant actors in developing wooden construction nationwide. The previous emphasizes the evaluation of the regulations and the existing regulatory framework, identifying existing obstacles and gaps; public policies to encourage sustainable construction; research and development on relevant topics for the development of the value chain and the positioning of wood products in the national and international market; technology transfer between the public sector and the private sector; and positioning of the national market at a regional and global level, among others.

There is a continuity of the "Petit Committee" made up of the consultants who carry out the Roadmap, representatives of the MVOT, and the IDB, where the progress of the tasks is monitored, as well as new initiatives and forms of financing are proposed.

Two technical secretaries were hired, who organized and monitored the meetings and the progress of the different technical groups. After adjustment, the Technical Groups are already constituted, meeting periodically.

Three international competitions are underway: one for the design and construction of a high-rise social housing building in the city of Durazno, which the ANV will develop; another, for the design and construction of new types of housing in extension with wood technology of 20 units in the town of Tranqueras, department of Rivera, which MEVIR will develop; and, finally, a third competition for the design and construction of a health Polyclinic, which the PMB will produce.

Figure 20: *Call for architectural competition for mid-rise residential buildings and extended housing, respectively.*

Finally, two international consultants are working to generate economic incentive instruments for construction in wood and design and implement a training strategy for building in wood in Uruguay.

4.3 DOCUMENTS OF THE PROCESS

The co-creation process of the Roadmap for the Construction of Social Housing in Wood in Uruguay was documented through a triptych for mass distribution and a book, both available since May 2022 at the Ministry of Housing and Territorial Planning (MVOT) and the Inter-American Development Bank (IDB).

Figure 21: *Book "Roadmap for the construction of wooden social housing in Uruguay".*

https://doi.org/10.52202/069179-0582

ACKNOWLEDGEMENTS

To all the actors from the public, business, academic, professional, and user sectors, who participated with extraordinary enthusiasm during this process.

USING ARIMA MODELS TO PROJECT SAWLOGS, AND SAWN WOOD PRICES IN THE CHILEAN CONSTRUCTION MATERIALS MARKET

Wilson Mejías[1], Janina Gysling[2], Carlos Kahler [3], Daniel Soto[4] Evaristo Pardo[5]

ABSTRACT:

One of the most remarkable factors when defining the materiality of a construction is the material cost. In this context, by having the tools to help reduce the uncertainty of wood cost will contribute to carry out projects with this material. The ARIMA models are management tools that have the potential to support projections in the short, and medium term. In the present research, the implementation of local ARIMA models were carried out in Biobío, La Araucanía, and Los Lagos regions, using as supplies the time series of radiata pine (*Pinus radiata*) sawn wood, and sawlogs prices, which have been collected periodically by the Forestry Institute (INFOR). The estimations on the implemented models had positive results in respect of validation data, with the exception of sawn wood prices from the four quarter of 2020, and part of 2021, which presented an unusual increase during the COVID-19 pandemic.

KEYWORDS: Sawn wood, sawlogs, construction with wood, ARIMA models, time series.

1 INTRODUCTION

The Chilean forestry industry produces near to 15 million m³ of radiata pine sawlogs, which are production supplies of approximately 7.9 million m³ of sawn wood, these figures make Chile one of the 15 largest producers of this material in the world [1]. Despite this, the national statistical institute (INE) indicates that approximately 13% of the area which is built annually in the country uses wood as a predominant structural material, which implicates a low consumption of wood estimated in approximately 500.000 m³ [2].

According to INFOR's figures, in 2021, the Biobío, La Araucanía, and Los Lagos regions produced approximately 4.5 million m³ of sawn wood, equivalent to 52% of what Chile produced that year [3]. On the other side, from 2020, a strong increase in sawn wood price has been observed, due to the increase of demand of this material during the COVID-19 pandemic. This increase in consumption was the result of several government policies that allowed a partial withdraw of workers' pension funds, which generated an increase in repairs, and extensions of housing.

According to construction companies, one the most determining factors when deciding on the use of wood is the price [2], therefore, by having models with the ability to generate robust estimations, it would help to have more clarity, and to project costs in a better way for the forestry industry, as well as for the construction industry, and for planification of public investment in this matter.

A time series is a set of data recorded in a monthly, quarterly, or annual period [4]. Its analysis is useful for decision making in the present time, and to generate projection on information, on the assumption that the past behavior patterns will continue in the future. The time series consist in three components:

a) Trend: It can be defined as a change in the long term that it is produced in relation to the average, or the long-term change in the mean. The trend is identified as a smooth movement of series in the long-term period.

b) Seasonal variation: Several time series have certain periodicity, or, in other words, variation of a certain period (monthly, quarterly, etc.).

c) Irregular variation (random): This component does not respond to any behavior pattern, since it is the result of fortuitus, or random factors having a remote impact in a time series.

[5] Evaristo Pardo, (INFOR) Instituto Forestal, epardo@infor.cl

https://doi.org/10.52202/069179-0583

Depending on time-series behavior, they can be classified as:

i) Seasonal: the series are seasonal when it is stable in time, that is to say, when the mean, and variation are constant over time. This is graphically reflected on the fact that the values of series tend to range around a constant mean, and that the variance in respect of that mean also remain constant over time.

ii) Non-seasonal: These are series in which the trend, and/or variability change over time. The changes in the mean determine a long-term increasing, or decreasing trend, so the series do not vary around a constant value

In the biography, several time series models are described [5-7], however, the ARIMA model is noted due to its simplicity, and practicality in modeling, and forecasting [8]. This model consists in a combination of an autoregressive term (AR), and a moving average term (MA) with a differencing element given by the letter I, based on research conducted by Yaglom [9]. In overall, these models are represented with the word ARIMA (p,d,q)(P,D,Q)[s], where the first parenthesis –(p,d,q)-, refers to the regular part of the series, the second parenthesis –(P,D,Q)- refers to the seasonal variations, and [s] corresponds to the seasonality order, which is 12 in annual series, 4 in quarterly series, and 2 in monthly series.

There are many studies where the ARIMA models have been used to analyze, and predict the behavior in short, and medium-term of prices of forestry industry products [10-12], obtaining good results in this regard.

ARIMA models can be generalized as:

$$Y_t = -(\Delta^d Y_t - Y_t) + \phi_0 + \sum_{i=1}^{p} \phi_i \Delta^d Y_{t-i} - \sum_{i=1}^{q} \theta_i \varepsilon_{t-i} + \varepsilon_t$$

Where Y_t corresponds to the current value of a series; Δ^d are the differences needed to remove the trend from the series; $\phi_1, \ldots, \phi_p$ are the corresponding parameters of the autoregressive part of the model (AR); $\theta_1, \ldots, \theta_q$ corresponds to the parameters of the moving-average part of the model (MA); ϕ_0 is a constant, and ε_t is the error term.

With this background, in the present research the ARIMA models were fitted to the time series of Chilean forestry product prices to prove the utility of this tool in terms of sawlogs, and sawn wood prices within the selected regions of the country.

2 MATERIALS AND METHODS

In the present research it was analyzed the behavior of nominal values of forestry products: sawlogs, and sawn wood of radiata pine (in Chilean pesos/m³). Based on the information available in INFOR's Forestry Statistical Platform (PEF), time series of selected product prices were created, considering the regions of Biobío, La Araucanía, and Los Lagos, fitting local time-series models. The time series of prices available in the PEF are of quarterly nature, and comprehends year 1980 until now. The prices used to create the series consider the average of quarterly measures recorded in a region for each product, including different provinces, and delivery locations (sawmills, sales plant, or purchase plant).

In the analysis of time series, the Box, and Jenkins protocol [13] was used, which indicates a divided process in the following stages:

a) Identification: the time series are presented graphically indicating if the series are seasonal or not. If the series have a trend, the differencing method is applied until making it seasonal, proving this through the ADF Dickey, and Fuller test [14]. The difference consists in an operation where each of the series values are subtracted from the previous one in order to remove any trend accumulated. Once the transformations on series are carried out, a simple autocorrelation function (ACF), and partial correlation function (PACF) are determined, which allows to determine the series structure, that is to say, if it has mobile average, or autoregressive components.

b) Estimation, and verification: by observing the two ACF, and PACF graphics of the transformed series, the ARIMA (p,d,q)(P,D,Q)[s] candidate models are raised. The models randomly distributed, or in a white noise pattern were selected by using the Ljung-Box test [15]. The statistic associated to this statistical evaluation is defined as:

$$Q = n(n+2) \sum_{k=1}^{h} \frac{\hat{\rho}_k{}^2}{n-k}$$

Where $\hat{\rho}_k$: autocorrelation of the sample in the delay, k y h are lag numbers being proved, and n is the size of the sample. The significance level associated to the critical region to reject the hypothesis of randomness is:

$$Q > \chi^2_{1-\alpha,h}$$

As a second criterion of the evaluation, those models presenting better performance metrics were selected by calculating the values of "Akaike Information Criterion" (AIC) [16], and the "Bayesian Information Criterion" (BIC) [17], which are defined as:

$$AIC = 2k - 2\ln(\hat{L})$$

$$BIC = kln(n) - 2\ln(\hat{L})$$

Where k is the number of estimated parameters, and $\hat{L}$ is the maximum value of the model's likelihood function.

These information criteria help to differentiate the efficiency that the models gain when adding new parameters, therefore benefiting the simplicity, and flexibility of models.

c) Prediction: Once the model has been selected, predictions were made for the values of the series. To evaluate the accuracy of the model predictions, the "Root Mean Square of Error" (RMSE), and "Mean Absolut Error" (MAE) indicators were determined, which would also help in differencing according to the predictive capacity of the models. The formulas of these indicators are:

$$RMSE = \sqrt{\frac{\sum_{t=1}^{n}(\hat{y}_t - y_t)^2}{n}}$$

$$MAE = \frac{|\hat{y}_t - y_t|}{n}$$

Where: $\hat{y}_t$ is the value estimated by the model, y_t is the observed value, and n is the number of observations.

The last 5 records of time series were used to validate the model forecasts, and to determine the percentage difference between the recorded, and estimated values.

In addition to what it is stated in the methodology suggested by Box, and Jenkins, for each one of the time series, an automatic model was fitted which is suggested by "auto-ARIMA" function of the statistical software R [18].

Beside of the Box, and Jenkins methodology, for each one of the time series, an automatic model was fitted, which is suggested by the auto-ARIMA function of the statistical software R: tseries [19], forecast [20], ggplot2 [21], and gridExtra [22].

3 RESULTS

3.1 SAWLOGS

a) Biobío region

For the analysis of this region, it was considered the available information of sawlog prices in the platform of forestry industry (PEF) since 2007, to the last quarter of 2022, since in that period it showed more uniform records. The missing measure for the third quarter of 2011 was completed through linear interpolation. The data was transformed through a logarithmic function in order to improve the model forecasting.

When applying the ADT test to the time series of log prices in Biobío region, it indicated that differencing was needed to remove the trend from the series, for this to be a seasonal type of series. However, models with two differences were fitted, since these presented better metrics.

The PACF, and ACF associated to the differenced series of sawlogs prices in Biobío region presented significant values in the third lag (Figure 1). Besides, the PACF records a significant lag in the second year, which is similar to the ACF behavior.

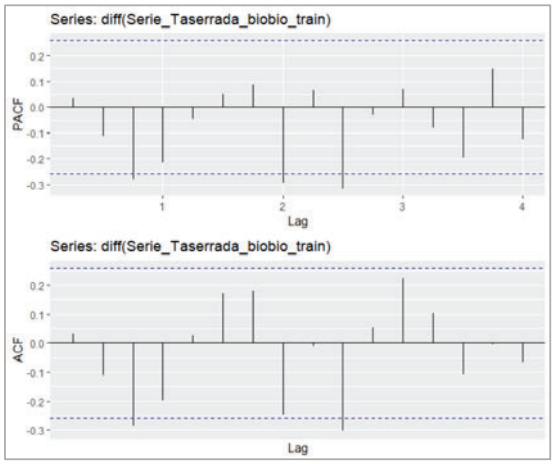

Figure 1: *The ACF, and PACF of differenced time series of sawlogs prices in Biobío region*

From the ARIMA models fitted to the series of sawlog prices in Biobío region (Table 1), the M_4 model showed better performance metrics at validation data level. This model also had no problems with the distribution of its residuals, since the Ljung-Box test did not deliver significant values.

Table 1: *Fitted models, and performance metrics of time-series prices of sawlogs in Biobío region.*

	ARIMA Models	AIC	BIC	Train		Test	
				RMSE	MAE	RMSE	MAE
M_1	(0,1,0)(0,0,2)[4]	**-181.69**	**-173.45**	0.0464	0.0354	0.1839	0.1761
M_2	(0,2,0)(0,0,2)[4]	-148.93	-141.79	0.0590	0.0427	0.1103	0.0927
M_3	(1,2,0)(0,0,2)[4]	-152.03	-143.86	0.0567	0.0431	0.0663	0.0515
M_4	(2,2,0)(0,0,2)[4]	-153.40	-143.19	0.0548	0.0410	**0.0459**	**0.0403**
M_5	(3,2,1)(0,0,2)[4]	-173.37	-161.11	**0.0386**	**0.0295**	0.2194	0.2116

Once the model is chosen, a validation of the forecast was carried out with the data slice that was not used in the model fitting, determining the percentage variation between the model prediction, and the observed values.

In Table 2, it can be observed that the error level of the model for the series values without logarithmic fitting varied between 1.58%, and 7.82%.

https://doi.org/10.52202/069179-0583

Table 2: *Variation of sawlog prices in Biobío region estimated with the M_4 model, and the values observed.*

Año	Trimestre	Observado ($/m3)	Predicción ($/m3)	Variación (%)
2021	Q4	40.271	37.122	7,82%
2022	Q1	39.759	39.129	1,58%
2022	Q2	43.057	41.323	4,03%
2022	Q3	45.501	44.043	3,20%
2022	Q4	45.251	46.653	-3,10%

In Figure 2 it can be seen the original data of time series, and the values that the m4 model fits, and predicts. It also can be observed that the validation data is included, almost entirely, within the defined range of the prediction generated by the model, following the trend that this data presents.

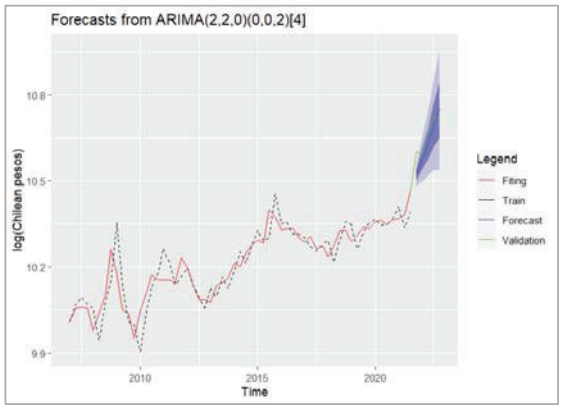

Figure 2: *Logarithmic time series of radiata pine sawlogs prices in Biobío region, forecast, and fitting made with the M_4 model.*

b) La Araucanía Region

For La Araucanía region, the prices recorded in the PEF since 2007, until the last quarter of 2022 were used, since this period has more uniform records. The missing measure in the third quarter of 2011 was linearly interpolated. The data was transformed through a logarithmic function in order to increase the forecast efficiency of the models to be fitted. The ADT test indicated that the prices series of sawlogs in La Araucanía region needed differencing to remove the trend from the data. With this information, models that consider a maximum of two differences were raised.

On the other hand, The PACF, and ACF associated to this time series (Figure 3) show that there is no significant time lag, which indicates a lack, or very low impact of the autoregressive term (AR), and the mobile average term (MA). The models presented in Table 3 were fitted by using the information of this analysis.

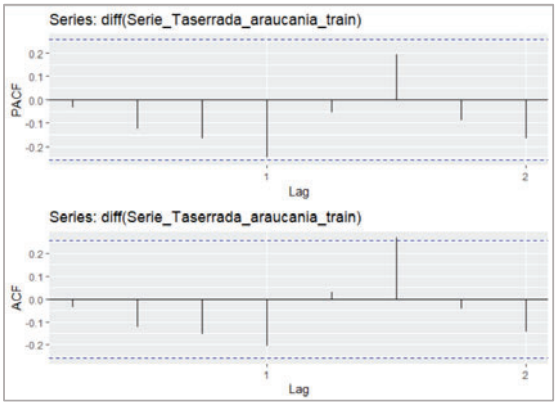

Figure 3: *ACF Y PACF de serie de tiempo diferenciada de precios de trozas aserrables en la Región de la Araucanía.*

From the model fitted for the sawlog series in La Araucanía region (Table 3), it was observed that the M_2 model shows the best validation metrics, which indicates that it generates better projections in relation to the last period data.

Table 3: *Fitted models, and performance metrics of time series of sawlog prices in Biobío region*

ARIMA Models		AIC	BIC	Train		Test	
				RMSE	MAE	RMSE	MAE
M_1	(0,1,0)(0,0,1)[4]	**-167.63**	**-173.45**	**0.0464**	**0.0354**	0.1839	0.1761
M_2	(1,2,0)(0,0,1)[4]	-137.30	-131.17	0.0672	0.0497	**0.0328**	**0.0273**
M_3	(0,2,1)(0,0,1)[4]	-159.01	-152.88	0.0535	0.0394	0.1742	0.1679
M_4	(1,2,1)(0,0,2)[4]	-157.25	-149.08	0.0533	0.0394	0.1796	0.1733
M_5	(0,2,0)(0,0,1)[4]	-123.67	-119.58	0.0774	0.0555	0.0533	0.0437

The residuals of this model were reviewed through the Ljung-Box test, which obtained non-significant values, concluding that the residual distribution corresponds to white noise. By validating the M_2 Model projections with data that was not used in the fitting (Table 4), it is observed that there is a percentage variation which range between 0.26%, to 5.71%.

Table 4: *Variations of sawlog prices in La Araucanía region estimated with the M_2 model, and the observed values.*

Year	Quarter	Observed ($/m3)	Forecast ($/m3)	Variation (%)
2021	Q4	41.032	38.689	5,71%
2022	Q1	42.587	41.431	2,71%
2022	Q2	43.582	43.468	0,26%
2022	Q3	46.179	45.202	2,12%
2022	Q4	45.976	47.216	-2,70%

In Figure 4 it can be seen the original data of time series, and the values that model fits, and forecast for the validation period.

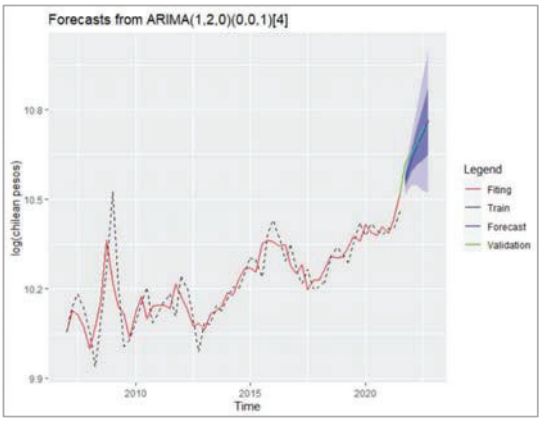

Figure 4: *Logarithmic time series of radiata pine sawlog prices in La Araucanía region, fitting, and forecast carried out with the M_2 model.*

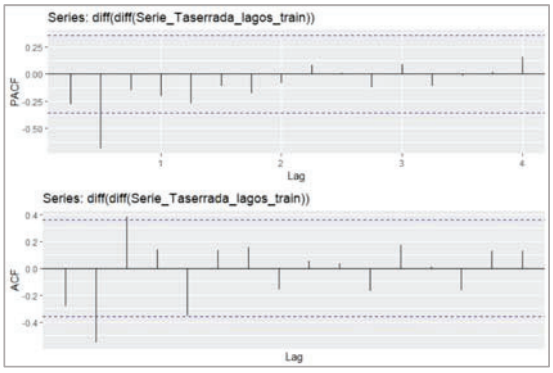
c) Los Lagos region

For Los Lagos region, prices recorded in the PEF since the last quarter of 2012 until the first quarter of 2020 were used, since this period has more uniform records.

The ADT test shows that two differences are needed for the series of Los Lagos region's sawlog prices to be seasonal.

Figure 5: *The ACF, and PACF of differenced time series of sawlog prices in Los Lagos region*



The M_4 Model presents the best validation, and train metrics in comparison with the rest that were fitted. While M_1 Model has better AIC, and BIC, this one has RMSE, and MAE validation values more than double that the ones presented in M_4 Model.

Under this analysis, the M_4 Model is the one with the best forecast from all the fitted ones. The M_4 residuals were reviewed through the Ljung-Box, which indicated that the residual distribution corresponds to white noise.

Table 5: *Fitted models, and performance metrics of time series of sawlog prices in Los Lagos region.*

ARIMA Models		AIC	BIC	Train		Test	
				RMSE	MAE	RMSE	MAE
M_1	(0,1,0)	**-101.86**	**-98.99**	0.0432	0.0331	0.1081	0.1046
M_2	(0,2,0)	-79.60	-78.19	0.0601	0.0455	0.1046	0.0836
M_3	(1,2,1)	-92.60	-88.39	0.0441	0.0300	0.0708	0.0698
M_4	(2,2,1)	-98.80	-93.20	**0.0383**	**0.0283**	**0.0277**	**0.0206**
M_5	(2,2,2)	-98.51	-91.51	0.0371	0.0281	0.0357	0.0296

When comparing the forecasts obtained with the M_4 Model, and the recorded values (Table 6), it was calculated that the variation between the values delivered by the model with respect to the real data was lower than 7%. Moreover, in Figure 6 it is observed the model fitting, and variations between the forecast, and the validation data set.

Table 6: *Variation of sawlog prices in Los Lagos region estimated with the M_4 model, and the observed values*

Year	Quarter	Observed ($/m3)	Forecast ($/m3)	Variation (%)
2021	Q4	43.911	43.782	0,29%
2022	Q1	46.333	44.343	4,30%
2022	Q2	47.444	44.478	6,25%
2022	Q3	48.778	46.772	4,11%
2022	Q4	50.223	48.476	3,48%

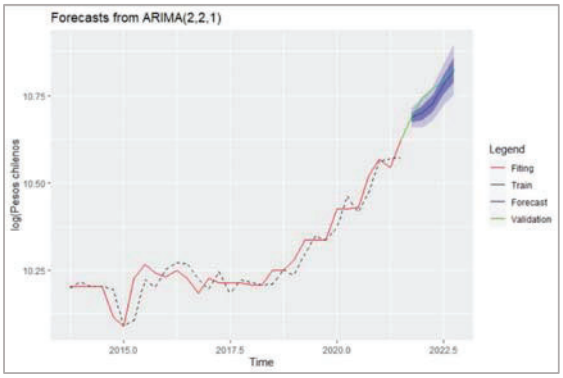


Figure 6: *Logarithmic time series of radiata pine sawlog prices in Los Lagos region, forecast, and fitting carried out with the M_2 model*

3.2 SAW WOOD

a) Biobío region

The series of sawn wood prices in Biobío region has complete information since the first quarter of 2007 until the last quarter of 2022, with the exception of the corresponding record in the third quarter of 2011, which was linearly interpolated.

https://doi.org/10.52202/069179-0583

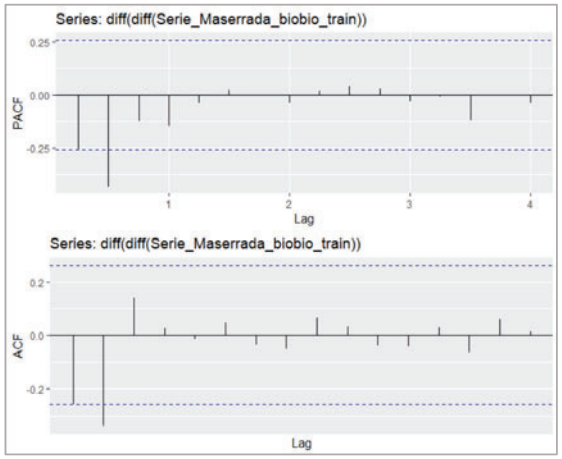

Figure 7: *The ACF, and PACF of differenced time series of sawn wood prices in Biobío region.*

Through the ADT test it was determined that differencing was needed to remove the trend from the series. Once the series are differenced, their PACF, and ACF were determined, which are shown in Figure 7, and they indicate that there is a significant lag associated to the autoregressive component, and another in the mobile average.

Table 7: *Fitted models, and performance metrics of the sawn wood prices time series in Biobío region.*

ARIMA Models		AIC	BIC	Train		Test	
				RMSE	MAE	RMSE	MAE
M_1	(0,2,3)	-209.90	-201.73	0.0350	0.0197	0.3144	0.2680
M_2	(1,1,1)	**-210.73**	**-204.55**	0.0369	0.0192	**0.0348**	**0.0291**
M_3	(1,2,2)	-208.42	-200.25	0.0350	0.0198	0.2115	0.1738
M_4	(2,2,2)	-208.75	-198.54	**0.0347**	**0.0203**	0.3202	0.2792
M_5	(2,2,3)	-206.79	-194.53	0.0347	0.0204	0.3495	0.3067

From the models fitted to the sawn wood prices series in Biobío region (Table 7), the M2 Model is the one with the best AIC, BIC, and validation metrics, forecasting in a better way the values of series beyond the range it was fitted with. The residuals associated to the M2 model were validated through the Ljung-Box test, indicating that it is distributed in a random pattern or as white noise.

Table 8: *Variation of sawn wood prices in Biobío region estimated with M_2 model, and the observed values.*

Year	Quarter	Observed ($/m3)	Forecast ($/m3)	Variation (%)
2021	Q4	134.830	128.604	4,62%
2022	Q1	136.771	136.425	0,25%
2022	Q2	140.650	142.917	-1,61%
2022	Q3	144.530	148.245	-2,57%
2022	Q4	144.530	152.579	-5,57%

When comparing the extrapolations that the M_2 Model produces (Table 8), it is observed that the variation between what is observed, and what is projected by this model is lower than 6%, where the minimum difference was 0.25% in the first quarter of 2022.

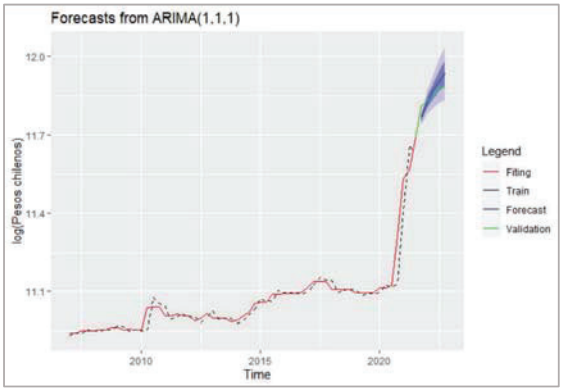

Figure 8: *Logarithmic time series of radiata pine sawn wood prices in Biobío Region, forecasts, and fitting carried out with the M_2 model.*

b) La Araucanía region

The series of sawn wood prices in La Araucanía region has information from the first quarter of 2007, until the last quarter of 2022, which is a period with more complete information, except for the records from the third quarter of 2011, which were linearly interpolated.

When applying the ADT test, it was determined that two differences were needed to remove the trend in the series of sawn wood price in La Araucanía region. Once the differencing was carried out, its PACF, and ACF were determined, which are shown in Figure 8, and they indicate that there is a significant lag associated to the autoregressive component, and another in the mobile average.

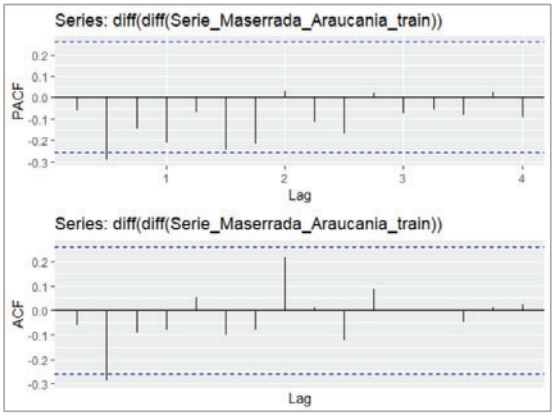

Figure 8: *The ACF, and PACF of differenced time series of sawn wood prices in La Araucanía region.*

From the models raised for the series of prices of radiata pine sawn wood in La Araucanía region (Table 9), the one with the best results in validation metrics fitting is the M_5 Model, at the same it has no significant lower indicators in train metrics, and its residuals are associated to white noise according to the Ljung-Box test.

Table 9: *Fitted models, and performance metrics of time series of sawn wood prices in La Araucanía region.*

ARIMA Models		AIC	BIC	Train		Test	
				RMSE	MAE	RMSE	MAE
M_1	(2,2,1)(2,0,0)[4]	**-224.73**	**-212.47**	**0.0289**	0.0181	0.1522	0.1374
M_2	(1,2,2)	-219.92	-211.75	0.0319	0.0170	0.0756	0.0636
M_3	(2,2,1)	-220.40	-212.23	0.0318	**0.0166**	**0.0679**	0.0562
M_4	(2,2,3)	-216.60	-204.35	0.0314	0.0177	0.0757	0.0642
M_5	(3,2,2)	-217.31	-205.05	0.0312	0.0177	**0.0679**	**0.0557**

When assessing the percentage differences between values provided by the model, and the ones used in validation (Table 10), it is observed that the difference in respect of the first two quarters is higher than 7%, while from this point it starts to decrease, reaching even 0.22%.

Table 10: *Variation of sawn wood prices in La Araucanía region estimated with the M_2 model, and the observed values.*

Year	Quarter	Observed ($/m3)	Forecast ($/m3)	Variation (%)
2021	Q4	133.645	124.421	6,90%
2022	Q1	146.308	129.809	11,28%
2022	Q2	142.267	136.781	3,86%
2022	Q3	144.423	144.110	0,22%
2022	Q4	144.423	151.212	-4,70%

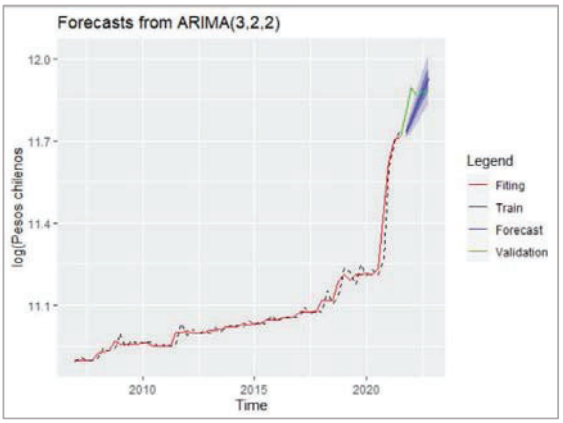

Figure 9: *Logarithmic time series of radiata pine sawn wood prices in La Araucanía region, forecasts, and fitting carried out with the M_2 model, and the observed values.*

Due to the lack of information on different periods, it was not possible to build a time series for the sawn wood prices in Los Lagos region with the necessary consistency to properly apply the methodology presented in this study.

4 CONCLUSIONS

The information collected, and managed by INFOR has an important potential that goes beyond of being a historical record of prices of several forestry products; it also can be used to generate new management tools allowing to promote construction with wood in Chile.

The models fitted for radiata pine sawlogs forecasted in a good way the prices of this product. In overall terms, the variations obtained were lower than 8%, which was validated with five quarter measures. The best results were obtained in La Araucanía region, where variations did not exceed 6%.

In case of time series of sawn wood prices, the models presented differences of up to 11.28%. In La Araucanía region, there were major differences between the last quarter of 2021, and the first quarter of 2022, which is due to unusual price increase of this material during the COVID 19 pandemic.

If the result obtained in this study are compared with other authors, it is observed that results are similar to Broz, and Viego [10], who obtained percentage differences lower than 10% by estimating the values of prices of forestry products in a 9-months period.

The ARIMA models are a good tool to carry out short, and medium-term projections of the forestry product prices, with a low level of uncertainty. Nevertheless, they cannot work efficiently with sudden market fluctuations, as the ones derived from the government policies for economic support in time of a pandemic.

ACKNOWLEDGEMENT

The present research have been carry out under the framework of the project entitled: *"Fortalecimiento de las Capacidades Tecnológicas del Instituto Forestal (INFOR), para el desarrollo de la Industria Secundaria de la Madera, a través de bienes públicos, orientados al sector de la construcción"*. The project was funded by *la Corporación de Fomento a la Producción* (CORFO).

World Conference on Timber Engineering Oslo 2023

CHARACTERIZATION OF GLUED-LAMINATED TIMBER SUPPLY IN CHILE

Janina Gysling[1], Carlos Kahler [2], Daniel Soto[3], Wilson Mejías[4], Pamela Poblete[5]

ABSTRACT: The rise of construction with wood in the world has its presence at local level, where there is great activity on this matter. The forestry institute (INFOR) actively participates in research projects carried out for the purpose of generate, and transfer economic, and technical information, which allow actors to make informed decisions to improve the development, and consolidation of construction with wood in Chile. In terms of economic information, for the first time the industry of wood engineering products is addressed, which is represented mainly by glulam (Glued laminated timber), whose supply is characterized in the present research. Thus, this study contributes to the decision-making process of private, and public actors involved in construction with wood; delivering an informed, and detailed analysis of the glulam in Chile; at the same time, the presentation of glulam industry profile aims to share this reality with the international interested community, and experts to gather opinions, and experiences about this industry's contribution in wood construction.

KEYWORDS: Engineered Wood Products, Glued laminated timber, Supply, Statistics.

1 INTRODUCTION

The Engineered Wood Products (EWP) corresponds to a series of construction structural products, made from beams, veneers, and other wood fibers mixed with adhesives, obtaining a larger dimensional unit, with superior resistance features than wood. It has a predictable performance, therefore reliable, additionally, it uses forests resources more efficiently [1].

The importance of these wood engineered products in construction it is demonstrated by the great development this industry has had in many countries where wood is a predominant material in this activity. While its use started, and reach notoriety in the non-housing construction sector, in the las few years, the use of engineered wood products has significantly increase in the housing sector, with important innovations in products, and applications, along with innovations in the architectural design.

Currently, Nordic countries are leading in wood construction projects, where the wide use of CTL (Cross Laminated Lumber) in high-rise housing building construction should be highlighted. Other countries that should be mentioned in this regard are: Japan, Italy, and Canada, among others. A lot of these developments are related directly to the need of countries of reaching in 2030 the UN's Sustainable Development Goals, due to the fundamental role the wood construction has played in matters of reducing the emissions of greenhouse gases. [2]

The number of companies in this sector is relatively small: 15 glulam facilities, one of I-joist beams, and six of industrialized truss. In CTL production there are two big companies in the Chilean forestry sector: Arauco, and CMPC (Niuform), and some sporadic actors.

The evolution of this sector has been relatively slow, in line with the evolution of construction with this material. However, in the last few years, the construction with wood has generated much interest, where the engineered products industry is becoming part of. For this reason, INFOR has added to its Forestry Statistic Platform this important sector of wood products, carrying out annual cadasters since 2020, which has allowed to understand the main parameters, and features, and the way the industry is evolving [1].

The main EWP elaborated in Chile is Glulam (Glued laminated timber). There are around a dozen facilities producing glulam, while other types of EWP for structural use, as in case of I-joist beams, and reticulated beams, have a limited participation. It should be noted that the first trails of glulam use in Chile are from 1960, when the forestry institute, supported by CORFO, brought Finnish experts with whom projects were developed as in case of the Universidad del Biobío sawmill in 1964; the industrial warehouse of the Sociedad Agrícola Forestal Copihue also in 1964, and the former Forestry Institute headquarters in Santiago, built in 1969 [3]. As a prove of

[4] Wilson Mejías, (INFOR), wmejias@infor.cl
[5] Pamela Poblete, (INFOR), ppoblete@infor.cl

https://doi.org/10.52202/069179-0584

the job done in 1960 by the Finnish experts is the Forestry Institute's 18 Technical Report [4]. Regarding the CLT, there are a few Chilean companies with project to produce CLT in large volumes. For example, the case of the Niuform company, a joint venture between CMPC, and Cortelima companies, which have carried out several construction projects with CLT, and glulam.

In this context, this research aims to contribute in decision-making processes made by public, and private actors involved in the wood construction sector, delivering an informed, and detailed analysis of glulam supply in Chile, industry with history in the country, and with highly relevant products for the wood construction development perspectives.

The 2151 NCh norm defines the glulam as "a resulting product of the assemble of structural graded lumber using adhesives, through their faces, ends, and edges, to finally create elements not limited by squareness nor length in which fibers must remain longitudinally parallel with each other, working as whole structural unit". The pieces of wood are longitudinally assembled through finger joints.

INFOR has series of glulam statistical information generated in three consecutive years of measurement. From these it can be seen that glulam production in Chile revolves around the 23.000 m³, far behind from records from other countries with long history like Germany, and Austria, whose production figures are near to 2 million m³ [6].

At world level, the wood species generally used in glulam production are coniferous, and in Chile, it is mainly manufactured with one of these species: radiata pine. The main use of this engineered product in Chile is as structural beams in non-housing works [3], while in United States, it is used massively as columns, beams, and headers in residential construction [7].

The glulam allows to design structures with different structural, and aesthetic qualities. There are industrial quality pieces (for those without aesthetic requirements), normal visual quality (for pieces to be use in construction in general), or selection quality (for pieces with high aesthetic requirements), the latter being treated to erase knots, and details of the material [8]. Another glulam feature is that it allows to work with variable, and lower squareness, and lengths, so when bonded together, it reaches the required structural quality, providing the project with an image of lightness, especially in works with big lights. Another advantage of glulam in respect of sawn wood it that it has 80% more resistance, and up to 40% more stiffness, which also contributes to the construction of big lights buildings with slender pieces [3]. The variety of forms, and dimensions that glulam allows is certainly its main attraction, therefore it is a material that has been used in several architectural projects, for housing, and non- housing purposes.

The norm related to glulam, where the procedures for its manufacture, and use are established, is included in the following Chilean norms:

- NCh 2148: *Madera laminada encolada estructural – requisitos e inspección* [8]. (Glued-laminated structural lumber – requirements, and inspection)
- NCh 2149: *Madera – Madera aserrada – determinación del módulo de elasticidad en flexión – método de ensayo no destructivo* [9]. (Wood – sawn wood, bending modulus of elasticity determination – non-destructive testing method)
- NCh 2150: *Madera laminada encolada – Clasificación mecánica y visual de madera aserrada de pino radiata* [10]. (Glued-laminated timber – Radiata pine sawn wood visual, and mechanical grading)
- NCh 2165: Madera laminada encolada – Tensiones máximas admisibles para la madera laminada encolada estructural de pino radiata [11]. (Glued-laminated wood – tension grades for radiata pine structural glulam)

2 MATERIALS AND METHODS

The information on glulam presented in this research comes from three cadasters carried out by INFOR on this product's manufacturer companies.

The cadasters of the glulam industry, carried out in 2020, 2021, and 2022, is an activity that INFOR will continue to do annually in order to provide the country with statistical series of this secondary industry remarkable segment, whether for the definition of public policies, as well as for the development of investment that contributes to increase this product supply.

Following the methodology INFOR uses when generating forestry statistics for the country, a total of 15 glulam manufacturer companies were identified. These companies were surveyed by INFOR's professionals through a survey form design for this matter. The information collected was added to the Forestry Statistical Platform, this is a tool to generate series, and statistical reports, which are available for the interested public. The information processing in the present research was carried out using EXCEL database.

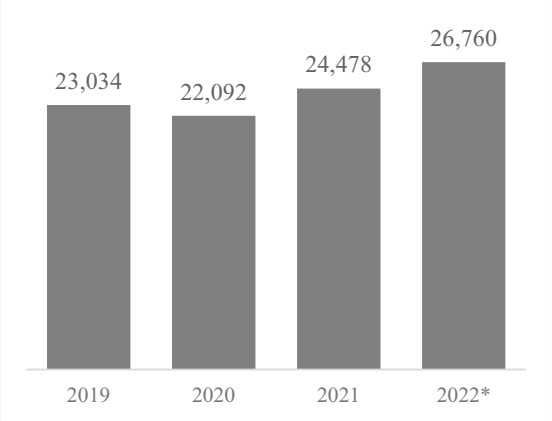
To know the problems, and goals the producers are facing, they were asked to choose from 10 options, the three most important by priority. Their responses were valued according to this prioritization, thus creating a value index for each option.

3 RESULTS

The glulam industry in Chile is constituted by 15 manufacturer companies, from which 12 were producing in 2021, and 3 were paralyzed, or without glulam projects. The glulam plants have presence in five regions around the country, but they are mainly concentrated in Metropolitan Region (7), and to a lesser extent, in Biobío region (4). Another 2 plants are located in La Araucanía Region, 1 in Ñuble Region, and 1 in Los Ríos Region.

3.1 PRODUCTION

In 2021, glulam production in Chile reached 24.478 m³ (Figure 1), which represented an increase of 10.8% in respect of the previous year. With these figures, the evolution of the 2019-2021 period shows an upward trend, in accordance with the forecast for the industry conducted in 2022, which indicates a growth of 9.3% in relation to 2021. The drop recorded in 2020 is attributed to the long periods where people could not go to work, with a consequent drop in the economic activity.



*: Industry estimation

Figure 1: *Evolution of glulam production in Chile*

The 2019 production was originated in 14 manufacturer plants, while in 2020 the number of plants dropped to 13, and in 2021 a new company was added, but three of the companies already added stop operations, therefore that year, the total of manufacturer companies was 12.

More than 90% of production is generated in regularly working plants, while some other plants only work occasionally or sporadically, this situation slightly increased due to the pandemic.

The glulam industry products are beams, and columns, impregnated or not (Figure 2). In the first two years of the analyzed period, beams, and then columns concentrated around 90% of production. However, in the last year of that period, the production of impregnated beams increased significantly, even exceeding non- impregnated beams, which is definitely in accordance with the requirements of specific projects where these products were used.

Production is determined mainly based on companies' orders. A proportion lower than 10% is made on the basis of last year production, and in 2021 also near 10% was produced to have a supply volume available. It should be noted that in the first two years, some companies did not provide information on this matter; however, the statistical procedure by itself, and the universal utility of the data it provides, contributes considerably to generate trust in all actors.

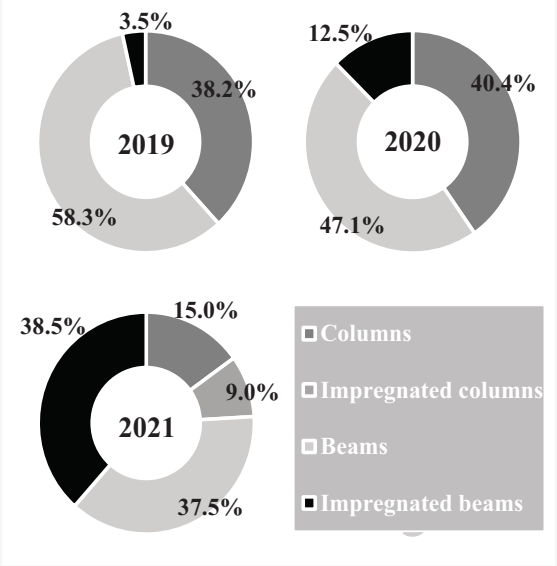


Figure 2: *Glulam production by type of product*

According to the information provided by the companies, approximately 83% of production was made based on orders (Figure 3). This means that it is a production generated in response to a known demand, through diverse construction projects in which the glulam industry participates as a structural elements provider.

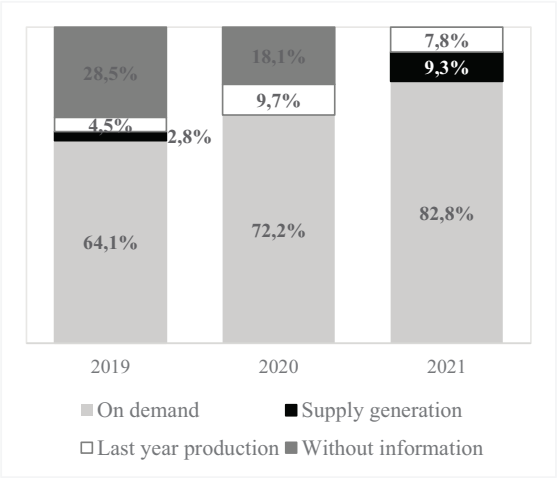

Figure 3: *How it determines the production of glulam in the*

https://doi.org/10.52202/069179-0584

industry?

In glulam manufacturing, radiata pine is by far the most dominant species, as well as in the whole forestry, and wood industry. However, the Douglas fir is highlighted with a relatively significant participation, even though this experimented a strong fall in 2021, as a result of the sawn wood prices increase, and a lower relative availability of Douglas fir (Figure 4).

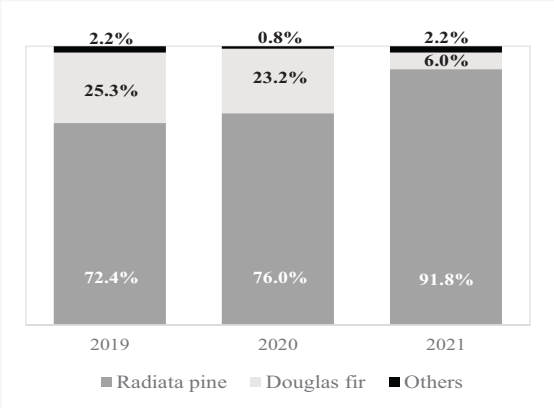

Figure 4: *Distribution of glulam production by species*

According to production volumes, there are three different groups of plants: with production >to 3.000 m³/year; with production between 1.000 – 3.000 m³/year, and plants with production < to 1.000 m³/year. It should be taken into account that, based on differencing according to annual production ranges, a plant can change of range from one year to another.

Glulam plants in superior ranges currently participate with more than 60% of production, while the ones in intermediate ranges produce 30%, and the one in inferior ranges participates with something more than 7%. Although proportions have varied between one and other ranges in the analyzed period, it can be affirmed that 2021 figures, with mitigated pandemic effects, are closer to the local industry reality (Figure 5).

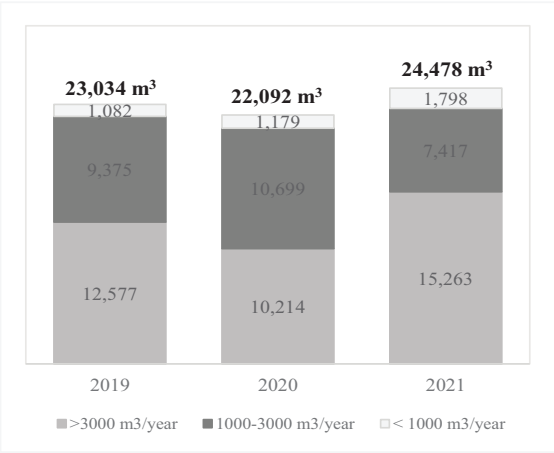

Figure 5: *Evolution of glulam production by annual production ranges*

On the other hand, the main variable cost of production is raw material, with a share of 42% in the first two years within the period, that grew in 53% in 2021. This growth reflects the significant increase in construction materials prices, like sawn wood, as a result of a demand activated by several state programs in support of families affected by the pandemic. Secondly, the workforce is included, that together with raw material represents more than two thirds of glulam's total production cost (Figure 6).

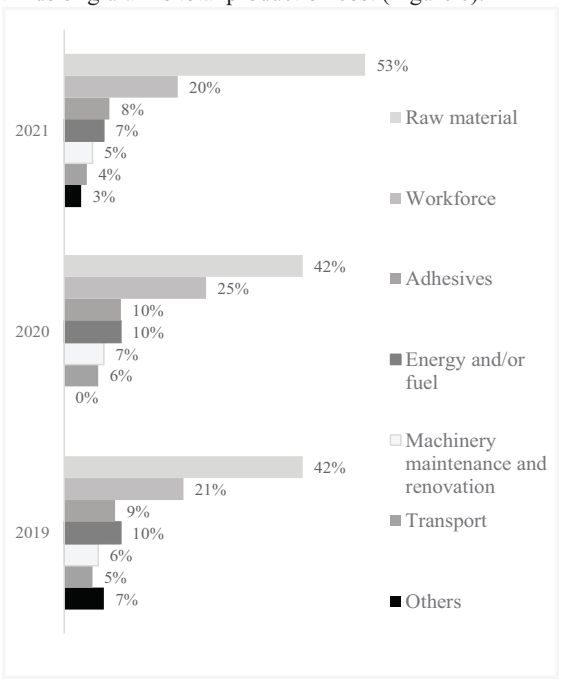

Figure 6: *Distribution of production variable cost by main items*

The occupation in glulam industry is relatively low, with 616 employed people in 2020, and 640 in 2021. Nearly 90% of occupation corresponds to permanent type of workers, mainly operators since the number of people working at the administration represent less than 10%. Moreover, more than 93% are men.

3.2 MARKETING

Glulam production is mainly destined to the internal market, but there is also a volume for exports, being Australia by far the main, and more stable market of destination.

During 2019 and 2020, the relation between the internal, and external market remained relatively stable, however, in 2021 exports increased until exceeding 40% of production (Figure 7). It could thus be supposed that the stimulus to increase production was the external market demand, more than the local market recovery.

https://doi.org/10.52202/069179-0584

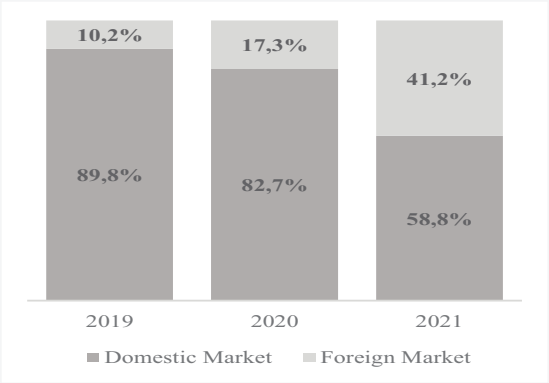

Figure 7: *Distribution of glulam production by market*

The main marketing channels for production that remain in the internal market are six, and their participation is relatively regular when compared with 2019, and 2021, however, in 2020, glulam producer sales in the internal market changed a lot in terms of destination, making marketing chains way more relevant, at expenses of the non-housing construction companies' participation (Figure 8).

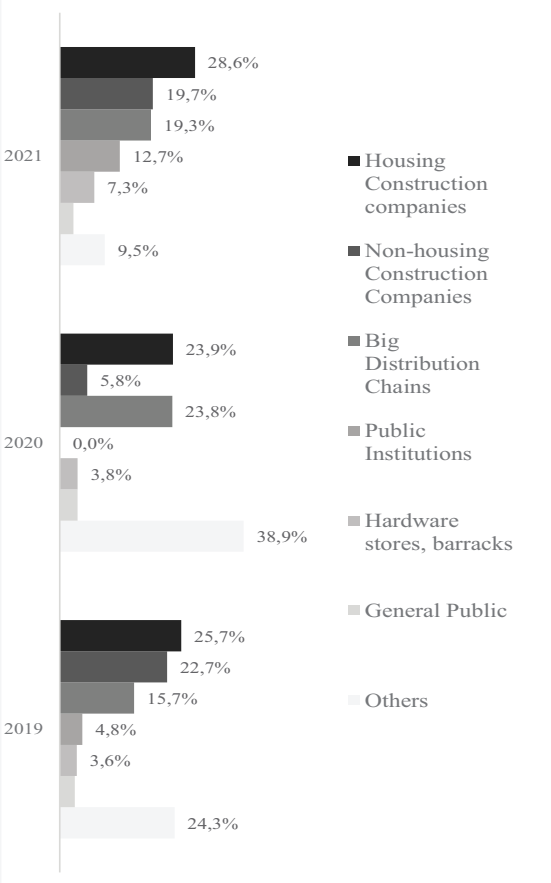

Figure 8: *Marketing channels in the domestic market*

In relation to the Chilean market perspectives in the next five years, glulam producers are solidly optimistic. In 3 annual consultations carried out, around 70% anticipates a growth in the market, while 10% thinks that the market will remain unchanged. The remaining 20% did not give a response, but none of the producers think that it will drop.

3.3 RAW MATERIAL

As mentioned before, the main raw material in glulam manufacturing is sawn wood, reaching in 2021 a total consumption of 34.010 m³, which reflects a decrease of 12.8% in respect of 2020. In Table 1, it can be seen that the most frequently way to obtain sawn wood is in dry state, although some plants purchase part of it in green state, and they dried it onsite. In other cases, sawn wood arrives impregnated or planned at the glulam plant. Only 9.4% of supply in 2020 was determined by the producers as structural sawn wood, meaning a classified wood with structural grade according to NCh 1198 norm, with moisture content lower than 20% according to NCh 1207 norm, dimensions, and tolerances according to NCh 2824, and preserved according to NCh 819 norm [12].

Table 1: *Sawn wood supply by state*

Type	2019	2020	2021
Green sawn wood	42	42	5,828
Impregnated sawn wood	313		104
Dry sawn wood	33,479	30,909	27,072
Impregnated sawn wood dried in chamber	1,116	1,519	509
Dry planned wood			497
Structural Sawn wood		3,682	
No information	3,469	2,867	
Total supply of sawn wood	38,419	39,019	34,010

On the other hand, glulam plants are supplied with sawn wood mainly from their own sawmills, this modality shows a growing tendency in the analyzed period, reaching a participation of 54% of supply in 2021 (Figure 9). On the contrary, the supply from sawmills with production lower than 1.000 m³/year is not significant, since in 2021 none of the glulam plant were provided from these productive units. The superior, and intermediate ranges participation does not show a clear tendency in the analyzed period, but they are very important when considering that together they provide something more than 40% of supply.

https://doi.org/10.52202/069179-0584

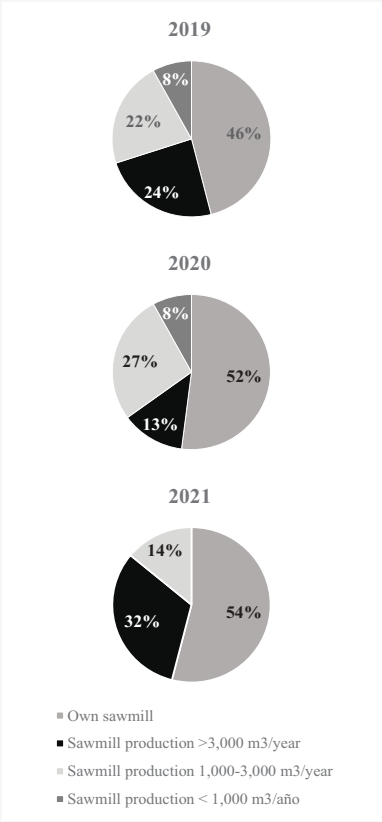

Figure 9: *Sawn wood supply distribution by type of sawmill of origin.*

3.4 PROBLEMS AND GOALS

The glulam producers were consulted about the main problems this activity faces, and the main goals they have planned. In respect of problems, the producer's prioritizations show differences year to year, but the one with higher valuation rate in the period is the low demand on glulam, and low availability of sawn wood for its manufacture. Way more behind is the lack of qualified workforce, sawn wood high cost, and its low quality. The valuation index for prioritized problems in 2021 are presented in Figure 10.

In the valuation of goals, the strong, and permanent disposition to increase production, and improve productivity is highlighted. In a second level, the produce's goals show the investment in technologic production, and diversification of products, and markets. It is worth to mention that even though one the biggest problems mentioned by the industry is the lack of trained workforce, there is no prioritization assigned in training the personnel in 3 years of consultation, which represents a contradiction. The valuation index for prioritized goals in 2021 are presented in Figure 11.

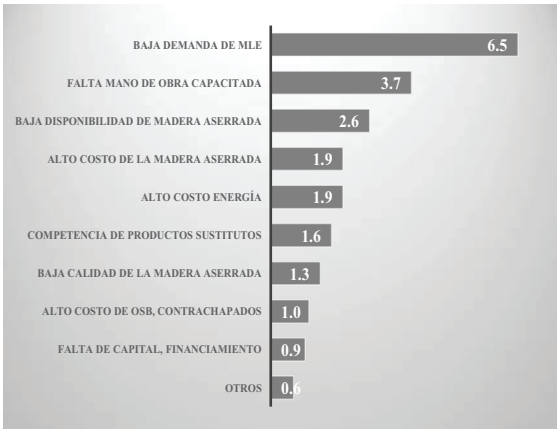

Figure 10: *Valuation index of problems in glulam industry, year 2021*

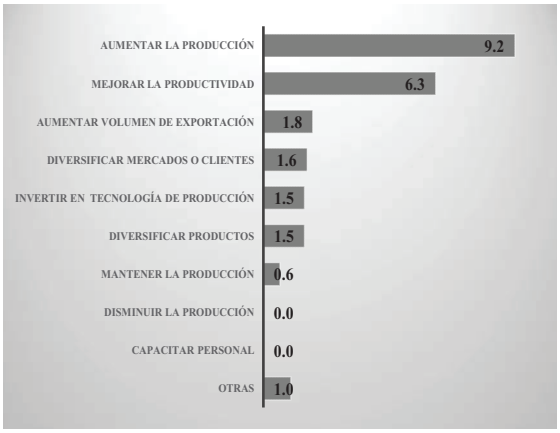

Figure 11: *Valuation index of glulam industry goals in 2021.*

3.5 PRODUCTION PROCESS

According to information collected through survey application, glulam plants are supplied almost entirely with dry sawn wood, but when they are supplied with green sawn wood, first it is dried, and then graded. Eventually, sawn wood is impregnated, depending on the component's requirements for it to be manufactured.

The first process in production of sawn wood laminations is obtaining this product with the allowed defects according to the structural grade required by the lamination (A, or B grades, according to NCh 2148). Then, the lumber is bounded together through finger joints to form laminations. When the length allows it, some companies are partially or totally supplied with laminations. After that, laminations are planed for they to reach desire dimensions. Subsequently, they are glued together and pressing to form laminated timber, before the curing of adhesives starts, whose thickness must remain as a thin layer. The most used adhesives in manufacture are melamine-urea-formaldehyde (MUF), and liquid polyurethane plastic (PUR). Lastly, the glued-laminated

timber piece is planed to reach its final dimension. Optionally, beams can include painting, or varnish finishings, which are applied depending on the client's requirements. The complete process of glulam production takes 4 days, being pressing the process that takes the longest time, between 4, and 12 hours, depending on the adhesive used.

Figure 12: *General Layout of glulam productive process*

Regarding the machinery used in the productive process, all consulted companies declare to have drying chambers, and impregnation to prepare the raw material. Then, in the lamination process, there are features to be highlighted, cutting tools like band saw blades, and sliding table saw, while two companies have CNC machines. The clamping process is carried out in a hydraulic, and mechanical press, and to a lesser extent, by hand press.

4 CONCLUSIONS

The most important EWP product in Chile, due to the number of companies involved, but overall due to its long history in the country, is glulam. However, the industry level of production is low, and has not been able to improve to superior levels of development, mainly due to limitation related to wood use, and its products in construction, resulting in, just as stated by producers, a low glulam demand.

Another limitation that producers have highlighted is the low availability of sawn wood, referring mainly to the structural sawn wood, which is the type of sawn wood that glulam requires to its production. This limitation comes from the sawmill industry, which produces low volumes of structural sawn wood, but this also originates from in the quality of lumber supply as a result of the predominant modalities in forest plantation management.

Even though the great activity existing in wood construction Chile has stimulated the interest, and expectations of wood products companies, the low production of structural elements allows to conclude that this is not enough to reach significant increases in the activity, in the short, and medium term, and what is probably needed is a more determined, and focalized boost from public policies.

ACKNOWLEDGEMENT

The present research has been carried out under the framework of the project entitled: *"Fortalecimiento de las Capacidades Tecnológicas del Instituto Forestal (INFOR), para el desarrollo de la Industria Secundaria de la Madera, a través de bienes públicos, orientados al sector de la construcción"*. The project was funded by *Corporación de Fomento a la Producción* (CORFO) and INFOR.

ESTIMATING THE GLUED-LAMINATED TIMBER DEMAND IN NON-RESIDENTIAL BUILDINGS IN CHILE

Daniel Soto Aguirre[1], **Janina Gysling Caselli**[2], **Carlos Kahler González**[3]

ABSTRACT: Glued laminated timber has taken center stage in recent years in Chile. The non-residential building sector is attracting the attention of local architects and builders, possibly due to the multiplicity of types of buildings, in which the attributes and advantages of this product are expressed. There is no record of the amount of glued laminated timber that is consumed annually in the country. The present study is a contribution to the knowledge of the demand, from the point of view of the potential that the non-residential construction market would offer. The main result indicates that, if all the potential non-residential area use glued laminated timber as a structural element, the associated demand would be in the range of 192 to 220 thousand cubic meters. This volume accounts for the enormous space that exists in the construction market to position this product, since production does not exceed 25,000 m3.

KEYWORDS: glued laminated timber, potential demand, non-residential building.

1 INTRODUCTION

In developed countries as Germany, Austria, and Japan, glued laminated timber (GLULAM) it is produced in large volumes, which is used in different types of residential, and non-residential building, usually found where large spans members are required [1].

In Chile, glulam has a vast history of usage since 1960's in the last century. The production is mainly oriented to internal market in architectural works with big spans, as warehouses, industrial plants, gyms, roofed sport centers, indoor swimming pools, pedestrian bridges, and other public infrastructure works. In Chile, there are different types of non-residential buildings which are highlighted by the use of glulam in wall, and roof structures. In general, this product operates as other materials complement which are more frequently found as concrete, or bricks. However, there are buildings whose wall, and roof structures are only composed by glulam. From some years now, glulam is drawing the attention of constructors, and architects to be used in non-residential building in the country [2].

In the present research, it was carried out an estimation of glulam cubic meter consumption that non-residential construction may reach in Chile, by means of potential demand.

In marketing, the potential demand is the maximum volume a product, or service can reach in a stablished time horizon. The marketing potential demand is calculated from an estimation of potential buyers' number, which are assign with an individual consumption rate. The potential demand represents the superior limit reached by the sum of sales of all companies participating in the market for a determined product or service [3].

2 MATERIAL AND METHODS

In order to develop this research, the main input in the analysis was the information contained in the building database recorded by the National Statistics Institute (INE). This information contains, among other fields, the following: region, and commune where works will be located, the type of building permit (new works permit, or extension permit), the purpose of building (public building, commercial premises, kindergartens, hospitals, among many others), the total authorized area to build (in square meters), and total area distribution according to predominant material in wall structure. The purpose of building was based on a table of purposes INE has elaborated to fill the Single Building Form (FUE), adding a broader definition. On the other hand, the list of predominant materials in wall structure, also elaborated by INE for the same purpose, was used without any changes [4].

The database of building from INE do not allow to determine directly the cubic meters of predominant materials contained in wall structure, since, as stated before, it is only available the information on area built in each one of them. Another difficulty in regards of obtaining the volume of materials in a direct way, and, particularly in timber category, is that there is no specification on type of wood, or to which wood product it is referred.

The individual consumption is given by the glulam volume needed in a built area unit, that is to say, the usage factor. The non-residential authorized area in a certain year is the potential area. Thus, with the quantities of predominant materials in walls, and roofing the potential demand is estimated. The amount of glulam in potential area is the expression of the volume that may be consumed by construction of non-residential works if this structural material was used ("potential demand").

To obtain the maximum demand, in first place it was carried out an estimation of potential non-residential area using INE's database, and subsequently, a documentary inquiry of non-residential works tendered by the State, to obtain the usage factor (m^3 glulam/m^2 built).

3 RESULTS

3.1 ESTIMATING THE NON-RESIDENTIAL POTENTIAL AREA

The total of new non-residential works area, according to data published by INE, was 4.216.362 m^2 in 2019. INE obtained this area considering the total of building permits authorized by the different municipalities in the country during one year.

In order to express in a better way, the "potential" feature of area to the used of glulam, in this research, it was considered appropriate to make some adjustments (reduction) on INE's figure:

- It was eliminated non-residential buildings from the database that could be interpreted as of small spans. This criterion is supported in that glulam emerges as a construction material mainly to cover large distances between building supports. Clearly, the relation between square meters of a determined building, and the size proception of it (large, or small) will depend on what it is being analyzed. In this research it was fixed arbitrarily a limit of 140 m^2 to establish non-residential building with large spans.

- From the remaining area, it was excluded works related to a mixed project, that is to say, building with more than one purpose. Among the most frequently found mixed constructions in urban areas are buildings with commercial premises in the first floor, and housing purpose from the second floor and up. According to INE's database, the majority of this mixed projects are characterized because of the predominant material in walls is concrete, and to a lesser extent, bricks, and metal, without the participation of wood in wall structures.

Figure 1: *Buildings with mixed purposes, Housing, and Market (Located in Avenida Irarrázaval avenue, Ñuñoa commune, Chile)*

- It was excluded the number of non-residential corresponding to large area works recorded under the purpose of storage, and transport, and industry purpose. The first one corresponds to large goods storage warehouses, which are commonly rented by retail companies by means of storage, and product delivery. In industry purpose, it is common that the extensions of roof coating under product processing plants, as well as the structural walls that support them, are made with predominant materials different from wood [5]. While the structures, and roof of both types of buildings (Storage, and transport, and industry) are a potential market for glulam use, so far it is thought that this may not bring positive results, due to that the alternative materials already being used, as steel, and concrete, have more competitive costs [6].

Figure 2: *Non-residential building, Industry purposes (Wood pellet plant, Biobío region, Chile)*

Figure 3: *Non-residential building, Industry purposes (Sawmill, Biobío region, Chile)*

The resulting area, after applying the previous three points, it was reduced due to not executed buildings. The municipal permit grant to build lasts for three years; in practice, this permit represents an intention of building on behalf of the architect, since the construction may not be finally carried out for various reasons. Given it was no found an official data on numbers of not executed building permits, nor the area involved, in this research it was considered that 5% of the building permits are not finally executed.

Table 3: *Total and potential area by purpose, for the estimation of glulam potential demand*

Categories of Construction purposes	Total area (m^2)*		Potential area (m^2)**	
	2019	2020	2019	2020
Agriculture and fishing (aviaries, yards, animal fodder storage facilities)	134,74	244,94	126,8	210,523
Storage and transport (product storage warehouses, bus stations, others)	570,033	462,544	164,67	140,348
Market (coomercial premises, supermarkets, pharmacies, bakeries, others)	901,042	562,889	653,081	446,412
Public buildings (custom, courts, mail, cultural centers, others)	102,081	42,177	92,162	37,336
Education (kindergartens, basic, and secondary education, professional institutes, universities, others)	162,231	107,028	152,55	100,677

3.2 GLULAM USAGE FACTOR

Once the potential area is defined, the usage factors were calculated for different purposes categories of non-residential buildings. In order to do this, it was used information available in different public tenders of the state in the website www.mercadopublico.cl [7] systemizing the documentation presented by tenderers adjudicated. It was analyzed nearly 80 public tenders to several works' constructions, among these: kindergartens, sports centers, public indoor pools, schools, universities, hospitals, family healthcare centers, primary health clinics, fire stations, civil registration offices, police stations, town halls, and others. From these, 20 that use glulam as a structural material were selected.

Table 4: *Public tender selection for calculation of glulam usage factor.*

Year	: 2020
Project Name	: Héroes de la Concepción high school
Purpose Assigned	: Secondary education
Region	: Biobío
Commune	: Laja
Tender N	: 3735-57-LR20
Authorized Area	: 3,570 m^2
Glulam Volume	: 45 m^3
Factor	: 0.013 m^3 MLE / m^2
Year	: 2016
Project Name	: Huechuraba Semi-Olympic Swimming Pool
Purpose Assigned	: Leisure and amusement
Region	: Metropolitan
Commune	: Huechuraba
Tender N	: 2793-113-LR16
Authorized Area	: 2.120 m^2
Glulam Volume	: 167 m^3
Factor	: 0.079 m^3 MLE / m^2
Year	: 2018
Project Name	: Consistorial Llanquihue Building
Purpose Assigned	: Public Buildings
Region	: Los Ríos
Commune	: Llanquihue
Tender N	: 1437-9-LR18
Authorized Area	: 2,243 m^2
Glulam Volume	: 81 m^3
Factor	: 0.036 m^3 MLE / m^2
Year	: 2019
Project Name	: Municipal Market Temuco
Purpose Assigned	: Markets and Fairs
Region	: La Araucanía
Commune	: Temuco
Tender N	: 1658-321-LR19
Authorized Area	: 12,000 m^2
Glulam Volume	: 1,010 m^3
Factor	: 0.084 m^3 MLE / m^2
Year	: 2020
Project Name	: Muñequitos Kindergarten
Purpose Assigned	: Kindergarten
Region	: Maule
Commune	: Cauquenes
Tender N	: 848-94-LR20
Authorized Area	: 946 m^2
Glulam Volume	: 17 m^3
Factor	: 0.018 m^3 MLE / m2

The selected tenders that use glulam were assigned to one of the construction purpose categories from the table of purposes. Those containing information on the use of glulam as a structural material in walls, and roofs were revised in more detail, particularly the itemized budget, the unitary price analyses (APU), elevation planes, and building technical specifications. Thus, it was obtained the volume (in m^3) of glulam used. With this data, in addition to the area built recorded in the building permit, it was obtained the usage factor for each construction work expressed in m^3 of glulam per unit of area built.

For each resulting purpose category, it was averaged the usage factors of assigned tenders in each one of them. The average factor was multiplied by the potential area of each construction typology. In table N°4 it is presented 5 of the 20 projects where glulam was used as a structural material, the project area, glulam volume, and usage factor.

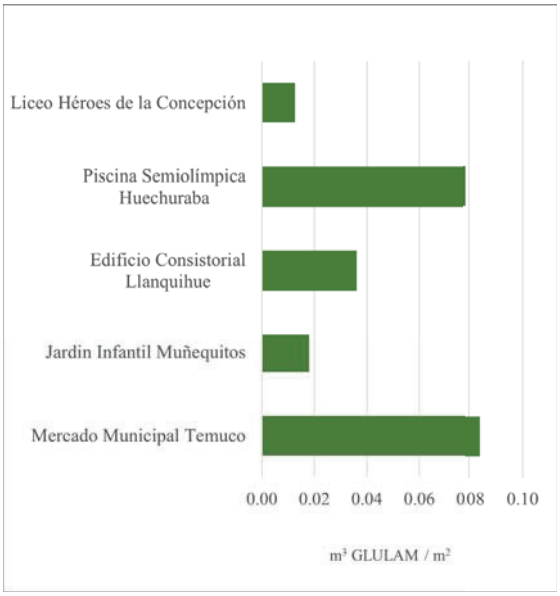

Figure 4: *Glulam usage factors expressed in cubic meters by square meter built*

Table 5: *Glulam usage factor by construction purpose*

Categories of Construction purposes	Volume (m^3)
Agriculture and fishing (aviaries, yards, animal fodder storage facilities)	0.107

4. CONCLUSIONS

The production of Glulam in Chile in 2019 reached 23,034 m³. This figure is only 10.5% of the potential volume of laminated timber that could be demanded in the country, therefore existing wide range to increase the use of this material in the national market.

A possible explanation of this gaps between supply, and demand of glulam, is the timber industry limited perception in terms of the remarkable market potential this product has. Certainly, the availability of the raw material to increase glulam production can be limiting; in this sense, sawmills play a very important role as suppliers of structural sawn wood (MAE) of companies producing glulam.

Regarding 2020, this estimation exercise shows that the potential area calculated decreased in 15.2%, and the potential demand volume in 12.4% in respect of the previous year. This drop it is attributed to less construction activity in 2020 due to COVID-19 pandemic effects.

While the research considered only the non-residential building segment, the gap between supply, and demand presented in this research may be higher, that is to say, the percentage of potential volume covered by the current supply could be lower than 10.5%, since the housing sector has not been included.

Moreover, there is a glulam demand volume which has not been evaluated in this research, that it would be determined by the structural reparations market in the existing buildings, that may contemplate a partial, or total reposition of glulam volume currently in operation.

DIGITAL TWIN FRAMEWORK FOR VISUAL EXPLORATION OF MATERIAL FLOWS AND CARBON IMPACTS OF ENGINEERED WOOD SUPPLY CHAINS FROM FOREST TO BUILDINGS

Stephan Ott[1], Andreas Rudena[2], Uwe Kies[3], Anna Wagner[4], Oliver Jancke[5]

ABSTRACT: Engineered wood products (EWP) can achieve a better environmental performance i.e. a lower carbon footprint than most conventional building materials, mostly due to the high carbon storage potential of such products and production processes with lower carbon emissions. Increasing the use of EWP in new built and renovation can thus play a major role for the transformation of the built environment into a large-scale carbon sink. The necessity to make the impact of this use both as a whole and in detail measurable and to directly make the optimization impact visible, the Forest2Building Digital Twin Framework (F2BDF) has been developed. The F2BDF aims at a holistic view of the entire wood construction supply chain and the whole life cycle, including all steps from forest biological production and supply of raw materials, to processing and engineering of products, their installation and use in buildings, and their recovery during deconstruction. The open framework provides a backbone for interconnecting digital twins and harvesting of data across different steps and scales of the supply chain for analytical and predictive purposes. Visual data exploration tools provide insight into material flows, traceability, pinpointing hotspots for optimizing industrial processes, and enable information-based decision making.

KEYWORDS: system, visualization, mapping, supply chain, substitution, environmental impact, resource consumption, circularity, recycling, change management

1 INTRODUCTION

Every consumption has consequences and "[we] are leaving a trail of devastation across the earth with our daily lives, and we don't care […]" [1]. This quote from the German Federal Minister of Economic Affairs and Climate Action was addressed to all consumers in general, but it applies just as much to the economic activities of companies: every action they take has consequences for the environment and especially for the global climate. Unfortunately, many businesses fail to recognize their own trail of devastation by their economic activities. This trail is connected to the entire upstream of resources and generates a significant impact on the global climate, especially in the construction industry. Here the need for lowering emissions through decarbonization actions is very urgent, because resource streams are massive. Due to Greenhouse Gas (GHG) emissions during the use stage and a high share of embodied carbon in products, developing strategies and tools to supervise the way to reach the 1.5 °C climate target is necessary. To meet the climate protection goals of the Paris Climate Agreement, the European Union (EU) has defined targets and measures. Within the scope of the Green Deal, which aims for a climate-neutral Europe by 2050, the EU's Fit for 55 legislative package is now being implemented [2].

Emission reduction or decarbonization as a way towards carbon neutrality in the industry is driven by carbon saving (sufficiency path), carbon reduction through low carbon resources (efficiency), and carbon substitution of fossil-based resources (consistency) by neutral carbon resources, such as bio-based raw materials sequestering CO_2 during growth. Research and development in all three dimensions can enable reduction in real construction projects, new products and innovative and transformative processes on local, regional or even international level. The urgent fields and most powerful levers for the construction industry to implement carbon neutrality are described as follows. Rockström et al. recommend that "[t]he construction industry must either use emissions-free concrete and steel or replace those materials with zero- or negative-emissions substances such as wood, stone, and carbon fibre" [3]. Achieving climate-neutral buildings requires the production of building materials and products that are themselves climate-neutral. This is a significant challenge because resources, transport, and processing require auxiliary substances and energy,

[1] Stephan Ott, Technical University Munich, Germany, ott@tum.de
[2] Andreas Rudenå, Paramountric, Sweden, andreas@paramountric.com
[3] Dr. Uwe Kies, InnovaWood, Belgium, uwe.kies@innovawood.eu
[4] Anna Wagner, Technical University Munich, Germany, anna.wagner@tum.de
[5] Dr. Oliver Jancke, InnovaWood, Belgium, oliver.jancke@innovawood.eu

https://doi.org/10.52202/069179-0586

resulting in environmental impacts from emissions to air, water and soil, which must be avoided [4].

There are several ways to reduce emissions, including avoidance strategies such as using alternative materials and technologies that produce little to no emissions or compensating for excess emissions through appropriate carbon neutral technologies or raw materials themselves. Additionally, building components and materials must be processed after dismantling, then be reused or recycled for secondary use, which again requires energy, technologies and auxiliary substances. Therefore, achieving a climate-neutral building in its entire life cycle requires two main tasks: i) optimizing the building to zero-emission operation itself over its useful life and ii) producing and dismantling the building and its materials in a way that generates no emissions or even sequesters CO_2 [6]. Making the supply chain more sustainable has very positive implications: companies and other actors will begin toavoid the path of destruction and take effective action towards protecting the climate through decarbonization and emissions reduction [7].

This exploratory essay studies how a digital framework can be created which can address and reduce environmental impacts and help to implement these strategies in the scope of the *BASAJAUN* project. We focus on decarbonized raw material transformation and logistics of EWP and bio-based materials in modular and hybrid building solutions, sequestration and long-time storage of biogenic carbon in bio-based construction products, and substitution of fossil carbon use, and innovative circular concepts, such as side streams, reuse, and recycling. *BASAJAUN* is a major European innovation action about sustainable building with wood. The main objective is to demonstrate with wooden demo buildings, how wood construction chains can be optimized to foster both rural development and urban transformation whilst being connected with sustainable forest management in Europe.

Our goal is to better understand the mechanisms behind the trail of devastation caused by economic activities and gain deeper insights into the eco-industrial system which at its core consists of supply chain networks. Through better information of connections and data from places of transformation in all networks, and by tracing end products back to their origins and examining raw material extraction, resource flows and processing, we can better understand the impact of supply chains on GHG emissions and value creation.

2 BACKGROUND

2.1 Product integration in sustainable construction

Integrators, such as timber construction companies, face multiple challenges, such as incorporating various eco-friendly precursors into their integrated end products. To manage the supply chain according to sustainability goals, data on technical product specifications, resource consumption, environmental impact, health, origin, manufacturing, and corporate governance must be collected and analyzed from the entire supply chain.

To achieve optimal product performance, integrators require an overview of a complex and multi-layered supply chain, along with the ability to collaborate with suppliers throughout the development process. The overall supply chain system is the bioeconomy, and its sub-systems addressed are originating from renewable resources cultivated in agriculture and forestry. The supply chain comprises various transformation stages of the raw material from first to second and following Transformation Production Systems (TPS), comprising their main product streams but also side streams. Tier Suppliers (TIER) is a method of organizing different suppliers into categories in order to delineate which materials are most important in your supply chain. Organizing suppliers into TIERS can stimulate better, necessary communication between a company and its suppliers. Understanding the system and its sub-systems with their interwoven production and supply chain hierarchy helps to trigger necessary transformation processes of the entire TPS to manage it more sustainably. *Industry 4.0* with its connected production systems that are designed to monitor, predict, and interact with the physical world, to enable decisions that support production in real- or right time, offers a technology approach to map the (micro) sub-systems of the wood supply chain as a macro eco-industrial system, visualize their interrelationships, and extract specific, characteristic data from almost all points in the system. With this characteristic data, the state and behavior of the system can be identified in the event of changes and managed in a targeted manner. However, keeping the data simultaneously up-to-date, consistent with the final product and adaptive to changes during the design, tendering, order, delivery, and construction process of each project is a significant challenge for the digital system design.

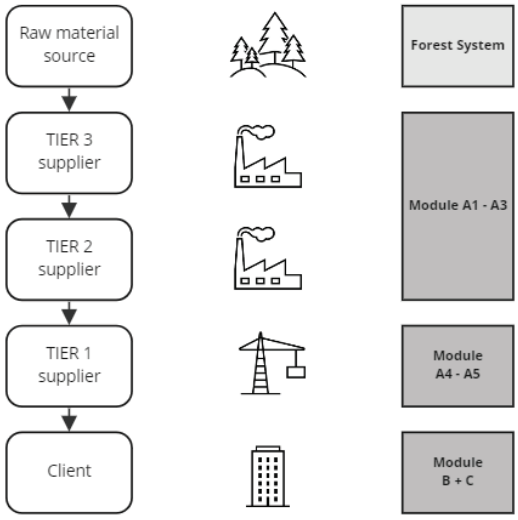

Figure 1: *Integrators deliver complex products or components by integrating lower-level suppliers' products*

The primary goals are to reduce GHG emissions and to close resource loops in supply chains. It is essential to

https://doi.org/10.52202/069179-0586

reduce primary resources, increase the use of secondary raw materials, increase durability, use renewable raw materials, and expand the CO_2 storage potential, which is especially high for renewable resources. However, the comprehensive knowledge needed to make informed decisions is often not available and sufficiently transparent, which makes it difficult to change established patterns of action and select products that are suited to build in a climate-, resource-, and recycling-friendly way. The main points of interest are the system build-up by means of the digital backbone F2BDF, which offers capabilities for mapping and visualization of resource flows within the chain, trace back raw materials to their upstream origin, follow their split into diverse products downstream, and target the resources and emissions along all processing steps.

2.2 SCM challenges in construction industry

In the construction industry, the supply chain faces several challenges, including complex and changing requirements of building projects, limited visibility and poor communication, limited supplier options and long lead times, and a lack of standardization on many levels. Effective supply chain management can improve efficiency, reduce costs, and increase customer satisfaction. Key strategies include efficient inventory management, transportation optimization, and effective communication and collaboration among supply chain partners.

Supply chain management (SCM) is a critical aspect of any industry. In the construction industry, managing the supply chain is especially challenging due to several unique factors. In this section, we will examine the challenges that SCM faces in the construction industry.

The construction supply chain involves a network of organizations and individuals that work together to design, produce, and deliver products and services to customers. This process includes sourcing raw materials, manufacturing, transportation, and distribution of products. Effective SCM can improve any businesses performance. To achieve these benefits, key strategies must follow each step and decisions along the supply chain and check and verify its compatibility with lowered impact on resource consumption combined with environmental impact as well as social and governance objectives.

Despite these benefits, the construction industry's supply chain faces several challenges. One of the most significant issues is the complex and changing project requirements. Construction projects are often large and complex, with changing requirements and tight deadlines. This can make it difficult for supply chain partners to plan and coordinate effectively, leading to delays, increased costs, and potential quality issues.

Another challenge is limited visibility and poor communication. Construction supply chains often involve multiple parties, such as architects, engineers, contractors, and subcontractors. Poor communication and a lack of visibility into the actions and decisions of other supply chain partners can lead to delays, errors, and increased costs.

Furthermore, some materials and equipment used in construction, such as steel and concrete, have long lead times and limited supplier options. This can make it difficult for supply chain managers to ensure that materials are available when they are needed, leading to delays and increased costs.

The lack of standardization is also a challenge in the construction industry's supply chain. This sector often involves a wide range of materials, equipment, and systems, with limited standardization. This can make it difficult for supply chain managers to ensure that materials and equipment are compatible and that quality standards are met.

Site-specific logistics is another issue that supply chain management must consider in construction. The construction site can be remote and difficult to access, requiring specialized logistics and transportation. This can include using heavy equipment and cranes to transport materials, as well as managing the logistics of waste disposal and recycling.

Safety and quality control are also critical considerations in construction supply chain management. Construction projects have a lot of risks, such as accidents and quality control issues. SCM must ensure that all materials and equipment meet safety and quality standards, and that adequate safety measures are in place to protect workers.

Finally, construction industry supply chain management must ensure compliance with regulations and standards on environmental protection, waste management, and recycling. This involves ensuring that all materials and equipment are environmentally friendly, and that adequate measures are in place to protect the environment.

2.3 Sustainable transformation of supply chains

Supply chains play a significant role in sustainable development. Sustainable transformation of construction supply chains is a complex and challenging process that requires the creation of new supply chains and their integration into existing business processes. In the bioeconomy, sustainable supply chain transformation is necessary to produce environmentally friendly products. The timber construction industry, as integrators, faces multiple challenges, including the incorporation of improved and eco-friendly precursors into integrated end products. Collaborating with suppliers throughout the development process can achieve optimal product performance. Data on various technical specifications, resource consumption, environmental impact, health, origin, manufacturing, and corporate governance must be collected from the supply chain to trigger necessary transformation processes of the system to manage it more sustainably.

The overall goal is to reduce greenhouse gas emissions and close resource loops in supply chains. The challenge is how to make informed decisions and select products that are climate-, resource-, and recycling-friendly.

2.4 Environmental challenges in construction SCM

The construction industry faces various environmental challenges that impact SCM. These challenges arise from environmental regulations and standards that demand strict compliance, sustainability considerations, carbon footprint reduction, and penalties for non-compliance. Additionally, the industry's reputation can suffer when it fails to meet environmental standards, leading to lost business opportunities.

Compliance with environmental regulations is vital in the construction industry, given its potential for negative impacts on the environment. These regulations may cover air and water pollution, hazardous waste disposal, and the use of certain materials and chemicals. To meet these regulations, supply chain managers must ensure that all materials and equipment used in construction comply with the required standards. Moreover, they must implement measures to protect the environment adequately.

Sustainability considerations are crucial in construction projects, which can have significant impacts on the environment. Supply chain managers must take steps to ensure that materials and equipment used are environmentally friendly. This includes sourcing from suppliers with sustainable certifications and promoting sustainable practices such as recycling, reducing energy consumption, and water usage.

Reducing the carbon footprint is another critical aspect of environmental SCM in construction. Supply chain managers must evaluate GHG emissions produced throughout the product life cycle and develop strategies to reduce them. This evaluation ranges from sourcing raw materials to final product disposal.

Non-compliance with environmental regulations can lead to significant penalties and fines, impacting companies' finances and reputations. In some cases, non-compliance can lead to legal action and suspension of construction projects. Additionally, companies that fail to meet environmental regulations and standards may struggle to win new business opportunities, impacting their reputations.

In conclusion, environmental challenges are significant for the construction industry and require a proactive approach in SCM. Effective strategies include compliance with regulations, sustainability considerations, carbon footprint reduction, and avoiding penalties and reputational damage. By addressing these challenges proactively, companies in the construction industry can gain a competitive edge while contributing positively to the environment.

2.5 Problem of GHG emissions reduction and closed resource loops in supply chains

As companies strive to reduce their environmental impact, they must consider how they can make decisions both as individuals and as representatives of the industry to reduce their use of primary, fresh resources and increase the use of secondary raw materials. This includes increasing product durability, using renewable raw materials, and expanding the potential for CO_2 storage, which is high for renewable resources. However, it often lacks comprehensive knowledge and transparency about the resources they use and the impact they have, making it challenging to make informed decisions and change established patterns of action.

To address this issue, companies need to narrow down the objects and subjects of knowledge and decision-making problems, focusing on the origin and production of materials and their effects in the industrial context. By doing so, they can formulate ways to build in a climate-, resource-, and recycling-friendly way.

To achieve this goal, we propose a digital backbone called the Forest-to-Building Digital Twin Framework (F2BDF) to companies, which uses mapping and visualization to analyze resource flows within the system. With F2BDF, they can trace the origin of raw materials upstream and their transformation into various downstream products. This allows them to target resources and emissions along processing steps and identify areas for improvement.

By implementing this framework, businesses can build a more sustainable and environmentally friendly industrial system by reducing GHG emissions and creating closed resource loops in supply chains.

2.6 Disrupting the supply chain

The wood construction industry is undergoing a digital transformation, with a clear vision presented by thinkers, innovators, and makers on the frontline. One aspect of disruption is the rising effort in integration of preliminary products into a prefabricated and integrated end-product. This integration is increasingly important for both large and small projects, as clients expect the end-product to fulfill superior properties, such as load-bearing, fire resistance, and other functions related to weather protection and resource-saving. The integration is expected to result in higher quality, improved manufacturing quality, on-time delivery, waste reduction, and faster construction activities.

However, to achieve this level of integration and quality, a detailed understanding of the supply chain is key. This includes the flows, stocks, processes, and upstream data that are characteristic for each product. This data is critical to enable sustainable, integrated, prefabricated, quality-controlled, durable, and on-time building projects. The concept of *Industry 4.0* and the *Internet of Things* (IoT) can help us see the big picture and system connections of Sustainability Supply Chain Management (SSCM) [8].

To achieve this goal, we propose a Digital Twin Framework for visual exploration of material flows and carbon impacts of engineered wood supply chains from Forest to Buildings. Digital twins can provide a virtual representation of a product or system, which can be used to optimize its performance and sustainability. In addition, the use of sensor data, real-time data, big data, machine learning, data mining, data analytics, simulation, and optimization can help to leverage the supply chain into a more sustainable direction.

The F2BDF will allow to analyze the entire supply chain from forest to buildings and identify areas where

https://doi.org/10.52202/069179-0586

improvements can be made. The framework will incorporate all data related to the supply chains of products and building materials, their origins, transparency, and impact on GHG emissions and value creation, allowing for a more sustainable and environmentally friendly system.

By using these concepts and technologies, the wood construction industry can transform its supply chain and create more sustainable and efficient projects. It can help to reduce waste, improve quality, and create more sustainable products that meet the needs of clients and consumers. With a focus on advanced SSCM and digital transformation, the wood construction industry can lead the way in creating a more sustainable economy.

3 METHODS AND DATA

3.1 Generic system representation and visualization

Development of the description of a generic system representation and the need of F2BDF backbone and other digital tools in combination with visualization tools, material flow tools as Sankey, LCA tools. Plus, the "resource" data from the digital twins, i.e. glulam factory, building design, and others.

The overall system of supply chain is the bio-economy and its sub-systems addressed are based on nature and renewable resources cultivated in agriculture and forestry and harvested from nature. The focus is dedicated to the timber supply chain from the forest over sawmills and downstream until urban timber buildings. The supply chain comprises various transformation stages of the raw material from first to second and following TPS with their main product streams but also side streams (logs, beams, wood cut-offs or particles, timber construction products, timber buildings).

We need this understanding of the system and sub-systems with their interwoven production and supply chain hierarchy to recognize single entities, dependencies, and routes between each of them. In an advancing digitalization through *Industry 4.0* concept, it is possible to map the (micro) sub-systems of the wood supply chain itself as macro eco-industrial system, visualize them in their interrelationships, and more importantly, extract specific, characteristic data from almost all points of the system. With this characteristic data, the behavior of the system can be read off in the event of changes and managed in a targeted manner.

We started to give a first overview on the necessary data pertaining to technical product specifications, resource consumption (including material, energy, and water usage), environmental data (including emissions), health data, origin data, manufacturing data (including social aspects), and corporate data (including governance). All this data changes continuously updated, and needs to be kept up-to-date, consistent with the final product and with changes during the design, tendering, order, delivery and construction process of each project.

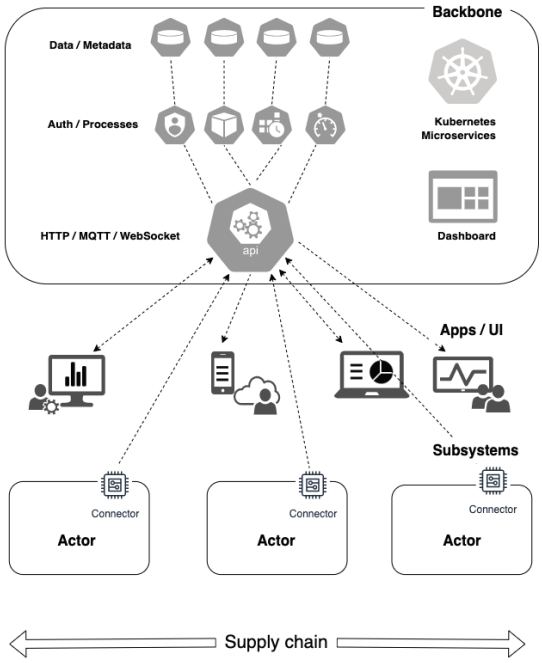

Figure 2: *System architecture of F2BDF*

3.2 Description of the F2BDF and Backbone

In the light of the *Industry 4.0* digitalization and automation transition a lot of work has been done in the area of systems interoperability. The F2BDF is specifically inspired by the *OPC UA* standard where information models can be used to define this interoperability layer with schema representation.

One challenge with the timber construction wood value supply chain is that it spans several industries and data domains making it difficult to rely on existing information models and schemas for data interoperability. A common and complete information model for the forest-to-building supply chain across Europe does not exist. Work could potentially be spent trying to define such data format for the full supply chain. However, taking into account the diversity of actors and traditions between countries this would not be feasible in relation to time and resources available in the *BASAJAUN* project. This work would also likely need to be connected to work in standardization and alignment in and between many domains that composes the wood material to building construction and life cycle supply chains. Instead, a more dynamic "data first" approach is proposed here based on bottom-up principles, where company data is collected and analyzed using flow visualization, and then mapped to indicators built through common understanding.

The studied approach for flexible data collection looks into work with digital twin city implementations where interoperability between actors and their data, products and artefacts, a similar major challenge can be identified as the diverse interconnections are quickly expanding. The change management in such a system with hundreds or thousands of actors is a challenge, and full

interoperability is still only theoretically imaginable. This is also connected to a wish to get started with sustainability work immediately and not wait for an industrial agreement or standard committees to finalize their work potentially still not reaching industrial consensus due to systemic boundaries and abstractions that in the end still does not fit some of the actors.

3.3 Mapping and Visualization of the Supply Chain

First, the F2BDF backbone is the representation of the entities; in the next step, the entities are connected, and their interrelationships and interaction options are represented. Here, the data can already be entered into the entities or transferred from sensors into the backbone. Through the representation as Sankey chart, it is possible to visualize the material flows between the entities and the size of the flows is represented proportionally. Main flows and gaps in the flow become visible. Side streams can leave the flow for other manufacturing processes and new side streams can be added, for example from secondary sources, if linearly thought in up- and downstream. The representation clarifies which quantities are on the way where in the system at point in time *x*.

4 RESULTS AND DISCUSSION

4.1 Analytics of the Supply Chain

The analytics of supply chains are an essential aspect of managing and optimizing the flow of goods and services from raw materials to finished products. One methodological approach to analyzing the supply chain involves the use of the forest-to-building digital framework introduced above. This framework collects data on raw materials, intermediary products, and end products as they move through various production systems, allowing for a comprehensive view of the entire supply chain.

Scientific and operational analysis of structured data from a production network involves various techniques such as network analysis, flow analysis, machine learning, prediction, scenario building, and concept verification.

Machine learning techniques can be used to analyze structured data from a production network to identify patterns and predict future trends. For example, machine learning algorithms can be used to predict demand for specific products, identify maintenance needs for machinery, or optimize production schedules. Scenario building involves using data from the production network to simulate different scenarios and identify potential outcomes. This can be used to evaluate the impact of different decisions or changes to the production network. Concept verification involves using data analytics to verify the effectiveness of new concepts or ideas in the production network. For example, a new production process can be simulated using data analytics to evaluate its feasibility and potential impact on the network. Other examples of data analytics for structured data from a supply chain and production network include:

- Quality control analysis to identify patterns of defects and improve product quality,
- Inventory management analysis to optimize inventory levels and reduce waste,
- Sustainability analysis to evaluate the environmental impact, circularity of the production network and identify areas for improvement,
- Risk analysis to identify potential risks and develop mitigation strategies.

4.2 Supply chain management and LCA

Digitalization has the potential to greatly enhance the integration of SCM and Life Cycle Assessment (LCA) [7]. Digital technologies can support the collection, analysis, and communication of data throughout the entire life cycle of a product, from the sourcing of raw materials to the disposal of the final product. Data collection and analysis: Digital technologies such as sensors, Internet of Things (IoT) devices, and cloud-based platforms can be used to collect data on the environmental impact of products and materials throughout their entire life cycle. This data can then be analyzed to identify areas of improvement and support decision making [7].

Collaboration and communication: Digital technologies such as Electronic Data Interchange (EDI) and Enterprise Resource Planning (ERP) systems can be used to improve collaboration and communication among supply chain partners [10]. This can include sharing information and tracking orders in real-time, improving coordination and reducing errors and delays [11]. In addition, applications such as social-LCA can be carried out with transparent supply chain documentation [13].

4.3 Data collection possibilities and needs

4.3.1 Tracking data and network analysis

Tracking data is an essential tool for identifying the origin of the materials used in construction, particularly the glulam used in the demo structure. By tracing the journey of wood through all the different locations and means of transportation, it is possible to pinpoint the forest stand from which the raw material originated. This process involves a location-based scenario that helps track the origin of wood backward from its source. Network analysis is a crucial aspect of this process, as it allows for optimization of the production network by identifying key nodes, bottlenecks, and dependencies, which can lead to improved efficiency and resilience.

Furthermore, linking the backtracked data to external certification label databases, such as the FSC/PEFC label database, can provide clients with additional information about the origin of the wood, such as logging type used in the forest and the sustainability and environmental friendliness of the materials used. This additional information can enhance transparency and improve client understanding of the materials used in the construction process. Apart from the logistics chain application, the backtracked data also help in quality control by detecting and querying wrong or damaged supplies in the chain, leading to better-quality products. The process of backtracking data and analyzing the production network

https://doi.org/10.52202/069179-0586

topology, together with linking to external certification label databases, can provide useful data for clients, including machine learning, prediction, scenario building, and concept verification.

Figure 3: *Tracking locations of production from raw materials extraction to construction sites of Northern (Finland) and Southern (France) demos*

In summary, backtracking data are a valuable tool for tracing the origin of materials used in construction, and network analysis can optimize the production network and improve efficiency and resilience. Linking to external certification label databases can provide clients with more detailed information about the sustainability and environmental impact of the materials used, while other forest-related information, such as logging type, can improve transparency and client understanding. Overall, the use of backtracking data and network analysis provides critical insights for the quality control and optimization of production networks in construction.

4.3.2 Environmental and sustainability data

The responsible use of resources and minimization of the impact of industrial processes on the environment are critical aspects of sustainable development. This can be achieved through collection and analysis of environmental and sustainability data. One important aspect is tracking the quantity of raw material flow and assessing the loss of wooden raw material throughout the supply chain. To accomplish this, producer- and quantity-based scenarios can be implemented. By tracking the flow of raw materials from the forest to the final product, it is possible to measure the net mass and volume at each stage of transformation and determine the amount of timber lost during processing.

At the sawmill, the gross volume of wood can be measured along with the output of the cut boards and their net volume, weight, and moisture content. Side streams, such as bark, sawdust, and low-quality wood, sorted during processing should also be documented. Intermediate wholesalers or refiners can also be included in the tracking process to measure the gross in and net out of wooden material, as well as any side-streams produced. At the glulam factory, the gross in of the boards can be measured along with the net out of the glulam beams and their volume. Side streams, such as quality sorting waste, cut-offs from finger jointing, and wood shavings from planing should also be documented. Finally, at the

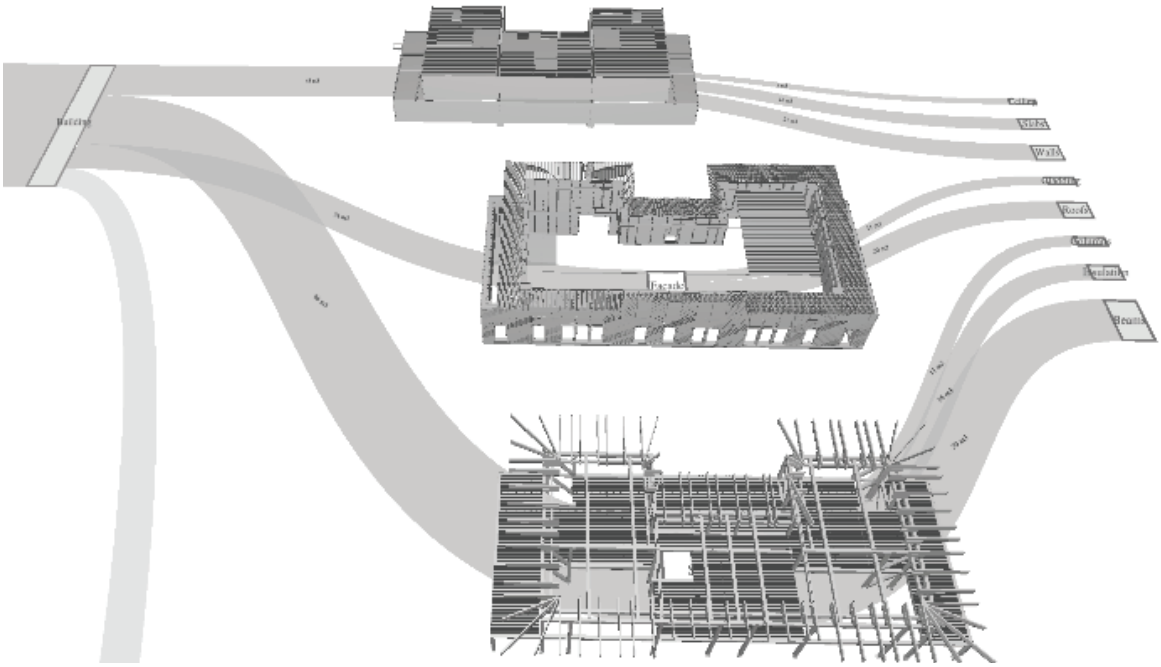

Figure 4: *IFC model of demonstrator connected to glulam Sankey chart of F2BDF backbone*

https://doi.org/10.52202/069179-0586

construction site, the gross in of the wooden material can be measured along with the net amount used in the structure.

By tracking all stages of production and linking with environmental impact data, it is possible to obtain a comprehensive picture of the supply chain's environmental impact. This information can be used to identify areas where improvements can be made, such as reducing the loss of raw materials or finding more sustainable methods of production. Additionally, BIM (Building Information Modelling) can be used in construction projects to ensure that materials and equipment are compatible with BIM systems and that BIM data are shared and integrated with all stakeholders, see [12]. The data collected can be linked to the BIM model, enabling stakeholders to visualize the environmental impact of the construction process and identify opportunities for optimization. Environmental performance tracking with digital tools such as digital dashboards, data visualization, and analytics can be used to track and monitor the environmental performance of products and materials throughout their life cycle. This can help supply chain managers to identify areas for improvement and to make data-driven decisions.

In summary, the collection and analysis of environmental and sustainability data are crucial for responsible resource use and minimizing the impact of industrial processes on the environment. Tracking the quantity of raw material flow and assessing the loss of raw wooden material throughout the supply chain can be achieved by measuring the net mass and volume of each stage of transformation. This information can be used to identify areas where improvements can be made, and BIM can be used to integrate the data and optimize the construction process.

4.3.3 Auxiliary streams and co-products

Flow analysis focuses on the movement of materials and products through the production network. By analyzing

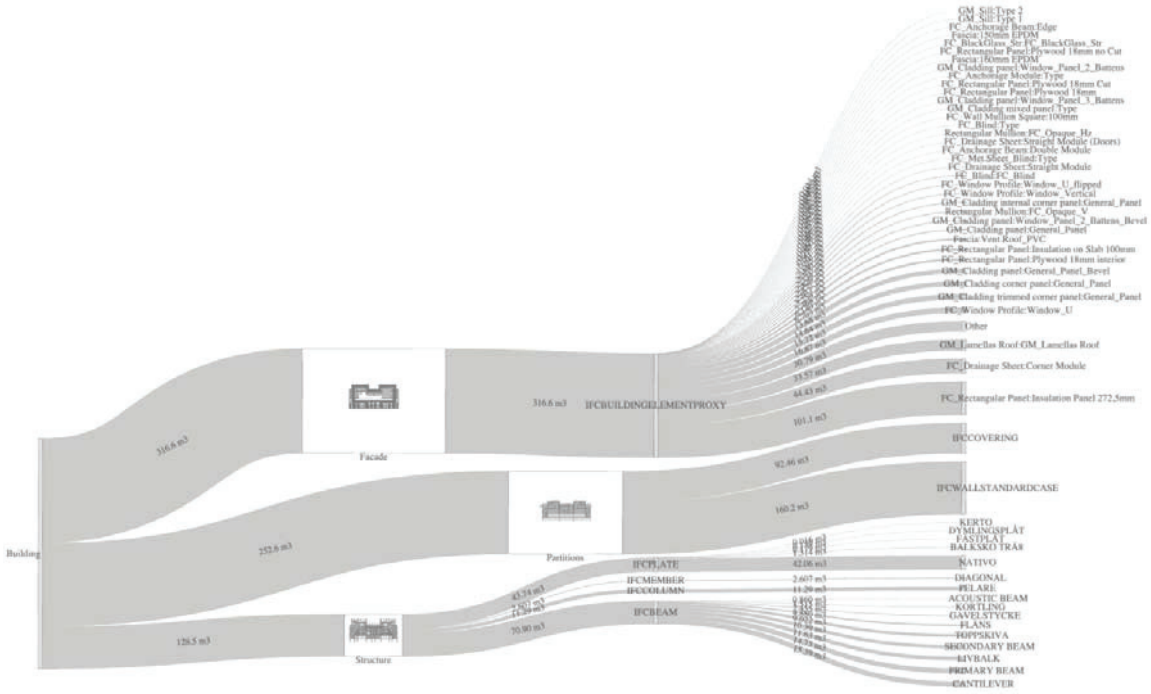

Figure 5: *Full Sankey chart of material flow from forest to building visualized from F2BDF backbone*

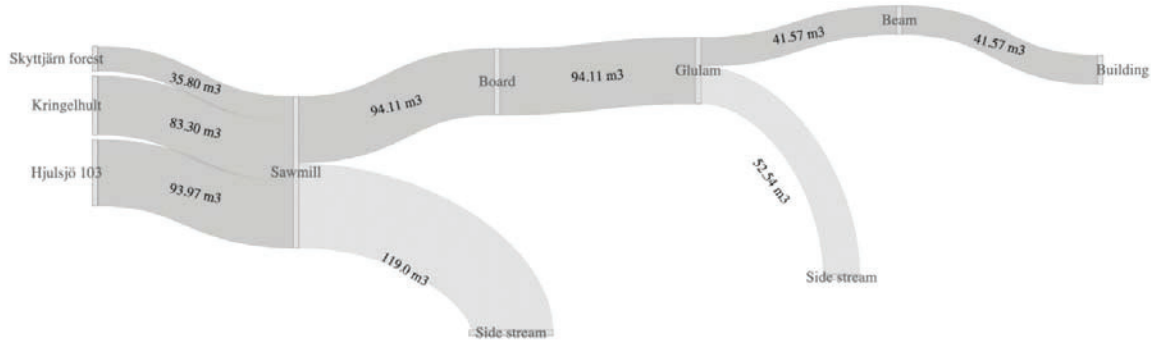

Figure 6: *Exemplary auxiliary streams of co-products taking place during the production of glulam from forest raw materials*

https://doi.org/10.52202/069179-0586

the flow of materials and products, bottlenecks and inefficiencies can be identified and addressed.

To better understand the flows in production of glulam, it's important to look not only at the main raw materials used but also at the auxiliary flows that are needed in the production process. This includes energy, glue, and other supplies. It's important to track these flows in each main production stage/phase and determine the quantity, supplier, and location of these supplies.

A flows-based scenario would be useful in analyzing other interesting flows in each main production stage/phase. For example, tracking energy flows for harvesting, sawmill operations, and drying of the wood would provide insight into the energy usage of the production process. Additionally, tracking the energy and emissions generated during transport would provide valuable data. Side streams, such as glue and packaging materials, should also be considered. It's important to track these materials at each step of the transformation process and determine their origin, quantity, and disposal method. Understanding the auxiliary flows and side streams of glulam production is crucial for identifying areas where sustainability and efficiency improvements can be made.

5 CONCLUSIONS

In conclusion, achieving climate-neutral buildings is an urgent goal that requires significant changes in the way we produce, use, and dispose of building materials and products. By applying the principles of efficient raw material transformation, long-time storage of biogenic carbon, innovative circular concepts, and using a Digital Twin Framework for Visual Exploration of Material Flows and Carbon Impacts of Engineered Wood Supply Chains from Forest to Buildings, we can make a difference and support the urgent goals of exceptional amounts of carbon reduction, up to carbon neutrality and positivity. We want to make the resource consumption that takes place in complex, interwoven systems visible and comprehensible, so that we are not overwhelmed by the complexity and confusion. We will need digital tools and *Industry 4.0* technology that helps to extract siloed data to allow us to map the current systems, especially the raw material and energy flows within them, to identify their quality, quantity and potential problems. From this, the next step is to think about change and to anticipate and understand the effects of change to be able to take corrective action if necessary or to control the change process.

As shown in the *BASAJAUN* project digital tools can be used to collect data about sustainable sourcing, identifying and tracking the environmental impact of products and materials throughout their life cycle. This can include using F2BDF digital tools to track the environmental impact of suppliers, identify sustainable materials and products, and monitor the environmental performance of logistics providers. Once these data are collected, there are various possibilities for their analysis which have to be done in follow up studies.

MATERIAL DISRUPTION: CROSS-LAMINATED TIMBER IN TEXAS

Ulrich Dangel[1]

ABSTRACT: The rise of mass timber construction in the U.S. can be traced to the introduction of one building product: cross-laminated timber, or CLT. Originally developed in Europe, CLT panels have revealed the potential for mid- and high-rise buildings with primary structural systems that are made almost entirely of timber. By combining these panels with glulam beams and columns, this novel approach competes with conventional steel and concrete building systems for structural performance. While many European countries have used CLT products for almost 20 years, the U.S. has been slow to adapt. Early pioneer projects relied on European manufacturers for their panels, and CLT fabrication in North America did not commence until 2011.

As one of the fastest-growing regions in the country, Texas continues to experience a substantial increase in its population. Most of this growth is concentrated in urban areas, and sustainable urban development will need to focus on affordable, healthy environments for living and working while also reducing carbon emissions. However, concrete and steel continue to be the building materials of choice. This paper will present case studies and recent developments in mass timber construction in a part of the world that is not known for its sustainability efforts.

KEYWORDS: Mass Timber, Texas, Cross-Laminated Timber, Multi-Story Timber Construction, International Building Code

1 INTRODUCTION

The rise of mass timber construction in the United States can be traced to the introduction of one particular building product: cross-laminated timber, or CLT. Originally developed in Europe in the 1990s, cross-laminated timber consists of several layers of lumber board that are stacked at right angles to one another and glued face-to-face to form large-format structural panels up to 3 meters (10 feet) wide, 18 meters (60 feet) long, and 30 centimeters (12 inches) thick. This cross-lamination yields exceptionally strong and dimensionally stable products with bi-directional load-bearing capacity, particularly suitable for floors, walls, and roofs in multi-story applications [1].

CLT panels have revealed the potential for residential and commercial mid- and high-rise buildings with primary structural systems that are made almost entirely of timber. By combining these planar panels with glulam beams and columns, this novel approach competes with conventional building systems for structural performance. Most important, building with mass timber takes advantage of one of the most significant benefits of wood: its ability to store, or sequester, significant amounts of atmospheric carbon. Substituting wood for energy- and carbon-intensive materials such as steel and concrete can therefore result in substantial carbon savings over time. Although wood is not necessarily the appropriate choice for all construction applications, there are clear environmental advantages to using it when possible. Contrary to popular belief, using wood does not contribute to deforestation as long it is obtained from responsible sources, making it a truly renewable building material. Each log harvested from a sustainably managed forest and processed into lumber makes room for new trees to grow, with the ability to absorb more carbon dioxide from the atmosphere. That's why well-managed forests can provide more significant climate change mitigation than unmanaged forests while also preserving wildlife habitats, increasing biodiversity, and improving water and soil quality. The widespread deforestation occurring in the tropics is rarely related to harvesting wood for construction but instead is caused by clearing land primarily for agriculture, particularly commodity crops and cattle ranching.

While many European countries have used cross-laminated timber products for almost 20 years, the U.S. has been slow to adapt. Pioneer projects here relied on European manufacturers for their panels. CLT fabrication in North America started in 2011 when Canadian companies Structurlam in British Columbia and Nordic in Quebec began operations. The U.S. trailed its northern neighbor by four years, with DR Johnson in Oregon and SmartLam in Montana starting commercial production in 2015. Since then, International Beams (now SmartLam in Alabama) and Katerra (now Mercer Mass Timber) in Washington have begun production. But in Texas, one of the fastest-growing states in the United States, concrete and steel continue to be the building materials of choice. Although dimensional lumber is used extensively for

[1] Ulrich Dangel, The University of Texas at Austin, USA, dangel@utexas.edu

https://doi.org/10.52202/069179-0587

residential and small commercial light wood framing, timber construction has played only a minor role in the state's construction industry. That is partly because trees big enough to supply large-scale commercial production do not grow in much of Texas. Regardless, architects, engineers, developers, and clients today, recognizing the environmental challenges of our times, are looking for new ways to improve the performance of the built environment. As the operational energy consumption of buildings has been vastly reduced, the need to lower their embodied energy becomes more apparent since it makes up a considerable portion of a building's life-cycle energy use. This is where mass timber and its potential for carbon sequestration comes in.

2 EARLY ADOPTERS OF MASS TIMBER

Eager to undertake aspirational building projects, enlightened clients have proven instrumental in teaming with Texas architecture firms to employ these novel technologies.

The architecture firm Lake|Flato of San Antonio has been at the forefront of bringing engineered wood products to the state. In 2018, the firm's rooftop addition to the Museum of Fine Arts in Houston — the Sarah Campbell Blaffer Foundation Center for Conservation — featured the first installation of dowel-laminated timber (DLT) panels in North America. Two more of Lake|Flato's DLT projects, the Hotel Magdalena in Austin and the 13,000-square-meter Soto Building in San Antonio, were completed in 2021.

Figure 1: *Hotel Magdalena, Austin, Texas; Architect: Lake|Flato; Engineer: StructureCraft*

The 4,500-square-meter complex of Hotel Magdalena consists of three buildings and is the first mass-timber boutique hotel constructed in North America (Figure 1). The primary structure for the hotel rooms is made of DLT panels, which are supported on light wood frame bearing walls. Exposed exterior DLT walkways connect the rooms and are supported by a glulam substructure. The interior panels are exposed at the ceiling, while the exterior panels are exposed on both sides, floor and ceiling. Other custom mass timber elements include DLT stair and elevator shafts, hanging balconies, hybrid timber-steel staircases, and a stand-alone porte-cochere [2,3]. The 13,000-square-meter Soto Building, a collaboration with BOKA Powell, consists of a glulam post and beam frame supporting dowel-laminated timber floor panels and is the first six-story, mixed-use mass timber building in Texas (Figure 2). Its well-thought-out systems integration strategy features a raised floor plenum with underfloor air distribution. The result not only maximizes flexibility for tenants but also removes the visual impact of suspended air ducts while highlighting the beauty of the exposed structural components [3,4].

Figure 2: *The Soto Building, San Antonio, Texas; Architect: Lake|Flato and BOKA Powell; Engineer: StructureCraft*

In Austin, TB/DS, a joint venture between Thoughtbarn and Delineate Studio, worked with ambitious client Endeavor Real Estate Group to reimagine a turn-of-the-century warehouse aesthetic for a contemporary five-story office building in its eclectic East Side context (Figure 3). Completed in 2019, 901 East Sixth is the first Texas project to use cross-laminated timber as part of a composite structural system. Steel beams and columns with bolted connections provide flexible, column-free spaces with an industrial feel, while mass timber floor decks add warmth and form the finished ceiling. The 12,000-square-meter, five-story hybrid structure went through a yearlong alternate materials and methods approvals process with the city, paving the way for future CLT projects [3, 5].

3 MASS TIMBER ESTABLISHES A PRESENCE

For the First United Bank branch in Fredericksburg, Gensler's Dallas office completed the state's first full mass timber structure in 2019 (Figure 4). The forward-thinking client wanted a building that not only reflected the bank's strong presence in rural communities but also aligned with their sustainability goals. The 800-square-meter building is also the first mass timber structure in the United States to use CLT panels made from Southern Yellow Pine. Using this species native to Texas, the architects delivered a net-zero energy design with a vernacular yet modern look, showcasing that any building can be a steward for the environment [3, 6].

Figure 4: *First United Bank, Fredericksburg, Texas; Architect: Gensler; Engineer: DCI Engineers*

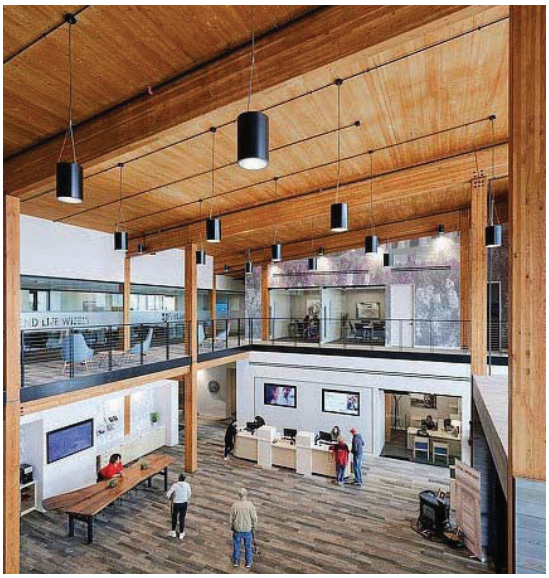

Figure 5: *First United Bank Regional Headquarters, Sherman, Texas; Architect: Gensler; Engineer: DCI Engineers*

Gensler is also behind the company's other mass timber building in Texas: the two-story First United Bank Regional Headquarters in Sherman, which opened in 2021 (Figure 5). The bank commissioned the architects to design the 3,500-square-meter building with the goal of attracting and retaining top talent, uniting its teams in one connected hub, and serving the wider community. The design creates an environment representative of the local area while placing a heavy emphasis on sustainable materials and practices using mass timber construction. In addition to using mass timber, the bank's regional headquarter meets net-zero energy objectives by having the ability to provide the entire building's power requirements with solar panels located on the roof. A collection system also harvests all rainwater runoff from the roof and condensation from the HVAC system to service the site's irrigation. The building fulfills the client's vision for a community-centric location that remains inclusive and sustainable [3, 7].

With Fifth + Tillery in Austin, Gensler recently completed an adaptive reuse project by reimagining a post-industrial site as a vibrant, wellness-focused office complex with indoor/outdoor connections (Figure 6). The repurposing of a large and dark existing warehouse was an opportunity to create a multi-tenant office space with the purpose of attracting creative businesses and talent. The client also wanted the design to minimize the environmental impact and positively contribute to the surrounding neighborhood, resulting in a high-performance building that embraces sustainable practices. Exposed wood, ample daylight, access to fresh air, and the integration of abundant landscaping were key elements of the project's biophilic design strategy. The 17,550-square-meter utilizes a hybrid steel and timber structural system to reduce embodied carbon while also introducing the natural beauty of wood into the spaces. Drilled piers support steel columns that are paired with long-span Douglas Fir glulam beams and a long-span metal deck with concrete topping. Even though this project does not specifically utilize CLT, it demonstrates the viability of using mass timber in the revitalization of existing structures in Texas [3, 8].

Figure 6*: Fifth + Tillery, Austin, Texas; Architect: Gensler; Engineer: MJ Structures*

Gensler is also collaborating with Duda|Paine Architects on the Offices at Southstone Yards, the first mass-timber office development in the Dallas-Fort Worth Metroplex (Figures 7+8). The seven-story, 22,000-square-meter building will anchor an 18-hectare visionary mixed-use development in Frisco, Texas, with the goal of creating well-located offices that accommodate the requirements

https://doi.org/10.52202/069179-0587

of future workers. The client is seeking to develop an office environment that caters to the increased expectations of employers and their teams in a post-pandemic world by delivering a dynamic experience that enriches their daily lives and is supported with virtues of wellness, flexibility, and enhanced amenities. With completion expected in the third quarter of 2023, the building is projected to become the largest mass-timber office building in the United States [9].

***Figure 7**: Offices at Southstone Yards, Frisco, Texas; Architect: Gensler and Duda|Paine; Engineer: Thornton Tomasetti and BDD*

***Figure 8**: Offices at Southstone Yards, Frisco, Texas; Architect: Gensler and Duda|Paine; Engineer: Thornton Tomasetti and BDD*

Kirksey Architecture in Houston is leading the way in the higher education sector with several mass timber university projects in East Texas. The three-story, 11,000-square-meter Anderson-Ball Classroom Building is a mass timber structure on the Central Campus of San Jacinto College (Figures 9+10). The structural system is made entirely out of mass timber, except for steel bracing used for lateral support, making it one of the first in the Greater Houston Area. Featuring a glulam post and beam frame, CLT floor plates, and CLT staircase enclosures, it was the nation's largest academic building constructed from mass timber when it opened for the 2022-23 academic year [10].

The firm is also collaborating with American/German architectural practice Barkow Leibinger on a five-story, 165-bed dormitory for Rice University (Figure 11). The 5,200-square-meter Hanszen College New Wing will replace an aging building with the goal of making on-campus living more attractive for upper-level students. The university hopes that the innovative design of the building will benefit the well-being of its inhabitants since early studies show that mass timber buildings can positively affect physical and mental health. In addition, Kirksey Architecture has recently begun working on a four-story, 338-bed dormitory on the Stephen F. Austin State University campus. The scheme is in its early planning stages and will include a new dining hall, welcome center, and an addition, as well as renovation of the school's fine arts facilities [11].

***Figure 9**: Anderson-Ball Classroom Building, San Jacinto College, Pasadena, Texas; Architect: Kirksey; Engineer: Armstrong-Douglass Partners*

***Figure 10**: Anderson-Ball Classroom Building, San Jacinto College, Pasadena, Texas; Architect: Kirksey; Engineer: Armstrong-Douglass Partners*

***Figure 11**: Hanszen College New Wing, Rice University, Houston, Texas; Architect: Kirksey; Engineer: knippershelbig*

All three higher education projects are supported by federal funding from the Mass Timber University Grant Program, a cooperative partnership established by the U.S. Department of Agriculture Forest Service and the U.S. Endowment for Forestry Communities. This

initiative aims to break barriers related to the design and construction of cost-competitive, code-compliant mass timber buildings while showcasing the architectural and commercial viability of these materials in sustainable construction. It also seeks to clearly demonstrate the direct relationship between the use of mass timber products, the health and resilience of American forests, and the potential for economic development in rural communities [12].

Hines, an international real estate developer, is collaborating with architecture firm DLR Group to bring its mass timber concept T3 (timber, transit, and technology) to Austin ((Figures 12+13). Deemed T3 Eastside, the project is poised to redefine the standard for modern, creative office space. The building will feature 8,500 square meters of Class-A office space and 850 square meters of residences, with the goal of inspiring creativity, attracting talent, promoting productivity, and honoring the unique spirit of Austin's Eastside neighborhood [13, 14].

***Figure 12**: T3 Eastside, Austin, Texas; Architect: DLR Group; Engineer: MKA*

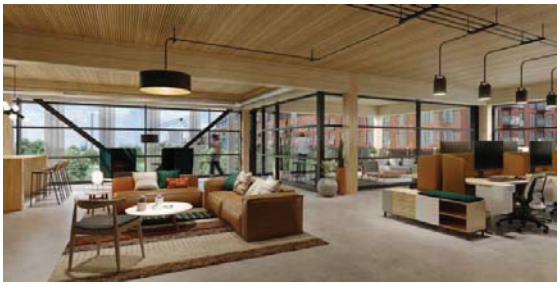

***Figure 13**: T3 Eastside, Austin, Texas; Architect: DLR Group; Engineer: MKA*

Mass timber is also replacing building materials in North American construction methods that have historically relied on concrete.

The Southfield Park 35 warehouse by architecture firm PDMS Group in Dallas uses CLT in place of the concrete tilt-wall panels of a typical industrial warehouse, with the goal of supporting the client's ambition to reduce the environmental impact of their developments (Figure 14). The decision to use CLT over traditional concrete tilt-up construction helped reduce the carbon footprint of the 15,000-square-meter building by more than 45% [3].

Architecture firm DesignTrait recently completed the mixed-use project The Duke in Austin's Webberville neighborhood (Figure 15). The 3,700-square-meter building consists of three stories of light wood framing over a ground floor podium. Instead of a commonly used concrete podium structure, the designers opted for glulam beams and columns with CLT floor slabs to create a more sustainable urban design project [3, 15].

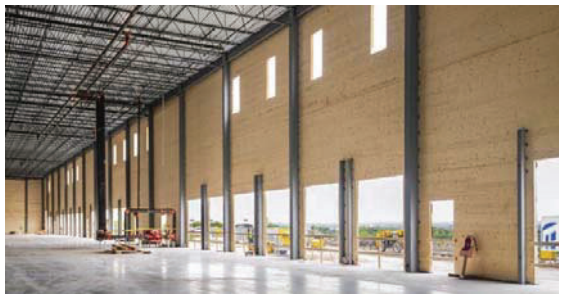

***Figure 14**: Southfield Park 35 warehouse, Dallas, Texas; Architect: PDMS Group; Engineer: Timberlab*

***Figure 15**: The Duke, Austin, Texas; Architect: DesignTrait; Engineer: WGI*

Other significant mass timber projects currently in development or under construction in Texas include the new San Antonio Spurs training facility, designed by architecture firm ZGF and Arup engineering. Twenty 40-meter-long glulam beams will support the roof structure, providing uninterrupted space for basketball training courts (Figure 16). When the 12,300-square-meter building opens in August 2023, it will be the largest practice facility made of mass timber in U.S. professional sports and the largest mass timber construction in Texas [16].

Architecture firm Bohlin Cywinski Jackson is bringing mass timber into the educational realm in Addison, Texas, with the Valdes STEM + Innovation Center for Greenhill School, an independent school serving the greater Dallas community (Figure 17). The 4,800-square-meter project will house flexible classrooms and labs for the school's math and science departments. A modular approach to

https://doi.org/10.52202/069179-0587

classroom design will ensure spaces can adapt to changing use and technologies over time while creating an open and collaborative environment that empowers students to incorporate STEM learning in all facets of their education. The building will provide opportunities for students to learn about integrated sustainable design through its exposed mass timber structure, daylight autonomy, rainwater harvesting, and visible energy conservation strategies, allowing them to draw connections between their work and the physical environment [17].

***Figure 16**: San Antonio Spurs Training Facility, San Antonio, Texas; Architect: ZGF; Engineer: Arup*

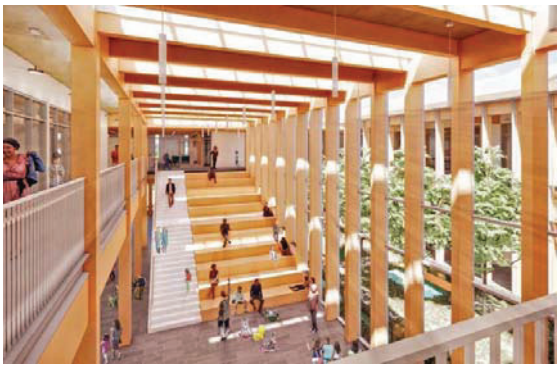

***Figure 17**: Valdes STEM + Innovation Center, Addison, Texas; Architect: Bohlin Cywinski Jackson; Engineer: DBR*

4 REGIONAL PRODUCTION

Many mass timber buildings in Texas have been completed with cross-laminated timber from European suppliers. Despite the disadvantage of long transportation distances and panel sizes limited by the dimensions of international shipping containers, these products have been very cost-competitive, thanks to the manufacturers' high production volumes and significant market shares.

North America's most established CLT production facilities are concentrated in Canada and the northern U.S., which can still present procurement challenges to early adopter projects in more distant states, including Texas. For example, there are no CLT production lines yet in Texas that manufacture for building applications, but several suppliers are in nearby states. SmartLam's Dothan, Alabama, plant, operating since 2018, is the first to offer certified CLT products made of Southern Yellow Pine. Located in Magnolia, Arkansas, Texas CLT gets its raw materials within a 160-kilometer (100-mile) radius of its facility. In addition, the company has plans to set up a second plant in Jasper in East Texas.

Canadian company Structurlam has expanded its operations to Conway, Arkansas, for its first U.S. CLT and glulam plant, which opened in 2021. About 40% of the facility's entire manufacturing output will be solely for Walmart for the first three years. The world's largest retailer has pledged to build its home office campus in Bentonville out of mass timber, and Structurlam will serve as its exclusive supplier.

Illinois-based Sterling has been manufacturing CLT mats for temporary access roads and working platforms in Lufkin, East Texas, since 2019. In 2022, the company received a Wood Innovation Grant from the U.S. Department of Agriculture to accelerate mass timber adoption with standard-format CLT panels. Its cross-laminated timber product line recently received PRG 320 certification, which is required in North America for CLT panels used in structural building applications. With its 700,000-cubic-meter annual production capacity, Sterling is poised to contribute to the mass timber construction market in Texas significantly.

Anyone interested in building with wood in Texas will surely welcome a ramp-up of production capacities. Broader availability of mass timber products throughout the Southern states will facilitate material procurement, reduce transportation costs, and foster healthy competition between manufacturers. Moreover, as the number of built projects made possible through regional production grows, the increased visibility is likely to lead to broader acceptance of timber buildings by the public and rising demand for their construction by future clients.

BUILDING TALLER IN WOOD

Most mass timber buildings completed in Texas have been permitted as Type III and Type IV construction under current applicable building codes. For these construction types, the 2018 International Building Code, or IBC, allows building heights of up to 26 meters (85 feet) with a maximum of five stories for residential and six stories for office occupancy.

While both types are similar in allowable height and the number of stories, there are some notable differences. Unlike Type IV, Type III requires char rate calculations for member sizes to determine residual cross sections for load capacity calculations, which can lead to oversizing of structural members to achieve the necessary fire rating. Exposed steel connections also are not permitted under Type III and require protection. Just these two examples highlight the potential impact of code limitations on architectural expression.

Therefore, it is advisable to engage the local Authority Having Jurisdiction early in the design process since it can serve as a valuable partner in selecting the most appropriate construction type. Mass timber structures taller than 26 meters (85 feet) and exceeding six stories are currently only possible in many parts of Texas if they undergo an Alternative Materials and Methods Request, a provision in the IBC. This gives local building officials the flexibility to address new concepts, innovations, and developments that the current code may not formally recognize yet. Depending on the extent of the request, this can be a lengthy, costly process that might require structural tests as well as fire resistance testing.

In response to the growing interest in tall timber construction, the International Code Council approved a set of proposals in 2019 to allow tall wood buildings as part of the regular code changes cycle. Based on the previous Heavy Timber construction type, which has been renamed Type IV-HT, the 2021 International Building Code (IBC) now includes three new construction types: Types IV-A, IV-B, and IV-C, arranged from the highest fire resistance and safety requirements to the lowest.

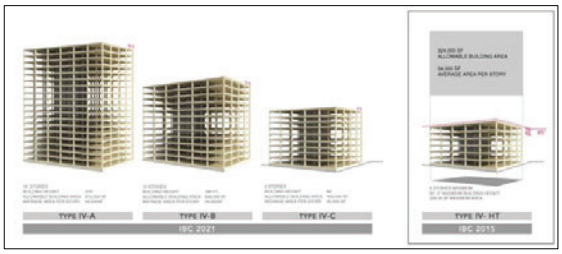

***Figure XX**: IBC new construction types: IV-A, IV-B, and IV-C; courtesy of atelierjones*

For business occupancy, Type IV-A allows buildings with 18 stories up to 82 meters (270 feet) tall with no exposed mass timber components. Type IV-B allows 12 stories up to 55 meters (180 feet) with some exposed mass timber elements, and Type IV-C allows nine stories up to 26 meters (85 feet) with almost all interior mass timber exposed.

Several jurisdictions in Texas have already adopted the tall mass timber provisions of the 2021 IBC, either in their entirety or with local amendments. This includes the cities of Allen, Austin, Bryan, Carrollton, Plano, Grand Prairie, and Fort Worth. In addition, the City of Dallas has incorporated some tall mass timber allowances of the 2021 IBC and the upcoming 2024 IBC [18, 19].

5 CONCLUSIONS

As one of the fastest-growing states in the nation, Texas will continue to experience a substantial increase in its population. Most of this growth will be concentrated in urban areas, and the increasing density of its cities will play a critical role in reducing the state's impact on climate change. Sustainable urban development will need to focus on affordable, healthy living and working environments while reducing carbon emissions.

Building with responsibly sourced timber can decrease the state's reliance on fossil fuels and turn its buildings and cities into carbon sinks rather than sources of CO_2 emissions. With wood deemed unsuitable for dense urban environments for so long, the recent development of engineered wood products and amendments to building codes have allowed its return to the city.

Innovative strategies for structural design and fire protection have enabled the construction of multi-story buildings that satisfy the most stringent standards, offering opportunities for the emergence of a new type of urban architecture. Increasing demand for timber buildings in cities will not only ensure that forests remain sustainably managed but also drive economic development in Texas' rural areas through new jobs from the manufacturing of wood products. Building with mass timber has the potential to positively impact the state's environment, local economies, and building culture.

ACKNOWLEDGEMENT

The author would like to thank Mark Bartlett, regional director of WoodWorks, for providing the latest information on current mass timber developments in Texas.

World Conference on Timber Engineering Oslo 2023

ACCELERATION OF UNITED STATES MARKETS FOR WOOD

Bill Parsons[1], Brian Brashaw[2]

ABSTRACT: While the United States (U.S.) market for wood products is well-established for single-family housing, there has also been a consistent and sustained effort over the past decade to significantly increase wood's share of the multi-family, commercial, and institutional segments. This paper examines the current state of wood construction in these markets, emerging trends post-COVID, opportunities, and obstacles to continued growth. It will utilize data and built projects to highlight key areas of momentum and provide examples where resources have had a direct market impact.

KEYWORDS: Wood-frame construction, Podium construction, Mass timber, Tall wood, Markets

1. INTRODUCTION

Over the last fifteen years, there has been growing interest in the use of wood in structures beyond single-family homes. This has coincided with a sustained effort to communicate wood's value for a wider range of building types, and to educate and assist design teams who have typically defaulted to other materials. WoodWorks – Wood Products Council plays a leadership role in partnership with the USDA Forest Service, Softwood Lumber Board, and others, on behalf of the North American wood industry.

In particular, larger structures and the use of innovative new systems pose challenges for building designers and construction professionals who seek to expand their use of wood. Modern projects also continually push the boundaries of wood engineering. In addition to encouraging the *desire* to use wood, the U.S. industry, through WoodWorks, provides expertise and resources that lead to quality wood buildings. Embodied carbon entering the conversation has further expanded the need for credible information around Whole Building Life Cycle Assessments (WBLCA).

2. DEFINING THE OPPORTUNITY

Although the COVID-19 pandemic has depressed construction markets in 2020 [1], there continue to be opportunities for increased wood use. As supply chain disruptions continue, cost will become an even greater concern. The most economically viable projects will come to fruition, and wood will be well-positioned as a low-cost/high-performance structural solution.

There is no shortage of economic predictions related to the future of construction markets. WoodWorks has been assessing data from a number of sources but is also in the unique position of working directly with developers and design/construction teams to assist on projects, which provides an additional layer of insight. Dodge Data & Analytics has provided some of the best information in terms that are helpful to the WoodWorks program. Dodge is projecting total construction starts will be flat in 2023.

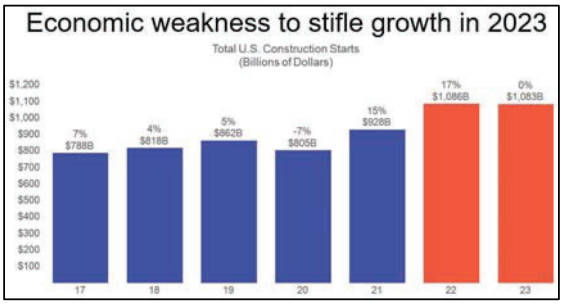

***Figure 1**: U.S. construction starts. Source: Dodge Data & Analytics*

In 2021, almost a billion square feet of new construction are accessible to wood each year in the U.S. About half of that area (over 17,000 structures) could be wood by code but are not utilizing wood today. Wood currently has a significant opportunity for increased market share.

***Figure 2**: US Markets for Wood Buildings (Source: Dodge Data & Analytics 2020, WoodWorks analysis)*

https://doi.org/10.52202/069179-0588

3. MULTI-FAMILY

Since the last Great Recession (2007-2009), the multi-family market has grown significantly as a percentage of all homes constructed. The trend toward greater densification and urbanization in all major metropolitan areas has led both to an increase in multi-family projects and more design variation. Buildings with five or more stories of wood-frame construction are becoming more common, as are podium structures, which further increase the value of buildings that are primarily wood-frame. There are now nearly 600 five-, six-, or seven-story wood-frame buildings constructed in the U.S. each year [2].

While the trend is positive, many designers are still unaware that wood can be used in buildings greater than four stories or that podiums can be more than one level. This underscores the need for continued education and outreach to help people understand where wood is allowed by code, and to assist designers with the more demanding requirements of larger wood projects.

Under most U.S. codes, a multi-family wood building can be up to five stories (Type III construction), and the wood structure can then be placed on top of a podium (typically concrete). So far, most podiums are a single story, but multi-level podiums were included in the 2018 International Building Code (IBC) and are growing in use. Overall, the total multi-family market is 687 million square feet built annually, or a total of 23,400 projects.

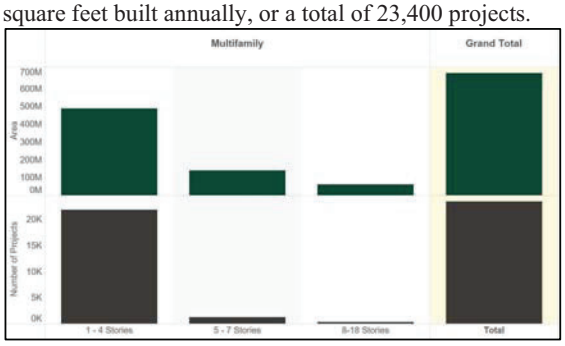

***Figure 2**: Total multi-family market in the U.S.; 687 million square feet annually, or 23,400 projects. Source: Dodge Data & Analytics 2021*

There are many examples of podium structures built throughout the U.S. Two are featured in case studies on the WoodWorks website, Crescent Terminus in Atlanta, GA and Stella in Marina del Rey, CA. The latest case study on a podium multifamily structure is Thomas Logan Apartments.

***Figure 3**: Thomas Logan case study Source: WoodWorks*

4. COMMERCIAL/INSTITUTIONAL

Initial gains in commercial and institutional market segments involved buildings that were similar in design to multi-family projects—e.g., hotels, motels and student housing. However, the performance capabilities of mass timber, and growing interest in products such as cross-laminated timber (CLT) as a carbon-friendly alternative to steel and concrete, have led to a much more diverse range. Mass timber has also become a significant draw for developers who want to attract quality, long-term tenants, and design teams eager to explore its creative potential.

WoodWorks tracks active mass timber projects and publishes an updated map each quarter [3]. (See Figure 4.)

https://doi.org/10.52202/069179-0588

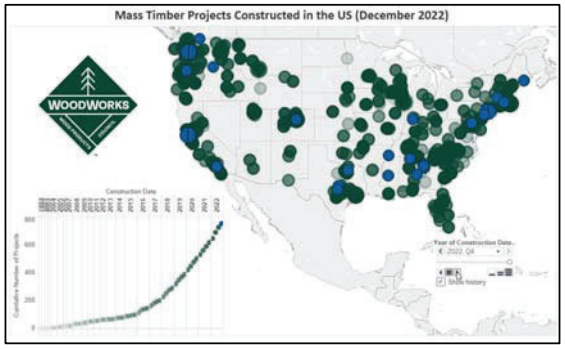

Figure 4: *Map of U.S. mass timber projects. Source: WoodWorks – Wood Products Council*

As of December 2022, 767 multi-family, commercial or institutional projects had been constructed out of mass timber in the U.S., and 910 were in design. (This includes mass timber and post-and-beam structures built since 2013.) The acceleration of mass timber is easily seen in Figure 4 — this growth is out pacing the growth seen with other wood systems.

WoodWorks is a leading provider of mass timber education, and assisted on more than 75% of the built projects noted in Figure 4. However, staff identified a significant barrier to continued growth. General contractors who had yet to build a mass timber project were adding risk premiums that priced wood out of the running, and projects were being converted to other materials. Recently, WoodWorks launched a program to address the issue through mass timber construction management and installation training.

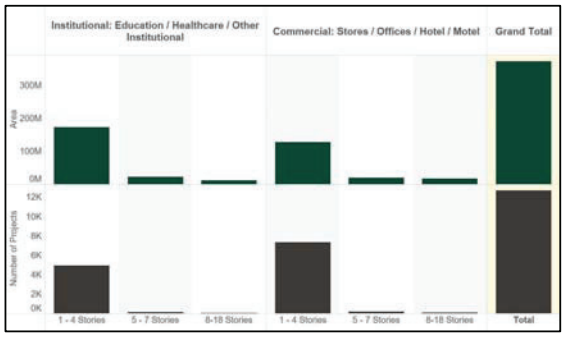

Figure 5: *Commercial and institutional market in the U.S. Source: Dodge Data & Analytics 2021*

The majority of commercial and institutional projects built in the U.S. are one to four stories. (See Figure 5.) In both of these categories, wood is only lightly penetrated and there are literally thousands of projects where wood can be used as the structural frame. Mass timber is gaining particular traction in these segments.

This is where the U.S. market narrative starts to diverge from other countries that have seen a trend toward the use of mass timber. After only a few years of product availability, the U.S. has 143 substantial multi-story mass timber business occupancy buildings (primarily offices) under construction or built. (See Figure 6.) These structures represent about 12.5 million square feet of cumulative construction. As far as WoodWorks is aware, this level of commercial building activity has not been seen in other countries—especially this early in the adoption phase. With 84 million square feet of annual construction opportunity in offices alone, the U.S. market has a great deal of room to expand this emerging technology.

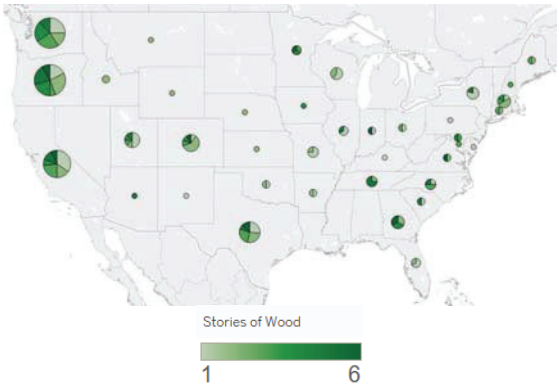

Figure 6: *Mass timber projects with business occupancies built or under construction (200 as of December 2022). Source: WoodWorks – Wood Products Council*

Exposed wood structure in office buildings is becoming a point of market distinction, both for the aesthetic and connection to nature. Post-COVID developers continue to look for ways to differentiate their products.

The WoodWorks case study, *Breaking Convention with Wood Offices*, outlines the benefits of wood for business occupancies and highlights examples of built projects. This resource has been very helpful in demonstrating the viability of wood in this segment. (See Figure 7.)

https://doi.org/10.52202/069179-0588

Figure 7: *Case study featuring multiple mass timber office buildings. Source: WoodWorks – Wood Products Council*

The educational and student housing segments have also shown an early uptick in the use of mass timber, with 31 projects under construction or built. (See Figure 8.) However, the financial impacts of COVID-19 may slow the growth in these markets, especially for university-owned buildings.

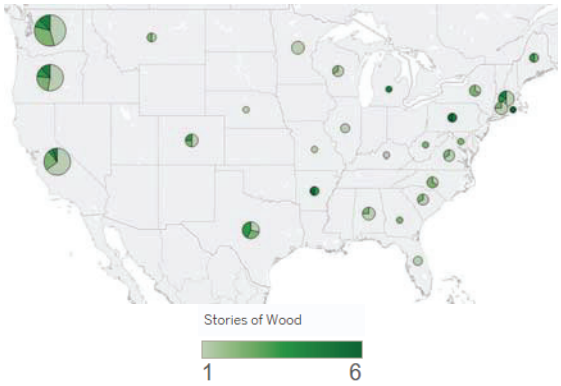

Figure 8: *Mass timber projects with education and student housing occupancies built or under construction (123 as of December 2022). Source: WoodWorks – Wood Products Council*

The 123 buildings noted above represent 5.4 million square feet of construction, which is very small in the context of over 106 million square feet built annually in this segment. In addition to aesthetics and connection to nature, drivers for these projects have included wood's sustainability and light carbon footprint.

A groundbreaking example in this category is the John W. Olver Design Building at the University of Massachusetts – Amherst. This project is featured in the WoodWorks case study, *Inspiration through Innovation*. (See Figure 9.) This includes a WBLCA analysis – which is a very hot emerging topic. We are active on several other case studies.

Figure 9: *Case study featuring the John W. Olver Design Building at the University of Massachusetts – Amherst. Source: WoodWorks – Wood Products Council.*

5. TALL WOOD (7+ STORIES)

Innovative wood products and building technologies are taking wood beyond new building types and opening markets that have been entirely out of reach for wood solutions. Changes approved for the 2021 IBC will allow wood buildings up to 18 stories, which creates the 90 million square feet of opportunity noted in Figure 2.

Figure 10 captures the opportunity by building height; Type IV-A has a maximum of 18 stories, Type IV-B has a maximum of 12, and Type IV-C has a maximum of nine. WoodWorks is currently assisting on nearly 200 projects over seven stories.

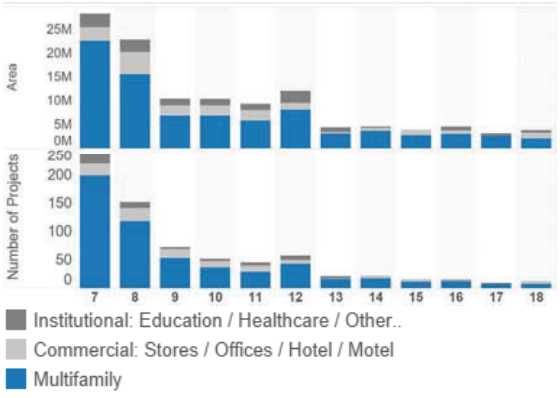

Figure 10: *Opportunity for tall wood (Source: Dodge Data & Analytics 2020, WoodWorks analysis)*

Many jurisdictions are adopting the 2021 IBC, which became the model code on January 1, 2021. At the end of

https://doi.org/10.52202/069179-0588

2022 there were nine tall projects built or under construction in the U.S.:

- Carbon12 – Portland, OR – Eight stories of mass timber.
- INTRO – Cleveland, OH – Eight stories of mass timber over a concrete podium.
- Ascent – Milwaukee, WI – Nineteen stories of mass timber over six stories of concrete.
- 80M – Washington, DC – Two new mass timber floors + habitable penthouse over an existing seven-story structure.
- Apex Clean Energy – Charlottesville, VA – Six stories of mass timber over two stories of concrete.
- 11 E Lenox – Boston, MA – Seven stories ofmass timber.
- Heartwood – Seattle, WA – Eight stories of mass timber
- 1510 Webster – Oakland, CA – 18 stories of mass timber over a concrete podium
- Minnesota Places – Portland, OR – Seven stories of mass timber over a concrete podium

Ascent is currently be the tallest mass timber building in the world.

Over 700 projects with seven or more stories are built in the U.S. each year. Early interest indicates that mass timber is poised for significant advancement in this market segment.

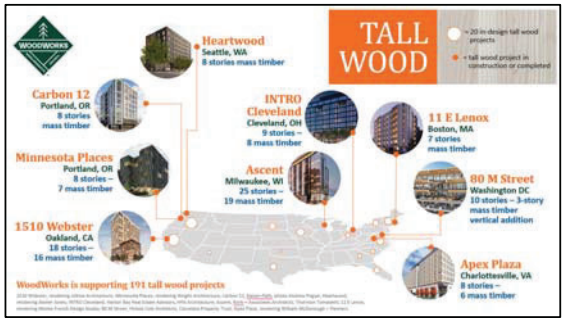

Figure 11: *Tall Wood Projects built or under construction at the end of 2022. Nearly 200 are in-design throughout the U.S. Source: WoodWorks – Wood Products Council*

WoodWorks has a number of resources and dedicated staff to assist with tall wood projects. (See Figure 12.) A common landing page for these topics can be found at: https://www.woodworks.org/learn/mass-timber-clt/tall-mass-timber.

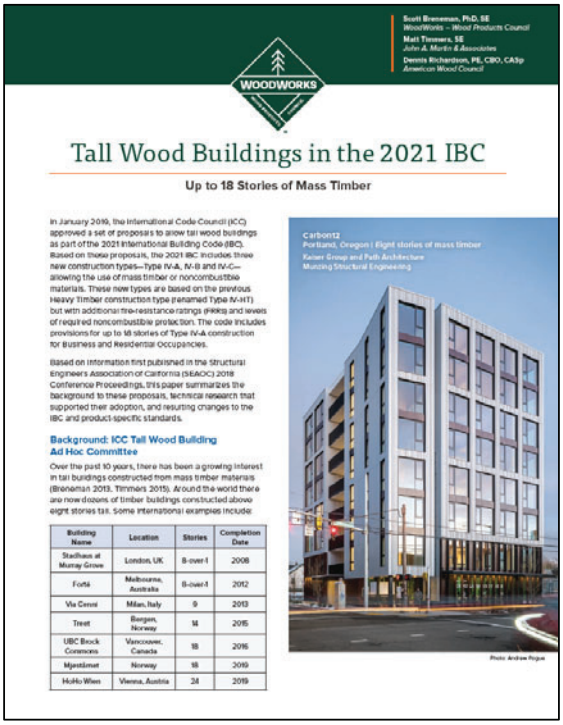

Figure 12: *One of many resources published by WoodWorks to assist with the design of tall wood buildings. Source: WoodWorks – Wood Products Council*

6. CONCLUSION

Historically, the U.S. single-family housing market has represented one of the most robust markets for wood in the world. With design teams turning to larger wood-frame and mass timber buildings, supported by the strategic combination of education and project assistance, the U.S. is poised to develop equally robust markets for these products in the multi-family, commercial and institutional sectors

World Conference on Timber Engineering Oslo 2023

RECENT ADVANCEMENTS IN MASS TIMBER CONSTRUCTION TECHNOLOGIES IN CANADA

Mohammad Mohammad[1], Julie Tourrilhes[2], Richard Coxford[3], Miranda Williamson[4]

ABSTRACT: Interest in mass timber is growing among designers, builders, developers and other stakeholders worldwide due to its environmental benefits as a low-carbon and sustainable building material. In Canada, several recent initiatives by industry and governments to expand the use of wood in construction have led to an increased number of mass timber buildings across the country and enhanced existing manufacturing capability. Supported by progressive building codes, a growing supply chain, and a rising number of designers and builders with mass timber expertise, mass timber construction is poised to continue to take off in Canada. To support this momentum, the Government of Canada launched the Green Construction through Wood (GCWood) program to expedite market acceptance and foster commercial uptake of mass timber products and systems in Canada.

This paper provides an overview of the GCWood program activities, showcasing the design and construction of several demonstration projects and the ongoing efforts to implement a national wood education roadmap. This is in addition to funding critical technical research to support the adoption of tall wood buildings in the Canadian building code and transitioning the code to become more performance based.

KEYWORDS: Tall wood buildings, demonstration projects, mass timber, building codes, advanced wood education

1 INTRODUCTION

The emergence of mass timber, and the use of engineered wood products in construction as a green building material, continues to gain traction in Canada and abroad. The Government of Canada recognized that in order to decarbonize the built environment and increase the acceptance of wood products and systems domestically, it is critical to showcase the use of wood in non-traditional applications. This led to several initiatives and programs being launched over the last 12 years. Funding demonstration projects, advancing wood education and training, and revising building codes to allow taller and larger wood buildings in Canada are the cornerstones of such initiatives.

2 DEMONSTRATION PROJECTS

In 2013, the Government of Canada launched the Tall Wood Building Demonstration Initiative (TWBDI), which supported the construction of two tall wood buildings in Canada (Figure 1). The first is an 18-storey hybrid mass timber student residence (Brock Commons - Tallwood House) located in Vancouver, which was the world's tallest hybrid wood building at the time of its completion. The second is a 13-storey residential building in Québec City (Origine). NRCan funded the critical incremental R&D activities required to design, approve, and construct the two demonstration buildings. This included fire, structural, and acoustics testing [1]. The success of the TWBDI led to new initiatives by the Government of Canada that further encouraged the design and construction of timber structures in non-traditional construction applications.

Figure 1: *Brock Commons on the left, and Origine on the right (Courtesy of Stéphane Groleau)*

[1]Mohammad Mohammad, NRCan, Canada, mohammad.mohammad@nrcan-rncan.gc.ca

https://doi.org/10.52202/069179-0589

The Green Construction through Wood (GCWood) program was launched in October 2017 with the objective of increasing the use of mass timber as a green construction material in infrastructure projects. This included not just high-rise applications, but also low-rise non-residential and bridge construction. The Canadian federal government's budget in 2017 provided funding of $55 million over 5 years for GCWood under the *Pan-Canadian Framework on Clean Growth and Climate Change* to support the various GCWood program activities. GCWood program has three key components:

1) Mass timber and hybrid demonstration projects (e.g., high-rise, low-rise non-residential and bridges)
2) Building code revisions and supporting research (i.e., targeting 12-storey tall wood buildings by 2020 and performance-based in 2025 and 2030)
3) Technology transfer and advanced wood education (i.e., training courses, design and costing tools for architects, engineers and builders, and Life Cycle Assessment data and tools)

To expedite market acceptance of mass timber products and systems in Canada, three calls for proposals (CfP) were launched for innovative wood-based buildings and bridges between 2017 and 2018. To support the construction of these proposed projects, the GCWood program funded up to 100% of eligible incremental project costs associated with the design, approval, construction, and post construction activities of the selected demonstration projects.

Sixteen high-rise, low-rise non-residential wood buildings and timber bridges across Canada were funded under the GCWood program. These projects were selected based on specific criteria focused on design innovation, the expertise of the design and project team, replicability of the proposed wood-based systems, and the strength of the project business case, among a number of other criteria. All selected demonstration projects showcased advanced use of engineered wood-based products and systems in their design and construction. Several of the buildings are now completed, currently under construction, or at an advanced stage of design and approval across Canada.

2.1 TALL WOOD BUILDINGS

The first CfP was for tall wood buildings (minimum of 10 storeys) which targeted innovative use of advanced wood products and systems in high-rise applications. The choice for the number of storeys was based on a close consultation with the industry and based on market intelligence data. With the help of an expert evaluation panel, a handful of highly innovative projects that showcase advanced wood-based technologies in their design and construction were shortlisted for funding. The following are some examples of several tall wood buildings funded by the GCWood program.

2.1.1. George Brown College's Limberlost Place

One of these shortlisted projects was "Limberlost Place" (formally The Arbour), a 10-storey innovative tall wood building located at George Brown College's waterfront campus in downtown Toronto, Ontario (Figure 2). This academic building will serve as a learning space and a living laboratory for students. It will likewise house a mass timber research and testing facility to study renewable energy systems, fire performance, and durability.

The relatively thin structural system requires no use of conventional drop beams, which reduces the building height, volume, and material costs. The lateral load resisting system is composed of concentric steel braced frame core, which is being erected in tandem with the mass timber superstructure. The structural systems employ an innovative 7-ply timber-concrete-composite "slab band" to achieve the 9.2 m span (Figure 3). Extensive structural testing of the composite floor system was conducted at the University of Northeren British Coumbia (UNBC) to support the design. Huge glulam columns of 1,725 x 630 mm spanning three storeys tall will be used to support the gravity loads. Renewable energy systems, such as rooftop photovoltaic arrays, heat pumps, and rainwater recycling mechanisms are incorporated in the building design. The building is currently under construction and is scheduled for completion by the end of 2024. It will be Ontario's first tall wood, low-carbon institutional building with assembly occupancy.

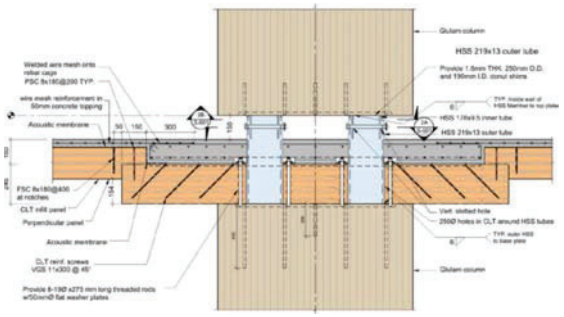

Figure 3: *Composite CLT/concrete slab and glulam floor system and connection (Courtesy of Fast+Epp)*

2.1.2. 2150 Keith Drive Tall Wood Building

Another shortlisted tall wood building was the 2150 Keith Drive project (Figure 4), a 10-storey mass timber tall wood building in Vancouver, British Columbia. This mass timber office building will be home to multiple office tenants from the technical and creative sectors. The design involves fully exposed mass timber elements, relying on charring to achieve a 2-hour fire-resistance rating.

The innovative design uses massive braced timber frame on the exterior as the main lateral load resisting system, complete with state of the art seismic dampers to improve the building's seismic resiliency. It likewise eliminates the need for a stiff interior concrete core by using four CLT shear walls in the interior which provide a design flexibility.

Figure 4: *2150 Keith Drive Office Building (Courtesy of DIALOG)*

2.1.3. University of Toronto's Academic Tower

Another project the GCWood program is providing funding to is the University of Toronto's Academic Tower (Figure 5). This 14-storey tower will be the tallest mass timber building in Ontario once completed, and will serve as an academic and research facility, as well as a living laboratory for the university.

The project is at the advanced design and approval stage with construction planned to begin in 2023. The top 10 storeys of this hybrid building will be made of glulam and engineered mass timber panels, with the four bottom storeys constructed of both timber and steel. One-way GLT slabs will be used for the deck to offer ample floor space, and to meet the required two-hour fire-resistance rating. The structural design uses wood super bracing as the lateral force resisting system against wind and seismic loads. Innovative connections engineered for off-site assembly will facilitate faster construction. The design involves partially exposed mass timber structural elements. Extensive engineering analysis and modelling including wind engineering studies has been conducted to support the design and approval of the building.

Figure 5: *Academic Tower (Courtesy of the University of Toronto)*

2.2 LOW-RISE NON-RESIDENTIAL BUILDINGS

The GCWood's second CfP targeted low-rise non-residential buildings including commercial, industrial, office, and institutional buildings of 4 storeys or less which demonstrate the innovative use of wood products or systems that could be easily replicated. Thirty applications were received and ten projects were short-listed for funding.

2.2.1. Toronto and Region Conservation Authority's (TRCA) New Administrative Office Building

One of the successful projects was Toronto and Region Conservation Authority's (TRCA) new Administrative Office Building. This is a 4-storey mass timber office building located in Toronto, Ontario and is part of the Canada Green Building Council's *Zero Carbon Building Pilot Program* (Figure 6*)*. The building is designed to achieve a low-carbon footprint through all lifecycle phases, with model simulations predicting a 50% reduction in operating emissions and over 75% reduction in embodied carbon compared to the average office building in Toronto. The mass timber structure is complete, and the remaining building construction will be completed by the end of 2023.

The structural system is composed of CLT mass timber floor panels supported on glulam beams and columns and uses a structural grid of approximately 6 m x 6 m. Metal steel strapping is installed on the top surface of the CLT floor/diaphragm where drag forces are concentrated to transfer the forces from the diaphragm to the shear walls. The lateral force resisting system for the office building utilizes a combination of stair and elevator cores

constructed of CLT wit lateral glulam bracing. There is no structural concrete utilized above the main floor concrete slab. The LCA study that was originally submitted was completed before the open loop modelling, so the results reflect operating emissions based on the closed loop system. It is expected the open loop system to improve energy efficiency by an additional 10-15%, which will lower operating emissions accordingly. The final updated model will be completed in 2023 with an updated LCA report.

Figure 6: *Toronto and Region Conservation Authority Administrative Office (Courtesy of TRCA)*

2.2.2. KF Aerospace Centre for Excellence

KF Aerospace Centre for Excellence is a highly visible commercial 2-storey project that serves as a working and display hangars, a centre of expertise, an aviation history museum, and community gathering place at the Kelowna International Airport in British Columbia (Figure 7).

The project uses long span roofs, floors and tall walls, which is a unique application of wood for this type of building application. The primary and secondary structural elements are glulam beams and glulam and DLT trusses. Pre-fabrication of large integrated components helped minimize on-site erection time. Building assemblies for the projects' central hub and two working hangars incorporate long span roofs, floors, and tall walls components and assemblies. The project was completed in the summer of 2022, and the building is now occupied.

Figure 7: *Centre for Excellence (Courtesy of KF Aerospace Centre for Excellence)*

2.2.3. Yukon Street Office Building

The Yukon Street Office Building is a 4-storey hybrid mass timber and steel commercial office building built tightly on the property line as an infill project and serves as a living laboratory to gather data to evaluate the performance of the hybrid mass timber design (Figure 8).

The project used prefabricated mass timber components, offering strength and structural simplicity, while helping decrease construction time. The system allows for long spans without interior columns. Composite panels accommodate the large spans, providing exposed soffits, and hide required services for the building. The CLT shear walls, as well as elevator and stair core, are specially designed to resist earthquake forces using an advanced seismic resistance hold-down system from New Zealand (Tectonus). CLT walls were prefabricated with the exterior envelope and cladding to minimize access and construction along the tight property line. A 2-hour structural fire-resistance rating for the exterior wall is achieved through the application of non-combustible insulation.

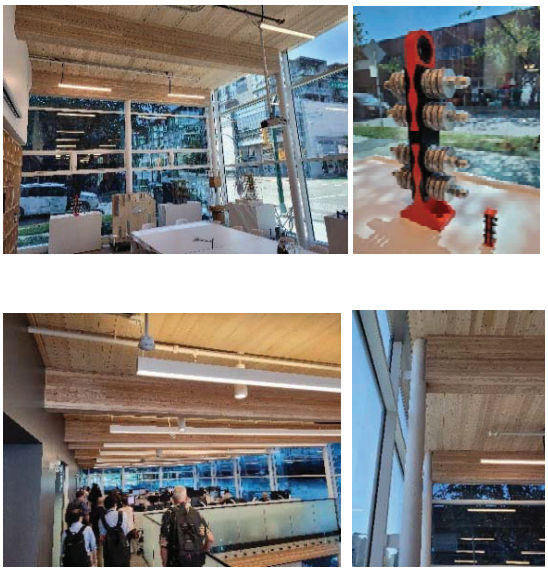

Figure 8: *Yukon Street Office Building with the Tectonus seismic hold-down system*

2.2.4. Bayview Elementary School

Bayview Elementary School is a 2-storey school in a high visibility location (Figure 9). It is one of the first schools to act on British Columbia's school seismic retrofit program. The design presents a large clear span roof using CLT panels and glulam webs, creating a "double T" design. The CLT shearwalls are installed throughout the building with multi-storey continuous shearwalls at the exterior to provide more efficient connections. There is CLT gravity walls at the upper level comprised of hybrid steel-CLT beams located at the second floor cantilevers over the ground level.

https://doi.org/10.52202/069179-0589

Figure 9: *Bayview Elementary School (Courtesy of Bayview Elementary School)*

2.2.5. wəkʷaʔnəs tə syaqʷəm Elementary School

The wəkʷaʔnəs tə syaqʷəm Elementary School, which in English means "the sun rising over the horizon", is completed and has a very similar design to the Bayview school described above, and aims to achieve the same environmental targets such as LEED Gold certified (Figure 10). Extensive structural testing on the hybrid floor system and shear walls took place at the University of Northern British Columbia (UNBC) to support the balloon type shearwalls design used in this project (Figure 11).

Figure 10: *wəkʷaʔnəs tə syaqʷəm Elementary School*

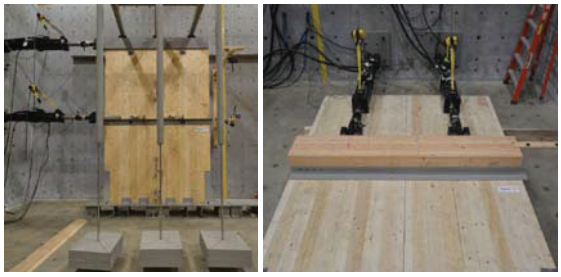

Figure 11: *Balloon Shearwall test setup (Courtesy of UNBC Wood Innovation Research Laboratory)*

2.2.6. Canadian Nuclear Laboratories

A series of three mass timber buildings and one with partial mass timber is being constructed as part of a first of its kind project in Canada at the Canadian Nuclear Laboratories (CNL) in Chalk River, Ontario. The site is owned by Atomic Energy of Canada Limited (AECL), a Canadian Crown corporation, and operated by CNL. The mass timber buildings showcase the use of advanced design and construction technologies, both structurally and aesthetically, at a nuclear science and technology campus. The mass timber buildings include a site entrance building, support and maintenance facility, administrative building (Science Collaboration Centre), and a large nuclear research facility, the Advanced Nuclear Materials Research Centre (ANMRC). NRCan provided funding through the GCWood Program for the Support and Maintenance Facility, the Science Collaboration Centre and the ANMRC. All four of these buildings are being constructed to revitalize the campus, thanks to a $1.2 billion investment by AECL.

The Science Collaboration Centre is a hybrid building that will serve as a collaboration complex to house a new data centre with S&T computing capabilities, a university-style auditorium, a welcoming library space, a roof-top terrace, and office space and meeting rooms for approximately 450 employees (Figure 12). The design incorporates CLT slabs with glulam columns, beams, and purlins as the main gravity structural system. The structure consists of a reinforced concrete lower level, elevator, and stair core. Mechanical, electrical, fibre optics, and life safety distribution system are all concealed within mass timber elements. The lateral bracing system against earthquakes and wind is a hybrid system of concrete shear walls and timber braced frames, with CLT slabs acting as diaphragms to transfer lateral loads to shear walls. The building is currently under construction.

Figure 12: *Science Collaboration Centre (Courtesy of CNL)*

The Support and Maintenance Facility is a 2-storey industrial use building which is home to various trades, transportation, and roads and grounds crews (Figure 13). The design includes a CLT elevator shaft, floors, and roof panels, which also act as diaphragms that are supported by glulam timber purlins, beams, and columns as the main structural system. The CLT mezzanine floors are suspended and supported by glulam beams. Glulam cross bracing is also provided to resist lateral loading. The construction of this building is complete.

Figure 13: *CNL's Support and Maintenance Facility mass timber project (Courtesy of CNL)*

The Advanced Nuclear Materials Research Centre (ANMRC) is a hybrid wood/concrete design, which includes a two-storey mass timber office wing, a two-storey laboratory wing, and a two-storey concrete hot cells wing (Figure 14). The prefabricated CLT and glulam components will include columns, posts and beams, floor panels, diaphragm, bracing, and exterior walls. The building will have exposed soffits, eliminating the need for an alternative ceiling system. CNL will be taking a modular prefabricated approach for the construction of both the laboratory wing and the office wing. The building is at advanced stage of design. The building is at advanced stage of design/development.

An Integrated Project Delivery approach was broadly adopted in the design and construction of all of mass timber projects at CNL. The process brings together the manufacturers of the mass timber products, the full design team, trades, and the construction manager to work collaboratively to optimize the design, increase value to the owner, and maximize efficiency through all phases of design, fabrication, and construction.

Figure 14: *Advanced Nuclear Material Research Centre (Courtesy of CNL)*

2.2.7. oN5 Office Building

oN5, a new 4-storey office building in downtown Vancouver was completed in 2022 and is being occupied by several engineering and architectural firms (Figure 15). The building uses CLT panels to demonstrate the potential for commercial mass timber. The structure utilizes a highly innovative self centering Lateral Force Resistance System (Tectonus) for resisting seismic loads. Prefabricated CLT panels were used in the design, from shearwalls to roof, and were produced by BC Passive House. The design aims to produce a replicable infill mass timber design for the construction industry. Exposed CLT panels offer great fire resistance and act as vertical supports, eliminating glulam or steel column requirements. Constructed at the property line, creative techniques were used to address the tight lot lines. The lightweight mass timber building elements were prefabricated and lifted into place quickly and efficiently (40-50% faster than typical construction).

Figure 15: *oN5 4-storey office building*

2.3 TIMBER BRIDGES

Industry and provincial and federal governments in Canada initiated several market and research efforts over the last 10 years to promote the use of timber in bridge applications. As a result, several modern innovative timber bridges have been built recently. The majority have been constructed in the provinces of Quebec, Ontario, and British Columbia. The Mistissini Bridge, built in 2014 and located at Uupaachikus Pass in Mistissini, Québec, is 160 m long and features four spans of straight girders supported by semi-continuous glulam arches (Figure 16). This is one of the longest modern timber bridges in Canada and was one of the first bridges to use CLT in the country.

The GCWood call for proposal for bridges (launched in the spring of 2018) builds on the success of previous efforts and projects, and ensures continued market momentum for timber bridges. The CfP received 13 applications for both vehicle traffic and pedestrian bridges that had a minimum clear span of 20 m. With the guidance of an expert evaluation panel, NRCan shortlisted several mass timber and wood-hybrid bridge demonstration projects for funding. Almost all selected demonstration bridges belong to provinces or municipalities, with many being a proposed replacement of an existing bridge. These bridges had been either closed to traffic, or their load carrying capacity reduced as they are showing signs of deterioration and require major maintenance.

The shortlisted timber bridges varied in length and complexity, but all demonstrated a high level of innovation in the engineering design, treatment, and the use of engineered mass timber products and systems. In

https://doi.org/10.52202/069179-0589

the end, only two timber bridges advanced to the design and construction stage with funding from NRCan.

Figure 16: *Mistissini Bridge (Courtesy of Stantec)*

2.3.1. Duchesnay Creek Bridge

One of shortlisted projects is the Duchesnay Creek Bridge in North Bay, Ontario (Figure 17). The new bridge replaces the original which was closed by the Ministry of Transportation (MTO) in 2019 for safety reasons due to its poor condition. The original bridge had a timber deck truss and was constructed in 1937. Replacement of this 74 m long heritage deck truss bridge on the existing alignment imposed challenges. To avoid multiple timber pile bents in the approach spans, it was decided to select a bridge type sympathetic to the cultural heritage value of the original structure and a timber design that is efficient and reflects the key attributes of the original timber structure in modern form [2]. The redesign of the bridge was done with the intention to maintain the original timber aesthetic. The bridge design is an innovative three-span hybrid glulam girder bridge with precast concrete deck and arched glulam braces at the piers. The utilization of the glulam braces at the piers helps with the reduction of the shear loads experienced by the structure. The deck is attached to the main glulam girders using shear connectors to allow for the transfer of diaphragm forces. The bridge is 83 m long and 13 m wide with three spans and was opened for traffic in August 2021.

Figure 17: *Duchesnay Creek Bridge (Courtesy of MTO)*

3 EDUCATION AND DESIGN TOOLS

3.1 NATIONAL EDUCATION ROADMAP

Until recently, only a few Canadian engineering and architectural schools offered wood design courses at the undergraduate level. To address this gap, the GCWood program funded the implementation of a Canadian wood education roadmap, led by the Canadian Wood Council (CWC). The goal is to expand wood education at Canadian universities and colleges, and consequently, contribute to the development of the future timber design capacity in Canada.

The architectural and engineering community is always changing, and professionals need access to state-of-the-art tools, resources, and continuing education to ensure the wood products industry remains competitive. Innovation doesn't always start on the construction site, but often through the students and recent graduates who shape the next wave of design and construction. Therefore, expanding the wood education curriculum in Canada requires supporting an engaged network of enthusiastic educators, as they are essential to equip future professionals with a solid foundation of education and skillsets. The focus of the education Roadmap is to:

1. Build a network to support educators and institutions to increase availability of curricula and encourage students to study wood design and construction.
2. Develop up-to-date curriculum/manuals/ materials, presentations, lectures, learning modules, design exercises, sample calculations and more.
3. Develop several teaching modules, interactive case studies, hold site visits and tours, and host student competitions to engage students and trigger their interest in wood structures.

Three new sets of teaching manuals are being developed: Wood Design for Architects, a Wood Handbook for Builders, and an Advanced Wood Engineering Manual. So far, project activities have led to the addition of wood design and construction curricula at 11 accredited civil engineering, architectural and construction management programs across Canada which is a huge success.

3.2 STATE OF MASS TIMBER IN CANADA

Until recently, there was no comprehensive database of modern mass timber projects or production capacity in Canada. In order to fill this gap, NRCan worked closely with industry partners to develop a "The State of Mass Timber in Canada" (SMTC) report, which was the first of its kind (Figure 18). The SMTC report was released in May 2021, and established a baseline of data with the intent to measure future growth against and help inform decision making associated with he future of mass timber construction in Canada [3].

Figure 18: *State of Mass Timber in Canada 2021 report*

The report presented a baseline dataset that included over 480 projects completed or currently under construction since 2007 and represented nearly 1.5 million m^2 (or 16 million sf) of gross floor area. This is in addition to data on 20 mass timber manufacturing facilities in Canada (Figure 19). A web-based interactive map was also developed and is updated quarterly to provide users with information on the locations of all the mass timber projects and producers from across the country [4]. The following figure outlines the number of manufacturers for each type of mass timber elements in Canada.

Figure 19: *Number of Canadian manufacturing facilities by product*

Several updates to the SMTC dataset and map since its publication have now brought the total project number to over 750 projects. The web-based dashboard shows the location of the mass timber projects and manufacturing facilities across Canada. Users can zoom in and select individual projects, or filter by categories such as project type and use, year of completion, size, region, and other criteria (Figure 20). The SMTC map dashboard was recently included in the Living Atlas, the biggest collection of maps and geographical based data and information in the world! The Living Atlas offers a variety of contextual tools to visualize and analyze data, and now users will be able to access the SMTC map and dashboard on both the Mass Timber Construction in Canada Page and the Living Atlas.

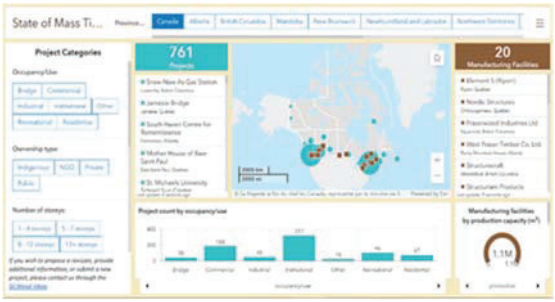

Figure 20: *SMTC map dashboard*

3.3 DESIGN TOOLS

To support the deployment of mass timber construction in Canada, the GCWood program has been funding the development and deployment of several advanced design tools to assist designers, builders, and decision makers. Overall, the program supported the development of over 10 new design guides, tools, and datasets. This includes advanced wood design handbooks for engineers, architects and builders, carbon calculators, and Life Cycle Assessment (LCA) tools to help demonstrate the environmental benefits of building with wood. To further the governments' carbon accounting goals, GCWood provided funding to a major 4-year initiative called *Low-Carbon Assets through Life Cycle Assessment* (LCA^2) led by the National Research Council of Canada (NRC). This initiative focused on developing a national Life Cycle Inventory (LCI) database and whole building LCA guidelines.

The LCI data and LCA guidelines will be used to facilitate procurement policies at the federal and provincial levels, and by the design and construction industry. This work will expand opportunities to build with wood, open new markets for manufacturers and provide stimulus to the broader forest sector.

4 UPDATES TO CANADIAN BUILDING CODES

The 2015 edition of the National Building Code of Canada (NBCC) included some significant changes with respect to wood design as it permitted 5 and 6 storey tall wood frame buildings [5]. Building on the revolutionary acceptance of 12-storey mass timber buildings as a "pre-approved" Alternative Solution by the province of Québec in 2015 [6], a code change proposal for Encapsulated Mass Timber Construction (EMTC) was submitted in 2016 by the Canadian Wood Council to the NBCC Code Committee for their consideration targeting the 2020 edition of NBCC.

A Task Group and several Working Groups were established by the Standing Committee on Fire Protection (SC-FP) to discuss the proposed EMTC code change and identify potential issues and research needs to be

https://doi.org/10.52202/069179-0589

addressed. Several research projects (mainly on fire and seismic performance) were conducted at the National Research Council (NRC), with funding from GCWood, to support the proposed code change provisions. The fire testing focused on the allowable percentage of exposed mass timber that should be permitted in EMTC buildings, and the effectiveness of water mist systems compared to conventional sprinkler systems that are commonly used in tall buildings.

The 2020 edition of the National Building Code of Canada (NBCC) was published in the Spring of 2022 and allows for EMTC up to 12 storeys. Several jurisdictions including British Columbia, Ontario, and Alberta have adopted the EMTC provisions in their respective codes. In addition, extensive efforts are being invested in transitioning the NBCC to become more performance-based in the future.

Additional research is ongoing to develop seismic design guidelines for mass shearwalls for tall wood buildings applications. A technical guide was developed recently by the Canadian Construction Materials Centre (CCMC) which will be used to support future code change provisions for tall wood buildings in the 2025 building code [7]. A series of design examples were also developed to validate and clarify how those guidelines will be used by engineers involved in the design and construction of tall wood buildings. The guidelines presented in the CCMC Technical Guide are being used to refine the current seismic design provisions in the 2024 edition of the Canadian Timber Design Standard CSA O86 [8].

NRCan has been funding critical research and development activities to support the NBCC code change process since 2010 and will continue to support future developments of the NBCC targeting a more performance-based code by 2030. Extensive efforts are currently underway to introduce performance-based design as one of the priorities for the current code cycle at the Canadian Commission for Buildings and Fire Codes (CCBFC) and its various standing committees.

4.1 MASS TIMBER FIRE DEMONSTRATION TEST

A national research program focused on demonstrating the fire performance of mass timber products in tall wood buildings was conducted in Canada over the past two years. The project was led by the Canadian Wood Council (CWC) and was jointly funded by the federal and provincial governments, including Natural Resources Canada, the provinces of Ontario, Quebec, British Columbia, and Alberta. The project's key objective was to encourage the acceptance of tall wood buildings in Canada and help inform the Authorities Having Jurisdictions (AHJs) about the performance of mass timber construction under various fire conditions. The fire tests were performed by the National Research Council of Canada.

The program comprised of two phases: Phase 1 involved conducting a series of pilot-scale fire demonstrations, which were carried out successfully in Vancouver in June 2021 (Figure 21). The tests represented typical construction fire scenarios. Phase 2 focused on testing a full scale 2-storey, 350 m^2, mass timber structure (Figure 22). Findings from Phase 1 pilot demonstration project were used to refine the design and testing approaches of the full-scale mass timber structure and supported the approval of several tall wood buildings in British Columbia.

In Phase 2, five different fire test scenarios were conducted on the full scale 2-storey mass timber structure designed and built at the Canadian Explosives Research Laboratory (CERL) in Ottawa. The tests investigated among other things, the fire performance of protected & unprotected mass timber, fire dynamics, and the behaviour of construction and garbage bin fires. The initial test conducted in Phase 2 was the world's largest mass timber demonstration fire presented to date. Preliminary observations have indicated that the fire performance of the mass timber structure was similar to that of non-combustible construction and have confirmed that mass timber performs well under the rare fire scenarios in which the sprinkler system fails, and the fire department is unable to respond.

One of the key objectives of the fire tests was to demonstrate to a host of decision makers (e.g., fire services, municipal building officials and regulatory authorities, insurance and finance industries, and other key construction stakeholders) that the fire performance of mass timber construction can meet, or even exceed, the performance achieved by non-combustible construction as permitted in the building code. Over 200 experts from across Canada, including fire officials, building regulators, insurance industry representatives, engineers, and architects (including some from governments), witnessed the tests to learn about the behaviour of mass timber construction under fire conditions.

Analysis and reporting of data collected from the tests will be used to support future code change proposals, including performance-based codes and the development of alternative solutions and new fire suppression systems.

Figure 22: *Ottawa Mass Timber Fire Demonstration Test during and after the test as the fire died down*

5 CONCLUSIONS

The Government of Canada is making significant investments in expanding the use of wood as a low-carbon building material in Canadian building and infrastructure projects. Through demonstration projects and strategic activities focused on advancing wood design education and supporting science-based code revisions, the GCWood program is supporting greater market and regulatory acceptance of wood in non-traditional construction applications across Canada.

INVESTING IN MASS TIMBER CONSTRUCTION IN AUSTRALIA: THE CLEAN ENERGY FINANCE CORPORATION TIMBER BUILDING PROGRAM

Christina Wijeratne[1] and Paolo Lavisci[2]

ABSTRACT: The built environment must play a significant role in achieving Australia's decarbonisation objectives. Whilst energy efficiency measures and renewable energy sources helping to address the operating emissions of Australia's built environment have gained significant traction, the embodied carbon in the materials used in construction is becoming an increasingly important component of the built environment's carbon emissions profile. Where application is appropriate, mass timber provides a lower embodied carbon alternative to conventional construction materials. The Clean Energy Finance Corporation (CEFC) Timber Building Program, launched in February 2022, offers AUD 300 million in debt financing to encourage greater use of mass timber in construction. The CEFC Timber Building Program looks to increase the use of mass timber in Australia, to achieve direct carbon savings through individual projects and drive demand for mass timber products in Australia. It also aims to enable increased exposure and capacity building for construction professionals and help to influence the broader market through providing demonstration value. The Timber Building Program highlights the unique and broad impact potential of targeted, purpose-driven financing.

KEYWORDS: Debt program, timber funding, embodied carbon, financing

1 INTRODUCTION

The Clean Energy Finance Corporation (CEFC) is Australia's 'green bank' with a 10-year track record of investing to reduce emissions across the economy, working with co-investors, business, industry, and government to deliver on Australia's ambitions to reach net zero emissions by 2050. In February 2022, the CEFC launched an AUD 300 million Timber Building Program, aimed at accelerating the use of mass timber construction in Australia, with the provision of tailored debt finance to eligible projects.

2 THE AUSTRALIAN CONTEXT

Australia produces approximately four-and-a-half times the world average per-capita CO_2 emissions, at over 14 tonnes in 2021 [1]. This is on par with the United States, and more than double that of the European Union [2]. With the building and construction sector accounting for 39 per cent of global emissions, [3] the built environment has a significant role to play in reaching net zero targets in Australia and globally.

2.1 THE EMBODIED CARBON CHALLENGE

Efforts to decarbonise the built environment have traditionally focused on operating emissions. As improvements to operational energy become common industry practice and net zero commitments become more mainstream, the market's attention is turning to the embodied carbon of materials used to build. According to the Green Building Council of Australia (GBCA), in 2019 operating emissions contributed 84 per cent of Australia's built environment emissions, with the remaining 16 per cent contributed through embodied carbon. Without intervention, and as the electricity grid continues to decarbonise, by 2050, this is expected to shift, with embodied carbon projected to contribute 85 per cent of Australia's built environment emissions [4].

The embodied carbon emissions of the materials used in Australia is 30–50 million tonnes of CO_2 emissions per year, which is approximately five to 10 per cent of national greenhouse gas emissions [5]. The economic value of the construction materials sector is approximately AUD 65 billion, contributing roughly three per cent of Australia's GDP [6]. The CEFC industry report *'Australian buildings and infrastructure: Opportunities for cutting embodied carbon'* (herein referred to as the '*Embodied Carbon Report'*) found that, depending on the initiatives and low carbon products utilised, it is possible to achieve embodied carbon savings of between three and 18 per cent whilst reducing materials costs by between 0.3 and three per cent [7].

2.2 THE ROLE OF MASS TIMBER

Conventional building materials such as concrete and steel are traditionally made by highly carbon intensive processes. Comparatively, the carbon emitted during the processes of making mass timber is much lower [8]

[1] Christina Wijeratne, Clean Energy Finance Corporation, Australia, christina.wijeratne@cefc.com.au
[2] Paolo Lavisci, FWPA, Australia, paolo.lavisci@woodsolutions.com.au

https://doi.org/10.52202/069179-0590

Furthermore, with sustainable timber production and improved building dis-assembly practices, mass timber has the ability to maintain substantial amounts of sequestered carbon [9]. The *Embodied Carbon Report* found that the embodied carbon emissions of a mass timber building can be up to approximately 75 per cent less compared to a conventional concrete and/or steel counterpart on a per square meter basis [10].

2.3 THE MASS TIMBER INDUSTRY

The use of mass timber construction materials in Australia lags that of more mature markets such as North America and Europe. Whilst Australian forests and plantations sequester, and wood products store, approximately 57 million tonnes of CO_2, equal to approximately 10 per cent of the total greenhouse gases emitted in Australia [11], Australia has a limited domestic supply chain, with only a handful of onshore mass timber manufacturers.

Australia's commercial building sector is highly competitive and has adopted efficiencies such as the use of precast concrete and steel. However, the market has not widely adopted the use of mass timber, with one important impediment being structural and fire engineering standards which, until the NCC 2016 revision, did not allow the use of mass timber in structures above three storeys within a 'Deemed-to-Satisfy' provision. This necessitated a 'performance solutions' approach requiring additional design time, costs, and greater approval risk.

The residential building sector is highly fragmented, largely comprised of many smaller scale builders. Australian residential buildings up to three storeys in height are typically built with reference to the largely prescriptive AS1684 standard, rather than seeking greater performance outcomes through the performance-based AS1720 (noting this provisions for GLT and LVL, but not for CLT) or through the reference to other standards such as the Eurocode 5. Thus, the residential building sector typically lags the commercial building sector in sustainability outcomes and progress.

The use of mass timber in medium-to-large scale construction is further limited due to the cost savings of reduced labour and build times often not being factored into project feasibility analyses, thus not considered to offset the often higher upfront costs of mass timber (on a 'bill of quantities' basis) compared with traditional construction materials in Australia. Further, limited builder experience constructing with mass timber, and resistance from lenders and insurers to support off-site prefabrication, pose additional hurdles to broader uptake.

While constructing with mass timber offers many benefits compared with traditional construction approaches, including the ability to achieve embodied carbon savings, increased productivity through shorter construction times, lower physical impacts to site surrounds from the construction process, and improved site safety, the adoption and growth in use of mass timber construction approaches seen in North America and Europe have not yet been achieved in Australia.

2.4 ENABLERS OF CHANGE

Driving change in the Australian mass timber market requires a broad and collaborative cross-sectorial approach. There are several initiatives currently underway which seek to address the barriers to the uptake of mass timber in Australia, including:

- Regulation: building standards have a significant impact on material selection and construction techniques. The National Construction Code (NCC) has been progressively updated in 2016 and 2019 to include positive changes in support of the use of mass timber in mid-rise construction (up to 25 meters in height) [12]
- Disclosure: the measurement of embodied carbon and collection of such data unlocks the ability to benchmark and drive higher standards. Rating tools play an important role in providing consistency and fostering positive behavioural changes in the market. The GBCA has launched a *Responsible Products Framework* which sets embodied carbon targets for buildings seeking high ratings [13], and the National Australian Built Environment Rating System (NABERS) is creating a framework for measuring, benchmarking, and certifying emissions from construction and building materials [14]. Some Australian states are using policy levers to introduce embodied emissions measurement and reporting requirements across residential and commercial developments [15].
- Industry partnership: industry collaboration between relevant stakeholders can enable a consistent understanding of economy-wide hurdles and provide a feedback loop to policy and regulation. The Materials and Embodied Carbon Leaders' Alliance (MECLA) is a collaborative thinktank which has attracted over 100 industry partners with a collective decarbonisation vision, including the CEFC [16].
- Education: technical knowledge building is required to increase building professionals' comfort and confidence in using novel construction materials and techniques. Forest & Wood Products Australia Limited (FWPA) is a not-for-profit company that, through its WoodSolutions program, provides integrated services to the Australian forest and wood products industry, the construction industry, and the broader community.
- Supportive capital: capital is necessary to influence progress across the economy. Supporting projects demonstrating the benefits of mass timber construction can support the development of the domestic market in a myriad of ways. The CEFC is providing financing in support of the use of mass timber through its targeted Timber Building Program.

2.5 FOREST AND WOOD PRODUCTS AUSTRALIA

FWPA has the mission of investing in effective and relevant research and development designed to grow the

https://doi.org/10.52202/069179-0590

market for forest and wood products, increase productivity and profitability across the value chain and ensure positive environmental and social outcomes. An example of FWPA's work in this area is its investment in fire testing and collection of engineering evidence to support the evolution of the NCC. The NCC 2016 revision introduced Deemed-to-Satisfy provisions for using timber structures in buildings up to 25 meters effective height.

In 2010, FWPA launched WoodSolutions, an industry initiative designed to provide independent, non-proprietary information about timber and wood products to professionals and companies involved in project development, design and construction in the built environment.

In 2011, the Grattan Institute, an independent Australia public policy organisation, quantified the growing gap between housing supply and demand and suggested that multi-residential timber framed construction was an innovative technique that would contribute favourably to the supply of housing [17]. In response to the new and growing demand for support in relation to multi-storey timber framed construction, WoodSolutions launched the Midrise Advisory Program (MAP), involving 22 industry and institutional partners.

MAP helped to build the mass timber knowledge base of developers, builders, architects, engineers, building surveyors, and quantity surveyors, supporting building professionals and decision makers in their designs, procurement, and construction activities. MAP demonstrated the benefits of wood-based construction using multiple free-access tools such as case studies, seminars, project-specific meetings and feasibility analyses, site visits, a demonstration building, a help desk, engineering software and design guides. An example of this is the *Cost Engineering of Mid-rise Timber Buildings* technical design guide which uses data from several mid-rise timber projects in Australia and overseas to quantify the cost savings associated with the use of timber structures, and provides guidance on how to appropriately capture their value proposition in activities related to the design, procurement and installation of mid-rise wood structures in Australia [18].

The primary target of the MAP was to support the use of timber in 'significant' projects. This was accomplished by supporting key decision-makers in developing their understanding of mass timber products and their complementarity within an optimised design. The 30 projects which were completed, started, or fully confirmed within the MAP's activity term (2016-2022) used approximately 53,000 cubic meters of structural wood products, as well as additional ancillary products and services. This represents approximately three per cent of the projects considered to have the potential of being developed using timber. Most of the projects supported by the MAP featured a significant design quality combining aesthetics, performance, cost efficiency, and quick delivery, reflecting the benefits of timber and enabling the successful introduction of the materials to major players in the market.

WoodSolutions has become well known and trusted as a provider of reliable educational tools for timber design and construction, supporting the development of new professional and technical competencies, with the organisation's website being one of the world's most visited in the field of timber information and education (with 1.9 million overall visits in 2022, as measured by Google Analytics). WoodSolutions' Technical Design Guides and Environmental Product Declarations, which are all free for public download from their website are frequently used as the de-facto industry standard, being referenced in design specifications and tender documents. As the number of contacts and projects grows, awareness of the benefits of timber is increasing in Australia. Many professional associations involved in construction (including developers, builders, architects, engineers, building surveyors, and quantity surveyors) have collaborated with WoodSolutions to develop their associates' awareness of the value proposition of timber structures in the market.

3 CEFC TIMBER BUILDING PROGRAM

An AUD 300 million Timber Building Program was established by the CEFC and launched in 2022 as part of its broader strategic focus on reducing embodied carbon as an essential component of a low emissions economy. The Timber Building Program is a novel approach to addressing the issue of upfront embodied carbon in the commercial construction context, using tailored finance solutions to support the increased adoption of mass timber in construction.

3.1 CLEAN ENERGY FINANCE CORPORATION

The CEFC is a specialist investor at the centre of efforts to help deliver on Australia's ambitions for a thriving, low emissions future. With a strong investment track record, it is committed to accelerating Australia's transition to net zero emissions by 2050. In addressing some of Australia's toughest emissions challenges, the CEFC invests to fill market gaps, collaborating with investors, innovators and industry leaders to spur substantial new investment where it will have the greatest impact.

CEFC lifetime investment commitments to 31 December 2022 were AUD 11.7 billion. Together with institutional investors, business, industry and cleantech innovators, the CEFC catalysed AUD 42.8 billion in investment in Australia's low emissions economy, with each dollar of CEFC capital leveraging an additional $2.62 from the private sector. In investing on behalf of the Australian Government, the CEFC has a strong commitment to deliver a positive return for taxpayers across its portfolio. The CEFC has a flexible approach to investment, which recognises the needs of an evolving market. CEFC financial products and structures, including debt and equity, are shaped to help drive private sector investment across a diverse range of activities.

In recognising the urgent nature of the emissions challenge, the CEFC has focused investment origination

activities, prioritising emissions challenges across the wider Australian economy. These include backing the clean energy system of the future, where Australia requires significant new investment to support a substantial uplift in renewable energy generation, storage and grid transmission project. The CEFC also invests in in low emissions solutions in property, infrastructure, industry, natural capital and resources, which can deliver benefits across the economy, from lower energy consumption to alternative approaches to production, reducing demand on the energy network and abating carbon emissions. In tapping into new investment models and opportunities the CEFC develops new financial markets and products, builds investor confidence and crafts tailored and innovative investment solutions for new and emerging industries.

3.2 THE ROLE OF CEFC FINANCE

Capital is a powerful tool able to influence technology, innovation, and growth across the economy. Finance can impact all aspects of the transition to net zero emissions, including through supporting utility-scale renewable energy, major infrastructure and real estate projects, innovative climate technologies, and broader debt capital market approaches.

By operating across all sectors of the economy, the CEFC mobilises capital to support both the supply of, and demand for, renewable energy, energy efficiency, and low emissions technologies. A strong governance approach helps ensure intended commercial and emissions outcomes are achieved across the portfolio. As well as direct carbon abatement impacts, investments have demonstration value, showcasing commercially viable solutions with key learnings leveraged and shared to influence and educate the broader market.

The CEFC is an active investor across the property sector. This extends from commercial office, retail and industrial segments through to alternative and emerging asset classes, including student housing, retirement living and residential markets. The CEFC also invests across the capital stack, using debt and equity instruments. CEFC cornerstone investments in new property funds continue to demonstrate the positive link between financial returns and Environmental, Social, and Governance outcomes. In order to optimise emissions performance and achieve long-term sustainability targets, the CEFC operates as a 'patient' investor, recognising there are opportunities to reduce emissions across the investment lifecycle, from the development approval process to design, procurement and construction, then finally into operations, as well as the need to address the emission of existing building stock and support circular economy principles. At 31 December 2022, the CEFC have made lifetime investment commitments of AUD 2.1 billion across the property sector.

In Australia, building with mass timber generally proves more expensive than conventional concrete and steel approaches, especially as the cost savings of reduced labour requirements and build times are often not factored into project feasibility analyses. An additional barrier relates to lack of awareness, with many contractors and developers not familiar with mass timber, and a perception of increased risk in relation to durability, fire resistance, and building code compliance. These factors present challenges to developers committing to the use of mass timber and being able to source investment and finance for mass timber projects.

The CEFC Timber Building Program has been designed to support an increase in mass timber projects in Australia, to provide direct exposure and capacity building for construction professionals involved in individual projects, as well as influencing the broader market through providing demonstration value and concerted knowledge sharing. As more projects utilise mass timber in construction, more data will be generated to combat myths around durability, fire resistance, and costs. Such data can also help guide policy, building standards, and rating tools to recognise the full benefits of mass timber, including its role in addressing the embodied carbon challenge. Supporting demand for mass timber products may also aid in the development of local supply chains. The Timber Building Program aims to drive demand to support these integral market enabling approaches.

3.3 CEFC PROGRAM PARAMETERS

The CEFC Timber Building Program is a tailored debt program designed to attract projects that are incorporating the material use of mass timber to achieve significant embodied carbon outcomes. Finance is bespoke and tailored to best suit each individual transaction and borrower. Funding can be project-specific senior secured property finance, or portfolio-level corporate debt secured by a pool of assets. The CEFC can offer fixed or floating interest rates, and can lend as sole financier, or alongside co-financiers in syndicated or club structures. Investments are made at commercial returns and financing packages are structured to optimise sustainability outcomes on a risk-adjusted basis. Governance is guided by the *Clean Energy Finance Corporation Act 2012* (the CEFC Act) and CEFC policies and guidelines.

Opportunities are evaluated on a case-by-case basis and with consideration of the overall commercial and carbon outcomes and initiatives. The program is sector agnostic, open to developments including commercial offices, retail, industrial, healthcare, education, multi-residential apartments, retirement living, aged care, hotel, and student accommodation, as mass timber can have a role to play across all asset types. The Timber Building Program is seeking to support scalable projects that drive strong demonstration value, and where possible, draw in third-party capital to optimise the program reach. The Timber Building Program has an Australian focus as per the objectives of the CEFC Act.

All projects must use low carbon mass timber products during the construction phase to achieve material embodied carbon outcomes and use appropriately sourced and accredited timber materials.

https://doi.org/10.52202/069179-0590

3.4 CEFC PROGRAM IMPACT

The CEFC Timber Building Program is anticipated to be a multi-year scheme, acknowledging that through-cycle investment certainty is necessary to drive the momentum required to achieve broader adoption of mass timber construction approaches in the Australian market. This also reflects the CEFC early engagement model required to ensure sponsor and project alignment with required carbon and impact outcomes; the necessary project and financial due diligence, approval, and documentation processes; and ultimately the financing and project construction timelines.

The CEFC February, 2022 launch of the Timber Building Program was positively received by the market, attracting a significant level of responses from property companies and developers, positive support from industry groups and the Australian government, and considerable attention from the respected and specialist media outlets.

3.5 FIRST PROGRAM INVESTMENT

The CEFC successfully executed on its first finance package under the Timber Building Program in September 2022, with its involvement in T3 Collingwood. T3 Collingwood is the first Australian addition to the Hines 'T3' global portfolio, a Timber, Transit, and Technology-oriented development methodology which is centred upon sustainable design, efficiency, and profitability, supporting the delivery of credible decarbonisation pathways. T3 Collingwood, a 15-storey prime-grade office tower in the inner-city Melbourne suburb of Collingwood, aims to deliver a dual emissions reduction impact – cutting embodied carbon levels by as much as 40 per cent during the construction phase and, once operational, targeting market-leading net zero emissions.

The hybrid construction approach used to build what will be one of Melbourne's tallest hybrid timber buildings will feature a glue laminated timber (GLT) post and beam structure with cross-laminated timber (CLT) flooring starting from the sixth level, on top of five reinforced concrete podium levels. Timber will be sustainably sourced from two specialist local mass timber manufacturers, with Xlam Australia supplying the CLT and Australian Sustainable Hardwoods supplying the GLT. T3 Collingwood will use approximately 4,000 cubic metres of mass timber components for the structural frame, storing approximately 3,000 tonnes of CO_2.

Hines Australia Managing Director Simon Nasa noted:

> 'Mass-timber construction is an important step in driving a sustainable future for the built environment we live and work in. Not only is timber a completely renewable resource, but timber offices are also biophilic in creating a more natural working environment for tenants and their staff. This results in increased productivity and better mental health outcomes, helping to create the people-friendly live-work-play communities that Hines is known for' [19].

Figure 1: *External façade architectural rendering of T3 Collingwood*

Figure 2: *Cross section architectural rendering of T3 Collingwood*

Figure 3: *Internal architectural rendering of T3 Collingwood*

https://doi.org/10.52202/069179-0590

T3 Collingwood was supported from its early concept stage by the WoodSolutions MAP through an established collaboration with the architects, engineers, program manager, and builder.

As one of the world's largest privately held real estate investors and managers [20], and with a global T3 portfolio, the Hines development of T3 Collingwood signals the readiness and investable nature of Australia's mass timber construction market.

T3 Collingwood aims to achieve significant carbon abatement outcomes, as well as create demand for Australian domestic mass timber, and encourage owners, developers, architects, engineers, and builders to use mass timber where appropriate as an alternative to conventional construction materials such as concrete and steel.

Learnings in relation to fire resistance and code compliance are expected to help inform regulatory approaches; embodied carbon measurement and outcomes can contribute to rating tool developments; and the project will help demonstrate the investable nature of mass timber buildings to the broader finance market, driving the adoption of larger-scale capital programs.

Through the Timber Building Program, the CEFC is encouraged to see interest from parties across the spectrum, from significant developers such as Hines, through to mid-market and private market participants, signifying the scale of the investable mass timber market, and the opportunity to educate and influence building professionals across the economy. The Timber Building Program aims to support more projects achieving strong emissions savings and broader positive market impacts.

4 CONCLUSIONS

The CEFC plays a unqiue role in supporting Australia's economy-wide decarbonisation ambitions. Embodied carbon is becoming an increasingly important challenge in the decarbonisation of the built environment, and as a low carbon alternative to traditional construction materials, where applicable, mass timber has a key role to play in addressing the challenge. The adoption of mass timber construction approaches in Australia faces multiple impediments, including from a lack of awareness across construction, development, investment, and finance industries, leading to perceptions of increased risk and cost. The CEFC has found that in the Australian context, working with early adopters can create significant behavioural change and shift key market drivers. The CEFC Timber Building Program looks to achieve direct carbon savings from investee projects, drive demand and increase the use of mass timber in Australia to provide direct exposure and capacity building for construction professionals, and to influence the broader market through demonstration value. Learnings from an increased number of projects can help to combat myths; guide policy, building standards, and rating tools; and aid in the development of local supply chains, highlighting the unique and broad impact of purpose-driven financing in accelerating emissions reduction.

TOWARDS A BROADER USE OF WOODEN CONSTRUCTION MATERIALS: INTERMEDIARY ORGANISATIONS IN THE SUSTAINABILITY TRANSITION OF THE CONSTRUCTION SECTOR

Antje Klitkou[1], Lina Ingeborgrud [2]

ABSTRACT:

Aim: This paper presents an ongoing study on sustainability transitions in the Norwegian construction sector, with a focus on increasing the use of wood. The construction sector is very conservative and path dependent. Existing path-dependencies and lock-mechanisms are interrelated and reinforce each other, contributing to an unsustainable development within the sector and preventing a sustainable transformation. These interacting lock-ins create social problems, such as the lack of affordable city dwellings, a high cost for energy efficiency and renovation measures, and less flexibility for adapting dwelling spaces to new needs. A crucial question is therefore how to change path-dependencies and overcome these interacting lock-ins by developing new pathways – what types of actors and efforts are required for such a change? In this paper, we pay attention to the specific role of different types of intermediary organisations in the transition to a more sustainable construction sector in Norway. We investigate how such intermediaries contribute to more sustainable pathways in the construction sector, with a focus on the use of wood.

Method: We apply a mixed methods approach, combining media analysis, interviews, and document analysis.

Findings: We find that intermediary organisations have been very active in the development of new pathways. This applies especially to cluster organisations, which have a clear aim of increasing the use of wood in the construction sector, but also intermediaries taking a more 'neutral' role concerning choice of materials, provide innovation arenas for experimenting with sustainable material use and architectures. We identified technological, institutional, and behavioural path dependencies and barriers for sustainable development. Correspondingly, we discuss new pathways for more sustainable and wood-based constructions and the role of intermediaries in shaping these new pathways.

Conclusions: Development and deployment of new technologies for wood construction need to be accompanied by changes in institutional conditions and in social practices of dwelling. Intermediaries need to broaden their horizon and networks when lobbying for new wood-based solutions addressing such social problems. Intermediaries evolve over time and get new roles, while older roles are taken over by other actors. Different types of intermediaries need to cooperate, have different roles, and interact with other actors in the innovation system.

KEYWORDS: Wooden construction, Intermediary organisations, Norway, Sustainability transition, Path creation, Path dependence

1 INTRODUCTION

This paper presents a study on the innovative use of wood in the Norwegian construction sector to facilitate a sustainable transition of the sector. The construction sector has a considerable economic and social importance, as well as major environmental impacts. Furthermore, it is very conservative and path-dependent, but also rather diverse, encompassing not only the entrepreneurs who are constructing buildings, but also those actors who order the construction, as well as architects, consultants, producers of construction materials, etc. Sustainability transitions must overcome path-dependencies.

Existing path-dependencies contribute to unsustainable development within the construction sector and prevent a sustainable transformation of the sector. A crucial question is therefore how we can change path-dependencies and barriers to enable sustainable development in the construction sector: what kind of new pathways have emerged and what types of actors are required for such a change? In this paper, we pay attention to the specific role of different types of intermediary

[1] Antje Klitkou, NIFU, Norway, antje.klitkou@nifu.no
[2] Lina Ingeborgrud, NIFU, Norway, lina.ingeborgrud@nifu.no

https://doi.org/10.52202/069179-0591

organisations in the transition to a more sustainable construction sector in Norway. We investigate how such actors work to facilitate the increased use of wood-based materials within the sector.

The research questions for this paper are therefore:

- Which new pathways have emerged for a more sustainable construction and building sector based on the use of wood?
- What is the role of different types of intermediary organisations in shaping these new pathways?
- How do intermediary organisations generate new users and markets for wood-based construction materials?

2 BACKGROUND

The construction sector has a considerable economic and social importance, as well as major environmental impacts. If we include the whole lifecycle of buildings, the global construction and building sector stands for 42% of total energy consumption, 35% of total greenhouse gas emissions, 50% of extracted materials and 30% of water consumption [1, 2]. Therefore, improving the resource efficiency and sustainability in the building sector has become an important climate policy goal in the EU and in the Nordic countries [3-7].

As one possible solution it has been suggested to use more wooden construction materials. Wood is a renewable material and has a considerably lower carbon footprint compared to steel and concrete. Studies on the mitigation potential of wood use in buildings and furnishing have shown that wood products have lower greenhouse gas emissions than alternatives over the complete life cycle of the product [8]. There is plenty of evidence supporting the substitution effects [9, 10], but this is still a niche market. Another problem is the large amount of waste generated in the construction and building sector. This includes the construction of new houses, the rehabilitation of buildings and the demolition of existing buildings and other constructions. Construction and demolition waste (CDW) accounts for more than a third of all waste generated in the European Union (Source: Eurostat)[6] and for 29 per cent in Norway (Source: SSB)[7]. Over the last 17 years, there has been a steady increase of waste generated in this sector in Norway: from 1.2 million ton in 2004, to 2.1 million ton in 2020 (data: SSB). Here, demolition waste stands for 46 per cent, rehabilitation of buildings for 24 per cent and new constructions for 30 per cent [11].[8] The highest shares belong to bricks and concrete: 0.6 million ton in 2004 and 0.87 million ton in 2020 (SSB).[9] Wood waste has increased as well: from 0.22 million ton in 2004 to 0.27 million ton in 2020 (ibid.). In addition, there are contaminated resources, which have increased as well.

In Norway, the use of wood as a construction material has dominated the marked for cottages in the countryside and, only to some extent, for houses with no more than two storeys. Normally, houses in the cities are multi-storied and mostly built in concrete and steel. This means that the challenges regarding high energy consumption, GHG emissions, use of extracted materials, water consumption, and waste generation, dominate in this sector.

In the literature, researchers have distinguished between six types of barriers for the extensive use of timber as a structural material for multifamily and non-residential buildings: "code implementation, technology transfer, costs, material durability and other technical aspects, culture of the industry and material availability" [12].

While the literature about the sustainability transition of the construction sector in general is targeting low-energy or passive houses [13], the literature on the wood construction industry has been mainly technical, focusing on quality of construction materials and assembling techniques [i.e., 10, 14, 15] or on specific projects and there used materials and assembling techniques [16]. Recently, there has been more research on the functions of technological innovation systems for wood-frame multi-storey construction [17].

3 THEORETICAL FRAMEWORK

The theoretical framework for this paper consists of three main conceptual building blocks: 1) path-dependence and lock-ins, 2) path creation for sustainability transitions, and 3) the role of intermediaries in sustainability transitions.

Path dependencies can be described as the ways in which a sector, here the construction sector, is 'locked-into' certain patterns due to historical developments [18]. Path dependency is not inherently negative, but when the chosen path turns out to be a hinder for new, more effective, and environmentally friendly solutions, those lock-ins function as a barrier for sustainable transitions. Such developments are, therefore, path dependent. Path dependencies are realised through lock-in mechanisms. The discussion of lock-in mechanisms in this paper is motivated by our interest in transition processes and their key barriers. We focus especially on transitions towards a more sustainable construction sector.

We can distinguish between *three groups of lock-in mechanisms:*

- Technological and infrastructural lock-ins,
- institutional lock-is, and
- behavioural patterns and shared social practices of everyday life.

All three types coevolve and are interdependent [19].

[6] https://ec.europa.eu/environment/topics/waste-and-recycling/construction-and-demolition-waste_en
[7] https://www.ssb.no/natur-og-miljo/avfall/statistikk/avfallsregnskapet
[8] https://www.ssb.no/natur-og-miljo/avfall/statistikk/avfall-fra-byggeaktivitet
[9] https://www.ssb.no/statbank/table/09247/tableViewLayout1/

https://doi.org/10.52202/069179-0591

The scientific discourse about lock-ins was originally mostly about technology-related lock-ins, and first later, institutional and behavioural lock-ins came on the agenda.

Technological lock-ins can be defined as positive feedbacks or increasing returns to the adoption of a selected technology [20-22]. Positive feedback mechanisms decrease production costs and create additional benefits for users. The costs and performance of a new technology are more uncertain compared to incumbent technologies [23].

High costs of supporting infrastructure can also contribute to a technological lock-in because it is a barrier to change. Infrastructure is often used for encompassing the communicative system, including transport or distributive systems, like the systems for producing and distributing heat, water, and electricity. Infrastructure systems are special types of societal systems that include the physical artefacts and the institutions, which regulate and manage these systems [24]. With Freeman, we argue that any larger built environments are long-lived fixed assets that can constrain investments in the deployment of new solutions [25].

A stable incumbent regime is the outcome of various lock-in processes, and it favours incremental as opposed to radical innovation. As a result, incumbent technologies have a distinct advantage over new entrants, not because they are necessarily better, but because they are more widely used and diffused. The concept of lock-ins has been extensively used to explain the persistence of fossil fuel-based technological systems, even though their well-known environmental externalities contribute to climate change. Moreover, this 'carbon lock-in' inhibits the diffusion and adoption of carbon-saving technologies [21, 24]. In this regard, initially "minor changes and marginal developments may evolve into massive structural configurations that then restrict the variety of directions to future changes" [26:13].

What are the differences between *institutional and technological lock-ins*? Seto et al. [19] have discussed these differences: (1) Institutional lock-ins are intended and coordinated efforts. They are *not* early chance events like technological lock-ins. (2) Those who enforce these institutional lock-ins profit from them, while others do not. (3) Institutional lock-ins "occur more often and with greater intensity than technological lock-in[s]" (p. 433). However, both institutional lock-ins and technological lock-ins contribute to a trajectory that is resistant to change and that creates increasingly costly and challenging barriers to switching to any alternative trajectory.

Social practices of everyday life can be understood as configurations of meanings, skills, and material objects [27]. Meanings are here referred to as shared understandings and purposes guiding a practice. Skills are forms of routinised, embodied know-how and competence. The material dimension highlights the importance of material objects and infrastructures, which significantly shape the possibilities of practices to change over time [28]. These three elements of social practice can act as lock-ins for change. The social practice of dwelling, for instance, encompasses the material dimension of dwelling, including houses, flats, streets, towns, etc. Meanings include social norms for what is understood as a good and preferred form of dwelling, for example a single house with an individual garden, a shared house, or a flat in a multi-storey building. Skills can encompass maintenance skills, competence for energy efficient living etc. The different social practice fields, such as dwelling, mobility, eating and working, interact and form bundles of practices which can also act as lock-ins [28].

So, how can we overcome path dependence and lock-ins? The concept of *path creation* has gained special relevance in analyses of sustainability transitions [29]. Path creation has been used as a concept to examine how new and more sustainable niches may overcome incumbent systems, and in this way contribute to a sustainability transition [30]. With Simmie [30], we distinguish between the initial conditions of path dependence and ongoing path-creation experiments by different niche actors, planned actions and new path establishment processes to achieve critical mass, key path creation barriers, and envisioned outcomes.

Research on path-creation processes highlights that engaged and entrepreneurial actors are central to technological and societal change [31]. Typically, through long-lasting efforts and interaction between many actors, new paths of development are created which move beyond existing path dependencies. One type of such engaged actors operating in niches are intermediary organisations. The role of different *intermediary organisations* in sustainability transitions has been in focus recently [32-36], and has been proposed as central in accelerating sustainability transitions [32]. A key issue relating to the activities of intermediaries is their survivability and the source and long-term stability of their funding [36]. Kivimaa, Boon [32] define transition intermediaries as:

> "…actors and platforms that positively influence sustainability transition processes by linking actors and activities, and their related skills and resources, or by connecting transition visions and demands of networks of actors with existing regimes in order to create momentum for socio-technical system change, to create new collaborations within and across niche technologies, ideas and markets, and to disrupt dominant unsustainable socio-technical configurations" [32].

Intermediaries can be classified according to their visions, sources of funding, scope of activities, and intended targets (short-term vs. long-term, actor level or system-level outcomes) [37]. We can also distinguish between systemic-, regime-based-, niche-, process-, and user intermediaries [32]. Systemic intermediaries have different functions, such as using and interacting, network building, brokerage, consensus building, long-term strategy development, and creating conditions for learning by doing [38-40].

https://doi.org/10.52202/069179-0591

In this paper we apply the classification developed by Kivimaa, Boon [32], and applied by Vihemäki, Toppinen [41] who investigated the role of intermediaries in the diffusion of wooden construction of multi-storey buildings. They point out that intermediaries are able

> "to work across the often-impermeable boundaries between different actor groups, arenas of action, or geographical scales. Intermediaries are seen to play an important role in connecting actors in situations in which direct interaction is challenging because of high transaction costs, communication challenges and information asymmetries" [41].

4 METHOD AND DATA

We apply a mixed methods approach, combining media analysis, interviews, and document analysis. The media analysis is based on the retrieval of all printed newspaper and magazine articles (national, regional, local, trade press and magazines) published in Norway on wooden construction between 2011 and 2021. The data source is Retriever, the leading media monitoring company in Northern Europe. We applied a keyword approach and downloaded all the articles. Following keywords were used in the search: *(wood-based OR wooden) AND (buildings OR construction*)*
This covers both wooden buildings and constructions, but also wooden construction materials.

We read all the articles retrieved from the search. Furthermore, all the relevant articles were registered in an event database, containing all the necessary bibliographic information and the thematic focus of the articles. We distinguished between unique events to avoid double counting: some articles have been published in several newspapers, either with the same or similar titles. They were identified and in the final analysis they were only considered once, to avoid artificially high numbers. We registered 179 unique articles out of 235 articles. The media analysis also informed the other steps of the analysis, such as the selection of interviewees and the selection of commissioned reports and policy documents. The next step was to gain a broader insight through interviews with different actors identified in the media analysis and via the snowballing technique among interviewees. We created an interview guide and conducted 20 interviews (see Table 1).

Table 1: *Interviews (N=20)*

Type of organisation	Number of interviews
Private intermediaries	7
Cluster organisations	4
Systemic intermediaries	2
Niche project	1
Public agencies, ministries	6

The interviews lasted for about an hour, were conducted online and were recorded and transcribed afterwards. The interviews were analysed with NVivo, a qualitative data analysis software. Document analyses of important commissioned reports and policy documents, highlighted in the media analysis and during the interviews, completed the empirical background of the study. These documents were included in the NVivo analysis as well. As a result, we created a narrative addressing the research questions. Here, we concentrated on path dependencies and major obstacles for new developments, new pathways for more sustainable and wood-based construction, and not least the role played by intermediaries in shaping these pathways.

5 FINDINGS

Based on the media analysis, a timeline was constructed to point out the main developments in the sector. This timeline includes the following elements:

- main companies, important projects, municipalities, and intermediary organisations,
- political events and policy strategies,
- and barriers and challenges.

The development of media coverage since 2001 can be grouped into three periods:

1. 2011–2012: Introduction of policy instruments, but rather limited awareness.
2. 2013–2016: Political lobbying for public procurement of wooden buildings, strategy development, and the start of the first forest-based cluster organisation.
3. 2017–2021: Industrial capacity building, pilot projects and new intermediary organisations.

When analysing the new pathways for a more sustainable construction and building sector based on the use of wood, we need to first identify the existing path dependencies and lock-ins.

5.1 PATH DEPENDENCIES

Path-dependencies in the construction sector concern technology and material infrastructure, including learning effects, use of technology and materials, existing physical building infrastructures, high costs and a lot of waste; as well as institutional lock-ins, such as policy instruments and quality standards for construction; and social practices, such as preferences for living in single houses, lacking flexibility in dwelling solutions and lacking competences about effects of building materials on residents' wellbeing.
We mainly identified the following path dependencies, which function as barriers for new path creation:

Technology and material infrastructure:
The building and construction sector is traditionally dominated by solutions based on concrete, bricks, and steel, and the related skills. The existing physical building infrastructure in larger cities is dominated by multi-storey houses in steel, concrete and bricks, while smaller towns have more 1–2 storey-houses in wood. Many larger dwelling complexes in larger cities need energy efficiency upgrading, such as better insulation of walls, which is rather costly.

The *circular economy* is still not well established in the construction sector in general. Reuse and material recycling of wooden construction material is not well established in normal practice yet. Wood-based waste has mostly been used for energy production. Skills regarding the maintenance and improved energy efficiency of dwellings are outdated. Waste production at the construction site has been the usual practice, also in wood-based construction. Demolition of buildings, instead of maintenance and upgrading, have contributed to more waste. The EU's waste directive, to which Norway is affiliated through the EEA agreement, had as a goal that 70 per cent of the waste from both building and construction activities should be materially recycled by 2020. However, in 2020, only 44 per cent of the waste from construction activity was delivered for material recycling.

Costs of wooden construction materials are not stable, and changes are less predictable: A strong growth in costs for all construction materials as energy has become more expensive due to the war in Ukraine, the Corona pandemic, and supply shortages in Canada and other countries. Access to processed wooden construction material from Norway is limited. The import of the material creates higher transport costs and therefore less sustainable projects.

Documentation: The sustainability effects of modern wooden construction are not well enough documented, and this knowledge is not systematized. Technical solutions for fire, sound, rot prevention, wall coverings etc. need to get prequalified, approved, tested, and documented.

Code implementation: Wood-based construction must engage more in developing industrial standards (see institutional path dependencies). Wooden construction projects often require a longer design phase.

Lack of digitalisation happens often due to limited digital competency in the sector. Here, digitalisation is related to information flow, application of data, input parameters in production, and how one can make use of it. A lack of digitalisation leads to higher operation and maintenance costs because the construction process is less effective, things have to be changed constantly, and learning over time is limited. Today, there are far too many opportunities for the digital chain to be broken and inaccuracies to occur. Building Information Modelling (BIM) is the foundation of digital transformation in the architecture, engineering, and construction industry. The signals that most BIM systems create are too inaccurate for a Computerized Numerical Control machine in a factory to understand and to produce the right goods based on them. Therefore, full digitalisation must start with architects and planners.

Institutions:
Existing policy instruments are not adapted to the need for more sustainable construction, and they do not facilitate the use of wood in construction. Too narrow building regulations favour minimal demands regarding environment and climate. They also focus more on energy requirements and less on GHG emissions of materials. Furthermore, they do not include the operation of a building, as well as all the stages of construction. There are many actors in the wooden construction industry who argue for stricter requirements: The environmental product declaration should include the entire value chain, from the production of raw materials and transport of the raw materials to the actual construction site, the construction process, operation and maintenance, and finally how the building materials can be reused at the end of a building's life.

The *governance of the construction sector* in general and of wooden construction specifically is distributed over many ministries and public agencies, which leads to fragmentation of the political steering. This political fragmentation hampers coordinated strategies and better regulations. All these ministries and agencies issue directives and support schemes, which go in different directions and are often just restricted to a short period. Because there are so many policy actors, this is perceived as very bureaucratic and less impenetrable. Thus(?), policy learning across those different actors is quite impossible.

Public procurement regulations are misinterpreted, and often local administrations do no not favour wooden solutions in their tenders. Competencies in public administration is not updated, and there exist tighter connections with concrete and steel construction.

The *lack of ordering competencies* in municipalities contributes to maintaining established path dependencies. Municipalities are obliged to publish tenders for constructing schools, childcare, or elderly care. There are several municipalities who have developed ambitious climate strategies and link such tenders to these strategies. However, very many municipalities still ignore the new possibilities for sustainable construction because they lack competencies about how to include sustainability requirements for the choice of material in their tenders. Wooden construction solutions were traditionally restricted to 1 or 2 storey-buildings due to fire regulations, with little architectonic innovation.

Behaviour and social practice:
The building and construction sector is very *conservative* and there exist many conflicts. New wood-based solutions must compete with well-established practices in the steel and concrete industry, which also has improved their carbon footprint, instead of combining the most innovative and sustainable solutions from wood, steel, and concrete. Established entrepreneurs mostly favour proved solutions, where they already have collaboration partners and supply chains, and know the costs and the risks.

There are big challenges regarding *construction waste:* Wooden construction waste is commonly used as an energy source – so-called energy recovery – but this is not

https://doi.org/10.52202/069179-0591

material recycling. Large amounts of waste come from the established practice of tearing down existing buildings, and building new ones, instead of maintaining, retrofitting, and upgrading existing buildings.

Small and medium-sized enterprises (SMEs) have less of a focus on developing new competencies, collaborate little with higher education and research institutions, do not hire many new candidates with new ideas and competencies, and are not at the forefront regarding the deployment of innovation. The collaboration between SMEs is not well developed because the SMEs are afraid of losing a competitive advantage. Some of the *larger companies* are more active. Often, they do not want to carry the costs of being a fast mover in wooden construction but would rather sit and wait until the costs decline further. The willingness and ability of the Norwegian state and other public builders to *pay the high prices* of construction firms is a part of why these firms are not being forced into become more effective and innovative.
There is a lack of living space in larger cities due to restricted space and due to inflexible dwelling solutions. Large dwellings are not used effectively because elderly people don't want to leave their social environment and alternatives are not offered.

These path dependencies and lock-ins are of course interlinked and reinforce each other: The consequences are high energy and water consumption, high waste generation, GHG emissions, and extended use of extracted materials.

5.2 NEW PATHWAYS

We identified four types of new pathways for more sustainable and wood-based constructions. We distinguish between pathways that are centred on organising sustainable construction processes differently, pathways that lead to more sustainable and innovative wood-based construction technology, pathways for broader market developments, and pathways that are supported by changes in institutions and policy.

New pathways for organising a more *sustainable* construction process:

- *Cooperation of the value chains in the construction process:* The construction process is traditionally divided into three main stages: an early stage which includes planning and designing, the main construction stage, and the operation and maintenance of the building. However, we must also include the other value chains, which ensure the access to the wooden building materials. A closer cooperation between different parts of the value chain is required. This includes the industrial production of wooden construction elements. Moreover, modules from local resources allow much faster and more effective production, with less wooden residues.
- *Transportation:* The reduction of costs concerning transport of construction materials is one of the priorities for the industry. This implies shorter distances from the sawmills to the producers and the factories, but also improved transportation infrastructure, such as forest roads and bridges that allow transportation of larger volumes and access to containers.
- *Sustainability criteria:* The introduction of GHG accounting and Life Cycle Assessments allows builders to identify the key areas for necessary improvements: necessary efficiency gains, transport costs and emissions, waste reduction, as well as reuse and recycling.

New pathways for more sustainable and wood-based construction *technology*:

- *New technologies for timber constructions:* Cross-laminated timber (CLT), often combined with Glued laminated wood (Gulam) is used for building larger wooden constructions which replace steel and concrete solutions. The use of CLT was initially more common through import of material and competence from Austria. Later, own production capacity has been developed, which allows the use of local or regional timber resources, which has also lower GHG emissions.
- *Timber stud partition:* Norway has traditionally used timber stud partition for buildings up to 4 storeys, but now there is a new development: a pilot for using timber stud partition for 8 storeys buildings.
- *Hybrid materials:* Wooden construction elements are combined with other low-carbon construction materials, such as low carbon concrete or steel, recycled aluminium or glass, to deploy wood where it has the most advantageous characteristics, such as low weight and easy add-ons.
- *Retrofitting & superstructures:* Besides constructing new buildings in wood, a new market segment has received attention: (1) retrofitting of existing buildings with the help of prefabricated wooden façade elements, which allows a faster and less costly retrofitting process; (2) construction of wooden superstructures on top of existing apartment buildings and adding a lift house which better utilises the building ground and existing infrastructure in cities.
- *Prefabrication:* By automating the prefabrication processes, the construction process at the building site can be much shorter. Moreover, the working environment at the building site, especially regarding noise and dust, will improve dramatically. Wooden residues minimise, and costs go down.
- *Digitalisation:* A stronger focus on documentation of characteristics of each construction element is essential to facilitate the reuse of construction elements in future disassembly of buildings, which also will allow the reuse of these materials. Moreover, it will benefit from the digitalisation of the whole value chain, from forestry to sawmills, to producers of

construction materials, to the planning and design stage, to the construction process, and finally to the operation and maintenance stage. The use of digital twins allows a much better coordination in these processes.

New pathways for *broader market development:*

- *Niche development from show cases to individual one-off buildings:* In the first years, wooden construction concentrated on interesting show cases, such as the famous buildings for the Winter Olympic games in Lillehammer 1997 or the Gardermoen Airport in Oslo. However, it is difficult to move from huge show cases to a broad deployment of wooden construction, to achieve an upscaling of this niche. Therefore, an important step in that direction was the construction of individual one-off buildings, such as schools, kindergartens, and health care homes, commissioned by municipalities. This allowed entrepreneurs to learn and build collaboration networks. Many of these projects, such as schools etc., had repetitive characteristics, which allowed economic gains and reusing existing solutions.
- *Niche upscaling towards a mass market:* An important pathway has been the construction of residential buildings for students. These were not just one-off buildings, and were based on collaboration with student welfare organisations, which commissioned many buildings, such as in Ås, Trondheim, Fredrikstad and Oslo. A further step has been to move into the private market for industrial buildings in wood, being it office buildings or factories.
- *Cooperation with housing associations:* While the cooperation with municipalities targets the construction of individual one-off buildings, the cooperation with housing associations opens a market for larger volumes. Housing associations often have many buildings which need to be renovated and retrofitted (new facades). Many of the newer buildings have flat roofs, which allow extensions on the roof in light-weight wooden construction. Combined with added lift houses, this allows for building more flats that the elderly people can stay in (due to the new lifts). Moreover, this lowers the costs for the residents.
- *Export market:* The sale of Norwegian wooden construction materials is still concentrated in the domestic market, and the possibilities of the international market are not in focus.

New pathways for more sustainable and wood-based construction regarding *institutions and policy*:

- *Policy instruments:* Three dedicated policy instruments have provided public support for the use of wood in construction: Innovation Norway had a wood innovation programme, which also included co-funding, together with regional authorities of a national network of intermediary experts – so-called *tredrivere* – to facilitate the use of wood. The Ministry of Agriculture and Food has financed subsidies for the construction of wooden farm barns, and the Directorate for Environment has a funding instrument, Klimasats, that is supporting municipal projects in different areas of sustainability transitions. In one period there was a focus on municipal projects using CLT for schools, daily childcare, nursing homes, etc.
- *Public procurement:* The development of competence on public procurement rules in municipalities is essential to facilitate more sustainable solutions.
- *Initiatives for reuse and material recycling:* In 2021, the development of a Circular Resource Centre was started, which operates a National Knowledge Arena for reuse in the construction industry and a warehouse centre for used building materials. While this centre is for the construction industry in general, it has also been necessary to address reuse and material recycling in wood-based building and construction.
- *Regulation and standards:* The regulatory framework conditions for building with wood changed around the year 2000. According to the Planning and Building Act and technical regulations, it was allowed to build higher than three storeys. The technical regulations on the construction side have been focused on steel and concrete construction, both how they are formulated and how they are exercised. What we are seeing now is that sustainability criteria, such a LCA and CO_2 footprints, will be included into technical regulations and standards for construction materials. The European revised construction products regulation will also be effective in Norway when it is approved. This will include an assessment of construction materials regarding sustainability and documentation requirements for reused materials. This will be a driver for using wood as it has a lower footprint than other materials.

5.3 INTERMEDIARY ORGANISATIONS

Intermediary organisations have been very active in the development of these new pathways and in addressing the path dependencies and barriers discussed above. In the following we discuss the roles of different types of intermediaries in shaping the new pathways and how they generate new users and markets for wood-based construction materials. We take the new pathways, discussed above, as a starting point.

New pathways for organising a more sustainable construction process: Here we included issues related to the cooperation of the value chains in the construction process, transportation of materials, and sustainability criteria in the construction sector.
For these issues, two types of intermediaries were very active: systemic intermediaries and industry associations, a type of niche intermediary.

https://doi.org/10.52202/069179-0591

Systemic intermediaries pursue sustainability goals on a systemic level, but they do not belong to the wood construction niche. We could identify systemic intermediaries which take a more 'neutral' role concerning choice of materials, but they provide innovation arenas for experimenting with sustainable material use and architectures. Examples are the Norwegian Green Building Council, a member organisation of the building sector, and the Future Built Programme, owned by municipalities, ministries, and public agencies.
Industry associations: Treindustrien (The wood industry) for example, is an industry association for manufacturers of lumber and other wood-based building materials. This association works towards the national government, regional authorities, municipalities, and other public actors, through lobbyism regarding better framework conditions for wooden construction, improvements of transportation possibilities, and stricter sustainability criteria in technical regulations, standards, etc.

New pathways for more sustainable and wood-based construction technology. Here, we cover new technologies for timber construction, timber stud partition, the use of hybrid materials, retrofitting and superstructures, and automated prefabrication and digitalisation.
Regarding technological pathways, there were especially two types of niche intermediaries that were very active: cluster organisations and private niche intermediaries, in addition to the Wood innovation programme under the regime-actor Innovation Norway.
Niche intermediaries mediate between local projects, and/or at a higher level of aggregation. They are part of, and advance, the wood construction niche. *Cluster organisations*, like WoodWorks!, Norwegian Wood Cluster, and Tre på Agder (Wood in Agder), set clear goals to increase the use of wood in the construction sector and to facilitate the development and deployment of new technologies in their member firms. The cluster organisations also include research institutes, universities, and providers of vocational education and training, which develop new knowledge and a competent work force.
Private niche intermediaries are small companies, such as TreFokus, Trebruk, and Tretorget, who distribute knowledge and competence about new technology to municipalities and entrepreneurs.

New pathways for broader market development: This encompassed niche development from show cases to individual one-off buildings, niche upscaling towards a mass market and cooperation with housing associations.
Here, different types of intermediaries were very active. *Systemic intermediaries*, like Future Built, have made innovative projects more visible so that they can function as show cases.
Many *regime-based intermediaries* contributed to this market development, such as Innovation Norway, the Wood innovation programme and subsidies for the construction of farm barns under the Ministry of Agriculture and Food, and Klimasats under the Directorate for Environment. Public procurement by municipalities and other regional authorities, led to funding of sustainability projects at the municipal or county level. Two types of niche intermediaries have to be highlighted: A network of knowledge mediators financed by Innovation Norway and county authorities who support lobbying activities of an expert in each county for deploying wood, a so-called *Tredriver*. Moreover, the private niche intermediaries were decisive for starting entrepreneurial activities together with student- and housing associations.
The efforts made by these intermediaries have contributed to a better collaboration within and across the wood-based industry, such as between the forestry sector and the wooden construction sector. For example, intermediaries create learning arenas and connect actors by hosting seminars, site visits, field trips—nationally and abroad (e.g., to the Netherlands and Germany) —. as well as dissemination and communication work. They also connect companies with research groups and act as translators by assisting companies in applying for research grants.

New pathways for more sustainable and wood-based construction, regarding institutions and policy: This includes the development of dedicated policy instruments, competence for public procurement, policy for a circular economy, and regulations and standards.
Industry associations like Treindustrien have been active in lobbying for better political framework conditions, including regulations, standards, and support schemes. The network of knowledge mediators and the small private niche intermediaries were mostly active regarding the development of ordering competencies in municipalities for facilitating public procurement of wooden construction projects. Moreover, they contributed to attracting new users to create a demand for wooden construction solutions, and to support competence development—among others by working to change education institutions towards a greater focus on wood-based constructions.
For addressing the circular economy of wooden construction, there has been established a new large green platform project, SirkTre, which targets reuse and recycling of wooden construction materials. In this niche project, the Circular Resource Centre is a member, beside many other players in the sector. One of the goals is to function as a "reverse sawmill" and produce lumber again, from material-recycled wood. Lobbying for supportive policies for reuse and material recycling is a priority.

It is important to point out that, very often, the intermediaries work together: the cluster organisations cooperate with the small private niche intermediaries, the network of experts and the industry associations. Moreover, the intermediaries have close connections to the different actors in the technological innovation system around wooden construction: to knowledge providers, such as research organisations and architecture and engineering consultancies; to education institutions at different levels; to entrepreneurs, who have gained a lot of experience in wooden construction; and to

municipalities and other public builders, who have commissioned wooden buildings and can serve as a source of inspiration and competence about how to organise such processes.

6 CONCLUSIONS

The development of wooden construction depends on an interplay between technological innovation and the different actors in the innovation system, contributing to new path creation and overcoming existing path dependencies and lock-ins.

Development and deployment of new technologies for wooden construction needs to be accompanied by changed institutional conditions, regulations which require more sustainable solutions in the construction sector leading to reduced GHG emissions, reduction of waste and energy consumption, and changes in social practices of constructing. This requires competence development in all parts of the innovation system.

We mainly identified the following path dependencies, which function as barriers for new path creation: technology and material infrastructure, institutions, as well as behaviour and social practices. They are interrelated and reinforce each other, and they create social problems, such as lack of affordable dwellings in cities, high costs for energy efficiency and renovation measures, low shares of material reuse and recycling, and less flexibility to adapt dwelling spaces to new needs (for young families or for elderly people).

Intermediaries must address and break up these interlinked path dependencies and barriers for new path development.

Intermediaries evolve over time and get new roles, while older roles are taken over by other actors. Intermediaries need to broaden their horizon when lobbying for new, wood-based solutions, addressing such social problems.

When organising a *more sustainable construction process*, there were especially two types of intermediaries which were very active: systemic intermediaries and industry associations, a type of niche intermediary.

For the development of *more sustainable and wood-based construction technology*, there were especially two types of niche intermediaries which were very active: specialised cluster organisations and private niche intermediaries, in addition to the innovation programme under the regime-actor Innovation Norway.

New pathways for broader market development have been facilitated by systemic intermediaries like Future Built. Regime-based intermediaries nevertheless also contributed to this market development, such as Innovation Norway, the Wood innovation programme, and other programmes, as well as two types of niche intermediaries: a network of experts in each county, a so-called *Tredriver*, and the private niche intermediaries, who have been decisive for starting entrepreneurial activities.

The efforts made by these intermediaries have contributed to a better collaboration within and across the wood-based industry, such as between the forestry sector and the wooden construction sector. It is important to point out that very often the intermediaries work together and that the intermediaries have close connections to the different actors in the technological innovation system around wooden construction.

ACKNOWLEDGEMENT

We acknowledge funding by the Research Council of Norway for the project “Addressing climate change with innovation in the forest-based industry (Inno4Tree)” (Project number: 324167).

World Conference on Timber Engineering Oslo 2023

STATUS QUO OF AUSTRIAN TIMBER CONSTRUCTION SECTOR

Aída Santana-Sosa[1,2], Martin Aichholzer[1], Elena Mitrenova[1], Iva Kovacic[2]

ABSTRACT: The application of industrialized timber in large-volume buildings is considered as one main strategy promoting sustainability in the construction sector. Austrian timber construction ecosystem is mainly conformed by small and medium sized enterprises (SMEs) that are mostly limited to single and multiple housing projects and it is rarely represented in multi-storey buildings. Within a five days' workshop, 19 experts from research and practice including SMEs, discussed the challenges and potentials, and specially the implication of SMEs, by the completion of those, exchanging experiences and expertise. The workshop was inductive coded looking for factors affecting the design and construction process, in which seven categories were defined containing 33 overall concepts with 105 factors embedded. Further, a SWOT analysis was conducted, in which over half of all factors are conflicts, mostly related to the coordination of the team along the process, mainly caused by the lack of an integrated design approach. Highly positive rated are those aspects related to greater levels of prefabrication, while general rising awareness together with political support represent relevant opportunities, and common prejudices a threat. This overview of the sector may help further research to develop strategies focused on handling internal factors to exploit opportunities and minimize threats.

KEYWORDS: Multi-storey timber buildings, off-site construction, design and construction process, SWOT Analysis

1 INTRODUCTION

Construction sector has been performing widely unsatisfactorily along decades. While productivity [1], digitalization, profitability and customer satisfaction remain low, risks, claims, fragmentation, insolvencies, and budget, and time overruns arise [2]. Its ecological and environmental impact has become also an issue, as it is responsible for 32% of the waste generated annually [3] and the largest producer of CO_2 emissions worldwide [4], being a large part of these a result of cement production [5]. A shift in construction sector, including processes and working methods, is expected in an early future, in which the introduction of new materials and the promotion of the digitization, the industrialisation and the automation will play a major role as a response to combination of higher sustainability requirements, increased cost pressure and a general shortage of skilled workers [2]. Industrialized timber construction is seen as an attractive ecological, economic and social solution to reshape the sector and assess its significant impact, especially in terms of resource efficiency, comfort and carbon emissions together with their atmospheric concentration [6–10]. This disruptive solution is gaining interest from various stakeholders, meaning great chances to take the lead in upcoming years, but also large concerns related to the lack of experience of new entrants. Due to its multi-layered character and own value and supply chain, planning and building with timber involves different actors, approaches and expertise [11, 12], and yet there exists no common understanding about interdependences what leads to inefficient collaboration and large conflicts meaning higher costs, time overruns, tension and dissatisfaction [13]. Previous studies have shown higher concerns in the production and assembly phase of a industrialized timber construction than in the acquisition and design phase [14]. Timber construction companies in Austria are small and scattered, and the structure of the industry is very fragmented and locally organized [15]. Its traditional approaches and its average sizes lead to mostly small projects. For example in 2019, 65% of all new buildings were residential and with one or two apartments, while just 11% had three or more apartments [16]. Nevertheless, a growing trend towards multi-storey timber construction can be appreciated within the last years [17], where the involvement of small and medium-sized enterprises

(SMEs) is very challenging. On the one hand, this small size reduces the competitiveness of those companies in the completion of large-volume residential constructions in comparison to their larger competitors on the market. On the other hand, through this regional supply chain and fragmented structure, local value is added and resilience in crises is ensured. In addition, the global monopoly positions of large companies should be reduced to the detriment of local companies in order to facilitate a social balance. This study deals with the identification and analysis of factors affecting the completion of multi-storey timber buildings, specifically from the point of view of SMEs.

2 METHODOLOGY

This explorative study was developed based on two previous projects, a series of round tables organised by *MAGK Architekten* and *ecoplus Bau.Energie.Umwelt Cluster NÖ* named *Holz.System.Bau* [18], and a multi-case qualitative analysis based on experts' interviews [14], where the main barriers against timber use in large-volume constructions were analysed and strategies were discussed. This specific workshop called *Holzbau 4.0* was developed and run by the Vienna University of Applied Sciences in cooperation with *ecoplus Bau.Energie. Umwelt Cluster NÖ,* and funded by the Austrian Agency for the promotion of research *FFG* (*Österreichische Forschungsförderungsgesellschaft*). The five days' workshop was recorded, documented and inductive coded within several iterative rounds. Additionally, a SWOT analysis was run, in which the defined codes were classified as Strengths, Weaknesses, Opportunities and Threats. Figure 1 represents the overall process of this study with its steps from data collection to analysis and findings.

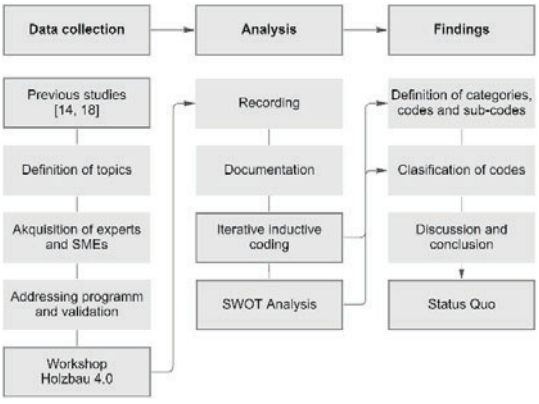

Figure 1: *Overview of the project*

2.1 DESCRIPTION OF THE WORKSHOP

The five days-workshop aimed to offer an exchange platform where to discuss the status quo of the industry with its barriers and opportunities. Once the overall topics were defined, participants were purposive sampled. Experts from science and practice including SMEs were selected to participate actively in the workshop. Several previous cooperative rounds were organized to address specific topics, goals and working methods, in alignment with the needs of all 19 participants, conformed by three researchers and seven planners with an average experience of 20 years, and nine professionals with key roles from six SMEs, including carpentry and timber components, glass construction, pluming, roofing, and lean management (Table 1).

Table 1: *Summary of participants within the workshop*

Area of expertise	N° participants
Research	3
Architectural design	5
Specialist consultants	2
SMEs employees	9

The workshop combined theoretical inputs and practical application in form of a cooperative project exercise with group discussions and reflexions, and was organized around the following five thematic blocks:

1. Team and process
2. Business models and cooperation processes
3. Systemisation and digital tools
4. Prefabrication and logistics
5. Equal opportunities

The first unit addressed a common understanding of an expected change in construction sector and its processes due to digitization and automation, exploring new ways of thinking, and establishing a common vision about the innovativeness, resilience and competitiveness of SMEs. Within the second unit, various business models and cooperation processes were explored, including legal framework and specific logistical, technical and digital aspects and requirements for large-volume timber buildings. The focus of the third unit was on systemisation, standardisation and digital tools for collaborative work. Design and production planning were compared in terms of level of information, development and detail, while several digital tools for design and production were explored, including their interfaces, working processes and information exchange. Building services and their standardization were extensively explored, together with prefabricated wall-elements and volumetric modules. The fourth unit was dedicated to production, prefabrication and logistics, where best practice examples were discussed, and methods based on Lean Management and efficient logistics were explored, together with their application to design, production and assembly. Topic of the last unit was equality and fair opportunities encompassing different social and political aspects, like funding, anti-discrimination, and laws. To conclude, feedback was collected, and a networking round offered to ease possible future cooperation.

To practically assess the acquired knowledge, participants were divided in two teams for an interdisciplinary and

cross-company teamwork to analyse two different existing multi-storey residential buildings and collaboratively develop a new planning and construction process, aligning trades, identifying interfaces and players, and optimising tasks with milestones and deliverables. Both projects were alike in terms of volume, construction and height, but different in the financing type, being one private and the other one public with their corresponding focus, process model and tendering as shown in Table 2.

***Table 2**: Description of both projects*

	Project A	**Project B**
Approach	Private	Public
Focus	Individuality	Fixed budget
Quality	High-Tech	Low-Tech
Process model	Cooperative	Traditional
Time of tendering	Irrelevant	Fixed

Besides exploring suitable cooperative planning and building systems and its intrinsic high competence level, other soft aspects like trust, willingness to work together and innovative ways of thinking were discussed.

3 FINDINGS

3.1 QUALITATIVE ANALYSIS

The five days' workshop was analysed qualitatively through an iterative process of coding and categorizing. Excerpts representing relevant factors affecting the correct and efficient design and construction of multi-storey timber buildings were referred into sub-codes and further organized into codes and overall categories. A total amount of 105 sub-codes were identified and structured into 33 codes and seven categories according to their content and relations. The distribution of categories and their codes is shown in Figure 2.

The category *team and process* is the one with the highest amount of codes with seven, followed by the categories of *product and performance*, *mind-set of the industry* and *competence and expertise* with six codes each (Figure 3). *State of the industry* has five codes and the categories with the fewest numbers of codes are *awareness* with two, and *politics and funding* with one. Attending to the sub-codes embedded in each code the relevance of the categories remains the same, being the only difference the higher amount of sub-codes by the category *state of the industry* with 15 in relation to the ones by *competence and expertise* with 13. Therefore, the same structure remains, being *team and process* the one with the highest amount of sub-codes with 25, followed by *product and performance* with 19, and *mid-set of the industry* with 17. The categories *awareness* and *politics and funding* encompass 11 and five each.

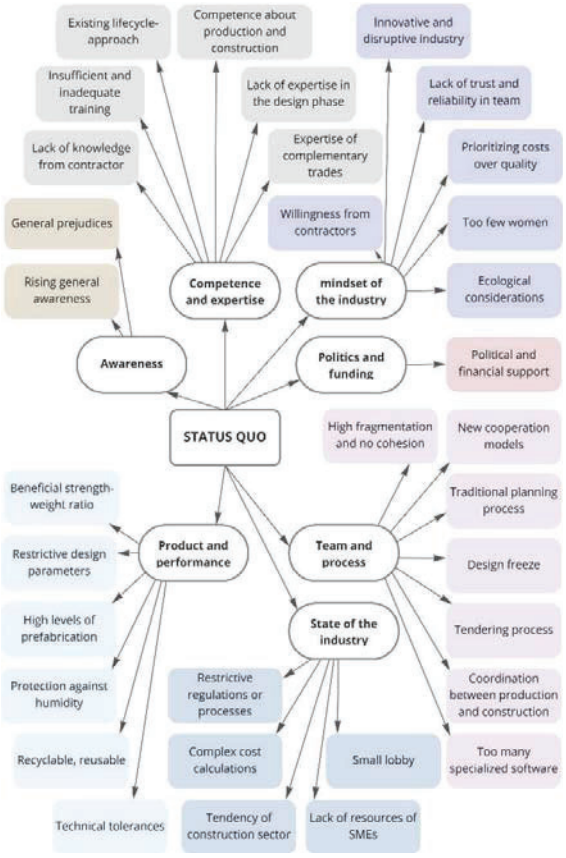

***Figure 2:** Relation of codes and categories*

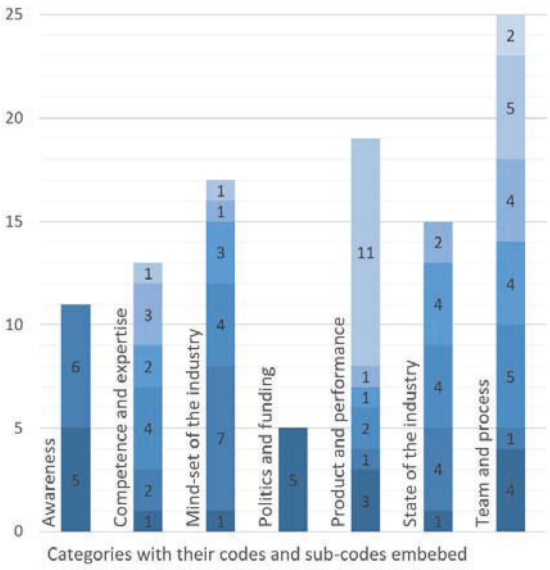

***Figure 3:** Categories with their embedded codes and sub-codes*

https://doi.org/10.52202/069179-0592

3.1.1 Awareness

This category refers to the consciousness of general society related to the capabilities and properties of timber applied to large volume construction and encompasses two codes with overall 11 sub-codes as represented in Table 3.

In common terms there exists a great deal of mistrust and scepticism towards industrialized timber constructions, based mainly on general prejudices of inadequate performance related to cost efficiency, fire protection, noise insulation, structural response and durability. Nevertheless, a changing attitude and a rising general awareness about more sustainable procedures have been recognized. The ecological and healthy properties of timber supports this shift as a response to the rising resource scarcity, the higher carbon emissions and the new social and economic requirements of the sector and society.

Table 3: *Sub-codes and codes in the category "Awareness".*

Awareness (2) (11)	
General prejudices (5)	**Aw1**
· Too expensive	
· Fast combustion	
· Not enough noise insulation	
· Lack of durability	
· Little structural resistance	
Rising general awareness (6)	**Aw2**
· End of fossil energy and materials	
· Ecological properties of timber	
· Aesthetics and comfort	
· New generation, new requirements	
· Resources scarcity	
· Shared economy incl. platforms	

3.1.2 Competence and expertise

Due to its multi-layered character, its material properties and its different value and supply chain, planning and building with timber implies specific approach and competence, which are different from those widely used within mineral constructions. Related to this issue, six codes with 13 associated sub-codes were defined and are represented in Table 4.

A common lack of knowledge and expertise was found from the side of the contractor, complementary trades and planners. Due to their little experience, contractors refuse to build with timber, while the lack of expertise of complementary trades implies higher mistakes rate on site and therefore higher coordination efforts to avoid them or minimize their impact. General architects and engineers also lack competence related to the higher complexity of large industrialized timber constructions, mainly due to insufficient and inadequate training, where little know-how is found as well in common architectural and engineering trainings, as in specialized. On the contrary, there exists a recognisable competence of manufacturers and construction companies about production and construction, and a beneficial lifecycle-oriented approach.

Table 4: *Sub-codes and codes in "Competence and expertise".*

Competence and expertise (6) (13)	
Competence about prod. and constr. (1)	**Co1**
· High competence of manufacturers and constr. companies	
Insufficient and inadequate training (2)	**Co2**
· Lack of know-how in conventional training	
· Lack of specialized trainings	
Lack of expertise in the design phase (4)	**Co3**
· Related to common planers	
· High complexity of specific software	
· Overestimation of own competence	
· Underestimation of complexity	
Existing lifecycle-approach (2)	**Co4**
· Interdisciplinary multi-layered character	
· Lifecycle costs approach	
Expertise of complementary trades (3)	**Co5**
· High mistakes rate related	
· Higher coordination effort on site	
· Lack of competence or expertise	
Lack of knowledge from contractor (1)	**Co6**
· Little knowledge and experience	

3.1.3 Mind-set of the industry

In this category, those aspects related to the attitude or way of thinking of the construction sector are referred, encompassing six codes and 17 sub-codes (Table 5).

Table 5: *Sub-codes and codes in "Mind-set of the industry".*

Mind-set of the industry (6) (17)	
Green washing (1)	**Mi1**
· Use of timber as marketing	
Innovative and disruptive industry (7)	**Mi2**
· Towards open mind-set, ready for new	
· Open-source databases (projects / network)	
· Rising number of small start-ups	
· Rising number of young experts	
· Little speculation	
· Transfer of Lean concepts	
· Rising number of independent planning eng.	
Lack of trust and reliability in team (4)	**Mi3**
· No transparency / communication	
· Lack of trust and reliability in design team	
· Lack of trust between SMEs	
· Silo thinking and lack of cooperation of SMEs	
Prioritizing costs over quality (3)	**Mi4**
· Criteria within arch. competitions	
· Criteria within tendering processes	
· Conventional investments' criteria	
Too few women (1)	**Mi5**
· Too few and with no key roles	
Willingness from contractors (1)	**Mi6**
· Rising willingness	

Although the rising willingness of contractors to build with timber is remarkable, conventional investment criteria based primarily on prioritising cost over environmental or health benefits make its actual implementation difficult, as it occurs within architectural competitions and tendering processes. At the same time, the misuse of timber as "green washing" represents a threat that must be kept under control. Focusing directly on the timber industry, its innovative character was highlighted, with the transfer of concepts from other industries as well as disruptive start-ups, open-source platforms, young experts and independent planning engineers playing a role, but in which women are too rare and with no key positions, and a general lack of reliability between players is found.

3.1.4 Politics and funding

Only one code with five sub-codes comprehends this category, where current topics related to political and financial support were addressed (Table 6).

The great environmental impact of construction sector has led to the development of several political initiatives to promote and accelerate a shift from a mineral-based and resource-intensive sector towards a bio-based and resource-saving one, including circular economy and re-densification as a reaction of current shortage of urban space and resources, with timber playing an important role. Existing European initiatives to promote sustainable building methods were discussed as examples for their application in further countries, including the French government's requirement to use at least 50% wood and other bio-based materials in all new public buildings [19]. Additionally, carbon fees and financial support for circular bio-based constructions help to minimise the use of carbon intensive materials.

Table 6: *Sub-codes and codes in "Politics and funding".*

Politics and funding (1) (5)	
Political and financial support (5)	**Po1**
· Carbon (CO_2) fees	
· Financing of bio-based construction	
· Reinforcement of re-densification	
· Fix % of timber in public financed projects	
· Rising awareness towards circular economy	

3.1.5 Product and performance

This category contains the higher amount of codes with six and sub-codes with 19 (Table 7) after the category *team and process*, and refers to the characteristics of timber as construction material.

Recyclability was highlighted as highly advantageous, as was the strength-to-weight ratio, which allows great degrees of prefabrication and therefore higher material efficiency and quality due to industrialised production processes, reliable stock-keeping, cost and time calculation, as well as shorter overall project time due to optimised assembly work on site with less coordination efforts and parallel work in the factory. Further benefits of prefabrication include the construction of mock-ups to run different tests and the possibility of tracking the whole supply and production chain. At the same time, specific parameters related to production, transport, assembly and structural performance influence the design. Particular attention must be paid to tolerances to other materials and moisture protection, especially on the construction site and for building elements, but also when planning the building services and the façade.

Table 7: *Sub-codes and codes in "Product and performance".*

Product and performance (6) (19)	
Protection against humidity (3)	**Pr1**
· Complex planning of building services	
· Protection of the façade	
· Protection of building elements and site	
Recyclable, reusable (1)	**Pr2**
· Recyclable, reusable	
Restrictive design parameters (2)	**Pr3**
· Raster (uneconomical free forms)	
· Transport requirements	
Technical tolerances (1)	**Pr4**
· Between concrete and timber	
Beneficial strength-weight ratio (1)	**Pr5**
· Beneficial strength-weight ratio	
High levels of prefabrication (11)	**Pr6**
· Higher production quality	
· High industrialized production	
· Material efficiency (excl. CLT)	
· Mock-up (simulation and technical proof)	
· Reliable cost estimations after tendering	
· Reliable stock planning	
· Reliable time estimation	
· Parallel work on-site and in the factory	
· Tracking (RFID / QR-Code)	
· Assembly site (shorter construction time)	
· Less trades on site (less coordination)	

3.1.6 State of the industry

Aspects related to the current situation of the industry, including its capacities and developments, are assigned to this category, which encompasses five codes and 15 sub-codes as represented in Table 8.

In general, there are restrictive or inadequate regulations or procedures that make the use of timber difficult, especially with regard to fire protection or maximal height, and their different local specifications, but also the material-neutral character of most architectural competitions and the required technical proofs for specific construction elements and connections, before and after tendering. One way to force the needed adjustment of those is seen in the move of the construction sector towards a digitally connected, product-based approach, in which timber can play a main role due to its increasingly digital and industrialised manufacturing. Nevertheless,

https://doi.org/10.52202/069179-0592

the timber sector has a small lobby with little influence on policies and a general low willingness of decision-makers to build with timber, partly due to the higher complex cost estimation before tendering and a lack of planners and reference projects, as well as an own timber oriented network. Also at the construction side, very few companies can act as general or total constructors and accomplish large timber constructions, as the ecosystem consists mainly of labour-overloaded SMEs with inadequate infrastructure and low financial strength and bank confidence.

Table 8: *Sub-codes and codes in "State of the industry".*

State of the industry (5) (15)	
Complex cost calculations (1)	**St1**
· Complex and not standardized	
Restrictive regulations or processes (4)	**St2**
· Material neutral arch. competitions · Technical proof of each solution · Restrictive regulations (fire, height…) · Lack of common standards (fire, noise…)	
Small lobby (4)	**St3**
· Acquisition of projects through own network · Small pool of partners · Lack of influence in policies · Little predisposition of decision-makers	
Lack of resources of SMEs (4)	**St4**
· Lack of financial capacity · Lack of infrastructure · Too few companies as general or total constr. · Resistance to adaptation (overloaded)	
Tendency of construction sector (2)	**St5**
· Towards product-based construction · Towards industry 4.0 (Smart/Virtual Factory)	

3.1.7 Team and process

This category has the highest number of both, codes with seven and sub-codes with 25 (Table 9), and includes aspects related to the coordination of stakeholders within design and construction along the course of a project.

The small and fragmented structure of SMEs limits cohesion due to locally organised logistics and own internal systems, resulting in an overwhelming repertoire of solutions that cannot be combined, and makes cooperation difficult, for which they often have to work as sub-constructor. The traditional linear planning process separates design and construction and therefore limits the inclusion of timber expertise in early design stages, including designers, manufacturers and suppliers. This results in complex and elaborate tendering processes with few bids, where details and joints have to be adapted, leading to an unnecessarily higher design workload forehand and extra redesign efforts after the tender. This planning process also complicates an interdisciplinary approach and the involvement of other disciplines such as building services, which reduces the required greater definition for the correct application of prefabrication. Several international cooperation models were discussed as examples of how to overcome this separation, which should be digitally supported, for what there are still too many incompatible specific software on the market. Another aspect to take into account is the need for a design freeze, where no late decisions or accompanying planning are possible, and therefore, an early inclusion of users' wishes is necessary. After the design freeze and tenders, the production line and construction site with their specific suppliers, capacities and delivery times must be coordinated including the combination of different elements, their transport and store logistics.

Table 9: *Sub-codes and codes in "Team and process".*

Team and process (7) (25)	
High fragmentation and no cohesion (4)	**Te1**
· Close systems and platforms (logistics) · Too many possible solutions · Lack of combination of 2D and 3D prefabrication · Traditional construction process (sub-constructor)	
New cooperation models (1)	**Te2**
· Alliances (UK, USA and Canada)	
Traditional planning process (5)	**Te3**
· No interdisciplinary approach · High influence of financing type to the process · Late inclusion of timber competence in design · Lack of prefabrication of building services · No inclusion of manufacturers and suppliers in the design (detailing)	
Design freeze (4)	**Te4**
· Early involvement of end-user (wishes, goals) · Late decisions (end-users, contractor, planners…) · Earlier higher definition · No accompanying planning possible	
Tendering process (4)	**Te5**
· Complex and elaborate tendering · Redesign after tendering (in-house systems) · Over-processing (interface between arch. to prod.) · Reduced bids, higher resources (redesign)	
Coord. between prod. and constr. (5)	**Te6**
· Higher logistics related to transport · Store capacity and time (logistics) · Different delivery times · Coordination between timber and concrete constr. · Coordination between prod. and constr. capacity	
Too many specialized software (2)	**Te7**
· Incompatibility between software · Open BIM still works like file transfers	

3.2 SWOT ANALYSIS

After coding and categorizing all identified factors, a SWOT analysis was carried out, checking that the sub-codes were also related to the character of the labelled code and ensuring coherence. Figure 4 represents all factors characterized as strengths, weaknesses, opportunities and threats, including codes and sub-codes.

Strengths and weaknesses refer to positive and negative internal aspects respectively. In contrast, opportunities and threats picture external factors that affect positively and negatively each. The amount of global internal aspects (strengths and weaknesses) is four times higher than the external ones (opportunities and threats). Analysing the proportion of positive and negative factors, the sector is represented with a two times higher amount of negative aspects (including weaknesses and threats), than overall positive factors (strengths and opportunities). Figure 4 represents the distribution of all codes and embedded sub-codes according to their character. Weaknesses embody over half of all factors, while strengths only around 1/5 of all factors, and opportunities and threats 1/6 and 1/17 each. That means that the sector is highly aware about its own issues and should develop strategies and set objectives to exploit own strengths and address own weaknesses with its current resources and capabilities, since its control over internal factors is higher than over external ones. These last ones can be influenced or at least anticipated, in order to avoid or minimize their impact, or to take advantage from them, but not fully controlled. All strengths, weaknesses, opportunities and threats are described in detail in the following sections.

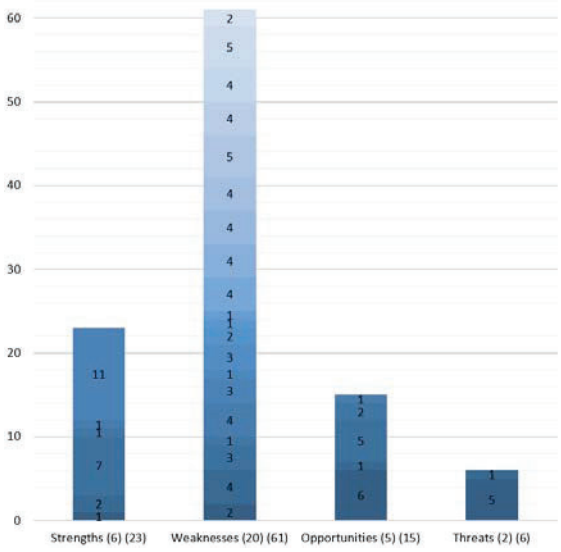

Figure 4: *Summary of all codes and their embedded sub-codes classified according to the SWOT analysis.*

3.2.1 Strengths

Table 10 shows a summary of all strengths, including their sub-codes, ranging from one to 11, with an average of 3.8, and representing around 1/5 of all factors with six codes and 23 sub-codes.

The high expertise about production and construction from manufacturers and construction companies together with the existing lifecycle-approach of the industry represent two strengths regarding *competence and expertise*, what ensure an efficient and effective erection of large timber constructions. Related to the *mind-set of the industry*, its innovative and disruptive character is a positive and significant factor with seven sub-codes that supports relevant improvement potential, while the recyclability and beneficial strength-to-weight ratio of timber represent two strengths related to the *product and performance*. Its consequent higher workability and greater prefabrication levels have the highest number of sub-codes with 11, being therefore the most discussed factor and the best-rated strength.

Table 10: *Codes identified as Strengths.*

Strengths (6) (23)	
Co1	Competence about prod. and const. (1)
Co4	Existing lifecycle-approach of the industry (2)
Mi2	Innovative and disruptive industry (7)
Pr2	Recyclable, reusable (1)
Pr5	Beneficial strength-weight ratio (1)
Pr6	High levels of prefabrication (11)

3.2.2 Weaknesses

Weaknesses encompass over half of all identified factors with 20 codes and 61 sub-codes ranging between one and five with an average of 3.3 (Table 11).

One of the most relevant weaknesses is the traditional linear planning process, which together with the lack of expertise in the design phase and reliability within the team, caused by inadequate specific training, constrain the right definition of industrialized constructions and their required design freeze. By separating design and construction, an integrated design is impracticable, where the amount of incompatible specialized software is also a problem. Mineral-oriented regulations, which have not been adapted to industrialised constructions mainly due to the small lobby of the sector, limit an earlier and correct assessment of timber buildings. Further, the high fragmentation and lack of cohesion of the industry make tendering processes complicated with complex cost calculations, fewer offers and re-design efforts, where also the prioritizing of cheapest offers over quality plays a negative role. Another major conflict is the coordination between production and construction, needing higher logistics, which may be caused by the lack of resources and infrastructure of SMEs. Although prefabrication was the most highly rated strength, the specific design parameters related to material properties and production and transport measures, and the consideration of technical tolerances to other materials are disadvantageous. Protection of the elements and the site from rain and moisture, together with increased coordination efforts on site due to the lack of experience of the complementary trades, represent further disadvantages.

https://doi.org/10.52202/069179-0592

Table 11: *Codes identified as Weaknesses.*

Weaknesses (20) (61)	
Co2	Insufficient and inadequate training (2)
Co3	Lack of expertise in the design phase (4)
Co5	Expertise of complementary trades (3)
Co6	Lack of knowledge from contractor (1)
Mi3	Lack of trust and reliability in team (4)
Mi4	Prioritizing costs over quality (3)
Mi5	Too few women (1)
Pr1	Protection against humidity (3)
Pr3	Restrictive design parameters (2)
Pr4	Technical tolerances (1)
St1	Complex cost calculations (1)
St2	Restrictive regulations or processes (4)
St3	Small lobby (4)
St4	Lack of resources of SMEs (4)
Te1	High fragmentation and lack of cohesion (4)
Te3	Traditional planning process (5)
Te4	Design freeze (4)
Te5	Tendering process (4)
Te6	Coordination between prod. and constr. (5)
Te7	Too many specialized software (2)

3.2.3 Opportunities

The five opportunities with their 15 sub-codes are shown in Table 12 with an average of 3.0., and representing 1/6 of all factors.

The main opportunity is the general increase in awareness, which can expand the collective pressure to accelerate the sector's shift towards more sustainable strategies that reduce embodied carbon and store carbon in buildings while forests sequester it. Political and financial support is seen as a major opportunity to support this transformation by promoting bio-based solutions. The tendency of construction sector from design-oriented to product-oriented is also considered as a chance to promote prefabrication, what together with a perceived higher willingness of contractors and the implementation of new cooperation models represent relevant opportunities for the right design and construction assessment of large timber constructions.

Table 12: *Codes identified as Opportunities.*

Opportunities (5) (15)	
Aw2	Rising general awareness (6)
Mi6	Willingness from contractors (1)
Po1	Political and financial support (5)
St5	Tendency of construction sector (2)
Te2	New cooperation models (1)

3.2.4 Threats

Threats summarize the fewest amount of factors with only two codes and six sub-codes, as shown in Table 13, and representing around 1/17 of the total discussion.

Common prejudices like insufficient fire protection or noise insulation represent the most threatening aspect that affect the wider implementation of timber in large constructions with five embedded sub-codes, where a better communication of its benefits could help. At the same time, its misuse as the so-called green washing could be enormously disadvantageous, and therefore should be avoided and coherently implemented.

Table 13: *Codes identified as Threats.*

Threats (2) (6)	
Aw1	General prejudices (5)
Mi1	Green washing (1)

4 DISCUSSION

Locating all strengths, weaknesses, opportunities and threats in their corresponding categories, an overview of the status quo of the timber sector with its positive and negative factors is shown in Figure 5.

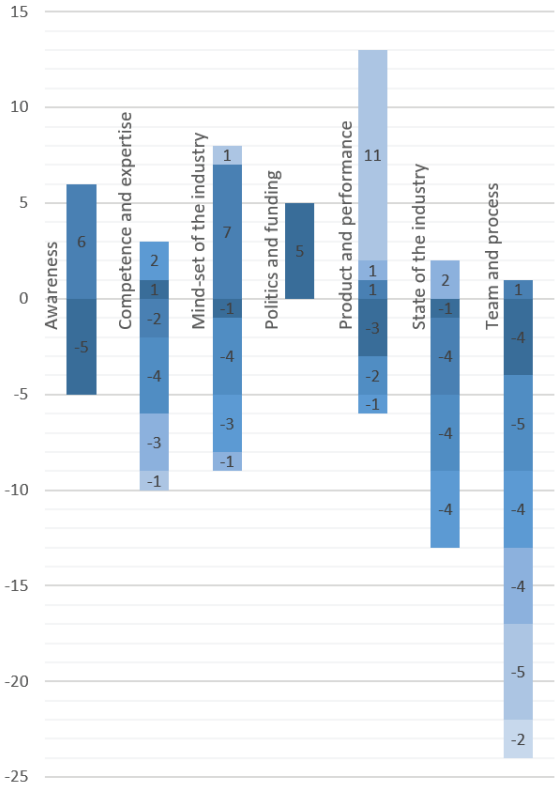

Figure 5: *Positive and negative aspects related to their categories*

Team and process, *product and performance* and *mind-set of the industry* were the most discussed categories with the highest number of codes and sub-codes as shown in Figure 3. *Team and process* account the greatest number of both codes and sub-codes with seven and 25, being all

of them except one classified as weaknesses what makes it the most conflictive category. Only the application of new cooperation models is seen as an opportunity to overcome all the weaknesses in this category, which are mainly caused by the traditional lineal and fragmented planning process with its separation of disciplines constraining a coordinated and cooperative working method with a design freeze and making tendering processes complicated.

Contrary, the second most discussed category, *product and performance*, is the one with the highest amount of strengths with three codes and 13 sub-codes which encompass aspects related to the recyclability and workability of timber and its associated higher levels of prefabrication. At the same time, three codes with six sub-codes were classified as weaknesses, which relate to the restrictive design parameters due to off-site construction and their correlated technical tolerances to other materials and the necessity of rain and moisture protection of the elements and the site.

Mind-set of the industry may be the most controversial category, being the third most discussed and sharing equally positive and negative sub-codes. Its innovative and disruptive character is seen as a great strength with seven sub-codes that could help against weaknesses by increasing trust in the team, and fostering gender equality, as well as rewards based on quality rather than on the cheapest offer. Further, a perceived increase in the willingness of contractors to build with timber is seen as a great opportunity to implement its use, but in a coherent way and no as green washing, what is considered a threat.

State of the industry is the second most conflictive category after *team and process*, where only one code with two sub-codes are classified as opportunities, and four codes with 13 sub-codes as weaknesses. Many regulations are not aligned with industrialized construction, which limit common standards and increase complexity, making the sector unattractive, which therefore consists on few overburdened experts lacking resources and infrastructure. The tendency of the sector from a design-based and labour-intensive construction site towards a product-based assembly site is seen as a chance to force the required adjustments and ease the completion of industrialized large timber constructions.

The third most conflictive category is *competence and expertise*, where two codes with three sub-codes are rated as strengths, while four codes with 10 sub-codes as weaknesses. There exists a lack of adequate specific training in architectural and engineering degrees, leading to very few competent designers or rather little expertise in design, and conflicts at the interface with construction. Parallel, complementary trades lack of experience causing greater coordination efforts on site due to higher risks. On the contrary, construction companies and manufacturers have remarkable knowledge regarding production and construction that should be exploited and transferred, together with the holistic design approach of experts covering the lifecycle of buildings and materials.

The category *awareness* encompasses equal number of codes and sub-codes classified as opportunities and threats. The rising general awareness about reducing carbon emissions and using more sustainable materials should be exploited, while general prejudices minimized.

The least discussed but most highly rated category is *politic and funding*, since its single code with five sub-codes are classified as opportunities. This category covers policy and financial support to move from lineal constructions with carbon-intensive materials to circular buildings with bio-based materials.

5 CONCLUSIONS

A wider use of timber within large-volume construction is seen as a disruptive ecological, economic and social solution to mitigate the great environmental impact of construction sector, while increasing wellbeing, productivity and promoting circular economy. On the one hand, its bio-based nature reduces carbon emissions, absorbs it from the atmosphere and stores it in the long term, while on the other hand, its renewable character and beneficial strength-to-weight ratio alleviates the scarcity of resources and the lack of urban space respectively. It also promotes higher productivity and resource efficiency thanks to its greater levels of prefabrication and advanced industrial production logistics. These characteristics imply different actors, processes and expertise than for mineral constructions, leading to a multitude of errors, inefficiencies and misunderstandings. This study takes a close look to the factors affecting the right definition and completion of large-volume timber constructions with a special focus on the production and construction side by implying SMEs with their expertise and experience. A five days' workshop was organized with 19 experts from science and practice including SMEs employees with key roles, where challenges and chances of their implication in the completion of multi-story timber buildings were discussed. The explorative study was inductive coded, where 105 factors were identified and labelled into 33 more generic concepts and organized into seven categories. Further, a SWOT analysis was run, in which the recognized strengths, weaknesses, opportunities and threats were located in their corresponding categories. The coordination of the team along the process to achieve an integrated design, which supports the right assessment of prefabrication, represents a major conflict, while prefabrication itself with their corresponding benefits is considered the greatest strength of the sector. Cooperation models supported by the tendency of construction sector towards a product-based approach are seen as opportunities to overcome this prominent barrier and exploit this strength. A general rising awareness together

https://doi.org/10.52202/069179-0592

with political support to move away from carbon intensive materials represent another relevant opportunity, while common prejudices related to insufficient fire protection constitute a main threat. Further research may use this overview of the status quo of the sector to develop strategies and set objectives, in which internal strengths can be used to exploit external opportunities (SO strategies), as well as to avoid or minimize the impact of external threats (ST strategies). At the same time, internal weaknesses can be overcome by exploiting external opportunities (WO strategies) while minimizing external threats (WT strategies).

ACKNOWLEDGEMENT

Authors want to express their gratitude to all contributors for their encouragement in seeking for sustainability. Special thanks to the Austrian Agency for the promotion of research "FFG" (*Österreichische Forschungs-förderungsgesellschaft*) for funding this project (Project number 884233).

THE ROLE OF BOARD INTERLOCKS IN INCREASING THE USE OF WOOD IN CONSTRUCTION

Silje Marie Svartefoss[1]

ABSTRACT: This paper studies the existence of board interlocks between wood-based firms in the construction supply chain and firms in other industries and their role in enabling increased use of wood in construction. Despite recent technological developments in wood-based construction, it is still a niche within the construction market. The literature highlights two main barriers to wood-based construction: (1) lack of material expertise and (2) lack of coordination and collaboration across the supply chain. Interfirm governance structures, such as board interlocks, may constitute a path towards innovation in construction by establishing strategic partnerships. By combining resource dependence theory and dynamic capabilities, we formulate expected findings and analyse these through social network analysis and interviews with board of director's members of wood-based firms in Norway. The dataset consists of 549,449 firms. We find that most wood-based firms have board interlocks with other firms. Furthermore, these other firms are spread across industries, but most belong to industries within the construction supply chain. Additionally, the role of these board interlocks is not to secure access to material resources but to access immaterial resources, such as knowledge, expertise and skill, which contribute to the firms' dynamic capabilities and consequently their competitive advantage.

KEYWORDS: Wood, construction, board interlocks, resource dependence theory, dynamic capabilities

1 INTRODUCTION

This paper studies a specific type of interfirm governance structure, namely board interlocks or directorate interlocks, which occurs when the same person is a member of the board of directors (BoD) in two different firms [1]. More specifically we study if there exists board interlocks between wood-based firms in the construction supply chain and firms in other industries, and their role in enabling increased use of wood in construction.

There is plenty of evidence supporting the substitution effects of replacing the most common building materials with wood-based products [2–4]. New solutions have also developed, such as wood multi-storey constructions [5–7], and the focus on digitalization of the supply chain has increased [8, 9]. Still, wood-based construction is a niche in the European and global construction market [10, 11]. The literature highlights two main barriers to the increasing use of wood in construction: (1) the lack of material expertise [5, 12, 13], and (2) the lack of coordination and collaboration across the construction supply chain [10, 14, 15]. Miozzo and Dewick [16] argue that interfirm governance structures may constitute a path towards innovations in construction by establishing strategic partnerships. One specific type of interfirm governance structure is board interlocks. Previous studies of board interlocks have shown that they secure access to resources of other firms, such as materials, technology and expertise [17–19], and that they enable coordination and collaboration across the supply chain [20, 21].

Moreover, we study board interlocks through the lens of resource dependence theory and the notion of dynamic capabilities. Resource dependence theory allows us to understand why and how organisations, such as wood-based firms, may establish relations to their external environment and, to some extent, the role of such relations. The notion of dynamic capabilities allows us to further elaborate the role of such relations, especially it's role within specific organisations, such as a wood-based firms. These allow us to formulate expectations for an empirical analysis of registry data, using social network analysis (SNA) and analysis of interview data.

2 LITERATURE REVIEW

In this section we review the literature on the use of wood in construction and main barriers to increasing the use of in construction, which forms the basis for our research question. The construction sector has a considerable economic and social importance and is a sector with major environmental impact. If we include the whole lifecycle of buildings, the global construction and building sector stands for 42% of total energy consumption, 35% of total greenhouse gas emissions, 50% of extracted materials and 30% of water consumption [2]. Improving the resource efficiency and sustainability in the building sector has thus become an important climate policy goal in the EU and in the Nordic countries [22–24]. In this context, an increased use of wood is seen as having large potential as a substitute for more energy intensive and non-renewable

[1] Silje Marie Svartefoss, Nordic Institute for studies of Innovation, Research and Education, silje.marie.svartefoss@nifu.no.

https://doi.org/10.52202/069179-0593

materials [25]. There is plenty of evidence supporting the substitution effects of replacing the most common building materials with wood-based products [2–4]. Studies on the mitigation potential of wood use in buildings and furnishing have shown that wood products have lower greenhouse gas emissions than the alternatives, considering the complete life cycle of the product [26]. It is also superior to common construction materials, such as concrete and steel, when considering all performance indicators [27]. Increasing the use of wood in construction is also important because it enables a transition to the circular economy through recycling [28].

Previous literature about the sustainability transition of the construction sector in general has targeted low-energy houses or passive houses [29], while the literature on the wooden construction industry has been mainly technical and focused on qualities of materials and assembling techniques [25, 30–32] or on specific projects [33, 34]. However, in recent years, a body of literature has developed concerning the role of wood multi-storey constructions (WMCs) in the sustainability transition of the construction sector, as the need for such a transition has become increasingly apparent. Research on new solutions, such as designs using cross laminated timber (CLT) or glulam, has developed [5–7]. In addition, there has been an increased focus on digitalization of the supply chain [8]. Even though wood-based construction is gaining momentum [35], it is still a niche in the European and global construction markets and so there is a potential for expansion beyond the niche [10, 11].

The literature highlights several barriers to the increased use of wood in construction and lack of material expertise among actors in the supply chain (e.g. consultants, architects, construction engineers and contractors) has previously been highlighted as one of the main barriers [36]. Gosselin et al. [12] further confirmed this finding in a review of scientific literature and major construction projects that used wood. More recently, an interview study in Finland concluded that the lack of construction expertise was considered one of the major obstacles [5]. Santana-Sosa and Kovacic [13], in their study based on a literature review and expert interviews, also highlighted the lack of material expertise as a barrier.

However, this is not the only barrier. Mlecnik [37] showed how the project-based approach may hinder innovation within the construction sector, and how enhanced coordinated collaboration may enable better conditions for innovation. Gosselin et al. [38] studied fifteen wooden construction projects in nine different countries, using a mixed methods approach. They showed how the increased use of wood is obstructed by the complexity of the supply chain relationship, and that partnerships along construction supply chains rarely reach outside the project level. A more recent study by Gosselin et al. [15] further supports the need for collaboration and tighter relations along the supply chain. Furthermore, Santana-Sosa and Kovacic [13] recommend that experts on wood construction should be included in the early stages of the design phase to avoid re-design, cost, and time overruns. Gharaibeh et al. [14] present a similar finding when studying the implementation of Building Information Modelling (BIM) in wood construction projects. Finally, the review by Jussila et al. [10] on WMCs market development calls for more research on forms of collaboration within the construction supply chain.

The outlined barriers to the increased use of wood in construction call for further research on this issue. Miozzo and Dewick [16] argue that interfirm governance structures can constitute a path towards innovations in construction, such as applying new materials or products based on new materials, by establishing strategic partnerships. A specific type of interfirm governance structures are board interlocks or directorate interlocks, which occurs when the same person is a member of the board of directors (BoD) of two different firms [1]. Studies have shown that board interlocks secure access to resources from other firms, such as materials, technology, expertise and information [17–19, 39]. Palmer [21] has also shown that multiple board interlocks increase the likelihood of collaboration through joint ventures. Gulati and Westphal [20] also found that board interlocks may be influential in forming strategic alliances, which enables collaboration, depending on the context of the board interlocks. Board interlock may also positively influence firms' innovation performance [40–42].

Drawing on this literature we formulate the following research question: *To what extent do board interlocks exist between wood-based firms and firms in other industries, and what role do they have in enabling increased use of wood in construction?*

3 THEORETICAL FRAMEWORK

The theoretical framework for this paper is draws on resource dependence theory and the notion of dynamic capabilities. Resource dependence theory allows us to understand why and how organisations, such as wood-based firms, may establish relations with their external environment and, to some extent, the role of such relations. The notion of dynamic capabilities allows us to elaborate the role of such relations further, especially their role within a specific organisation.

The premise of resource dependence theory states that the environment surrounding organisations is uncertain, and that the organisations try to gain control over this uncertain environment, and avoid dependence, because they need a persistent and reliable flow of resources [1]. The source of uncertainty is the existence of interdependencies, which describes a situation where "one actor does not entirely control all of the conditions necessary for the achievement of an action or for obtaining the outcome desired from the action" [43, p. 40]. Furthermore, a central assumption of resource dependence theory, which separates it from ecological

and institutional perspectives, is that managers within an organisation have discretion, which entails the ability to actively manage the uncertainties of the external environment [44]. Another important distinction is that resources are not just material, but may also be immaterial resources such as expertise or specific skills [45].

Malatesta and Smith [46] present three main strategies for reducing uncertainty and dependence: (1) Mergers, (2) alliances and (3) co-opting or board interlocking (hereafter board interlocking). The choice of strategy depends on how much control over resources the focal organisation views as necessary [47]. The strategies can be viewed as a part of a continuum because they require varying degrees of coordination and loss of autonomy [46]. Furthermore, the control gained by applying these strategies is highly dependent on the characteristics of the organisation's environment. The literature suggests that board interlocking is the most likely strategy for gaining control in environments characterised by low concentration and high levels of competition [43, 46]. A study by Boyd [48] showed that the number of board interlocks is greater in such environments. The assumption is that through board interlocks, the focal organisation trades sovereignty to an organisation in which the focal organisation is dependent on, which in turn establishes self-interest in the focal organisation's development and survival [49]. The construction sector is characterised as a highly competitive sector with low concentration [50–53]. Therefore, we expect wood-based firms to use board interlocks as a strategy for gaining control and reducing their dependency on the environment.

Expectation 1: A majority of the wood-based firms will have board interlocks with other firms.

Another relevant characteristic of the construction sector is the complexity of the supply chain relationship [15, 37, 38]. A construction supply chain encompasses architects, engineers, builders and suppliers [15, 54]. Papadopoulos et al. [55] describe how the construction supply chain differs from the manufacturing supply chain because of the frequent changes in product, production, and location. Board interlocks may enable better coordination with the environment because it establishes a channel for communication between firms [46, 56, 57]. Given the need for coordination, we expect the wood-based firms to have board interlocks with actors across the construction supply chain.

Expectation 2: The wood-based firms have board interlocks with actors across the construction supply chain.

We rely on both resource dependence theory and the notion of dynamic capabilities to understand the role of board interlocks. Within resource dependence theory, board interlocks are viewed as a way to secure access to material and immaterial resources [46, 56]. Wood-based firms are particularly dependent on access to wood and wood-based materials. This dependency suggests that wood-based firms will be more likely to have board interlocks with firms that may supply the necessary material, due to the potential to secure a persistent and reliable flow of resources [1].

Expectation 3: Wood-based firms use board interlocks to secure access to material resources.

Board interlocks also have the potential to function as transfer channels for immaterial resources such as knowledge, expertise and skills between organisations [43, 45, 58]. However, the role of immaterial resources within an organisation is less clear within resource dependence theory. Teece [59, p. 516] developed the notion of dynamic capabilities, which he defines as: "the firm's ability to integrate, build, and reconfigure internal and external competences to address rapidly changing environments". Furthermore, he suggests that the extent to which a firm has this ability forms the basis of a firm's competitive advantage. More recently, Teece [60] disaggregated dynamic capabilities into three processes: sensing, seizing and reconfiguration. Sensing entails identifying opportunities in the environment which requires market understanding, seizing entails addressing the identified opportunity which often require new knowledge and skills. Finally, reconfiguration entails restructuring assets and organisational structures to environmental changes which demands business and management skills.

Expectation 4: Wood-based firms use board interlocks to secure access to immaterial resources such as knowledge, expertise, and skills.

4 METHODS

This paper builds on two types of data: registry data and interview data. The two types of data are used in combination because while the registry data allows for investigation into if, and to what extent, there exists board interlocks between wood-based firms and firms in other industries, it does not contribute to the understanding of the role of these potential board interlocks.

4.1 REGISTRY DATA

We collected the data for this study in February 2022 from the Central Coordinating Register for Legal Entities (CCR), a registry of all firms in Norway. To collect the data, we used the R software and web scraping. Each firm registered in Norway is given a unique identifier. We used this unique identifier to access and collect information about each firm. The information we collected for each firm was the NACE (Nomenclature of Economic Activity) code, the number of employees and the BoD members, if the firm had a BoD. 549 449 firms were registered with a BoD at the time of data collection.

https://doi.org/10.52202/069179-0593

To collect data on firms in the construction supply chain that use wood-based materials in their products, we gathered information on firms that were members of the primary industry organisations in Norway[2] for the promotion of wood-based products. In addition, we collected information on firms that are partners in initiatives working on solutions that promote the use of wood-based products. Based on the collected information, we had a list of 357 firms. Given that we have information about the NACE-code of each firm, it is possible to argue that it is better to use these to identify groups of wood-based firms. This method is problematic because the basis for the classification of firms is activity rather than material used which may lead to inclusion of many non-wood-based firms. A potential limitation with our approach is the reliance on our knowledge of the industry, we may have inadvertently excluded wood-based firms.

For the analyses we created a two-mode network, using the data collected from CCR and the list of wood-based firms. A two-mode network connects firms through persons. The two-mode network allowed us to create a projection of a one-mode network of firms connected to firms from the two-mode network. To get an overview of how connected wood-based firms are to other firms in the network, we calculated the distance from the wood-based firms to all other firms in the network. By only considering directly connected firms (distance = 1) and their NACE-codes, we get an overview of to what extent wood-based firms are interlocked with firms in other industries. An additional measure used in the analysis is degree centrality. Degree centrality measures the number of links (interlocks) a node (a firm or board member) has to other nodes (a firm or board member) in the network. The basis for this measurement is that nodes with many links have a more prominent position in the network [61].

It should also be noted that one firm may be registered with several NACE-codes, which may question the reliability of our analyses based on NACE-codes. We consistently used the first NACE-codes of each firm, but most firms are only registered with one NACE-code [62]. In the remainder of this paper, we will use the term "industry" when we refer to the NACE sections and the term "industry subdivision" to refer to NACE divisions.

4.2 INTERVIEW DATA

Our interview data was collected in the period from June 2022 until October 2022. Our initial sampling strategy entailed creating a one-mode network of persons connected to persons from our two-mode network. From this one-mode network, we calculated the degree centrality. We then selected potential informants among those BoD members of wood-based firms who were well connected to firms in other industries. Furthermore, we added a requirement, that among the firms, the potential informant who was connected to at least one firm should have a couple of employees, as we wanted to avoid sending requests to board members of very small firms. Subsequently, we collected information about the informant's email address and phone number and sent them requests, by email and phone calls, for an interview. However, it was difficult to get any response, after 40 requests with no response we changed strategy. We changed our strategy to something more similar to the snowballing method. This entailed that we reached out to persons we knew or collaborated with in the industry and asked them to recommend informants. In some instances, they made the first request, and we followed up with a more formal request. We made sure that most of these informants were board members of wood-based firms and that they had connections, through board interlocks, to firms in other relevant industries. This strategy led to interviews with seven informants that were well distributed across industries in the construction supply chain. We also conducted two additional interviews: one interview with someone who was not a board member of a firm on our list of wood-based firms, but several firms involved in real estate development, and one with another informant who was a board member of several firms. This informant also had in depth knowledge about the legal and operational aspects the work of BoD.

The interviews were semi-structured, and we used an interview guide as the starting point for each interview. We also adapted our questions depending on the background of the informant and topics that came up during the interview. In the interview guide, we listed several probes that we used if a topic we were interested in was not raised or discussed by the informants themselves. The interviews were all recorded and transcribed. To analyse the interviews, we developed a codebook and used NVivo to code the interviews. The interviews were coded by one person, which can question the reliability of the coding. However, the interviews were conducted as part of a larger project and two persons jointly conducted all of the interviews and discussed the coding and findings, which increases the reliability.

5 RESULTS

The results from the analysis of the different types of data are presented separately. The results from the quantitative analysis of the registry data are presented first, and second the results of the qualitative analysis of the interview data.

5.1 RESULTS – REGISTRY DATA

The results from the analysis of registry data are primarily related to the first two expectations. These state that a majority of the wood-based firms will have board interlocks with other firms, and that the wood-based firms have board interlocks with actors across the construction supply chain. Our analysis showed that of the 357 firms in our list of wood-based firms 81% (N = 289) were

[2] These are: Treindustrien, Norske Trevarer, Byggevareindustrien and Treforedlingsindustrien.

connected to other firms through board interlocks. The wood-based firms were interlocked to 3,113 other firms. Of these 3,113 firms 84 % (N = 2629) are unique firms.

Our analyses show that the wood-based firms are interlocked with firms in all industries across the construction supply chain. However, there is a great deal of variation regarding the degree of interlocks to each of these industries. A majority of the firms, that the wood-based firms are interlocked with are found within the following industries: real estate (24%), construction (13%), manufacturing (7%), and professional, science and technical activities (7%). Only 3% of the firms that the wood-based firms are interlocked with are within the industry of agriculture, forestry of fishing.

The division into industries can be even more detailed by applying industry subdivisions which is a more fine-grained classification. Table 1 shows the most common industry subdivisions, within the most common industries that the wood-based firms are interlocked with. It is interesting that 73% of the construction firms that the wood-based firms are interlocked with are found within the industry subdivision "construction of buildings". This industry subdivision consists of firms involved in development of building projects and construction of residential and non-residential buildings. This indicates that few of the construction firms, that the wood-based firms are interlocked with, are involved in other types of construction, such as construction of bridges. It is also interesting to note that the most common industry subdivision within professional, science and technical activities is related to head-office activities, business, and management activities, and not architectural and engineering activities. However, the second most common industry subdivision within this industry, is architectural and engineering activities, with 30%.

Table 1: *Most common industry subdivision within each industry.*

Industry	Industry subdivisions	Percentage of firms
L Real estate activities	Real Estate activities	100% (734)
F Construction	Construction of buildings	73% (297)
C Manufacturing	Manufacture of wood and products of wood and cork, except furniture; manufacture of articles or straw and plaiting materials	42% (91)
M Professional, science and technical activities	Activities of head offices; management consultancy activities	46% (100)
A Agriculture, forestry, and fishing	Forestry and logging	55% (47)

The firms that the wood-based firms are interlocked with also seem to have a higher mean number of employees, compared to all firms in the same industries. These firms also have a higher mean score on degree centrality, compared to all firms in the same industries, which indicates that the firms that the wood-based firms are interlocked with may have a more prominent position in each industry.

5.2 RESULTS – INTERVIEW DATA

The results from the analysis of interview data primarily relate to the last two expectations which state that wood-based firms use board interlocks to secure access to material resources and immaterial resources such as knowledge, expertise and skills.

5.2.1 Access to material resources

We interviewed several informants with various connections to other firms in other industries through board interlocks. However, when we asked them about how these interlocks might enable a steady supply of material resources, such as wood or more advanced wood-based products, few seemed to think of or use interlocks to secure access to a steady supply of such resources. One informant (2), who was on the board of a carpenter firm and a firm supplying forest plants for planting after trees have been cut down, alerted us to the large difference between the business each firm was in. The products of the forest plant firm would not become usable lumber for the carpenter firm until several decades have passed. Another informant (5) suggested that firms might use interlocks in this way, but added that, in most cases, firms would select the material most suited for a specific purpose, and that this consideration would be given a substantial weight in the decision on material selection. However, the same informant (5) also suggests that an interlock might give some influence in the interlocked firms future developed. This informant is on the board of a firm that often functions as a contractor in larger construction projects and of a smaller firm that builds private houses and prefabricated elements. The informant (5) explains how the additional element of a costumer relation between the contractor firm and the smaller firm enables the firm to give input on future development.

Furthermore, a board interlock might not be a strong enough connection between firms for it to function as a way to secure access to material resources. One informant (1), who was interlocked with several firms across the supply chain because of ownership through a parent company, describes the interlocks something reassuring, in light of the uncertainty caused by the recent pandemic, in the supply of material resources. At the same time, it is also noted by the informant that they are mindful not to make this a too big advantage.

Even so, our interviews show that this should not be interpreted as the only motivation for parent companies to have interlocks with firms they have ownership shares in. Several informants (1, 6, 7 and 8) noted that ownership shares were one of the main motivations for interlocks. One of the informants (6) explain that this is not because

https://doi.org/10.52202/069179-0593

of the parent companies' interest in securing access to material resources, but because of having made investments and wanting to influence and have information about the development of the firm. This finding lends more support to our expectation about immaterial resources, which we now turn to.

5.2.2 Access to immaterial resources

It seems that board interlocks function as a way to secure access to immaterial resources such as knowledge, expertise, and skills. We asked the informants about why they were appointed to the BoD of the various firms. Several (2, 6 and 8) noted that knowledge and experience from wood-based firms was important. One informant (1) also noted that they were actively seeking potential board members with such knowledge and experience, but that they are hard to come by. Many of the informants (2, 3, 4, 6 and 9) also had previous work experience from firms that worked with wood as a material.

Several informants (1, 2, 3, 4, 5, 7 and 9) stressed knowledge and experience from business management, and the ability to engage and understand how the market develops, as important for their appointment as a board member. One informant (3) described how the informant was recruited to the board of a wood-based firm because the firm was facing economic struggles, and that they were subsequently recruited to other firms when the economic situation was improved. Another informant (4) described the importance of having board members that understand the firm's business model and elements that influence the firm's failure or success.

The importance of experience from business management and market understand seems to be related to how the informants perceive the role of the BoD. Many of the informants (2, 3, 5, 6, 7 and 9) view the role of the board BoD as particularly responsible for the long-term development of the firm. They describe how the BoD should be a partner for the CEO in thinking about the future development of the firm. Moreover, they should try to have a more long-term perspective, than the operative management, focusing on future development opportunities, but at the same time, be a supporting actor for the short-term development. Most of the informants (1, 2, 3, 4, 6, 7 and 8) also said that they had experience form previously being on a firm's BoD.

5.2.3 Disqualification, procedures, and competition

Throughout the interviews, the informants also mentioned some issues related to the role and use of board interlocks. The first issue relates to qualification of the board members in making decisions which may benefit the firm of the board member. Some informants (8 and 9) mentioned that in these situations the board member in question would be disqualified from taking part in the decision. The task of the board member is to act in the best interest of the firm in question. This is also in accordance with the legal regulations [64].

This is seemingly not only a legal issue, but it may also be seen as an unfair advantage by the outside world. One informant (1), who had owned several wood-based wholesale firms previously, mentioned this issue. They described how builders became sceptical towards their business and suspected that the sawmill might sell their materials at a cheaper price to their own wholesale firms. According to the informant, ownership increases the need to conduct business in a transparent manner. Another informant (3), who moved from interest organisations to industry, had to cut ties with the former to avoid suspicions around a dual role.

Another aspect which might make it difficult to use boards in a strategic manner is that there may be election procedures in place for selection of board members, especially in larger firms. One informant (3) suggested that the possibility of appointing a strategically important member to the BoD might be difficult, since the election committee might not think of or be aware of the possibility. Another informant (7) suggested that the committees might resort to selecting the person who is next in line, because it is the most convenient, instead of considering the firm's needs.

The final issue relates to competition among firms. One informant (1) mentioned that they tried to collaborate with other firms, but that it was difficult because of the competition. Moreover, collaboration often lead to conversations about acquisition or mergers. This informant also mentioned that the price is of course an important factor for deciding which material to use. This was also repeated by another informant (5). This suggests that it might be difficult to select materials or products that a firm is interlocked with if the price is not competitive.

6 DISCUSSION

According to resource dependence theory, board interlocks allow the focal firm, in case of interdependencies to other firms in the environment, to trade sovereignty for self-interest in the focal firm's development and survival [43, 49]. In contrast to other methods for reducing interdependencies and thereby uncertainty of the focal firm, such as mergers and alliances, establishing board interlocks involves less coordination and loss of autonomy, it is also viewed as the most likely strategy in environments with low concentration and high levels of competition [43, 46]. In the literature, the construction sector is characterised as a highly competitive sector with low concentration [50–53]. We therefore expected that a majority of the wood-based firms would have board interlocks with firms in other industries. Our results, based on the analysis of registry data, show that of the 357 wood-based firms 81% (N = 289) are interlocked with other firms, which supports our expectations. However, our data does not cover the prevalence of mergers and alliances among wood-based firms. This means that we are not able to conclude that

board interlocking is the most likely strategy for the wood-based firms.

The second expectation relates to another characteristic of the construction sector which is the complex supply chain. A construction supply chain encompasses architects, engineers, builders, and suppliers [15, 54]. The complexity of the supply chain also increases because of the frequent changes in product, production, and location [55]. We expected that this complexity of the supply chain would lead to wood-based firms having board interlocks with actors across the construction supply chain, based on the potential for needed coordination board interlocks provide by establishing communication channels between firms [46, 56, 57]. Our results show that the wood-based firms have board interlocks with industries across the construction supply chain. A majority of the firms that the wood-based firms are interlocked with is found within the following industries: real estate (24%), construction (13%); manufacturing (7%), professional, science, and technical activities (7%). However, only 3% of the firms that the wood-based firms are interlocked are found within industry of agriculture, forestry, and fishing which is an important due to their role as the supplier of wood and wood-based materials. Our results also show that most of the interlocked firms within construction are related to the construction of buildings, while few of the interlocked firms are involved in other construction activities, such as construction of bridges. If we consider the interlocked firms within the industry of "professional, science and technical activities", which is where engineering and architectural firms belong, the most common industry subdivision was the one related to head-office activities, business, and management activities (46%). Moreover, the industry subdivision related to engineering and architectural activities was the second most common (30%). Even so, we find support for the expectation that wood-based firms will have interlocks with actors across the construction supply chain. The firms that the wood-based firms are interlocked with also seem larger, in terms of number of employees, compared to all the firms within each industry. They seem to have a more prominent position in the industry network.

The third expectation stated that wood-based firms use board interlocks to secure access to material resources. Wood-based firms are especially dependent on one type of material. We expected them to be more likely to have board interlocks with firms that may supply the necessary materials, due to board interlocks having the potential to secure a persistent and reliable flow of resources [1]. However, our results show that this does not seem to be the case. This is supported by the fact that the main supplier industry, agriculture, forestry, and fishing, is among the industries which few of the firms that the wood-based firms are interlocked are found within, compared to the industries mentioned above. In the interviews, one informant highlighted the fact that there may be a large difference between the materials and products a firm produces and the materials and products a firm needs, even if there exists a board interlock between the two firms. It also became clear that material selection must be based on a consideration of what the best material is for a specific purpose. This suggests that even if there exists a board interlock between a wood-based firm and a construction firm, wood might not be viewed as the best material for a specific purpose, and so another material is used. One implication of this is that it may be difficult to use board interlocks in this way because it creates an expectation between firms that may be difficult to fulfil. Another important aspect is that board interlocks may be too weak of a connection. Based on the interviews, it seems like stronger connections, such as ownership, is needed to secure access to material resources. However, this should not be interpreted as the only motivation for parent companies to have interlocks with firms they have ownership shares in. The interviews highlighted that an important motivation for board interlocks, in the case of ownership, is to have control over the parent companies' investments, receive information, and have influence over the future development of the firm. Additionally, the informants described how using board interlocks in this way may be difficult because of the issue related to disqualification and things may appear to the outside. As a result, is does not seem like board interlocks function the way we expected. In terms of securing access to material resources, there seems to be too weak of a link. Furthermore, the legal and appearance aspects make it difficult for board interlocks to have this role.

The fourth and final expectation was related to the use of board interlocks as a method for securing access to immaterial resources, such as knowledge and skills. In the literature, it is suggested that board interlocks have the potential to function as transfer channels for immaterial resources [43, 45, 58]. Teece [60] describes how such immaterial resources are important for the dynamic capabilities of a firm which involve sensing, seizing and reconfiguration. Our informants highlighted knowledge and experience for wood-based firms as a reason for becoming a board member, and several of them had work experience from firms that uses wood as a material. Moreover, they stressed the need for experience and knowledge about business management and market understanding, which seem to relate to the role of the board as having a special responsibility for the long-term development and future opportunities for the firm. Thus, our expectation about the use of board interlocks as a method for securing access to immaterial resources seems to be supported. It also seems like they contribute to all aspects of Teece's [60] notion of dynamic capabilities: sensing, through their understanding of the market; seizing, through their knowledge and experience concerning new opportunities; and reconfiguration, through their business and management skills.

7 CONCLUSION

This paper contributes to the understanding of the role of board interlocks in increasing the use of wood in

https://doi.org/10.52202/069179-0593

construction. Trough analyses of registry data we show that board interlocks exist between wood-based firms in the construction supply chain and other firms. Furthermore, the firms that the wood-based firms are interlocked with belong to industries across the construction supply chain. Most importantly, the additional analyses of the interview data allow us to nuance our understanding of the role of such board interlocks. We find no support for our expectation that they function as a way to secure access to material resources. However, they do have an important role in securing access to immaterial resources, such as knowledge, expertise and skills. Knowledge and experience from using wood as a material, business and management skills, and market understanding are all important and contribute to important aspects of Teece's [60] notion of dynamic capabilities, which forms the basis of a firm's competitive advantage.

There are certain limitations to this study. The comprehensive registry data allows for a very broad analysis, but it also limits our ability to study the data in a detailed manner. The selection of wood-based firms in the construction supply chain is probably not complete. There may be wood-based firms that have not been included. However, other methods may have been too broad in terms of inclusion or required an extensive amount of time and resources. Historic data was not available, which does limits us to study data collected at one point in time. This means that we were not able to discuss development over time. Regarding the interview data, more interviews would have been preferrable, but given the difficulties of recruitment, this was not possible in the time available.

Future research should focus on further exploring the role of board interlocks in increasing the use of wood in construction. We specifically suggest case studies of BoD to further the understanding of internal dynamics within firms. Future studies may also consider board interlocks and their relation to alliances and mergers. Finally, we suggest that studying firms who have made or are in a transition towards use of more wood-based materials may be an important avenue for future research.

ACKNOWLEDGEMENT

I would like to express my gratitude to Antje Klitkou and Marco Capasso. Antje Klitkou for providing valuable feedback and support throughout the process of writing this paper. Marco Capasso for sharing his knowledge about social network analysis and for valuable contributions to the early draft of this paper.

World Conference on Timber Engineering Oslo 2023

HARMONISATION OF THE ENVIRONMENTAL PRODUCT DECLARATIONS FOR WOOD PRODUCTS

Lauri Linkosalmi[1], Harald Schwarzschachner[2], Tuovi Valtonen[3]

ABSTRACT: Environmental Product Declarations (EPD) are developed to compare materials and solutions in building level to achieve sustainable choices for the built environment. European standardisation body, CEN/TC 350 Sustainable Construction, have developed harmonised standard EN 15804 to create EPD's for the building products. Although harmonised standards exist, different methodologies and scenarios are used under different EPD operators and countries, which is not supporting sustainability assessment in building level. Identified challenges are e.g. generic background datasets, allocation in modules A1–A3, use of guarantees of origin for purchased energy, scenarios for transportation and installation, and end-of-life scenarios. Different assessment approaches challenge the assessment in the building level to achieve targets for sustainable buildings.

KEYWORDS: Wood products, Life cycle assessment, Environmental product declaration, Harmonisation

1 INTRODUCTION

In this study Environmental Product Declarations (EPDs) of wood products were examinate, looking differences in assessment methods and how those are affecting to the reporting of the results in EPDs. Study was done by using selected EPDs of wood products published by EN 15804 standard. All studied EPDs were third-party verified and published by an EPD operator.
Earlier studies shows the importance of the harmonisation of the EPDs [1–6]. EPDs helps decision making in building level assessment to ensure sustainable choices for the building design and construction. In this perspective, comparison of the products and solution in building level should base on harmonised and verified data [7]. Where assessment methods are aligned and based on same scenarios.

At the moment, differences between data are challenging use of EPDs by designers and decision makers. As result might vary based on selected method to imply in assessment.

2 MATERIALS AND METHODS

In the Environmental product declaration - Core rules for the product category of construction products standard (EN 15804) [8] the life cycle phases are divided in four stages; production stage (A1–A3), construction stage (A4–A5), use stage (B1–B7) and end-of-life stage (C1–4). Also, additional information beyond the product system can be stated in the module D, information module. In this study assessment is following life cycle principle presented in Fig. 1.

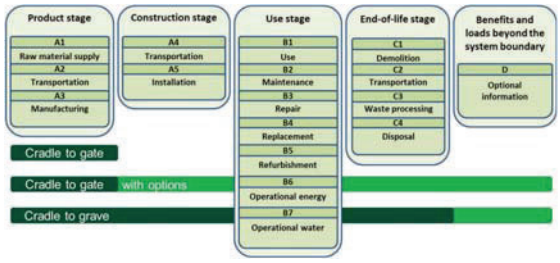

Figure 1: *Life cycle stages and environmental product declaration coverage according EN 15804 standard.*

In this study specific methods for different life cycle stages were studied. From product manufacturing perspective A1–A3 stage is most accuracy, based on annual inventory of raw material supply and production. Following life cycle stages are based on specific scenarios or scenarios recommended by the publishing platform (EPD Operator). For each life cycle module or stage, can be identified typical assessment/methodological options which will have effect on results.

In EN 16485 standard [9], Product Categories Rules are defined for wood-based products. Standard gives

guidance's how to implement some assessment method specifically for wood products.

For this study data were collected from the published EPDs of wood-based products. All available EPDs or datasets following EN 15804+A1, EN 15804+A2 and ISO 21930 were included to the assessment. Table 1 shows EPDs used for the assessment. CLT data is separated by EPDs and French FDES, as FDES have some specific rules to follow. Study focused to review reported CO_2 eq. emissions from product stage (A1–A3) and the biogenic carbon content of the product. Also, other methodological differences reported in EPDs where assess.

3 RESULTS

Firstly, production stage data were assessed for Sawn dried timber, CLT and LVL. Results of global warming potential and biogenic carbon content in modules A1–A3 are shown separately for each product. In Figure 2, sawn dried timber results are shown. Major findings for classic sawn goods are:

- Only generic forestry data available – own research field to create more precise data for different regions where logs are felled.
- In some cases, no mentioning of biogenic carbon content. Biogenic carbon content is calculated based on product density by authors.
- Wrong calculation of biogenic carbon content, not following principle of "material inherent properties" - CO_2 biogenic carbon is referred to whole log entering the mill.
- Possible different assumption for utilization rate in A2 transportation and differences in back-and-forth transportation is considered.
- Difference requirements from EPD operators, like "shall declare the emissions for energy mix" kg CO_2/kWh in EPD Norge.

Results of CLT - EPD, CLT - FDES and LVL are shown in Figures 3–5. Major findings for further processed CLT and LVL are:

- Difference between integrated operations (basic and further production in same site) and mills who have purchased timber from external suppliers.
- Primary vs generic data for glues. Modelling of glue data based on supplier information can vary.
- Correct consideration of dry content of glues.

https://doi.org/10.52202/069179-0594

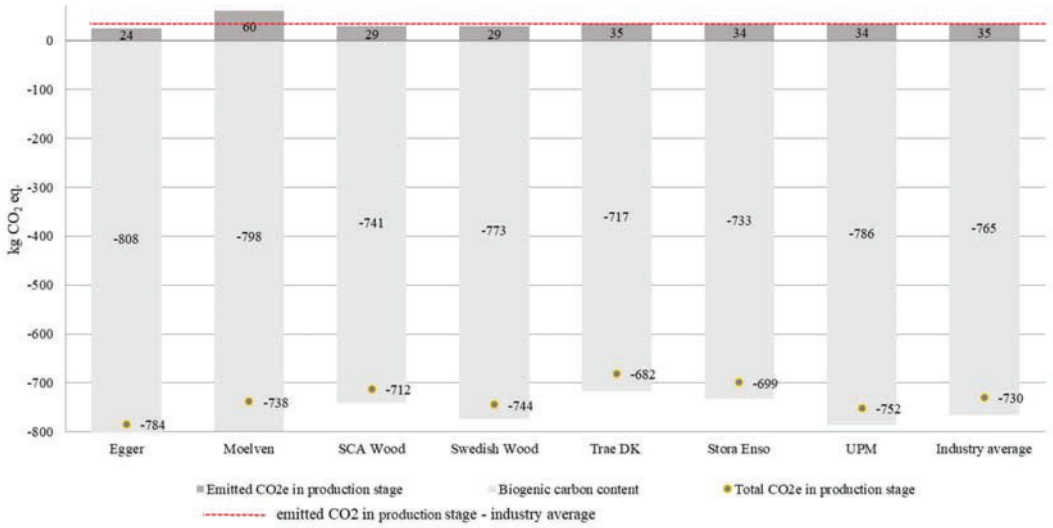

Figure 2: *Global warming potential (GWP) [kg CO_2-eq/m³] of sawn dried timber in modules A1–A3 according EPDs.*

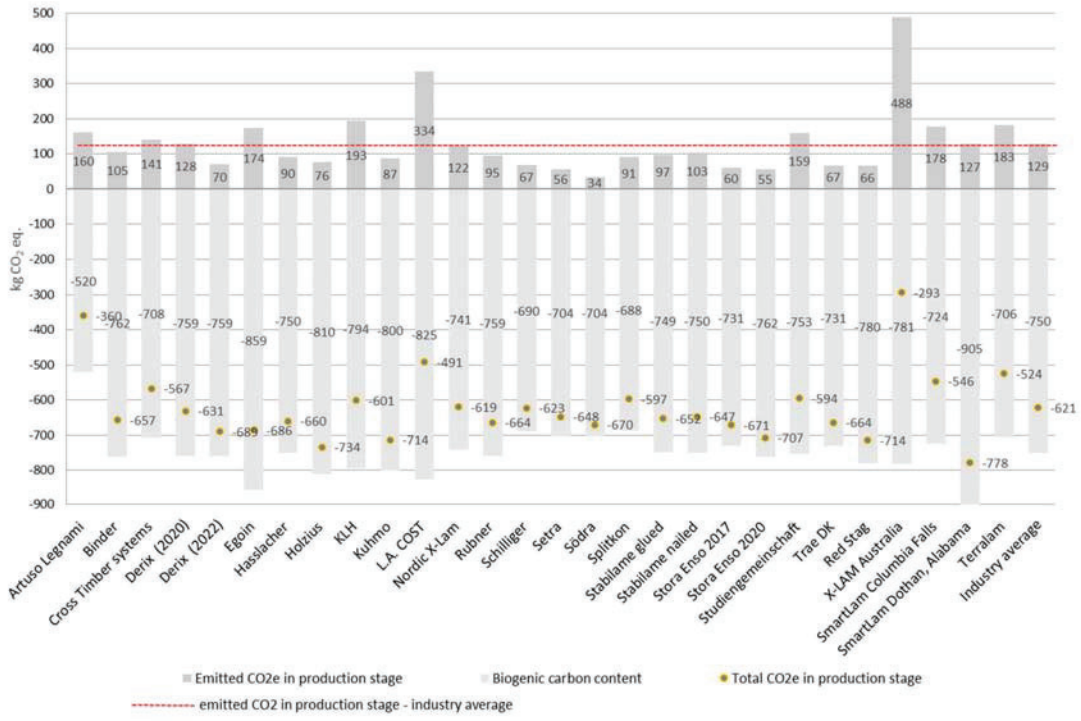

Figure 3: *Global warming potential (GWP) [kg CO_2-eq/m³] of CLT in modules A1–A3 according EPDs.*

https://doi.org/10.52202/069179-0594

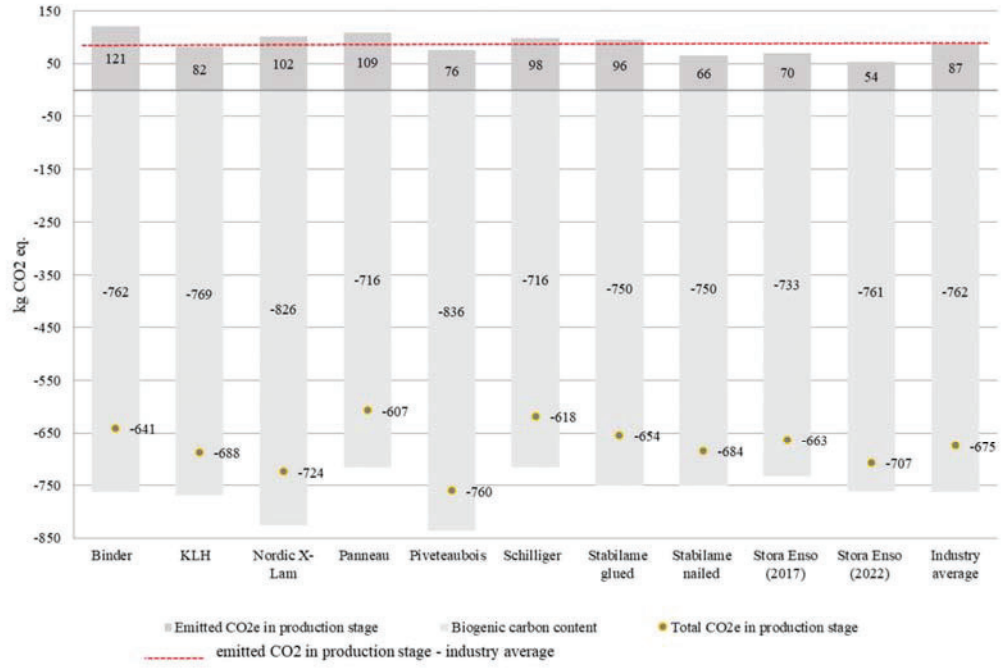

Figure 4: *Global warming potential (GWP) [kg CO_2-eq/m³] of CLT in modules A1–A3 according FDESs.*

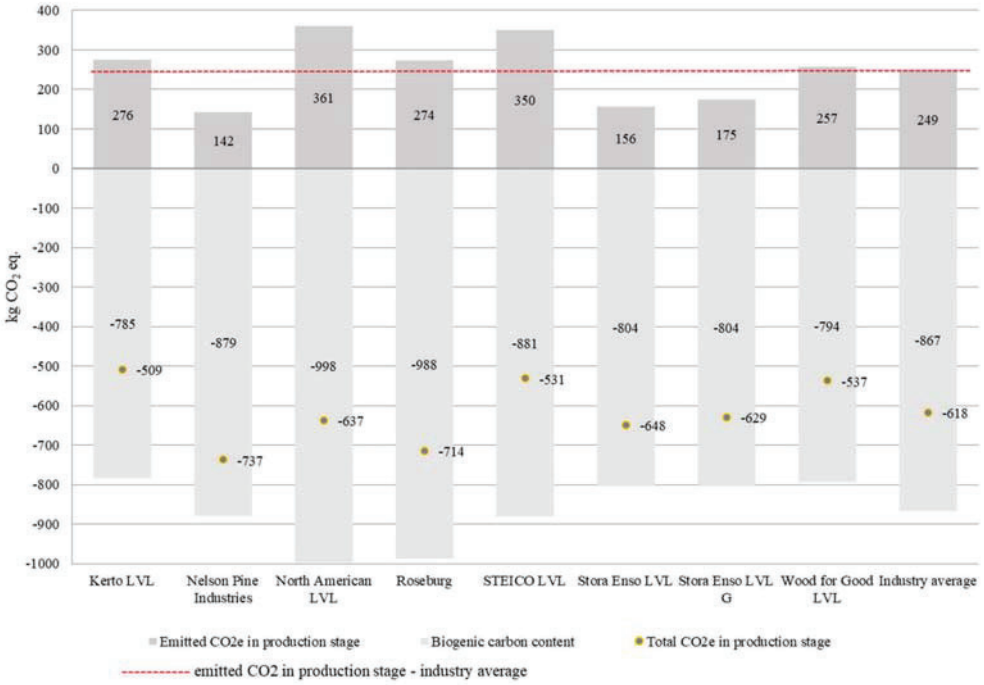

Figure 5: *Global warming potential (GWP) [kg CO_2-eq/m³] of LVL in modules A1–A3 according EPDs.*

Other identified findings based on EPD reporting data are:

- Energy consumption in A1 (EN 15804) vs. A3 (ISO 21930). Is guarantees of origin of purchased energy allowed to be used.
- By-product's allocation and interpretation:
    - Everything is allocated to sawmill residues and products according economic values without considering different level of processing ("Blackbox").
    - Allocation acc. Economic values separated by different product stages.
- Volatility of prices and effect on results, depending on reference year of data [10].
- Product transportation and installation (modules A4–A5):
    - Back-and-forth transportation.
    - Installation can vary depending on final application. Functional unit vs. declared unit.
    - Lack of specific installation data or estimate.
- End-of-life scenarios (modules C1–C4 and D):
    - Reference scenario for the end-of-life.
    - Lower Heating Values for wood and glue end-of-life scenarios.
    - Thermal and electrical burning efficiencies.
    - Database version used for assessment (e.g. ecoinvent version).
    - Used data for the substituted fuel in module D.

4 CONCLUSION

Based on the data collection more and more EPDs on wood-based products are available. This is highlighting the importance to have an EPD to claim the environmental impacts of a construction products. Many European countries have established regulation for embodied carbon or whole life carbon of building [10]. Building level assessments are depending on product level data.

Results indicate that EPDs are more harmonised in reporting and data quality than earlier. Non-harmonised methods are leading lack of comparability of EPDs in building level assessment. Many questions are arising by EPD users when there are major differences in the results of EPDs. Some differences are explained by the background datasets (generic data) and different energy mixes by countries. But some differences exist by the different assessment approaches, like by-products allocation influenced by volatility of prices [10].

To be able to calculate construction products environmental impacts harmonised approach is needed. As the complexity of the life cycle assessment modelling and different standard existing guiding the modelling in European (EN standards) and international (ISO standards) levels.

As shown in this study, choice of the assessment method can have a significant effect to the CO_2 emissions of the wood-based products. It is recommended in EPD standard [8] to use harmonised assessment methods, but it gives some freedom to do the assessment. Also, verification process of the EPDs differ by EPD Operators and individual verifiers.

A practical solution is that Product Category Rules of wood-based products [9] are revised to support common assessment method. This would harmonise environmental impacts assessments in woodworking industry field and provide more comparative datasets of wood-based building products.

World Conference on Timber Engineering Oslo 2023

6x6x6: INTRODUCING THE CONCEPT OF REUSE OF TIMBER MATERIALS IN THE 1ST YEAR OF ARCHITECTURAL EDUCATION

Colm O'Brien[1], Anna Røtnes[2], Mads Øiern[3], Petter Kveseth[4], Lone Sjøli[5], Sindre Wam[6], Katherina Putzer[7], Kristoffer Røgeberg[8]

ABSTRACT: 6x6x6 is a student design project in 1st year Architecture that takes place during the spring semester.

In 2022 the students designed a house in timber measuring a maximum of 6m x 6m x 6m. The project focused on teaching students how to use different timber construction principles and how to actively, and creatively, re-use structural timber components. The project had 3 parameters: a timber construction method, a hypothetical site, and a client.

The 6 timber construction methods were columns, beams, plates, trusses, shell, and solid log building (laft). For each construction principle the students were given a specific number of materials to be reused, for example 60 recycled columns 30 cm in diameter. The students produced a timber model of their project in the scale of 1:20 as well as a cross section drawing in the scale of 1:50

This project is the first-time students are introduced to timber as a construction material. They are instructed to look at their principle as more than just a technical requirement but something that inspires design. The result of the project for the students is a better understanding of timber as a construction method, how to incorporate reused materials into their projects, as well as dealing with how a client and a site influence a design.

KEYWORDS: Timber, reuse, education, construction principles

1 INTRODUCTION

In the UN's most recent climate report from March 2023 it was shown that the aim of reducing the global temperature increase to less than 1,5 degrees has become more unrealistic and that more drastic changes in society are needed to tackle the climate crisis [1]. Everyone needs to contribute but architects have an especially important role and responsibility. The building industry contributes up to 40% of the global C02 emissions through building, energy use and the demolition of existing buildings [2].

The climate crisis is immediate and gloomy, but it is important to remember that a crisis also offers new opportunities. The current situation allows us to rethink our way of designing architecture and educating future architects.

One of the clear consequences of the climate crisis and the building boom in Europe the last 10 years is that we need to build less new buildings. It's been suggested that 80% of the buildings that we will be using in 2050 are already built. So, transforming and re-using existing buildings will be a larger and larger part of how architects work.

There is a huge sustainable potential in reusing existing building materials and resources. Research shows that transforming existing buildings can reduce the amount of C02 emissions by 50% in contract to building new. This is mainly associated with the production of building materials and elements [3].

Tine Hegli, professor at AHO, emphasizes that we must have circular economic principles in the building sector: - to reuse resources that are already used would be the most radical approach in terms of reducing emissions [4].

Introducing ideas about reuse early in the education of architecture students is vitally important for the future of the profession. Reuse must be seen as an essential part of the design and building process and the earlier we can introduce this to students the better. The teaching team in

first year architecture at AHO have been exploring different ways to thematise reuse in the projects the students work with.

2 REUSE AS A THEME IN ARCHITECTURAL EDUCATION

2.1 FUNDAMENTALS OF THE PROJECT

Students in first year architecture at AHO work on five main design projects throughout the first year of their studies. The projects become increasingly complex as students gain more experience. New parameters and more complex issues like context or construction are introduced with each new project. The fourth project in the year, which starts at the beginning of the spring semester is called 6 x 6 x 6 and has been a part of the course plan since 2020.

6x6x6 project is inspired by the house *Huset i Mellbyedalen* on Bygdøy designed by Terje Moe, completed in 1970. The house is a timber construction with a volume of 6m x 6m x 6m. Moe designed the space for himself and his family. The house contains a living / dining space, 2 bedrooms and an office. Moe designed and built most of the house himself. He had a retractable bench in the living room and a standard tool set which he used to make almost all the elements in the building. [5] This has led to an architecture which is easily understood and readable. It makes for an excellent case study for students to study because of the focus on constructions and creating space being completely interdependent.

The students design a project in timber measuring a maximum of 6m x 6m x 6m. The project focused on teaching students how to use different timber construction principles The project had 3 parameters: a timber construction method, a hypothetical site, and a client/ function. The 6 timber construction methods were columns, beams, plates, trusses, shell, and solid log building (laft).

In 2021 we introduced how to actively, and creatively, re-use structural timber components as part of the construction method.

2.2 MATRIX

6 x 6 x 6 refers to the size of the project the students will work on but also to a matrix we have set up to create enough variations between the three parameters to guarantee that no students end up with the same combination of factors.

The students receive a brief with all the required information for the project at the beginning of the spring semester. Students are introduced the project and the 6 construction methods. In the brief we include the matrix with the three parameters (construction method, client, site) and all sixty students. By staggering the 6 options in each parameter it is possible to create 216 unique combinations. This means that none of the 60 students will have the same project. If for example two students have the same client, they will have a different site or a different construction principle.

The matrix is really the DNA of the entire project- it guarantees that all the students work on similar but not the same project, it creates a dynamic class environment, inspiring students to discuss their project with each other without being protective of their own solution. The total work in the project enlightens all the students, it is not 1 project repeated 60 times but 60 individual projects.

The matrix also generates strange and contradictory combinations, for example a solid log building on pier edge, which instead of being problematic create interesting starting points for a project and tests the extents of the construction principle they have been given.

2.3 REUSE

In the 2021 project we included an element of reuse in the construction principle. This was to introduce students to the idea of re use of materials as an essential part of architecture in the future. Students were given a set number of materials to reuse so for example if a student was working with columns, they received 60 reused columns of a set dimension to be incorporated into their project. The students were free to rework the materials in any way they saw fit, for example dividing them or combining them. The students were not limited to only using the reused materials but were encouraged to incorporate them into their design as an integral part of the project.

2.4 SECTION

In the fall semester of their first year in architecture the students work mostly with models and plan drawings. The 6 x 6x 6 project time the first-time students being to work with section drawings as a method of representing a project but also developing the design of a project. The nature of the 6 x 6 x6 project forces students to work in section as the full brief is not possible on one floor plan, this makes the students work with more than one level and vertical connections in their project. Section drawings allow students to fully explore the projects in height as well as in plan.

Section drawings are also a fundamental way of understanding the construction method the students have been given as it encourages them to investigate the floor, roof, and wall construction. Finding out for example the largest span, which direction is the most efficient to span in, standard sizes for construction elements etc.

3 RESULTS OF STUDENTS' WORK

By the end of the project the students had produced an exciting and wide range of solutions to the parameters they were given. The students had a much deeper understanding of working with timber construction principles by the end of the project. Also, a whole the students learned more about each other's construction's principles leading an increase in the overall knowledge of the class.

Students produced a large 1:20 model of their project and detailed 1:50 drawings. The models in Fig. 2 and Fig. 3 act almost as structural prototypes, allowing students to text spans and thicknesses which relate closely to the real-world dimensions.

The influence of reuse varied from project to project. Some students willingly engaged with reuse as a theme, developing their own briefs and parameters beyond what was set out in the original project description. Some students found existing buildings which were for sale and actively reused these real buildings in their design. This gave their project an extra dimension of reality and tactility.

Other students struggled with differentiating between reused materials or regular materials, The authors believe this problem mostly relates to the hypothetical nature of the project. If students are dealing with a hypothetical material, it is difficult to differentiate or relate to it being new or re used.

4 DISCUSSION AND CONCLUSION

The authors found introducing an element of reuse in a student project in first year to be successful. Students engaged with the theme and were inspired by it. Some students actively incorporated it into their project as a key design driver. However, as it is the first year of their studies the students were limited by how far into detail they could go with reusing materials. More experience developing projects and working with detail drawings would be needed for the theme of re use to be more central in a student's project.
But as the first step towards moving architectural education to embrace the world of reusing timber elements we feel the project was a success.
.
If 2023, we have also included re use of architectural materials and elements into a design project. However, this time the authors have found an existing building in Oslo which will be demolished in the coming year. Students have visited the building, map the existing materials there and have begun making both analogue and digital models of the elements which they will then use in their own project. The project will be finished by May 2023 and the authors believe this strategy of using an existing building to be even more effective as the students will have a tactile relationship to the material, they are re using. It is also a part of their final project, which is twice the length of the 6 x 6 x6 project. This will give the students more time to study the existing materials and explore how they can be used in different ways.

As final note, the authors find the including on reuse to be an inspiring and unpredictable aspect to add into students' design project in first year. The authors are still testing how best to do this but are committed to making reuse a permanent and essential part of the curriculum in first year architecture studio at AHO.

ACKNOWLEDGEMENT

The authors thank the students of GK2 2022, and colleagues at the Institute of Architecture AHO for their support producing this paper.

World Conference on Timber Engineering Oslo 2023

FINDINGS FROM THE 2022 NORTH AMERICAN MASS TIMBER RESEARCH NEEDS ASSESSMENT WORKSHOP

Samuel L. Zelinka[1] Richard Bergman[2], Marco Lo Ricco[3], William A. Martin[4], Bill Parsons[5], Iain Macdonald[6], Jennifer Cover[7]

ABSTRACT: The 3rd North American Mass Timber Research Needs Assessment Workshop sponsored by the US Forest Service, Forest Products Laboratory was held September 20-22, 2022. The purpose of the workshop was to convene experts on mass timber and cross laminated timber to develop a prioritized list of research needs for the North American mass timber industry. Invited workshop participants included design professionals, academics, industry leaders, and government employees. The workshop built upon prior mass timber research needs workshops that were conducted in 2015 and 2018.

KEYWORDS: mass timber, cross laminated timber, building codes, structural design, fire design, life cycle analysis, economics

1 INTRODUCTION

Mass timber typically refers to engineered wood composites such as cross laminated timber, glulam, and structural composite lumber that have been laminated into large members with unique fire and structural properties. Of the composites that comprise mass timber, cross laminated timber (CLT) has received the most attention in recent research [1-3].

CLT is unique among mass timber composites in that it consists of large panels (up to 18 m long) that can be shipped to the job site with precut fenestrations and easily erected as wall or floor systems [4,5]. CLT was first recognized in the International Building Code (IBC) in 2015 [6]. Following this recognition within the IBC, interest in mass timber, especially CLT has rapidly increased within the United States and Canada. As of December 2022, the number of projects using modern MT and post-and-beam construction in multifamily, commercial, and institutional buildings had grown to 1,677 across all 50 states in the United States, an increase of approximately 40% in just 18 months [7].

In 2015, the US Forest Service, Forest Products Laboratory held a workshop to characterize what was needed to move the mass timber industry in North America forward [8]. A subsequent meeting was held in 2018 [9]. These research needs workshops helped to focus research activities and funding towards high impact research projects within the field of mass timber. Since the original workshop in 2015, research findings have justified code changes that have resulted in increases to the height and area requirements for mass timber buildings recognized within the 2021 and 204 version of the IBC [10].

2 2022 NORTH AMERICAN MASS TIMBER RESEARCH NEEDS WORKSHOP DEMOGRAPHICS

The workshop organizers solicited participation from members of industry, academia, government, and other research institutions. In total there were 132 workshop participants.

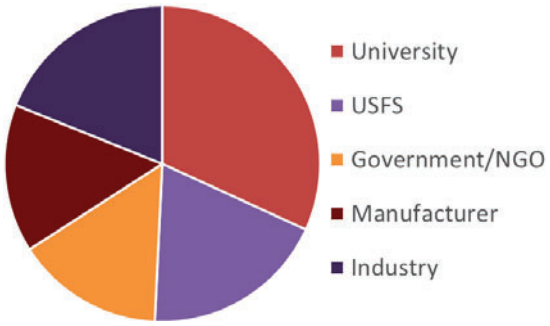

***Figure 1**: Professional composition of the 2022 North American Mass Timber Research Needs Workshop.*

Figure 1 illustrates the composition of the workshop attendees. The largest group was University participants, with 42 members. The US Government had 32 attendees. The remaining 58 participants represented the industry, including non-governmental organizations that represent the wood industry. The geographical locations of the attendees are shown in (Figure 2), and is highly correlated with North American forest products manufacturing production in the Southeast US, Northeast US and Eastern Canada, and the West Coast of the US and Canada.

Figure 2: *Geographical location of the participants.*

Interestingly, nearly two-thirds of workshop participants had not participated in any of the previous mass timber research-needs workshops. Twenty percent of participants had participated in both previous workshops (Figure 3).

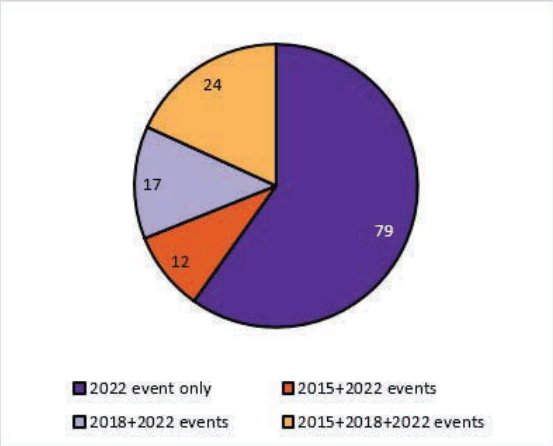

Figure 3: *Number of workshop attendees that had attended either the first or second Research Needs Workshops.*

3 PRIORITIZING RESEARCH NEEDS

Workshop participants were asked to give numerical scores to each research topic (Table 1) in both "effort" and "impact". The results were then plotted in real time on an impact-effort graph (Figure 4). The zero to one hundred scale of *effort* was calibrated by equating fifty percent effort with a 2-year $500,000 total investment of research time and money. This mark was chosen as it corresponds with a single Wood Innovation Grant. No other scaling was offered, so participants had to discuss and judge lower and higher impact efforts as a multiple of the time and budget assigned to the fifty percent effort. Scaling for *impact* was much less certain, because workshop participants were instructed to consider a variety of criteria. High impact could be judged by moving large volumes of wood, making commercial construction more sustainable, or developing a technology that fulfils a niche that competing materials cannot satisfy.

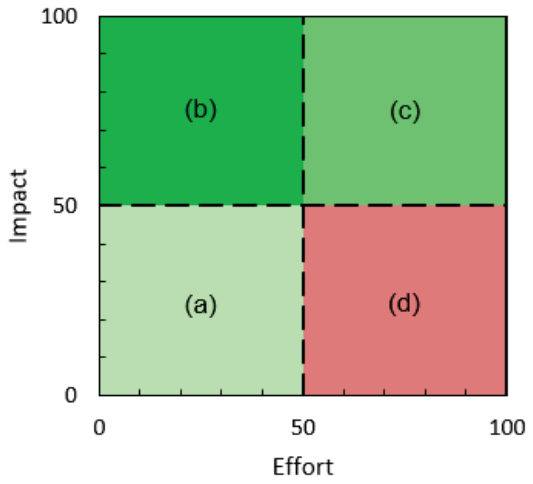

Figure 4: *Example of the impact effort matrix used to plot the results of the research needs symposium.*

Proponents of the impact-effort matrix recommend this type of group evaluation, because the results may be plotted and divided into four quadrants that may assist prioritization [11]. According to the vernacular terms, the bottom left (a), top left (b), top right (c), and lower right (d) quadrants respectively represent *incremental* gains, *easy wins*, *big bets*, and *money pits* [12]. Gilad critiques the standard effort-impact ranking system because people often underestimate effort and overestimate impact. To account for this bias, Gilad suggests using confidence values to redraw proportions of the chart quadrants, which typically renders the regions unequal in size. In addition, Gilad argues that negative impacts should be considered to identify potential *loss generators* in a fifth region of the plot.

https://doi.org/10.52202/069179-0596

3.1 BREAKOUT SESSION TOPICS

The workshop contained seven breakout sessions for the prioritization of research needs. Workshop participants were divided into four rooms for the prioritization of research needs. Each room contained a moderator and a notetaker. An effort was made to shuffle the composition of the breakout rooms throughout the workshop while keeping the overall demographics similar to the workshop demographics (Figure 1).

Each of the seven breakout sessions covered a different topic (Table 1). Most breakout sessions were two hours long. However, the breakout sessions for "Architectural Research and Construction" and "Sustainability and Economic Analysis" were each only 1 hour long.

Table 1: *Breakout session topic areas*

Order	Subject
1	Fire performance
2	Durability and building physics
3	Architectural and construction research
4	Structural system design and performance
5	Materials and manufacturing processes,
6	Sustainability and economic analysis
7	Infrastructure and nonbuilding applications

The moderators began each session by collecting scores on ten topics that were identified as research needs by the meeting organizers. These topics were typically developed by identifying high priority topics from the previous workshop [9] that had not been addressed.

The 10 research topics suggested for prioritization in the *fire performance* breakout session are included below.

Table 2: *Topics prioritized in the fire performance breakout session*

Order	Subject
1	Non gypsum methods of encapsulation/fire protection
2	Penetrations in CLT for fire protection
3	Char rates for CLT (linear/non-linear models)- extending out to 3 hours
4	Safe amounts of exposed CLT
5	Hybrid connections (Steel + CLT)
6	Adhesives, lamella thicknesses, and delamination risk
7	Minimum separation distances for exposed mass timber surfaces (column to wall/floor or corner)
8	Fire spread in cavities and concealed spaces
9	Construction fires in mass timber buildings
10	Traveling fires in open floorplans

In addition to these research topics, moderators and notetakers were encouraged to collect "write-in" topics from the audience. These write-in topics were also scored within rooms.

3.2 DATA ANALYSIS

Following the workshop, the scores for research topics were then compared across rooms. Each room had a different method for determining a consensus score for the research topic. The polling method in one room asked participant to raise hands at the beginning of each polling period and lower them, when the level of effort that was called out seemed too high. Some hands were lowered early, while others remained up for the entirety of the topic scoring. The moderator, having the best perspective of the entire room had to judge the consensus score, based on values when most participants lowered hands. In other rooms, vocal participants proposed an initial score and revised it higher and lower via debate. Because individual and anonymized input was not recorded during the live polling sessions, the consensus score may be significantly influenced by moderator discretion and peer interactions within each room.

To account for these differences across rooms, it is important to examine both the mean value of the score along with the variation in the score across rooms. To illustrate this variation in the impact-effort matrices, a diagonal line was included for each data point. The length and slope of the error bars provides more insight. Short error bars indicate good consensus, in contrast to long error bars that indicate dissension among the consensus scoring of each room. Error bars with a shallow slope,

nearly horizontal, indicate variations in assessing effort while there is general agreement on impact. Error bars with a steep, nearly vertical slope, indicate variations in assessing impact while there is general agreement on effort. Diagonal error bars of approximately one-to-one slope indicate differences in judging both impact and effort. The absence of an error bar typically indicates that a *write-in* topic was mentioned and scored only in one of the discussion rooms.

4 RESULTS

4.1 FIRE PERFORMANCE

The impact-effort graph for the fire performance breakout session is shown in Figure 5. The pre-determined topics for the group are illustrated as numbered topics shown in Table 2 and the write-in topics are listed in Table 3.

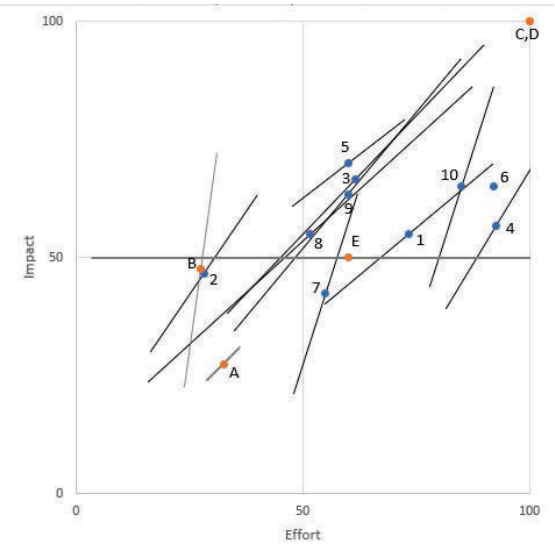

Figure 5:*Impact-Effort matrix for the fire performance breakout session. Numbered points refer to prepared research topics. Lettered points refer to a write-in topic. The topics associated with the numbers and letters are given in Table 2 and Table 3.*

Numerical values of the effort and impact along with the coefficients of variation are given in
Table 4. No topics in the fire research were ranked as "easy wins", that is, lying in the top left quadrant. However, Item B was nearly ranked as an easy win, falling just below the 50% impact. This item involved developing a database of fire tests that could be used for code approvals.

The fire research breakout session had only one item that could be characterized as fell in the lower right quadrant of the graph. This research topic involved determining the minimum safe separation distances for exposed wood members in mass timber structures. It should be noted that different rooms had a widely different view of the impact of this research item; the coefficient of variation was 50%. Most items fell in the upper-right quadrant (which Gilad [12] calls "*big bets"*). This speaks to the cost, and potential impacts of additional fire testing on mass timber.

Table 3: *List of write-in topics for the fire performance breakout session.*

	Subject
A	Post fire impacts: insurance loss models and post-fire repair.
B	Database development for approvals (prescriptive and performance-based design)
C	Fire retardant treated CLT
D	Exterior fire protection systems for mass timber buildings/infrastructure/structures
E	Development of guidelines or tools for performance-based design

Table 4: *Average effort and impact of the topics discussed in the fire performance breakout session along with their coefficients of variation (COV). A description of the items is given in Table 2 and Table 3. There was no COV for Item 6 as only one session provided results.*

	Average		**COV**	
	Effort	**Impact**	**Effort**	**Impact**
Item 1	73	55	25%	27%
Item 2	28	47	42%	36%
Item 3	62	67	46%	43%
Item 4	93	57	12%	31%
Item 5	60	70	20%	13%
Item 6	92	65	-	-
Item 7	55	43	13%	50%
Item 8	52	55	69%	57%
Item 9	60	63	42%	45%
Item 10	85	65	8%	33%
A	33	28	11%	13%
B	28	48	13%	52%
C	100	100	-	-
D	100	100	-	-
E	60	50	94%	0%

https://doi.org/10.52202/069179-0596

4.2 STRUCTURAL SYSTEM DESIGN AND PERFORMANCE

The impact-effort graph for the structural system design and performance breakout session is shown in Figure 6. The prepared topics for the group are illustrated as numbered topics (1-10) and the numbers correspond with the topics in Table 2 and the write-in topics are listed in .6 and are represented by numbers 11-25.

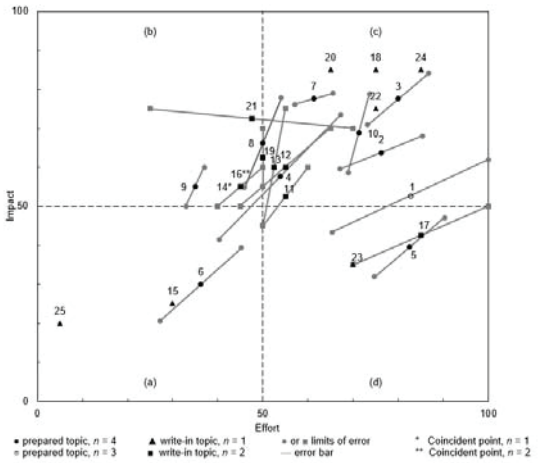

Figure 6: *Impact effort matrix for the structural system design and performance breakout session. Numbered points refer to prepared research topics. Lettered points refer to a write-in topic. The topics associated with the numbers are given in Table 5 and 6 .*

Table 5: *Topics prioritized in the structural system design and performance breakout session*

Order	Subject
1	Full-scale validation testing of structural assemblies (seismic, wind, blast, or progressive collapse simulations)
2	Braced frame development of various configurations (BRBs, specially detailed, concentric, range of ductility R = 3 to R = 6, etc.)
3	Shear wall development of various configurations (rocking post-tensioned or passive, conventional, hybrid, stiff R= 1.5 vs. ductile R= 6, etc.)
4	Diaphragm development of various configurations (simple span, cantilever, service, failure, load and displacement capacity, chord and fastener details)
5	Moment-frame development of beam-to-column connections (post-tensioned or passive systems)
6	Protective performance for multi-hazard resilience (wind-launched debris, blast and ballistics, disproportionate/progressive collapse)
7	Two-way slab development (post-tensioning, punching shear, load distribution, etc.)
8	Glued-in and cast-in connection development for improved force transfer in panelized and hybrid assemblies
9	Perp to grain bearing capacity and characterization of deformations under uniform and varying loads
10	Mass timber slab development for composite action, enhanced stiffness and vibrational characteristics

https://doi.org/10.52202/069179-0596

Table 6: *Write-in topics for the structural systems design and performance session*

	Subject
11	Standardization of mass timber rocking walls
12	Compare panelized SCL alternatives to CLT (e.g. GLT, NLT, DLT, LVL, MPP)
13	Mass timber moment connections
14	Screw reinforcement of mass timber
15	Edgewise bending of CLT beams
16	Penetrations and holes through mass timber panels and beams
17	Full-scale progressive collapse testing
18	Connection details for seismic displacement compatibility
19	Period estimation via vibrations monitoring for seismic and wind design
20	Intermediate shear wall - ordinary with ductile hold downs
21	Reinforcing at notches/openings of mass timber panels and beams
22	Timber-to-timber composites and built-up structural members
23	Full scale blast testing- windows, connector system
24	Seismic tests of 4-8 story buildings with fully wood systems
25	CLT tornado saferooms

The structural design section contained one item that fell into the lower right quadrant of the graph, Item 5, "Moment-frame development of beam-to-column connections (post tensioned or passive systems). The session also contained one "*easy wins*" in the top right quadrant, Item 9, "Perp to grain bearing capacity and characterization of deformations under uniform and varying loads." A summary of the scores along with the coefficients of variation are given in Tables 7 and 8.

Table 7: *Average effort and impact of the topics discussed in the structural system design and performance breakout session along with their coefficients of variation (COV). A description of the items is given in Table 5.*

Topic	Average		COV	
Number	Effort	Impact	Effort	Impact
1	83	53	36%	31%
2	76	64	24%	13%
3	80	78	17%	17%
4	54	58	50%	55%
5	83	40	19%	38%
6	36	30	50%	62%
7	61	78	14%	4%
8	50	66	16%	35%
9	35	55	12%	18%
10	71	69	7%	29%

Table 8: *Average effort and impact of the topics discussed in the structural system design and performance breakout session along with their coefficients of variation (COV). A description of the items is given in*

Topic	Average		COV	
Number	Effort	Impact	Effort	Impact
11	55	53	13%	20%
12	53	60	26%	24%
13	53	60	7%	35%
14	45	55	-	-
15	30	25	-	-
16	45	55	16%	13%
17	85	43	25%	25%
18	75	85	-	-
19	50	63	0%	17%
20	65	85	-	-
21	48	73	67%	5%
22	75	75	-	-
23	70	35	-	-
24	85	85	-	-
25	5	20	-	-

Note: COV = Coefficient of variation
No COV reported if $n = 1$
$n = 2$ unless noted otherwise

4.3 OTHER BREAKOUT SESSIONS

Given the space constraints of the proceedings paper, it is not possible to present all the data collected at the 2022 Mass Timber Research Needs Workshop. However, the full proceedings from the workshop will be available from the Forest Products Laboratory and WoodWorks.

5 FUTURE WORK

The research needs collected during the 2022 Mass Timber Research Needs Workshop will be used to guide mass timber research over the next few years. Coordinated efforts on mass timber research can continue to help the adoption of CLT and other engineered wood composites in building sectors of the United States and Canada.

6 ACKNOWLEDGEMENT

The workshop was partially funded through a joint venture agreement, 21-JV-11111137-026 between the US. Forest Products Laboratory and WoodWorks – Wood Product Council. The findings and conclusions in this report are those of the author(s) and should not be construed to represent any official USDA or U.S. Government determination or policy.

HYBRIDTIM, DESIGN AND CONSTRUCTION OF ENVIRONMENTAL HIGH PERFORMANCE HYBRID ENGINEERED TIMBER BUILDINGS

Kamyar Tavoussi[1], Alireza Fadai[1], Laia Haurie[2]

ABSTRACT: Immediate actions need to be taken to reach the sustainability target for 2050 of the European Commission for reduction of greenhouse gas emissions and net zero carbon (CO_2) emissions. Architects and engineering companies have already started designing hybrid timber buildings. In order to satisfy the needs of the labor market, it is necessary to prepare students with innovative applied skills in the area of design, construction and onsite construction management of hybrid timber buildings. The HybridTim project promotes sustainable, environmentally friendly design and construction of hybrid timber buildings.

KEYWORDS: Multi-story buildings, hybrid structures, study module, Erasmus+ program

1 INTRODUCTION

To educate a new generation of students, it is necessary to develop and integrate an innovative multi-disciplinary BSc/BA study module. Main target groups are higher education institutions (HEIs), in particular teachers/trainers and BSc/BA students.
Project HybridTim [1] aims to fulfil the future demands in higher education of students in design and construction of high environmental performance hybrid engineered timber buildings by trans-disciplinary innovative student-centered learning approaches. The objectives are:
1) To develop and deliver new trans-disciplinary module on design and construction of engineered hybrid timber buildings, which meets the needs of the HEIs and labor market representatives.
2) To improve competencies of students and teachers in problem solving and teamwork, innovative thinking, motivation, awareness of cross-professional project input and project management by using project-based learning, learning by doing and blended learning approaches.
3) To educate all participants (students, teachers, entrepreneurs) in the field of the engineered hybrid timber construction.
4) To ensure open awareness of the project results to local, national, European Union (EU) level and international target groups. The project is implemented by five higher education institutions from Denmark (Via University College, VIA UC), Lithuania (Vilniaus Gedimino Technikos Universitetas, VGTU), Spain (Universitat Politècnica de Catalunya, UPC), Latvia (Rigas Tehniska Universitate, RTU) and Austria (Technische Universitaet Wien, TU WIEN), assisted by Study and Consulting Center in Lithuania and Spanish association Gremi Fusta i Moble.

The aim is the development of a module of 9 ECTS (**E**uropean **C**redit **T**ransfer and Accumulation **S**ystem) for bachelor. The module will be dedicated to architectural design, architectural technology, construction technology, civil engineering, real estate management and related BSc/BA specializations. Working on one project in an intensive course seems to be the most effective way to transfer the knowledge to students. A module of 9 ECTS in one semester is recommended. Each HEI will adapt this module to local requirements. It means that also 3 times 3 ECTS courses in 3 following semesters are possible and optional. In this case it would be necessary to get sure, that the students are going through all courses.

2 MODULE PHASES

The new module will be tested during the project in three intensive learning/teaching courses. The first part of the module was held in Vienna, Austria in September 2021. The second part took place in Spain (September 2022) and the third one will take place in Latvia (April 2023). International building and construction project phases, which are used in most EU countries, have been adapted in the HybridTim project as a main template, namely brief phase, outline proposal, scheme design, detail 1 and detail 2 phases.

[1] Kamyar Tavoussi, Institute of Architectural Sciences, Structural Design and Timber Engineering Vienna University of Technology, Austria, tavoussi@iti.tuwien.ac.at

[1] Alireza Fadai, Institute of Architectural Sciences, Structural Design and Timber Engineering, Vienna University of Technology, Austria, fadai@iti.tuwien.ac.at

[2] Laia Haurie, Department of Architectural Technology, Universitat Politècnica de Catalunya, EPSEB, Barcelona, Spain; laia.haurie@upc.edu

https://doi.org/10.52202/069179-0597

In total, 75 BSc/BA students will be educated. Students will gain innovative trans-disciplinary knowledge in hybrid timber construction; using innovative learning approaches they will develop their research, teamwork, communication, and cooperation, creative thinking, problem-solving skills required in modern daily work environment. Stakeholders whose activities are related to construction and, in particular, timber construction, e.g. associations and private enterprises, will be involved in development of new module, therefore they will have an opportunity to share their expertise and include the topics that will help to acquire competences, required in labor market. In this way collaboration between academic and business sector will be strengthened.

3 FIRST MODULE IN VIENNA

The first module was held successfully in Vienna in September 2021, 25 students and a dozen lecturers from 5 participating universities took part.
The task was the development of a multi-story hybrid timber building for a given property in the area of "aspern Seestadt" in Vienna's fast-growing 22nd district in the north-east of the city - one of Europe's largest urban development projects. (Figure 1, 2, 3).

Figure 1: *Location of "Seestadt" inside Vienna (@google Earth)*

Figure 2: *Location of building site in "Seestadt" (@google Earth)*

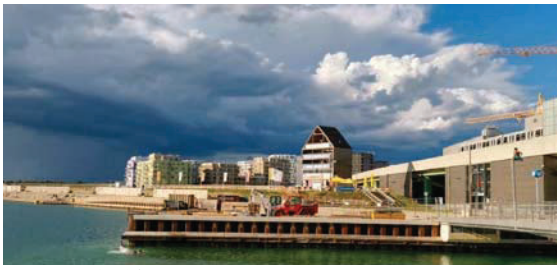

Figure 3: *building site*

The predefined task can be briefly summarized as follows:
"The developer wants to build a 10-story high multi-story house where timber is the dominating material. The plinth level 1-3 (first 3 stories) must be built with concrete as load bearing material. On top of this plinth a terrace must be created/designed, where there is common access for the inhabitants of the building, and also public access for people from the area. From level 1-3 the building must be designed as business-related functions (shops, restaurants, offices etc.) included common access areas is 985m² gross area in 3 floors.
From Level 4-6, there must be designed 8 apartments of different sizes where the apartments included common access areas is 810m² gross area. The rest of the roof for level 3 must be arranged as green area for common use.
From Level 7-10, there must be designed 4 apartments where the apartments included common access areas is 545m² gross area. The rest of the roof for level 6 must be arranged as green area for common use. (Figures 4 and 5).
Generally, the project must not contribute to adverse effects on the surrounding environment. The aim should be for the project to contribute to the improvement of the environment in the area, and to create an attractive building that simultaneously affects users for environmentally responsible behavior."

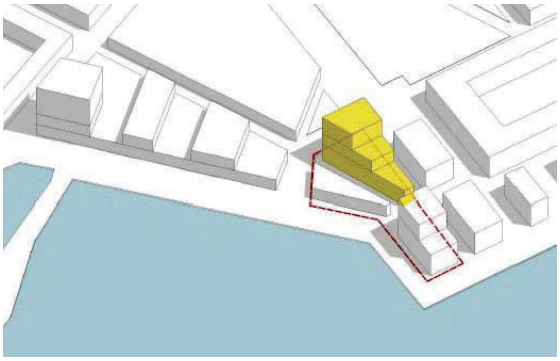

Figure 4: *Predefined building volume*

https://doi.org/10.52202/069179-0597

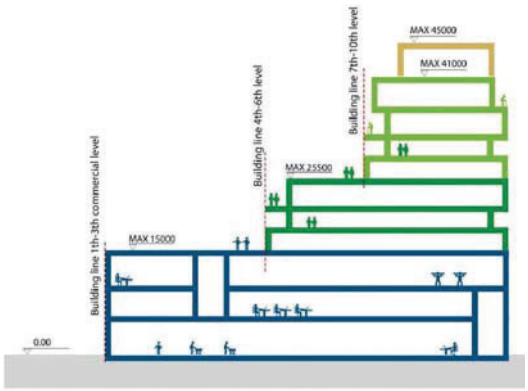

Figure 5: *Predefined section of the building*

Some face-to-face and online lectures have been held in the morning of the first week in the historical building of TU WIEN (Figure 6). The topics were about teaching methodology **p**roblem-**b**ased **l**earning (PBL), Architectural concepts, technical aspects of timber buildings, building management, building systems, statics and dynamics, sustainability, façades and building physics.

Figure 6: *Lectures*

In the afternoon, student groups developed and presented their project ideas (Figure 7).

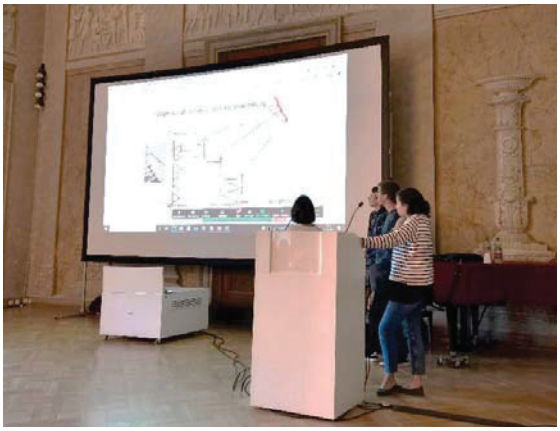

Figure 7: *Student presentation*

In the second week, site visits (Figure 8) and the workshop next to the project property were on the agenda (Figure 9).

Figure 8: *Site visit*

Figure 9: *Workshop*

Five projects were presented at the end.
In the following, one figure per group shall represent the results. The names of the group members are indicated.

4 SECOND MODULE IN BARCELONA

The second module was held in the Barcelona School of Building Construction of the UPC, during two weeks in September 2022. The number of participants was similar to the Vienna course, 25 students from the 5 participant universities and around a dozen lecturers. This intensive course had the aim to cover the scheme design phase of a multi-story hybrid timber building. In order to have enough information about the outline proposal phase it was selected an existing social housing complex located in Barcelona made with reinforced concrete structure and the students had the task to implement a structural system that maximizes the use of timber. The architects of the original project provided us with information and drawings that the students received as starting working material. Figure 16 shows an image of the existing building.

Figure 16: *Social Housing in Trinitat Nova. Source: Ruisánchez Arquitectes*

In the same way as in Vienna, the assignment for the students was contextualized with the area in which they were going to develop the project. In the case of Barcelona, the location was the neighborhood of Trinitat Nova in the district of Nou Barris (figure 17). This district located in the outskirts of Barcelona has one of the lowest household incomes of Barcelona and it is part of a program of urban regeneration from the Barcelona council. Among other actions the council has promoted social housing buildings, recovery of green spaces and increase of public services.

Figure 17: *Map of the districts of Barcelona*

The students were divided in five groups with participants from each university in each group. The task that they had to solve was as follows:

On 2005 the council of Barcelona set a public competition to build 189 units of social housing. The selected project consisted of a main building of ground floor plus 7 floors with a structure of reinforced concrete. The experience has been successful and the residents are happy with the outcome of the project. Now the city council wants to build a new social housing in the neighborhood, but they want to minimize the environmental impact of the building. Therefore, the use of timber structures is highly encouraged. On the other hand, for this project the maximum height restrictions allow to increase the number of floors to ground floor plus 9 floors.

Your studio has decided to modify the project of 2005 and adapt it to the new requirements. Therefore, your work team has to:

- *Implement a timber structural system.*
- *Define a ground plan at 1:50 to define the modularity and the integration of the structural elements in the spatial distribution.*
- *Pre-dimension of the constructive elements. Give one example of the structure and the façade.*
- *Description of the horizontal and vertical efforts and deformations.*
- *Description of the strategies to comply with the fire resistance requirements.*
- *Description of the joint system.*
- *Proposal to guarantee acoustic insulation and to reduce acoustic impact transmittance.*
- *Examples of constructive façade details.*
- *CO_2 footprint of the structural system.*
- *Compliance with the thermal transmittance of the envelope.*

As it can be seen in figure 18, during the course the students received some lectures related with relevant topics to develop the assignment, such as hybrid timber systems, statics and dynamics of timber constructions, acoustics and fire protection strategies. There were also organized technical visits to timber buildings in Barcelona city, including the Nou Barris area (figure 19) and to some timber constructions outside from Barcelona (figure 20).

Figure 19: *Technical visit to a building site near Nou Barris*

Figure 20: *Visit to a Passive House timber building*

The working groups also had time and space to work in their proposal, which they presented on the last day of the course. Figures 21 to 25 display an example of the outputs obtained by each group.

5 CONCLUSION AND OUTLOOK

The third module will take place in Riga in April 2023.
In the near future timber buildings will form a much bigger part of the European and international built environment. The future sustainable hybrid timber buildings will be designed and constructed with sustainable-engineered timber components.
The project aims are to fulfil the future demands in higher education of students in design and construction of high environmental high-performance hybrid engineered timber buildings by trans-disciplinary innovative student - centered learning approaches. Along Europe there is still a significant difference in the level of development of timber construction of different countries. This project has allowed the participant institutions to share experiences that could be later implemented in different bachelor degrees at a local level. Participation of professional associations help to increase the collaboration with stakeholders of the building sector

ACKNOWLEDGEMENT

This project, HybridTim 2020-1-DK01-KA203-075045 [1], is funded as an Erasmus+ program for education, training, youth and sport by the European Union.
The authors gratefully acknowledge the support of the UPC, Spain and the TU Wien, Austria.
Special Thanks to project leader Vijoleta Sulciene and all other colleagues for their excellent work: Roger Howard Taylor, Steen Fynbo, Agata Golab-Nielsen, Keld Bossow Nielsen, Frank Bertel, Martin Aicholzer, Daniel Stephan, Laura Tupenaite, Tomas Gecys, Mariana Palumbo, Pilar Giraldo, Edgar Segués, Alina Avellaneda, Ana Lacasta, Janis Zvrigzdins, Girts Zarins, Marta Loza.

HIBIWOOD – DIDACTIC APPROACHES FOR ACADEMIC EDUCATION ON MULTI-STOREY TIMBER BUILDINGS

Elena Mitrenova[1], Martin Aichholzer[2], Aída Santana-Sosa[3]

ABSTRACT: Due to climate change, political and societal demands for the greening of the building sector are increasing. The use of regionally renewable building materials, such as wood, is recognised as one of the main strategies whose potential cannot be fully exploited due to the lack of specialised know-how in the building sector. The present project responds to this challenge through a cross-border cooperation between five European universities. The partnership aims to conduct strategic research on the conditions necessary for the design and construction of multi-storey timber buildings, and to develop guidelines and principles to align the demands of the building sector with current academic education. The transdisciplinary elective module, developed through three international workshops and combined with innovative teaching and learning methods such as problem-based learning (PBL) and integral planning, provides students with specialized training in timber design methods and prepares them for the global requirements and changing demands in the construction industry.

KEYWORDS: cross-border academic cooperation, multi-storey timber buildings, transdisciplinarity, problem-based learning, integral planning, didactic approaches, academic education

1 INTRODUCTION

The EU Green Deal, the EU Taxonomy and the New European Bauhaus are initiatives of the EU Commission that aim at leading Europe into a climate-neutral future by 2050. The construction sector is currently responsible for an immense contribution to global warming, where about 8% of anthropogenic CO2 emissions worldwide come from the manufacturing process of cement [1]. To meet the EU climate targets for the reduction of greenhouse gas emissions, a rethink in the construction industry is unavoidable. One of the greatest opportunities for reducing emissions in the building industry lies in the increased use of regionally, renewable building materials. Timber has excellent constructive properties and is also ideal to bind CO2 in the long term due to its carbon storing effect. In addition, it offers high levels of prefabrication, which means that construction time spent on site can be remarkably reduced compared to conventional methods [2]. Timber is increasingly being used globally, but it requires specific expertise as well as a general rethinking of current planning and construction processes [3]. For fully exploiting its potentials, the current training of civil engineers and architects is still insufficient, especially in highly prefabricated construction, where extensive knowledge is already required during preliminary design due to fire protection, building physics and panelization of building components. The industry needs specially trained experts who understand the technical and economic interrelationships with other trades and building materials, which makes the embedding of timber specific design methods in the civil engineering and architecture curricula necessary [4]. Due to the complexity of the matter, the traditional academic transmission of knowledge is not sufficient. An integrated approach that brings together several disciplines and the acquisition of real-life skills are necessary.

2 HIBIWOOD – PROJECT DESCRIPTION AND OBJECTIVES

The project HiBiWood is implemented within the framework of ERASMUS+ Strategic Partnerships for Higher Education. It aims to satisfy the future demands of European higher education in the field of design and construction of sustainable, high performance building solutions in timber. It explores the following questions: how to integrate the latest timber-specific knowledge in the classic university curricula and how to guide students during the learning process by applying innovative didactic approaches. The cross-border partnership of five European universities (FH Campus Vienna, Austria; HAMK Finland; RBC Latvia; Cracow University of Technology, Poland and KVK Lithuania) ensures the international exchange of knowledge on sustainable building practices and increases the competences of all project participants (students, teachers, but also construction companies). The main target groups are European higher education institutions, especially teachers/trainers and BSc/BA students of architecture, civil engineering and building site management.

https://doi.org/10.52202/069179-0598

Focus of the project is the assessment of the framework conditions and requirements for planning and implementation of multi-storey timber buildings in the partner countries. A comprehensive survey was conducted among over 100 companies and experts within the timber construction industry, using a combination of questionnaires and expert interviews as the data collection methods. The results of the survey indicated a critical need for skilled workers within the timber construction sector. Over 70% of the respondents indicated that recent graduates lack the fundamental knowledge and expertise in timber construction. An analysis of the data revealed that a lack of familiarity with the matter among architects is crucial for the timber construction industry, as architects who were not well-versed with the material were unlikely to design wooden buildings due to time and respectively financial constraints. Furthermore, architects who are specialized in the subject often face challenges in finding contractors to execute their buildings.

A comparison of the markets in Austria and Finland with those in Poland, Latvia, and Lithuania showed that the former had a significant advantage due to the presence of companies producing high-quality timber building products. In contrast, the need to import them in the latter countries results in increased costs for erecting timber buildings and consequentially in a significantly smaller percent of constructed multi-storey timber buildings nationwide. Although all the analysed countries have traditional wooden constructions, projects of modern high-performance timber buildings are still mainly limited to the scale of single-family houses. Multi-storey residential buildings and larger-scale structures using wood construction are scarce in the case of Poland, Latvia, and Lithuania, and underrepresented in the case of Austria and Finland. However, due to political interest and related strategic programs promoting timber construction in Austria and Finland, there has been a growing trend of constructing multi-storey wooden buildings in these countries.

This tendency is also reflected in the education and training programs for timber construction specialists. Strategic research on available timber-related education in the respective countries is conducted with the aim to identify gabs and inconclusiveness with the requirements of the construction industry. In Poland, Latvia, and Lithuania, timber construction topics are minimally included in educational programs, while in Finland and Austria, they are widely offered as part of the bachelor's and master's programs in architecture and civil engineering at various universities and universities of applied sciences. In some cases, the topic is becoming increasingly essential to construction studies due to the high demand for multi-story timber buildings.

However, educational analysis and company surveys indicate an inconsistency between the programs offered and the graduates' perceived lack of real knowledge and know-how by the companies. The complex nature of timber construction may explain these results, as the design and implementation of timber buildings require a comprehensive understanding of various legal, planning, technical, economic, and logistical aspects. Knowledge transfer of these aspects should occur gradually and simultaneously, as close to reality as possible and in an interdisciplinary way, to create a tangible and long-term understanding of the matter.

Based on the analysis, guidelines and principles are developed jointly by the universities. The identified challenges are addressed through a transdisciplinary elective module with nine ECTS, that will be embedded in the academic programmes of the partner universities. The module is designed to provide a comprehensive coverage of the key aspects related to multi-story timber construction – architectural design, structural systems, timber technology, building physics, building site management. The approach taken is interdisciplinary and holistic, integrating these various aspects in all module phases, with varying levels of depth to address students with different levels of knowledge. Simultaneously, it complements conventional academic teaching by implementing innovative approaches, as integral planning, problem-based learning, problem solving, learning by doing and blended learning.

3 DIDACTIC APPROACH AND METHODOLOGY

At the core of the didactic concept of the module is the PBL method (problem-based learning) [5] [6] – students from different European countries and fields of study (architecture, civil engineering and building site management) plan a multi-storey building in timber in small groups, carrying out all real-life project phases (from preliminary design to detailed planning and building site management) and implementing sustainable principles. Three workshops are held as part of the project (Vienna 2021, Cracow 2022, and Riga 2023), which serve as test runs for the development of the module curriculum. Each workshop focuses on different real-life project phase (architectural design, construction solutions and building site management), while dealing simultaneously and holistically with the complexity of planning a multi-story timber building. The workshops require the collaboration and mutual understanding of the different disciplines involved, while visits to timber construction companies provide a realistic picture of acute challenges in the timber construction industry. The following subchapters will give an overview of the concrete didactic approaches and the tasks of the individual workshops.

3.1 WORKSHOP VIENNA 2021 – ARCHITECTURAL DESIGN AND “THINKING” IN TIMBER

Bachelor students of architecture, building site management and civil engineering enrolled in the 2nd and 3rd year of their respective programs were brought together within an international and integral design workshop. Having a team of different disciplines involved and working together from the conceptual phase is essential for optimizing the design process and increasing prefabrication level of timber buildings. A well-coordinated team encourages creativity while simplifying the design. This approach minimizes confusion and misunderstandings between team members, resulting in a more streamlined planning process. The diverse

https://doi.org/10.52202/069179-0598

perspectives of an interdisciplinary team allow for early identification of interdependent planning decisions and their consequences, providing a solid foundation for making informed decisions in the early stages of the project.

Nevertheless, the project faced some challenges regarding this approach. A comprehensive knowledge across various disciplines simultaneously, including structural systems, building physics, and timber technology is required for the design phase of wooden buildings. The lack of education in timber construction offered in the partner universities resulted in limited prior knowledge among the participants. To adequately apply the PBL-method in the design of a timber building, students must be brought up to an appropriate level of knowledge and taught how to "think in timber" – conceptualize construction using timber as a primary material. The issue was addressed through a preparatory exercise in which students were organized into groups of 5 and assigned the task of analysing an existing timber building using specified criteria. The parameters for analysis were: 1) architecture: concept, typology, plans, urban integration, flexibility; 2) structural system: vertical and horizontal load transfer, bracing; 3) building construction: timber technology, details, assembly site and construction process, tendering process, joining technology; 4) building physics: sound, head and moisture management, fire protection; 5) sustainability concept: social, ecological (life cycle assessment), and economical; dismantling strategies. The comprehensive theoretical and technical research and analysis served as a foundation for future elaboration of the workshop assignment.

The two-week workshop was conducted in September 2021 at the University of Applied Sciences Campus Vienna. The thirty students from the five universities who participated in the project were organized into six multidisciplinary teams. Each team was composed of three architects and two representatives from the fields of civil engineering and/or building site management.

The primary objective of the project was to create high-quality residential units with flexible planning and direct access to outdoor spaces. To achieve this, the focus of the project development was to explore and exploit the potential of industrial prefabrication, including an organized configuration grid with high architectural quality that allows modular-based construction with the possibility of small modifications for customisation. The workshop tasked the students to design a multi-storey timber building with 3 to 4 storeys tailored to the needs of young people and young families. The design should include individual flats with sizes of 30 to 45 m2 and larger ones of approx. 60 to 90 m2, with the possibility that two small flats could be merged into one bigger flat. Additional common areas, community rooms, gardens and a bicycle storage room should be included for better usability of the residential area and staircase. The construction should meet the criteria of an Austrian construction class III and the maximum building height should not exceed 11 meters. Furthermore, the design had to be quick and cost-effective, with innovative serial or modular construction, high architectural quality, and the greatest possible conservation of resources in production, construction, operation, and dismantling. In terms of sustainable conceptualisation, the life cycle aspect, and the question of reuse (resource-saving, dismantling, and recycling) were also highlighted.

The project partners provided continuous guidance and supervision to the students throughout the duration of the assignment, as well as face-to-face lectures that covered the essential planning aspects of timber buildings. These lectures were introductory in nature and aimed to provide a comprehensive understanding of the various criteria needed for the design process of timber constructions, such as architectural planning and specific requirements for the design process; forestry and sustainable aspects; structural systems and static requirements; timber technology and products; tendering, structural systems and elements; building physics - sound, moisture, heat, fire protection.

To ensure a real-life learning experience, two field trips were organised. The students visited the timber production hall of the Austrian company "Handler Group" and were given an inside-view of the prefabrication process of building elements. Additionally, a visit was paid to the timber construction site of "Forum Am Seebogen" in Seestadt Aspern, Vienna, which was designed by the architectural studio "heri @ salli" and executed by the construction company "Strobl Bau GmbH". This gave the students a first-hand experience of a timber and modular construction site.

As the final output of the workshop, the students prepared a presentation of their projects, along with a poster containing all plans, basic calculations, and a physical model. This was then presented and defended in front of a jury.

The constructability of the project was evaluated through a structural analysis and design, which identified the vertical and horizontal load transfers and estimated the dimensions of the main elements. As a result of the workshop, the students gained an excellent understanding of timber constructions systems, their load bearing properties, and its effect on the design requirement. This understanding enabled them to creatively incorporate the analysis into the design process, resulting in the design of multi-storey timber buildings with high architectural quality.

3.2 WORKSHOP CRACOW 2022 – CONSTRUCTION SOLUTIONS AND DETAILING IN TIMBER

The second instalment of the HiBiWood workshops took place over a period of two weeks, commencing in May of 2022, at the Cracow University of Technology (CUT). It was attended by thirty-six participants, two-thirds of whom were architects. The task of the workshop was to build on the projects designed in Vienna and develop details of building elements (superstructure catalogue) considering the physical and technical properties of timber. Of the participants, eight had also attended the workshop in Vienna and were able to explain the peculiarities and development of the projects to the additional participants.

During the workshop, the lecturers encountered again the issue of heterogeneous knowledge levels among the

students regarding timber buildings. To mitigate this discrepancy, a preparatory exercise was conducted. The students were divided into pairs and assigned to write a two-page short paper in response to a question focused on either building physics or structural aspects of timber constructions. The aim of these questions was to equip the participants with a foundational understanding of the aspects, prior to engaging in the main workshop task. The questions covered the topics of vertical and horizontal load transfer and bracing; cantilever structures; roof, ceiling, and wall systems; airborne and impact insulation; decoupling; summer suitability in timber buildings; moisture protection; air tightness; systematization and prefabrication. The students who effectively addressed these questions were designated as subject matter experts and were available to provide guidance and support to their peers besides the supervisors during the workshop activities.

The initial phase of the main workshop assignment involved a comprehensive static analysis of the projects. This analysis comprised of the explanation of the structural grid, the transfer of vertical and horizontal loads through the primary and secondary constructions and bracing concept, and the examination of the foundation and roof system spanning. Based on the results of this assessment, the selected timber technology was re-evaluated, and necessary modifications were made to the architectural plans and building element dimensions.

Subsequently, informed decisions regarding the building systems were made, including the selection of roof systems (warm roof vs. cold roof) and the explanation of ventilated structures, the selection of wall systems (bar-shaped, flat components, mixed forms) and their bracing, prefabricated elements and modules, and constructive moisture protection. The facade design was also evaluated with regards to its energy efficiency, and the construction system of cantilevers was considered. These decisions were based on a sustainability concept that emphasized the temporary approach, combinability, and dismantling potential of the building.

The final objective of the task was to develop a superstructure catalogue that detailed the connections of exterior wall-roof, exterior wall-ceiling, interior wall-ceiling, plinth (exterior wall), interior wall-roof, and cantilever components. These details were created in a scale of 1:10 or 1:5 considering important aspects such as the thermal insulation (u-value) and thermal envelope, seals and thermal breaks, impact and airborne sound insulation (Rw, Lnw), and moisture protection.

The task was executed through comprehensive, in-depth face-to-face lectures that built on the knowledge acquired during the first workshop. They had a profound emphasis on construction engineering and building physics, encompassing topics such as structural systems and mechanics, Eurocodes, thermal insulation, soundproofing, and moisture management. Additionally, they were specifically geared towards the elaboration of constructive details. The deepened examination of roof, ceiling, wall systems, openings, facade finishes, interior finishes, and cantilevers was emphasized in the context of prefabrication and utilization of digital tools. Furthermore, a practical exercise was provided to the participants aiming to reinforce their understanding of how to develop appropriate details that meet project specifications and technical requirements.

The examination of building physics with regards to longevity, durability, and sustainability was performed. An assessment of appropriate regional and low-carbon materials was carried out and fire protection, noise insulation, and moisture control were analysed. In addition, initial considerations were made regarding the assembly sequence of the construction elements. Skills related to communication and project management were developed, including the ability to plan collaboratively, make informed decisions, and integrate interdisciplinary knowledge.

As a result, the students demonstrated an in-depth understanding of timber's physical and technical properties. They were capable of effectively incorporating sound, heat, fire, and moisture protection concepts into the projects, which were successfully integrated into the elaborated constructive details.

3.3 WORKSHOP RIGA 2023 – BUILDING SITE MANAGEMENT AND BUILDING PROCESS WITH TIMBER

The final HiBiWood workshop, the third in a series of two-week workshops, will be held at the Riga Building College (RBC) in March 2023. It will concentrate on the aspects of required planning processes and building site management in the construction of timber buildings. Thirty-three bachelor students of architecture, building site management and civil engineering from the five partner universities will continue the work on the projects in small international and interdisciplinary groups, following the didactic approaches (integral planning and problem-based learning) of the previous two workshops. For the successful elaboration of the tasks is to be ensured that at least one participant per group is enrolled in a program of building site management.

To establish a shared knowledge base among the participants, the topics/ fact sheets developed during the second workshop are peer-reviewed by the project partners and utilized as teaching materials. Participants should familiarize themselves with the materials as preparation for the third workshop. During the workshop a random assignment process is to be employed to allocate a topic to each student. Subsequently, the students will be expected to collaboratively present the main points of the assigned topic, alongside some of their peers. This method will provide a solid knowledge foundation, which will be built upon by the lectures and workshop activities.

The assignment during the workshop involves the development of preliminary building site management concepts for the projects. Students are expected to consider various factors such as: costs, logistics, moisture protection on the building site, transportation and dimensions of building elements, prefabrication, digital processes, life cycle assessment, and management of all involved trades. By incorporating these aspects, students will be able to transition from planning to implementation and erection phase of the buildings. This know-how will have several benefits for the building process, including reduced time and costs, improved quality and life-cycle

https://doi.org/10.52202/069179-0598

optimization, and enhanced communication and transparency.

At the conclusion of the workshop, students will be able to understand the workflow of construction processes in timber, assess the advantages and disadvantages of various structural systems and building components, understand the impacts of changes, and make informed decisions. They will submit and present a report to a jury, including the topics of: 1) construction: level of prefabrication, modularity, selected products, applied digital processes; 2) logistics: dimensions of building components, transportation, assembling, timeline and coordination of trades, moisture protection and management of the building site; 3) assembly sequence from the foundation to the roof in chronological order; 4) rough cost estimation; 5) sustainability concept: temporary approach and combinability, dismantling concept, life cycle considerations; 6) reflection on the design mistakes from the first workshop that could be identified as roots of the encountered challenges and rectified in light of the acquired knowledge.

In addition to the report, students are expected to select one of the projects and construct a physical model in 1:20 scale, representing all storeys of the building, from the foundation to the roof, including the individual layers of the building elements. The model should be capable of being disassembled into the individual components, visualizing the chronological order of erection, building element dimensions by the transportation, prefabrication level, assembly process, and dismantling concept.

These assignments aim to create a tangible understanding of the process of erecting a timber building and require effective coordination, time management, and teamwork. Through implementation of this approach, the participating students can acquire and enhance their abilities in communication, project management, and interdisciplinary planning.

The elaboration of the assignments will be supported by in-depth face-to-face lectures on cost estimation, digital approaches, prefabrication, transportation, logistics, and dismantling. Leading timber construction companies are invited to present their building site processes, as well as best-practice examples of successful large-scale international projects in timber, with the aim to provide students with real-world insights. A comprehensive training session will be held at the beginning of the workshop with the aim to illustrate the corelation between the parameters: physical properties, costs, and sustainability of building materials. This approach will equip students with the crucial abilities to make well-informed choices regarding building material selection during the implementation phase of the projects. Continuous oversight by the supervisors aids in the elaboration of the assignments and guarantees the high quality of the completed projects.

As a result of the workshop, students will have a holistic and tangible understanding of the planning and execution process of multi-storey timber buildings. They will be able to make informed decisions and changes considering costs, logistics, and sustainable requirements, and incorporate them into a rough building site management concept.

4 RESULTS

The present publication reports on the outcomes of the first two international workshops that were completed at the time of writing.

Following the completion of the workshop in Cracow, six design projects were developed with a high level of detail. The didactic approaches implemented in the workshops demonstrated significant advantages in the elaboration of these projects. The use of wood as a building material motivated the students to incorporate sustainable aspects in their designs and to minimize the impact of the buildings on the environment. Sustainability concepts, such as green roofs, unsealing and leaving green areas free, screws instead of glue for joining components, sustainable insulation materials, and self-generated energy systems (including solar panels, heat pumps, district heating, and rainwater collection ponds) were integrated into the projects.

The students' elaborated plans, characterized by a compact design and simple shape, won the jury's approval. This simplicity encouraged cheaper and more creative solutions, and the projects included flexible internal walls that allowed for adaptation to the residents' needs and living situations. Furthermore, smaller units were designed to optimize cost and space efficiency.

Cross-laminated timber (CLT) was chosen as the primary construction material for most of the projects due to its durability, sustainability, and personal contact with Stora Enso employees during the first workshop in Vienna. During the second workshop, the students identified some oversized components in their designs, which were corrected to save material according to the corresponding load calculation. Some of the projects had also used CLT in the partition walls, which were replaced with lightweight frame structures in the second workshop.

The projects were characterized by a clear configuration grid with high architectural quality that facilitates the repetition of building elements for a modular-based construction, with small adaptations for customization. The students also prepared detailed planning of the repeating building elements (number, size, and endings for transport purposes), which had a prefabrication degree of over 80%. They selected local production companies to minimize transport costs and relied on a few suppliers. The selection of materials was based on an assessment of the correlation between durability of the materials during the life cycle and their costs. Façades and balconies were designed to be easily degradable and exchangeable due to the different life cycles of the individual building components.

Initial concept for the construction process was also developed that employed cost and time optimization strategies while minimizing the local area's exposure to traffic, noise, and dust due to the high level of prefabrication. The sustainability of the buildings was evaluated throughout their lifecycle, including resource-efficient production, construction, and operation, dismantling, reuse and recycling.

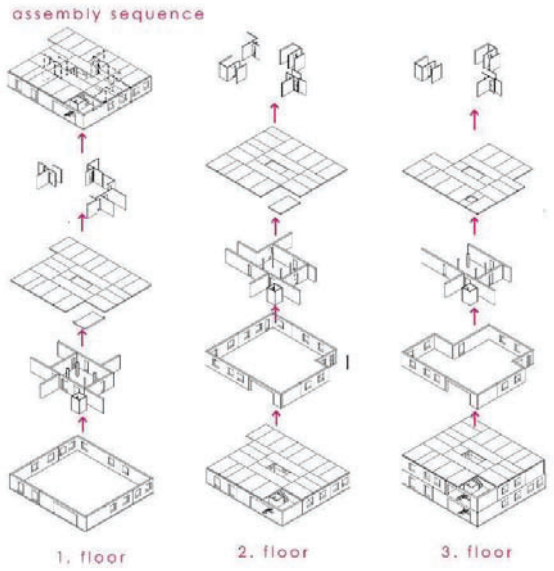

Figure 1: *Assembly sequence of project 4.*

The workshop implemented a didactic methodology where each discipline had predetermined tasks and deliverables that provided structure to the team's work. However, due to the different thematic focuses of the workshops (architecture, construction, site management), collaboration was sometimes challenging, as each discipline had different workloads at different stages of project development. This was particularly evident during the first workshop with focus on architectural design, where civil engineers and building site managers initially contributed less to the project and acted in more of an advisory or observational role. As the workshop progressed, these disciplines became more involved and completed their sub-tasks. Despite these challenges, students from both architecture and civil engineering disciplines gained a mutual understanding of each other's roles and challenges, which was given as feedback by several students at the end of the workshop. Early involvement of the different disciplines during the conceptualization phase prevented collisions and misunderstandings at the technical interfaces and significantly benefited the projects by allowing informed design decisions that facilitated the planning process in further phases. This approach resulted in fewer changes during the advanced phases of the planning process, leading to reduced time and costs, minimized errors, and higher quality and lifecycle optimization. Furthermore, better communication and transparency among the students increased shared knowledge, leading to a more collaborative and productive planning process.

The role allocation of the teams greatly influenced the successful completion of the projects. In projects where students lacked leadership positions, coordination of group task distribution and time management suffered noticeably. Significant progress in project development occurred after individual supervisor talks. These talks were conducted informally, at least twice per workshop per group, with lecturers providing direct feedback and answering questions.

The applied nature of the assignments and targeted in-depth input from the project partners had an impressive effect on the speed and the depth at which students acquired knowledge and know-how. This was particularly evident in students with little to no prior knowledge of timber construction, who were able to catch up on gaps in knowledge and get on the same level as their peers with prior know-how by the end of the workshops.

Overall, the workshops were evaluated positively by the students. The applied didactic approaches provided several benefits, including improved and applied knowledge and know-how about timber constructions, quality of designed timber buildings, international exchange, and the ability to act in a global context.

5 DISCUSSION: APPLYING THE DIDACTIC APPROCH TO EXISTING EDUCATIONAL PROGRAMES

The HiBiWood project employed experimental learning techniques in a series of international workshops. They demonstrated significant improvements in learning outcomes and designed timber projects, and thus outlined the need for alternative didactic approaches due to the complexity and diversity of the subject matter. The project's main objective is to implement sustainably the applied didactic approaches in partner universities' educational programs after the end of the project and make them available as open source to the broader scientific and academic community.

This challenge is addressed by the development of a BSc/BA module with 9 ECTs (240 academic hours), which has the overall objective to be both flexible and adaptable to meet the varying needs and levels of expertise of the target audience. It aims to provide a comprehensive understanding of timber construction, encompassing both foundational knowledge for those with no prior exposure, as well as more advanced topics for those with existing knowledge on the matter.

This is achieved by structuring the module into two stages, with the first half focusing on introductory concepts, such as architectural conceptualization, sustainable aspects, timber building products, building physics and technical properties, modular thinking, decomposability, and structural systems. The second half deals with the content in much greater detail, and includes additional topics of detail development, logistics, cost estimation, and the consideration of LCA in product selection. The module can be completed in one or two semesters, allowing universities to choose specific parts based on their needs (study program and/or previous knowledge of the students).

The educational module is composed of three distinct components. The first component consists of 25% of the total module duration (equivalent to 60 educational hours), delivered via four lecture courses with different deepening of the content, which provide fundamental theoretical inputs. The second component, also representing 25% of the module, is designed for individual self-directed learning, and comprises provided

https://doi.org/10.52202/069179-0598

learning materials and interactive problem-solving tasks such as in-depth analysis of best-practice timber construction projects or elaboration of timber-specific topics. The remaining 50% of the module follows the problem-based learning (PBL) methodology presented in this paper, centred on the design, and detailed planning of a multi-storey wooden building, covering all (or as needed, individual parts of) real-life project phases.

Ensuring interdisciplinarity and involving students from different disciplines is a key aspect of the module, albeit its implementation may be challenging for certain universities and technical colleges that offer programs only in architecture or engineering disciplines.

FH Campus Wien aims to introduce the second phase of the module in the regular curriculum, with the aim to provide an in-depth understanding of timber construction, building upon the fundamental knowledge and introductory concepts covered in the offered study programs. The module is intended as an optional advanced design exercise for architecture and civil engineering students, which can replace a pre-defined regular course. To maintain the international character of the program, the module is planned to be conducted as a summer school and open to international students from other universities. In the summer semester, students are expected to acquire the necessary background knowledge about timber constructions through blended lecture courses and preparatory assignments. In summer, students from diverse academic and national backgrounds will collaborate for several weeks to complete the practical construction task. The proposed summer academy will take place at the University of Applied Sciences Campus Vienna with the possibility of being hosted by partner universities in the future. It emphasizes practical experience, testing of different building approaches, and the inclusion of additional bio-based materials in the learning content, i.e., straw, clay in combination with timber. The summer school aims at active participation and mutual exchange of students and experts from different international universities, companies, and research institutions. The ultimate goal of this project is to establish an academic and scientific community that promotes the use of timber and other bio-based building materials and sustainable construction practices via interdisciplinary learning approaches.

6 CONCLUSIONS

HiBiWood responds to the increasing demands for greening the building sector by disseminating expert knowledge of multi-storey timber buildings. It promotes international networking, valuable exchange of knowledge and experience, and thus leads to an increased quality in teaching and research. The development and implementation of a module on timber construction in the academic programs of the partner universities ensures sustainable and lasting training of alumni with the required timber construction skills and expertise, which consequentially leads to sustainable promotion of multi-storey timber buildings. The teaching process is supported through innovative teaching methods that allow the students to work internationally and interdisciplinary, elaborate all actual project phases of a timber construction holistically and find solutions to real-life problems. The international teamwork deepens the intercultural competence of the participants and leads to open-mindedness towards others, cross-cultural thinking, and responsible action in a global context. The students are prepared for the future global requirements and changing demands in the construction industry.

Through strategic research, development of guidelines and principles and implementation of an innovative academic module, different actors at local, national, EU and international level are sensitised to sustainable building processes. The project bridges the gap between workforce and education on timber construction by meeting the needs of the building sector, providing university apprentices with actual real-life expertise, and guiding them through the learning process. It empowers the students to take sustainable action and contribute to achieving the climate goals.

ACKNOWLEDGEMENT

The project is funded by the European Union within the framework of ERASMUS+ Strategic Partnerships for Higher Education.

The authors express their gratitude to all students for their active participation in the project and their enthusiasm towards implementing the didactic methods outlined.

Appreciation is extended to MAGK Architektur Aichholzer Klein for facilitating the architectural assignment and construction site documentation.

The authors express sincere gratitude to all lecturers and construction companies who guided the students during the workshops and provided them with a real-life understanding of the subject matter.

HORIZONTAL AND VERTICAL KNOWLEDGE MANAGEMENT IN MULTIDISCIPLINARY RESEARCH AND DESIGN-BUILD TEACHING: A TIMBER-ONLY TRAIL

Günther H. Filz[1], Gengmu Ruan[2]

ABSTRACT: "The Kouvola Trail" is part of our timber-only research project and consists of 2 realized parts, (i) the prefabricated, "Modular Trail" and the customized "Plaza" modules. On the example of the trail project, this paper describes its combined systemic horizontal and vertical processes, network, knowledge management and multidisciplinary collaboration. Based on systemic knowledge management and the concept of the vertical design studio, we have simultaneously implemented and exposed our research in timber-only structures and architecture to teaching, real world application and manufacturing to enable both, horizontal and vertical alignments. We provide insights into how our academic research on using locally salvaged timber and wooden nail connections vertically links both, disciplines within Aalto, to the Kouvola region vocational college and to industrial partners and manufacturers. This vertical alignment and collaboration not only facilitated academic and practice-oriented knowledge transfer but also increased project-complexity by exchanging ways of thinking. Consequently, we recognized a significant increase of students´ technical expertise, functional development of knowledge, skills, and also motivation, as demonstrated by the "Street Furniture" prototype. Additionally, horizontal learning and collaboration as an inter-organizational system-relationship was fostered by setting up multidisciplinary design teams including the disciplines of civil engineering, architecture, arts and design, plus practical approaches to construction by the vocational school. Expanding this approach e.g. to business schools may open new perspectives and opportunities for industrial partners in future.

KEYWORDS: knowledge management, horizontal and vertical teaching, vertical studio, timber-only structure, wooden nails, architecture, timber engineering, multidisciplinarity.

1 SYSTEMIC KNOWLEDGE MANAGEMENT

Today, we can increasingly recognize the importance of knowledge and expertise as the basis for successful products and services. Not only companies have to adapt to this change, but also organizations of all kinds with respect to the transformation to a knowledge society [1]. In addressing the specific question of systemic knowledge management, according to [1], the task is to consider "knowledge management as an element of a context of social, organizational, technological and individual factors". However, one essential aspect of knowledge management is differentiating personal knowledge from organizational knowledge. In the context of knowledge-based societies and organizations, "knowledge work" has become a crucial factor for success, and in distinction from purely scientific work it involves the application of knowledge to practical tasks [2]. The interplay between individuals and organizations is essential in knowledge work, with an emphasis on how the expertise of the individual is continuously revised and refined in this context. Expertise has become a control element in knowledge-based societies, and this highlights the significance of personal and organizational knowledge. One of the critical insights in knowledge management is the need to organize both personal and organizational knowledge effectively including a departure from an exclusive focus on the individual. The challenge of managing increasing amounts of knowledge is often seen as a threat rather than an opportunity. Systemic knowledge management offers valuable and effective support wherever increasing amounts of knowledge have to be managed or the intention is to generate this increase [3]. In this regard various disciplines and branches from the supply chain management of companies to the curriculum planning of universities take into consideration both, vertical and horizontal alignments, when it comes to achieving specific strategic goals [3].

2 HORIZONTAL AND VERTICAL TEACHING, LEARNING AND COLLABORATION

The UNESCO International Bureau of Education (IBE) describes the organization of contents according to the sequence and continuity of learning within a given knowledge domain or subject over time as vertical articulation to improve coherence, and the scope and integration of curricular contents from different knowledge domains within a particular grade level as

[1] Günther H. Filz, Aalto University, ENG | Department of Civil Engineering ° ARTS | Department of Architecture, Finland, guenther.filz@aalto.fi & LSU Lightweight Structures Unit, Universität Innsbruck, Austria, guenther.filz@uibk.ac.at

[2] Gengmu Ruan, Aalto University, ENG | Department of Civil Engineering, Finland, Gengmu.ruan@aalto.fi

https://doi.org/10.52202/069179-0599

horizontal articulation or balance to develop integration between subjects, disciplines or knowledge domains [4]. In other words, alignment in teaching can be vertical when a specific subject or topic is taught to various grades, or horizontal when those in the same grade level teach different subjects. The steps that can be taken to make sure every student is receiving the same level of quality instruction is curriculum alignment that brings teams of teachers together to plan instructions. Therefore, vertical alignment is when teachers who teach the same content area meet across grade level bands, while horizontal alignment is when teachers at the same grade level meet to coordinate learning activities. Educators who use vertical alignment to support cohesive instruction find it helps them save instructional minutes by reducing repetition. On the other hand, horizontal alignment provides a higher probability that the majority students will be brought to a certain level, which can consequently be built upon.

Some architecture, design and arts schools have introduced for example so-called "vertical design studios", where students from multiple cohorts are taught together to provide holistic and contextual thinking skills essential to architectural design education [5–8]. Basically, [8] describes the vertical studio as a single-class combination of students at different levels in a given program of study, and [9] argues that the “Vertical Studio” system challenges traditional, sequenced design studio organization by allowing students of various developmental and skill levels to interact and compete with one another in a topical, thesis–based studio. To [10] the key feature of a vertical studio model is the collaboration of students across all years to address specific themes without overriding the traditional curriculum, but to both add, as well as, amplify design skills, and to create peer-to-peer learning opportunities.

In the context of systems design, [11] identifies three learning approaches that can be applied to vertical studio learning; learning through confusion, single versus double loop learning, and social learning through the "Master-Apprenticeship" model. The process of learning often involves confusion and uncertainty, and learning through this experience can help students develop a deeper understanding of the subject matter. Single versus double loop learning involves taking for granted versus questioning the assumptions and frameworks that inform goals and strategies. Social learning through the "Master-Apprenticeship" model involves project-based learning and critiques, allowing students to learn from experienced designers and develop the social competence and personal experience needed for collaborative design projects. The motivation behind most of these approaches is not only to train students to solve complex design problems or even research questions [12], but also to familiarize them with teamwork in which individual group members depend on each other's performance.

From the students´ perspective horizontal learning is about developing competencies such as communication, active listening skills, and responding effectively and constructively to conflict [13]. In addition to these general aspects, they also expand their technical and artistic knowledge and skills through collaboration with other disciplines [14]. They also gain expertise and an awareness of the potential and practical challenges that arise from interactions. So, the main focus of horizontal learning is the functional development of knowledge, skills, and behaviours that strengthen key competencies. Vertical learning from the students´ perspective, is about changing the way they think [15], feel, and make sense of the world; it is about increasing the complexity of how one sees and relates to the world and what one knows.

The authors of this paper conducted a review of literature pertaining to systems approaches, teaching and learning in vertical and horizontal articulation. The majority of the literature reviewed, which is related to vertical and horizontal articulation, highlights approaches and case studies from the design and arts disciplines, with a particular focus on architecture, industrial design, and the arts.

While the International Bureau of Education (IBE) describes horizontal and vertical curricular contents from various knowledge domains, it appears that even in architecture or design schools, these approaches are not systematically or explicitly implemented in the curricula. While we found single course descriptions that explain the contents and methodology to students, it is not reflected or incorporated into the overall curriculum. Interestingly, it appears that these approaches are not commonly followed or even known in engineering and business disciplines, as the authors could not find indication of vertical studio practices in those curricula or related publications. And even though we found extensive literature about multi- and transdisciplinary teaching and learning, to the authors knowledge there is marginal to no literature on combined multidisciplinary vertical teaching and learning articulations. In addition to our observations, we found that also only few companies and organizations seem to use an organizational development process that acknowledges the power of vertical learning conflict [13, 16].

3 VERTICAL AND HORIZONTAL, MULTIDISCIPLINARY RESEARCH AND DESIGN-BUILD TEACHING OF TIMBER-ONLY STRUCTURES AND ARCHITECTURE

In the context of the co-author´s research on timber-only structures and architecture, we investigate the topic both, from an engineering [17–19] as well as from an architectural and artistic point of view [20–22].

On the example of “The Kouvola Trail”, a timber-only trail project [17], this paper describes its systemic

horizontal and vertical processes, network, knowledge management and multidisciplinary collaboration.

Kouvola is a city and municipality in southeastern Finland. It is located along the Kymijoki River in the region of Kymenlaakso. “The Kouvola Trail” is part of a development initiative by the city of Kouvola and Kouvola Innovation Oy (Kinno) a business development company, which supports local companies and boosts the overall business environment.

Figure 1 provides an overview of the network of involved entities. As mentioned the PhD project “Timber-only Structures and Architecture” is located at the threshold of architecture and structural timber engineering, at the Department of Architecture, School of Arts, Design and Architecture and the Department of Civil Engineering, School of Engineering, Aalto University, Finland.

dimensions, orientations, and arrangements to determine their performance in timber-to-timber connections. Results showed that inclined wooden nails exposed to shear and tensile forces had a higher shear resistance due to their activated tensile capacity, with failure predominantly observed in nails loaded in tension rather than at the interface with the timber. An analytical model, later validated with experimental test, was developed using the results from shear tests to predict the load bearing capacity of timber-to-timber connections exposed to bending stresses.

At Aalto University, both of the above studies were presented to an almost equally distributed numbers of Master´s students from architecture and from civil engineering, whereas roughly 30-40% of students had international background including Spain, Belgium Austria, Italy and Latvia (Figure 1). All students took part

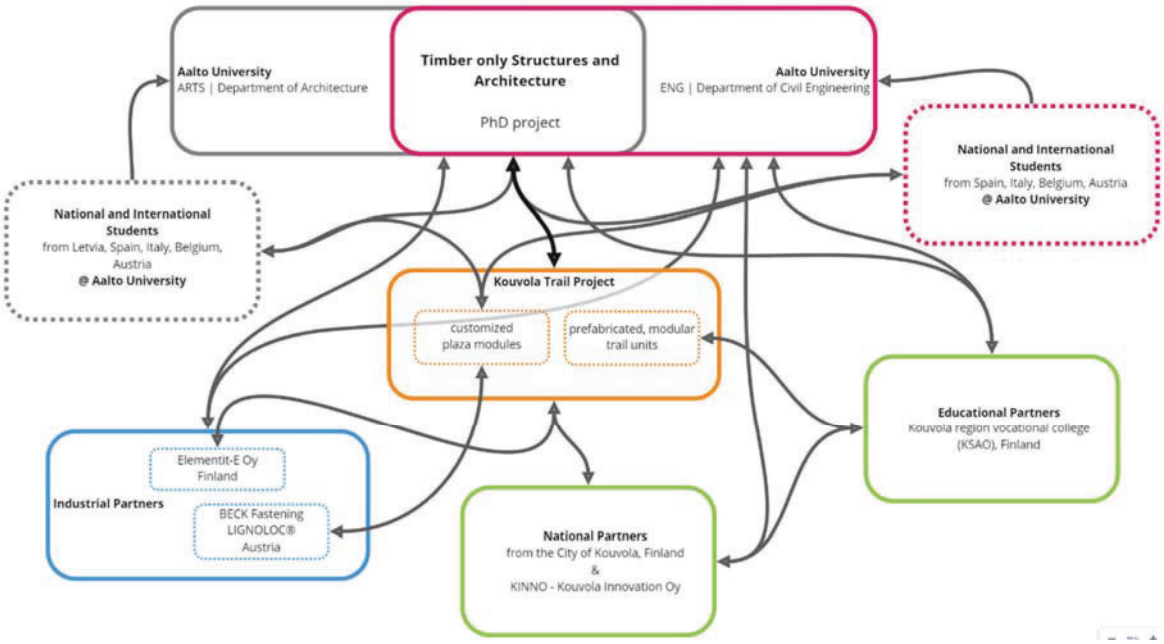

Figure 1: *Network of entities involved in the research and design-build teaching of the Kouvola trail with an emphasize on its systemic horizontal and vertical processes, network, knowledge management and multidisciplinary collaboration.*

The study [17] introduces a new low-tech design concept for short span structures using salvaged timber products and hardwood nails. Different design proposals for batches of salvaged materials with varying dimensions are guided by three aspects: timber board patterns, assembly process, and nail arrangement. The design concept is first conceptually applied short span bridges on a natural trail path in Finland. As a follow-up, in [18] we report about a series of 90 shear tests to explore the shear capacity and slip modulus of timber-to-timber connections with wooden nails. As densified wooden nails might become an alternative to metallic fasteners, this study examined different specimens of wooden nails in varying

in the same courses and classes. Leaving the exclusive focus on the individual the shared knowledge and expertise formed the basis for multidisciplinary groupwork, initially in pairs of architects and engineers and later as a larger group. After an introduction to the technological aspects and full-scale testing, the students rapidly got into the subject and were then challenged to creatively design structures and spaces based on the knowledge they had previously gained. From a course-of-study perspective, the approach may seem horizontal, but in reality, it is a more vertical articulation, as the level of knowledge about each other's disciplines put all participants on both an expert and novice level at the same time. The disadvantage of this approach is sometimes the slower development speed of projects, as the "expert input" is sometimes perceived as a limitation, but in the authors' experience, this delay is later more than made up for and the results are comparatively superior in quality.

https://doi.org/10.52202/069179-0599

However, the horizontal teaching and learning component could be most recognized by the increased technical expertise, functional development of knowledge, material understanding [23] and skills for all involved parties by disciplinary exchange between the individuals and groups. Additionally, an underestimated horizontal learning and collaboration effect as an interorganizational system relationship was fostered by the fact that the participating students came from different nationalities and (design) cultures.

Our academic research at Aalto University on using locally salvaged timber and wooden nail connections only vertically linked with the Kouvola region vocational college (KSAO), now Eduko (Kouvola Vocational Institute Ltd.) and industrial partners and manufacturers. Compared to academic research, teaching and learning, Eduko follows other principles. Eduko, an Erasmus+ accredited organization, is a vocational training institute involving annually approximately 6500 students in various training activities, and employs more than 300 experts on education, counselling, administration and other services. Training programmes focus on enhancing skills and expertise that are essential in the working life, including basic, advanced, or specialized qualification. On-the-job learning is a vital part of the learning process.

Similar to the previous experience within multidisciplinary courses at Aalto, the vertical alignment and vertical collaboration between Eduko and Aalto not only facilitated academic and practice-oriented knowledge transfer [20] but also an increase of complexity by exchanging ways of thinking [24]. The horizontal collaboration of same level or stage but different studies allowed greater ease of work and cooperation towards achieving common objectives, while emerging additional design and manufacturing options.

4 THE SIMPLEXITY OF A MODULAR TIMBER-ONLY TRAIL

"The Kouvola Trail" is part of above-mentioned timber-only research project and consists of 2 parts, (i) the prefabricated, "Modular Trail" units and (ii) the customized "Plaza" modules. Not least because of its low-tech [25, 26] and low processing approach, the Kouvola trail project can also be seen as a case of simplexity [27, 28], an emerging theory that proposes a possible complementary relationship between complexity and simplicity. Presently, both types of physical outputs have been realized, the more industrialized modular set of prefabricated trail units realized by Eduko, and a set of customized, bespoke but also modular elements for a plaza area of the trail by Aalto University.

4.1 PREFABRICATED "MODULAR TRAIL"

Due to practicality reasons, the fabrication of the "Modular Trail" was organized as a workshop at the facilities of Eduko in Kouvola. The expectations were to communicate the design intend and the approach to fabrication of modules from salvaged wood and wooden nails, with the aim to assembly a few prototypes.

6 Eduko-students were involved (3 female and 3 male), all of them vocational school students in construction. At the time of the workshop, their age was in the range of 25 to 60 years. The supervising team was formed by the co-author and one teacher from Eduko.

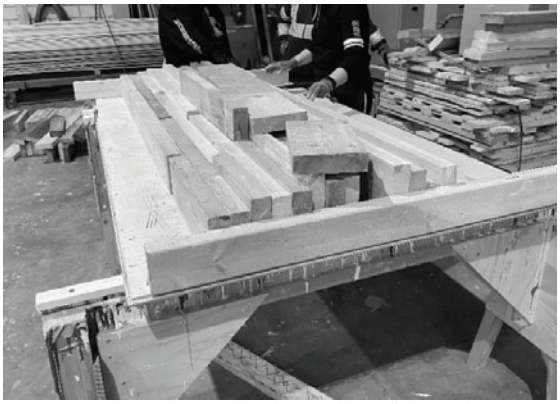

Figure 2: *The working table, designed by Eduko students to ease and expedite the precise fabrication of the modular trail elements*

Figure 3: *First finished modular elements*

Based on previously gained knowledge and expertise in the assembly of specimen for testing purposes, the supervisor provided an input lecture regarding the trail project, which covered the design concept, the intended salvaged material, and the connection details. Following this, a 5-day hands-on workshop was conducted, during which the first two elements were constructed under the guidance of the supervisor, serving as examples for the students to comprehend the process and the nailing gun with wooden nails. Due to their practical education and backgrounds, which provided them with a strong foundation in construction techniques and materials, the students were trained to act and improvise within specific boundaries and restrictions. They brainstormed ideas to streamline and simplify the work process, including considerations for working height, ergonomics, and efficiency. Consequently, they designed specific tools

such as the working table and nailing marker, to expedite the process. This practical approach enabled them to maximize their efficiency and fabricate an unexpected additional number of 10 elements, a total of more than 30m of trail, during the workshop days.

4.2 CUSTOMIZED "PLAZA" MODULES

In the context of the "Plaza" within the design build phase of "The Kouvola Trail", 7 university students were involved (5 female and 2 male), 6 of them Master students (3 in Engineering, 2 in Architecture and 1 in Architectural Engineering) plus 1 bachelor student in Engineering. Their age is in the range of 19 to 25 years. The supervising team was formed by the authors.

Figure 4: *Working process using templates and guides for precise fabrication of bespoke plaza elements*

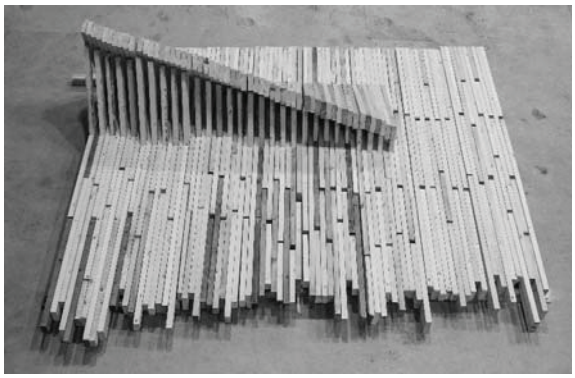

Figure 5: *Finished plaza part as exhibited at the exhibition SALVAƎƎ – sustainable use of salvaged wood [29]*

The fabrication of the "Plaza" clearly took advantage from the experience with Eduko students and their processes. Additionally, the fabrication process followed the above-mentioned course, its theoretical inputs and students´ work on their design proposals. Again a 5-day workshop was organized, but Aalto students prepared both digital drawings and working tools such as the working platform and nailing marker, based on the lessons learned from the fabrication of modular elements. During the first of a 5-day workshop, the students received instruction on the use of the tools and the arrangement of the timber boards from the supervisors, resulting in the completion of one element as a showcase on the first day. Then, the students were assigned different roles, such as nailing, arranging the timber boards and marking nailing locations, and cutting, in order to finalize the remaining elements. Interestingly, the role assignment was perceived in a very positive way by the students, since they were equally informed and updated on the processes, aims and results. As a consequence of this collaborative effort, seven elements were successfully completed over the course of the following four workshop-days.

5 STREET FURNITURE: A FOLOW-UP PROJECT

As a follow-up two students, one Master student in Engineering and one Master student in Architecture, who continuously followed the design as well as the design-build course and the workshop, gained experience on many levels. Besides expanding their skills and knowledge in each other´s discipline, they familiarized themselves with sustainability aspects such as the use of salvaged timber, with structural testing and architectural design or with using nailing guns.

Figure 6: *Preassembled units for a novel slide-in connected, planar reciprocal frame structure. The units are assembled from salvaged wood by the use of wooden nails.*

Figure 7: *Students on the assembled Street Furniture on campus of Aalto University, Finland [19]*

Consequently, they applied for involvement in the design of reciprocal frame structures from salvaged timber, another project within the research in timber-only structures and architecture. Based on our investigations in this field and their collected skills, the students successfully built and assembled a small-scale prototype of "Street Furniture" in just one day.

https://doi.org/10.52202/069179-0599

6 DISCUSSION AND CONCLUSIONS

Even though vertical studio practices are known and used in architecture, design and arts education, they are not reflected or incorporated into many curricula, and it appears that these approaches are not commonly followed or even known in the engineering and business disciplines. Combined multidisciplinary vertical teaching and learning articulations seem almost non-existent.

The attempt of combined multidisciplinary vertical teaching and learning articulations in the presented approaches and setting took advantage from involving at least one discipline, architecture, that is more familiar with the concept. Architectural students are also more used to problem-framing [14] and learning through confusion as described by [11]. Combined with problem-solving [14] skills and analytical work style, as they are very much taught at engineering schools, as well as practical down-to-earth and even improvising approaches, can significantly enhance the final quality of a project.

Obviously, the student groups of 15 in earlier design courses and 6 to 7 in the design-build phase have been of small size. With larger groups the risk of losing overview drastically increases for both sides, the students and teachers. In earlier courses with up to 290 students we perused similar vertical studio and multidisciplinary approaches. Although we could prove a significantly positive effect on students' creativity through creativity tests, such as Alternate Uses Tests (AUT) and ShapeStorm (SS) Exercises [30, 31] but together with challenging pedagogical and logistic tasks a relatively high number of students complained about lack of clarity and meaningfulness.

However, any system that allows free choice does so at the expense of rigorous control. The vertical studio provides considerable freedom of choice but with this freedom come some distinct limitations and new responsibilities for both faculty and students. For the success of the presented workshops and the project consequently, it was crucial to be well organized, with clear milestones and a very clearly communicated aim. In best case, the vertical studio advances the idea of collaborative design pedagogies. Not only does it promote and encourages a close working relationship between students of all years, across disciplines and the teaching staff but demonstrates an overall improvement of student's general development and self-responsibility as they identify their individual roles and contribution to the project. The confidence in decision-making is a side-effect of what [11] describes as social learning through the "Master-Apprenticeship" model. The follow-up project of the "Street Furniture" is an excellent example for the empowerment of students by this approach. The "Master" is both peer-to-peer learning and learning from teachers, that serve as a backup in case.

Accordingly, we have simultaneously implemented and exposed our research in timber-only structures and architecture to teaching, learning, manufacturing and real-world application by utilizing both, horizontal and vertical approaches, offering unparalleled opportunities for teaching, learning research and potential projects.

As the business value is hidden, only few companies and organizations seem to use an organizational development process that acknowledges the power of vertical learning [10, 12]. The collaboration with Eduko may be seen as a step in this direction and may open new perspectives and opportunities for companies but also academic partners from business schools in future.

ACKNOWLEDGEMENT

Thanks to the involved schools, departments and students across Aalto University, to Eduko (former KSAO) for their active participation in the manufacturing process of the modules, to the city of Kouvola and Kinno for their project support and for providing the opportunity for a first prototypical timber-only trail, to the industrial partners for providing the materials and tools, and to Gerhard Fink for the suggestion to write this paper.

World Conference on Timber Engineering Oslo 2023

RESOURCE-EFFICIENT MATERIALIZATION | SUSTAINABILITY FUTURE TRENDS

Alireza Fadai[1], Daniel Stephan[2]

ABSTRACT: The growing enormous number of mid-rise timber buildings in European metropolitan areas leads to the investigation of a possible optimization potential in the use of timber in combination with other building materials.
Within the framework of the Master's Course "Resource-efficient materialization" the Department of Structural Design and Timber Engineering at the Vienna University of Technology developed a multidisciplinary course including design concepts, feasibility studies and performance assessments of the timber components in order to improve the overall performance.
Due to this process, the focus in the development of a Master's Course lies on the feasibility and optimization of the structures on overall component level on the one hand, as well as on the normative realization aspects of innovative timber-based composite structures on the other hand. The Master's Course "Resource-efficient materialization" has formulated the integration of the natural building material timber to the current requirements of the construction industry as a parent research objective.
This paper shows the results of the studies and the conceptional design. The objective of the studies is to develop application-optimized timber systems with a special focus on the sustainability. A construction-optimized design with increased resource efficiency can be achieved.

KEYWORDS: Education, Sustainable building, Wood-based building systems, Life cycle assessment, Quality control

1 INTRODUCTION

In the past twenty-five years, an increasing number of timber-based buildings have been constructed in Europe. In fact, nearly all European countries allow at least six-story buildings in timber as regular solutions and pilot projects had been built up to twenty-four-stories.
In Austria, timber construction has increasingly gained market share over the last 20 years. Currently around one quarter of the construction volume in building construction is made of timber [1]. In the study [1], it is assumed that buildings with a timber content of 50 percent or more are classified as timber constructions. Here, only the statically supporting parts (wall, floor, roof) are used to assess this classification. Based on the total constructed usable space in the building sector, it has increased from 14 up to 24% between 1998 and 2018. Further increases are to be expected, especially for large-volume buildings (residential and public buildings). The timber-based proportion in housing construction is distributed to 53% (newly built single and multi-family houses as well as extensions and conversions) and 47% in non-residential construction (public, commercial and industrial buildings as well as agricultural buildings). At the residential segment, the proportion of timber-based construction has risen particularly strong with an increase from 10 up to 23% in the mentioned period [1].
The analysis in [2] show that the share of multi-story residential buildings between 2008 and 2019 was below 2% in Vienna, slightly above 3% in the other federal provinces and around 10% in federal province Styria (because there is a politically enforced timber construction quota).
Parallel to this, the number of start-ups of companies in timber construction is growing. On the whole, they are small: on average, five employees work in the companies. 83% of the companies have nine or fewer employees [3].
Not only the depicted timber-based building sector is under continuous change, but also the related building codes are in constant revision. Due to this process, the focus in the development of a Master's Course lies on the feasibility and optimization of the structures on overall component level on the one hand, as well as on the normative realization aspects of innovative timber-based composite structures on the other hand.

1.1 TEACHING A COMPREHENSIVE SET OF SKILLS

The Vienna University of Technology (TU Wien) is Austria's largest research and educational institution in the field of technology and natural sciences. More than 4,000 scientists are researching "technology for people" in five main research areas at eight faculties. The content of the studies offered is derived from the excellent research. More than 27,000 students in fifty-five degree-programs benefit from this. As a driver of innovation, TU Wien strengthens the business location, facilitates cooperation and contributes to the prosperity of society [4].
At the TU Wien, teaching and research are closely intertwined: excellent teaching depends on excellent research, and only leading researchers in their field are able to take the students forward to the next levels of science and technology [5].
TU Wien has been conducting research, teaching and learning under the motto 'Technology for people' for over 200 years. TU Wien has evolved into an open academic institution where discussions can happen, opinions can be voiced and arguments will be heard. Although everyone may have different individual philosophies and approaches to life, the staff, management personnel and students at TU Wien all promote open-mindedness and tolerance [4].
Aiming for relevance to practical applications is an essential component of teaching at the TU Wien, giving students a rich learning experience. The university also gives its students a great degree of freedom in choosing their curricula to promote a sense of personal responsibility for learning at the university and throughout life. This method-oriented solid foundation gives students the tools required for lifelong learning. Involving students in ongoing research programs at the TU Wien is key to train young scientists and to prepare them for future challenges in academia, industry, or business [5].

For several years, the Department of Structural Design and Timber Engineering (ITI) at the TU Wien has been offering neutral expert advice on the planning of multi-story timber construction projects. In the course of this expert advice and numerous discussions with developers and project managers, it has become apparent that no compactly summarized answers are available for the most common questions. In most cases, decisions with far-reaching consequences have to be made in a short time during planning and execution. Therefore, that proven processes, materials and methods are often relied upon, leaving little time and scope for new ideas.

Within the framework of the Master's Course “Resource-efficient materialization” the ITI at the TU Wien developed a multidisciplinary course including design concepts, feasibility studies and performance assessments of the timber components in order to improve the overall performance.

2 TEACHING METHODS

Timber construction requires a different planning and construction process than mineral construction. Due to the high degree of prefabrication, decisions have to be made in the planning phase in order to benefit from all the advantages of timber construction.
The approach in timber construction differs from the conventional construction processes in mineral-based solid construction. In mineral solid construction, it is economical to erect the shell of building in first step and then to install the windows and façade, as well as the building services and interior fittings.
In timber construction, on the other hand walls are produced in the workshop, irrespective of the weather. Windows, façades and interior cladding can be already ready for installation. This guarantees a high quality of workmanship and reduces installation time on site.
Prefabrication requires a different approach from design to construction. Many decisions have to be made at the beginning, in the planning phase. Prefabrication brings a high degree of planning, scheduling and cost reliability. It reduces the transport of materials to the construction site, the coordination of the trades on the construction site and the space required for construction site equipment (construction containers, material storage, debris troughs ...) [6].

Therefore, the Master's Course “Resource-efficient materialization” deals with the materialization of supporting structures and building envelopes in dense urban construction; special attention being paid to the use of resource-saving building materials, especially natural building materials.
The focus is on the interaction between choice and use of materials and the architectural, technical and ecological requirements to be met in the design and implementation.

The course offers a selection of solutions for implementing technically and economically successful projects and shows a way into the world of timber housing as well as helps to break down entry barriers due to a lack of knowledge among students. Investigated topics thereby are related to a wide range of structural and building physical indicators, such as strength and weight properties, thermal and noise insulation properties, as well as fire protection properties, always under a simultaneous focus on an optimized sustainability of the developed systems.

After having successfully completed the course, students are able to

1. define and apply criteria for sustainability and energy efficiency, acquire a technical way of thinking with the criteria of sustainability and energy efficiency, which have a direct impact on the design in an interdisciplinary exchange.
2. to acquire architectural and design possibilities of hybrid construction in the context of the requirements for flexible and adaptable building;

https://doi.org/10.52202/069179-0600

3. to learn the possibilities for the production and assembly of large-volume hybrid structures and to use methods for quality control Rationalization is addressed as well as the question of costs.
4. to deepen oneself in background and in design and calculation methods of hybrid construction (static, physical, ecological and economic aspects).

2.1 CONCEPTUAL STUDIES

The course teaches the basic skills of architectural design. It pursues an integrative approach that introduces students to all the central practical fields of architecture - from building design, structural and detailed planning to urban planning and landscape design.

The basis of the course is formed around the project-based learning, learning by doing and blended learning education methodologies. This will lead to the transfer of new innovative educational practices, where critical thinking, problem solving and flexibility will be implemented in multicultural group work.

Working in multidisciplinary groups students increases their knowledge and will obtain a wider overview in present and future challenges of design and construction of timber buildings. The intensive learning course consists of two main parts: theoretical face-to-face lectures (25% of all hours), practical teamwork on project (75% of all hours). Project work of students are guided by prepared assignment book, site visits and instructors.

In close succession of presentations and demonstrations of practice-oriented solutions, a flexible feedback culture is established in order to consolidate the student's ideas. While the student's group is working different ways of solving problems, special emphasis is placed on providing them with impulses in the right direction through practical inputs given by experts from business, industry and research at the appropriate time. In doing so, the students are encouraged to pursue the challenges independently instead of simply accepting prefabricated systems.

3 LEARNING OUTCOMES

The course conveys an understanding of the tasks of architecture in society, of its aesthetic, technical, economic and ecological foundations, and of the interaction of various disciplines in planning and construction processes. The focus is on the training of technical, aesthetic and intellectual competencies that enable the successful handling of complex design tasks. Methodological clarity and conceptual thinking are just as much a part of this as the ability to communicate and cooperate in a team.
Learning outcomes describe the knowledge, skills or competences students acquire until the end of the course. The skills acquired provide the best prerequisites for starting a successful professional career after graduation.

The students work on real hybrid timber building projects and share different skills according to their specialization and prepare proposals that will include project program, location and floor plans, façades and sections, room and wet room layouts, structural design, fire precautions, floor and wall partitions, acoustic airborne and impact sound, moisture and cold bridge prevention, building services pathways, choice of materials and building components, important key assembly details (sketches to scale), façade cladding, roof construction, balcony design and construction, external building components insulation and stair enclosure and stairways etc. [6].

An optimized ratio of investment costs to utilization costs should be reached by means of construction and technical measures.
In the design concept the manufacturing, operating and maintenance costs are to be taken into account by the appropriateness of the construction measures (especially area efficiency, building form, supporting structure, façade, etc.).

Additionally, working on real hybrid timber projects results in a number of synergies, such as the exchange with the people involved in outstanding projects or the opportunity to take part in national and international competitions.

3.1 ENERGY AND ENVIRONMENT

The ever-increasing demand for energy affects both the extraction of resources and the climate and environment. Alternative energy sources must be further developed, reliable solutions to climate issues must be found, and there are still some serious problems relating to harmful substances that have not yet been solved. Although significant progress has already been made in these areas, there are still many outstanding questions that are almost impossible to answer using traditional technological approaches.
Currently, the required energy standard for buildings in Austria according to the Building Standards Act is at the low-energy residential level. With the introduction of the Energy Performance of Buildings Directive, the European Council has created the basis for a harmonized assessment. These directives state that buildings must be sustainable, the building materials and components used must be recyclable and the use of environmentally friendly resources and secondary materials is desirable [7].
The high level of thermal insulation in timber construction saves on investments in heating, ventilation and air conditioning (HVAC) as well as operating costs. This means that the necessary technology can be implemented much more simply, is less prone to errors and takes up less space. The fewer water-carrying pipes in the building, the lower the risk.

https://doi.org/10.52202/069179-0600

High thermal insulation, even a thermal transmittance (U-value) of about 0.1W/m²K, is easy to achieve in timber construction with little additional expense. With suitable insulation, less heating is required in the winter and less cooling in summer. This also affects the HVAC. The amounts of energy required for heating and cooling are significantly lower than in a conventional building. In high-efficiency buildings, because of the low power the proportional distribution and circulation losses are particularly high. In the case of central water heating, these amount to up to 85% of the energy demand. Therefore, decentralized water heating can be can be more efficient [6].

In order to address not only the ecological and resource-efficient aspects of sustainable construction, but also to contribute to the discussion on climate-resilient construction, studies and analyses have been carried out. Simulations already carried out in [8, 9] discusses the main factors influencing the overheating of buildings in summer.
The zone overview in Figure 1 shows that the average temperature values vary greatly in relation to individual zones (rooms). The temperature difference between the coolest and warmest room is approx. 2.5 °C. Nevertheless, when comparing the individual room temperatures due to different construction methods, the difference is hardly noticeable.

In all simulated scenarios, these show a maximum difference of only 0.2 degrees Celsius between the individual building types. On the other hand, as the scenarios studied show, increased shading and effective air exchange can reduce the average summer temperatures by several degrees Celsius.
As an effective storage mass, the centimeter inside the building component is particularly important. Deeper layers do not participate significantly in the 24-hour buffering. Building simulations show that the masses act symmetrically. Heavy buildings react slower, light buildings react faster. Both have their advantages.

3.1.1 Investigation of influencing parameters

The case studies on existing buildings in the course include various thermal simulations in the cities Vienna and Wels (Austria), Bochum (Germany) and London using the 3D online simulation tool Thesim 3D [10]. Thesim 3D simulates the thermal behavior of a room in a steady-state, periodic condition (period length: 1 day). It is therefore particularly suitable for standardized summer overheating tests according to EN ISO 13791 [11] or ÖNORM B 8110-3 [12].

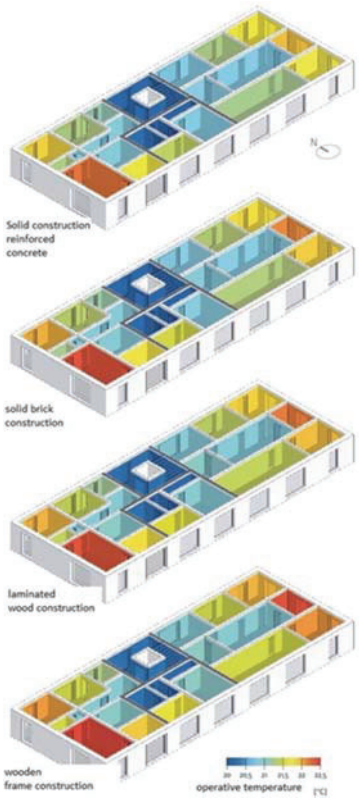

Figure 1: *Analysis model Temperature averages of the individual zones for the four construction methods (© proHolz Austria and the authors* ***[8]****)*

The framework conditions in several European cities are unquestionably different. The simulations in the cities Vienna and Wels, Bochum and London with regard to different constructions made of timber, reinforced concrete and brick as well as their summer overheating variants are intended to cover a wider range of climatic conditions and lead to more differentiated solutions. The following factors are identified as influencing a proper investigation: orientation and size of windows, g-values of window panes and awnings.
Therefore, differentiated measures are developed to avoid summer overheating and to save energy while maintaining sufficient natural light.
The building design contributes significantly to the desired indoor climate in summer. Thermal-dynamic building simulations investigate the placement of exterior windows, the reduction of window area and the effects of balconies and canopies. The zones with the highest solar radiation are mainly located in the southwest.

https://doi.org/10.52202/069179-0600

In simulations carried out on passive house standard buildings in reinforced concrete skeleton construction combined with wooden panel shells (U-value = 0.7W/m^{2}K; g-value = 0.48 coated 3S insulating glass) in Bochum (Germany), the temperature remains comfortable as long as night ventilation (20:00 to 8:00) and sun protection provided by a sun shade system (the shading factor Fc-value = 0.27) are assumed.
The average summer temperatures in Bochum are cooler than in Vienna. However, when the building is placed in Vienna, it can be observed that the indoor temperature is hot but still does not reach the limit of 27 degrees (cf. Figure 2). This shows that the surface elements and window sizes are well designed even in hotter conditions. In Vienna's outdoor climate, efficient night ventilation also proved to be an effective measure against summer overheating of indoor spaces.

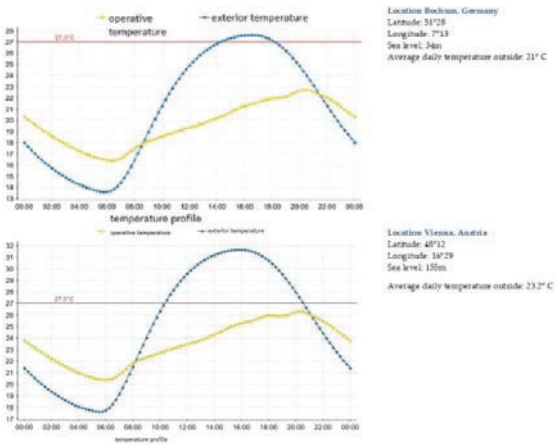

Figure 2: *Thermal dynamic building simulation in Bochum (left) and Vienna (right) (© ITI/TU Wien)*

Thermal simulations on existing buildings show that the construction method has no significant effect with a good U-value. Orientation, night ventilation and sun protection have been shown to have significantly higher effects and have been investigated.

In Wels (Austria), solar radiation is almost constant throughout the year due to the low horizon elevation. In the simulations, no shadows from surrounding buildings influenced the study area, as the surrounding houses are built relatively low.
All common rooms in the building have high daylight quotients. This is at least 2% for all common rooms. In Austria, a daylight quotient of at least 1.9% should be achieved [13]. Basically, this means a pleasant quality of life even in a north-facing room. There are no pure north-facing flats, essentially as a result of the good placement of the flats in the overall floor plan.
The bedroom in the attic, which is to be regarded as a problem room in this calculation, is characterized by two external walls (south-west) and south-facing windows. The room size is relatively small at around 11m² and can quickly overheat. However, due to the smaller room volume, it can cool down more quickly during the night. At first, different combinations of night ventilation (20:00-8:00) and blind use with direct sunlight (Fc value = 0.27) are compared in the current state of the building. A comfortable indoor climate is only possible if ventilation is provided during the night and the blinds are automatically closed when the sun is shining. Consequently, it is preferable to keep the blinds closed if the flat is not visited for a longer period of time (e.g. when travelling). However, the room heats up to 37°C even when the blinds are closed (cf. Figure 3).

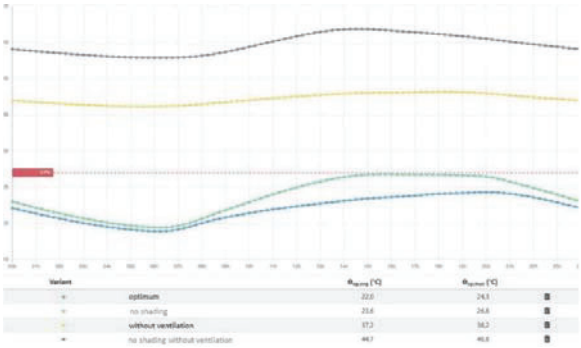

Figure 3: *Thermal dynamic building simulations of the building in Wels; comparison of optimization measures (© ITI/TU Wien)*

The next step is to compare the different constructions for optimal ventilation and blind use. Lightweight timber constructions are hottest during the day, but coolest at night due to their low storage capacity. Reinforced concrete structures provide the less heating during the day but more heat accumulation at night. This is due to its high heat storage capacity.

3.2 LIFE CYCLE ASSESSMENT

The ecological and resource-efficient aspects of sustainable construction are analyzed during the course. To ensure comparability, all values refer to 1m² of components and they have similar thermal transmittance values (U-values) and load-bearing capacities in each category.
The life cycle of buildings is analyzed according to EN 15978 "Sustainability of buildings - Assessment of the environmental performance of buildings - Calculation methods" [14], considering recyclability. The ecological properties of the building materials compared are taken from the databases "IBU-EPD" [15] and "ÖKOBAUDAT" [16]. Both are standardized databases for ecological assessment of the German Federal Ministry of Housing, Urban Development and Building (BMWSB) [16]. The considered criteria are the use of non-renewable primary energy (PEIne), the use of renewable primary energy (PEIe), the global warming potential (GWP) during a time horizon of 100 years based on the German Sustainable Building Council (DGNB) [17].

https://doi.org/10.52202/069179-0600

As an example, the analyses and optimization are presented on an existing building in France.
The corrugated sheet metal façade with the fastening steel angles, as well as the rock wool have the most impact in the production stage. The wood, on the other hand, has much less impact (Figure 4 und Figure 5).

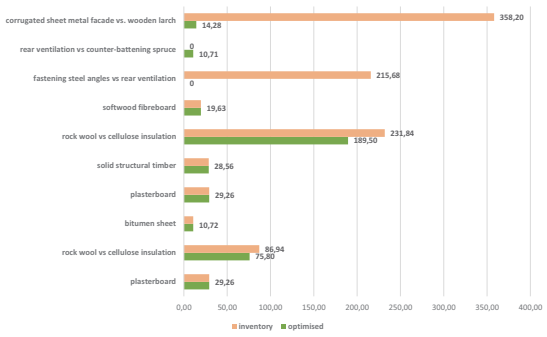

Figure 4: *Non-renewable primary energy (PEIne) [MJ] in production stage; comparison of inventory and optimization (© ITI/TU Wien)*

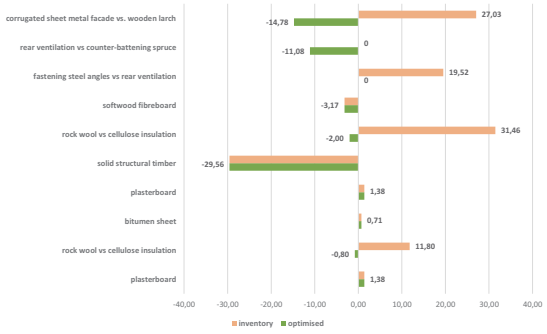

Figure 5: *Global warming potential (GWP) [kgCO_2 equ.] in production stage; comparison of inventory and optimization (© ITI/TU Wien)*

To achieve an improvement in the production stage, the outer wall is optimized. The corrugated metal façade is replaced by a wooden façade with counter battens and the rock wool is replaced cellulose insulation. Through these measures the values significantly smaller and improved (Figure 4 und Figure 5). Therefore, it is important to pay attention to the decisive materials to be considered and also to make appropriate economic decision.

4 CONCLUSIONS

Timber construction requires a different planning and construction process than mineral construction. Due to the high degree of prefabrication, important decisions have to be made already in the planning phase in order to benefit from all advantages of timber construction. For this purpose, more value and time must be put into the planning process itself in order to achieve improvements in the construction phase. This preliminary planning is elementary in wood-based architecture.

The Master's Course “Resource-efficient materialization” has formulated the integration of the natural building material timber to the current requirements of the construction industry. In terms of architectural and engineering questions, the focal point is the cooperation between all professions while integrating sustainability aspects. The intention of the course is to increase student's awareness of holistic lifecycle-oriented approaches. Interdisciplinarity is crucial to the success of the course. This means that master students will be in a position to implement the principles of sustainability, inter alia, economic and ecological aspects in project development and design as well as realization, especially in the operation stage and demolition of building structures.

Through a sustainable materials concept, avoidance of high-maintenance building technology and low energy costs through reduced energy demand as well as optimized energy demand coverage sustainable solutions can be achieved.

ACKNOWLEDGEMENT

The course is a collaborative effort of the ITI/TU Wien and the working group of the Austrian timber industry proHolz Austria. The authors gratefully acknowledge the support of the TU Wien and the proHolz Austria.

PROFESSIONAL WORKSHOP IN WOOD: STRUCTURAL EFFICIENCY INDEX, FOR ARCHITECTURE STUDENTS.

Martín Hurtado C.,[1] Andrés Sierra M.[2]

ABSTRACT: The Professional Wood Workshop, developed within the School of Architecture of the Pontifical Catholic University of Chile, proposes to students in the final stage of their careers the analysis of different case studies with various architectural programs, such as houses, buildings, schools, and factories, auditoriums, gyms, and warehouses, before the design of their projects, through a quantitative index of the efficiency of the structures that compares the volume (m3) of wood used per surface (m2) of construction.

With the objective that architecture students can identify and understand what criteria and strategies are behind a wooden design, it is that, through tools such as 3D modeling of the referents, they obtain exact parameters of the volume of the foundations, of the primary structure and the secondary structure, managing to comparatively systematize several historical and contemporary examples of good wooden architecture, before beginning to design their projects. The results obtained, quantitative (index) and qualitative (what and how the designer thinks), motivate permanent realization of the workshop, participation in national competitions for students, and a book as a permanent contribution to knowledge in this area.

KEYWORDS: Wooden Architecture, Teaching of Wood Technologies, Educational Theory, Architectural Education.

1 INTRODUCTION

During the professional performance of architects (especially those specialized in wooden constructions), each project is determined by efficiency parameters since the needs are too many, while the resources are limited.

Typically, the design process establishes a maximum expected cost per floor area (USD/m2). This parameter determines many of the decisions of the project, even before deciding its physical form and its materiality since it is a "reality criterion" that conditions the development of the form. We are interested in including and transmitting this concept in the academic context of the last year of undergraduate architecture.

For this, it is necessary to understand the origin and history of these principles, shape a methodology that fits the curriculum for the training of architects in Chile (which comes from the world of Fine Arts) and transmit those results from a quantitative and qualitative.

1.1 THE CRAFT

The craft is an accumulation of knowledge created in a slow process of trial and error: what will I do, how will I do it, and who it will be for.

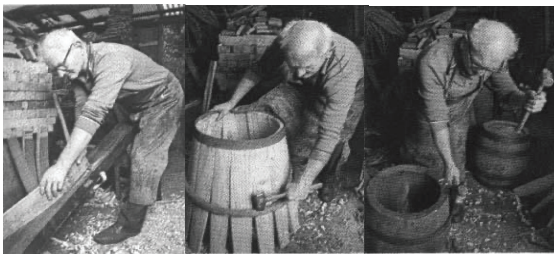

Figure 1: *Wine barrel cooper.*

Every construction system is based on a trade, which usually brings together three elements: (a) The availability of resources or "site material"; (b) The uses and customs associated with the climate, topography, and landscape, which result in what we know as "local culture" as a material good; (c) A heritage that we want to preserve, which we call "culture of origin."

Seen this way, the way of building each place says a lot about the nature of the site; their customs, ways of life, food, clothing, festivals, rituals, and shelter needs that force local builders to seek simple and common solutions so that anyone can carry them out, what we call "Vernacular Culture."

[1] Martín Hurtado Covarrubias, Pontifical Catholic University of Chile, mhurtada@uc.cl
[2] Andrés Sierra Martínez, Pontifical Catholic University of Chile, agsierra@uc.cl.

https://doi.org/10.52202/069179-0601

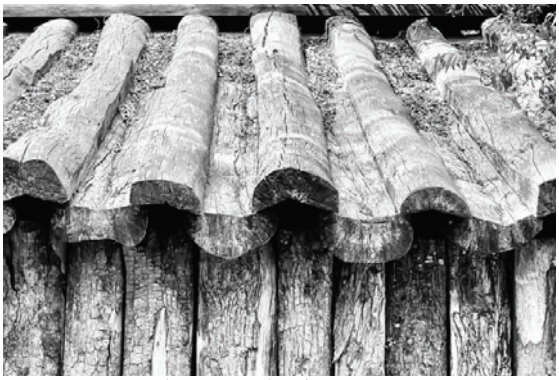

Figure 2: *Pewenche Ancestral Refuge.*

In recent years, wood construction has once again positioned itself as a valid option to respond to the many building needs due, among other factors, to good environmental indices, being a renewable, recyclable, low-cost, and flexible, added to its exemplary environmental behavior and lower carbon footprint, the possibility of being industrialized, and its flexibility and warmth properties in the finishes.

1.2 THE TRAINING OF THE ARCHITECT

Architects learn, above all, by studying reference projects, which serve as a guide to see how others have solved a project in similar conditions. Although technical construction manuals are helpful in many cases, helping to clarify how a detail is designed, they do not solve the fundamental questions of any project, which are related to the totality of the problem: What to do and how to do it.

As the Chilean architect Cristian Valdés says, "more important than thinking about the 'form' that I am going to give to a project, the central thing is to think about the 'attitude' that I am going to take towards it" [1]. Thus, for example, if it is determined that the main thing will be to build with local materials and technology, the range of possibilities is limited, probably rescuing a trade related to the degree of technical precision that can be chosen.

Figure 3: *J. Vignola and his translation on Chiloe wood.*

This apprenticeship method does not prevent the necessary questioning that architects must undertake to "move the border of the possible." Still, it makes the difference between the virtuosity of someone who, mastering a trade, explores new possibilities. Conversely, someone seduced by novelty risks the resources of others by trying untested solutions that usually result in construction defects that jeopardize the stability and durability of the building.

We study, for example, the "Churches of Chiloé," a series of Catholic temples built in the archipelago of that name, located in the wooded area of southern Chile, where, since the 17th century, more than 20 prominent temples were built in wood. Declared a World Heritage Site by Unesco, based on the manual by Jacopo Vignola brought by the Jesuits, are examples of the adaptation of classical architecture thought of stone to a language built of wood. The local carpentry trade, highly developed for constructing wooden houses and boats, allowed us to produce these marvelous temples. It seemed to us a critical case study since it let us know the amount of wood used based only on knowledge of the trade of the local carpenters and compare these data with buildings of similar characteristics currently developed, with all the support of the current structural modeling and calculation. That is to say, to contrast carpenters' and engineers' logic.

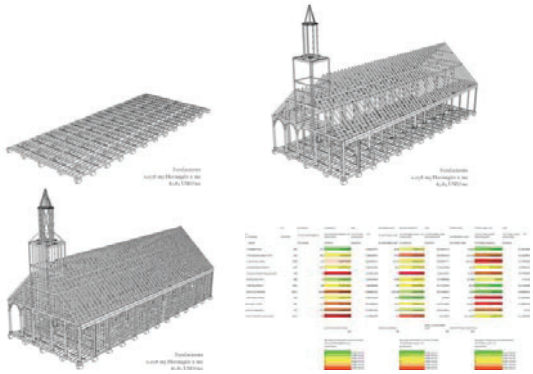

Figure 4: *"Achao Church" index of efficiency of structures.*

We did the same with a series of 25 historical and current works in wood to contract the data that quantifies its structure with the constructed surface area and thereby provide quantitative reference information associated with specific projects that students can know and ponder based on whether or not they can serve as reference models for your project.

Knowing this information at the beginning of the development of a project, even before its formal composition, makes a difference since, in wooden buildings, the adequate modulation of the structure is the fundamental basis to ensure optimal performance.

The trade of good wood construction involves the associated technical solutions and, very exceptionally, considers the architectural variables that are usually not named and therefore forgotten. The questions discussed during the course are: What happens with the concepts in large part of architecture treatises, such as proportion, scale, rhythm, order, and, ultimately, the harmony of the whole? How can you safeguard the constructive wisdom

https://doi.org/10.52202/069179-0601

and, at the same time, the beauty of any well-designed wooden structure?

We call this “The aesthetics of logic” or, in other words, the wise way of arranging the pieces and parts that make up the supporting structure of a built body that always result in a harmonious and beautiful skeleton.

Figure 5: *San Francisco Javier School, in Puerto Montt.*

An example of the above is the natural structure that makes up the skeletons of vertebrate animals. So fair, precise, and efficient to support the demanding loads and, at the same time, respond during its life.

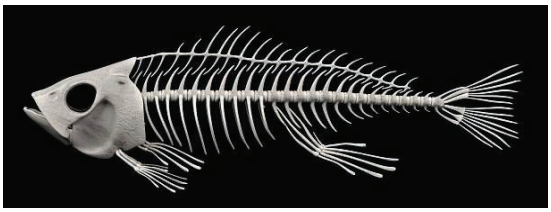

Figure 6: *Animal structure*

1.3 EXPECTED RESULTS

The course intends to discuss the questions posed by rescuing examples of the construction trade present in different wooden buildings, taking both historical and current cases, and measuring them under the same parameter, a structural efficiency index, which quantifies the volume (m3) of wood used in the supporting structure of the building and relates it to the surface (m2) built, allowing reflection and knowing in a single data, in a figure, the amount of wood required for its structure.

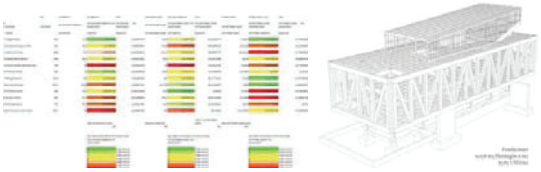

Figure 7: *IEE Comparative table 25 cases.*

This index makes it possible to understand the process behind designing a wood system and allows obtaining a parameter that can be used as a comparison and help make decisions about how the most efficient supporting skeleton of a new building in this material should be.

2 EFFICIENT WOODEN STRUCTURES

In this academic activity, the criteria used to measure and compare the efficiency of the structure of the different wooden buildings were cost, proportion, and language.

2.1 COST

The "cost" is always a priority in any actual project, not only the monetary cost but also the cost of technical and physical resources.

For example, to build the Sewell mining camp - a group of light-framed wooden buildings located in the high mountains of central Chile - at the beginning of the 20th century, North American engineers from the Braden Cooper company determined that all the construction material had to be loaded by "oxen yoke," given the problematic accessibility on steep slopes. This condition decided that the primary construction material for the structures and finishes would be wood due to its characteristics, such as being light, resistant, malleable, and workable by hand.

Figure 8: *Sewell housing building, Chile, 1920.*

Hundreds of carpenters could build large warehouses, bridges, pipelines, levees, retaining walls, offices, restaurants, and accommodations for all staff. The low cost and the availability of abundant wood brought by ships as ballast on their return voyages from North America were the starting point for determining that everything built-in mining operations would be made with this wood.

https://doi.org/10.52202/069179-0601

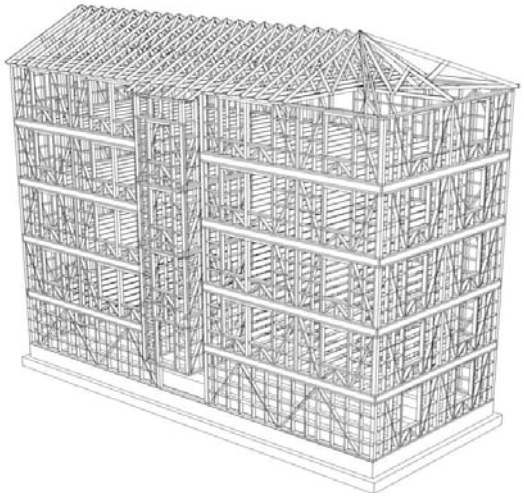

Figure 9: *Sewell bedrooms light-frame structure, Chile, 1920.*

The low weight of wood implied low transportation costs and the possibility of building with only hand tools, taking advantage of hermetic enclosures in extreme climates, and even constructing ponds and wooden pipes to store and transport water with high corrosion resistance.

Students are taught that every project is determined by the conditions of the environment where it will be built. Thus, deciding what material to build with always derives from a chain of implicit consequences, which go beyond the physical form of the project. It is not just an aesthetic problem; it is integral.

In summary, the cost of a structure is a variable that involves the value per m3 of the material plus the cost of the resources necessary to build with the chosen material and sizes in a specific place.

2.2 PROPORTION

Any building built based on a reticular structural system must combine these variables: "Architectural Module" and "Structural Module."

The architectural modulation provides the minimum dimensions necessary to house the activities required by a project, depending on the acts it hosts, which results in different sizes of enclosures.

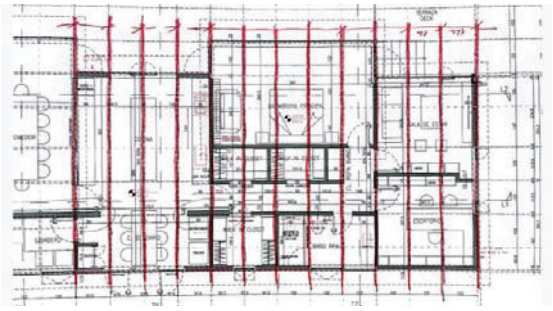

Figure 10: Architectural Module vs. Structural Module.

Structural modulation provides a system of columns, beams, or walls to cover the minimum free spans necessary to house the program's activities, generally determined by the dimensions of the construction materials used.

The students are taught that the first thing is to make a detailed analysis of the program and verify the dimensions of the "free span" necessary for the room with the most significant demand in size, and with this, decide the system of pillars and beams to use, in the "simple, most economical and best way".

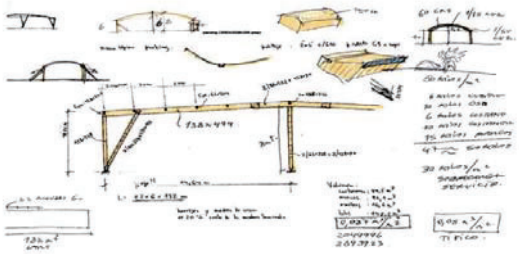

Figure 11: *Calculations of the Greenvic Packing structure.*

Then, we ask the students to analyze from evaluating the different materials to use the modulation or primary grid of dimensions that best suits the program's requirements.

In these cases, a grid's initial design allows the program's different parts to be organized in a simple matrix. However, care must be taken that this matrix is accessible enough for the base module to adapt to the size of the rooms necessary for the program. The smaller the dimension of the modules, the more freedom to adjust the program to the exact needs and not oversize or undersize an enclosure.

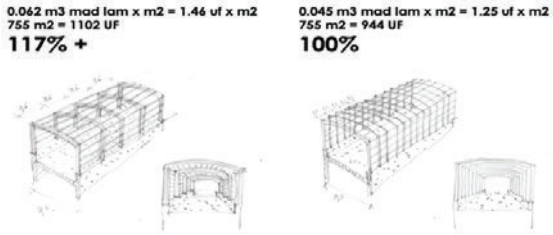

Figure 12: *Venue-Scale Rhythm and Efficient Modulation.*

After that, the "rhythm" determines the expression of the constructive skeleton matrix. In general, the timing of the grid is appropriate to the size of the project and is based on the dimensions of the materials in your commercial site measurements, such as columns, beams, plates, and cladding to be used.

In our country, it is customary to use a 1.22 x 2.44-meter grid, or its derivatives, from the size in which many construction materials are marketed. You can use the module divided into 3, 2, or 1, 40.5, 61.0, or 122 centimeters for smaller buildings, 244 centimeters for

https://doi.org/10.52202/069179-0601

medium buildings, and 366 4.88, 6.00, or 7.32 centimeters, or more, for large (extra large) structures.

2.3 LANGUAGE

In the words of Peter Zumthor, "construction is the art of configuring a whole with meaning from many particularities" [2]. Wooden architecture brings with its discontinuity. To build a wooden building, it is necessary to join pieces and parts, assembling and joining different components to achieve a unitary body. For this reason, the carpentry trade is essentially the trade of joining and assembling.

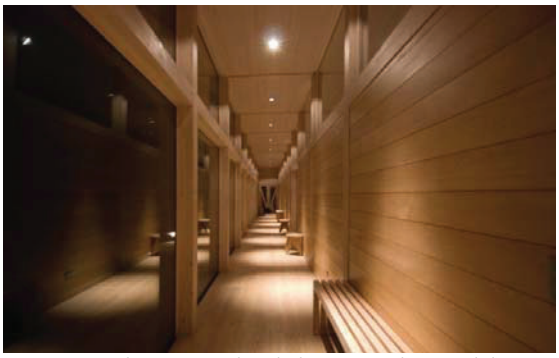

Figure 13: *The parts vs. the whole. Casa Colico 2, Chile.*

Once the decision is made on the most appropriate modulation for the program that will be housed, the detail emerges as an assembly point, a solidary union to build a continuous envelope, where the gaze does not stop at the discontinuity of the detail but rather the totality traps that.

"The details, when they come out well, are not decoration. They do not distract, do not entertain, but lead to the understanding of the whole, to whose essence they necessarily belong." [3].

Figure 14 : *Craft Structure Galpon Osorno.*

Architecture has always needed to find a language that supports the physical image of the project. The buildings developed with reticular structures have exposed the supporting structure as the accurate skeleton that underlies the form, expressed through the vectors that conduct the static and dynamic loads derived from the structural weight.

Modernism, supported by mathematical calculation as an indisputable truth, which uses the aesthetics of constructive logic in a spirit of stripping away everything that is not strictly necessary to sustain the building, resulted in an abstract aesthetic of elements that conduct the forces of gravity. Still, they do not necessarily resolve the physical expression of the building envelope, which is mediated by other needs of the architectural form.

Figure 15: *Main structure and secondary structure.*

Mies Van der Rohe, perhaps one of the fathers of constructive puritanism, in his well-known Seagram Building project in Chicago, uses two structures for the façade: (a) load-bearing steel covered with concrete, which remains "hidden" as the main load-bearing structure; (b) a second façade structure, built with slimmer steel profiles that give rhythm and proportion to the building's walls.

This freedom in design possibly allows for play, assigning to the main supporting structure the static and dynamic requirements of the system, plus the required fire resistance requirements, and freeing the secondary structure of the façade to build with it the visual language of the building.

3 THE INDEX

The index is a figure which summarizes, in a number, a complex web of factors that determine a reality. The carbon footprint is a good example. Let's compare it with the automobile industry, and we have to design, for example, a very affordable city car. We use as a parameter that its fuel consumption should be between 25 and 30 km/lt.

This index involves several parameters at the beginning of a design to achieve the objective. For example, size, weight, and relative dimensions will be present before starting to study the form of the model to be developed.

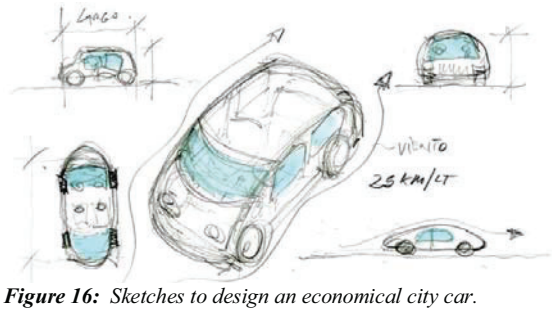

Figure 16: *Sketches to design an economical city car.*

https://doi.org/10.52202/069179-0601

In our case, applied to wood construction, the index should be a helpful tool for architecture students to identify a primitive order before defining a shape based on a premise: the best structure is the one that uses the least quantity. Of wood to achieve the same results required.

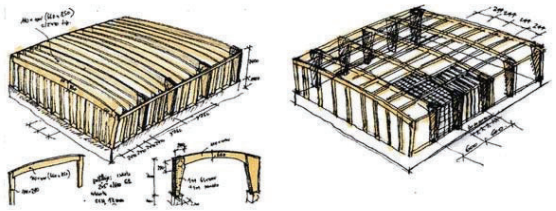

Figure 17: *Sketches of an example of an economic structure.*

3.1 A TOOL FOR ARCHITECTURE STUDENTS

In the same way, the design of a building begins specified by qualitative parameters, also determined by the enclosure program, but also by specific quantitative metrics usually determined by the expected cost per m2. The first parameter has been studied for various types of buildings, even forming part of construction laws and ordinances that set minimum standards according to the activity to be carried out, which determines lighting and ventilation conditions, average comfort temperature, acoustic reverberation, etc.

The cost of the structure of a wooden building in Chile is determined by the concurrence of three factors: seismic stability, fire resistance, and wind resistance. Given its low weight, it is not the problem of seismic stability that mainly determines the sections of the elements. Even so, studying it is essential to develop the system of joints and hinges necessary to resist earthquakes. At the same time, the most critical conditions for a wooden structure are its stability against the wind and its resistance to fire. Quantifying these variables allows the study of different combinations of parts and components, which imply different costs.

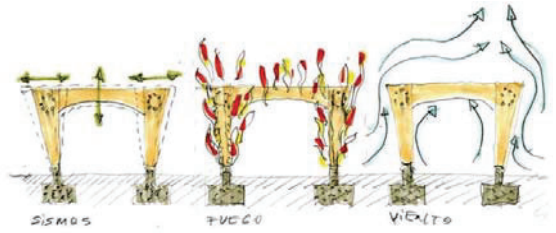

Figure 18: *Sketches of seismic stability, fire resistance and wind resistance.*

Understanding the above, through 3D modeling of different projects, students quantify and compare the volume of concrete in cubic meters and the steel foundation; sawn timber structures; glued laminated wood structures; the fittings and connection components, and the square meters of coatings and skins for each project.

The initial results in a structure efficiency index or IEE, associated with the cost per m3 of material, determine a quantitative parameter of design efficiency concerning the built area.

This index can also be associated with a recycling rate for the building -generally associated with the wooden elements it uses- to show its sustainability and the estimated carbon footprint index.

3.2 MORE THAN A FORM, AN STRUCTURE.

As Alberto Campo Baeza points out, “gravity builds the space (…) the load-bearing structure, rather than transmitting loads of the building to the ground, what it transmits is the order of the space, it builds the space. As a result, the structure supports not only endures but is well resolved, tuned, waiting to be pierced by light” [4].

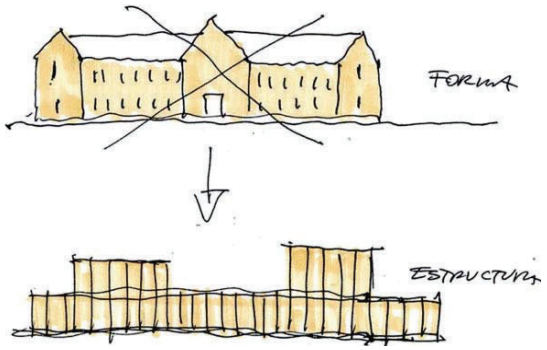

Figure 19: *Sketches of the “More than a shape, an structure” concept.*

To develop a wood project, the first thing that students do in the course, after carefully studying the conditions of the place, the program in charge, and the available resources, is to discover the deep organization that will order it. More than finding a plastic form, which depends on the design of a "skillful hand" of the person who makes it, an order is sought, a deep structure that organizes the program and the construction in a straightforward matrix, which builds the entire project.

Once this internal order is discovered, the project flows into a sequence of reasonable, appropriate, and consistent decisions between what, to quote Louis Kahn, a building "wants to be" [5] and the material that will be used to make it.

In this previously described way, innumerable data, intuitions, tastes, and sensibilities converge to know "what" and "what" should be what we are doing. The form is thus a consequence and not a goal.

https://doi.org/10.52202/069179-0601

3.3 A METHOD FOR AUSTERITY

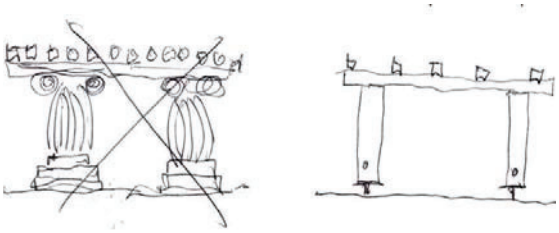

Figure 20: *"A method for austerity" scheme.*

For various reasons, most of the carpentry in Chile has been developed under the premise of an essential economy of resources.

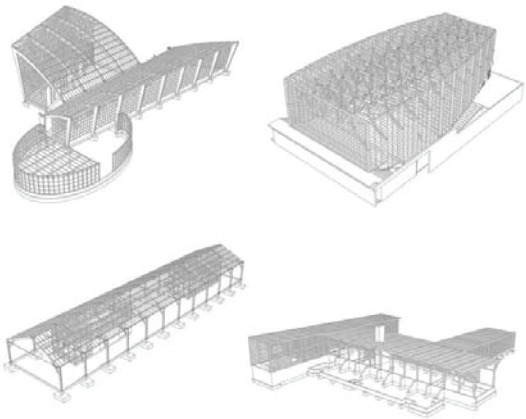

Figure 21: *Mim Museum, Matucana Theater 100, Haras Las Camelias and House 2 wooden structure models.*

Chile is a country that hardly looks at the benefits of development, where most people live at subsistence levels. Therefore, preparing a student to work under strict austerity measures seems ethically prudent. This self-discipline has meant that when tackling each project, we are very strict in leaving what is essential or the minimally necessary to accommodate the requested program, and with this finding the most suitable material for the available budget.

In this way, based on years of experience in the design of a significant number of wooden buildings and university teaching on building with this material, the need arose to have quantitative judgment elements when making decisions arose. Decisions regarding the supporting structure of a building are a way to optimize and create more efficient use of resources.

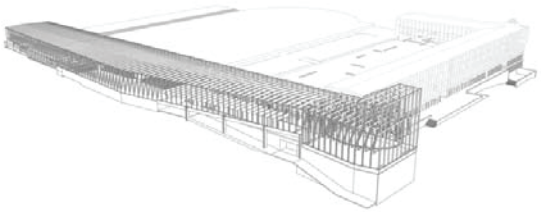

Figure 22: *Wooden structure model of the San Francisco Javier School Puerto Montt.*

4 CONCLUSIONS

After different editions of the course, studying and measuring the m3 of wood per m2 of the building became a way of helping to decide and project the structure of a building without this being a mere result of the structural calculation at the end the process.

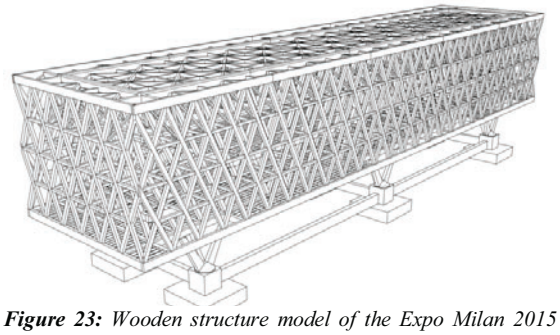

Figure 23: *Wooden structure model of the Expo Milan 2015 Chilean Pavilion. Undurraga Deves Architects.*

The students, by modeling and drawing the details of each building studied, the product of a careful selection of significant works of architecture in wood, allowed us to understand why the author decided on one or another modulation of the structure, to know how he solved the details, to question his plastic expression and increase their architectural culture.

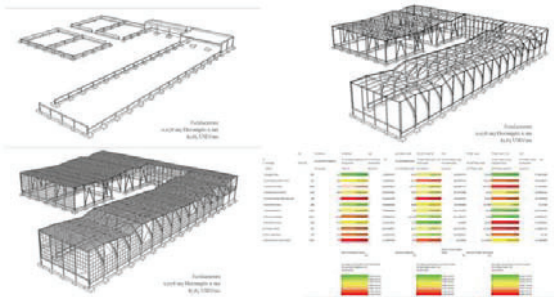

Figure 24: *Foundations, main structure and secondary structure of the Greenvic Packing.*

4.1 THE PROBLEM

Regarding the concepts present in large part of the architecture treatises, such as proportion, scale, rhythm, order, and, ultimately, the harmony of the whole, the idea of parameterizing cases and extracting valuable lessons for future projects, He delivered a method of systematization in decision-making based on the consideration of seismic, fire and wind conditions, which make evident what determines the dimensions of the structure of a building. Being able to identify the craft and constructive wisdom, later managing to design with criteria of beauty by taking into account costs, but also the proportion and language of the structures as plastic resources to provide "architectural identity" to the buildings.

https://doi.org/10.52202/069179-0601

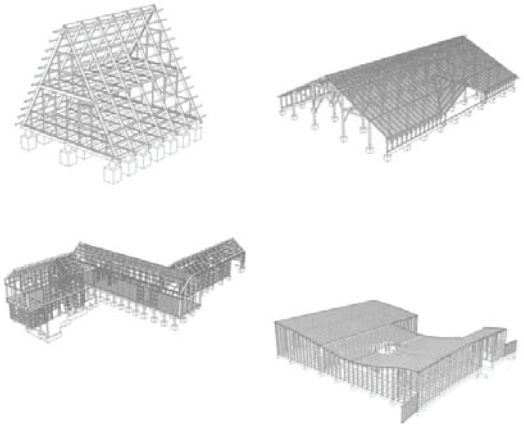

Figure 25: *A-Frame House, Osorno Warehouse, Molinahue House and Nadalie Barrel Factory wooden structure models.*

4.2 MAIN FINDINGS AND RESULTS.

From a methodological point of view, the results obtained, both quantitative (index) and qualitative (what and how the designer thinks), have motivated: the permanent realization of the workshop, the participation and obtaining of prizes in different national competitions for students and the creation of a book as a permanent contribution to knowledge in this area.

4.3 CONTRIBUTION TO LITERATURE AND KNOWLEDGE IN THE AREA: THE MANUAL

After two years, the study managed to comparatively systematize several historical and contemporary examples of good wooden architecture, finding efficiency parameters in terms of discovering the wisdom of the trade present in the amount of material necessary to build a wooden building, similar to the index used by engineers in reinforced concrete constructions, which measures the weight (kg) of steel per volume (m3) of concrete, knowing a priori when a structure is within reasonable efficiency margins.

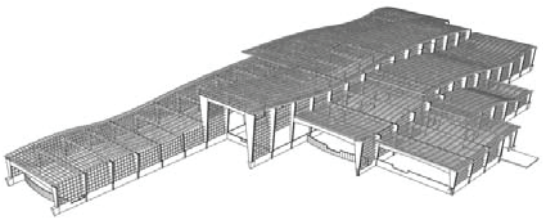

Figure 26: *Viña Almaviva Winery wooden structure model.*

This result will become a Manual for architects, builders, and students, to verify the amount of wood in the structure during the design process, involving in this edition, thirteen projects developed in our architecture office, four historical projects and three contemporary wooden buildings.

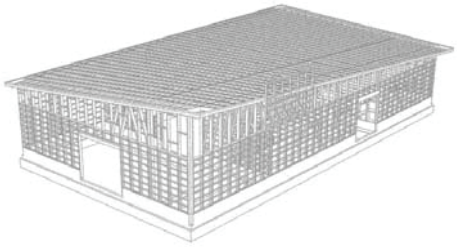

Figure 27: *Wooden structure model of the INFOR Laboratories.*

THEORISING A NEW EDUCATIONAL AGENDA FOR SUSTAINABLE BUILT ENVIRONMENT PROFESSIONALS: TIMBER TECHNOLOGY, ENGINEERING, AND DESIGN PROGRAMME

Aghlab Al-Attili[1], Robert Hairstans[2], Tim Belden[3], Gabriele Tamagnone[4], Sarah Hitt[5], Tabitha Binding[6], Joseph Walters[7]

ABSTRACT: (200) The paper reports on the most recent activities undertaken on the local and national levels to create a competency framework for timber engineering in an effort to change the traditional construction methods into more sustainable and environment friendly methods based on the use of biogenic materials. The paper further details the various pilot projects and educational programme developed to upskill professionals of the built environment. More details are provided on the capstone educational programme including its structure, strategy, delivery and content.

KEYWORDS: Timber Design Education, Sustainability, Architecture

1 INTRODUCTION

The construction sector, including building materials, is at the centre of a climate change and global warming since it represents 33% of global final energy use, generates nearly 40% of global energy-related Green House Gases emissions and consumes 40% of global raw materials [1]. In the UK, Co_2 emissions from construction industry reached 13.5 million metric tons in 2019 [2]. The direct cause for emissions might be the elements mentioned above, but in reality, there is an underlying cause which contributes and converges to form the results above. One might argue that the main contributors are lack of research into sustainable building materials, the education which is not based on sustainability, and the economic drivers that favours financially short-term cost-effective measures over long-term sustainability.

The desire to use sustainable materials needs to be coupled with active research into sustainable biogenic materials that effectively competes with the currently available non-sustainable traditional construction materials.

On the other hand, the formative educational outputs from higher education institutions and training centres around the globe revolve around old and traditional knowledge that has the economic costing feasibility at its centre, whereas sustainability and environmental friendly materials come as an afterthought when compared to project design, construction and economic costing considerations.

Moreover, the current practices in-place within the construction industry are direct responses to the market demand which sees construction and built environment professionals under-trained and ill-equipped with the knowledge to tackle sustainability considerations for two reasons: a) they do not have the knowledge required for sustainable construction, and b) the context in terms of practices and materials does not necessarily aid the endeavour to achieve sustainability. In other words, a construction manager, or an architect, or even an architectural technologist will not necessarily have the experience of running sustainable projects, and their knowledge of designing, detailing or running projects includes traditional materials that are not necessarily sustainable.

Triple factors above; namely practice, education, and knowledge are not up to date with sustainable options. Each of the factors need to be addressed on a global scale. The paper and its outcome describe an attempt on a national scale in the UK to address the issue by proposing a new triple helix action to address the emergency. Our efforts and reaction are demonstrated using Biogenic materials as an example of sustainable construction materials, and in specific, we are using timber as an

https://doi.org/10.52202/069179-0602

example of such sustainable materials. So, what follows will be addressing timber.

It is evident that the sector's contribution is an issue that requires addressing. This paper reports on the unique approach developed and implemented by the Centre for Advanced Timber Technology within The New Model Institute for Technology and Engineering that predicates over multiple axioms linking professionals of the built environment, operations in construction industry and its supply chain, and finally materials used in construction. Through this multiple approach, analysis is carried out in the sector to outline a new agenda for sustainable built environment education that redefine the built environment professional, equips him/her with new knowledge, skills and tools to address the climate crisis through net zero carbon design, and finally offers alternative sustainable construction materials (biogenic) with specific focus on Timber as an example. This forms our future action triple helix of research into sustainable materials, education of sustainability in construction using sustainable materials, and finally informing the new standards of professional practice that is based on sustainable education and sustainable materials.

2 THE COMPETENCY FRAMEWORK

The first step in creating an agenda, is understand the professional practice environment, which in turn requires a survey that covers the construction and built environment needs as derived from various professional roles within it. To be able to conduct such survey and link it to all levels of the problem on the one hand, and feed it to all levels of solution, on the other, it is important to have an overarching strategy that regulates the relationship between different elements and parties. The development of such strategy was the first step in our endeavour, and the outcome, (figure 1), and identifies the delivery partners (namely NMITE, Edinburgh Napier University and Timber Development UK) and the steering group committee which consists of various key players in the market.

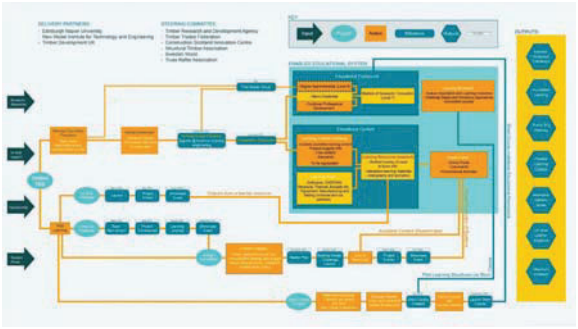

Figure 1: *The overarching strategy*

The strategy identifies areas of investigation that links the market assessment, and the resulting working group, to market needs leading to a series of projects, actions and outputs. From the outset, the educational output was a major key player in that it required a survey of requirements, and a framework that regulates the knowledge to help identify the gap.

The result is an educational framework that acts as a guide to any trail-blazer group that reacts to the requirements above. The reactions required were in the form of continuing professional development short courses, undergraduate and postgraduate degrees. The content of the degrees will respond to the market assessment which included analysis of roles and duties of each built environment profession, and assessment of the knowledge gap.

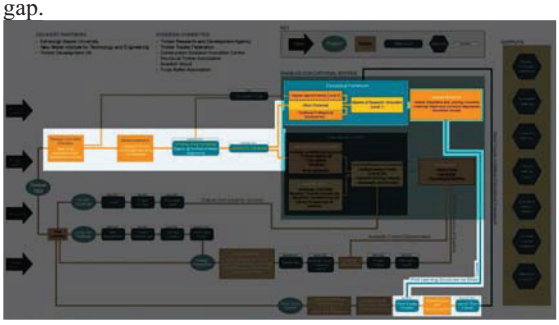

Figure 2: *Development process*

Figure 2 above highlights the educational process stemming from the strategy. It progresses from the survey of the market needs into the development of an educational framework that outlines the content and type of knowledge required for the educational intervention. What follows below is a description of the process of developing the educational framework.

2.1 FRAMEWORK DEVELOPMENT

The competency framework is developed to document the knowledge, meta skills, and industry experience the next generation of timber professionals in construction need in order to drive the change in the construction industry towards biogenic offsite manufacture.

Figure 3: *Steps to be taken produce a feamwork*

The process starts by analysing available resources to the project in the form of logistics, then establishing action frameworks for each individual component listed in figure 3, and then moving to an interview phase where key stakeholders were asked to share their reflections and views in order to draw the themes that frame the intended outcome. Several revisions saw the final framework through. The process also saw the creation of a working group of different contributing parties and a steering group to oversee the implementation.

https://doi.org/10.52202/069179-0602

2.2 COMPETENCIES

The competency framework sought to answer the question of what are the competencies underpinned in the practice for sustainable construction and therefore education? To which, the answer came from the surveys and partners and after an extensive analysis of different built environment roles in contrast with activities and processes linked to sustainable practices taking timber as the main construction material. The result was divided into two categories: core technical competencies (figure 4), and cross-disciplinary competencies (figure 5).

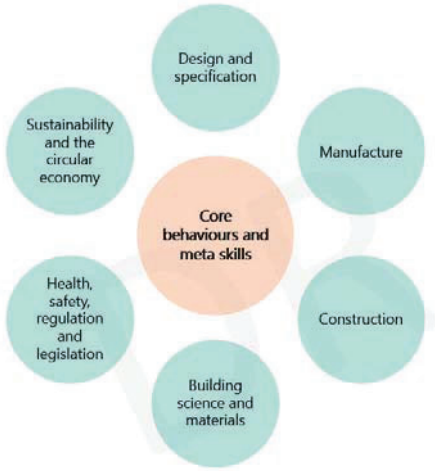

Figure 4: *Core technical competencies*

The former cover aspects like sustainability, manufacture, health and safety, construction, building science, and design and specification, while the latter include the topics of communication, business and commercial, quality, management and digital data.

Figure 5: *Cross-disciplinary competencies*

At the heart of the cross disciplinary competencies, we have certain core behaviours and meta skills (table 1), that revolve around qualities like teamwork, critical thinking, innovation, organisation, professionalism, and ethics.

Table 1: *Core behaviours and meta skills*

Behaviour
Collaboration and teamwork
Critical thinking and problem solving
Innovation
Organisation
Professionalism and career development
Ethics

Each of the competencies contain several knowledge topics, which will be tested in several learning experiences or activities in order to ensure its effectivity in addressing the challenge that is the climate emergency. In what follows, we will have a brief description of learning experiences.

3 PILOT LEARNING EXPERIENCES

The learning experiences suggested predicate on three axioms:

a) the concept of deconstructing existing professional knowledge and its method of attainment into various constituting components and then augmenting the knowledge with our competencies, with the focus being on the technical competences.

b) the action of gauging existing learning styles in the market, with the professional reception of activities being a measure of success through demonstrated demand, and

c) the multiplicity of pedagogic approaches utilised and demonstrated in the learning experiences act as a method of assessment for the efficacy of the approaches.

The learning experiences are described in what follows.

3.1 SUSTAINABILITY ENRICHMENT WEEK

The Sustainability Enrichment Week is series of events involving postgraduate university students within the field of the sustainability in the built environment, who will assemble at our living lab centre in Hereford to engage in several activities, such as workshops focusing on topics like sustainability in construction, environmental ethics, or organisational change management; field trips; and seminars. This is treated as an opportunity to assess their existing knowledge of the topic and find out any potential gaps in this knowledge in order to allow us to trial different techniques to top up the knowledge and experience and take it into the level required by the competency framework. While the participating students are at university level, the intention is to have learners from different parts of the built environment sector. The choice of sample for this activity (postgraduate students) reflects the midpoint in the spectrum of professionals in the field which has undergraduate students on one end of the spectrum, and experienced professionals on the other end. Within the spectrum postgraduate students tend to have the underpinning experience in addition to some professional experience.

https://doi.org/10.52202/069179-0602

3.2 ICE BOX CHALLENGE

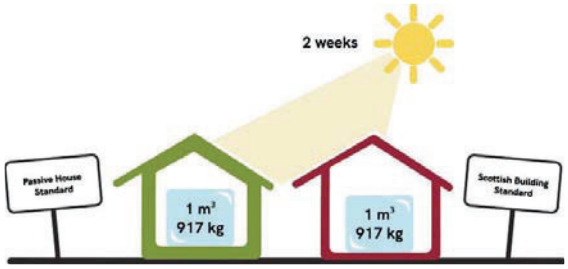

Figure 6: *Ice Box Challenge concept*

The Ice Box Challenge was presented as part of the COP26 event held in Glasgow. The learning experience is designed to allow participants to interrogate existing energy-efficiency building design standards and codes when it comes to sustainability within the built environment. This is carried out through showcasing the potential of an energy-efficient, Passivehaus standard design against a Scottish building standard design.
Two groups are tasked with designing, manufacturing and building two different box structures and applying the insulation as coded by the two different standards. Not only did the outcome favour the Passivehaus standards, but the two structures which were designed, manufactured and assembled, are acting as demonstration for both critical and comparative thinking all while allowing learners the opportunity to examine the result of applying the codes into practice.

Figure 7: *Actual ice boxes designed and manufactured by participants.*

The two boxes have been shipped to Hereford and will be used to carry out further research and as a learning tool for students to learn about thermal efficiency and to be used as a model to learn about manufacture software.

3.3 TDUK DESIGN COMPETITION

TDUK, in association with the Passivehaus Trust, NMITE, and ENU, have launched a university design challenge for built environment students and 2021 graduates from across the UK.
The design competition is learning experience based on forming groups of built environment students to undergo a Passivehaus design in reaction to a real design brief. The group of students need to design and make all the calculations to ensure their work is a NetZero design, or even negative. In its most recent iteration, the aim of the competition is to design a new building to be built in Hereford that will serve as a sports, food, and skills community focal point for the people of South Wye, UK. As part of the programme, students had the chance to learn from webinar series hosting several experts of the sector.
The pedagogic approach behind the learning experience is to allow graduating students to have first-hand experience of working on a project with a real targets. This is one of the cases where work-place challenge is proposed to participants with the outcome to be built. The groups are supported with design and production software and tutoring sessions to guide their design.

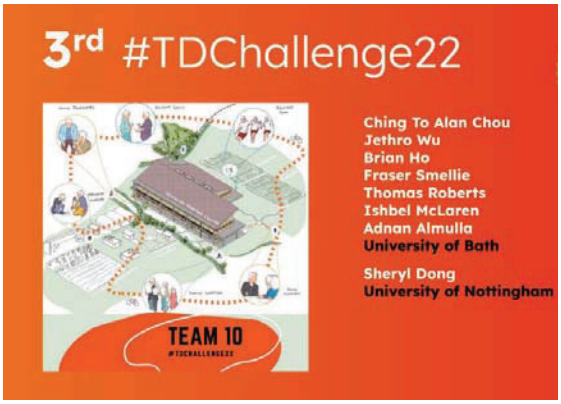

Figure 8: *The winning entry and team members' names and affiliations*

4 THE PROGRAMME

4.1 TIMBER TED SHORT COURSES

The Timber Technology, Engineering, and Design (Timber TED) short courses create comprehensive and flexible upskilling and reskilling training on modern methods of timber construction. Micro-credentials approach is utilised to aid learners in gaining specialist timber construction knowledge and skills for built environment 'better, faster and greener' delivery, addressing the climate emergency and affordable housing crisis. Underpinned by the competency framework described in section 2, identifying the evidence-based technical knowledge and meta-skills required, the short courses are grounded in immersive 'learning by doing' activities, stimulating critical thinking and instilling new knowledge and skills for net zero carbon.
The courses are also based on all of the previously trialled learning experiences, and that leads up to the main experience which is embedded in (Timber TED) series. Combining various competencies from the framework to compile short 12-week courses with different learning and teaching strategies, embeds resilience into the content and delivery mode of the course. All courses are based on workplace challenges that sees students take on activities that mimic their workplace activities and apply different areas of knowledge and application to create learning outcomes (figure 9).

https://doi.org/10.52202/069179-0602

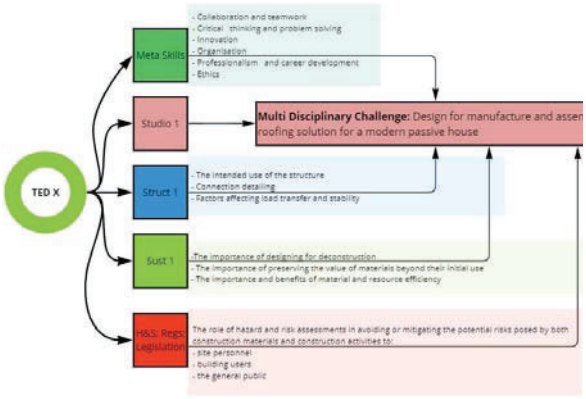

Figure 9: *Example of different areas of knowledge and areas of application compiled to form learning outcomes.*

Once areas of knowledge are compiled, the themes of the TED short course are decided and are ready for development. The diagrams in figure 10 and figure 11 show TED1 and TED2 themes respectively. It is worth noting that the Design and specifications demonstrated in Figure 4 is translated into 'studio' element in the figures below as in our view, the studio element is the place where learners have the chance to design and apply the technical knowledge they attain other modules. This is a crucial element as it prepares the learners to experiment and make mistakes as opposed to learning only how to repeat ready-made of the shelf solutions.

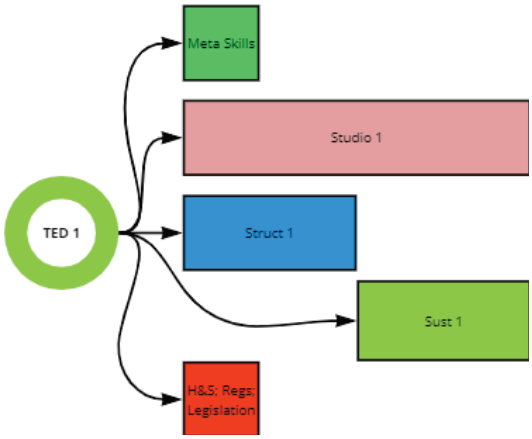

Figure 10: *Different thematic technical competencies are mixed with cross disciplinary skills to form TED1*

TED 2 in figure 11 shows yet another different themes in the technical competencies, namely 'construction' and 'technology'. Both areas are applied in the studio element to allow learners to put their gained knowledge to test.

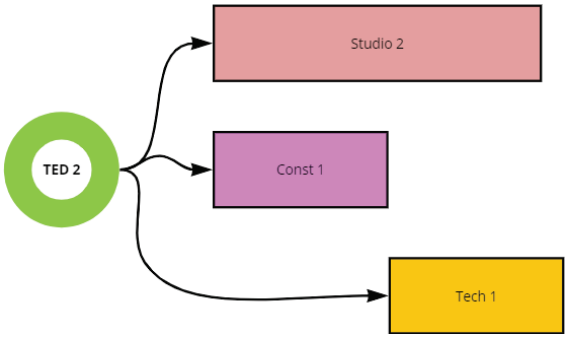

Figure 21: *Different thematic technical competencies are mixed with cross disciplinary skills to form TED2*

The main *aim* of Timber Technology, Engineering and Design (Timber TED) courses is to cover the 'core technical competencies' in the framework (figure 4). From now, on, we will be using Timber TED1 as a subset and an example.

Figure 32: *TED1 core technical competencies*

In the figure 12, competencies are derived from the Timber competency framework which was developed based on a market survey involving Timber engineering and design stakeholders. In addition, an extra layer that covers the 'cross-disciplinary competencies' is introduced to each element of the technical competencies. The three areas covered are: a) Timber Design, b) Timber Material Science, and c) Sustainability. The way they are lined up is visually demonstrated in the diagram below where the first part of the 'Design' module runs concurrently with the 'Materials' module for six weeks. The second part of the 'Design' module runs concurrently with the 'Sustainability' module for the following six weeks. The total is 12 weeks. During the twelve weeks, learners will have residential weeks in the first, sixth and twelfth week

https://doi.org/10.52202/069179-0602

at our campus in Skylon Park. The rest of the activities are delivered online.

4.1.1 Teaching and Learning Environment

The teaching and learning environment of Timber TED1 is divided into real environment and virtual environment. The latter is hosted on our VLE, whereas the former is divided into 3 major parts: a) the CATT building in Skylon Park, b) workplace environment of our course learners, and finally c) the selected locations that the course will drive learners to in the form of fieldtrips.

4.1.2 Teaching and Learning Strategy

The strategy is, therefore, divided into various techniques and methods, but all revolve around NMITE ethos and principles of learning by doing, and utilising workplace challenges as a method to achieve hands-on experience.

The 'Material Science' module is delivered online with some interactive elements that are examined on campus. Learners are required to review the resources provided online (read, listen, watch and sometime answer questions to frame their gained knowledge. Learners are also invited to obtain sample timber pieces during their first week on campus, and to take it back with them to their homes and keep it exposed to their local weather conditions for twelve weeks and bring it back during their last residential week in order to allow all to have a look at the weathering effect on each sample from different geographic location. During their first residential week, learners are taken in a field trip to a forest, sawmill and an under-construction timber building. This is to take them through the different stages of timber lifecycle.

The direct interaction with the expediated timeline lends itself to the metaphor of time-travel, where learners meet the experts in each field and watch a synoptic 'time-slice' of the intended lifecycle.

Similarly, the 'Timber Design' part of the course is delivered partially online. The main metaphor behind the delivery of the module is to mimic the professional environment in firms. Learners from different professional backgrounds and career paths engage in the following activities:

a) Week 1 begins by revealing the first design challenge they need to respond to. They are presented with a design brief asking them to individually carry out a design and build exercise (design a timber joint). From that point they are taken through a journey of learning:

b) Sketch design exercise where they express their initial raw ideas and demonstrate their current level of knowledge and skills. It also allows the tutors to supervise the activity and provide guidance on how to brain storm concepts and sometimes contradicting demands to reach an outcome in a short space of time.

c) Week 2 presents another challenge where learners are tasked with producing a technical report. Again the idea is to present the knowledge gained in Material Science module about timber and deploy it in the Timber Design module to justify their choice of timber that they are going to use in their design and build exercise. Writing the report also mimics professional activities in the workplace and can be produced within each learner's work environment. Learners will also present further sketches/technical drawings of their idea to demonstrate the research and development work they carried out.

d) Week 3 sees learners delivering their CAD drawings to finalise their ideas.

e) Week 4 is the first chance for learners to discuss manufacture techniques. They consult the learning facilitators to find out what working drawings they need to produce and what activities and tools they will consider in the process of manufacture. The advantage of this activity is that it ties together the information gained in weeks one and the work that will be carried out in week 6

f) Week 5 will be reserved for presentation work.

g) Week 6 will see learners arrive on campus and use our facilities in the CATT workshop to:

I. Produce their design. This is a hands-on exercise where they work under the supervision of the learning facilitator, to produce their design using manual carpenter's tools.

II. Present their work to a critique panel and their colleagues and answer questions

Week 7 to 12 will run a similar design and build activity with two major distinctions:

- The design project will increase in complexity.
- The learners will be divided into groups.

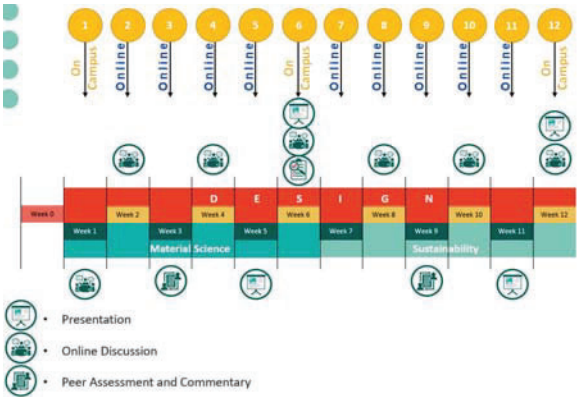

Figure 43: *Distribution of different activities over the period of 12 weeks.*

The second design brief is a group work exercise. Learners bring all their backgrounds and experiences and work together to design and build a relatively complex outdoor structure. They navigate group-work dynamics to achieve their target. They replicate the steps in weeks 1 to 6 and they produce a group technical report, group drawings presentation and work collectively in the workshop to produce their design. Throughout week 7 to 12, they will take special consideration of sustainability concepts in their design.

The 'Sustainability' module runs from week 7 to week 12 and will see learners carry out the following activities:

a) They will appraise the key reading and provide a short critical commentary and reflective account on their ideal definition for sustainability. This is a chance to digest the readings and decide the view that they align with, then try and apply it to their professional area. The exercise will be submitted on the VLE.

b) Following the initial submission, Learners will be asked to provide comments on one of their colleagues' posts. The exercise serves two purposes:

I. It mimics classroom discussions that take place in tutorials by asking each learners to express their ideas and then ask colleagues to respond and discuss.

II. It also provides an element of peer assessment where the feedback is diverse and reflects the background of the different learners, which would enrich the discussion.

The posts described above, and the instructions related to them are all made available on the VLE

c) Learners are asked to identify some of the key information from the readings and share it with their colleagues on the VLE as a way of framing their knowledge on the subject.

d) Some self-assessment exercises are also available on the VLE.

5 TEACHING RESOURCES

Multiplicity of resources are developed and made available and those created for the delivery of the programme are presented together with the intended kind of activities learners will engage with.

5.1 THE CATT BUILDING – THE STUDIOS

The building is part timber, part steel. The timber part is where the studios and communal areas are. This part will be used as a case study to offer a variety of examples, ranging from structural design to building performance, thanks to the implemented living lab approach. Further, the supply chain involved in the delivery of the building, with a special focus on timber elements (CLT, GLT, and insulated panels), will be mapped to offer additional insights on what's needed to calculate the embodied carbon and energy consumption of a building.

5.2 THE CATT BUILDING – THE WORKSHOP

The steel frame part of the building house a factory-like workshop and its intended use is presented in this section. The activities students will be likely to be involved in are described and the philosophy followed in the equipment of the space is explained. The activities may be different every year depending on the industrial partner, but will be of the type that can allow for the same level of assessment, requiring various pieces of knowledge and several skills.

5.3 INDUSTRY ENGAGEMENT

The link with industry, current partnerships and future possibilities, is described and the involvement of the sector in the professional development is depicted in this section. Industrial partners will be involved in the challenge-based learning system, presenting real life problems students will need to work on, and possibly solve, and collaborating in the preparation of scaled and full-scale models for the assessments, sharing their experience and knowledge or manufacturing specific elements that can't be made in the workshop. The CATT is already cooperating with several association, e.g., Timber Development UK or the Association of Sustainable Alliance for Sustainable Building Products (ASBP), and will expand its net of collaborations to increase this academic-industry cross-fertilization.

5.4 OTHER RESOURCES

Other teaching material available, such as case studies reports, or research outcomes, and related activities are presented in this section. Edinburgh Napier University (ENU), which is partner of NMITE in the establishment of the CATT, has been asked to help rewrite and update the knowledge library of the Timber Research and Development Association (TRADA), part of Timber Development UK (TDUK), key collaborator of the CATT. This material will be available for students and will help teachers shaping the different modules.

6 CONCLUSIONS

It is evident that the climate emergency is urging an action against the odds of survival and this paper reports on the approach taken by the NMITE in collaboration with national parties to account for some of the changes that need to be made in order to reach our targets for the climate change. The learning experiences reported in this paper culminated in the Short Timber TED courses that theorise a new agenda for education in the built environment, and each element of the courses is being trialled and enhanced.

The proposed short courses come with many types of challenges. For example, it is evident from the outset, that different learners come from different backgrounds (architects, technologists, structural engineers, timber production operatives, technical sales, project managers or even those switching to a built environment profession and seeking to expand knowledge). Therefore, learners have varying knowledge backgrounds and skill levels. This forms a continuum where on one side we have no knowledge and no skills, and on the other we have highly knowledgeable and highly skilled and everything else in between.

The challenge posed by this variety is mainly:

- Ensuring that the resources and knowledge offered in the course caters for the variety.
- Ensuring that the- learners all have the minimum Built Environment Knowledge and skills not only to attain the knowledge offered in the content, but actually to progress through it at the same pace and be able to get through it.
- Since the course is partially based on learning by doing, it was important to ensure that learners are able to progress through the practical tasks at a similar pace, given that they have different levels of skills.

This introduces a strategic challenge when it comes to teaching and learning because catering for all learners

https://doi.org/10.52202/069179-0602

would require applying one of two strategies: a) use minimum baseline, where we provide the information from the baseline of the lowest point, but this could potentially make the more advanced learners feel they are not learning anything new, or b) use customised personal learning approach, where we help each individual improve according to their level.

The team uses a combination of both, where the online materials are baseline for all participants with the opportunity to advance using optional readings. Sometimes the texts selected, and topics are more generic to allow for a common grounds between different professional backgrounds.

In the 'Timber Design' module, learners are allowed to advance according to their skills and passion. Group work allows for a different dynamic where different learners use different skills and therefore complement the shortcomings of others.

This is a work in progress and is developing over expanding scale in terms of knowledge and geographic expansion. While the work started in our centre in Hereford, we are currently in the process of entering into agreement with another centre in Scotland to act as a regional hub to mirror and further our efforts within the UK.

ACKNOWLEDGEMENT

We would like to acknowledge the support of the New Model Institute for Technology and Engineering, (NMITE), Edinburgh Napier University (ENU), which is partner of NMITE in the establishment of the CATT, has been asked to help rewrite and update the knowledge library of the Timber Research and Development Association (TRADA), part of Timber Development UK (TDUK), key collaborator of the CATT.

FIRE SAFE USE OF WOOD IN BUILDINGS -GLOBAL DESIGN GUIDE

Christian Dagenais[1], Andy Buchanan[2], Birgit Östman[3], Michael Klippel[4], David Barber[5], Ed Claridge[6], Andrew Dunn[7], Paul England[8], Marc Janssens[9], Alar Just[10], Esko Mikkola[11], Colleen Wade[12], Norman Werther[13]

ABSTRACT: Building codes around the globe dictate the design and construction of buildings. For most buildings, designers will follow prescriptive code provisions to demonstrate code compliance. However, some building codes allow the use of performance-based design to demonstrate code compliance. Performance-based design is usually more complex but allows for greater flexibility in the selection of materials and systems. Regardless of the code compliance methods, the combustibility of timber structures and wood products needs to be well-understood and properly accounted for in building designs. This paper describes the development of a new international guidance document on fire safety in timber buildings within the Fire Safe Use of Wood (FSUW) network, written by 13 lead authors assisted by more than 20 experts in over a dozen different countries.

KEYWORDS: Fire safety, mass timber, light timber frame, fire spread, encapsulation, structural fire design, active fire protection, performance-based design, robustness, building control, firefighting.

1 INTRODUCTION

Building codes around the globe dictate the design and construction of buildings. In a prescriptive building code, the type of building occupancy, the building floor area, the building height, and the presence of an automatic sprinkler system often dictates whether a timber structure is permitted and if timber surfaces can be exposed. For most buildings, designers follow prescriptive code provisions to demonstrate code compliance. Prescriptive design allows for a straightforward design and approval and reflects the academic training of most designers. However, some building codes allow the use of performance-based design (PBD) to demonstrate code compliance. PBD is usually more complex but allows for greater flexibility in the selection of materials and systems.

Regardless of the code compliance methods, the combustibility of timber structures and wood products needs to be well-understood and properly accounted for in building designs. This is of utmost importance when a PBD is being developed and where other aspects of fire science need to be considered, such as fire dynamics, reaction-to-fire, fire-resistance, and design to prevent the spread of fire within a building and to adjacent buildings.

2 OBJECTIVE

The objective of this international guideline, shown in Figure 1, is to present information for wood products in a wide range of new buildings [1]. It provides state-of-the-art scientific knowledge on a global level for practical applications. The guideline includes extended use of design codes and standards, practical guidance and examples of fire-safe design methods and principles of PBD. It is published both as a hard-bound book and as an

open access version available for free PDF download via the Fire Safe Use of Wood website (www.fsuw.com).

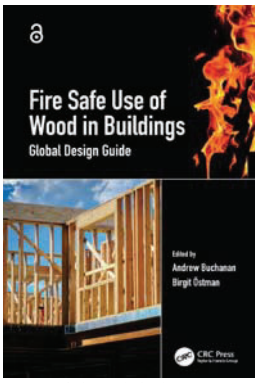

Figure 1: *Cover page of the Global Design Guide*

The guideline is based on the 2010 European guideline, Fire Safety in Timber Buildings – Technical Guidelines for Europe [2], enhanced with the latest outcomes from the recently completed COST Action FP1404 - Fire Safe Use of Bio-Based Building Products [3], to which many of the authors have actively contributed. This COST Action was intended to create a platform for networking, exchange and collection of research results and design skills, including performance data, design expertise, and many other factors which affect the design of bio-based building materials for fire safety.

This new international guideline was produced in the framework of the Fire Safe Use of Wood (FSUW) network. It is also inspired by recent code changes to allow taller and larger timber buildings in Australia, Canada, the US and elsewhere. The guide is supported by various eminent research centres and universities conducting research in this area.

The core audience is all those involved in the fire safety of timber buildings, including architects, engineers, firefighters, educators, regulatory authorities, insurance companies and others in the building industry.

2.1 INTERNATIONAL RELEVANCE

Many well-known fire scientists and engineers worldwide wrote the different chapters to ensure its quality and relevance for use in all countries, see Table 1. More than 20 expert co-authors supported the lead authors. The emphasis is on describing basic principles of fire science and fire engineering for buildings using timber as a structural or lining material, leading to practical solutions, rather than specific details of building regulations in any one country.

Future research topics in relation to fire safety in timber buildings are also proposed on an international level.

National and international building codes in different regions of the world are compared, but not explained in detail. The guideline is of benefit to design engineers in any country and will be of special interest to code writers in countries where timber buildings are not established and the use of modern structural timber elements are only just being considered.

2.2 TECHNICAL CONTENT

The guideline consists of 14 chapters, starting with a description of the various timber products, types of structures and their use in buildings, to a more in-depth chapter dealing with PBD, as shown in Table 1.

The guideline addresses structural fire engineering by providing the latest detailed guidance on structural design of separating and load-bearing elements of timber structures. It also contains guidance on design for surface flammability and limiting fire spread. The importance of proper detailing in building design is stressed with examples of practical solutions to limit the spread of fire or smoke. Active fire protection and building execution and control are presented as important means of fulfilling fire safety objectives. In the following, the key elements of each chapter are summarised.

2.2.1 Chapter 1: Timber structures and wood products

This chapter 1 introduces timber structures and wood products. The types of construction presented in this chapter may have different names in different countries, but the fundamentals and design principles remain essentially the same. Some building codes may limit the use of timber and wood products, either for structural elements or interior finish materials, but these materials are being used throughout the world in many types of buildings and occupancies. With the increasing demand for sustainable buildings and performance-based design, it is expected that timber will gain even more popularity in the near future. Fire performance of timber structures and wood products can be evaluated by the guidance and design methods detailed in the following chapters.

One of the main advantages of timber structures is the variety of systems that can be designed and constructed to suit almost any need and to provide the level of fire performance required in building codes. Traditional light timber frame construction are widely used in low-rise and mid-rise buildings (Figure 2). As shown in Figure 3, innovative systems such as modern post-and-beam construction, mass timber construction, long-span and hybrid structures allow for expanding the use of timber in impressive and innovative structures, such as taller buildings. Prefabrication of timber elements and modules is also gaining popularity, due to the speed of construction, increased building control and waste reduction at the job site.

Another factor facilitating the use of timber in buildings is the variety of products available to designers. A broad range of structural engineered wood products has been developed over recent years to provide high-valued timber products through more efficient use of the raw material. For most countries, timber and engineered wood products are required to be manufactured, tested and evaluated by applicable standards. Quality control procedures are usually required to ensure high-quality end products and buildings with acceptable fire safety. Given the large variety of timber products around the globe, some of the engineered wood products presented herein may not be available in all countries.

This chapter is not intended to provide an exhaustive historical review of timber constructions and wood products but rather aims to provide sufficient information for designers, builders, building officials/authorities and fire services to better understand and differentiate the various wood products and timber building systems available.

https://doi.org/10.52202/069179-0603

Figure 3: *Curved beams and decking at a commercial centre in Canada (photo: Western Archrib)*

2.2.2 Chapter 2: Fire safety in timber buildings

Chapter 2 provides an overall description of the strategy for delivering fire safety in timber buildings (Figure 4). As in the design of all buildings, the goals are to provide life safety for occupants, safe access for firefighters and protection of affected property. It is essential to control the severity and duration of any accidental fire and prevent it from spreading elsewhere in the building. An important design objective for timber buildings is to control the burning or charring of exposed timber or protected timber, because this can add to the fuel load, and it will reduce the load capacity of structural timber members due to loss of cross section. Many of the topics introduced here are expanded on in the following chapters.

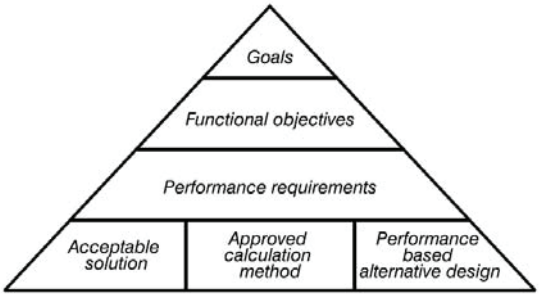

Figure 4: *Typical hierarchical relationship for fire safety design*

Fire safety during construction is a hazard for all timber buildings. Light timber frame buildings under construction are especially vulnerable before protective linings and other fire safety design features have been installed. Severe fires during construction have caused large financial losses in several countries. The construction fire hazard may be less severe in mass timber structures than in light timber frame buildings, but comprehensive fire precautions are essential. Management to control fires during construction is covered in Chapter 13.

2.2.3 Chapter 3: Fire dynamics

The third chapter provides information on fire dynamics in timber buildings. It summarises the fire behaviour in compartments with a focus on buildings with exposed timber structures and wood linings. It includes basic information on the pyrolysis and charring of wood, along with fire dynamics in compartments and the impact of having exposed timber surfaces. A description of common approaches to characterising post-flashover fires with parametric time–temperature curves is provided with guidance on a simplified design method to account for exposed timber surfaces based on parametric fire curves (Figure 5). Limitations in current knowledge are highlighted.

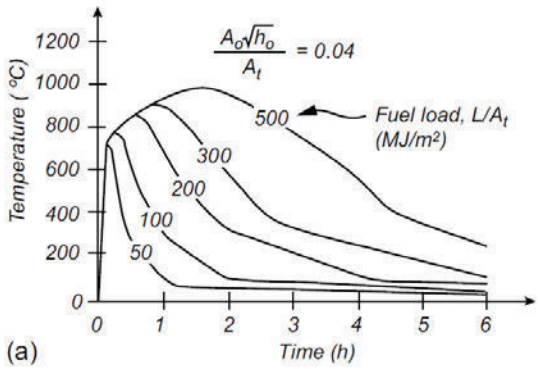

Figure 5: *Time-temperature curve for varying fuel load and constant ventilation factor*

2.2.4 Chapter 4: Fire safety in different regions

The regulatory control systems for fire safety design of buildings differ between regions around the globe, but it is based on the same principles of saving life and property and specifying requirements for structural and non-structural applications. This chapter 4 summarises the regulatory control systems for the fire safety design of buildings in different regions around the globe.

The possibilities for building in wood have gradually increased in recent decades in many countries, mainly due to the environmental benefits of using wood. But there are still restrictions in terms of fire regulations in many countries, especially for taller buildings. The situation has therefore been mapped in 40 countries on four continents as an update to a survey in 2002 (Figure 6). The main issues are how high buildings with load-bearing wooden frames may be built and how much visible wood may be used both inside and as façade claddings.

The requirements shown in this chapter apply primarily to prescriptive fire design according to so-called simplified design with detailed rules, which are mainly used for residential buildings and offices. For more complicated construction e.g. public buildings, shopping centres, arenas and assembly halls, performance-based design can be used by fire safety engineers using, for example,

https://doi.org/10.52202/069179-0603

engineering methods for predicting evacuation and smoke filling, which increases the possibilities of using wood in buildings.

In most countries, the possibilities of using wood in buildings increase if sprinklers are installed. More information on sprinklers is presented in Chapter 10.

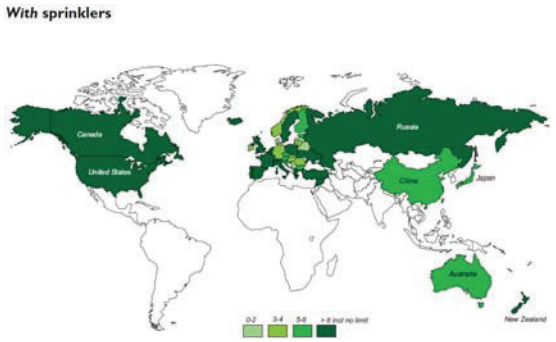

Figure 6: *Maximum number of storeys allowed for structural timber elements in prescriptive residential buildings (with sprinklers)*

Major differences between countries have been identified, both in terms of the number of storeys permitted in wood structures and of the amounts of visible wood surfaces in interior and exterior applications. Several countries have no specific regulations or do not limit the number of storeys in wooden buildings, mainly due to limited experience and lack of interest in using wood in taller buildings. The differences between countries are still large, and many countries have not yet started to use larger wood buildings despite supplies of forest resources.

Performance-based design may be used in several countries to verify further applications of wood (as presented in Chapter 11).

2.2.5 Chapter 5: Reaction to fire performance

This chapter 5 presents the reaction to fire performance of wood products used in buildings as internal surface finishes, exterior wall claddings, roof coverings and façade claddings. For façade claddings, the several different ways of assessing and regulating the fire performance of exterior wall systems are included. The chapter also describes the systems used for compliance with prescriptive regulations in different regions (Table 2), and the characteristics of wood products for performance-based design and methods for improving the reaction to fire performance of wood products.

2.2.6 Chapter 6: Fire separating assemblies

This chapter 6 describes the important role of fire-separating assemblies for passive fire protection in any type of building. Fire-separating assemblies provide essential compartmentation, which limits fire spread, contributing to both life safety and property protection. It gives design recommendations for providing fire resistance to timber- and wood-based separating assemblies, including walls, floors and roofs.

Table 2: *Comparison of reaction to fire classification in different countries*

Product	United States	Australia / New Zealand	Europe	Japan
DF[(1)] plywood	C	Gr. 3	D	[(4)]
FRT[(2)] DF plywood	A	Gr. 1 or 2	C	[(4)]
OSB 1	C	Gr. 3	D	[(4)]
PSB 2	C	Gr. 3	D	[(4)]
White pine[(3)]	C	Gr. 3	D	[(4)]
White oak[(3)]	C	Gr. 3	D	[(4)]

[(1)] DF: Douglas fir
[(2)] FRT: Fire-retardant treated
[(3)] Timber planks
[(4)] Unclassified

In addition to maintaining the load-carrying capacity of the structure during a fire, the concept of compartmentation is one of the most effective passive measures for providing fire protection for life safety and property protection. Without firefighting or automatic fire suppression, the concept of compartmentation is the only way of preventing a fire from spreading beyond its room of origin. This concept has become an essential requirement in both prescriptive and performance-based building codes all over the world.

The main objective of applying fire-resistance rated separating assemblies is to limit the probability that fire or smoke will spread from the compartment of fire origin to other compartments at the same or other storeys in a building, or to neighbouring buildings, within a defined time. By an optimum arrangement of separating assemblies (Figure 7), the development and spread of fire is slowed down, property damage is reduced, fire exposure to multiple sites is limited, safety of occupants is improved, and firefighting and rescue operations will be more effective.

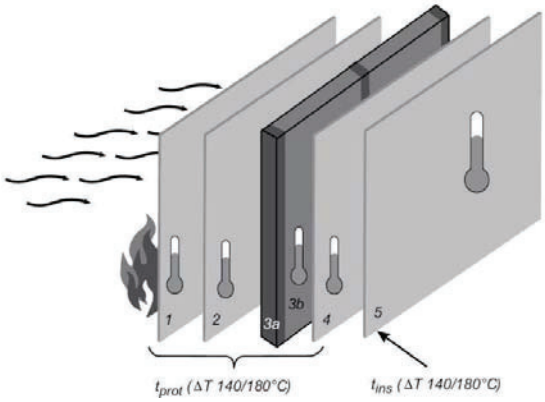

Figure 7: *Design approach of the European Separating Function Method (SFM)*

https://doi.org/10.52202/069179-0603

2.2.7 Chapter 7: Load bearing timber

Chapter 7 gives guidance for design of load-bearing timber members exposed to a standard fire. An overview of the principles needed to predict the effect of charring and heating is presented. Simplified design models around the world are described, including design models from the second generation of Eurocode 5.

The design objective in the event of a fire is determined by regulatory requirements and the fire safety strategy for the building. Most fire safety strategies are for load-bearing timber structures to resist the design loads for a specified fire exposure time. In this chapter, only the standard fire exposure is considered, according to e.g. ISO 834-1. Design of timber members in a standard fire situation requires an assessment of the reduction of cross-section caused by charring and the effect of heat on strength and stiffness of the residual cross-section. Charring may be influenced by protective linings and cavity insulation. For engineered timber members the glueline integrity in fire can also affect the rate of charring and load bearing capacity.

Unlike steel and concrete, thermal expansion of timber does not need to be taken into account because it is negligible. Timber members can be analysed individually without considering possible thermal actions from other timber members.

Fire resistance of structures can be assessed by fire testing or by simplified and advanced calculation methods. Calculation methods, as illustrated in Figure 8, typically give conservative results compared to fire testing. The design parameters for timber and protective materials are needed for calculation methods. If these parameters are unavailable or unknown, fire testing will be the only option for verifying the fire resistance.

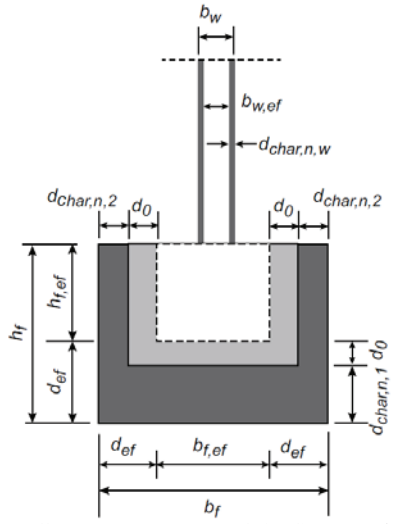

Figure 8: *Effective cross-section of the flange and web with cavity insulation*

Applicable fire exposures are stated in national building codes. For example, in Canada exterior walls are to be exposed on the interior side, interior walls on either side and floors are only exposed to fire on the underside. In Europe, Australia and New Zealand, walls delimiting a fire compartment are to be designed for fire exposure from one side, walls located within a fire compartment are to be designed for fire exposure from two sides, floors and roofs are usually to be designed for fire exposure from underneath. In some countries there are requirements to design floors for fire exposure from above (e.g. attics). In the UK and other countries there may be building types and storey heights where the stability of the structure is to be maintained in the event of a fire that is not controlled by firefighters, resulting in design of the load bearing timber structure to maintain its load-bearing function throughout fire decay until burnout.

Calculation examples of timber members are also presented. The examples demonstrate that for a timber product of similar strength and stiffness, the design for fire resistance will provide similar results whether the European, Canadian or US approach is used. However, design assumptions and load combinations must be consistent with the appropriate building codes and design standards.

2.2.8 Chapter 8: Timber connections

Chapter 8 introduces structural timber connections and provides information on potential failure modes and methods to provide fire resistance to connections exposed to a standard fire. Timber structures and their connections must be designed to have strength to resist all anticipated loads during the required fire resistance period and where required, to prevent the passage of heat and flames. Figure 9 shows an example of modern mass timber concealed connections.

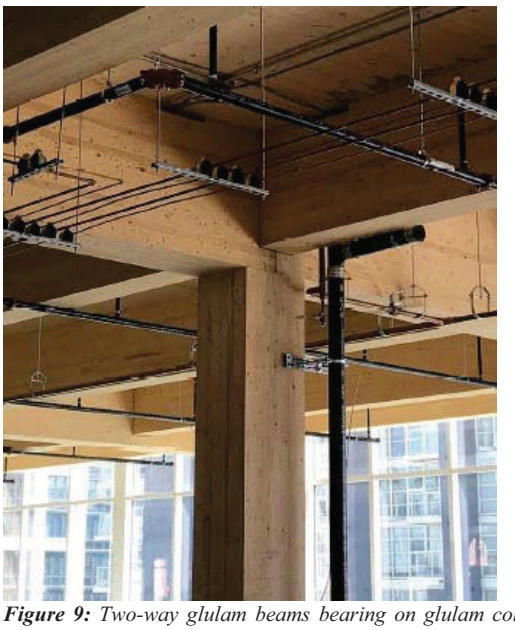

Figure 9: *Two-way glulam beams bearing on glulam column (photo: David Barber)*

https://doi.org/10.52202/069179-0603

2.2.9 Chapter 9: Prevention of fire spread

Fire spread within the structure is one of the main challenges for the fire safety of timber buildings. This chapter describes means of preventing spread of fire and smoke between compartments in timber buildings. Much of this applies to all buildings independent of materials used, but some topics are especially relevant for timber buildings. The chapter highlights critical paths of possible spread of fire into, within and through timber structures including solutions and detailing to prevent uncontrolled spread of fire and smoke (Figure 10).

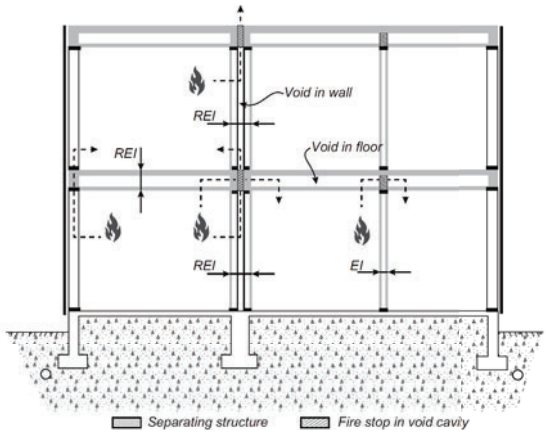

Figure 10: *Fire-stopping in voids – REI is for load-bearing and separating assemblies, EI is for separating assemblies*

It is important that the designers of all timber buildings consider prevention of fire and smoke spread through joints in and between building elements/assemblies, and through penetrations of building services and openings, including external walls. Chapter 9 is complementary to Chapter 6 which describes fire-separating elements and assemblies.

2.2.10 Chapter 10: Active fire protection by sprinklers

A wide variety of active fire protection systems are available to fire safety practitioners. In addition to passive fire protection measures, some level of active fire protection is normally required to meet the expected minimum level of fire safety in modern buildings. Active fire protection can also be used to increase the fire safety in order to achieve a more flexible fire safety design and an acceptable level of fire safety in buildings, especially in tall timber buildings. There are many types of active fire protection systems, but this chapter deals mainly with automatic fire sprinkler systems, since they are often used to facilitate the use of timber as structure, internal linings and external facades in large or complex buildings (Figure 12). Sprinklers, such as those shown in Figure 11, are required in some countries for taller timber buildings, as described in Chapter 4.

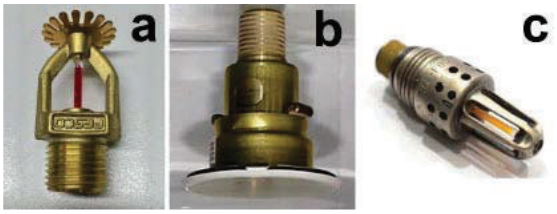

Figure 11: *Typical sprinkler heads for a) pendent, b) concealed pendent and c) water mist sprinklers*

An automatic fire sprinkler system can play an important role in the fire safety design of timber buildings. Provided that they are installed correctly and operate effectively, sprinklers will control or extinguish a fire at an early stage and prevent flashover. An increased use of sprinklers in residential buildings would considerably decrease the number of fire victims, independent of the construction materials used in those buildings. Building designs to incorporate sprinkler systems may facilitate increased use of timber, to be used as the structural material, the internal linings or the external facade. Reliable sprinkler systems are essential in tall buildings of any material, and especially so for tall timber buildings.

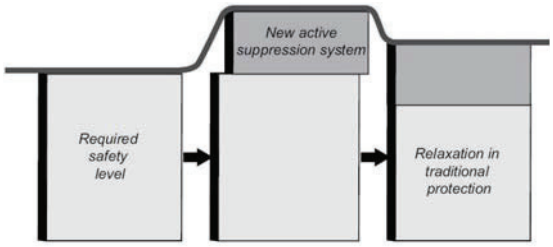

Figure 12: *Principle for fire safety design by sprinklers*

2.2.11 Chapter 11: Performance-based design

An overview of the application of performance-based approaches to the fire safety design of timber buildings is provided in Chapter 11. Performance-based designs, as illustrated in Figure 13, are relevant for the design of tall timber buildings and other timber buildings that vary from accepted prescriptive solutions. Performance-based design approaches are commonly categorised as deterministic or probabilistic and should be applied in accordance with the applicable regulations, building codes and standards. This chapter provides references to detailed information that should be consulted when undertaking performance-based designs or risk assessments.

https://doi.org/10.52202/069179-0603

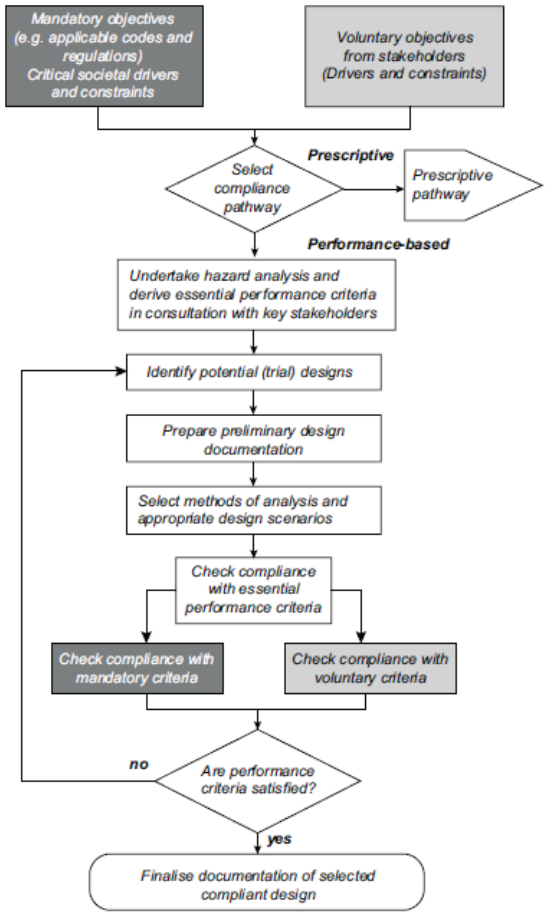

Figure 13: *Overview of a performance-based design process*

2.2.12 Chapter 12: Robustness in fire

With the increasing number of complex and tall timber buildings with a significant area of unprotected timber surfaces, questions arise about the robustness of these buildings in fire. In recent building projects, measures for robustness have been implemented on an ad hoc basis in agreement between the designers and the authorities. This chapter 12 discusses general approaches to achieve a robust fire safety concept which includes providing structural redundancy to prevent the failure of critical load-bearing elements such as isolated columns. Further, guidance is provided on how robustness of a fire safety concept can be enhanced for buildings using timber as a structural member.

2.2.13 Chapter 13: Building execution and control

Chapter 13 covers standards of workmanship and quality control of fire safety precautions during design and construction of timber buildings. Quality and inspection of workmanship are vital for high-quality buildings, whether of timber or other construction materials. Timber buildings require certain precautions due to the risk for greater exposure of combustible materials, namely hot works (Figure 14). Furthermore, not all fire safety measures for the final building will be in place throughout the construction period, so adequate processes are required to maintain the fire safety of building sites until the building is completed. All construction sites require formalised fire safety management systems, including auditing of contractors and subcontractors.

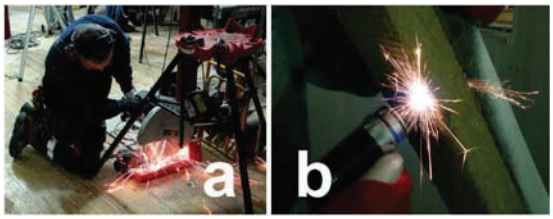

Figure 14: *Examples of hot works on a construction site (photos: Rohlén, Brandskyddslaget)*

2.2.14 Chapter 14: Firefighting considerations

Firefighting practices may be different in timber buildings compared with non-combustible construction. Internationally, fire services have raised concerns regarding the increased use of wood within buildings and specifically the use of timber structural elements of tall buildings. These concerns often stem from lack of knowledge of timber performance in fire, and firefighter experience from fires in non-combustible steel and concrete construction and traditional low-rise timber buildings. This chapter discusses relevant concerns of firefighters regarding large and tall timber buildings.

There is a significant lack of knowledge and practical experience with firefighting in tall timber buildings. The fire environment associated with exposed timber surfaces is different to non-combustible construction and may present new hazards and risks for occupants as well as for firefighters. There is a need for collection of data, knowledge and case studies from firefighting events, in order to develop a better understanding and new strategies and approaches for firefighting in tall timber buildings (Figure 15).

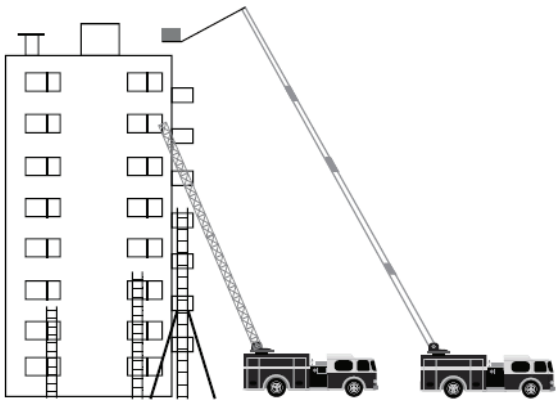

Figure 15: *Firefighting appliances for buildings up to about 8 storeys*

As combustible structures become larger, taller and more complex, the robustness and resilience of the buildings

and their fire safety features also need to increase. This will require appropriate changes to national and international building codes.

There is a critical need for more understanding of the smouldering combustion of large timber elements after fire exposure. As structural concepts progress and move away from the traditional assumption of burnout, a greater reliance will inevitably be placed on firefighters to extinguish fires and ensure that continued smouldering of the timber structure does not occur.

Lastly, it is essential that all emergency responders be knowledgeable and have an understanding of how combustible structures and tall timber buildings perform in severe fires. Without sufficient fire-ground experience of mass timber buildings, the emergency response must be informed by education and research that considers the needs of the responders (Figure 16). As buildings evolve, so must the firefighter response, with new strategies to ensure the most favourable outcomes for all stakeholders.

Figure 16: *Firefighter team during a timber fire test scenario at the Technical University of Munich in 2021*

3 CONCLUSION

Further to the success of the 2010 European guideline, combined to the latest outcomes from the recently completed COST Action FP1404 - Fire Safe Use of Bio-Based Building Products, a new collaborative international effort was made to produce a Global Design Guide on Fire Safe Use of Wood in Buildings, with the main objective to provide state-of-the-art scientific knowledge on a global level for practical applications. More than 20 expert co-authors supported the l3 lead authors.

This new Global Design Guide is expected to be of use to a wide range of stakeholders involved in designing fire safety in timber buildings, including architects, engineers, educators, regulatory authorities, building industry personnel, the timber industry and building code writers.

The Global Design Guide is published both as a hard-bound book and as an open access version available for free PDF download via the Fire Safe Use of Wood website (www.fsuw.com).

ACKNOWLEDGEMENTS

The lead authors wish to thank all their co-authors and a large number of colleagues and reviewers in many countries who provided much assistance in the preparation of this guide. Melody Callahan produced the line drawings and managed the delivery of text and images to the publisher.

We also acknowledge the large number of consulting firms, research institutions, universities and professional organisations around the world who supported this project through in-kind support of authors and reviewers. Generous financial contributions were made by FPInnovations, Natural Resources Canada (Canadian Forest Service), Softwood Lumber Board, BRANZ, SFPE New Zealand, Federation of the Finnish Woodworking Industries and Linnaeus University, Sweden.

Architecture for a Sustainable Life

White Arkitekter is one of Scandinavia's leading architectural practices. We work with sustainable architecture, urban design, landscape architecture and interior design for current and future generations. Our mission is to enable sustainable life through the art of architecture. Our vision is that by 2030 all our architecture will be carbon neutral, through design excellence. We are an employee-owned architect collective with just over 700 employees and a presence in Sweden, Norway, the UK, Germany, Canada and East Africa.

NÅR DU SKAL BYGGE MED TRE

Med inspirasjon fra norsk natur og nordiske byggetrender, har vi utviklet unike kolleksjoner innen fasader, interiør og uterom til hus, hytter og leilighetsprosjekter.

SATURE Uterom – Miljø- og vedlikeholdsvennlige terrassebord

SATURE Fasade – Miljø- og vedlikeholdsvennlige kledninger

NORD Eksteriørkolleksjon - Kledning og tilbehør til barske fasader

TRYR Eksteriørkolleksjon - Kledning til all slags vær

NORD Interiørkolleksjon - Tidløse paneler og listverk

TELE Interiørkolleksjon - Storslåtte paneler og listverk

BERGENE HOLM AS

- Beste valg når du skal bygge med tre -

PRODUSERT I NORGE

Massivtre – lagrer CO2 i enorme mengder

Treet suger til seg CO2 når det vokser og lagres som karbon i trestrukturen.

Splitkon leverer komplette byggesystemer i massivtre og limtre.

Moderne og miljøvennlige trebygg er fremtiden. Fra en av verdens største massivtrefabrikker, forsyner vi den norske byggebransjen med bærekraftigeløsninger.

Massivtre fra Splitkon lages kun med PEFC-sertifisert trelast fra norsk skog. Dette gir den høyeste kvaliteten – tilpasset nordiske forhold.

Avansert CNC-teknologi gir oss uendelige muligheter, og en presisjon på millimeternivå selv på elementer som er opptil 3,5 x 16 m.

Tre er både sterkt, lett i forhold til styrke og kan formes i alle fasonger. Tre er det mest miljøvennlige byggematerialet vi har.

Fakta: Miljøgevinsten/ besparelsen ved bruk av massivtre vs betong er 1 tonn CO2 per m³.

Les mer på **splitkon.no**

Se video om massivtre

Spor X – et av verdens mest miljøvennlige kontorbygg

Spor X i Drammen er et tietasjers kontorbygg med kortreist massivtre fra Splitkon. Prosjektet består av over 200 tilpassede limtrebjelker og 2500 m3 massivtre. Helt uten betong og stål fra grunnmur og opp.

WITH OUR
SOLUTIONS
IS THIS WHERE WE'LL END UP?
It doesn't matter what heights we'll reach in the future. Tomorrow will have shapes and sizes imagined by today's designers, and solutions from those, like us, who believe in timber construction. Let's build the future together, let's climb higher.

WORLD CONFERENCE ON TIMBER ENGINEERING 2025

BRISBANE, AUSTRALIA

IT'S LIVE! in Queensland

WCTE 2025 THEMES:

- Material Performance & Durability
- Sustainability and Timber in a Circular Economy
- Timber Engineering & Structural Performance
- Timber Architecture & Biophilic Design
- Education, Innovation & Challenges
- Exemplars & Construction Case Studies

Brisbane, Tourism Queensland

Murdoch University Boola Katitjin Building: Aurecon Group

25 King St, Brisbane: Lend

Advancing Timber for the Future Built Environment

It is with great pleasure, that the Australian Organising Committee invite delegates from around the world to join us in Brisbane to attend the next WCTE, from 22nd to 26th June 2025.

Our host organisation for the conference is The University of Queensland, home of the recently established Australian Research Council Industrial Transformation Research Hub to Advance Timber for Australia's Future Built Environment (ARC Advance Timber Hub).

The use of timber in building construction is growing at a rapid pace in Australia and the government continues to provide incentives for the utilisation of engineered timber products in construction, including a commitment of $100 million for the creation of a national institute for Forest Products Innovation, designed to position the Australian Timber Industry to make huge contributions to Australia's carbon positive bio-future.

Australia is bringing innovative timber solutions to the tall buildings market, developing uniquely performance-based design solutions to make timber viable for building of height and complexity equal to that of any other country in the world.

There is a rise in engineering and architectural firms, developers and investors, now emphasizing timber engineering as a preferred solution for many projects, providing further relevance and importance to the research carried out by the timber design and construction community.

A number of exemplar buildings and structures are located within Brisbane, providing an ideal opportunity for site visits as part of WCTE 2025; whilst some stunning examples of modern timber buildings can also be seen in Sydney, Melbourne and Perth.

Our host city of Brisbane, is the capital of the State of Queensland; Australia's favourite tourist region and host of the 2032 Olympic Games. It is an ideal location for both the WCTE conference and extending your trip to visit some of the natural wonders of this part of Australia.

WCTE 2025 is supported by the Queensland Government through Tourism and Events Queensland and features on the It's Live! in Queensland events calendar.

For more information on WCTE 2025, please visit **www.wcte2025.org**
