All authors have submitted two-page extended abstracts, which were peer reviewed by the WCTE2023 International Scientific Committee. The full papers have not been further reviewed, but checked for conformity. Many of these papers represent ongoing research and it is expected that many of the papers will appear in a more comprehensive form in scientific journals in due course.

Proceedings from the 13th World Conference on Timber Engineering, Oslo, Norway 19-22 June 2023

The World Conference on Timber Engineering (WCTE) is the premier forum of the world for dissemination of the latest developments, technologies and innovations in wood materials and timber design, engineering and construction.

The scope covers research, education and practice topics from all over the globe. The conference has attracted wide international representation and attendance.

The name WCTE exists since 1998 when the world's timber engineering society decided to coordinate the former world events and to introduce biennial consecutive conferences in Europe, America, Asia & Pacific.

About WCTE

History

The forerunner of WCTE dates back to May 1984, and the Pacific Timber Engineering Conference (PTEC) in Auckland, New Zealand. The first World Conference on Timber Engineering (WCTE) started in 1998 in Montreux, Switzerland, when the world's timber engineering society decided to coordinate the former world events and to introduce a biennial rhythm with consecutive conferences in Europe, America, Asia & Pacific.

Today WCTE is the world's premier scientific dissemination forum for presenting and discussing the latest technical and architectural developments and innovations in timber engineering and construction.The scope covers research, education and practice topics from all over the world. The conference has attracted wide international representation and attendance.

1984 PTEC Auckland, New Zealand
1988 ICTE Seattle, USA
1989 PTEC Auckland, New Zealand
1990 ITEC Tokyo, Japan
1991 ITEC London, UK
1994 PTEC Surfer's Paradise, Australia
1996 IWEC New Orleans, USA
1998 WCTE Montreux, Switzerland
2000 WCTE Whistler, Canada
2002 WCTE Shah Alam, Malaysia
2004 WCTE Lahti, Finland
2006 WCTE Portland, USA
2008 WCTE Miyazaki, Japan
2010 WCTE Trentino, Italy
2012 WCTE Auckland, New Zealand
2014 WCTE Quebec City, Canada
2016 WCTE Vienna, Austria
2018 WCTE Seoul, Rep. of Korea
2021 WCTE Santiago, Chile
2023 WCTE Oslo, Norway
2025 WCTE will be held in Brisbane, Australia

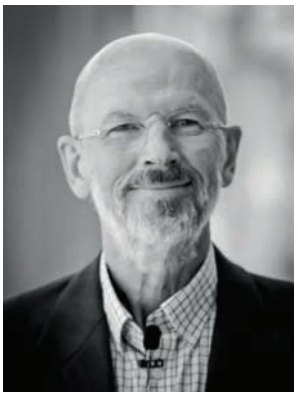
Preface WCTE2023



Kjell Arne Malo

Anders Q. Nyrud

Dear colleagues, Dear readers

Despite the exceptional COVID-pandemic situation experienced, we are now back on track with a physical gathering at the 13th World Conference on Timber Engineering (WCTE2023) in Oslo, Norway. Thanks to extensive effort by our Chilean colleagues, who organized the conference in 2021, WCTE could take place also during the COVID pandemic. We all do, however, appreciate to be back in the traditional physical conference context.

The slogan of the WCTE2023 is: Timber for a Livable Future. This is indeed a relevant slogan.

We are now experiencing increased interest in timber as a structural material as well as wood used for surface in architecture. Timber is in fact used in many different types of products and structures. It is a bio-based material, in which humanity has created shelters, tools and objects of art. Throughout history humans have adapted to timber. How do we take this wisdom into our modern timber structures?

Climate change is a driving force and pushes all of us to toward severe changes with more environmentally friendly, sustainable and circular materials in our built practice. Everyone with an interest in wood as a construction material in research, industry and education has a role for development of the field of timber engineering so that we can meet future demands and societal needs.

The forerunner of WCTE dates back to May 1984, at the Pacific Timber Engineering Conference (PTEC) in Auckland, New Zealand. The first World Conference on Timber Engineering (WCTE) took place in 1998 in Montreux, Switzerland. It was decided to consolidate the former world events and to introduce a biennial rhythm with consecutive conferences in Europe, America, Asia & Pacific. The conference has been hosted in the Nordic region only once before, in Lahti, Finland in 2004.

The conference has maintained its important position on the world scene with currently more than 600 papers accepted for presentation. WCTE2023 is the major event within the timber engineering society in 2023 and has attracted more than 800 attendants and more than 600 presentations. Participants have the opportunity to share ideas on nearly any subject related to timber engineering, from codes of practice, regulations and legislations, to innovations, new practices, and future trends of bio-based sustainable and circular building materials used in construction. WCTE2023 reflects the state-of-the-art in timber engineering.

This proceeding provides a collection of all the scientific contributions to the conference. The conference has attracted a wide range of academics, scientists, researchers, students, designers, policymakers, and other industrialists with a wide variety of backgrounds, including fields of engineering, materials, sustainable development, architecture, ecological technologies, biomaterials, materials sciences, environmental engineering, government agencies, end-users, and more.

The Organizing Committee of WCTE2023 would like to express our sincere gratitude to all contributors and participants for their carefully prepared, stimulating, and interesting manuscripts.

Kristine Nore

Knut Werner Lindeberg Alsén

Thanks are also extended to the members of the WCTE2023 International Scientific Committee for review of nearly one thousand submissions. Without their dedicated efforts, the conference and the proceedings would not have been realized in this way. The cooperation of the authors in accepting reviewers' suggestions and revising their manuscripts accordingly is greatly appreciated.

The organization of a conference of this scale was possible with the support and contributions from many organizations and individuals including financial support. We are grateful to Innovation Norway for supporting grants for conference preparation. We also would like to express our thanks to the Oslo Convention Bureau for their important support throughout the entire process, from application to implementation of WCTE 2023.

We would like to thank the Norwegian supporting organisations Oslo Metropolitan University (OsloMet), Norwegian Institute of Wood Technology (Treteknisk), Norwegian Institute of Bioeconomy Research (NIBIO), SINTEF and Bergen School of Architecture (BAS).

We would like to thank our platinum sponsors SWECO, Paper Province and Region Värmland, and the gold sponsors Moelven and Aanesland Treindustri, as well as sponsors on silver, bronze and supporting level.

We would like to thank PEFC Norge, Moelven, Hunton, Ny Struktur, Splitkon, County Governor of Vestland, Norwegian Wood Cluster, NTNU Wood, Wood Works Cluster, Norsk Folkemuseum, for participating in planning and preparations for the technical conference tours and other events.

A special thank you goes to AHO, SWECO, Aanesland Treindustrier, Bergene Holm, SirkTRE and Bymiljøetaten Oslo kommune, for making the WCTE-pavilion outside the conference venue such an exciting demonstration of timber engineering in real life.

We would also like to thank all those who have devoted their time and effort to the organization of the conference. We would like to thank the Coordinating Council of the WCTE for support and trust as well as our colleagues in WCTE2021 from Chile for sharing their expertise and experience with us.

Finally, we would like to thank the four hosting institutions, NMBU, NTNU, AHO and the City of Oslo, for cooperation and efforts in the process of planning and conducting the conference.

Oslo, 19 May 2023

TABLE OF CONTENTS

1.1. STRUCTURAL PERFORMANCE OF MATERIALS

COMPARISON OF THE STRUCTURAL CAPACITY OF SHEAR WALLS SHEATHED WITH ORIENTED STRAND BOARD AND RECYCLED MATERIAL SUBJECTED TO CYCLIC LOADING 1
David Dinehart, Eric Musselman, Edward Bolte, Bridget Lasala

PENDULUM IMPACT HAMMER TESTS ON TIMBER BEAMS - EXPERIMENTAL SETUP 6
Alex Sixie Cao, Andrea Frangi

NUMERICAL AND EXPERIMENTAL EVALUATION OF WOOD NAILER OPEN WEB STEEL JOISTS 14
Sameer Fares, David Dinehart, Shawn Gross, Joseph Yost, Rebecca Hoffman

BEHAVIOR OF TIMBER BEAMS STRENGTHENED WITH CFRP 24
Zhang Shengdong, Blanche Blondel De Joigny, Jianrong Cui

MICROWAVE TECHNOLOGY AND ITS APPLICATIONS TO WOOD TREATMENT AND MODIFICATION 31
Fernando Mascarenhas, Alfredo Dias, André Christoforo, Rogério Simões

STRUCTURAL PERFORMANCE, AND FAILURE MECHANISM, OF HARDWOOD CROSS LAMINATED TIMBER CONCRETE COMPOSITE UNDER SHEAR LOAD 41
Aamir Khokhar, David Bell, Roshan Dhonju

SCALING STUDY ON VISCOUS DAMPING FOR GLULAM AND HYBRID GLULAM-FRP BEAMS 51
Tomas Bravo Tetlak, Joseph M. Gattas, Cristian Maluk

EXPERIMENTAL AND FINITE ELEMENT MODELLING (FEM) OF TIMBER-TIMBER COMPOSITE (TTC) UNDER HOGGING MOMENT 57
Mahmoud Wajdi Hammad, Hamid R Valipour

QUASI-STATIC OUT-OF-PLANE TESTING OF REINFORCED CROSS-LAMINATED TIMBER 65
Eric Kjolsing, Mark Weaver, Marco Lo Ricco, C. Adam Senalik, Jason Cattelino, Jim Henjum, Russell Edgar, Edwin Nagy

BALLISTIC TESTING OF CROSS-LAMINATED TIMBER LAYUPS TO FURTHER DEVELOP PROTECTIVE PANELS 75
Marco Lo Ricco, Mark Weaver, C. Adam Senalik, Jim Henjum, Jason Cattelino

PREDICTING MODULUS OF RUPTURE OF HEAT-TREATED WOODS BY ARTIFICIAL NEURAL NETWORK COMBINED WITH GENETIC ALGORITHM 84
Mehdi Nikoo, Reza Abbasi Malekabadi, Ghazanfarah Hafeez

TENSION LOADED CONNECTIONS WITH WOOD DOWELS 89
Matthias Brieden, Max Braun, Werner Seim

MECHANICAL PROPERTIES OF GLUE LAMINATED TIMBER BY SMALL SIZE TREE SPECIES (CASE STUDY OF OKINAWAN FOREST) 98
Juan Castro, Shogo Omi

EXPERIMENTAL INVESTIGATION ON IN-PLANE PERFORMANCE OF NAIL-LAMINATED TIMBER FLOORS 105
Zhaozhuo Gan, Minjuan He, Zheng Li, Xiaofeng Sun

AN EXPLORATORY STUDY ON MIXED-MODE FRACTURE AND STRAIN DISTRIBUTION NEAR A CRACK TIP OF ADHESIVELY-LAMINATED WOOD SPECIMENS USING THE MODIFIED ARCON FIXTURE AND DIGITAL IMAGE CORRELATION 112
Zizhen Gao, Meng Gong, Ling Li, Mohsen Mohammadi

GREEN OAK BUILDING WITH HIGH-TECH METHODS, PART 2: LOG BENDING TESTS FOR DETERMINATION OF STRENGTH AND STIFFNESS 119
Kay-Uwe Schober, Beate Hörnel-Metzger, Maximilian Leonhard Müller, Nicolas Hofmann, Franka Brüchert, Udo H. Sauter

EXPERIMENTAL STUDY ON IN-PLANE SHEAR PERFORMANCE OF CROSS-LAMINATED TIMBER 126
Kaito Yamagata, Ryo Inoue, Takuro Mori

SHEAR TESTS ON FULL-SCALE EUROPEAN ASH GLUED LAMINATED TIMBER BEAMS 132
Pedro Palma, René Steiger, Thomas Strahm, Ernst Gehri

STRUCTURAL USE OF CUT-OFFS FROM CLT-PRODUCTION – THREE EXAMPLES THAT UTILIZE THE UNIQUE PROPERTIES 139
Johan Vessby, Mikael Perstorper, Florian Demonte, Jacob Eriksson

EXPERIMENTAL STUDY ON CHARACTERISTIC VALUES OF PARTIAL COMPRESSION PERPENDICULAR TO THE GRAIN OF HARDWOOD WITH EDGE DISTANCE ORTHOGONAL TO THE LONGITUDINAL DIRECTION 147
Hiroto Suesada, Kohta Miyamoto

COMPARISON BETWEEN ACTUAL AND EQUIVALENT CRACK RESISTANCE R-CURVE FOR TIMBER AND TIMBER BOND UNDER MODE-II FRACTURE 153
Shaikh Atikur Rahman, Mahmud Ashraf, Mahbube Subhani

MODE I TESTS OF NORWAY SPRUCE USING SEN-TPB: DETAILED ANALYSIS OF THE CRACK LENGTH DETERMINED USING OPTICAL METHOD 162
Martin Hataj, Jirí Kunecký, Michal Kloiber

BAMBOO GRIDSHELL: FROM THE MATERIAL TO THE STRUCTURE 168
Esti Nurdiah, Tsung-Hsien Wang, Wen-Shao Chang

PRELIMINARY INVESTIGATION ON SAFETY PERFORMANCE OF CLT WALL PANELS UNDER IMPACT AND SUSPENSION TESTS 175
Gabriela Lotufo Oliveira, Fabiana Lopes De Oliveira

ENABLE THE USE OF MASS TIMBER PRODUCTS FOR NON-RESIDENTIAL BUILDINGS IN HIGH VELOCITY HURRICANE ZONES 182
Sovanroth Ou, Michael Stoner, Weichiang Pang

BENDING BEHAVIOR OF GLT-STEEL BEAM CONNECTED BY INCLINED SCREWS 188
Sung-Jun Pang, Kyung-Sun Ahn, Gwang-Ryul Lee, Min-Jeong Kim, Jae-Won Oh, Jung-Kwon Oh

THE PRODUCTION OF ADHESIVE FREE CROSS-LAMELLA TIMBER (CLT) PANEL USING PRODUCTS GENERATED BY THE SUSTAINABLE FOREST MANAGEMENT OF THE AMAZONIAN OLD GROWTH FOREST 196
Marcos Cesar Pereira, Adma M. D. Higuchi, Geraldo Lira, Antonio Alves Dias, Niro Higuchi

AN EXPERIMENTAL INVESTIGATION OF FAILURE MODES IN SHORT SPAN FRP REINFORCED GLULAM BEAMS 202
Catherine Shrimpton, Serena Siciliano, Herry Chen, Yannick Vetter, Daniel Lacroix

DAMAGE MODEL FOR A BIOSSOURCED HETEROGENEOUS MATERIAL: APPLICATION TO TIMBER 209
Amal Rebhi, Myriam Chaplain, Jean-Luc Coureau, Cedric Perez

NUMERICAL EXAMINATION OF THE BEHAVIOUR OF DOWEL LAMINATED TIMBER ELEMENTS UTILISING COMPRESSED WOOD DOWELS 216
Conan O'Ceallaigh, Annette M. Harte, Patrick J. McGetrick

BONDING OF FIRE-RETARDANT TREATED SPRUCE LAMELLAE FOR USE IN CROSS LAMINATED TIMBER (CLT) 225
Karl-Christian Mahnert, Stine Lønbro Bertelsen

EVALUATION OF TIMBER-CONCRETE SLAB CONNECTED WITH NOTCHED CONNECTION MADE OF KOREAN LARCH STRUCTURAL PLYWOOD 232
Kyung Sun Ahn, Sung-Jun Pang, Jiyong Kim, Jaewon Oh, Min-Jeong Kim, Gwang-Ryul Lee, Jung-Kwon Oh

MEASURING FIRE SAFETY PERFORMANCE: A COMPARATIVE EXPERIMENTAL STUDY ON DOVETAIL MASSIVE WOODEN BOARD ELEMENTS AND CROSS-LAMINATED TIMBER 238
Hüseyin Emre Ilgin, Markku Karjalainen, Mikko Malaska, Mika Alanen

LABORATORY INVESTIGATION OF CROSS-LAMINATED DECKS FOR BRIDGE APPLICATIONS 244
Justin M. Dahlberg, James P. Wacker, Douglas R. Rammer

COMPRESSIVE STIFFNESS PARALLEL TO GRAIN IN TIMBER 251
Marina Totsuka, Robert Jockwer, Kenji Aoki, Masahiro Inayama

COMPARISON OF THE DEGREE OF INFLUENCE OF VARIOUS CONDITIONS ON THE BEARING CAPACITY OF WOOD-BASED PANELS 259
Ryutaro Sudo, Kenji Aoki

REINFORCEMENT OF TIMBER STRUCTURES VERSUS CLIMATE IMPACT 268
Bettina Franke, Steffen Franke, Marcus Schiere

COMPONENT METHOD IN TIMBER CONNECTIONS: END-PLATE COMPRESSING TIMBER PARALLEL TO GRAIN COMPONENT STRENGTH 276
Arthur S. Rebouças, Jorge M. Branco, Paulo B. Lourenço, Hidelbrando J. F. Diógenes

COMPARISON BETWEEN EXPERIMENTAL RESULTS AND DESIGN EQUATIONS OF ARTIFICIALLY DEGRADED SINGLE STEP JOINTS 285
Daniel F. Lima, Jorge M. Branco, Lina Nunes

STUDY ON THE RELATIONSHIP BETWEEN INTERLAYER DEFORMATION ANGLE AND TORN WALLPAPER OF WOODEN HOUSES 292
Sora Sunakozawa, Kiyotaka Terui, Hideyuki Nasu

GLUED-LAMINATED TIMBER UNDER EXTREME COLD TEMPERATURES SUBJECTED TO IMPACT LOADING 299
Nicole Wight, Christian Viau, Patrick Heffernan

EXPERIMENTAL AND NUMERICAL ANALYSIS OF CLT FLOOR SUBASSEMBLIES UNDER CATENARY ACTION 307
Alicja Przystup, Thomas Tannert, Yong Lu, Thomas Reynolds

UNREINFORCED AND STEEL-REINFORCED COLUMNS MADE OF EUROPEAN BEECH GLUED-LAMINATED TIMBER 315
Katharina Sroka, Pedro Palma, René Steiger, Thomas Ehrhart, Andrea Frangi, Thomas Strahm, Ernst Gehri

MECHANICAL BEHAVIOUR OF COLUMN BASES FOR CLT ROCKING FRAMES 323
Akira Masuda, Chisato Inutsuka, Kazuhiro Matsuda

INVESTIGATION OF CROSS LAMINATED TIMBER'S LONG-TERM PERFORMANCE (CREEP) 333
Aaron Desantis, Michael Stoner, Weichiang Pang

LOW-TEMPERATURE BONDING OF TIMBER STRUCTURES 339
Morten Voss, Tobias Evers, Till Vallée

RAPID BONDING OF TIMBER STRUCTURES 345
Morten Voss, Jona Haupt, Till Vallée

EXPERIMENTAL RESEARCH ON POINT-SUPPORTED CLT PANELS: PHASE 1: ROLLING SHEAR STRENGTH 352
Md Shahnewaz, Carla Dickof, Houman Ganjali, Christian Slotboom, Mandy Tam, Robert Jackson, Marjan Popovski, Thomas Tannert

PRELIMINARY TEST RESULTS ON THE IN-PLANE STRENGTHENING OF TIMBER FLOORS WITH THE DOUBLE PLANKING TECHNIQUE 358
Giovanni Metelli, Alessandra Marini, Stefania Cominelli, Francesca Feroldi, Anna Maria Basso Bert, Ezio Giuriani

1.2. MATERIAL MODELLING

A NEW APPROACH TO DETERMINE AND EVALUATE THE POISSON´S RATIO OF WOOD 366
Klara Winter, Roland Maderebner, Philipp Dietsch

THEORETICAL AND EXPERIMENTAL INVESTIGATION ON PREDICTING LONGITUDINAL AND TANGENTIAL ELASTIC CONSTANTS AND RATIOS OF WOOD 376
Shaghayegh Kurzinski, Paul L. Crovella

PYTHON-BASED PLATE MODEL TO SIMULATE THE EFFECT OF KNOTTY AREAS ON SAWN TIMBER 383
Jorge Uribe Cisternas, Diego Valdivieso Cascante

SIMULATION OF WOOD FRACTURE MECHANICS USING THE PHASE FIELD METHOD FOR FRACTURE 391
Sebastian Pech, Markus Lukacevic, Josef Füssl

NUMERICAL SIMULATION OF MOISTURE INDUCED CRACKING IN INDOOR CLIMATE 398
Florian Brandstätter, Maximilian Autengruber, Markus Lukacevic, Josef Füssl

EXPERIMENTAL DETERMINATION OF R CURVES FOR EUROPEAN SPRUCE USING DCB TESTS 407
Marija Todorovic, Marko Pavlovic, Ivan Glišovic, Mathieu Koetsier

THE INFLUENCE OF WOOD COATINGS ON THE MOISTURE BUFFERING CAPACITY OF CLT AND THE INDOOR ENVIRONMENT 413
Ulrich Hundhausen, Robbe Heyvaerts, Sameer Ullah, Dimitrios Kraniotis

EVALUATION OF MODELS OF FIBRE ORIENTATION IN SAWN TIMBER USING SYNCHRONISED COMPUTED TOMOGRAPHY AND OPTICAL SCANNING DATA 421
Johannes Huber, Osama Abdeljaber, Johan Oja, Anders Olsson

MODELLING THE EFFECT OF THREE-DIMENSIONAL GRAIN ANGLE ON THE TENSION STRENGTH OF BIRCH WOOD 428
Steven Collins, Joonas Jaaranen, Gerhard Fink

HYGROTHERMAL PERFORMANCE OF SHEEP WOOL IN COLD AND HUMID CLIMATES ..... N/A
Yuchen Chen, Dehong Li, Bin Li, Denis Rodrigue, Xiaodong Alice Wang

EFFECTS OF THE CROSS-LINKING OF THE CELLULOSIC FIBRILLAR NETWORK ON THE EFFECTIVE MACROSCOPIC BEHAVIOUR OF WOOD 443
Nhat-Tung Phan, François Auslender, Joseph Gril, Rostand Moutou Pitti

A MULTI-PHASE HYGRO-THERMAL MODEL FOR WOODEN BRIDGE COMPONENTS EXPOSED TO SOLAR RADIATION 449
Stefania Fortino, Petr Hradil, Timo Avikainen, Keijo Koski, Ludovic Fülöp

NUMERICAL MULTI-SCALE HOMOGENIZATION OF MECHANICAL PROPERTIES OF PINUS PINASTER (AIT.) LAMELLAE CONSTITUTING GLUED LAMINATED TIMBER 455
Romain Chevalier, Bruno Vuillod, Mathilde Zani, Marco Montemurro, Régis Pommier, Anita Catapano

SIZE EFFECT OF LARGE GLUED LAMINATED TIMBER BEAMS – CONTRIBUTION TO THE ONGOING DISCUSSION 465
Christoffer Vida, Markus Lukacevic, Georg Hochreiner, Milena Stavric, Josef Füssl

MODE I FRACTURE ENERGY OF AUSTRALIAN NATIVE HARDWOOD SPOTTED GUM AT VARIOUS MOISTURE CONTENTS 474
Peiqing Lu, Benoit P. Gilbert, Chandan Kumar, Robbie L. McGavin, Hassan Karampour

FLEXURAL REINFORCMENT OF TIMBER ELEMENTS ON-SITE WITH PRF ADHESIVE AND WOOD-BASED PRODUCTS 482
Andreas Stenstad, Karl-Christian Mahnert, Kristine Vik

1.3. LONG-TERM BEHAVIOUR

WEAR RESISTANT PROTECTION OF WOODEN POLES IN ADVERSE ENVIRONMENTS 488
Thomas Lindblad, Knut Magnar Sandland, Andreas Treu

WOOD AND STEEL VISCOELASTIC DAMPERS: SHORT AND LONG-TERM PERFORMANCE 493
David W. Dinehart, Edward D. Bolte, David E. Lewicki

DURATION OF LOAD UNDER LONG-TERM BENDING LOAD OF LAMINATED VENEER LUMBER AND WOODEN I-BEAM 498
Ryuya Takanashi, Takahiro Tsuchimoto, Yoshinori Ohashi, Wataru Ishihara

DERIVATION FROM EN927 METHOD FOR EVALUATING OUTDOOR DURABILITY OF COATED FIRE-RETARDANT-TREATED WOOD 505
Ryo Takase, Atsuko Ishikawa, Daisuke Kamikawa

DIMENSIONAL VARIATIONS MONITORING OF RADIATA PINE CLT PANELS: A CASE STUDY IN CONCEPCIÓN, CHILE 512
Víctor Rosales, Fernanda Pascal, Franco Benedetti, Pedro Rebolledo, Alan Jara-Cisterna, Mauricio Vargas

EFFECTS OF PANEL DIRECTION, LOAD LEVEL AND AMBIENT HUMIDITY ON THE CREEP OF DOWNSCALED CROSS-LAMINATED TIMBER 521
Dawei Wang, Meizhen Chen, Meng Gong, Zhuo Cheng

SHEAR CREEP OF POLYSTYRENE CORES IN WOODBASED PANELS 529
André Jorissen, Johnny Van Rie, Jeff Modderman, Hèrm Hofmeyer

INTEGRATED APPROACH TO PREDICT DETERIORATION OF MECHANICAL PROPERTIES OF DECAYING WOOD 536
Petr Hradil, Stefania Fortino

CREEP TESTS ON NOTCHED BEAMS OF SILVER FIR WOOD (ABIES ALBA) 542
Arthur Bontemps, Gaël Godi, Rostand Moutou Pitti, Eric Fournely, Joseph Gril

SIMPLIFIED ENVIRONMENTAL ANALYSIS OF THE LONG-TERM PERFORMANCE OF WOOD CLADDING AND DECKING 549
Jonas Niklewski, Jakub Sandak, Philip Bester Van Niekerk, Christian Brischke, Richard Acquah, Anna Sandak

ON THE USE OF ARUCO MARKERS IN LONG TERM MONITORING OF TIMBER STRUCTURES 558
Jirí Kunecký

EXPERIMENTAL STUDY OF THE EFFECTS OF ACCELERATED AGING CYCLES ON THE FIRE REACTION PERFORMANCE OF FIVE WOOD SPECIES 564
María Pilar Giraldo, Alina Avellaneda, Laia Haurie, Marcel Vilches, Ana M. Lacasta

LONG TERM BEHAVIOR OF A TWO-WAY SPANNING TIMBER CONCRETE SLAB WITH STEEL TUBE CONNECTOR 571
Julian Brogli, Andrea Frangi

INVESTIGATING THE EFFECTS OF MOISTURE INGRESS ON THE PERFORMANCE AND SERVICE LIFE OF MASS TIMBER PANELS IN AUSTRALIAN CLIMATES-CHARACTERIZATION OUTCOMES 578
Maryam Shirmohammadi

EXPERIMENTAL INVESTIGATION ON LONG-TERM BEHAVIOR OF TIMBER-TO-TIMBER SHEAR CONNECTIONS MADE BY INCLINED SELF-TAPPING SCREWS 586
Alessandra Gubana, Massimo Melotto, Luca De Cillia, Alessandro Mazelli

PATINA AND ITS FORMATION ON A WOODEN CHURCH FLOOR – CASE PETÄJÄVESI OLD CHURCH AND VIIKKI CHURCH IN HELSINKI 593
Jonna Silvo

1.4. ENGINEERED TIMBER PRODUCTS AND PRODUCTION

ON THE UTILISATION OF THE WORKSPACE OF AN INDUSTRIAL ROBOT FOR MILLING STRUCTURAL TIMBER COMPONENTS – EXPERIMENTAL TRIALS WITH DIFFERENT ARM POSITIONS AND EVALUATION OF MACHINING QUALITY 599
Marc Pantscharowitsch, Finn Linzer, Hans-Berndt Neuner, Benjamin Kromoser

SHEAR THROUGH THE THICKNESS PROPERTY OF SCREW LAMINATED CROSS LAMINATED TIMBER 609
Shiro Nakajima

BIRCH FOR ENGINEERED TIMBER PRODUCTS: PART II 615
David Obernosterer, Georg Jeitler, Gerhard Schickhofer

INVESTIGATIONS ON MULTIFUNCTIONAL TIMBER ELEMENTS IMPREGNATED WITH PARAFFINIC PHASE CHANGE MATERIALS 621
Jens Hartig, Peer Haller

ADDITIVE MANUFACTURING OF WOOD COMPOSITE PARTS BY INDIVIDUAL LAYER FABRICATION – THE PRODUCTION PROCESS AND RESPECTIVE MACHINERY 629
Birger Buschmann, Daniel Talke, Klaudius Henke, Carsten Asshoff, Frauke Bunzel, Bettina Saile

ELASTOMECHANICAL PROPERTIES OF GLUED LAMINATED TIMBER MADE OF STRENGTH GRADED OIL PALM LUMBER 638
Katja Fruehwald-Koenig

FLEXURAL PROPERTIES OF OIL PALM WOOD BASED GLUE LAMINATED TIMBER USING FINITE ELEMENT METHOD 647
Martin Hackel

BENDING PROPERTIES OF 100 NARROW CLT-BASED BOARDS – STATIC AND DYNAMIC TESTS AND DIC ANALYSIS 657
Mikael Perstorper, Johan Vessby, Emil Lockner

DENSIFIED WOODEN NAIL FOR ADHESIVE- AND METAL- FREE TIMBER ASSEMBLES 666
Lei Han, Dusan Pauliny, Anna Sandak, Mariapaola Riggio, Andreja Kutnar, Dick Sandberg, Jakub Sandak

EXPERIMENTAL INVESTIGATION OF FINGER JOINTS UNDER TENSILE AND BENDING LOADS 671
Farid Vafadar, Steven Collins, Gerhard Fink

POTENTIAL OF REUSING SALVAGED WOODEN MATERIALS IN FABRICATING DOWEL LAMINATED STRUCTURAL ELEMENTS WITH WOODEN CONNECTORS 677
Mohammad Derikvand, Gerhard Fink

STRUCTURAL SAWN WOOD PRODUCTION IN THE CHILEAN SAWMILL INDUSTRY, DATA ANALYSIS FROM SURVEYS CARRIED OUT FOR 4 YEARS 683
Pamela Poblete, Janina Gysling, Carlos Kahler, Wilson Mejías, Daniel Soto, Verónica Álvarez, Evaristo Pardo

ROTATIONAL STIFFNESS OF NEWLY DEVELOPED LVL-BASED COLUMN-HEAD REINFORCEMENT FOR POINT-SUPPORTED SLAB-COLUMN BUILDING SYSTEMS 688
Cristóbal Tapia, Felix Amtsberg, Aaron Münzer, Simon Aicher, Achim Menges

MECHANICAL PROPERTIES TESTS OF DELIGNIFIED AND DENSIFIED WOOD 698
Jörg Wehsener, Martina Bremer, Peer Haller

DEVELOPMENT OF CONSTRUCTION METHODS WITH NATURALLY GROWN TIMBER AND BENDING-RESISTANT JOINTS 705
Kevin Moreno Gata, Alex Seiter, Denis Grizmann, Martin Trautz

1.5. QUALITY CONTROL OF TIMBER-BASED MATERIALS

GREEN OAK BUILDING WITH HIGH-TECH METHODS, PART 1: CHARACTERISATION OF THE RAW MATERIAL 711
Nicolas Hofmann, Franka Brüchert, Udo H. Sauter, Kay-Uwe Schober, Beate Hörnel-Metzger, Maximilian L. Müller

VARIATION IN MECHANICAL PROPERTIES WITHIN AND BETWEEN PLANTATION-GROWN GMELINA ARBOREA TREES 717
Stanley Emeka Iwuoha, Werner Seim

IN-GRADE CLT FROM UNGRADED PINUS RADIATA BOARDS 723
Paolo Lavisci, Marco Molinari, Michele Brunetti

COLLAGE QUALITY OF BRAZILIAN WOODS FOR USE IN GLUED LAMINATED TIMBER BEAMS 729
Julio Cesar Molina, Natália Andrade Bianchi, Felipe Dutra Lisboa, Nádia Barros Gomes

NON-PARAMETRIC LOWER CONFIDENCE BOUNDS FOR THE FIFTH PERCENTILE - EN 14358 IN COMPARISON TO A FULLY NON-PARAMETRIC APPROACH 735
Andreas Weidenhiller, Dan Ridley-Ellis, Andreas Neumüller

NEW CRITERIA FOR VISUAL STRENGTH GRADING OF SAWN TIMBER FROM BIRCH GROWN IN SWEDEN 740
Ulf Lemke, Marie Johansson, Rune Ziethén, Andreas Briggert

FIBRE-OPTIC MEASUREMENTS FOR MONITORING ADHESIVELY BONDED COMPOSITE BEAMS 750
Jens Frohnmüller, Werner Seim, Ann-Charlotte Spangenberg

ESTIMATION OF MOISTURE DISTRIBUTION IN SAWN TIMBER USING COMPUTED TOMOGRAPHY 759
Boris Poupet, José Couceiro, Sara Florisson, Lars Hansson, Dick Sandberg

PREDICTION OF DOUGLAS FIR SAWN TIMBER YIELD BASED ON LOG COMPUTED TOMOGRAPHY 766
Andreas Weidenhiller, Boris Sandor, Thomas Simlinger, Franka Brüchert, Johannes A. J. Huber

CONSIDERATIONS FOR GRADING SPECIES COMBINATIONS. THE EXAMPLE OF DOUGLAS FIR WITH LARCH IN IRELAND AND UK 773
David Gil-Moreno, Dan Ridley-Ellis, Annette M. Harte

CONSIDERATIONS FOR GRADING SPECIES COMBINATIONS. GENERAL REMARKS ON SCENARIOS AND REQUIREMENTS. 780
Dan Ridley-Ellis, David Gil-Moreno, Annette M. Harte

PREDICTION OF TIMBER TWISTING BASED ON MEASURED SPIRAL GRAIN OF SPRUCE TRUNKS AND LOGS 787
Michal Kloiber, Jirí Kunecký, Miroslav Kotmel

ULTRASONIC-BASED DEFECT IDENTIFICATION IN TIMBER USING UNIFORM MANIFOLD APPROXIMATION AND PROJECTION (UMAP) 794
Prashanth Gunasekaran, Mehrisadat Makki Alamdari, Hamid Valipour Goudarzi

2.1. SUSTAINABLE ENVIRONMENT AND USE OF WOOD

GLUED-IN HARDWOOD RODS USING BIO-SOURCED ADHESIVES — PART I: INVESTIGATIONS UNDER LABORATORY CONDITIONS 804
Jana Kolbe, Stephanie Koesling, Till Vallée, Nils Monard, Jona Haupt

GLUED-IN HARDWOOD RODS USING BIO-SOURCED ADHESIVES — PART II: INFLUENCE OF ENVIRONMENTAL CONDITIONS 812
Jona Haupt, Nils Monard, Till Vallée, Stephanie Koesling, Jana Kolbe

MATERIAL FLOW ANALYSIS AND CARBON FOOTPRINT OF FOREST RESOURCES IN JAPAN: A CASE STUDY ON BUILDING MATERIALS 819
Hongjun Wang, Atsushi Takano

GROUND IMPROVEMENT EFFECT OF TIMBER PILES BURIED IN SOFT CLAY GROUND 829
Tadashi Hara, Yoshitaka Kubojima, Hidao Kato, Satomi Sonoda

STUDY ON ENVIRONMENT DECOMPOSITION AND STRENGTH OF CLT WHEN TEMPORARILY USED ON CIVIL ENGINEERING 836
Naoya Iizawa, Kei-Ichi Imamoto, Chizuru Kiyohara, Hideyuki Nasu, Satoshi Onishi

DEVELOPMENT OF FUTURE-ORIENTED CONCEPTS FOR AGRICULTURAL CONSTRUCTION WITH WOOD 842
Carina Hartmann, Özlem Özdemir, Annette Hafner

BUILDING TOWARD ZERO EMBODIED CARBON 849
Richard Hough, Carsten Moeller

TRADE-OFFS IN EMBODIED CARBON AND ACOUSTIC INSULATION FOR MASS TIMBER FLOOR ASSEMBLIES 858
Samantha J. Leonard, Mohamad B. Eddin, Morgan K. Prichard, Jonathan M. Broyles, Nathan C. Brown, Sylvain Ménard

ECOLOGICAL PERFORMANCE AND RECYCLABILITY OF TIMBER-BASED CONSTRUCTIONS 868
Alireza Fadai, Daniel Stephan

EMBEDMENT STRENGTH OF RECOVERED SPRUCE AND OAK 875
Caitríona Uí Chúláin, David Gil-Moreno, Daniel F. Llana, Mitja Plos, Goran Turk, Paul Hogan, Annette M. Harte

PROPOSAL OF A METHOD FOR ESTIMATING THE RESIDUAL STRENGTH FROM THE DEPTH OF PILODYN PENETRATING FOR A CYLINDRICAL MEMBER 882
Makoto Imai, Hironobu Kobayashi, Tadashi Hara

BENDING CHARACTERISTICS OF CLT FROM RECOVERED SPRUCE 888
Caitríona Uí Chúláin, Daniel F. Llana, Paul Hogan, Patrick McGetrick, Annette M. Harte

COMPARISON OF ENERGY EFFICIENCY BETWEEN WOODEN-BASED HYBRID STRUCTURE SYSTEM AND RC STRUCTURE SYSTEM IN SUBTROPICAL AND TROPICAL AREA 895
Cheng-Chieh Hsu, Meng-Ting Tsai, Shao-Chi Wu

ENVIRONMENTAL PERFORMANCE OF NEXT-GENERATION TIMBER SCHOOLS FOR CLIMATE ACTION: A SIMULATION APPROACH 903
Ramit Debnath, Antiopi Koronaki, Dario Marino, Yiping Meng, Darshil U. Shah, Peter Hazzard, Simon Smith, Kirsten Haggart, Michael H. Ramage

DEVELOPMENT OF MATERIAL FOR CIVIL CONSTRUCTION WITH BABASSU PALM FIBERS 909
Antonio Da Silva, Francisco Lahr, Antonio Costa, Joaquim Costa

EXPLORING THE STRUCTURAL DESIGN, COST, AND DURABILITY OF MASS TIMBER NOISE BARRIER FOR HIGHWAY APPLICATIONS 914
Weichiang Pang, Michael Stoner, Harsh Bothra, Laura Redmond, Patricia Layton

CORROSION INHIBITOR POTENTIAL WITH BOLDO BRASILEIRO COMPARED TO COMMERCIAL INHIBITOR IN WOOD CONNECTIONS 920
Letícia Costa, Ana Farias, Antonio Da Silva, Francisco Lahr

2.2. SUSTAINABILITY AND LIFE CYCLE ASSESSMENT

REVIEW AND COMPARISON OF DIFFERENT TIMBER BUILDING PRODUCTS' EMBODIED EMISSIONS USING FREE DATABASES 927
Felipe Victorero, Daniela Mendez, Felipe Bascuñan, Waldo Bustamante

LIFE CYCLE ASSESSMENT ON DIFFERENT TIMBER BRIDGE TYPES: DECK BRIDGE, BLOCK GIRDER BRIDGE, TROUGH BRIDGE, PYLON BRIDGE..... 935
Özlem Özdemir, Annette Hafner

STRUCTURAL AND LIFE CYCLE ANALYSES FOR A TIMBER-CONCRETE HYBRID BUILDING..... 941
Xiaoyue Zhang, Wanru Huang, Mehdi Khajehpour, Mehrdad Asgari, Thomas Tannert

EVALUATION OF THE RECYCLABILITY OF WOODEN BEAM STRUCTURES 948
Zsofia Varga, Antonia Birkholz, Anna Wagner, Stefan Winter

SUSTAINABLE ASSESSMENT: A CONTRIBUTION TO IMPROVE THE RELIABILITY OF NDT ON OLD CHESTNUT PURLINS..... 957
Vittoria Borghese, Silvia Santini, Lorena Sguerri

COMPARATIVE LIFE CYCLE ASSESSMENT OF TIMBER-CONCRETE-COMPOSITE WALLS WITH CONCRETE AND CLT-WALL ELEMENTS 967
Anna Wagner, Klara Winter, Anna Nestmann, Stephan Ott, Stefan Winter, Oliver Fischer

GHGS EMISSIONS FROM SAWNWOOD PRODUCTS IN NORWAY– THE IMPORTANCE OF HARMONISED LCA METHODOLOGY IN ENVIRONMENTAL PRODUCT DECLARATIONS (EPDS) 976
Johann Kristian Næss, Ana Maria Santos Bouzada, Roja Modaresi

INFLUENCE OF DIFFERENT END-OF-LIFE CYCLE SCENARIOS ON THE ENVIRONMENTAL IMPACTS OF TIMBER-CONCRETE COMPOSITE FLOOR SYSTEMS 982
Hooman Eslami, Alireza Yaghma, Laddu Bhagya Jayasinghe, Daniele Waldmann

A STRUCTURAL-MEMBER LEVEL ASSESSMENT OF THE ENVIRONMENTAL IMPACT OF TIMBER, REINFORCED CONCRETE AND STEEL IN BUILDING CONSTRUCTION..... 989
Jae-Won Oh, Sung-Jun Pang, Kyung Sun Ahn, Jung-Kwon Oh

MEETING THE 2050 PARIS AGREEMENT TARGETS USING MASSIVE TIMBER IN SCHOOL BUILDINGS. 995
Efthymia R. Stæhr, Thomas K. Thiis, Arnkell J. Petersen, Leif D. Houck

HOLISTIC DESIGN OF TALLER TIMBER BUILDINGS – COST ACTION HELEN (CA20139) 1001
Gerhard Fink, Robert Jockwer, Iztok Šušteršic, Mislav Stepinac, Pedro Palma, Chiara Bedon, Daniele Casagrande, Steffen Franke, Giuseppe D'Arenzo, Daniel Brandon, Christian Viau

DESIGN AND CRADLE-TO-GRAVE LIFE-CYCLE ASSESSMENT: FULLSCALE SIX-STORY SHAKE-TABLE TEST BUILDING LATERAL SYSTEMS 1009
Steven Kontra, Andre R. Barbosa, Arijit Sinha, Gustavo A. Araujo Rodriguez, Patricio Uarac, Nathan C. Brown, Jace Furley, Tu X. Ho, Gustavo F. Orozco, Barbara G. Simpson, John W. Van De Lindt, Seyed Hossein Zargar

HYBRID STRUCTURES IN HIGH-RISE BUILDINGS: THE USE OF APPROPRIATE MATERIALS 1017
Guido Nieri, Carsten Hein, Stuart Smith

BENCHMARK LIFE-CYCLE AND CONSTRUCTABILITY ASSESSMENT OF COMPOSITE STEEL-TIMBER SYSTEMS 1027
Emma E. Rohde, David B. Roueche, Kadir C. Sener, Brian K. Via

2.3. ZERO EMISSION BUILDING TECHNOLOGIES

DEVELOPING AN APPLICATION FOR MASS PLYWOOD PANELS IN SEISMIC AND ENERGY WALL RETROFITS 1034
Mark Fretz, Jason Stenson, Gustavo Fernando O. Orozco, Payton Narancic, Flynn Casey, Dale Northcutt, Kevin Van Den Wymelenberg, Judith Sheine, Andre R. Barbosa

2.5. HUMAN PERCEPTION & HEALTH

EMISSION OF VOLATILE ORGANIC COMPOUNDS FROM WOOD MATERIALS AND IMPACT ON INDOOR AIR QUALITY 1044
Ingrid Bakke, Anders Nyrud, Roland Kallenborn, Lina Aarsbog

COMBINED EFFECTS OF VISUAL AND OLFACTORY STIMULATION BY INTRODUCING WOOD WHILE WORKING OR RESTING 1050
Takashi Shima, Katsuhiko Sakata, Motoki Yairi, Daisuke Fujii, Haruki Momose, Yuko Tsunetsugu

WOOD INTERIORS IN ARCHITECTURE: AN EYE-TRACKING STUDY 1056
Pasi Aalto, Martin Steinert

CROSS-LAMINATED PANELS WOOD PANELS IN A PATIENT ROOM AND STUDIES OF INTERIOR ENVIRONMENT 1062
Bror Sundkvist, Olena Myronycheva, Sarka Langer, Ingrid Liljelind, Bo Glas, Tomas Nord, Björn Nordin

CIRCULAR WOOD CONSTRUCTION – EXPECTATIONS, EXPERIENCES AND ACCEPTANCE AMONG USERS, ARCHITECTS AND INDUSTRY REPRESENTATIVES 1067
Kaja Heltorp, Ute Groba, Anders Q. Nyrud

2.7. BUILDING OPERATION & MAINTENANCE

FUNDAMENTAL STUDY ON REPAIR BY EPOXY RESIN MIXED WITH CELLULOSE FIBER TO RECOVER BENDING PERFORMANCE OF WOODEN PARTS 1075
Akiko Ohtsuka, Nozomi Satou, Naoyuko Itagaki, Run Minoura, Shinichi Terasaki

QUALITY ASSURANCE OF TIMBER STRUCTURES BY NEW MONITORING METHODS FOR THE MOISTURE CONTENT OF WOOD 1081
Bettina Franke, Steffen Franke, Marcus Schiere, Andreas Müller

CURRENT STATUS OF MAINTENANCE OF THATCHED ROOFS IN SHIKOKU 1088
Naoki Kakehashi, Miyako Kamatoko

3.1. CONNECTIONS

POSSIBILITIES TO PROMOTE CIRCULAR ECONOMY IN MID-RISE TIMBER CONSTRUCTION IN THE PROJECT PLANNING AND EARLY DESIGN PHASES 1095
Ninni Westerholm, Juha Franssila

EFFECT OF RESIN IMPREGNAITON INTO WOOD CELL ON LATERAL RESISTANCE OF SCREWED JOINT CONNECTING SOLID WOOD AND STEEL PLATE 1104
Keita Ogawa, Kenji Kobayashi, Satoshi Fukuta

STRUCTURAL PERFORMANCE OF GLULAM TIMBER-STEEL BRACE CONNECTIONS REINFORCED WITH SELF-TAPPING SCREWS.....1110
Thomas Breijinck, Joshua Woods, Colin Macdougall

PREDICTION OF WITHDRAWAL STIFFNESS OF SELF-TAPPING SCREWS 1117
Md Abdul Hamid Mirdad, Jan Niederwestberg, Arman Jucutan, Ying Hei Chui

RNN-BASED MONOTONIC LOADING BEHAVIOR PREDICTION OF CLT JOINTS.....1123
Yewei Ding, Haibei Xiong, Cheng Yuan, Lin Chen, Yurong Lu

CYCLIC BEHAVIOR OF MORTISE-TENON JOINTS REINFORCED BY SELF-TAPPING SCREW 1129
Tianxiao Yin, Chenyue Guo, Zhiqiang Wang, Wei Zheng, Jianhui Zhou, Meng Gong

SERVICEABILITY STIFFNESS OF TIMBER CONNECTIONS WITH DOWELS AND SLOTTED-IN STEEL PLATES.....1136
Kjell Arne Malo, Haris Stamatopoulos, Francesco Mirko Massaro, Saule Tulebekova

MOISTURE AND ASSEMBLY HISTORY EFFECTS ON EMBEDMENT PROPERTIES OF STEEL DOWELS IN SPRUCE AND BIRCH LOADED IN GRAIN DIRECTION 1146
Michael Schweigler, Romain Lemaître, Zijad Shehadeh, Thomas K. Bader

EXPERIMENTAL AND NUMERICAL ANALYSES OF A CONNECTION FOR CLT STRUCTURES 1154
Lars Blomqvist, Roberto Crocetti, August Claesson, Zakaria Ben Osmane, Rune Ziethén, Marie Johansson

ROBUSTNESS OF ADHESIVELY BONDED PANEL-TO-PANEL CONNECTIONS IN CLT FLOORS.....1160
Lei Zhang, Muster Marcel, Thomas Tannert, Hercend Mpidi Bita

EXPERIMENTAL INVESTIGATIONS ON THE STIFFNESS OF STEEL-TIMBER DOWEL-TYPE CONNECTIONS IN BEECH LVL 1168
Lea Buchholz, Ulrike Kuhlmann

SEISMIC PERFORMANCE OF BOLTED GLULAM TIMBER BRACE CONNECTIONS WITH INTERNAL STEEL PLATES 1176
Zoe Baird, Joshua Woods, Christian Viau, Ghasan Doudak

DEVELOPMENT OF A NOVEL JOINT SYSTEM FOR MID-TO-HIGHRISE CLT WALL BUILDINGS IN SEISMIC REGIONS 1183
Ahmad Ghazi Aljuhmani, Eito Atsuzawa, Arata Minegishi, Kazuki Tsuda, Yutaka Goto, Masaki Maeda

A NOVEL LIMITED-DAMAGE 3D-PRINTED INTERLOCKING INTERMODULE CONNECTION SYSTEM FOR CROSS LAMNINATED TIMBER (CLT) VOLUMETRIC STRUCTURES 1192
Zhengyao Li, Konstantinos Daniel Tsavdaridis

IMPACT OF MOISTURE CYCLING ON SCREW WITHDRAWAL CAPACITY OF TREATED AND UNTREATED RADIATA PINE 1200
Luis Yermán, Zidi Yan, Wen Feng, Lisa-Mareike Ottenhaus

ANALYSIS AND DESIGN ASPECTS OF MOMENT-RESISTING, BEAM-TO-COLUMN, TIMBER CONNECTIONS WITH INCLINED THREADED RODS: FROM FASTENER LEVEL TO CONSTRUCTION LEVEL 1206
Haris Stamatopoulos, Osama Abdelfattah Hegeir, Kjell Arne Malo

APPLICATION OF A TUBE CONNECTOR FOR CATENARY ACTION IN CLT FLOORS 1216
Johannes Huber, Yunbo Huang, Sivert Knutsen, Alicja Przystup, Thomas Tannert, Sven Berg

EXPERIMENTAL VALIDATION OF PROPOSED CAPACITY-BASED DESIGN APPROACHES FOR MULTI-PANEL CLT SHEARWALLS 1224
Mohammad Masroor, Ghasan Doudak, Daniele Casagrande

GLUED-IN ROD CLT CONNECTIONS WITH FLEXIBLE POLYMER ADHESIVE 1231
Boris Azinovic, Václav Sebera, Meta Kržan, Andreja Pondelak, Jaka Gašper Pecnik, Arkadiusz Kwiecien

EVALUATION OF BEARING STRENGTH PERFORMANCE OF STS CONNECTION ACCORDING TO BEARING SECTION ON LOADING DIRECTION 1238
Keonho Kim, In-Hwan Lee

INCLINED SCREW CONNECTIONS WITH INTERLAYERS: BEAM ON FOUNDATION NON-LINEAR MODELLING 1244
Yuri De Santis, Angelo Aloisio, Dag Pasquale Pasca, Igor Gavric, Iztok Šušteršic, Massimo Fragiacomo

A FRACTURE MECHANICAL AND ANISOTROPIC FEM MODEL OF THE “RECONWOOD JOINT” AND EXPERIMENTAL VERIFICATION 1252
Jesper Kierkegaard Hansen, Mads Friborg Nielsen, Søren Gustenhoff Hansen, Anja Kunic, Roberto Naboni

NUMERICAL AND EXPERIMENTAL STUDY OF GLULAM BEAMS JOINTED WITH SLOTTED-IN STEEL PLATE CONNECTION 1261
Sigurdur Ormarsson, Le Kuai, Musaab Ahmed Mahjoub, Simon Aicher

PERFORMANCE OF GLUED-IN RODS IN GLULAM AND MPP IN TENSION AND COMPRESSION 1269
Alexander Salenikovich, Étienne Lapointe, Bruno Zumbrunn-Maurer, Thomas Brotschi, Anthonie Kramer

QUASI-STATIC CYCLIC TESTS OF NOVEL HIGH-PERFORMANCE SHEAR-CONNECTORS FOR MASS-TIMBER PANELS 1275
Blériot Vincent Feujofack Kemda, Cristiano Loss

JOINT PERFORMANCE TESTING OF A CLAMPED JOINT FOR TIMBER STRUCTURES AND APPLICATION TO STRUCTURAL DESIGN 1283
Yoshisato Esaka, Tatsuki Ishizaki, Tsubasa Seguchi, Tokuma Azemi

EXPERIMENTAL STUDY ON CONTROL PARAMETERS FOR AUTOMATED APPLICATION AND IN-SITU PERFORMANCE ASSESSMENT OF JOINTS WITH SELF-TAPPING TIMBER SCREWS 1289
Alexandra Eckert, Reinhard Brandner, David Glasner

INFLUENCE OF LOW CURING TEMPERATURES ON THE STRENGTH DEVELOPMENT OF END-GRAIN BONDED TIMBER 1299
Dio Lins, Steffen Franke

EXPERIMENTAL CHARACTERIZATION OF THE MULTI-DIRECTIONAL BEHAVIOUR OF ANGLE BRACKETS AND HOLD-DOWNS 1305
Riccardo Fanti, Andrea Polastri, Daniele Casagrande, Ernesto Callegari, Alvise Ramazzini, Luca Sestigiani, Peter Lang

ASSESSMENT OF COMBINED EFFECTS OF AXIAL AND LATERAL LOADING OF GLUED-IN ROD CONNECTIONS IN LVL 1312
Daniel Fawcett, Eleni Toumpanaki

SOLUTIONS FOR EDGE CONNECTIONS TO BUILD TWO-WAY SPANNING CROSS LAMINATED TIMBER SLABS 1322
Thomas Stieb, Bernhard Maurer, Maximilian Bestler, Philipp Dietsch, Roland Maderebner

EXPERIMENTAL AND ANALYTICAL ANALYSIS OF TIMBER CONNECTIONS WITH INTERPOSED ACOUSTIC RESILIENT STRIP 1330
Luca Pozza, Giulia D'Amato, Paola Brugnara, Ernesto Callegari, Luca Sestigiani

ON-SITE GLUING AND WEATHER EFFECTS ON TALL WOODEN WIND TURBINE TOWERS 1336
Viktor Norbäck, Pierre Landel, Erik Dölerud, Anders Wickström

INFLUENCE OF DENSITY AND PREDRILL IN THE EMBEDMENT STRENGTH OF TWO HARDWOOD SPECIES 1342
Gonzalo Cabrera, Gonzalo Moltini, Vanesa Baño

STRUCTURAL PERFORMANCE OF HIGH CAPACITY GLULAM MOMENT CONNECTIONS 1350
Ryan Guay, Christopher Pitt, Reid B. Zimmerman, Ignace Mugabo, Peter Dusicka

THE IMPACTS OF SCREW TIP, INCLINATION ANGLES AND NUMBER OF PENETRATION LAYERS ON SCREW WITHDRAWAL CAPACITY IN AUSTRALIAN MACHINE GRADED PINE 1358
Zidi Yan, Lisa-Mareike Ottenhaus, Jingyuan Lin, Robert Jockwer, Andreas Ringhofer

DESIGNING AND TESTING OF A WOOD-ONLY TIMBER FRAME CONNECTION INSPIRED BY THE GROWTH FORMATION OF TREES' STEM-BRANCH JUNCTION 1365
Firas Hawasly, Naoyuki Matsumoto, Mikio Koshihara, Koji Adachi

EXPERIMENTAL STUDY OF A TYPICAL EXTERNAL WALL-FLOOR-WALL CONNECTION IN A CLT PLATFORM TYPE CONSTRUCTION 1375
Luka Vojnovic, Eleni Toumpanaki, James Norman

AN EXPERIMENTAL STUDY ON SHEAR PERFORMANCE OF CLT DOWEL JOINTS WITH SHEAR PLATES 1383
Tsuyoshi Akutagawa, Hiroya Hanaoka, Masamichi Sasatani

EXPERIMENTAL AND NUMERICAL INVESTIGATION OF CROSSLAMINATED TIMBER JOINTS WITH MULTIPLE GLUED-IN RODS 1389
Younes Shirmohammadli, Ashkan Hashemi, Reza Masoudnia, Pierre Quenneville

BEAM-ON-ELASTIC FOUNDATION MODEL OF MECHANICAL PROPERTIES OF RING NAILS AND HEAVY-DUTY SCREWS 1397
Petr Sejkot, Asif Iqbal

DUCTILITY OF WOOD CONNECTIONS WITH SDS SCREWS OR RING NAILS AND ANGLE BRACKETS 1403
Petr Sejkot, Asif Iqbal

EXPERIMENTAL INVESTIGATIONS ON TIMBER STEP JOINTS DETERMINING THE INFLUENCE OF INTENTIONALLY PLACED INACCURACIES ON THE LOAD-BEARING BEHAVIOUR 1409
Matthias Braun, Benjamin Kromoser

PREFABRICATED FOUNDATION SYSTEMS FOR TIMBER BUILDINGS 1416
Davide Canetti, Francesca Paoloni, Riccardo Fanti, Alessandro Setti, Andrea Polastri, Fabrizio Tamburini

UPPER AND LOWER RESISTANCE OF SMALL STEEL-TO-TIMBER CONNECTIONS AND COMPARAISION WITH REVISED EYM 1422
Jørgen Munch-Andersen

STRENGTH CHARACTERIZATION OF OVERLAPPED TIMBER SCREWS 1431
Luca Marchi, Davide Trutalli, Luca Pozza, Roberto Scotta

MEASUREMENT OF AXIAL FORCE OF SCREWS FOR SPLIT REINFORCEMENT AT TIMBER-STEEL-TIMBER DOWEL JOINT 1437
Kenji Kobayashi, Keita Ogawa

RIGID GLULAM JOINTS TO CONCRETE ABUTMENTS WITH GLUED-IN STEEL ROD 1443
Kai Simon, Simon Aicher

GLULAM FRAMES ADHESIVELY BONDED BY MEANS OF BIRCH PLYWOOD PLATES: PRELIMINARY INVESTIGATIONS 1453
Tianxiang Wang, Yue Wang, Roberto Crocetti, Magnus Wålinder, Pontus Persson, Patrik Hedlund

STRUCTURAL CHARACTERISTICS AND DEFORMATION BEHAVIOUR OF AN ADVANCED CARPENTRY CONNECTION IN TIMBER CONSTRUCTION 1462
Katrin Vögele, Moritz Tronnier, Yannick Plüss, Mike Sieder

REPAIR CONNECTION WITH WOODEN WEDGED DOWELS: AXIAL TENSILE AND SHEAR VERIFICATIONS 1472
Elena Perria, Mike Sieder, Svenja Siegert, Cordula Reulecke

PERFORMANCE VERIFICATION AND TRIAL DESIGN FOR HIGH-RISE TIMBER FRAME BUILDINGS WITH BUCKLING-RESTRAINED BRACES - PART.1 CONNECTION AND FRAME TESTING 1481
Kazuki Tachibana, Hiroki Nakashima, Taisuke Nagashima, Ryota Minami, Toshio Maegawa, Nobuhiko Akiyama, Yoshihiro Yamazaki, Takahiro Tsuchimoto

HASLETRE: NORWAY'S FIRST TIMBER OFFICE BUILDING DESIGNED FOR DISASSEMBLY AND REUSE 1491
Ona Flindall, Jørgen Tycho, Moritz Groba

TOWARDS ADAPTABILITY AND CIRCULARITY OF TIMBER BUILDINGS 1497
Robert Jockwer, Vera Öberg, Lisa-Mareike Ottenhaus, Paola Leardini, Yutaka Goto

INVESTIGATION OF STRUCTURAL BEHAVIOR OF WOODEN TRADITIONAL JOINTS VIA FINITE ELEMENT ANALYSIS 1506
Hafshah Salamah, Seung Heon Lee, Thomas Kang

BONDED-IN RODS IN BEECH GLULAM – EFFICIENCY OF A RECESS IN THE BONDLINE 1512
Steffen Franke, Bettina Franke, Alexander Salenikovich

3.2. FIRE ENGINEERING

USING X-RAY COMPUTED TOMOGRAPHY TO MEASURE FIRE DEGRADATION OF A TIMBER CONNECTION 1519
Quentin Rodrigues, Johannes Huber, Lars Hansson, Rhoda Afriyie Mensah, Rostand Moutou Pitti

ANALYTICAL MODELLING OF POST-TENSIONED TIMBER BEAM-COLUMN CONNECTIONS IN FIRE 1526
Paul D. Horne, Anthony K. Abu, Alessandro G. Palermo

MECHANICAL PERFORMANCE AT ELEVATED TEMPERATURES OF NON-METALLIC DOWELS FOR MASS TIMBER STRUCTURES 1536
Alexandra Boloux, Rafik Nizarali, Luke Bisby

FIRE PERFORMANCE OF PENETRATIONS IN GLULAM BEAMS: A PRELIMINARY STUDY 1545
Laura Hasburgh, Keith Bourne, David Barber

CALCULATION METHOD OF COLLAPSE TIME OF WOOD MEMBERS EXPOSED TO FIRE HEATING WITH HEAT AND WATER TRANSFER ANALYSIS: INFLUENCE OF INITIAL MOISTURE CONTENT ON CHARRING RATE AND MECHANICAL PROPERTIES OF REMAINING SECTION OF WOOD MEMBERS 1551
Tatsuro Suzuki, Yuji Hasemi

HEAT DELAMINATION IN CROSS LAMINATED TIMBER: INTERMEDIATE SCALE TEST BASED UPON THE NORTH AMERICAN STANDARDS 1559
Samuel L. Zelinka, Keith J. Bourne, Laura E. Hasburgh, Kara Yedinak

A NEW METHOD FOR MODELLING TEMPERATURE WITHIN STEEL BAR - TIMBER COMPOSITE BEAM USING DATA BY BURNING TEST 1566
Shizuka Matsushita, Shinichi Shioya

TRAVELLING FIRES IN COMPARTMENTS WITH EXPOSED CROSS-LAMINATED TIMBER SURFACES 1576
Andreas Sæter Bøe, Kathinka Leikanger Friquin

CHARACTERIZING THE FIRE PERFORMANCE OF ADHESIVES USED IN GLUED-IN RODS CONNECTIONS 1583
Diego Flores, Christian Dagenais, Pierre Blanchet

NUMERICAL MODELLING OF CONTEMPORARY MASS TIMBER CONNECTIONS IN FIRE 1592
Bronwyn Chorlton, Mathieu Létourneau-Gagnon, Christian Dagenais, Marc-André Langevin

BURNING TEST OF STEEL BAR - TIMBER COMPOSITE BEAM 1602
Shizuka Matsushita, Shinichi Shioya

ADVANCED FIRE MODELLING IN SUPPORT OF PERFORMANCE-BASED FIRE DESIGN OF TIMBER BUILDINGS 1610
Christian Dagenais, Zhiyong Chen

EFFECT OF THE SACRIFICIAL LAYER THICKNESS AND THE BARRIER LAYER TYPE ON SELF-EXTINGUISHING FOR WOODEN FIREPROOF-STRUCTURAL ELEMENTS..... 1620
Tomoyo Hokibara, Yuji Hasemi, Daisuke Kamikawa, Tsutomu Nagaoka

FIRE TESTING EXTERIOR CROSS-LAMINATED TIMBER WALLS TO NFPA 285 1627
David Barber, Hans-Erik Blomgren

FIRE SAFETY OF MID-RISE BUILDINGS WITH LIGHT TIMBER STRUCTURES – STUDIES OF THE FIRE RESISTANCE OF A NOVEL CONSTRUCTION SYSTEM..... 1637
Kathinka Leikanger Friquin, Johan Kr. Møller

EXPLORING THE INFLUENCE OF HEATING CONDITIONS IN THE CHARRING PROFILE OF BARE TIMBER AND TIMBER PROTECTED WITH A THIN INTUMESCENT COATING..... 1644
Stavros Spyridakis, Jeronimo Carrascal, Felix Wiesner, David Barber, Cristian Maluk

MEASUREMENT OF DIRECTIONAL CHARACTERISTICS OF MOISTURE TRANSPORTATION IN WOOD UNDER HEATING 1653
Hirokatsu Kimura, Tomoyo Hokibara, Yuji Hasemi, Soma Suzuki, Tatsuro Suzuki, Ryo Takase

FIRE SAFETY ENGINEERING OF BUILDINGS WITH VISIBLE TIMBER CONSTRUCTIONS..... 1660
Leif Tore Isaksen, Martin Hagen

OBSERVATIONS OF SMOULDERING FIRE IN A LARGE TIMBER COMPARTMENT..... 1667
Harry Mitchell, Rikesh Amin, Panagiotis Kotsovinos, Mohammad Heidari, Daniel Thomson, David Barber, Guillermo Rein

EXPERIMENTAL INVESTIGATION OF THE RELATIONSHIP BETWEEN TIMBER SPECIES AND SMOULDERING 1673
Wenxuan Wu, Luis Yermán, Juan P. Hidalgo, Jeffrey Morrell, Felix Wiesner

PREDICTING THE EFFECTIVE CHAR DEPTH IN TIMBER ELEMENTS EXPOSED TO NATURAL FIRES, INCLUDING THE COOLING PHASE..... 1681
Andrea Lucherini, Daniela Šejnová Pitelková, Vladimír Mózer

EXPERIMENTAL AND FINITE ELEMENT ANALYSIS OF IRISH SITKA SPRUCE CLT WALL PANELS UNDER EXPOSURE TO STANDARD FIRE CONDITIONS..... 1691
Muhammad Yasir, Conan O'Ceallaigh, Kieran Ruane, Andrew Macilwraith

A DESIGN APPROACH TO EXTERNAL FIRE SPREAD FROM BUILDINGS WITH EXPOSED MASS TIMBER 1701
Adam Glew, Rory Turnbull, Frederik Møller Poulsen, Eirik Christensen, Panagiotis Kotsovinos, Eoin O'Loughlin, David Barber, Judith Schulz

NUMERICAL ANALYSIS ON THE FLEXURAL PERFORMANCE OF COMPOSITE STEEL-TIMBER BEAMS UNDER FIRE CONDITIONS 1712
Zhiyuan Liu, Binsheng Zhang, Huijuan Jia, Tony Kilpatrick

FIRE-PROTECTED TIMBER ELEMENTS OF CONSTRUCTION – RESPONSE DURING FIRE DECAY AND COOLING PHASE 1721
Paul England, Boris Iskra

NUMERICAL SIMULATION OF FIRES WITH EXPOSED TIMBER 1728
Sabrina Spörri, Chamith Karannagodage, Joachim Schmid, Andrea Frangi

EXPLICIT FIRE SAFETY FOR MODERN MASS TIMBER STRUCTURES – FROM THEORY TO PRACTICE 1738
Laura Schmidt, Ryan Hilditch, Adam Ervine, Joshua Madden

FIRE CHARACTERISTICS OF A COMPARTMENT WITH EXPOSED CLT WALLS: AN EXPERIMENTAL INVESTIGATION USING THE STANDARD ISO 834 CURVE 1748
Andrianos E. Koklas, Dionysios Kolaitis, Maria A. Founti

FLAME SPREAD CHARACTERISTICS IN LARGE COMPARTMENTS WITH AN EXPOSED TIMBER CEILING 1758
Panagiotis Kotsovinos, Eirik G. Christensen, Harry Mitchell, Rikesh Amin, Mohammad Heidari, Guillermo Rein, David Barber, Judith Schulz

ACCOUNTING FOR POST-PEAK COMPARTMENT TEMPERATURE THERMAL DEGRADATION OF MASS TIMBER 1768
David Barber, Eirik Christensen, Panos Kotsovinos, Mohammad Heidari, Judith Schulz

PROTECTION AND THERMAL EXPOSURE OF CLT CEILING AND FLOOR SURFACES 1778
Eirik G. Christensen, Benjamin Khoo, Panagiotis Kotsovinos, David Barber, Judith Schulz

COMPARATIVE PERFORMANCE OF PROTECTIVE COATINGS FOR MASS TIMBER STRUCTURES 1788
Lorna Johnson, David Morrisset, Antonela Colic, Luke Bisby

FIRE DESIGN OF GLULAM CONNECTIONS WITH TIMBER-TO-TIMBER BEARING INTERFACES 1798
Hans-Erik Blomgren, David Barber, Graham Montgomery

FIRE RESISTANCE TESTING OF CLT-CONCRETE COMPOSITE FLOOR SLABS WITH STRIP NOTCH SHEAR CONNECTIONS 1807
Javad Tashakori, Sam Salem

FIRE RESISTANCE TESTING OF CLT-CONCRETE COMPOSITE FLOOR SLABS UTILIZING GLUED-IN STEEL PLATES AS SHEAR CONNECTORS 1814
Adam Petrycki, Sam Salem

FIRE RESISTANCE TESTING OF CLT-CONCRETE COMPOSITE FLOOR SLABS UTILIZING SELF-TAPPING SCREWS AS SHEAR CONNECTORS 1821
Sarah Barclay, Sam Salem

IMPLICATIONS OF A DOWN-STAND BEAM ON THE CEILING FLAME EXTENSION CHARACTERISTICS IN A LARGE-SCALE CLT ENCLOSURE FIRE EXPERIMENT 1831
Danny Hopkin, Michael Spearpoint, Renaud Blondeau, Tim Sleik, Harald Krenn, Gordian Stapf, Wojciech Wegrzynski

PERFORMANCE OF PASSIVE PROTECTION OF CROSS LAMINATED TIMBER DURING STANDARD FURNACE TESTS AND NATURAL FIRES 1839
Siyimane Mohaine, Antonela Colic, David Morrisset, Jean-Christophe Mindeguia, Jean-Marc Franssen, Jochen Zehfuss, Robert McNamee, Luke Bisby, Fabienne Robert

NATURAL FIRE TESTS ON GLT COLUMNS INCLUDING THE COOLING DOWN PHASE 1848
Fabienne Robert, Jean-Marc Franssen, Jochen Zehfuß, Sven Brunkhorst, Patrick Bamonte, Silvio Renard, Robert McNamee, Thomas Gernay

3.3. VIBRATIONS & ACOUSTICS

FULL SCALE VIBRATION TESTS ON A LONG SPAN TIMBER FLOOR 1855
Patricia Hamm, Valentin Knöpfle, Johannes Ruf, Philipp Bacher, Tobias Götz

ACOUSTIC SENSITIVITY ANALYSIS AND MODELING OF SOUND INSULATION PERFORMANCE OF LIGHTWEIGHT WOODEN FACADE STRUCTURES 1863
Mohamad Bader Eddin, Sylvain Menard, Delphine Bard, Jean-Luc Kouyoumji

DESIGN OF LONG-SPAN LIGHTWEIGHT TIMBER FLOORS SUBJECT TO WALKING EXCITATIONS: A CASE STUDY 1873
Hassan Karampour, Farid Piran, Adam Faircloth, Chandan Kumar, David Zhang, Benoit P. Gilbert, Hong Guan, Lin Hu, Ying Hei Chui, Wen-Shao Chang

EXPERIMENTAL STUDY ON THE VIBRATION CHARACTERISTICS OF A PREFABRICATED CROSS-LAMINATED TIMBER-STEEL COMPOSITE FLOOR 1880
David Owolabi, Cristiano Loss

EXPERIMENTAL INVESTIGATIONS ON VIBRATION PERFORMANCE OF TIMBER-CONCRETE COMPOSITE BEAMS USING LIGHTWEIGHT AGGREGATE CONCRETE 1888
Bo Wen, Benkai Shi, Haotian Tao, Huifeng Yang, Bowen Huang

DEVELOPMENT OF A STAND-ALONE VIBRATION MEASUREMENT SYSTEM FOR BRIDGE MONITORING 1894
Dio Lins, Steffen Franke, Roger Weber, Bettina Franke, Joel Karolin

ACTIVE MASS DAMPERS FOR TIMBER FLOORS 1900
Thomas Hillberger, Thomas Furtmüller, Philipp Dietsch, Roland Maderebner

FIELD MEASUREMENT OF VIBRATION LEVEL DIFFERENCE ACROSS VERTICAL JUNCTIONS IN A TIMBER FRAME BUILDING 1908
Simone Conta, Anders Homb

CHARACTERISATION OF RESILIENT INTERLAYERS 1914
Paola Brugnara, Alice Speranza, Luca Barbaresi, Luca Sestigiani

VIBRATION SERVICEABILITY PERFORMANCE OF MASS TIMBER FLOORS UNDER VARIOUS SUPPORT CONDITIONS 1921
Chenyue Guo, Jianhui Zhou

DYNAMIC CHARACTERISTICS AND DYNAMIC RESPONSE OF TIMBER FOOTBRIDGES TO DYNAMIC HUMAN ACTIVITIES 1930
Marek Pantak, Whokko Schirén, Carl Larsson, Michael Dorn

A COMPARATIVE STUDY OF DESIGN STANDARDS FOR ASSESSMENT OF LONG-SPAN STEEL-TIMBER COMPOSITE FLOORS UNDER HUMAN-INDUCED VIBRATION 1936
Sardar Malek, Najmeh Cheraghi-Shirazi, Keith Crews, Roger Parra, Ariel Creagh, Parham Khoshkbari

ASSESSING THE EFFECTS OF BOUNDARY CONDITIONS ON THE VIBRATIONAL COMFORT OF ON-SITE TIMBER-CONCRETE COMPOSITE FLOORS 1943
Francesca Lanata, Clement Boudaud

LOCAL DAMAGE ASSESSMENT STRATEGY OF A TWO-STORY CLT WALL THROUGH VIBRATION-BASED NON-DESTRUCTIVE TECHNIQUES 1953
Alexander Opazo-Vega, Franco Benedetti, Alan Jara-Cisterna, Peter Dechent

PREDICTION OF THE ACOUSTIC INSULATION OF A PREFABRICATED WOODEN-BASED SYSTEM FOR COLLECTIVE BUILDINGS 1960
Marina Tenório, Sandra M. Silva, Jorge M. Branco

IMPACT SOUND INSULATION PERFORMANCE OF RAISED DISCRETE FLOATING FLOOR ASSEMBLIES ON MASS TIMBER SLABS 1968
Jianhui Zhou, Zijian Zhao, Chenyue Guo

SOUND INSULATION IN CROSS LAMINATED TIMBER BUILDINGS AND THE EFFECT OF JUNCTIONS AND FASTENERS 1975
Eli Toftemo, Anders Løvstad

INFLUENCE OF MECHANICAL FASTENER SPACING ON ACOUSTIC PERFORMANCE IN TIMBER COMPOSITE PANELS 1983
Aedan Callaghan, Wilson Byrick

3.4. CYCLIC LOADING, EARTHQUAKES & FATIGUE

PLASTIC DEFORMATION CONTRIBUTIONS OF CLT AND LTF SHEAR WALLS: DEVELOPMENT OF AN ANALYTICAL CAPACITY MODEL 1988
Angelo Aloisio, Francesco Boggian, Massimo Fragiacomo, Roberto Tomasi

ASEISMIC DESIGN LEVEL USING RESPONSE SPECTRUM FOR WOODEN HOUSES 1994
Koji Yamada

MASS TIMBER BRACED FRAMES WITH MASS TIMBER BUCKLING RESTRAINED BRACES 2000
Emily Wiliamson, Chris Pantelides, Hans-Erik Blomgren, Douglas Rammer

EFFECT OF SMALL DEFORMATION DUE TO MODERATE EARTHQUAKES ON THE SHEAR PERFORMANCE OF SHEAR RESISTING WALL 2008
Ryo Inoue, Takuro Mori, Shinya Matsumoto

EXPERIMENTAL TESTING OF HIGH-CAPACITY SINGLE AND COUPLED CLT SHEAR WALL SYSTEMS 2014
Benjamin Moerman, Minghao Li

EXPERIMENTAL TESTING OF MIXED ANGLE SCREWED HOLD-DOWN CONNECTIONS FOR CLT SHEAR WALLS 2020
Thomas Wright, Minghao Li

DYNAMIC PERFORMANCE OF A FULL-SCALE WOOD FRAME SUBJECTED TO CYCLIC LOAD TESTING 2030
Félix Bouffard, Jean Proulx

EXPERIMENTAL PARAMETER STUDY ON CLT SHEAR WALLS WITH HIGH-PERFORMANCE SELF-TAPPING SCREW CONNECTIONS 2040
Yuxin Pan, Thomas Teflissi, Thomas Tannert

HORIZONTAL-LOADING TEST OF STEEL BAR-TIMBER COMPOSITE COLUMNS FOR LOW-RISE BUILDING 2046
Yuuto Shimoirisa, Takahiro Iju, Takao Ohta, Kazuya Mori, Shinichi Shioya

EVALUATION OF VIBRATION PROPERTY OF HIGH-DAMPING TWO-STORY TIMBER STRUCTURE BASED ON RESONANCE CURVE 2056
Yuji Miyazu

YIELD MECHANISM OF PERFORATED PLATE CONNECTIONS FOR MASS TIMBER SYSTEMS 2063
Hossein Daneshvar, Thomas Tannert, Ying Hei Chui, Carla Dickof

EXPERIMENTAL CHARACTERISATION OF GLULAM SHEAR WALLS UNDER LATERAL CYCLIC LOADING 2070
Giuseppe D'Arenzo, Werner Seim

CYCLIC LOAD TESTS AND NUMERICAL ANALYSIS OF CLT SHEAR WALLS WITH GIR JOINTS 2077
Shuhei Uesugi, Daisuke Kadono, Katsuhide Murakami, Masahide Murakami

FULL-SCALE 3-D SHAKE TABLE TEST OF A TEN-STORY MASS TIMBER BUILDING 2084
Shiling Pei, John W Van De Lindt, Jeffrey Berman, Keri Ryan, James D. Dolan, Steve Pryor, Sarah Wichman, Aleesha Busch, Reid Zimmerman

CONSTRUCTIVE REHABILITATION OF THE FLOOR STRUCTURES OF ZAGREB'S DOWNTOWN BUILT IN THE FIRST HALF OF THE 20TH CENTURY 2090
Dean Cizmar, Krunoslav Pavkovic, Marija Babic Toncic, Ivana Iljkic

EXPERIMENTAL RESEARCH ON THE SEISMIC PERFORMANCE OF WATTLE AND DAUB INFILLED CHUAN-DOU TYPE TIMBER FRAMES 2098
Rui Xu, Yunyang Qi, Hao Huang

EVALUATION OF SEISMIC PERFORMANCE OF WOODEN HOUSES WITH SLIDING BASE BY FULL-SCALE SHAKING TABLE TEST 2104
Ai Tomita, Yuji Miyazu, Takehiro Wakita, Takaki Tojo, Takashi Aoki, Masayuki Nagano

CYCLIC TESTS OF INTERLOCKING CROSS LAMINATED TIMBER SHEAR WALLS 2111
Wyatt Payne, Alex Winward, Johnn Judd

FATIGUE RESISTANCE OF ADHESIVE BONDED CONNECTIONS WITH AND WITHOUT INTERNAL STEEL PLATES IN LARGE TIMBER STRUCTURES 2118
Robert Jockwer, Pierre Landel, Viktor Norbäck, Rune Ziethén, Erik Dölerud, Leo Anderson Naveda, Carl-Johan Åkerström

TESTING OF STRONG MULTI-LAYERED WOOD FRAME SHEAR WALLS WITH NON-STRUCTURAL LAYERS 2125
Diego Valdivieso, Diego Lopez-Garcia, Jairo Montaño, Pablo Guindos

TESTING THE INFLUENCE OF 3D COUPLING EFFECTS ON THE LATERAL RESPONSE OF NON-PLANAR T-SHAPE WOOD FRAME SHEAR WALLS 2134
Diego Valdivieso, Diego Lopez-Garcia, José Luis Almazán, Jairo Montaño, Pablo Guindos

DATA-DRIVEN APPROACH FOR ASSESSMENT OF SEISMIC DAMAGE IN WOOD BUILDINGS 2143
Sifat Muin, Asif Iqbal, John W. Van De Lindt

EFFECT OF SMALL OPENINGS ON SHEAR CAPACITY OF PLYWOOD SHEATHED SHEAR WALLS 2150
Yuta Sakai, Kenji Aoki

CYCLIC TESTING AND NUMERICAL MODELING OF A THREE-STORY MASS-TIMBER BUILDING WITH A PIVOTING MASS PLY PANEL SPINE AND BUCKLING-RESTRAINED ENERGY DISSIPATORS 2156
Gustavo Adolfo Araujo Rodriguez, Barbara G. Simpson, Tu X. Ho, Gustavo F. Orozco O., Andre R. Barbosa, Arijit Sinha

HYSTERESIS - A PYTHON LIBRARY FOR ANALYSING STRUCTURAL DATA 2166
Christian Slotboom

MONOTONIC TESTS ON BEAM-TO-COLUMN JOINT WITH STEEL LINK FOR TIMBER SEISMIC RESISTANT STRUCTURES 2173
Giacomo Iovane, Leonardo Rodrigues, Jorge Branco, Beatrice Faggiano

MODELLING SEISMIC ISOLATION BEARING FOR WOOD BUILDINGS 2179
Asif Iqbal, Angelo Aloisio, Massimo Fragiacomo

EXPERIMENTAL MONOTONIC AND CYCLIC TESTING ON GLULAM BEAM-TO-COLUMN CONNECTIONS 2185
Erica Fischer, Haley Madland, Sujit Bhandari, Arijit Sinha

SEISMIC CONNECTIONS FOR CLT STRUCTURES WITH TUBULAR ELEMENTS AND UNCOUPLED TENSION-SHEAR INTERACTION 2194
Luca Marchi, Davide Trutalli, Luca Pozza, Roberto Scotta

VARIABILITY OF THE CROSS-LAMINATED TIMBER (CLT) SINGLE-PANEL SHEAR WALLS' RESPONSE UNDER IN-PLANE LATERAL LOADS 2200
Vincenzo Rinaldi, Igor Gavric, Massimo Fragiacomo

SHEAR PERFORMANCE ESTIMATION OF WOODEN LATHS AND PLASTER WALLS THROUGH EXPERIMENTS AND NUMERICAL ANALYSIS 2207
Naoyuki Matsumoto, Katsuhiko Yamawaki, Kaori Fujita

A SEISMIC RESPONSE ESTIMATION MODEL FOR CROSS-LAMINATED TIMBER WALLS USING MACHINE LEARNING 2214
Eknara Junda, Christian Malaga-Chuquitaype

ADAPTIVE COMPOSITE RUBBER BEARINGS FOR TIMBER STRUCTURE: A CASE STUDY FOR EARTHQUAKE-PRONE REGIONS 2221
Weichong Liao, Kin Sang Michael Wong

SEISMIC DESIGN OF A CLT MULTI-STOREY BUILDING IN DIFFERENT DUCTILITY CLASSES 2227
Giuseppe Cenci, Maurizio Follesa, Vincenzo Rinaldi, Daniele Casagrande, Massimo Fragiacomo

SEISMIC RESPONSE OF BALLOON TYPE CLT SHEAR WALLS 2234
Zhiyong Chen, Marjan Popovski

EFFECTS OF VARIABLE CLIMATE CONDITIONS ON THE BEHAVIOR OF POST-TENSIONED MASS TIMBER WALL PANELS 2244
Jacob Gesh, Esther Baas, Ryan Longman, Mariapaola Riggio, Andre R. Barbosa, Lech Muszynski, Gabriele Granello

OPTIMIZED CLT-RC FRAME CONNECTION FOR SEISMIC RETROFITTING 2253
Zabih Mehdipour, Jorge M. Branco, Elisa Poletti, Paulo B. Lourenço

3.5. STRUCTURAL MODELLING, ANALYSIS & DESIGN

LESSONS LEARNED FROM A DECADE OF RESEARCH ON WOOD ASSEMBLIES UNDER BLAST LOADING 2261
Ghasan Doudak, Christian Viau, Daniel Lacroix

A NONLINEAR DYNAMIC MODEL FOR COLLAPSE INVESTIGATIONS IN TALL TIMBER BUILDINGS – PRELIMINARY RESULTS 2268
Alex Sixie Cao, Lukas Esser, Ben Glarner, Andrea Frangi

RESEARCH AND DEVELOPMENT OF SMALL-SCALE TIMBER CONSTRUCTION SYSTEM “BI-TREE STRUCTURE” WITH SMALL-DIAMETER TIMBER 2278
Toko Kamata, Satoru Ito, Yuya Takaiwa

MODELLING OF TIMBER STRUCTURES 2288
Zhiyong Chen, Dorian Tung, Erol Karacabeyli

PREDICTIVE CAPABILITIES OF FINITE ELEMENT MODELLING FOR TIMBER MEMBERS SUBJECTED TO BLAST LOADS 2298
Damian Oliveira, Christian Viau, Ghasan Doudak

EXPERIMENTAL INVESTIGATIONS ON CLT PANELS WITH OPENINGS 2306
Xiaoyue Zhang, Lu Xuan, Weitian Li, Thomas Tannert

SEISMIC PERFORMANCE EVALUATION OF REINFORCED WOODEN TEMPLE BASED ON LONG TERM EARTHQUAKE OBSERVATIONS 2312
Toshiaki Sato, Yasuhiro Nambu, Yuji Miyazu, Masayuki Nagano

GLUED-LAMINATED TIMBER BEAMS WITH LARGE ROUND HOLES: AN EXPERIMENTAL AND NUMERICAL INVESTIGATION 2318
Francesco Mirko Massaro, Kjell Arne Malo

ASSESSMENT OF THE FUNDAMENTAL PERIOD OF MULTI-STOREY CROSS LAMINATED TIMBER BUILDINGS 2327
Ebenezer Ussher, Angelo Aloisio, Roberto Tomasi

NUMERICAL MODELLING OF LIGHT TIMBER FRAME WALLS – COMPARATIVE STUDY OF THREE FASTENER REPRESENTATIONS 2335
Lukas Rauber, Benno Hoffmeister

INCREMENTAL DYNAMIC ANALYSIS OF A FIVE STOREYS CLT BUILDING DESIGNED THROUGH FORCE-BASED METHODS 2342
Franco Benedetti, Tomás Valenzuela, Alan Jara-Cisterna, Alexander Opazo-Vega, Víctor Rosales

ESTIMATION METHOD OF DEGRADATION STATE FOR TIMBER BRIDGES USING VIBRATION ANALYSIS 2350
Daisuke Oikawa, Shuya Nemoto, Humihiko Gotou, Yukari Aoki

TECHNICAL DESGIN GUIDE FOR TIMBER-CONCRETE COMPOSITE FLOORS – A CANADIAN APPROACH 2356
Samuel Cuerrier Auclair, Christian Dagenais, Sylvain Gagnon

AN ENGINEERING MODEL FOR THE DESIGN OF CUT-BACKS IN RIBBED PANELS 2365
Medhanye Biedebrhan Tekleab, Manfred Augustin, Gerhard Schickhofer

LATERAL DEFORMATION AND KINEMATIC MODES OF MULTI-PANEL BALLOON-TYPE CLT SHEARWALL SYSTEM 2376
Dalu Xing, Ghasan Doudak, Daniele Casagrande

SEISMIC ASSESSMENT OF BALLOON-FRAMED CLT BUILDING WITH SELF-CENTERING HOLD-DOWN 2384
Yuxin Pan, Md Shahnewaz, Carla Dickof, Thomas Tannert

STUDY OF THE EFECT OF SEISMIC REINFORCEMENT USING CFRTP STRANDS ON WOODEN BUILDINGS 2390
Koji Kubo, Nobuji Sakurai, Yuya Takaiwa

SHEAR FAILURE MECHANISM III IN CROSS LAMINATED TIMBER – NUMERICAL INVESTIGATIONS OF FRACTURE BEHAVIOUR 2396
Henrik Danielsson, Erik Serrano

ANALYTICAL STUDY ON P-Δ EFFECT ON MEDIUM-RISE WOODEN BUILDINGS 2406
Shogo Aoki, Naohito Kawai, Takafumi Nakagawa

DETERMINATION OF THE EFFECTIVE WIDTH OF CROSS-LAMINATED TIMBER RIB PANELS USING DIGITAL IMAGE CORRELATION 2416
Miriam Kleinhenz, Martin Viertel, Thomas Demschner, Andrea Frangi

MODELLING OF OSB SANDWICH PANELS WITH ORIGAMI-INSPIRED CORE 2426
Jan Pelczynski, Kamila Martyniuk-Sienkiewicz, Anna Al Sabouni-Zawadzka

INNOCROSSLAM – ADDING KNOWLEDGE TOWARDS INCREASED USE OF CROSS LAMINATED TIMBER (CLT) 2432
Boris Azinovic, Erik Serrano, Henrik Danielsson, Josef Füssl, Markus Lukacevic, Philipp Dietsch, Matthias Arnold, Martin Schenk, Stefan Winter, Jose Manuel Cabrero, Pablo Gonzalez Serna, Tomaž Pazlar

REINFORCED NOTCHED CROSS-LAMINATED TIMBER PLATES: LOAD-BEARING CAPACITY AND METHODOLOGY FOR PREDICTING THE FORCE IN REINFORCEMENT 2442
Alen Malagic, Erik Serrano, Manfred Augustin, Gerhard Schickhofer

ANALYSIS OF DIFFERENT NUMERICAL MODELLING STRATEGIES OF MULTI-STOREY CLT SHEAR WALLS 2454
Elisabetta Maria Ruggeri, Giuseppe D'Arenzo, Marinella Fossetti, Werner Seim

IN-PLANE DEFLECTION OF CROSS-LAMINATED TIMBER DIAPHRAGMS 2464
Mahboobeh Fakhrzarei, Hossein Daneshvar, Ying Hei Chui

EVALUATION OF THE BEHAVIOUR FACTOR BY INCREMENTAL DYNAMIC ANALYSES FOR THE SEISMIC DESIGN OF LIGHT-FRAME TIMBER BUILDINGS 2471
Alessandra Gubana, Alessandro Mazelli

MODULE FOR ANALYSIS AND CAPACITY-BASED DESIGN OF BRACED TIMBER FRAMES 2479
Hossein Daneshvar, Brian Qi, Tahiat Goni, Md. Abdul Hamid Mirdad, Marjan Popovski, Zhiyong Chen, Ying Hei Chui

INVESTIGATING THE EFFECTS OF THE INTERACTIONS BETWEEN FLOOR DIAPHRAGMS AND SEGMENTED CROSS-LAMINATED TIMBER SHEAR WALLS 2489
Giuseppe D'Arenzo, Werner Seim

EXPERIMENTAL CHARACTERIZATION OF STIFF ALUMINIUM CONNECTORS FOR MULTI-PANEL CLT SHEAR-WALLS 2497
Pietro Rigo, Andrea Polastri, Daniele Casagrande, Ernesto Callegari, Alvise Ramazzini, Luca Sestigiani

REPRODUCTIVE ANALYSIS OF FULL-SCALE SHAKING TABLE TESTS OF WOODEN HOUSES USING QUALITY ENGINEERING 2504
Tokikatsu Namba, Takafumi Nakagawa, Yuji Kado, Atsuo Takino, Hiroshi Isoda

STIFFNESS OF WOODEN FLOORS FOR SEISMIC EVALUATION OF EXISTING MASONRY STRUCTURES IN NORWAY 2510
Joakim P. Munden, Francesco Graziotti, Guido Magenes, Roberto Tomasi

MODAL IDENTIFICATION AND MODEL UPDATING OF AN INNOVATIVE AUTOMATIC SELF-SUPPORTING TIMBER WAREHOUSE: THE CASE STUDY OF ROTHOBLAAS HEADQUARTERS EXPANSION 2517
Ernesto Callegari, Roberto Girardi, Luca Gottardi, Andrea Incerti, Claudio Mazzotti, Luca Pozza, Sebastian Rodemeier, Luca Sestigiani, Mirko Tommasini

EVALUATION OF THE STRUCTURAL PERFORMANCE OF SHEAR WALLS BUILT WITH MULTI-LAYER COMPOSITE LAMINATED PANELS 2523
Lin Zheng, Sigong Zhang, Meng Gong, Ying Hei Chui

TIMBER INTERACTIVE MODELLING AND POST-PROCESSING SOFTWARE (TIMPS) 2531
Manuel Sánchez-Solís, Màxim Lliso, Fernando Ibáñez

NUMERICAL AND EXPERIMENTAL INVESTIGATIONS ON THE STRESS STATE OF CLT-PLATES NEAR CONCENTRATED LOADS 2537
Heinz Wimmer, Christoph Huber, Robert Eder

ANALYTICAL STUDY ON SEISMIC BEHAVIOR OF NEWLY BUILT FIVE STORY PAGODA IN TENDO-CITY JAPAN 2548
Naohito Kawai, Mikio Koshihara, Iuko Tsuwa, Kohei Nakamichi

INNOVATIVE HIGH PERFORMANCE SEISMIC RESILIENT TIMBER WALL STRUCTURES WITH LOW DAMAGE FLOOR CONNECTIONS 2556
Soheil Assadi, Ashkan Hashemi, Pierre Quenneville

EVALUATION OF SEISMIC PERFORMANCE FACTORS AND FRAGILITY FUNCTIONS FOR POST-TENSIONED MASS PLY PANEL ROCKING WALLS 2562
Tu X. Ho, Patricio Uarac, Andre R. Barbosa, Arijit Sinha, Barbara Simpson, Gustavo A. Araújo, Gustavo F. Orozco

THE USE OF PARAMETRIC WORKFLOW ON TIMBER CONSTRUCTION AT SERVICE STATION TORGHATTEN 2570
Paul Hufnagel, Philipp Vehrenberg, Matthias Stracke

TIMBER PAVILION CONSTRUCTED IN COMBINATION WITH PARAMETRIC DESIGN AND THE ZOLLINGER CONNECTION SYSTEM 2577
Franziska Häuptle, Camilla By Kampenes, Matthias Stracke

DEVELOPMENT OF THE ANALYTICAL METHOD TO REPRODUCE SEISMIC BEHAVIOR OF CLT BUILDINGS AT LARGE DEFORMATION 2584
So Momose, Tatsuya Miyake, Hiroshi Isoda, Takafumi Nakagawa

RACKING RESISTANCE OF CLT PANELS MANUFACTURED FROM C16 GRADE TIMBER 2594
Conan O'Ceallaigh, Rimjhim Kashyap, Annette M. Harte, Patrick McGetrick

NUMERICAL ANALYSIS OF BIAXIAL HOLLOW TIMBER SLAB ELEMENTS 2600
Dominik Bissig, Marcel Muster, Andrea Frangi

EFFICIENT FINITE ELEMENT MODELS FOR ADHESIVE-FREE MULTI-LAYERED TIMBER STRUCTURES 2609
Jeanne Paroissien, Tuan-Anh Bui, Marcel Oudjene, Pascal Lardeur

STUDY ON THE STRUCTURAL PERFORMANCE OF PLYWOOD BEARING WALL WITH THE RUSTED NAIL AND DECAYED WOOD 2617
Yuki Ota, Hiroki Ishiyama, Shigefumi Okamoto

DEVELOPMENT OF A NUMERICAL MODEL TO CONSIDER THE FOUNDATION FLEXIBILITY EFFECTS IN CLT ROCKING WALLS 2627
Irshad Qureshi, Gustavo Acuña, Daniel Dolan

PRESCRIPTIVE SEISMIC DESIGN PROCEDURE FOR POST-TENSIONED MASS TIMBER ROCKING WALLS IN THE UNITED STATES 2633
Aleesha Busch, Reid B. Zimmerman, Shiling Pei, Erica McDonnell, Philip Line, Da Huang

EFFECT OF THE ASPECT RATIO ON THE SEISMIC PERFORMACE OF POST-TENSIONED CROSS-LAMINATED TIMBER ROCKING WALL SYSTEMS 2642
Gustavo Acuña Alegría, J. Daniel Dolan, Irshad Qureshi

THE ROLE OF INTERMODULAR CONNECTIONS IN THE GLOBAL BEHAVIOR OF HIGH-RISE MASS TIMBER BUILDINGS 2650
Juan Sebastian Zambrano Jaramillo, Erica C. Fischer

A COMPARISON OF PUNCHING SHEAR DESIGN APPROACHES FOR POINT SUPPORTED CLT PANELS 2660
Christian Slotboom, Carla Dickof, Robert Jackson

SEISMIC AND ENERGY RETROFIT OF MULTIFAMILY LIGHT-FRAME TIMBER RESIDENTIAL BUILDINGS USING MASS PLY PANEL (MPP) WALL FAÇADE SYSTEM 2669
Gustavo Orozco, Andre R. Barbosa, Mark Fretz, Judith Sheine, Jason Stenson, Kevin Van Den Wymelenberg, Payton Narancic, Flynn Casey

CROSS-LAMINATED TIMBER FLOORS WITH OPENINGS – SERVICEABILITY LIMIT STATE VERIFICATIONS 2678
Martin Schenk, Anja Husel, Philipp Dietsch, Pablo González-Serna, José Manuel Cabrero, Stefan Winter

TIMBER-FRAMED SHEAR WALLS WITH LARGE OPENINGS AS PART OF THE LATERAL FORCE-RESISTING SYSTEM - OPTIMIZATION OF THE SHEATHING-TO-FRAMING CONNECTION LAYOUT 2686
Nadja Manser, René Steiger, Martin Geiser, Lukas Kramer, Andrea Frangi

EXPERIMENTAL AND NUMERICAL INVESTIGATION ON THE EFFECT OF CIRCULAR HOLES ON GLULAM COMPOSITE BEAMS 2695
Dag Pasca, Yuri De Santis, Angelo Aloisio, Andreas Stenstad, Karl Christian Mahnert

EVALUATION OF HARDENING MODELS TO SIMULATE JOINTS IN TIMBER SHEAR WALLS 2709
Rajan Maharjan, Johan Vessby, Le Kuai

COLLAPSE FRAGILITY OF A 5-STORY CLT STRUCTURE UNDER CHILEAN SUBDUCTION EARTHQUAKE RECORDS 2717
Alberto Aravena, Alan Hellman, Joaquín Miranda, Franco Silva, Diego Valdivieso Cascante

FINITE ELEMENT ANALYSIS OF GLULAM BEAMS WITH TRANSVERSE AND LONGITUDINAL NOTCHES 2724
Sardar Malek, Azadeh Goodarzi, Roger Parra, Parham Khoshkbari

A STUDY ON THE SEISMIC PERFORMANCE OF SHEAR WALLS UNDER A DYNAMIC LOAD 2731
Tomoki Furuta, Masato Nakao

STRUCTURAL PERFORMANCE EVALUATION OF A TIMBER HOUSE USING NEW CONSTRUCTION SYSTEM WITH CLT HORIZONTAL DIAPHRAGM 2739
Masato Nakao, Tomoki Furuta

NUMERICAL ANALYSIS ON SEISMIC BEHAVIOUR OF TIMBER FRAME STRUCTURE WITH HYBRID SCREWED-IN ROD CONNECTIONS 2745
Jiwei Liu, Benkai Shi, Huifeng Yang

EXPERIMENTAL AND NUMERICAL ANALYSIS OF HIGH-CAPACITY SHEAR WALLS WITH MULTIPLE ROWS OF NAILS 2752
Ruite Qiang, Lina Zhou, Chun Ni

BUCKLING ANALYSES OF CROSS LAMINATED TIMBER PANELS 2761
Martina Sciomenta, Yuri De Santis, Chiara Bedon, Massimo Fragiacomo

CONNECTIONS TESTING AND RELIABILITY ASSESSMENT OF TIMBER CONNECTIONS WITH DOWEL-TYPE FASTENERS 2768
Ezequiel Moreno-Zapata, B. Iraola, R. Quinteros-Mayne, I. De Arteaga, P. Tanner, C. Lara, J. M. Cabrero

EFFECTS OF CONSTANT AND ELF STRENGTH PROFILES ON THE PERFORMANCE OF WOOD FRAME SHEAR WALL STRUCTURES 2776
Francisco Flores, Philip Line, Finley A. Charney

AN ANALYTICAL MODEL TO INVESTIGATE THE EFFECT OF DIAPHRAGMS ON THE ELASTIC BEHAVIOUR OF MULTI-STOREY COUPLED-PANEL CLT SHEARWALLS 2783
Damian Oliveira, Ali Mikael, Daniele Casagrande, Ghasan Doudak

DEFLECTION OF CANTILEVER CROSS-LAMINATED TIMBER DIAPHRAGMS UNDER IN-PLANE LOAD 2792
Bibek Bhardwaj, Weichiang Pang, Michael Stoner, Douglas Rammer, Steve Pryor

EXPERIMENTAL ANALYSIS OF THE INFLUENCE OF OPENINGS IN THE DEFLECTION OF CROSS-LAMINATED TIMBER PLATES LOADED OUT OF PLANE 2798
Pablo Gonzalez-Serna, Miguel Yurrita, José Manuel Cabrero

PHENOMENOLOGICAL MODEL FOR SEISMIC DESIGN OF MULTISTOREY CLT BUILDINGS: CALIBRATION OF INPUT PARAMETERS 2805
Luca Pozza, Stefano Pacchioli, Andrea Polastri, Valentino Nicolussi, Diego A. Talledo, Ian Smith

AN ACCURATE FINITE ELEMENT MODEL TO STUDY THE PROGRESSIVE COLLAPSE OF POST-AND-BEAM MASS TIMBER BUILDINGS.....2811
Chunhao Lyu, Benoit P. Gilbert, Hong Guan, Hassan Karampour, Shanmuganathan Gunalan, William Leggate

TIMBER STRUCTURES IN SUBTROPICAL CLIMATE ON DESIGN: BOIS DURAMHEN PROGRAMS FOR GUADELOUPE, MARTINIQUE AND GUYANE 2820
Paul Quistin, Eric Fournely, Joseph Gril, Gael Godi, Luc Cador, Thierry Lamadon, Laurence Romana, Jacques Beauchêne, Rostand Moutou Pitti

FRACTURE ANALYSIS OF CROSS LAMINATED TIMBER SHEAR-WALLS WITH OPENINGS 2826
Martina Sciomenta

EMBEDMENT STRENGTH AND STIFFNESS FOR LARGE DIAMETER MECHANICAL FASTENER 2834
Krunoslav Pavkovic, Dean Cizmar, Mislav Stepinac, Nina Pospiš

NUMERICAL MODELLING OF MASS TIMBER BEAM-COLUMN CONNECTIONS 2841
Labuwatte M. M. B. Jayasekara, Robert M. Foster

A NEW MULTI-SPRING ELEMENT TO SIMULATE CLT CONNECTIONS UNDER COMBINED LOADINGS 2851
Matías F. Chacón, Pablo Guindos, Jairo Montaño

EXPERIMENTAL AND NUMERICAL ASSESSMENTS OF LONG-SPAN MASS TIMBER FLOOR SYSTEMS SUBJECTED TO FOOT-FALL INDUCED VIBRATION..... 2861
Christian Slotboom, Carla Dickof, Tobias Fast

STRUCTURAL PERFORMANCE OF TWO-PANEL CLT SHEAR WALL WITH BOLTED CONNECTION 2870
Daiki Hinata, Jun Kubota, Takashi Shima, Shinji Takatani, Masanori Hisada, Naohiro Haneda

3.6. TALL TIMBER BUILDINGS

FORCED RESPONSE MEASUREMENTS ON A SEVEN STOREY TIMBER BUILDING IN SWEDEN 2877
Andreas Linderholt, Pierre Landel, Marie Johansson

SYSTEM IDENTIFICATION OF TALL MASS TIMBER STRUCTURES EMPLOYING AMBIENT VIBRATION TEST AND FE MODELLING..... 2885
Samira Mohammadyzadeh, Jianhui Zhou, Lin Hu, Fei Tong

ON FINITE ELEMENT MODELLING AND MODEL UPDATING OF MULTI-STOREY TIMBER BUILDINGS 2892
Blaž Kurent, Boštjan Brank, Wai Kei Ao, Aleksandar Pavic, Manuel Manthey

AMBIENT VIBRATION TESTS AND MODAL ANALYSIS OF A SIX-STORY LIGHTWEIGHT TIMBER FRAME BUILDING 2898
Carmen Amaddeo, Michael Dorn

DYNAMIC RESPONSE OF TALL TIMBER BUILDINGS UNDER SERVICE LOAD – RESULTS FROM THE DYNATTB RESEARCH PROGRAM 2907
Rune Abrahamsen, Magne A. Bjertnæs, Jacques Bouillot, Boštjan Brank, Roberto Crocetti, Olivier Flamand, Fabien Garains, Igor Gavric, Ludwig Hahusseau, Alan Jalil, Marie Johansson, Thomas Johansson, Wai Kei Ao, Blaž Kurent, Pierre Landel, Andreas Linderholt, Kjell Arne Malo, Manuel Manthey, Petter Nåvik, Alex Pavic, Fernando Perez, Anders Rönnquist, Iztok Šušteršic, Saule Tulebekova

QUANTIFYING ROBUSTNESS IN TALL (TIMBER) BUILDINGS: A CASE STUDY 2915
Konstantinos Voulpiotis, Styfen Schär, Andrea Frangi

LONG-TERM MONITORING OF TALL MASS TIMBER BUILDINGS – EVALUATION OF DYNAMICS PROPERTIES 2922
Samuel Cuerrier Auclair, Christian Dagenais, Girma Bitsuamlak

DIFFERENTIAL MATERIAL MOVEMENT IN TALL MASS TIMBER STRUCTURES 2930
Richard McLain, Josephine Racine, Bryce Lumpkin

SERVICEABILITY PERFORMANCE OF TIMBER DUAL FRAME-WALL STRUCTURAL SYSTEM UNDER WIND LOADING 2940
Osama Hegeir, Haris Stamatopoulos, Kjell Arne Malo

INVESTIGATION OF LONG-TERM MODAL PROPERTIES OF A TALL GLUE-LAMINATED TIMBER FRAME BUILDING UNDER ENVIRONMENTAL VARIATIONS 2950
Saule Tulebekova, Kjell Arne Malo, Anders Rønnquist, Petter Nåvik

INVESTIGATIONS ON SUITABLE LATERAL STIFFENING SYSTEMS FOR TALL TIMBER BUILDINGS 2958
Charles Binck, Andrea Frangi

PERFORMANCE VERIFICATION AND TRIAL DESIGN FOR HIGH-RISE TIMBER FRAME BUILDINGS WITH BUCKLING-RESTRAINED BRACE - PART 2: ANALYSIS OF THE TRIAL DESIGN BUILDING 2968
Ryota Minami, Toshio Maegawa, Taisuke Nagashima, Kazuki Tachibana, Hiroki Nakashima, Nobuhiko Akiyama, Yoshihiro Yamazaki, Takahiro Tsuchimoto

POINT-SUPPORT REINFORCEMENT FOR A HIGHLY EFFICIENT TIMBER HOLLOW CORE SLAB SYSTEM 2978
Cristóbal Tapia, Hans Jakob Wagner, Simon Treml, Achim Menges, Simon Aicher

R&D PROJECT FOR TECHNOLOGIES ABOUT MID- AND HIGH-RISE TIMBER CONSTRUCTION IN JAPAN 2987
Takahiro Tsuchimoto, Nobuhiko Akiyama, Yoshihiro Yamazaki

3.7. INTERNATIONAL CODES & TIMBER ENGINEERING

A PROPOSAL FOR THE MECHANICAL CLASSIFICATION OF BEAM-TO-COLUMN JOINTS FOR TIMBER STRUCTURES 2995
Giacomo Iovane, Raffaele Landolfo, Celeste Noviello, Federico M. Mazzolani, Beatrice Faggiano

SECOND GENERATION OF EUROCODE 5-2 ON TIMBER BRIDGES, AN OVERVIEW 3001
Matthias Gerold, Hauke Burkart

TALL WOOD BUILDINGS WITHIN THE 2020 NATIONAL BUILDING CODE OF CANADA 3007
Marc Alam, Rodney McPhee

BEARING SUPPORTS REINFORCED WITH SCREWS: EXPERIMENTAL INVESTIGATION AND DISCUSSION OF THE DESIGN MODELS IN EUROCODE 5 3015
Roberto Tomasi, Angelo Aloisio, Ebenezer Ussher, Kari Ryen Thunber, Eldbjørg Aaraas Hånde, Harald Liven

MODIFICATION OF PARTIAL SAFETY FACTORS FOR A SEMI-PROBABILISTIC EVALUATION OF EXISTING TIMBER STRUCTURES 3023
Maria Loebjinski, Wolfgang Rug, Hartmut Pasternak

REVIEW OF THE CODE DEVELOPMENT EFFORTS FOR TALL MASS TIMBER BUILDINGS IN THE US 3033
Lori Koch, Matthew Hunter, M. Omar Amini

IMPROVEMENT OF THE DURABILITY OF TIMBER BRIDGES BY INTELLIGENT DESIGN AND RESPONSIBLE MAINTENANCE 3041
Antje Simon, Markus Jahreis, Johannes Koch

WOOD DURABILITY BASED IN THE NEW BRAZILIAN TIMBER STRUCTURES CODE ABNT NBR 7190: 2022 3048
Leandro Dussarrat Brito, Everaldo Pletz, Carlito Calil Junior

UPDATING EUROCODE 5 – DESIGN GUIDANCE FOR INCREASING THE ROBUSTNESS OF TIMBER STRUCTURES 3054
Pedro Palma, Jørgen Munch-Andersen, Philipp Dietsch

THE NEW BRAZILIAN TIMBER STRUCTURES CODE NBR7190: 2022 3062
Carlito Calil Junior, Felipe Hideyoshi Icimoto, Leandro Dussarrat Brito

EVALUATION OF CLT SHEAR WALLS FOR INCREASED STRUCTURAL HEIGHT LIMIT AND FOR EFFECT OF VARYING PANEL ASPECT RATIO 3069
M. Omar Amini, Philip Line, John W. Van De Lindt, Doug Rammer, Francisco Flores

BEAVER: A PARAMETRIC DESIGN FRAMEWORK FOR TIMBER ENGINEERING 3076
Renan Prandini, João Tavares Pini, Márcio Sartorelli Venâncio De Souza

STRUCTURAL CHARACTERIZATION OF NATIVE SPECIES ACCORDING TO THE NEW BRAZILIAN STANDARD ABNT NBR 7190: 2022 – PART 4 3084
Fabiana Yukiko Moritani, Felipe Hideyoshi Icimoto, Rodrigo De Souza Nogueira, Carlito Calil Junior, Lorenzo Lube Dos Santos, Adriano Wagner Ballarin

3.8. MIXED, COMPOSITE & HYBRID STRUCTURES

PREFABRICATED TIMBER CONCRETE COMPOSITES 3091
Sam Winder, Daniel Chapman, Panayiotis Papastavrou, Simon Smith, Allan McRobie

NUMERICAL MODELLING OF A CROSS-LAMINATED TIMBER-TO-CONRETE DOWEL-TYPE CONNECTION USING THE BEAM-ON-FOUNDATION MODEL 3101
Joan W. Gikonyo, Eva Binder, Michael Schweigler, Thomas K. Bader

EXPERIMENTAL AND NUMERICAL STUDY OF MOULDED WOOD TECHNOLOGY WITH FIBRE-PLASTIC COMPOSITE NODE ELEMENTS 3111
Siavash Mahjourian Namari, Peer Haller

MECHANICAL BEHAVIOUR OF NOTCH CONNECTION FOR MARITIME PINE CLT-CONCRETE COMPOSITE 3121
Carlos Albino, Carlos Martins, Cláudio Ferreira, Renato Augusto, Alfredo Dias

EXPERIMENTAL INVESTIGATION OF AN INNOVATIVE BEAM-TO-COLUMN CONNECTION UNDER CYCLIC LOADING 3127
Ahmed Mowafy, Ali Imanpour, Ying Hei Chui, Hossein Daneshvar

AN EXPERIMENTAL STUDY ON THE SAFETY PERFORMANCE OF A WOOD MASONRY STRUCTURE 3134
Daiki Iwamoto, Joichi Nakakuki, Waikong Lam, Hiro Kawahara, Masamichi Sasatani

STRUCTURAL PERFORMANCE OF REINFORCED GLULAM BEAMS 3141
Laith Gharaibeh, Ghasan Doudak

BENDING TESTS ON TIMBER CONCRETE COMPOSITES WITH PERFOBOND CONNECTIONS 3148
Elif Appavuravther, Bram Vandoren, José Henriques

DESIGN OF ASYMMETRIC FRICTION CONNECTION FOR SESIMIC RETROFITTING OF RC FRAMES WITH CROSS-LAMINATED TIMBER PANELS 3154
Angelo Aloisio, Francesco Boggian, Roberto Tomasi

SHEAR TESTS ON PERFOBOND CONNECTIONS IN TIMBER CONCRETE COMPOSITES 3161
Elif Appavuravther, Bram Vandoren, José Henriques

DELTABEAM® WITH TIMBER FLOOR JOINTS – LOAD BEARING CAPACITY AT AMBIENT TEMPERATURE AND IN FIRE SITUATION 3167
Salla-Mari West, Elena Camnasio, Simo Peltonen

MECHANICAL BEHAVIOUR OF TIMBER-STEEL COMPOSITE CONNECTION SYSTEMS 3177
Alireza Shahin, Craig J. L. Cowled, Henri Bailleres, Sabrina Fawzia

FINITE ELEMENT MODELLING OF HYBRID WOOD/ALUMINIUM ASSEMBLY WITH WOOD-FILLED ALUMINIUM AND STEEL DOWELS 3184
Gotre Bi Djeli Bienvenu Boli, Marc Oudjene, Daniel Coutellier, Hakim Naceur

EXPERIMENT ON AXIAL CAPACTY-BENDING CAPACITY RELATIONSHIP OF STEEL BAR-TIMBER COMPOSITE COLUMN 3191
Keisuke Hayata, Motohiro Mukai, Shinichi Shioya

FINITE ELEMENT ANALYSIS OF BUCKLING BEHAVIOR OF TIMBER ENCASED STEEL COMPOSITE COLUMNS SUBJECTED TO AXIAL LOAD 3201
Ying Gao, Feiyang Xu, Minghao Geng, Qibin Hu, Xinmiao Meng

EFFECTS OF ELEVATED TEMPERATURE ON BENDING CAPACITY OF STEEL BAR-TIMBER COMPOSITE BEAM 3211
Tsukasa Ueno, Nao Matsuoka, Shinichi Shioya

THE ADHESIVE SHEAR CONNECTION OF TIMBER AND CONCRETE SLABS IN HUMID ENVIRONMENT 3221
Viktória Bajzecerová, Jan Kanócz, Viktor Karla, Miroslava Javoríková

CYCLIC TESTS ON AN INNOVATIVE FRICTION DISSIPATIVE DEVICE FOR SEISMIC RETROFIT WITH CLT PANELS 3229
Francesco Boggian, Angelo Aloisio, Roberto Tomasi

NAIL-LAMINATED TIMBER-CONCRETE COMPOSITE BEAMS WITH NOTCHED CONNECTIONS AND STEEL FIBRE REINFORCEMENT 3235
Hamidreza Chaboki, Lei Zhang, Thomas Tannert, Jianhui Zhou

PUSH-OUT TESTS OF WET-PROCESS ADHESIVE-BONDED BEECH TIMBER-CONCRETE AND TIMBER-POLYMER-CONCRETE COMPOSITE CONNECTIONS 3241
Matthias Füchslin, Philippe Grönquist, Sandro Stucki, Tim Mamie, Steffen Kelch, Ingo Burgert, Andrea Frangi

SEISMIC FRAGILITY OF A NEW MASS TIMBER-STEEL HYBRID BUILDING SYSTEM EQUIPPED WITH CLT FLOOR DIAPHRAGMS 3248
Chaoyue Zhang, Cristiano Loss

STRUCTURAL BEHAVIOR OF TIMBER-STEEL-JOINTS WITH EITHER DOWEL-TYPE FASTENERS OR CONTINUOUS JOINTS 3256
Simon Aurand, Jakob Boretzki, Peter Haase, Thomas Ummenhofer, Philipp Dietsch

SEMI-INTEGRAL FULL-SCALE STUTTGART TIMBER MODEL BRIDGE 3264
Simon Aicher, Kai Simon

LIMBERLOST PLACE: A 10-STOREY SLAB-BANDED STRUCTURE 3272
Md Shahnewaz, Robert Jackson

STRUCTURAL DESIGN OF HYBRID STRUCTURE WITH CLT SEISMIC PANELS AND STEEL FRAME 3281
Kouji Fukumoto, Marina Koda, Hiroshi Isoda

TECHNICAL CONCEPT AND FEASIBILITY OF STEEL SHEET REINFORCED SYNTHETIC WOOD BEAM 3290
Shogo Oda, Chikako Tabata, Yoshito Tomioka

TIMBER-CONCRETE-COMPOSITE BEAMS WITH DISCRETE PERFORATED STEEL PLATE SHEAR CONNECTORS 3296
Dolores Otero-Chans, Javier Estévez-Cimadevila, Emilio Martín-Gutiérrez, Félix Suárez-Riestra, José A. Vázquez-Rodríguez

A NEW BUILDING STRUCTURAL SYSTEM USING TIMBER-CONCRETE-COMPOSITE MEMBERS 3303
Javier Estévez-Cimadevila, Dolores Otero-Chans, Emilio Martín-Gutiérrez, Félix Suárez-Riestra, José A. Vázquez-Rodríguez

STUDY ON FAILURE MECHANISMS OF HYBRID STRUCTURE OF REINFORCED CONCRETE FRAME WITH CLT INFILL 3309
Hamood Alwashali, Ahmad Ghazi Aljuhmani

PRELIMINARY STUDY ON THE TENSION-ONLY BRACED SELF-CENTERING STEEL-TIMBER HYBRID FRAME 3318
Fei Chen, Minghao Li, Minjuan He, Zheng Li

DEVELOPMENT OF HYBRID RIGID FRAME STRUCTURE METHOD USING SEMI-RIGID TIMBER BEAMS 3325
Akihiko Miyake, Ryoma Murata

AN EXPERIMENTAL AND NUMERICAL INVESTIGATION ON A DOVETAIL NOTCHED CONNECTION FOR CROSS-LAMINATED-TIMBER-CONCRETE COMPOSITE SLABS 3333
Vanthet Ouch, Piseth Heng, Hugues Somja, Thierry Soquet

A 3D DUCTILE-NOTCHED CONNECTION FOR TIMBER-CONCRETE COMPOSITE BEAM : EXPERIMENTAL INVESTIGATION 3342
Adham Al Rahim, Piseth Heng, Clemence Lepourry, Hugues Somja, Franck Palas

HIGH CAPACITY SHEAR CONNECTORS AND APPLICATION FOR TIMBER-CONCRETE BRIDGES 3351
Raitis Lacis, Maris Karlsons

DEVELOPMENT OF LVL-CONCRETE COMPOSITE FLOOR SYSTEMS 3357
Alireza Fadai, Johann Scheibenreiter, Alex Müllner, Marie Theres Brunauer

ANALYTICAL AND EXPERIMENTAL STUDY ON REVERSIBLE STEEL-TIMBER COMPOSITE CONNECTION SYSTEMS 3364
Fabiana Yukiko Moritani, Pedro Santos, Luís Jorge, Alfredo Dias

EXPERIMENTAL AND NUMERICAL INVESTIGATIONS ON THE USAGE OF CLT PANELS TO FORM TIMBER-STEEL COMPOSITE FLOOR SYSTEMS 3373
Hugh Merryday, Megan Potuzak, David Roueche, Kadir Sener

EXPERIMENTAL TESTING OF SMALL-SCALE TIMBER-CONCRETE COMPOSITE BEAMS UTILIZING ADHESIVE SHEAR CONNECTIONS 3382
Adam Petrycki, Sam Salem, Matthew Leitch

3.9. WOOD-BASED BUILDING SYSTEMS

EFFECT OF DIFFERENT TESTING METHODS ON THE STRUCTURAL PERFORMANCE OF WOODEN SHEAR WALLS 3392
Yua Kosuge, Satoshi Onishi, Hideyuki Nasu

DEVELOPMENT OF HIGH STRENGTH BEARING WALLS FOR FRAMEWORK CONSTRUCTION METHOD USING 2X4 LUMBER AND PLYWOOD MADE OF JAPANESE TIMBER 3398
Hideyuki Nasu, Kenji Aoki, Hiro Kawahara

IMPACT OF EXTERIOR SIDING WALLS AND THE CONNECTING METHODS IN WOODEN HOUSES: COMPARATIVE VERIFICATION FOR STRUCTURAL PERFORMANCE WITH DIFFERENT CONNECTION METHODS OF WALL SIDINGS 3404
Kouta Matsumoto, Kiyotaka Terui, Hideyuki Nasu

STUDY ON THE EVALUATION OF THE RESTORING FORCE CHARACTERISTICS OF FLOOR OF TRADITIONAL WOODEN BUILDING IN KYOTO 3410
Rongji Fu, Mina Sugino, Yasuhiro Hayashi

INFLUENCE OF PLASTERBOARD ON THE STRUCTURAL PERFORMANCE OF TIMBER-FRAMED SHEAR WALLS 3417
Craig Cowled, Tom Slattery, Keith Crews, Harrison Brooke

EXPERIMENTAL CHARACTERIZATION OF CLT SHEAR WALLS CONNECTED TO PERPENDICULAR WALLS 3423
Elisabetta Maria Ruggeri, Giuseppe D'Arenzo, Denise Li Cavoli, Ignazio Casiraro, Marinella Fossetti

FULL-SCALE LATERAL TESTING AND MODELLING OF INDUSTRIALIZED TIMBER DIAPHRAGMS INCLUDING ONLY FRAMING AND NON-STRUCTURAL SHEATHING 3430
Fernando Véliz, Xavier Estrella, Pablo Guindos

FEASIBILITY STUDY ON LONG-SPAN CLT-GLULAM COMPOSITE FLOORING SYSTEM CONNECTED WITH BAMBOO-TENON SHEAR CONNECTORS 3439
Yue Diao, Cristiano Loss

STUDY ON FRAME DESIGN OF CONVENTIONAL WOODEN HOUSE 3449
Tomoya Sahata, Naohito Kawai, Hideyo Tsukazaki

EXPERIMENTAL ANALYSIS OF A SCREW-GLUED SHEAR CONNECTION FOR USE IN MASS TIMBER COMPOSITE PANELS 3455
Tyler Hull, Daniel Lacroix

LOADING TEST OF CLT-SHEAR WALL CONNECTED WITH STEEL BAR-TIMBER COMPOSITE COLUMN DISSIPATING HIGH-ENERGY 3465
Takumi Suyama, Riko Kawasaki, Atsuya Kawasoe, Tomokazu Yoshioka, Shinichi Shioya

TIMBER VAULTS FOR ULTRA-LOW-CARBON BUILDING STRUCTURES 3475
Shane Hossell, Will Hawkins, Antony Darby, Tim Ibell, Nicola Lines

SEGMENTED COMPOSITE SECTIONS WITH WOOD DOWELS 3485
Matthias Brieden, Max Braun, Werner Seim, Kristina Schramm, Philipp Eversmann

LIGHT-FRAME TIMBER SHEAR-WALLS WITH DIAGONAL BOARD SHEATHING: EXPERIMENTAL AND NUMERICAL INVESTIGATION 3492
Alessandro Setti, Daniele Casagrande, Andrea Polastri, Riccardo Fanti, Maurizio Follesa, Ezio Riggi

SEISMIC PERFORMANCE OF CLT SHEAR WALL INFILLED HYBRID STEEL MOMENT FRAME WITH CONCEALED STEEL PLATE AND DRIFT PINS CONNECTIONS 3499
Hiroshi Isoda, Richard Yip Je Too, Kazumi Kanazawa

INVESTIGATION OF A NOVEL TIMBER-MORTAR CONSTRUCTIVE SYSTEM 3507
Andrea Polastri, Riccardo Fanti, Pietro Rigo, Efrem Demarchi

SHEAR PERFORMANCE OF STRUCTURAL PARTICLEBOARD-SHEATHED LIGHT-FRAME WALL 3513
Chul-Ki Kim, Min Lee, Kugbo Shim

DEPLOYABLE WOOD STRUCTURES FOR DISASTER RELIEF AND MILITARY USE 3518
Jayson Leonard, Weichiang Pang, Michael Stoner, Dustin Albright

3.10. CIRCULAR DESIGN FOR SUSTAINABILITY, ALTERED USE, AND REUSE OF BUILDINGS & COMPONENTS

GLUED TIMBER TRUSSES 3526
Tuomo Poutanen, Markku Karjalainen, Valtteri Paananen, Jouko Tanskanen

3DP BIOWALL - CIRCULAR ECONOMY IN WOOD CONSTRUCTION THROUGH ADDITIVE MANUFACTURING OF FULLY RECYCABLE WALLS 3535
Benjamin Kromoser, Sara Reichenbach, Roman Myna, Raphaela Hellmayr, Bernhard Reinholz, Rupert Wimmer

SEISMIC ANALYSIS OF A MULTI-STORY TIMBER-CONCRETE BUILDING AND DESIGNING FOR REUSE 3542
Sivert Lie, Themistoklis Tsalkatidis

DEVELOPMENT OF TEMPORARY STRUCTURE USING CLT PANEL - INVENTION OF CONSTRUCTION AND VERIFICATION BY CONSTRUCTION EXPERIMENT 3551
Hiroaki Kubotera, Toshiaki Sato, Yohei Aioi, Kazuo Niikuma

HOW TIMBER BUILDINGS CAN BE DESIGNED FOR DECONSTRUCTION AND REUSE IN ACCORDANCE WITH ISO 20887 3558
Ylva Sandin, Marlene Cramer, Karin Sandberg

PUSH-OUT TESTS ON CONNECTIONS FOR DEMOUNTABLE AND REUSABLE STEEL-TIMBER COMPOSITE BEAM AND FLOORING SYSTEMS 3568
Alfredo Romero, Jie Yang, François Hanus, Hervé Degée, Christoph Odenbreit

STRUCTURAL PERFORMANCE OF TIMBER-CONCRETE COMPOSITE FLOOR ELEMENTS WITH DECONSTRUCTABLE CONNECTORS AND ITS POTENTIAL FOR REUSE 3575
Mohammad Derikvand, Gerhard Fink

ENVISIONING MASS TIMBER BUILDINGS FOR CIRCULARITY: LIFE CYCLE ASSESSMENT OF A MASS TIMBER BUILDING WITH DIFFERENT END-OF-LIFE (EOL) AND POST-EOL OPTIONS 3581
Namhyuck Ahn, Christina Bjarvin, Mariapaola Riggio, Lech Muszynski, Laurence Schimleck, Catarina Pestana, Ambrose Dodoo, Maureen Puettmann

A REUSE-READY TIMBER SLAB-AND-COLUMN SYSTEM FOR MODULAR BUILDING STRUCTURES 3588
Xavier Estrella, Alex Muresan, Dario Redealli, Jan Brütting, Jonas Warmuth, Corentin Fivet

ENGINEERED WOOD PRODUCTS MANUFACTURED FROM RECLAIMED HARDWOOD TIMBER 3594
Daniel Fernandez Llana, Violeta González-Alegre, María Portela, Justo García-Navarro, Guillermo Íñiguez-González

REUSE OF LOAD-BEARING TIMBER ELEMENTS – CASE STUDY OF A LOOKOUT TOWER IN LAUSANNE, SWITZERLAND 3600
Jonas Warmuth, Xavier Estrella, Benoît Kälin, Johannes Natterer, Corentin Fivet

VALUES OF RECLAIMED TIMBER 3608
Maxence Lebossé, Franck Besancon, Gilles Halin, Alain Fuchs

CHALLENGES IN THE DESIGN OF A MODULAR MULTI-STOREY CLT BUILDING USING IRISH TIMBER 3618
Hung Quang Phung, Conan O'Ceallaigh, Patrick McGetrick, Annette M. Harte, Rimjhim Kashyap

RE:SOURCE PAVILION – EXPLORING THE CIRCULAR USE OF WOODEN BUILDING MATERIALS 3625
Ute Groba, Samuel Blumer

ADAPTABILITY IN MULTI-STOREY TIMBER BUILDINGS – TOWARDS DIFFERENTIATED DURABILITY LAYERS IN ARCHITECTURE 3634
Esther Vandamme, Mario Rinke

PROPOSAL OF INTERACTIVE WORKFLOW FOR CIRCULAR TIMBER STRUCTURE DESIGN 3644
Marcin Luczkowski, Sverre M. Haakonsen, Artur Tomczak, Bunji Izumi

3.11. RILEM TC TPT

ENERGY DEMAND FOR THE DRIVING IN OF SELF-TAPPING TIMBER SCREWS AND ITS APPLICABILITY 3649
David Glasner, Andreas Ringhofer, Gerhard Hubmann, Werner Braun

INFLUENCE OF THE SPECIMEN PREPARATION ON THE EMBEDMENT STRENGTH OF SELF-TAPPING SCREWS 3660
Michael Gstettner, Andreas Ringhofer

INFLUENCE OF TEST METHODS ON THE PARALLEL TO GRAIN EMBEDMENT STRENGTH AND FOUNDATION MODULUS CHARACTERIZATION 3667
Caroline Dapieve Aquino, Leonardo G. Rodrigues, Meta Kržan, Michael Schweigler, Zheng Li, Jorge M. Branco

DEVELOPMENT OF COMPREHENSIVE TESTING PROCEDURES FOR HIGH-PERFORMANCE BONDED-IN RODS 3675
Robert Jockwer, Pedro Palma, Arthur S. Rebouças, Alexander Salenikovich

PROTOCOLS AND RESULTS ANALYSIS METHODS FOR CYCLIC TESTS OF TIMBER JOINTS. A DISCUSSION 3685
Meta Kržan, Caroline D. Aquino, Michael Schweigler, Zheng Li, Jorge M. Branco

4.1. ARCHITECTURAL POTENTIAL OF NEW WOODEN MATERIALS & TECHNOLOGIES

USAGE OF A BAMBOO HONEYCOMB STRUCTURE (COMBOO) IN TIMBER ARCHITECTURE 3694
Andreas Loth, Ralf Förster

BENDING OF CLT BY THE LATTICE HINGE METHOD 3701
Laurane Néron

STRATOCONCEPTION®, AN ADDITIVE MANUFACTURING PROCESS FOR TIMBER ARCHITECTURE: CHALLENGES AND OPPORTUNITIES 3708
Victor Fréchard, Laurent Bléron, Julien Meyer, Franck Besançon, Gilles Duchanois

HYPERBOLIC PARABOLOID SHELLS MADE OF DIAGONAL LAMINATED TIMBER ELEMENTS 3718
Matthias Arnold, Philipp Dietsch, Stefan Winter

MASS TIMBER PANELIZED WORKFORCE HOUSING IN OREGON, U.S. 3728
Judith Sheine, Mark Fretz, Simone O'Halloran, Mikhail Gershfeld, Jason Stenson

UTILIZING LOW-VALUE WOOD SPECIES FROM FOREST RESTORATION PROJECTS IN LOCAL CLT MANUFACTURE AND DESIGN 3738
Payton Narancic

AMAZONIAN MASS TIMBER IN THE NEW CIPEM'S HEADQUARTERS – MATO GROSSO, BRAZIL 3747
Roberto Lecomte, Sheila Beatriz

INTEGRATING TIMBER PANEL ELEMENTS INTO HISTORIC CHINESE TIMBER-FRAMED HOUSES TO ENHANCE MULTIPLE BUILDING PERFORMANCES 3753
Harrison Huang, Kapulanbayi Ailaitijiang, Zhan Hui

ARCHITECTURAL POTENTIAL OF NEW WOODEN MATERIALS & TECHNOLOGIES 3761
Ramona Schwertfeger, Markus Lager

SPECIAL SIZED TIMBER POLES AS MAIN STRUCTURAL MATERIAL IN TWO SPORTS GYMS AND A WINERY – BRAZIL 3769
Roberto Lecomte, Sheila Beatriz

MODULAR CONSTRUCTION WITH LOW-GRADE HARDWOOD CROSS-LAMINATED TIMBER 3775
Edward Becker

4.2. INTEGRATION OF PARAMETRIC ARCHITECTURAL DESIGN & CNC MANUFACTURING

MASS TIMBER, SMALL FORMAT: OPEN SOURCE FURNITURE PROTOTYPING FROM MASS TIMBER SCRAPS 3782
Cory Olsen, Linda Zimmer

CARPENTER AND ROBOT: HOW TO BENEFIT FROM THE KNOWLEDGE OF CRAFTSMEN AND THE STRENGTH OF ROBOTS 3788
Wolfgang Schwarzmann

A BIM-BASED MODULE DESIGN METHODOLOGY FOR THE ROOF PLANNING OF MODERNIZED KOREAN TRADITIONAL WOODEN BUILDINGS 3794
Dongwook Kim, Bonghee Jeon, Gee Heon Kim

STEPS TOWARDS A UNIVERSAL SCHEME FOR PARAMETRIC DETAILING OF COMPOUND TIMBER STRUCTURES 3801
John Haddal Mork, Sveinung Ørjan Nesheim

4.3. BUILDING PHYSICS & BUILDING SKINS

MOISTURE PREDICTION OF TIMBER FOR DURABILITY APPLICATIONS USING DATA-DRIVEN MODELLING 3808
Seyyed Hasan Hosseini, Jonas Niklewski, Philip Bester Van Niekerk

HYGRO-THERMAL EXPERIMENTAL ANALYSIS OF A FLAT ROOF STRUCTURE INTEGRATING A VARIABLE VAPOR-DIFFUSIVITY MEMBRANE 3816
Riccardo Pinotti, Paola Brugnara, Stefano Avesani

DEVELOPING SLIMMER TIMBER WINDOW FRAME 3823
Katarzyna Ostapska, Tore Myrland Jensen, Lars Gullbreken, Petra Ruther

OUTDOOR PANELS FROM NORWAY SPRUCE – THE EFFECT OF COATING COLOUR ON THE TEMPERATURE 3829
Sebastian Svensson Meulmann, Åsa Rydell Blom, Michael Dorn

HYGROTHERMAL PERFORMANCE OF NATURE-BASED INSULATION MATERIALS INTEGRATED IN TIMBER-BASED WALL-SYSTEMS 3835
Dimitrios Kraniotis, Samee Ullah, Stine Lønbro Bertelsen

ALCOHOLS AS A PHASE CHANGE MATERIAL WITH EXCELLENT THERMAL STORAGE PROPERTIES IN BUILDINGS ..... N/A
Dehong Li, Yuchen Chen, Bin Li, Alireza Kaboorani, Denis Rodrigue, Xiaodong Alice Wang

TIMBER CLADDING DISCOLOURATION IN TROPICAL MONSOON CLIMATES 3851
Shinya Okuda, Laurent Corpataux, Kua Harn Wei

4.4. SENSOR SYSTEMS FOR BUILDING PROCESS AND OPERATION

CREEP TESTING OF A TIMBER LATTICE FRAME USING IMAGE RECOGNITION 3860
Nicolas Giron, Hideyuki Nasu

A MOISTURE MANAGEMENT STRATEGY FOR CLT USING SENSOR TECHNOLOGY TO CREATE A ROBUST NORWEGIAN SCHOOL 3868
Laura Vestergaard Kellgren, Astrid Charlotte Seeberg, David Hagle, John Øvregård, Jeppe Rasmussen

PRINTED SENSORS FOR MONITORING WOOD MOISTURE CONTENT INSIDE TIMBER BUILDING ELEMENTS 3874
Boris Forsthuber, Michael Truskaller, Irene Spitaler, Pavel Kulha, Maximilian Scherf, Gabriel Partl, Albert Rössler, Gerhard Engelbrecht, Gerhard Grüll

MOISTURE AND TIGHTNESS MONITORING WITH DIFFERENT MEASURING SYSTEMS AND METHODS - EXAMPLE APARTMENT BUILDING 3880
Anton Kraler, Andreas Pomaroli

A PROMISING APPROACH OF LINEAR TIMBER STRUCTURAL HEALTH MONITORING 3888
Johannes Koch, Martin Ganß, Martin Kästner, Antje Simon

FEDERATED USE OF HYGROTHERMAL MONITORING DATA IN MASS TIMBER BUILDINGS: OPPORTUNITIES AND CHALLENGES 3896
Mariapaola Riggio, Jan Vcelak, Pekka Kaitaniemi, Andre R. Barbosa, Niki Hrovatin, Anna Sandak, Jakub Sandak, Michael Mrissa, Miklos Kresz, Anssi Yli-Jyrä, Ritva Toivonen, Laura Alakukku

4.5. NEW DESIGN PRACTICE AND BUILDING SYSTEMS

TOWARDS DESIGN FLEXIBILITY AND FREEDOM IN MULTI-STOREY TIMBER CONSTRUCTION: ARCHITECTURAL APPLICATIONS OF A NOVEL, ADAPTIVE HOLLOW SLAB BUILDING SYSTEM 3905
Hana Svatoš-Ražnjevic, Anna Krtschil, Luis Orozco, Gregor Neubauer, Jan Knippers, Achim Menges

RECIPROCAL FRAMES: AN ANCESTRAL STRUCTURAL PRINCIPLE TO USE NATIVE WOOD SPECIES IN CHILE 3917
Suzanne Segeur-Villanueva, Natalia Caicedo-Llano

DEVELOPMENT OF A NEW TYPE OF BUILDING IN TROPICAL REGIONS BASED ON THE ENERGETIC PERFORMANCE AND RECOVERY OF RECYCLED WOOD 3924
Horly Luzolo Nsumbu, Régis Pommier, Denis Bruneau, Alain Sempey

USING CO-DESIGN FOR DEVELOPING A NEW WOODEN FAÇADE SYSTEM 3931
Camilla Schlyter, Karin Sandberg

MULTI-CRITERIA ASSESSMENT FOR FLEXIBILITY IN MODULAR TIMBER SCHOOL PROJECT BASED ON AHP-TOPSIS 3937
Puxi Huang, Yiping Meng

MONO-MATERIAL TIMBER CONSTRUCTION RE-INVENTION OF PRESS-FIT TIMBER CONSTRUCTIONS 3944
Hans Drexler

A DESIGN FRAMEWORK FOR TIMBER BUILDING SYSTEMS 3954
Marius Nygaard, Kjetil Nordby

TAMANGO BUILDING: TYPOLOGICAL EXPLORATION FOR A 12-STOREY WOODEN APARTMENT BUILDING IN A SEISMIC AREA 3963
Gerardo Armanet, Juan José Ugarte G., Sebastián Cárcamo, Andrés Sierra, Diego Valdivieso, Juan José Ugarte Á.

MORPHOLOGIC STUDY OF HYBRID TALL BUILDING TOWARDS AN INTERDISCIPLINARY DESIGN 3973
Sebastian Carcamo, Diego Valdivieso

4.6. USE OF TIMBER IN TRANSPORT SECTOR (BRIDGES, AIRPORTS, HARBOURS)

AN INSIGHT INTO THE DEVELOPMENT OF TIMBER BRIDGES IN NORWAY AND SWEDEN 3979
Martin Cepelka, Per-Anders Fjellström, Ashish Aeran

NEBY BRU: ONE FOOTWAY, THREE WAYS OF SUSTAINABILITY 3989
Manuel Sánchez-Solís, Gaute Mo, Fernando Ibáñez

SKYTEBANEN BRIDGE – A TIMBER TRUSS BRIDGE WITH AN INTERMEDIATE SUSPENDED CONCRETE DECK 3995
Alfredo Skartveit, Kristian Mæland Rasmussen, Kristian B. Dahl

4.7. EXPLORATION & RESTORATION OF EXISTING STRUCTURES

METHODOLOGY OF REHABILITATION OF TIMBER STRUCTURES IN HISTORIC BUILDINGS 4001
José Amorim Faria

WEB-GIS-TOOL: ESTIMATION OF GREENHOUSE GAS SAVINGS DUE TIMBER USE IN THE URBAN BUILT ENVIRONMENT 4010
Caya Zernicke, Annette Hafner, Andreas Abecker, Harro Stolpe

IN-PLANE SHEAR TEST AND APPLICATION STUDY OF SEISMIC RETROFIT TIMBER FRAME WITH CFRTP STRANDS 4020
Hina Takizawa, Nobuji Sakurai, Yuya Takaiwa

POST-EARTHQUAKE ASSESSMENT AND DOCUMENTATION OF TIMBER ROOFS 4029
Mislav Stepinac, David Andic, Juraj Pojatina

EVALUATION OF VIBRATION CHARACTERISTICS OF EXISTING TIMBER ARCHITECTURE BY MICROTREMOR MEASUREMENT - EXAMINATION WHEN IT IS DIFFICULT TO INSTALL AN ACCELEROMETER IN THE ATTIC 4035
Hiroki Yoshinuma, Yuya Takaiwa

DEVELOPMENT OF SIMPLE REPAIRING HARDWARE FOR DAMAGED ENDS OF WOODEN BEARING WALLS 4043
Wataru Kambe

STUDY ON THE MECHANICAL PERFORMANCE OF MULTI-LAYERED BRACKET COMPLEX 4050
Kohei Komatsu

EXPERIMENTAL STUDY ON LATERAL PERFORMANCE OF A FRAME WITH DEEP BEAMS AND HANGING MUD WALLS IN TRADITIONAL JAPANESE RESIDENTIAL HOUSES 4058
Zherui Li, Hiroshi Isoda, Akihisa Kitamori, Takafumi Nakagawa, Yasuhiro Araki

ASSESSMENT OF NAILED CONNECTIONS IN EXISTING STRUCTURES 4064
Lars Völlmecke, Sascha Schwendner, Ai Phien Ho, Jens Fischer, Werner Seim

TESTING OF CONNECTIONS TAKEN FROM OLD NAILED ROOF TRUSSES 4071
Sascha Schwendner, Lars Völlmecke, Phien Ho, Jens Fischer, Werner Seim

INFLUENCE OF MOISTURE CONTENT ON THE ASSESSMENT OF DECAY LEVELS BY MICRO-DRILLING MEASUREMENTS IN WOODEN FOUNDATION PILES 4079
Michele Mirra, Giorgio Pagella, Wolfgang Gard, Geert Ravenshorst, Jan-Willem Van De Kuilen

A STUDY ON COORDINATED EXPRESSION OF THE SEISMIC DIAGNOSIS SCORE AND ITS APPLICATION TO RETROFIT REINFORCEMENT PROJECTS UNDER COST CONTROL FOR JAPANESE TIMBER HOUSES 4087
Daisuke Shimizu, Chikako Tabata, Yoshito Tomioka

SCALING UP ENGINEERED TIMBER FOR NEIGHBOURHOOD SCALE DEEP RENOVATION: FINDINGS FROM A STUDY IN COIMBRA, PT 4093
Nelson Brito, Thomas Thiis, Roberto Tomasi, Alice Airoldi, Andrea Penna

MODIFICATION OF ROOF STRUCTURE OF THE TRADITIONAL WOOD HOUSES IN THE URBAN AREA OF DAEGU, KOREA DURING MID TWENTIETH CENTURY 4102
Jaemo Cho

HYBRIDIZATION OF WESTERN TIMBER TRUSS AND TRADITIONAL KOREAN ROOF SHAPE IN THE EARLY 20TH CENTURY 4108
Jeonghyun Kim, Jihong Kim, Bonghee Jeon

SEISMIC PERFORMANCE EVALUATION OF A TRADITIONAL WOODEN TOWNHOUSE THAT DID NOT COLLAPSE IN THE 2016 KUMAMOTO EARTHQUAKE 4114
Yasuhiro Nambu, Toshihiko Ninakawa, Hiroki Tabata, Akio Kitahara

DEVELOPMENT OF TIMBER ROOF FRAMES IN KOREAN MODERN ARCHITECTURE 4122
Kangmin Lee, Don-Son Woo

COMBINATION OF NDT AND DESTRUCTIVE TESTS FOR GRADING THE STRENGTH CLASS OF TIMBER TO REHABILITATE STRUCTURES 4128
Marcel Vilches-Casals, Eduard Correal-Mòdol, Carles Labèrnia Badia, Giraldo M. P.

THE PRESENT STATE AND ISSUES ON RETROFITTING OF HISTORIC TIMBER-FRAMED BRICK CONSTRUCTION BUILDINGS IN JAPAN 4134
Manabu Fujimoto, Naoyuki Matsumoto, Mikio Koshihara

REUSE OF WOOD, LEARNING ABOUT THE BENEFITS AND CHALLENGES OF HIGH- AND LOW-TECH DIAGNOSTIC METHODS THROUGH ACTION RESEARCH IN NORWAY 4141
Wendy Wuyts, Artur Tomczak, Kristine Nore, Lizhen Huang, Thomas Haavi

FERROCEMENT WOODEN HOUSE: LEARNING FROM POST-DISASTER RECONSTRUCTION IN INDONESIA 4151
Andry Widyowijatnoko, Dibya Kusyala, Fajar Ikhwan Harnomo

HARVESTING THE URBAN FOREST: A CASE STUDY OF THE CIRCULAR BUILDING SEMINAR AT UHASSELT IN BELGIUM 4157
Rafael Novais Passarelli, Peggy Winkels, Ronald Rovers, Elke Knapen, Griet Verbeeck

5.1. BEST PRACTICE EXAMPLES

ADHESIVELY BONDED TIMBER-CONCRETE COMPOSITE CONSTRUCTION METHOD (ATCC) – PILOT APPLICATION IN A SCHOOL BUILDING IN GERMANY 4164
Jens Frohnmüller, Werner Seim, Christian Umbach, Johannes Hummel

APPLICATION OF A WOODEN PREFABRICATED SHELL EXOSKELETON FOR THE INTEGRATED AND SUSTAINABLE RETROFIT OF A RESIDENTIAL BUILDING 4173
Jacopo Zanni, Chiara Passoni, Alessandra Marini, Ezio Giuriani, Andrea Belleri, Simone Labò, Giovanni Brumana, Simone Castelli, Claudio Abrami, Stefano Santini, Giuliano Venturelli, Angelo L. Marchetti

BUILDING WITH WOOD STRUCTURES – SUCCESFULL DESIGN PROCESS 4182
Alain Bradette, Geir Glasø, Tor Øistein Andresen

CAN RISING DEMAND FOR TIMBER IN CONSTRUCTION ACCELERATE DEFORESTATION? 4190
Eduardo Rojas Briales, Simon Flinn

5.2. CASE STUDIES AND VISIONS

RIGID JOINTS ON GLUED-IN RODS OF BENDING AND COMPRESSION-BENDING ELEMENTS OF LARGE-SPAN LAMINATED TIMBER STRUCTURES 4201
Alexander Pogoreltsev, Stanislav Turkovsky, Vladimir Stoyanov

MJØSTÅRNET: THE WORLD'S TALLEST TIMBER BUILDING..... 4209
Harald Liven, Rune Abrahamsen

THE FIRST MASS TIMBER BUILDING IN BRAZIL..... 4215
Carlito Calil Neto, Alexander Takata, Vitor Afonso Neves Silva

SPOR X – 10-STOREY TIMBER OFFICE BUILDING, DRAMMEN, NORWAY 4222
Katie Overton, Gaute Mo, Ivana Katavic, Manuel Sánchez-Solís

CASE STUDY IN THE NEXT GENERATION OF POINT-SUPPORTED CLT STRUCTURES..... 4232
Jamie Pobre Sullivan, Carla Dickof, Christian Slotboom

TALLWOOD 1: LESSONS LEARNED ON COMPLETION OF CANADA'S FIRST 12 STOREY TIMBER-STEEL HYBRID BUILDING 4240
Ornagh Higgins, Ilana Danzig, Brendan Fitzgerald, Jackson Pelling, Mehrdad Jahangiri

SUITABILITY OF SLIM-FLOOR STEEL-TIMBER COMPOSITES AS INTERMEDIATE FLOOR CONSTRUCTIONS - CASE STUDY BASED ON PROJECTS IN FINLAND 4247
Aku Aspila, Lauri Lepikonmäki, Sami Pajunen

THE BV2020 SOLUTION – GOING BIG WITH LIGHT TIMBER STRUCTURES..... 4253
Knut Magnar Sandland, Julia Bosnes Tønne, Per Gunnar Nordløkken

THE BENEFITS AND CHALLENGES OF WOOD IN HIGH CORROSIVE SURROUNDINGS 4259
Sigurdur Gunnarsson, Tim Skotheimsvik

THE NEW CENTRE FOR ADVANCED TIMBER TECHNOLOGY: A LIVING LAB FOR DESIGNERS, INDUSTRY, AND EDUCATION..... 4265
Gabriele Tamagnone, Robert Hairstans

QUANTIFYING AND REDUCING EMBODIED CARBON IN THE ACOUSTIC DESIGN OF MASS TIMBER BUILDINGS..... 4273
James Bligh

NEW HQ COPENHAGEN A NEW STANDARD FOR SUSTAINABLE BUILDINGS IN AN INTERNATIONAL CORPORATION 4279
Elias Mohr Wilson, Dorthe Keis, Mai Marcussen Yoon

A WORKABILITY AND SUSTAINABILITY ASSESSMENT OF MULTI-STOREY EARTHQUAKE-RESISTANT TIMBER BUILDING..... 4286
Kazuki Tsuda, Ahmad Ghazi Aljuhmani, Arata Minegishi, Yutaka Goto, Masaki Maeda

COMPUTATIONAL DESIGN DEVELOPMENT OF A WOODEN FAÇADE SYSTEM..... 4295
Camilla Schlyter, Karin Sandberg

STUDY CASE: REFURBISHMENT OF THE GARE MARITIME IN BRUSSELS 4303
Charline Lefèvre

WIDE-SPAN LVL ROOF STRUCTURE FOR AN INDOOR SWIMMING POOL 4309
Laurent Giampellegrini, Samuel Blumer, Hendrik Pfeffinger

DESIGN OF A TALL MASS TIMBER TOWER FOR OCCUPANT COMFORT UNDER WIND-INDUCED ACCELERATIONS 4316
Laurent Giampellegrini, Anthony Rety, Guillaume Caussarieu, Tim Sleik, Lucia Theurer, Johannes Pohl, Tobias Wacker

BUILDING INFORMATION MODELING OF A TIMBER BRIDGE – A CASE STUDY 4325
Alvdis Hardeng

NLT DEVELOPMENT FOR BRAZILIAN MARKET – TESTS AND USE 4332
Carlito Calil Neto, Alexander Takata, Vitor Afonso Neves Silva

A SURVEY OF THE DESIGN OF TIMBER-CONCRETE HYBRID BUILDINGS IN SWEDEN 4338
Carl Larsson, Michael Dorn

CASE STUDY: A 10-STOREY TIMBER BRACED FRAME AND CLT STRUCTURE IN VANCOUVER, BC 4345
Carla Dickof, Robert Jackson, Jenna Kim, Ashkan Hashemi

HUT – INDOOR CLIMBING CENTRE, SKIEN, NORWAY 4353
Katie Overton, Gaute Mo, Fernando Ibañez, Sondre Dolsvåg

ECONOMIC COMPARISON OF MASS TIMBER AND CONCRETE CONSTRUCTION IN THE NORDIC REGION 4360
Julie Swartz Andersen, Yutaka Goto, Michael Englund, Henning Johansen, Ketil Armann Hansen, Alexander Hollberg, Daniela Grotenfelt

THE RELATIONS IN THE PLANAR AND SECTIONAL SCALES AND KAN COMPOSITION OF TRADITIONAL KOREAN ARCHITECTURE 4370
Sangyeon Park, Bonghee Jeon

COMPARATIVE RESEARCH OF SINGLE-FAMILY HOUSING CONSTRUCTION SYSTEMS BY CONSTRUCTION COST USING STRUCTURAL WOOD AND OTHER MATERIALITY 4377
Carlos Kahler, Janina Gysling, Daniel Soto, Wilson Mejías, Francisco Jiménez, Carolina Molina

CASE STUDY ON A LARGE-SCALE TIMBER ACADEMIC BUILDING DESIGNED TO ADDRESS CURRENT INDUSTRY CHALLENGES 4383
Javier Fierro, Herry Chen, Tyler Hull, Andrea Atkins, Daniel Lacroix

EUPHORBIA: MASS TIMBER STADIUM 4393
Alexandros Kitriniaris, Sotiris Monachogios, Zannis Konteas

PLASTIC DESIGN OF BESPOKE INTERLOCKING TIMBER-TO-TIMBER CONNECTIONS FOR ROBOTIC ASSEMBLY 4399
Davide Tanadini, Giulia Boller, Pok Yin Victor Leung, Pierluigi D'Acunto

CASE STUDY: TERMINUS – NEW FRONTIERS IN HYBRID MASS TIMBER SEISMIC DESIGN 4409
Brendan Fitzgerald, Ilana Danzig, Mehrdad Jahangiri, Ornagh Higgins, Jackson Pelling

HARDWOOD GLULAM IN COMPLEX STRUCTURES: DESIGN AND CONSTRUCTION OF THE MACA MUSEUM IN URUGUAY 4415
Vanesa Baño, Leandro Domenach, Carlos Mazzey, Thomas Vieillard, Jean-Bernard Journot

CASE STUDY – THE USE OF ROBOTICS IN THE CONSTRUCTION OF TIMBER STRUCTURES USING WESTERN AUSTRALIA'S LARGEST MASS ENGINEERED TIMBER BUILDING AS A TEST BED 4423
Ralph Belperio, Pratik Shrestha

VALIDATING MOISTURE-SAFE ENERGY EFFICIENT CLT ASSEMBLIES IN HOT AND HUMID CLIMATES USING EXPERIMENTAL TESTING 4429
Marcus Strang, Paola Leardini, Maryam Shirmohammadi

LOAD LEVELS AND CRITICAL DESIGN ISSUES IN A MULTI-STOREY RESIDENTIAL TIMBER BUILDING BUILT UP BY PREFABRICATED VOLUMETRIC ELEMENTS 4439
Johan Vessby, Tomas Forsberg, Marie Johansson, Rajan Maharjan

ARBORETUM, THE LARGEST EVER WOOD OFFICE CAMPUS IN EUROPE: TECHNICAL, ORGANIZATIONAL, AND SUSTAINABILITY CHALLENGES : AN EXAMPLE OF LOW CARBON PROJECT FAR BEYOND THE ALIGNMENT WITH THE EUROPEAN TAXONOMY 4447
Laurent Petit, Renaud Blondeau-Patissier

CLEAR THE STAGE FOR TIMBER CONSTRUCTIONS 4453
Jonas Schmidt

TRANSFORMATION OF RECLAIMED MATERIALS FROM BARN BUILDINGS – DESIGN OF A NEW TIMBER BUILDING FRAME..... 4460
Terje Planke, Kristine Nore, Victoria Rygh Nordhagen, André Bockelie, Dimitrios Kraniotis

5.3. PUBLIC INCENTIVES AND STRATEGIES

DESIGN OF THE ROADMAP FOR THE CONSTRUCTION OF WOODEN SOCIAL HOUSING IN URUGUAY 4465
Juan José Ugarte, Andres Sierra, Keren Codriansky, Marcia Croci, Carolina Pérez-Gomar, Virgina Campodónico

5.4. INDUSTRY STRATEGIES TO IMPROVE MODERN TIMBER USE IN CONSTRUCTIONS

USING ARIMA MODELS TO PROJECT SAWLOGS, AND SAWN WOOD PRICES IN THE CHILEAN CONSTRUCTION MATERIALS MARKET..... 4475
Wilson Mejías, Janina Gysling, Carlos Kahler, Daniel Soto, Evaristo Pardo

CHARACTERIZATION OF GLUED-LAMINATED TIMBER SUPPLY IN CHILE 4483
Janina Gysling, Carlos Kahler, Daniel Soto, Wilson Mejías, Pamela Poblete

ESTIMATING THE GLUED-LAMINATED TIMBER DEMAND IN THE NON-RESIDENTIAL BUILDINGS IN CHILE..... 4491
Daniel Soto, Janina Gysling, Carlos Kahler

DIGITAL TWIN FRAMEWORK FOR VISUAL EXPLORATION OF MATERIAL FLOWS AND CARBON IMPACTS OF ENGINEERED WOOD PRODUCT CHAINS FROM FOREST TO BUILDINGS 4496
Stephan Ott, Andreas Rudenå, Uwe Kies, Anna Wagner, Oliver Jancke

MATERIAL DISRUPTION: CROSS-LAMINATED TIMBER IN TEXAS 4505
Ulrich Dangel

ACCELERATION OF UNITED STATES MARKETS FOR WOOD 4513
Bill Parsons, Brian Brashaw

RECENT ADVANCEMENTS IN MASS TIMBER CONSTRUCTION TECHNOLOGIES IN CANADA 4518
Mohammad Mohammad, Julie Tourrilhes, Richard Coxford, Miranda Williamson

INVESTING IN MASS TIMBER CONSTRUCTION IN AUSTRALIA: THE CLEAN ENERGY FINANCE CORPORATION TIMBER BUILDING PROGRAM 4528
Christina Wijeratne, Paolo Lavisci

TOWARDS A BROADER USE OF WOODEN CONSTRUCTION MATERIALS: INTERMEDIARY ORGANISATIONS IN THE SUSTAINABILITY TRANSITION OF THE CONSTRUCTION SECTOR 4535
Antje Klitkou, Lina Ingeborgrud

STATUS QUO OF AUSTRIAN TIMBER CONSTRUCTION SECTOR 4545
Aida Santana Sosa, Martin Aichholzer, Elena Mitrenova, Iva Kovacic

THE ROLE OF BOARD INTERLOCKS IN INCREASING THE USE OF WOOD IN CONSTRUCTION 4555
Silje Marie Svartefoss

HARMONISATION OF THE ENVIRONMENTAL PRODUCT DECLARATIONS FOR WOOD PRODUCTS 4565
Lauri Linkosalmi, Harald Schwarzschachner, Tuovi Valtonen

5.5. EDUCATIONS AND FUTURE TRENDS

6X6X6: INTRODUCING THE CONCEPT OF REUSE OF TIMBER MATERIALS IN THE 1ST YEAR OF ARCHITECTURAL EDUCATION 4571
Colm O'Brien, Anna Røtnes, Mads Øiern, Petter Kveseth, Lone Sjøli, Sindre Wam, Katherina Putzer, Kristoffer Røgeberg

FINDINGS FROM THE 2022 NORTH AMERICAN MASS TIMBER RESEARCH NEEDS ASSESSMENT WORKSHOP 4576
Samuel L. Zelinka, Richard Bergman, Marco Lo Ricco, William A. Martin, Bill Parsons, Iain Macdonald, Jennifer Cover

HYBRIDTIM, DESIGN AND CONSTRUCTION OF ENVIRONMENTAL HIGH PERFORMANCE HYBRID ENGINEERED TIMBER BUILDINGS 4583
Kamyar Tavoussi, Alireza Fadai, Laia Haurie

HIBIWOOD – DIDACTIC APPROACHES FOR ACADEMIC EDUCATION ON MULTI-STOREY TIMBER BUILDINGS 4590
Elena Mitrenova, Martin Aichholzer, Aída Santana Sosa

HORIZONTAL AND VERTICAL KNOWLEDGE MANAGEMENT IN MULTIDISCIPLINARY RESEARCH AND DESIGN-BUILD TEACHING: A TIMBER-ONLY TRAIL 4597
Günther H. Filz, Gengmu Ruan

RESOURCE-EFFICIENT MATERIALIZATION | SUSTAINABILITY FUTURE TRENDS 4604
Alireza Fadai, Daniel Stephan

PROFESSIONAL WORKSHOP IN WOOD: STRUCTURAL EFFICIENCY INDEX, FOR ARCHITECTURE STUDENTS 4611
Martín Hurtado C., Andrés Sierra M.

THEORISING A NEW EDUCATIONAL AGENDA FOR SUSTAINABLE BUILT ENVIRONMENT PROFESSIONALS: TIMBER TECHNOLOGY, ENGINEERING, AND DESIGN PROGRAMME 4619
Aghlab Al-Attili, Robert Hairstans, Tim Belden, Gabriele Tamagnone, Sarah Hitts, Tabitha Binding, Joseph Walters

FIRE SAFE USE OF WOOD IN BUILDINGS - GLOBAL DESIGN GUIDE 4627
Christian Dagenais, Andy Buchanan, Birgit Östman, Michael Klippel, David Barber, Ed Claridge, Andrew Dunn, Paul England, Marc Janssens, Alar Just, Esko Mikkolo, Colleen Wade, Norman Werther

World Conference on Timber Engineering Oslo 2023

COMPARISON OF THE STRUCTURAL CAPACITY OF SHEAR WALLS SHEATHED WITH ORIENTED STRAND BOARD AND CELLULOSIC FIBER BOARD SUBJECTED TO CYCLIC LOADING

David W. Dinehart[1], Eric S. Musselman[2], Edward D. Bolte[3], Bridget LaSala[4]

ABSTRACT: Eight wood framed shear walls were subjected to the ASTM E2126-11 cyclic testing protocol at 0.5 Hz. Four 2.44 m x 3.66 m shear walls were sheathed with 12 mm (15/32") thick oriented strand board (OSB), oriented vertically and connected to the frame with 60 mm x 2.9 mm (2 3/8" x 0.113") nails spaced at 150 mm along all edges. Four walls were sheathed with 3.43 mm thick Cellulosic fiber board (CFB) sheathing connected to the frame with 16-gauge, 23.8 mm (15/16") crown staples spaced 75 mm on center along the perimeter and in the field. The TPB sheathing is comprised of 94% post-consumer recycled materials.

Hysteresis results show that both the OSB and CFB walls exhibited typical wood frame shear wall behavior, characterized by elliptical hysteresis with pinched behavior at low levels of displacement. For cycles 1 through 31 (displacements less than 25 mm), the percent difference in average load capacity from the CFB and OSB walls ranged from +10% to -1.2%. At large displacements (greater than 45 mm) the CFB walls exhibited less capacity than the CFB walls. The OSB average maximum load is 25.9 kN and occurs at a wall displacement of 61 mm (cycle 35), while the CFB average maximum load is 24.1 kN at a displacement of 43 mm (cycle 32).

KEYWORDS: wood shear wall, sustainable sheathing, recycled sheathing, load capacity, cyclic testing

1 INTRODUCTION

Plywood and oriented strand board (OSB) have traditionally been the most common and effective sheathing used on wood shear walls to provide strength against lateral loads. Drawbacks to utilizing traditional sheathing include construction time, moisture absorption, and in recent years, wildly fluctuating prices. Cellulosic fiber board (CFB) serves as an alternative to traditional sheathing. Construction utilizing CFB can be more efficient (time and effort); it can be moisture and mold resistant; and it is largely made from post-consumer material making its prices more stable. It is critical that the strength of these materials be understood for use in wood shear walls subjected to lateral loading.

2 BACKGROUND

Seismic and wind forces acting on wood structures are generally carried by wood framed shear walls. Until the mid 1980's shear walls were sheathed with plywood. At this time the use of oriented strand board gained in popularity and acceptance for lateral force resistance. [1] Research demonstrated that shear walls sheathed with comparable thicknesses of plywood and OSB performed similarly under static and cyclic lateral loading. Load capacity, walls stiffness, energy dissipation and failure modes were nearly identical. [2, 3]

While the construction industry continues to investigate sustainable, green, and recycled materials, CFB has not gained the same widespread acceptance as OSB. This may be in part due to the strength of CFB not being well understood. A review of the strength and stiffness of oriented wood and cellulose-fiber materials that indicates the strength potential inherent to biobased cellulosic materials has been conducted to ascertain their suitability for potential applications.[4] Each type of material was described in terms of structure and corresponding representative values for strength and modulus of elasticity in fiber direction.[4]

Structural sheathing products utilizing CFB can be made from recycled material, are much thinner than comparable OSB panels, and are connected to the wall framing via staples. Proprietary information regarding the strength of these products is shared with manufacturers; however,

there has been little published data available. The structural sheathing utilized in this study is made from 94% post-consumer recycled materials and is marketed as Thermo-Ply®.[5]

3 SHEAR WALL TEST SPECIMENS

Eight, 2.44 m tall x 3.66 m long (8' x 12') shear walls were supplied by Ox Engineered Products, LLC. All studs and plates consisted of 2x4 SPF No. 2 lumber, with studs spaced at 406 mm (16") on center, continuous bottom and top plates, top plates fastened with 76.2 mm x 3.33 mm (3" x 0.131") nails at 610 mm (24") on center, staggered from each side. Studs were fastened to the plates with two 76.2 mm x 3.33 mm (3" x 0.131") toenails. Double end studs (each end) were fastened with 76.2 mm x 3.33 mm (3" x 0.131") nails at 609.6 mm (24") on center from each side.

Four walls were sheathed with OSB, oriented vertically, and connected to the frame with two 9.53 mm x 2.87 mm (3/8" x 0.113") nails spaced at 152 mm (6 inches) along all edges. Four walls were sheathed with CFB oriented vertically and connected to the frame with 16 gage, 23.81 mm (15/16") crown staples [minimum penetration of 25.4 mm (1") into the stud] with the crown parallel to the framing and spaced 76.2 mm (3") on center along the perimeter and in the field. The staple head was in contact with the CFB surface. The edge distance for all fasteners was 9.53 mm (3/8") and sheathing panel joints were butted. Figure 1 shows a completed CFB wall. The CFB used in this study was ThermoPly Blue.

Figure 1: *CFB Shear Wall Test Specimen*

4 EXPERIMENTAL TEST SETUP

4.1 TEST FRAME AND LOADING MECHANISM

The test frame consists of a frame base, actuator, load spreader device, and lateral restraints. An elevation of the framing plan is exhibited in Figure 2. Three W8x24 beams in series formed the frame base of the system. The beams were anchored to the concrete floor to ensure no slippage of the frame during the test. A 38.1 mm thick by 88.9 mm wide (1 ½" x 3 ½") plate was welded to the top flange of each beam, allowing for sheathing rotation and deformation without interference by the beam flange.

Threaded holes, 22.23 mm (⅞") in diameter, were drilled every 203 mm (8 inches) into the plate to accommodate the different anchorage patterns needed for the various wall configurations. Two 3.66 m 50.8 mm x 101.6 mm (12'-0" 2"x4") pieces of #2 Hem Fir were placed atop the welded plate, anchored to the beams using four 19.05 mm (¾") diameter hex bolts, and tightened down in countersunk holes to be flush with the wood surface. Two additional 19.05 mm (¾") holes were drilled, one at either end of the planks and in line with the existing holes of the welded plate, to accommodate the 15.88 mm (⅝") anchor bolts of the 10-gauge Simpson Strong-Tie HD5B hold-down anchors at the corners of the shear walls.

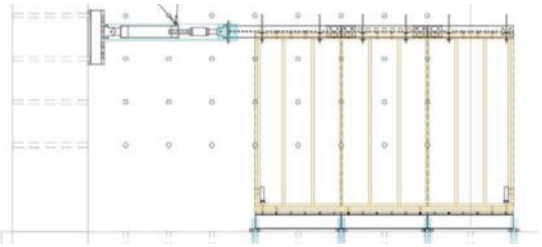

Figure 2: *Elevation view of experimental test setup*

The two 50.8 mm x 101.6 mm (2"x4") boards were incorporated to provide a realistic connection between the bottom plate and frame base. The single bottom plate of shear wall is nailed to the 50.8 mm x 101.6 mm (2"x4") plates using 76.2 mm x 3.33 mm (3"x0.131") nails at 152 mm (6") on center to resemble the connections used in practice and to lessen the influence of the support stiffness on the shear wall stiffness and ultimate capacity.

A hydraulic actuator was used to impart the lateral load during the testing sequence. Connected to the actuator, the load spreader acts as the mechanism imparting the horizontal force of the actuator to the wall specimen. The load spreader consisted of three W10x30 beams, situated such that the beam web rests on the top plate of the wall. The W10x30 beams were connected at each end using 12.7 mm (½") plates and 8 bolts on each side.

To connect the load spreader and the shear wall, 300 mm long, 19.05 mm diameter (1'-0", 3/4") rods were threaded through the beam web holes and corresponding holes in the shear wall double top plate. The rods were anchored to the shear wall top plate using a plate washer and nut on either end, such that the rod could not move, and the load spreader sits directly on the nut. A brass bushing was threaded through the hole in the beam web to ensure no slippage laterally between the rod and the load spreader. However, vertical movement was allowed as there was no restraint above the load spreader. The purpose of this connection was to prevent the stiffness of the load spreader from impacting the wall behavior.

https://doi.org/10.52202/069179-0001

To eliminate out-of-plane movement by the shear wall during testing, additional bracing was provided by roller bearings along the top of the framing system. As shown in Figure 3, roller supports were spaced every 1.22 m (4 feet) and positioned to be in contact with the flanges on both sides of the load spreader beam. A total of 6 rollers were mounted on columns anchored to the strong floor and cantilevers anchored to the strong wall.

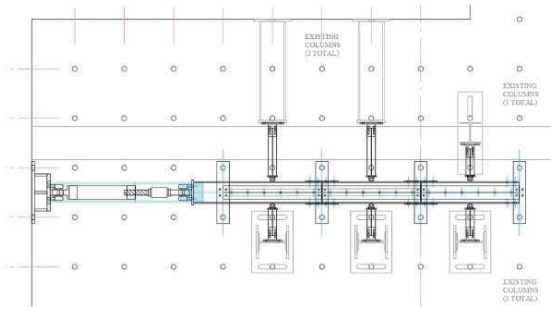

Figure 3: *Plan view of experimental test setup*

4.2 TESTING PROTOCOL

ASTM E2126-11, Test Method C, the CUREE Basic Loading Protocol was used for all tests. The basis for the loading sequence is a reference displacement founded on the maximum displacement, D, for which the specimen exhibits acceptable behavior when undergoing the given protocol. Alternatively, it can be described as a fraction of the reference displacement D_m, the displacement where the load of the primary cycle remains greater than 80% of the ultimate load on the degradation portion of the monotonically loaded curve. The reference displacement cannot exceed 1/40 the height of the wall, or 60.96 mm (2.40 in.) for the given specimen. For these tests, 60.96 mm was used. Figure 4 provides a graphical representation of the procedure.

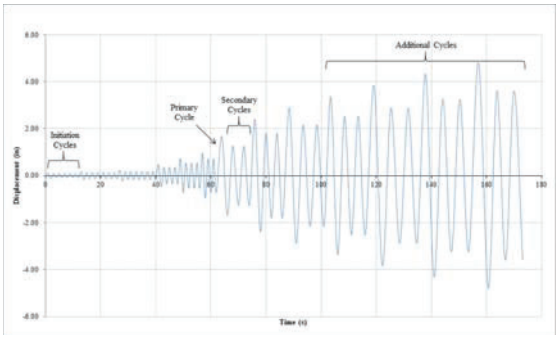

Figure 4: *ASTM E2126-11, CUREE Basic Loading Protocol*

To begin the loading sequence, six low amplitude initiation cycles are performed to allow equipment calibration. Following the first set, the remaining steps have a singular primary cycle amplitude a fraction of the established reference displacement, and several trailing secondary cycles of an amplitude 75% of the primary cycle. The amplitude and cycles for each set of cycles are provided by the standard, and the sequence is performed until failure occurs. Due to loading rate restrictions by the actuator, the frequency of the cycles decreased at higher amplitudes. The first 31 cycles of testing were rated at 0.50 Hz. The remaining cycles were measured as follows: Cycles 32 to 37 (0.25 Hz), and Cycles 38 to 43 (0.2 Hz).

5 EXPERIMENTAL RESULTS

5.1 OSB SHEAR WALL TEST RESULTS

Figure 5 presents the hysteresis plot for OSB shear wall specimen 3. This was typical of the four tests and is characterized by pinched behavior at small displacements with large loops for the primary cycles (1, 7, 14, 21, 25, 29, 32, 35, 38, 41).

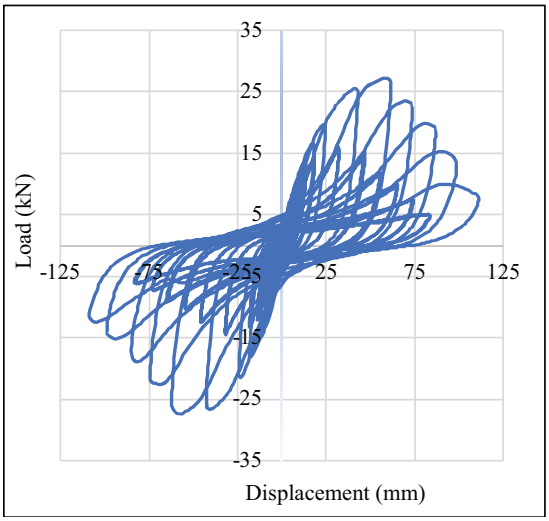

Figure 5: *Typical hysteresis plot for OSB walls (Test 3).*

Table 1 provides a summary for maximum load (P) at each primary step cycle for each shear wall tested, the average load, and the standard deviation. Maximum loads for each shear wall are shown in italic. A maximum average load capacity of 25.9 kN (5.8 k) was achieved during cycle 35 at a displacement of 61.0 mm (2.4 in). Tests were repeatable as evidenced by the standard deviations presented.

There were no visible signs of damage in the OSB walls at displacements below 25.4 mm (1 inch). As displacement levels increased nail pullout along the bottom and seams of OSB walls became evident. Beyond the maximum load, more significant nail deformation was seen, and the sheathing was separated from the frame along some seams and bottom edge. Some nails were broken.

5.2 CFB SHEAR WALL TEST RESULTS

Figure 6 presents the hysteresis plot for CFB shear wall specimen 3. This was typical of the four tests and is characterized by pinched behavior at small displacements with larger loops for the primary cycles compared to the secondary cycles.

Table 2 provides a summary for maximum load (P) at each primary step cycle, the average load, and the standard deviation. Maximum loads for each shear wall are shown in italic. A maximum average load capacity of 24.1 kN (5.4 k) was achieved during cycle 32 at a displacement of 42.7 mm (1.68 in). Tests were repeatable as evidenced by the standard deviations.

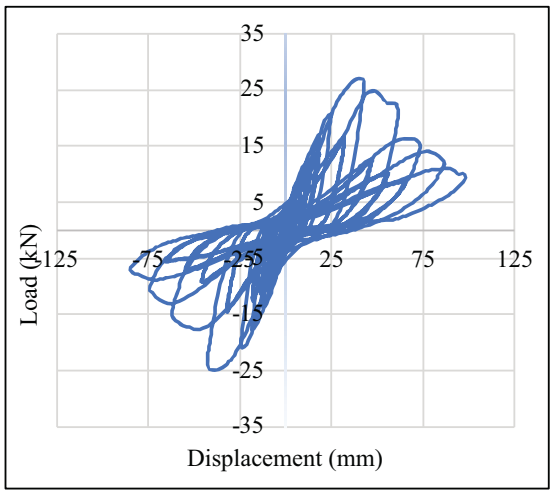

Figure 6: *Typical hysteresis plot for CFB walls (Test 3).*

Table 2: *Experimental CFB shear wall capacity*

Step	Cycle	Δ	Cellulosic Fiber Board (CFB) Walls					
			1	2	3	4	AVG	STD
		[mm]	P [kN]	P [kN]	P [kN]	P [kN]	P [kN]	P [kN]

10	41	80.3	11.7	10.6	11.4	11.4	**11.3**	0.42

There were no visible signs of damage in the CFB walls at displacements below 25.4 mm (1 inch). As displacements increased beyond 25.4 mm (1 inch), the CFB walls exhibited additional damage. Post ultimate load the CFB sheathing buckled between vertical framing studs. Following test completion, residual damage included highly deformed, unattached, and broken staples, as well as buckled sheathing.

5.3 COMPARISON OF OSB AND CFB LOADS

Table 3 presents a comparison of the average shear wall loads corresponding to the primary displacement cycles for both OSB and CFB walls. The percentage difference between the walls is also presented. For displacements below 12 mm (0.5 in) the CFB walls are slightly stiffer than the OSB walls. Between 12 mm (0.5 in) and 24 mm (1 in) the walls have the same load capacity.

The walls reached maximum capacity at different levels of displacement. At a displacement of 42.7 mm (0.47 in) the CFB reaches the maximum capacity of 24.1 kN (5.4 k), while the OSB reaches the maximum capacity of 25.9 kN (5.8 k) at a displacement of 61.0 mm (2.4 in)

Table 3: *Shear wall capacity and percent difference.*

Step	Cycle	Δ	OSB	CFB	Percent
			Avg Load	Avg Load	Difference
		[mm]	[kN]	[kN]	[%]
1	1	3.0	5.5	5.9	5.7
2	7	4.6	7.1	7.4	4.7
3	14	6.1	8.3	8.7	5.1
4	21	12.2	13.1	13.0	-1.2
5	25	18.3	16.8	16.6	-1.0

10	41	80.3	18.5	11.3	-38.9

https://doi.org/10.52202/069179-0001

Figure 7 presents the data in Table 3 graphically. The load displacement response of the OSB and CFB shear walls is comparable up to a displacement of 42.7 mm (1.68 in). The drift limit used in wood shear wall design is generally far below this level of displacement. Beyond cycle 32 the CFB walls start to lose capacity while the OSB walls continue to carry addition load until cycle 35. Following maximum capacity both walls lose structural capacity; however, the CFB walls deteriorate at a far greater rate. This was verified visually by the damage patterns exhibited during testing as well.

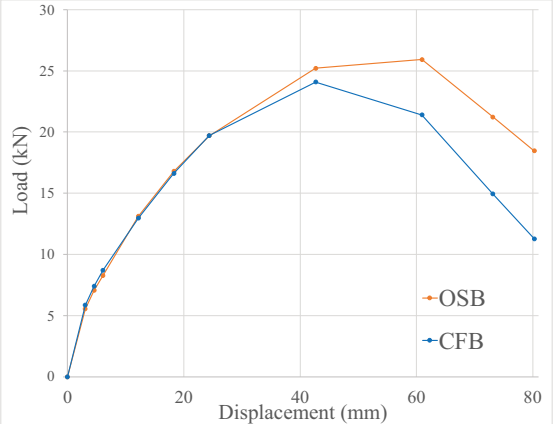

Figure 7: *Backbone plots for OSB and CFB shear walls.*

6 CONCLUSIONS

The four OSB and four CFB walls tested behaved as typical shear walls with repeatable results when subjected to ASTM E2126, Test Method C, CUREE Basic Loading Protocol. It is concluded that the OSB and CFB walls were structurally equivalent up to approximately 42.7 mm (1.68 in) of wall displacement.

The OSB average maximum load was 25.9 kN (5.8 k) at a wall displacement of 61 mm (2.4 in) (cycle 35), while the CFB average maximum load was 24.1 kN (5.4 k) at a displacement of 42.7 mm (1.68 in) (cycle 32). The CFB walls lost capacity at a faster rate than the OSB walls beyond the maximum load as the sheathing buckled.

Additional testing of shear walls sheathed with CFB is needed to verify comparable performance to OSB for other conditions, such as large window and door openings and/or alternative loading sequences.

ACKNOWLEDGEMENT

The authors thank Mulhern and Kulp, Inc. for financial support for this research. The guidance of Nicholas Martignetti and Richard Zabel is greatly appreciated. The authors are grateful for the laboratory assistance and support provided by Jeff Cook, Director of the Structural Engineering Teaching and Research Laboratory at Villanova University.

PENDULUM IMPACT HAMMER TESTS ON TIMBER BEAMS – EXPERIMENTAL SETUP

Alex Sixie Cao[1], Andrea Frangi[2]

ABSTRACT: In this paper, a test setup for conducting impact testing of full-size timber beams is presented. The test setup comprises a pendulum impact hammer with an effective length of 4750 mm, mass of 3475 kg, and can be released from a near-horizontal position. On the impact hammer, 100g accelerometers and a shock-resistant high-speed camera with a capacity of up to 5700 pictures per second were installed. In addition, other cameras were installed, as well as an angular encoder to record the position of the pendulum impact hammer. The pendulum impact hammer was released using an electromechanical release system attached to a crane. The impact hammer was designed for impact tests on timber beam specimens with cross-sections ranging from 160x160 mm to 200x320 mm and lengths between 2700 and 4300 mm. The results include the energy release of the specimens upon failure, peak impact forces, time to failure, and high-speed imagery. With the test setup, similar knowledge can be gained for other engineered wood products.

KEYWORDS: Glued laminated timber, Impact loading, Pendulum impact hammer, Full-size tests

1 INTRODUCTION

In recent years, the popularity and use of timber as a structural material for tall buildings and bridges has increased [1,2] as the drive for sustainability continues. Because of the growing volume of structural timber in our built environment, structural robustness and disproportionate collapse prevention [3–7] is receiving renewed attention from timber engineers worldwide as timber buildings reach record heights with recent technological developments [3,8–15].

To assess the collapse behaviour and resistance of timber buildings, advanced numerical models are needed [4]. An important feature of the numerical models is the ability to simulate member failure and separation from rapid loading [3,14,15]. The rapid loading may stem from impact loading from vehicles, falling debris, projectiles, explosion debris, blast loading, and more.

Previous impact tests on wood or timber were conducted on 10 to 20 mm square small clearwood [16], 50 to 150 mm square lumber [17,18], and single boards [19–21] using either a small pendulum impact hammer or a drop test. However, the size effects in timber are considerable because of the natural growth imperfections in wood such as knots, distorted grains, and more [22,23]. In addition, the results from single boards cannot be generalised to glued assemblies, such as glued laminated timber (GLT) or laminated veneer lumber (LVL). Thus, it is necessary to conduct full-size impact tests on engineered wood products commonly used in practice.

Timber is known to be rate-dependent, which is reflected in the current set of design codes in Europe [24,25]. However, the shortest codified loading duration is in the order of seconds, which is not valid for impact loading, where the loading occurs within milliseconds [26].

To address these challenges, pendulum impact hammer tests were conducted on 86 full-size spruce GLT specimens without finger joints and nine full-size beech laminated veneer lumber specimens. The cross-sections were between 160×160 and 200×320 mm, and the lengths between 2700 and 4300 mm. The test setup was instrumented with accelerometers, angular encoders, and high-speed cameras. The effective length of the impact hammer was about 4750 mm, with a mass of 3450 kg.

In this paper, the conceptual framework and the most important aspects of the test setup are presented.

Data from the sensors are shown, as well as images from a high-speed camera. The full results of the experimental campaign are published in a test report [27]. The bespoke test setup was designed and built at ETH Zurich.

2 THEORETICAL FRAMEWORK

2.1 PENDULUM IMPACT HAMMER

A pendulum impact hammer setup was chosen because of the possibility of a direct measurement of the energy release E_r from the failure of a specimen. In such a setup, the energy balance can be written as:

$$m_p g h_0 = m_p g h_1 + E_r + E_c, \quad (1)$$

where m_p is the effective mass of the impact hammer, g=9.806 m/s^2 is the gravitational acceleration in Zurich, h_0 is the initial height of the impact hammer, h_1 is the post-impact height of the impact hammer, E_r is the energy release from the failure of the specimen, and E_c are other sources of energy loss, such as friction and drag. The

[1] Alex Sixie Cao, Institute of Structural Engineering, ETH Zurich, 8092 Zurich, Switzerland, cao@ibk.baug.ethz.ch
[2] Andrea Frangi, Institute of Structural Engineering, ETH Zurich, 8092 Zurich, Switzerland, frangi@ibk.baug.ethz.ch

https://doi.org/10.52202/069179-0002

concept of the pendulum impact hammer setup is shown in Figure 1, where L_{CM} is the length from the point of rotation to the centre of mass of the impact hammer, and θ_i are the initial and post-impact angles of the impact hammer. The energy release E_r can be used to find the peak dynamic impact force P_d and to quantify the toughness U_T of the tested material [28].

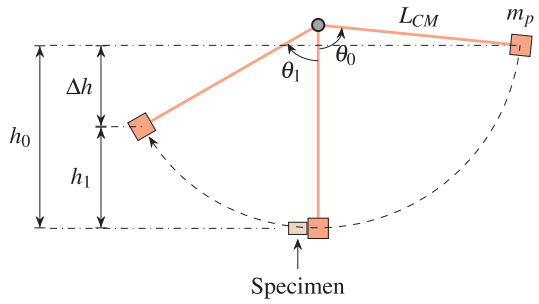

Figure 1: *Conceptual framework of the tests. The figure is reproduced from Cao et al.* [28].

2.2 PEAK IMPACT FORCE

To compare the energy release E_r in Equation (1) of different specimens or materials, it can be normalised with respect to the cross-sectional area A of the specimen:

$$U_T = \frac{E_r}{A}. \tag{2}$$

U_T in Equation (2) is defined as the toughness of the material. By assuming that the specimen can be idealised as an Euler-Bernoulli beam without shear deformations, and the load-displacement behaviour as linear-elastic perfectly brittle, the peak impact force P_d can be found by considering the equivalent single-degree-of-freedom system in Figure 3. In Figure 3, v_p is the impact velocity, U is the strain energy, U^* is the complementary strain energy, w is the mid-span deflection, and $k=48EI/L^3$ is the equivalent stiffness.

Since the load-displacement curve is linear-elastic perfectly brittle, the strain energy U is the same as the complementary strain energy U^*. The energy release E_r is the same as the strain energy U or the complementary strain energy U^*. Therefore, the peak impact force P_d can be found by considering the triangular area above the load-displacement curve:

$$E_r = \frac{1}{2}\frac{P_d^2}{k} \therefore P_d = \sqrt{2E_r k} = \sqrt{E_r \frac{96EI}{L^3}}, \tag{3}$$

where L is the length, E is the elastic modulus, and I is the second moment of area of the specimen. Equation (3) can also be found by following a strain energy approach.

If the collision between the impact hammer and the specimen is considered as perfectly inelastic until failure, the peak impact force P_d can be found by considering the deceleration a of the impact hammer. With Newton's second law, the peak impact force P_d can be expressed as:

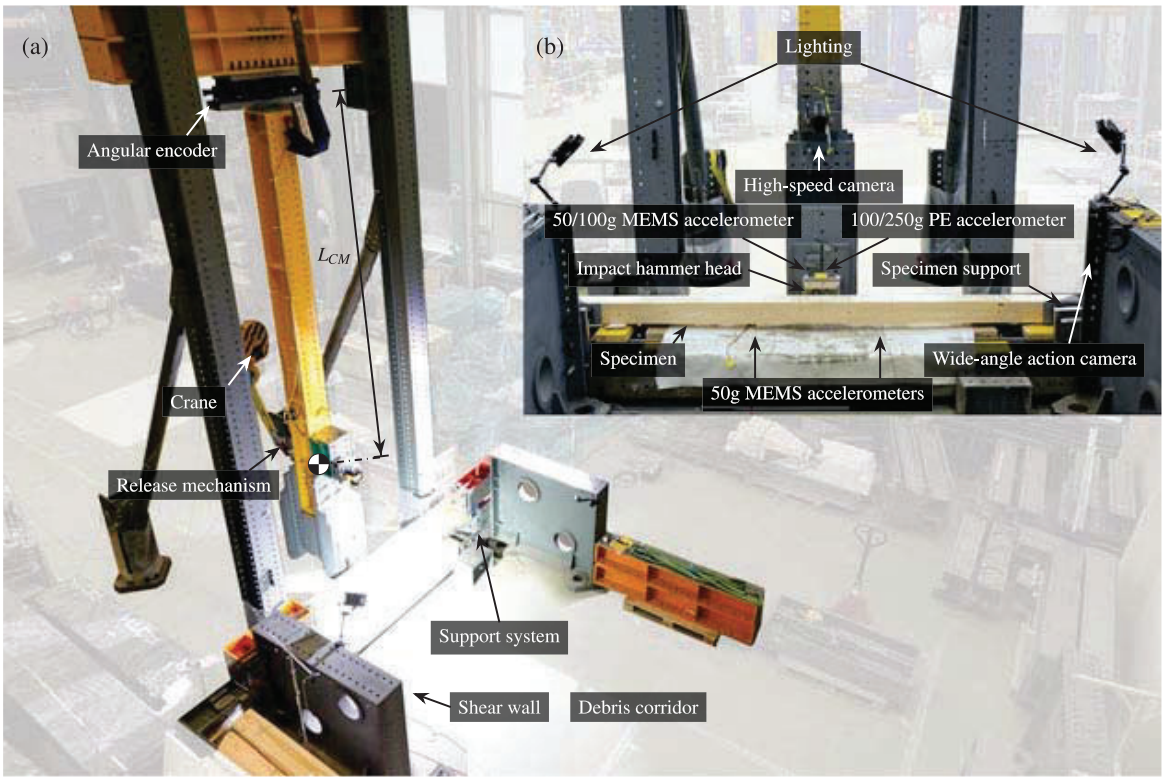

Figure 2: *Experimental setup, where PE denotes piezoelectric, and MEMS micro-electromechanical system. (a) Bird's-eye view; and (b) front view of the test setup. The figure is reproduced from Cao et al.* [28].

https://doi.org/10.52202/069179-0002

$$P_d = m_p a. \quad (4)$$

3 EXPERIMENTAL SETUP

3.1 PENDULUM IMPACT HAMMER

The test setup was designed using the computer-aided-design software Autodesk Inventor to accommodate simply supported specimens with and without axial restraints of dimensions between 160×160×2900 mm and 200×320×4300 mm. Because of the limited available information on the expected energy release E_r of the specimens, the energy capacity mgh_0 of the impact hammer setup was maximised. The length h_0 was constrained by the physically available space in the laboratory at ETH Zurich, and the mass m by the steel plates in the laboratory inventory. The effective length L_{CM} of the impact hammer became 4650 mm, and the mass was 3475 kg. The impact hammer could be raised to a maximum angle of about 87°, which results in a maximum potential energy mgh_0 of about 158 kJ.

To support the impact hammer, an S355 steel frame comprising two IPE 360×7040 mm columns and two stacked and bolted HEB 300×2050 mm beams was used, where the impact hammer was suspended from the HEB 300×2050 beams. To provide lateral stiffness to the frame in the pendulum's direction of motion, two ROR 159×25×4000 mm diagonal trusses were bolted to the IPE 360×7040 mm columns. The frame and the diagonal trusses were fixed to a strong floor using two M55 10.9 steel bolts for each steel footing, post-tensioned to 1000 kN. Most of the bolts were M24 8.8, with a few M16 8.8 bolts used in the shear pin. The experimental setup is shown in Figure 2.

3.1.1 SHEAR PIN & HINGE SYSTEM

The impact hammer was suspended from the two HEB 300×2050 mm beams via an elaborate hinge system. The hinge system comprised a Ø40×1210 mm 10.8 steel shear pin with a hardened surface, four double hinges, five single hinges, and various S355 adapter plates. In addition, steel tubes were attached at the ends of the shear pin to prevent the shear pin from sliding out of the hinges. This is shown in Figure 4.

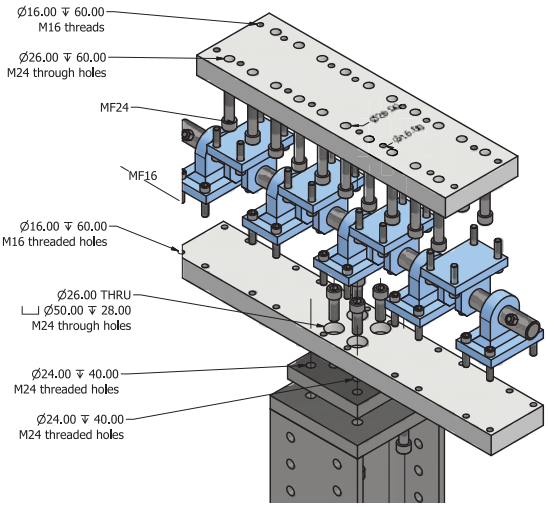

Figure 4: *Shear pin and hinge system, which connects the impact hammer to the pendulum frame. The figure is reproduced from Cao et al.* [27].

The shear pin was designed as a beam with a circular cross-section subjected to equidistant point loading on the characteristic material strength level. Since the hinges were standard inventory in the laboratory, the cross-section of the shear pin was fixed. Therefore, the design was focused on the necessary number of hinges to satisfy von Mises stresses on the characteristic level, as well as an L/400 maximum deflection criterion. The system was designed against a maximum shear force of 1000 kN, in combination with a 100 kN centrifugal force. The maximum allowable deflection was the governing design criterion. The thicknesses of the adapter plates were governed by the minimum thread length of the M24 bolts.

3.1.2 SPECIMEN SUPPORTS

The specimen ends were placed in steel brackets, which were bolted to rotation hinges. The hinges provided the simply supported support conditions. To enforce axial restraints, the specimens could be fixed to the steel brackets using glued-in or threaded rods. This is shown in Figure 5. In Figure 5a, the screws were mounted for transportation and were removed before testing.

To account for uncertainties in the specimen lengths and other parts of the setup, a sliding system with several centimetres of adjustability was designed. The sliding system comprised a steel plate with long holes, which was bolted to a shear wall. The reaction forces were transferred to the strong floor through the shear walls, which were connected to the pendulum frame via two connected HEB 300 mm beams. This is shown in Figure 6. To accommodate different specimen lengths, the shear walls could be moved with rough precision, and the steel plate with the long holes provided exact precision.

https://doi.org/10.52202/069179-0002

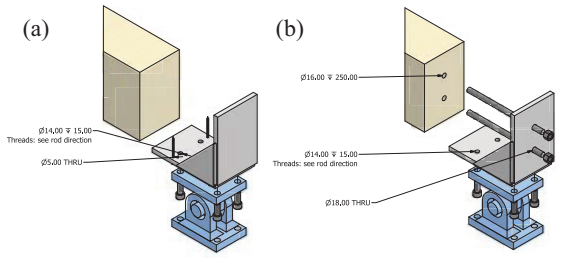

Figure 5: *Steel brackets with simply supported boundary conditions (a) without axial restraints, and (b) with axial restraints. The figure is reproduced from Cao et al.* [27].

For the axially unrestrained specimens, the halves of the specimens would fly out of the steel brackets in the direction of the impact hammer motion. However, this was not the case for the axially restrained specimens. Because of the axial restraints, the two halves were kept in the steel brackets by the glued-in rods. To prevent a reverse impact by the impact hammer on its return to the side of the initial release, a recoil control system was implemented for safety reasons. The recoil system comprised a pair of steel rods, which were released vertically after the first impact. This prevented the halves of the specimen from returning to its initial position, ensuring a gap that the impact hammer could return through. This is shown in Figure 7.

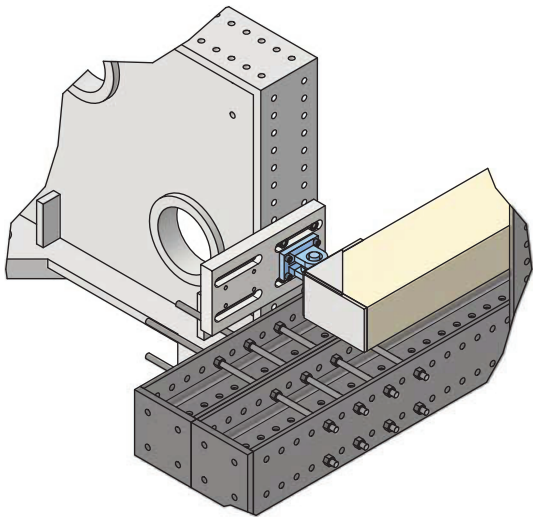

Figure 6: *Specimen support system. The figure is reproduced from Cao et al.* [27].

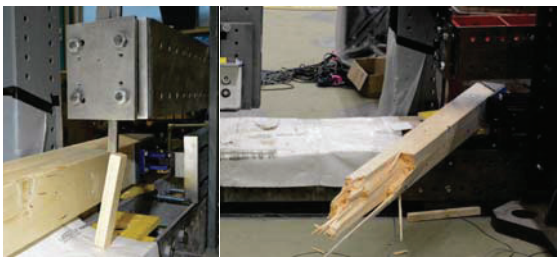
3.1.3 IMPACT HAMMER HEAD

The head of the impact hammer comprised steel plates of various dimensions to ensure a sufficient mass of the impact hammer. The steel plates were post-tensioned using M24 and M16 8.8 threaded rods. To provide a clean impact surface, a 300×350×70 mm S355 steel plate with rounded edges was machined and mounted at the tip of the impact hammer head. The effective contact surface between the impact hammer tip and the specimen was 250×200 mm. The total mass of the impact hammer head



(a) Activated rods. (b) Rods post-release.

Figure 7: *Recoil system for the axially restrained specimens. The figure is adapted from Cao et al.* [27].

was about 2736 kg. The total mass of the impact hammer, including instrumentation, was approximately 3475 kg, with a centre of mass from the shear pin of 4649 mm. The impact hammer head is shown in Figure 2b, and the impact hammer tip in Figure 8.

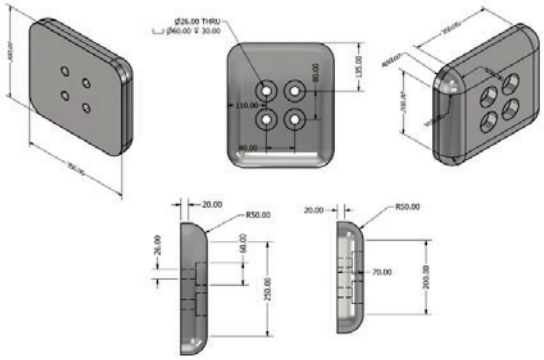


Figure 8: *Impact hammer tip. The figure is reproduced from Cao et al.* [27].

3.1.4 RELEASE SYSTEM

A crane was used to lift the impact hammer to its release height and an electromechanical release mechanism was used to release the impact hammer. This is shown in Figure 2a. Because the loading capacity of the electromechanical release mechanism was limited to 2500 kg, a load reduction system was necessary to reduce the weight $m_p g$ of the impact hammer on the electromechanical release mechanism.

The load reduction system comprised steel shackles, lifting slings, and a dynamic climbing rope. These parts were organised in a pulley system, such that the final load on the electromechanical release mechanism was reduced to $m_p g/6$. The load reduction system is illustrated in Figure 9. A dynamic climbing rope was preferred over steel cables or static ropes because of its ability to damp out vibrations and its flexibility and adjustability. The dynamic climbing ropes had a total length of approximately 1.6 m and were inspected after each test. Unless damage was detected during the visual inspection, they were used four to six times before being replaced. Figure of eight knots were tied at each end of the ropes, which is a standard knot used in sports climbing.

Once the release mechanism was triggered, the dynamic climbing rope would unloop itself from the shackles and remain on the crane. The induced energy loss from the

https://doi.org/10.52202/069179-0002

unlooping action was corrected for in the tests by comparing the energy loss between subsequent harmonic oscillations. This is described in Section 4.2.

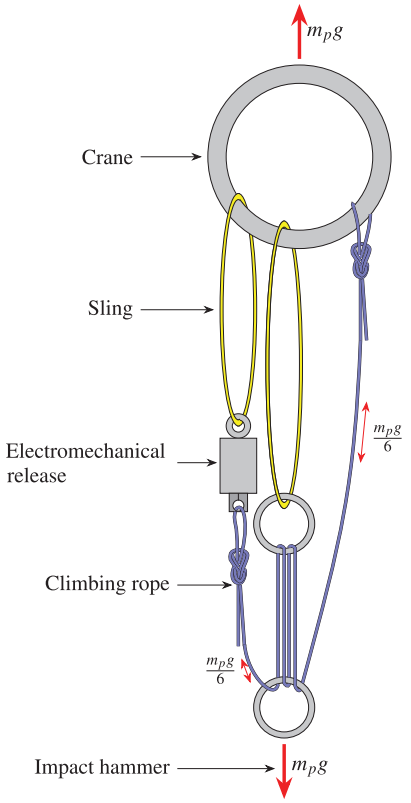

Figure 9: *Release and load reduction system of the impact hammer.*

3.2 CAMERAS AND SENSORS

To capture the impact and failure process of the specimen, several cameras were used. The main camera was an AOS M-VIT 4000 shock-resistant high-speed camera operating at 5700 pictures per second, which was mounted on the impact hammer facing the specimen. Because of the high frame rate and the sensor size of the camera, two GSVitec Multiled MT 50 000 lm lights were used with the camera. The AOS M-VIT 4000 camera was triggered to record for a minimum shock of 10g and had a memory capable of a few seconds of footage. Besides the AOS M-VIT 4000 camera, a GoPro Hero 10 action camera was mounted in the debris corridor to record the impact at 240 frames per second. The location of the AOS M-VIT 4000 and GoPro Hero 10 cameras can be seen in Figure 2b. A Nikon D7100 camera was placed at the end of the corridor and was also used to document the broken pieces of the specimen post-impact.

The primary measurement of the tests was the position of the pendulum, pre- and post-impact. This was recorded with an analog Baumer EIL580P angular encoder with a resolution of approximately 0.005°, which corresponds to a positional resolution at the centre of the impact tip of over 0.5 mm. The Baumer EIL580P was mounted at the shear pin, and its position can be seen in Figure 2a.

To measure the peak impact force P_d in Equation (4), accelerometers were mounted on the impact hammer beside the impact hammer tip in Figure 8. The positions of the accelerometers are shown in Figure 2b. Because of the difficulty in estimating the peak impact force P_d in the design phase, 10g micro-electromechanical (MEMS) accelerometers were initially used. In theory, the 10g MEMS sensors could measure impact forces of up to 700 kN. The estimated static strength for the shortest specimens with the largest cross-sections was in the order of 120 kN. After testing a few of the weakest specimens, it was apparent that the capacity of the 10g MEMS sensors was insufficient. Therefore, 50g and 100g MEMS sensors were ordered, with the same results. It was believed that piezoelectric accelerometers would give better results, which led to the use of 100g and 250g piezoelectric accelerometers. The capacities of these accelerometers were occasionally exceeded, which is equivalent to forces of over 6 900 and 13 800 kN, respectively. Upon post-processing of the accelerometer data and the high-speed imagery, this data was deemed unfit for determining the peak impact force P_d. This is discussed in Section 4.

10g MEMS accelerometers were used to measure the dynamic elastic modulus E_d of each specimen. Two 10g MEMS accelerometers were mounted ±500 mm from the mid-span of the specimens, and non-destructive impact hammer tests at the mid-span were used to induce vibrations in the specimens. The vibration data was then processed to find the natural period T_n. Together with the mass m of the specimen, the natural period T_n was used to compute the dynamic elastic modulus E_d.

A linear variable differential transformer (LVDT) was also used with a manual hand-crane and weights to conduct static three-point bending tests to find the static elastic modulus E_s. However, the displacements from the LVDT resulted in inconsistent static elastic moduli E_s. Therefore, the dynamic elastic modulus E_d from the vibration-based method was used for all further processing of the data. A complete list of the cameras and sensors can be found in Cao et al. [29].

4 RESULTS

4.1 HIGH-SPEED CAMERA IMAGERY

Images from the AOS M-VIT 4000 high-speed camera of a typical failure process are shown in Figure 10. Initially, the impact hammer made initial flat contact with the specimen at its centre. During the initial contact, momentum was transferred to the specimen via shock loading. This is shown in Figure 10a. After the initial impact, a gap formed between the impact hammer and the specimen. The first crack always appeared on the tension side of the specimen, and often in the outermost lamella close to a material imperfection. The first crack often developed when there was no physical contact between the impact hammer and the specimen. This is shown in Figure 10b. Eventually, the impact hammer made contact with the specimen again and pushed through the specimen. During this time, the failure propagated from the tension side towards the compression side of the specimen. This is shown in Figure 10c.

The high-speed imagery was used to describe the impact process qualitatively and uncovered a clear bouncing behaviour of the specimen on the impact hammer. The imagery enabled the classification of the failures into five different failure modes and the determination of the time to failure of each specimen [28,29].

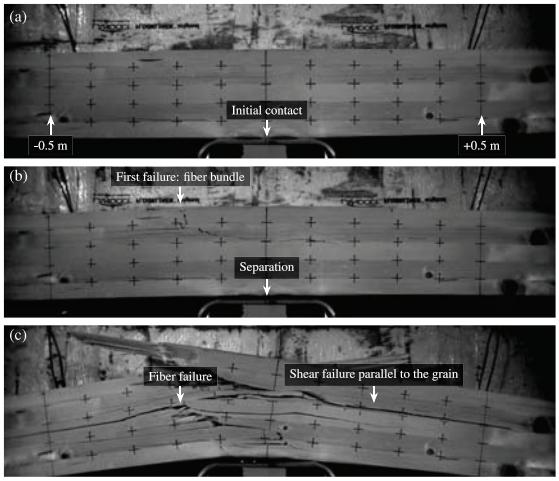

Figure 10: *Typical imagery and failure process from the AOS M-VIT 4000 high-speed camera with (a) initial contact between the impact hammer and the specimen at t=0 ms; (b) bouncing of the specimen with a gap forming between the impact hammer and the specimen at t=3.8 ms; and (c) full failure of the specimen with several failures at t=19.6 ms. The images are from tests on specimen 160×200×3600-F-4. The figure is reproduced from Cao et al.* [27,28]

4.2 SENSOR DATA

Data from an accelerometer mounted on the impact hammer is shown in Figure 11. If the 1 ms RMS-signal is interpreted, the peak impact force P_d based on Equation (4) was about 3500 kN. Compared with the mean value bending strength of GL24h [30], the peak impact force P_d was over 85 times higher with this method. It is obvious that this is not physically possible. This method of finding the peak impact force P_d can be further disowned by comparing the acceleration time history in Figure 11 with the high-speed imagery in Figure 10. Between t=3.0 ms and t=5.8 ms, there was no contact between the impact hammer and the specimen. The peak accelerations were measured at around t=3.3 ms. Therefore, there was no contact between the impact hammer and the specimen when the peak accelerations were measured. Moreover, the impact could not be characterised as perfectly inelastic based on imagery from the high-speed camera. Therefore, Newton's second law in Equation (4) cannot be used to compute the peak impact force P_d in such tests. The periodicity of the raw signal $|A|$ in Figure 11 corresponds to the natural period T_n of the impact hammer itself. The RMS accelerometer signal corresponded well to the observed bouncing of the specimen [26].

Figure 12 shows the data from the Baumer EIL580P angular encoder for specimen 160×200×3600-F-4. The release angle was 85.01°, which is equivalent to a potential energy mgh_0 of 146.7 kJ. The post-impact energy was measured after the pendulum impact hammer had completed a full cycle, coming back to the side of

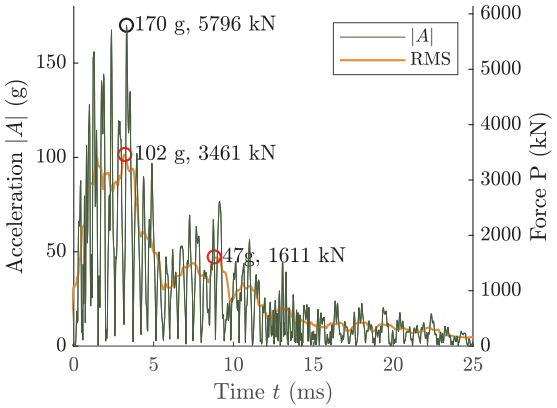

Figure 11: *Absolute values of the acceleration time history and the gliding 1 ms RMS signal for specimen 160×200×3600-F-4 from an accelerometer mounted on the impact hammer. The figure is adapted from Cao et al.* [27]

initial release. For the data shown in Figure 12, the post-impact angle was 80.32°, or 133.6 kJ. Because of the initial energy release from the electromechanical release system in Figure 9, the energy release during this cycle was corrected for by using data from free swing tests. By comparing the difference in potential energy mgh or the measured angles θ of the amplitudes following the impact hammer release for free swing conditions, the energy release E_r could be corrected for the release mechanism. Besides corrections for the release mechanism, corrections were also conducted for the intrinsic system damping by comparing free swing amplitudes with testing amplitudes, as well as the kinetic energy E_k from the propulsion of the broken halves of the specimens. This was done with the modal approximation technique [31].

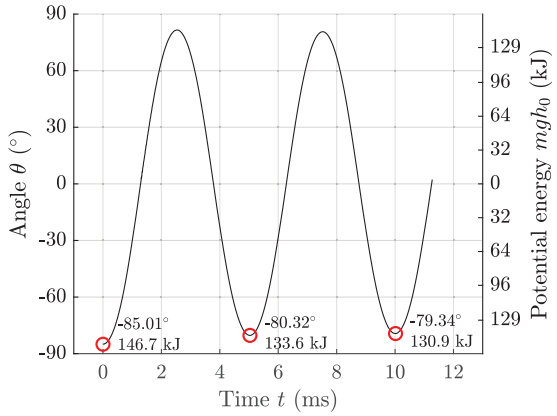

Figure 12: *Angular encoder data for specimen 160×200×3600-F-4.*

In Figure 12, the uncorrected difference between the initial and the first return peak was 4.69°, or 13.1 kJ. After corrections, the energy release E_r was $\Delta\theta$=3.22°, or E_r=8.99 kJ. The full results are presented in the test report [27]. By normalising the energy release E_r by the cross-sectional area, the toughness U_T can be found. For specimen 160×200×3600-F-4, the toughness U_T was 281 kJ/m^2.

5 CONCLUSION & OUTLOOK

In this paper, a pendulum impact hammer setup for impact testing of full-size timber beams was presented. The impact hammer was designed using computer-aided-design, and had a mass of 3450 kg, an effective length of 4750 mm, and could be released from a near-horizontal position. It was designed to accommodate simply supported timber beam specimens with and without axial restraints for cross-sections between 160×160 mm and 200×320 mm, and lengths between 2700 mm and 4300 mm. The main data from the tests was the energy release of the specimen throughout the impact, which was measured directly by the position of the impact hammer. The position of the impact hammer was recorded with an angular encoder. Besides the angular encoder, a shock-resistant high-speed camera operating at 5700 pictures per second was mounted on the impact hammer, and other cameras were also used to record the impact from several angles. Several accelerometers were also mounted on the impact hammer to measure the peak impact force. To date, 89 spruce glued laminated timber specimens without finger joints, nine beech laminated veneer lumber specimens, and four calibration specimens were tested.

Throughout the current experimental campaign, the test setup worked reliably at a high success-rate. Based on the current results, it is not recommended to measure the peak impact force by using accelerometers mounted at the impact hammer. For future tests, it is planned to measure the reaction forces at the supports directly via load cells. To extend the current knowledge on the behaviour of glued laminated timber subjected to impact loading, tests are also planned for specimens with finger joints. The pendulum impact hammer can also be used for impact tests of other materials with little or no modification.

ACKNOWLEDGEMENT

The authors would like to thank Roth Burgdorf AG and Pollmeier Massivholz GmbH & Co. KG for their contributions to the project. In addition, the authors remain thankful for the assistance and support provided by the Bauhalle team at ETH Zurich. NUMERICAL AND EXPERIMENTAL EVALUATION OF WOOD-NAILER OPEN WEB STEEL JOISTS

Sameer Fares[1], David Dinehart[2], Shawn Gross[3], Joseph Yost[4], Rebecca Hoffman[5],

ABSTRACT: The wood-nailer open web steel joist is a steel truss intended for use with a wood roof or floor deck. The wood-nailer is attached via mechanical shear connectors (self-drilling screws) to the full width and length of the top chord of steel joist. Current engineering practice does not consider the contribution of the wood-nailer to the strength and stiffness of the steel and wood hybrid system. This paper investigates the composite behavior of wood-steel joist systems through full-scale experimental testing and comprehensive 3-D finite element (FE) modelling. The FE model was calibrated by comparing results to full-scale experimental results on the wood-nailer steel joist system. The validated FE model of the wood-nailer-steel joist system is then used to conduct parametric studies that investigate the influence of screw spacing and wood-nailer thickness on the structural performance of the wood-nailer joist. This information is critical for developing a comprehensive composite design procedure.

KEYWORDS: wood-nailer, finite element modelling, composite behavior, full-scale testing

1 INTRODUCTION

An open web steel joist is a standard steel truss that consists of three components: the top chord (TC), the bottom chord (BC), and the web members, which are connected to the top and bottom chord by welds [1]. Chord members are typically double angles, with a gap in between, while web members can be either angles, channels, or rods. The conventional wood-nailer open web steel joist (WNOWSJ) is a standard steel joist with a wood-nailer attached to the top chord, as shown in Figure 1.

Figure 1: Hybrid Wood-on-Steel Roof System

The wood-nailer (WN) acts as a filler to attach the wood deck to the steel joist using mechanical fasteners. It consists of several wood-nailer segments, butted but not joined, attached to the joist's top chord steel angles via mechanical shear connectors (self-drilling screws), as shown in Figure 2.

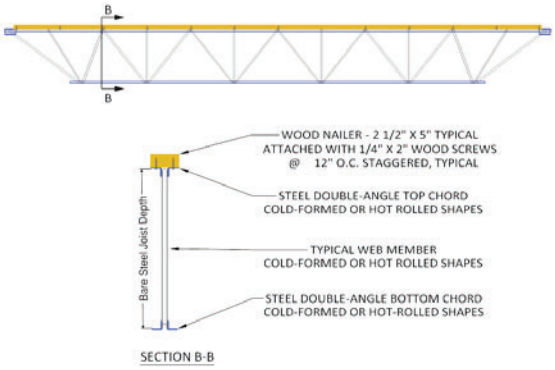

Figure 2: Wood-Nailer Steel Joist

Holes are punched in a staggered pattern into the horizontal legs of the top chord angles so self-drilling ¼-in (6.35 mm) diameter screws can be installed in pre-cut holes. The screw is then driven into the wood to attach the wood-nailer. A WNOWSJ is used in the panelized hybrid wood /steel roof system offering an attractive alternative to conventional timber joists. The conventional wood-nailer open web steel joist structural performance can be improved by making the wood-nailer structurally continuous and an integral component of the steel joist [2]. The structural continuity of the wood-nailer is achieved either through splicing the wood segments together along the length of the joist or by providing a

single full-length wood member for each joist. As a structurally continuous wood-nailer, the strength of the wood-nailer can be incorporated in the steel joist design as either non-composite, partial composite, or fully composite with the joist steel top chord, depending on the shear connection behaviour. This paper investigates the composite behaviour of wood-steel joist systems through full-scale experimental testing conducted by Martignetti [4] and comprehensive 3-D non-linear finite element (FE) modelling. The FE model was validated by comparing the FE results to full-scale experimental data on the wood-nailer steel joist system. The validated FE model of the wood-nailer-steel joist system is then used to conduct a parametric study that investigates the influence of wood-nailer thickness and screw spacing on the structural performance of the wood-nailer joist.

2 EXPERIMENTAL

Martignetti et.al. [4] experimentally evaluated wood-nailer steel joist marks (J1) and bare steel joists (J3) performances. A total of four full-scale wood-nailer joist pair tests were conducted. Two full-scale joist pair tests involved a wood decking system, and the other two full-scale bare steel joist pair tests involved a steel decking system. The steel joists were 40 ft (12.19 m) long. Both joist marks J1 and J3 had a bare steel depth of 28-in (711 mm). J1 also had a 2 ½ in (64 mm) thick wood-nailer on the top chord for a total depth of 30.5 in (775 mm). The joist top and bottom chord angle sizes are described in

Table 1.

Table 1: Wood-nailer Steel Joist Dimensions

Joist Mark	J1
Steel Joist Type	Wood-Nailer

Top Chord in (mm)	LL 2 x 3/16 (LL 51 x 5)
Bottom Chord in (mm)	LL 1.75 x 0.17 (LL 44 x 4)

All wood-nailer steel joists used in the experimental study had a wood-nailer 2.5-in (64-mm) thick x 5-in (127 mm) wide, attached to the top of the steel top chord angles with ¼-in (6.35 mm) diameter x 2-in (51 mm) long self-drilling screws staggered at 24-in (610 mm) on center. Figure 3 shows the attachment between the wood-nailer and the steel joist [2].

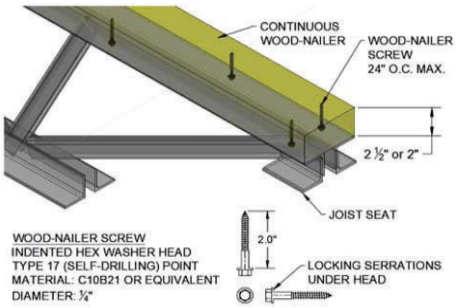

Figure 3: Wood-nailer Attachment to Steel Joist [2]

2.1 JOIST TEST SETUP

The wood-nailer steel joist pair was positioned 8 ft (2.44 m) apart to accurately simulate the joist's behaviour in a floor or roof system. Wood sub-purlins with nominal dimensions 2-in (51-mm) by 4-in (102-mm), and 24-in (610-mm) on center, are installed between the joists, and ½-in (13-mm) thick plywood sheathing is nailed to the sub purlins and joist wood-nailer by standard nailing techniques, creating a section of the roof. Figure 4 shows the wood-nailer joist (J1) specimen [4]. Steel joists (J3) were set up similarly to (J1). Figure 5 shows the steel joists (J3) and deck setup [3].

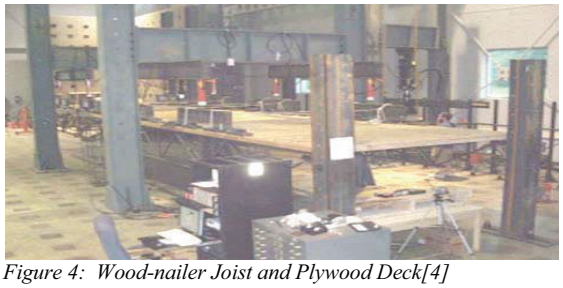

Figure 4: Wood-nailer Joist and Plywood Deck[4]

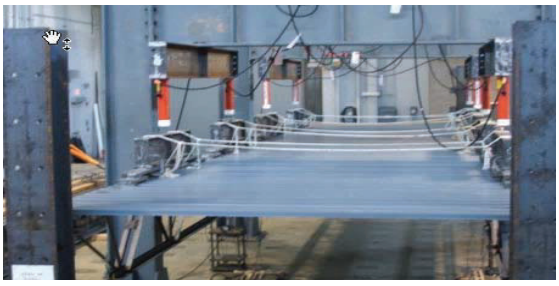

***Figure 5:** Steel Joist and Deck [4]*

2.2 LOADING

A loading pyramid was used to create a distributed load over the middle 32 ft (9.75-m) of the wood-nailer steel joist span. The load was applied to the wood deck directly above the top chord of the joists. Figure 6 illustrates the

https://doi.org/10.52202/069179-0003

distributed loading pattern. A 10,000-psi (69 MPa) manual hydraulic pump was used to apply a static load.

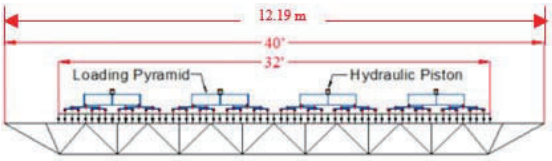

Figure 6: *Load Distribution Setup [4]*

2.3 DATA ACQUISITION

Linear variable displacement transducers (LVDTs) were used to measure the displacement near the mid-span of each joist. Eighteen strain gages were placed at the mid-span of each joist chord and wood-nailer to measure the strains and stresses in each component. Three Vishay Micro-Measurements scanners and the associated computer software recorded the signals from the load cells, LVDTs, and strain gages. Figure 7 shows strain gauge locations described in [4].

Figure 7: *Wood-Nailer Steel Joist Strain Gage Locations*

2.4 WOOD-NAILER MATERIAL TESTING

Martignetti [4][4] conducted a total of 28 tests per ASTM D4761 [5] to verify the modulus of elasticity of the Douglas-Fir wood-nailers. The statistical analysis of the test data shows that the median and the mean for the wood-nailer modulus of elasticity were both 1600 ksi (11000 MPa). The standard deviation was 314 ksi (2165 MPa)[4].

2.5 DETERMINATION OF STEEL PROPERTIES

Forty-eight steel coupons, one coupon per chord, were taken from all steel joists, then tested per ASTM E8-04 [6] for tensile testing. The statistical analysis of the test data shows that the median and the mean for the steel yield strength were both about 56 ksi (386 MPa), and the ultimate strength was about 81 ksi (559 MPa). The standard deviation for yield strength was 1.66 ksi (11.6 MPa), and for ultimate strength was 2.23 ksi (15.6 MPa)[4].

3 FINITE ELEMENT MODELLING

The finite element (FE) software package ANSYS [1][7] was used to develop a comprehensive 3-D non-linear finite element modelling (FEM) capable of replicating the experimental studies conducted on (J1) by Martignetti [4]. In addition, a bare steel joist (J3) was also simulated to serve as a reference structure against which the partial composite wood-nailer steel joist (J1) could be compared. The geometry, loads, and support conditions were applied to the numerical models. Steel joists were modelled as simply supported and subjected to a uniformly distributed load to simulate the experimental conditions.

3.1 MODELLING PROCEDURE

The following sections will describe the modelling procedure for material, geometry, shear connectors, boundary conditions, and mesh.

3.2 MATERIAL MODELLING

3.2.1 Hot-Rolled Steel

A simplified bi-linear stress-strain curve is used. The following mechanical properties were used:

Table 2: *Hot-Rolled Steel Mechanical Properties*

Property	Strength ksi (MPa)
Yield Strength	56 (386)
Modulus of Elasticity	29000 (199948)
Tangent Modulus	1450 (9997)

3.2.2 Shear Connector

The screw material is AISI-1021(C10B21). A simplified bi-linear stress-strain curve is used. Table 3 shows the mechanical properties that were used in the FE model.

Table 3: *Shear Connector Mechanical Properties*

Property	Strength ksi (MPa)
Yield Strength	57.3 (395)
Tensile Strength	68.2 (470)
Tangent Modulus	1450 (9997)

The AISI 1021 carbon steel is equivalent to ASTM 29.

3.2.3 Wood-Nailer

The variability of wood mechanical properties can significantly influence the structural performance of wood and steel-wood connections. Wood is an orthotropic material with unique and independent properties in different directions. However, since the primary strains and stresses are along the length of the joist, an isotropic material model using material properties for this direction are assumed. A simplified bi-linear stress-strain curve is used. Dowel bearing strength is used for the wood-nailer yield strength. Table 4 shows the Douglas-Fir wood's physical properties used in the FE model.

Table 4: *Douglas-Fir Wood-Nailer Mechanical Properties*

Property	Strength ksi (MPa)
Yield Strength	5 (34)
Modulus of Elasticity	1600 (11000)

https://doi.org/10.52202/069179-0003

Tangent Modulus	0.25 (1.73)

3.3 GEOMETRY

Symmetry constraints were used at the steel joist mid-length, as shown in Figure 8, to reduce the model size.

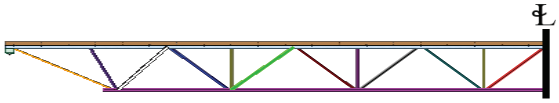

Figure 8: *One-Half FE Model of Wood-Nailer Steel Joist Span*

3.4 BOUNDARY CONDITIONS

Boundary Conditions in FEA are critical and significantly impact the outcomes. The wood-nailer steel joist has several components, and the contact types among the parts can significantly affect the results and require special consideration.

3.4.1 Support Conditions

Wood-nailer steel joists were modelled as simply supported at the ends of the span, as shown in Figure 9.

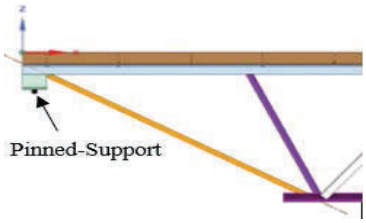

Figure 9: Pinned- Support

3.4.2 Shear Connector

The self-drilling screws acting as shear connectors between the steel joist and wood nailer were modelled as solid bodies, as shown in Figure 10.

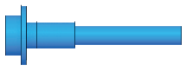

Figure 10: Screw Model

Threads on the shear connector were removed to reduce computational time and avoid convergence issues. Root diameter or the solid core of the screw was used. A pretension load of 150 lb (445 N) was applied to each shear connector.

3.4.3 Contact

ANSYS offers five different contact formulations [7]. In the FE model, bonded and frictional contacts were used. In bonded contact, separation, sliding, or penetration are not allowed. However, in frictional contact, the bodies in contact can slide relative to one another in the tangential direction and also can translate in the normal direction [8]. Bonded contacts were used to model the contact between the screw shank and the wood-nailer. In addition, frictional contact was used between screw shanks and the inner walls of the holes in the steel joist top chord. The fillet-welded connection between each web member end and the chord member was modelled with edge-bonded contacts.

3.4.4 Applied Load

A uniform load was applied directly over 16 ft (4.88 m) of the top surface area wood-nailer steel joist one-half FE model to replicate the applied distributed load, as shown in Figure 11.

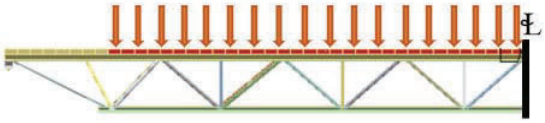

Figure 11: *Load Applied Directly to the Wood-Nailer*

3.4.5 Bracing

In the FE model, the wood-nailer was constrained laterally, in the perpendicular direction to the length of the steel joist, every 6 inches to simulate the lateral bracing provided by the wood deck to the steel joist top chord.

3.5 MESH

A rigorous mesh sensitivity analysis was conducted to determine the model discretization that provides the best cost-effectiveness and accuracy combination. The wood-nailer, top and bottom chords, and webs were meshed by quadratic hexahedral elements. For screw fasteners, axisymmetric hexahedra mesh with sweep method was used. Contact sizing was used to increase the number of elements to minimize mesh transitions. Figure 12 shows the FE mesh elements for different components.

3.6 VALIDATION OF THE DEVELOPED FINITE ELEMENT MODEL

3.6.1 (J1) Experimental and Numerical Deflection Results

Figure 13 shows the experimental load-deflection plots for the wood-nailer steel joists (J1) [4]

https://doi.org/10.52202/069179-0003

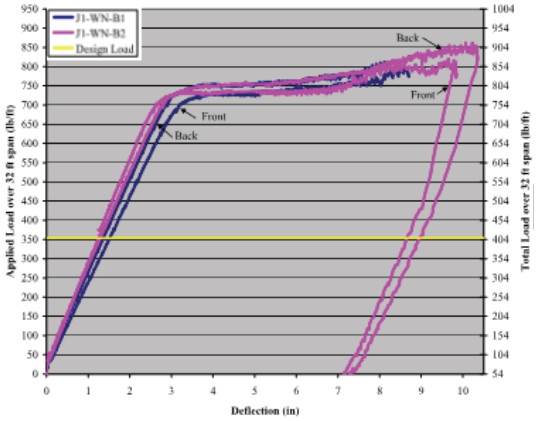

Figure 13: *(J1) Experimental Load (lb/ft) vs. Deflection [4]*

The experimental and finite element model mid-length deflection for wood-nailer steel joist (J1) mid-length is shown in Table 5.

Table 5: *J1 Experimental vs. FE Model Deflection*

Wood-nailer thickness- in (mm)	2.5 (64)
Screw Spacing- in (mm)	24 (610)
Uniform Load- lb/ft (kN/m)	700 (10.22)
Load Length- ft (m)	16 (4.88)

Wood-nailer Steel Joist Mid-Length Deflection		
Joist Mark	Experimental in (mm)	FE Model in (mm)
J1	2.61-3.15 (66-80)	2.71(69)

(J1) FE load-deflection plot is shown in Figure 14. At a point load of 11.2 kip (49.82 kN), the wood-nailer steel joist mid-length deflection is 2.71-in (69 mm).

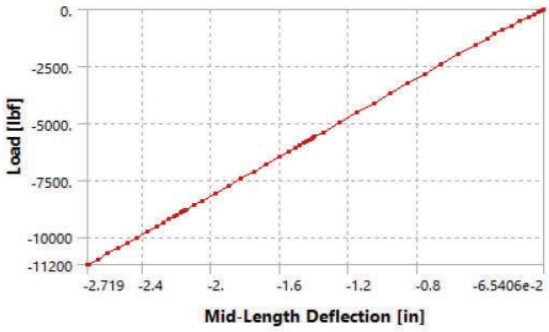

Figure 14: *(J1) FE Model Load(N) vs. Deflection*

As shown in Figure 15, (J1) FE model deflection prediction in the linear range shows a reasonably good agreement with the experimental data.

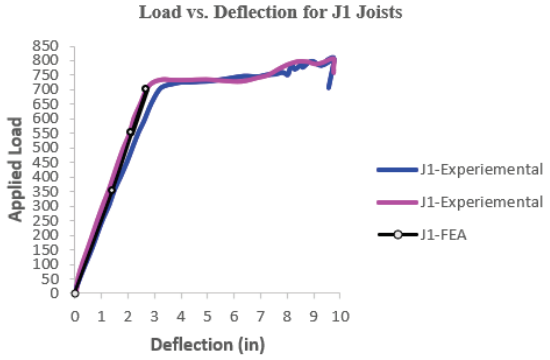

Figure 15: *(J1) Experimental vs. FE Load-Deflection Curves*

(J3) Experimental and Numerical Deflection Results

Figure 16 shows the experimental load-deflection plots for the bare steel joists (J3) [4].

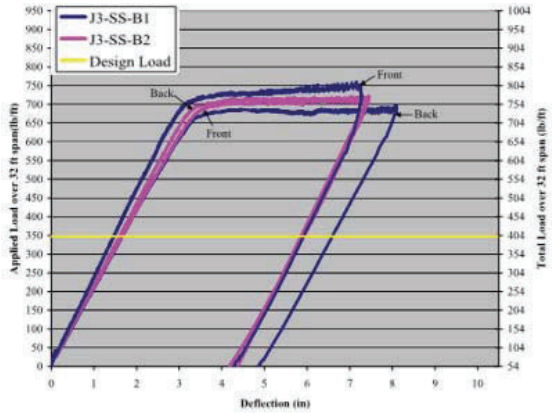

Figure 16: *(J3) Experimental Load (lb/ft) vs. Deflection [4]*

The experimental and finite element model mid-length deflection for bare steel joists (J3) is shown in Table 6.

Table 6: *J3 Experimental vs. FE Model Deflection*

Uniform Load- lb/ft (kN/m)	700 (10.22)
Load Length- ft (m)	16 (4.88)

Bare Steel Joist Mid-Length Deflection		
Joist Mark	Experimental in (mm)	FE Model in (mm)
J3	3.08-3.42 (78-87)	3.19 (81)

(J3) FE model load-deflection plot is shown in Figure 17. At a concentrated load of 11.2 kip (49.82 kN), the bare steel joist deflection at mid-length is 3.19-in (81 mm).

https://doi.org/10.52202/069179-0003

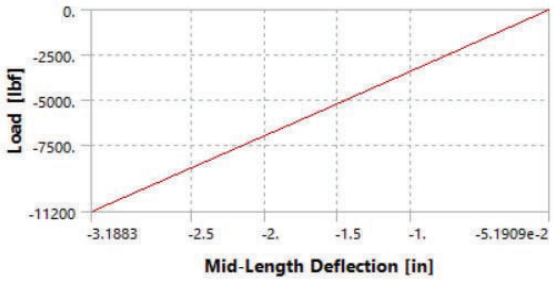

Figure 17: *(J3) FE Model Load-Deflection Plot*

Figure 18 depicts (J3) deflection at mid-length from the FE model.

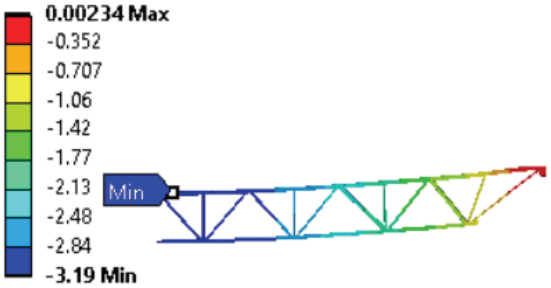

Figure 18: *(J3) FE Model Deflection in (in)*

As shown in Figure 19, (J3) FE model deflection prediction in the linear range shows a reasonably good agreement with the experimental data. Furthermore, as the FE model deflection data shows, the deflection of (J1) is less than (J3), indicating that the wood-nailer steel joist (J1) has a higher flexural stiffness than (J3). The higher flexural stiffness confirms that some level of partial composite action was attained in the wood-nailer steel joist.

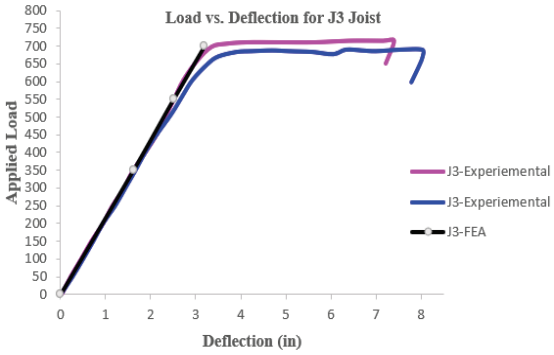

Figure 19: *(J3) Experimental vs. FE Load-Deflection Curves*

3.6.2 (J3) Experimental and Numerical Normal Strain Results

Load Length- ft (m)		16 (4.88)
WN Steel Joist Mid-Length Normal Strains		
Member	Strain Gauge Location	Experimental (microstrain)	FE Model (microstrain)
TC	Top	1400-1500	1480
	Bottom	600-700	978

3.7 (J1) WOOD-NAILER STEEL JOIST STRAINS

3.7.1 Experimental and Numerical Strain Results

Figure 22 shows the applied load-strain plots for the wood-nailer, top chord, and bottom chord at the locations described in Figure **7**.

https://doi.org/10.52202/069179-0003

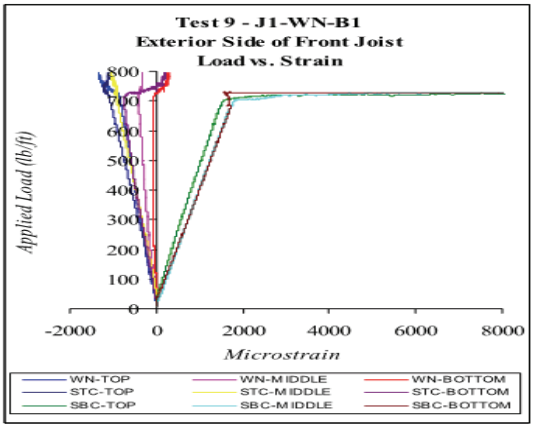

Figure 22: *J1-B1 Exterior Side of Front Joist Strain Plots. Experimental data from [4]*

3.7.2 (J1) Finite Element Model vs. Experimental Strains at the Top and Bottom of Each Member

Table 8 shows the experimental vs. FE model normal strains at the top and bottom of each component. The FE model analysis agrees well with the experimental strain results.

Table 8: *(J1) FE Model vs. Experimental Normal Strains*

Wood-nailer thickness- in (mm)	2.5 (64)
Screw Spacing- in (mm)	24 (610)
Uniform Load- lb/ft (kN/m)	700 (10.22)
Load Length- ft (m)	16 (4.88)

WN Steel Joist Mid-Length Normal Strains			
Member	Strain Gauge Location	Experimental (microstrain)	FE Model (microstrain)
WN	Top	600 - 000	980 - 1000
	Bottom	130-170	520-540
TC	Top	1080-1100	930
	Bottom	300-960	730-770
BC	Top	1500-1800	1700
	Bottom	1790-1820	1800

Figure 23 through **Figure 25** shows the normal strains in the wood-nailer, top chord, and bottom chord from the FE model.

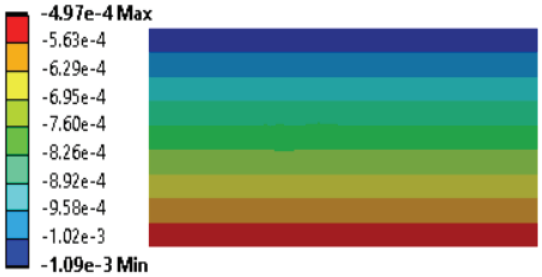

Figure 23: *(J1) Wood- Nailer (WN) Normal Strains*

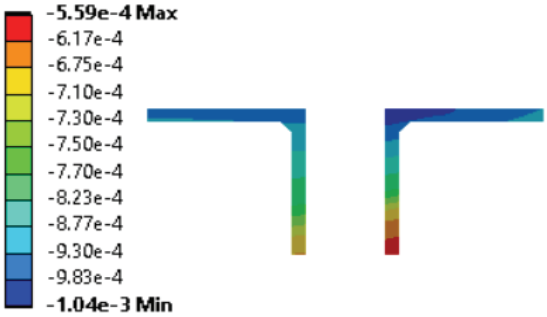

Figure 24: *(J1) Top Chord (TC) Normal Strains*

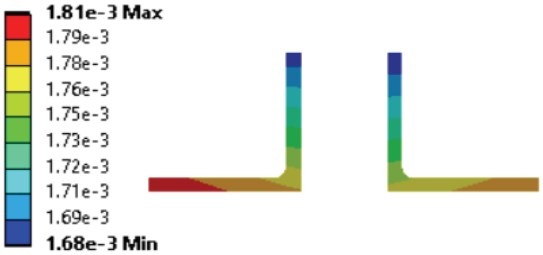

Figure 25: *(J1) Bottom Chord (BC) Normal Strains*

Table 7 and Table 8 show that the top chord combined normal strains in the wood-nailer steel joist (J1) are smaller than the bare steel joist (J3), which confirms that the wood nailer reduces the axial and bending stresses in the joist top chord through load-sharing under design loading.

3.7.3 Wood-Nailer Steel Joist (J1) And Steel Joist (J3) Component Axial Forces

Table 9 shows the FE model component axial forces for wood-nailer steel joist (J1) and steel joist (J3).

Table 9: J1 and J3 Component Forces

Wood-Nailer Thickness- in (mm)	2.5 (64)
Screw Spacing- in (mm)	24 (610)
Load- lb/ft (kN/m)	700 (10.22)
Load Length- ft (m)	16 (4.88)

FE Model Mid-Length Component Axial Forces			
Mark	WN kip (kN)	TC kip (kN)	BC kip (kN)
J1	19.9 (88.3)	37.5 (166.9)	57.8 (257.6)
J3	N/A	58.3 (259.5)	59.1(262.7)

The reduction in the bottom chord axial forces demonstrates that the wood-nailer steel joist's effective depth has increased. The increased joist effective depth with identical steel joist and added wood-nailer is evidence of the top chord elastic neutral axis moving upward due to composite behaviour between the steel top chord and the wood-nailer. The combined effect of the wood-nailer composite behaviour with the steel top chord,

https://doi.org/10.52202/069179-0003

the resulting change in the top chord neutral axis, and the resulting increased joist effective depth increase the overall joist moment capacity. Figure 26 shows the FE model axial load in the wood-nailer, top, and bottom chords.

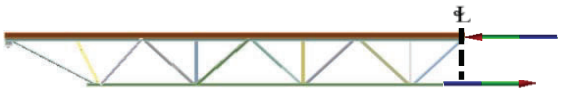

Figure 26: *Wood-Nailer, Top and Bottom Chord Axial Forces*

4 PARAMETRIC STUDIES

An essential part of a numerical study is conducting a parametric study. The validated FE model was used to conduct a parametric analysis to investigate the effect of screw spacing and wood-nailer thickness on the structural performance of the wood-nailer steel joist. First, for the standard screw spacing of 24-in, two alternative wood-nailer thicknesses, 2.25-in and 2-in, were modelled. Second, for a wood-nailer, 2.5-in thick, two alternative screw spacings, 20-in (508 mm) and 16-in (406 mm), were modelled.

4.1 WOOD-NAILER THICKNESS

The first parameter investigated was the effect of wood-nailer thickness on the joist component axial forces and the joist stiffness or deflection.

4.1.1 Wood-Nailer Steel Joist Deflection

FE model deflection results for two alternative wood-nailer thicknesses, 2.25-in and 2-in, are shown in Table 10. As expected, increasing the wood-nailer thickness resulted in a reduction in the wood-nailer steel joist deflection.

Table 10: (J1) FE Model Deflections

Screw Spacing- in (mm)	24 (610)
Load- lb/ft (kN/m)	700 (10.22)
Load Half Joist Length- ft (m)	16 (4.88)
FE Model Deflection at Joist's Mid-Length	
WN Thickness- in (mm)	Deflection- in (mm)
2.5 (64)	2.71 (69)
2.25 (57)	2.76 (70)
2.0 (51)	2.80 (71)

4.1.2 Wood-Nailer Steel Joist Component Axial Forces

Table 11 shows the FE model component axial forces for two alternative wood-nailer thicknesses, 2.25-in (57 mm) and 2-in (51 mm).

Table 11*: FE Model Component Axial Forces*

Screw Spacing- in (mm)		24 (610)	
Load- lb/ft (kN/m)		700 (10.22)	
Load Length- ft (m)		16 (4.88)	
FE Model Mid-Length Component Axial Forces			
WN Thickness in (mm)	WN kip (kN)	TC kip (kN)	BC kip (kN)
2.5 (64)	19.9 (88)	37.5 (167)	57.8 (257)
2.25 (57)	18.5 (82)	39.1 (174)	58.1 (258)
2.0 (51)	17.5 (78)	40.3 (179)	58.2 (259)

The FE model component axial force results shown in Table 11 demonstrate that increasing the wood-nailer thickness resulted in the following:

- An increase in the wood-nailer steel joist's effective depth decreases the axial force in the bottom chord.
- An increase in the axial force resisted by the wood-nailer and a decrease in the axial force resisted by the top chord. The shear strength of the screws limits the axial force transferred to the wood-nailer.

The FE analysis results demonstrate that there is a partial composite action in the wood-nailer steel joist system.

4.2 SCREW SPACING

The second parameter was to investigate the effect of screw spacing on the joist stiffness or deflection and component axial forces. Two alternative screw spacings, 20-in (508 mm) and 16-in (406 mm), were used, while the wood-nailer thickness is the standard 2.5-in (64-mm).

4.2.1 Wood-Nailer Steel Joist Deflection

Table 12 shows (J1) FE model deflections at mid-length using two alternative screw spacings, 20-in (508 mm) and 16-in (406 mm).

Table 12: *FE Model Wood-Nailed Steel Joist Deflection*

Wood-Nailer Thickness- in (mm)	2.5 (64)
Load- lb/ft (kN/m)	700 (10.22)
Load Half Joist Length- ft (m)	16 (4.88)
FE Model Mid-Length Deflection	
Screw Spacing- in (mm)	Deflection- in (mm)
24 (610)	2.71 (69)
20 (508)	2.64 (67)
16 (406)	2.55 (65)

Figure 27 and Figure 28 depict the FE model deflection when the screw fasteners are spaced at 16-in (406 mm) and 24-in (610 mm) on center, respectively.

https://doi.org/10.52202/069179-0003

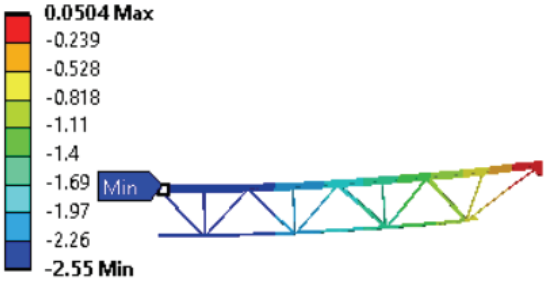

Figure 27: *FE Model Deflection (in) for screw spacing 16-in (406 mm)*

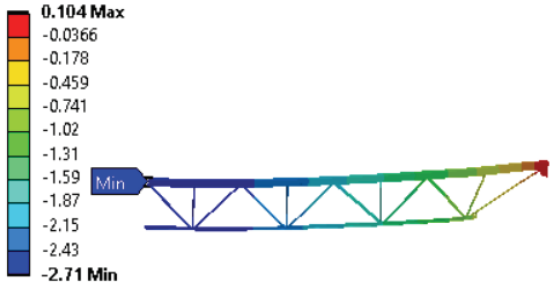

Figure 28: *FE Model Deflection (in) for screw spacing 24-in (610 mm)*

The FE model deflection results indicate that as the shear connector spacing decreases, the wood-nailer steel joist attains a higher level of composite action leading to 6% higher flexural stiffness.

4.2.2 Wood-Nailer Steel Joist Component Axial Forces

Table 13 shows the FE model component axial forces using two alternative screw spacings, 20-in (508 mm) and 16-in (406 mm).

Table 13: *FE Model Component Axial Forces for Screw Spacings 20-in(508-mm) and 16-in (406 mm)*

Wood-Nailer Thickness- in (mm)	2.5 (64)
Load- lb/ft (kN/m)	700 (10.22)
Load Length- ft (m)	32 (9.75)

FE Model Mid-Length Axial Forces			
Spacing in (mm)	WN Kip (kN)	TC Kip (kN)	BC kip (kN)
24 (604)	19.9 (88)	37.5 (167)	57.8 (257)
20 (508)	21.8 (97)	34.4 (153)	56.4 (251)
16 (406)	23.5 (105)	31.6 (141)	55.3 (246)

As expected, the FE model component axial force results indicate that a 33% reduction in the shear connector spacing results in an 18% increase in the axial force transferred to the wood-nailer. The axial force transferred to the wood-nailer is limited by the shear strength of the screws. In addition, the wood-nailer steel joist attains a higher level of composite action leading to an increase in the effective joist depth, which results in a larger moment capacity.

5 CONCLUSIONS

The structural performance of wood-nailer steel joists was numerically investigated. The non-linear finite element (FE) models were developed and analysed using Ansys software. The FE model developed was verified against available experimental data. The numerical predictions showed reasonably good agreement with the experimental data. Parametric analyses were conducted using the validated FE models, and the following conclusions can be drawn from the results of FE analyses.

- The wood-nailer acts partially compositely with the steel top chord and the transformed wood-nailer increases the effective depth of the steel joist.
- The continuous wood-nailer reduces bending stresses in the joist top chord through load-sharing under design loading.
- The combined effect of the wood-nailer composite behaviour with the steel top chord, the resulting change in the top chord neutral axis, and the resulting increased joist effective depth, increase the overall joist moment capacity and flexural stiffness.
- A higher level of composite action is achieved with a larger shear connector density.

6 FUTURE RESEARCH

There is a need to conduct push-out research to investigate the strength and ductility of the screw connection. The push-out tests would allow a direct data analysis of the connection itself, without the additional variables of truss load paths, composite behaviour, and relative stiffness of different materials. The load-slippage data collected from the push-out test will provide valuable connection strength and stiffness data to refine the current finite element model of the wood-nailer steel joist.

ACKNOWLEDGEMENT

The authors are grateful to New Millennium Building Systems for providing the financial support of this research and Joe Pote for his technical guidance.

BEHAVIOR OF TIMBER BEAMS STRENGTHENED WITH CFRP

Shengdong Zhang[1], Blanche Blondel de Joigny[2], Jianrong Cui[3]

ABSTRACT: This paper shows a study on the flexural behavior of Larch and Douglas Fir beams strengthened with Carbon Fibre Reinforced Polymers (CFRP). 60 specimens are subjected to a three-point bending test; some are reinforced only on their lower face, and others on the lower and lateral faces (U-shape reinforcement). The maximum load and the mid-span deflection at rupture lead to the determination of the mechanical properties of timber elements. A finite element analysis is proposed to complete the experimental analysis of the flexural behavior of the beams. An elasto-plastic behavior is assumed for reinforced timber and interface elements are used to model the interaction between CFRP and timber. It is observed that the predicted FE results are in good agreement with the measured test data.

KEYWORDS: CFRP, Reinforced Timber Beams, Flexural Behavior, Three-point Bending Test, FE Analysis

1 INTRODUCTION

Wood is the only renewable and most environmentally friendly construction material in the world. It has been used for ages in construction and perform well. But properties of wood are easily degraded due to its natural defects (knots, etc.) and environmentally impacts (variation of humidity, fungi, insects, etc.) on it. Reinforcements on the degraded timber members are necessitated, especially for the existing timber structures with long service time. This paper focuses on the flexural behavior of structural timber strengthened with Carbon Fibre Reinforced Polymer (CFRP).

Usually, the ruptures of bending beams are located around the knots or the other defects of the wooden pieces, or around the butt-joints next to the tensile strength. This is why they need to be reinforced in those areas to improve the tensile resistance.

CFRP is a good solution to strengthen timber elements for its high tensile strength and durability. The efficiency of the strengthening is evaluated by comparing the timber mechanical properties of the different specimens including the Modulus of Elasticity (MOE), the stiffness and the ductility of the beam, the failure modes, the resistance under bending stresses, etc.

Fiorelli and Dias[1] realized a reinforcement of small samples with G(Glass)FRP and CFRP taped on lower face. They studied the mechanical behavior of the wood under compression, then under tensile strength and then under shear, and highlighted an increase in resistance and stiffness. The defects influence is diminished.

John and Lacroix[2] studied the effects on the length of CFRP taped on the lower face of timber beams under bending constraints. They noticed an increase of the resistance from 40% to 70% compared to the non-reinforced specimens. They also enhanced the importance of the length of the reinforcement or to implement the reinforcement in a U-shape.

Hernandez et al[3] investigated the bending resistance and the stiffness of glulam beams reinforced with GFRP. Three percent of the volume were added as a reinforcement, gluing two layers of GFRP on the stretched area. Some specimens were also reinforced on the top. It is noticed an increase of the resistance and the stiffness in tension: adding 3 percent of GFRP by volume increased bending stiffness by as much as 18 percent, and bending strength by as much as 26 percent. The improved efficiency of top and bottom reinforcement appears to be not significant enough to offset the added material and handling costs of two layers of GFRP, even if it enhances the beam bending strength.

Borri et al[4] taped CFRP in the stretched zone. Some of the beams were reinforced with a prestressed reinforcement. An increase of the maximum capacity and of the stiffness compared to the other beams that were not reinforced is respectively by 22.5% to 29.2%, and by 40% to 60%. The prestressed beams do not show significant improve compared to the non prestressed ones.

Ogawa[5] worked on the reinforcement of glulam beams made with Japanese cedar and limber pine with CFRP, around 0.08% and 1.3% of the wood volume. An epoxy resin was used to improve the shear capacity at the interface wood-carbon and the fire resistance. The bending capacity has highly increased, whatever the type of wood or the amount of CFRP used. The coefficient of the resistance variation dwindles to reach

6% to 8% compared to 10% to 25% for the non-reinforced wood.
The use of CFRP to reinforce wood structural elements is the object of more and more studies over the past decades. But we still lack a centralized data base with all the results of the literature. In this paper, the flexural behavior of Larch and Douglas Fir beams strengthened with CFRP only on their lower face, and on the lower and lateral faces (U-shape reinforcement) was experimentally and numerically studied.

2 MATERIALS AND METHODS

2.1 THE SAMPLES

60 specimens of Chinese North-eastern Larch (with mean moisture content 17.7% and density 595kg/m^3) and North American Douglas Fir (with mean moisture content 13.7% and density 527kg/m^3) were subjected to a three-point bending test. The size of the samples was decided according to the ASTM Standard D 143-14 "*Standard methods for Small Clear Specimens of Timber*" [6]. The specimens were as clear as possible, however few knots remained in some of them. The cross section is 50 mm by 50 mm, and the length is supposed to be 780 mm. The length of the beam between two supports is equal to 720 mm. This span was established in order to maintain a minimum span-to-depth ratio of 14. There are 30 specimens of each species, divided into 3 categories of 10 specimens each.

Type 1: Without any reinforcement (Figure 1-a). This group of timber specimens are the witness samples.
Type 2: With a reinforcement on the lower face of the timber beam (Figure 1-b), where wood fibers are the most solicited in bending.
Type 3: With a reinforcement on the lower face and on the two lateral faces (U shape) (Figure 1-c).

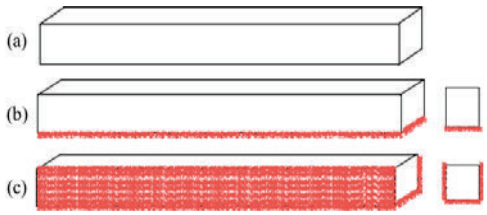

Figure 1 *a-Witness Specimen, b-Reinforcement on the lower face, c-U shape Reinforcement*

The carbon fibres used to reinforce the specimens have thickness 1.67mm, MOE 230000 MPa, tensile strength 3400 MPa, elongation percentage 1.7%. The taping of CFRP is parallel to the wood grain. The glue used is an epoxy resin mixed with a hardener at the ratio 1/2. A layer of 1 mm is applied 24 hours before the tapping of the CFRP sheets in order to let the resin impregnate the wooden fibers. Another layer of resin is applied just before the tapping, and a final layer above the CFRP sheet to ensure the fixing on the timber specimens.

Figure 2*. Cutting and gluing the Carbon Fibers on the specimens*

2.2 THE TESTING PROCEDURE

An electrohydraulic servo system was used for the destructive tests. The charge was thus applied continuously up to the specimens' failure, according to the pattern of Figure 3. The load was applied at mid-span with a speed of 5.0 mm/min. Termination of the test was at 80% of peak load of descendent stage. During the test the peak load and the load at rupture, the displacements at mid-span at the peak load and at the load of rupture were recorded for each specimen. The rupture mode was also carefully observed.

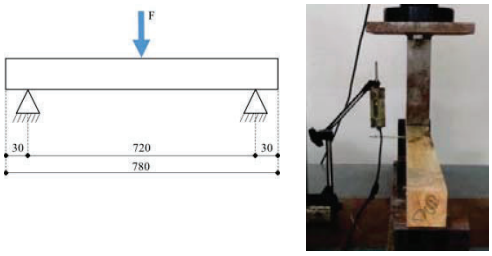

Figure 3. *Disposition of the specimen on the benchmark*

3 TEST RESULTS

3.1 FAILURE MODES

Larch specimens shows more flexible than Douglas Fir specimens (Figure 4) in this test.

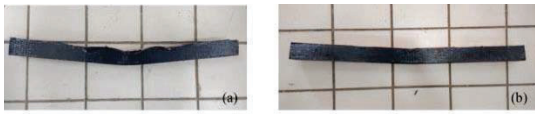

Figure 4*. Larch (a) and Douglas Fir (b) reinforced beams after the test*

With the same conditions of test (disposition on the benchmark, loading speed), the time before failure lasts on average 17% longer. This difference increases for the reinforced specimens, which means that the more flexible the timber is, the more efficient the CFRP strengthening is.
Except for the specimens having knots in their lower part, most of the failures occurr in tension or compression. As planned, all the witness specimens

https://doi.org/10.52202/069179-0004

break in tension. The specimens with one face reinforced have failure most of the time in both tension and compression, or tension only. And almost all the specimens reinforced on 3 faces have failures in compression. Some wrinkles are observed on the compressive side at the point of contact between the load and the wood (Figure 5). Those wrinkles are very tiny on the witness specimens and sometimes inexistent, but on the reinforced specimens they are more important which highlights the buckling from compression strengths.

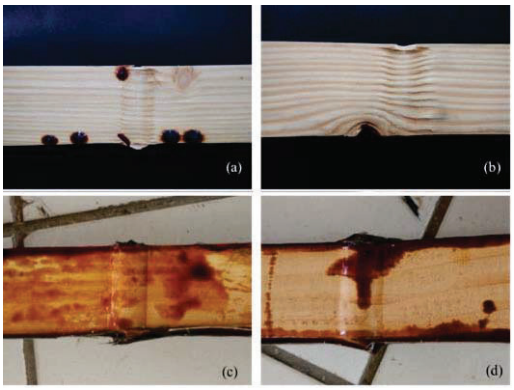

***Figure 5**. Buckling on compression side for the Larch specimens with one face reinforced (a, b) and for the Douglas Fir specimens with 3 faces reinforced (c, d)*

3.2 LOAD-DISPLACEMENT GRAPHS

The deflection of the beams at mid-span was recorded during the tests in order to sketch the load-displacement graphs. Figure 6-Figure 11 present the results for the 60 specimens.

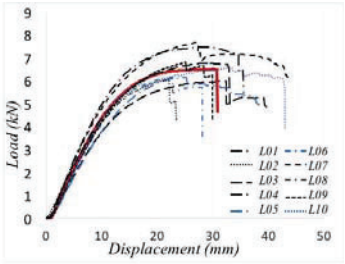

***Figure 6**. Load-displacement curves for Larch witness specimens*

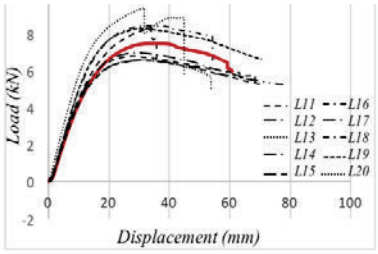

***Figure 7**. Load-displacement curves for Larch specimens with 1 face reinforced*

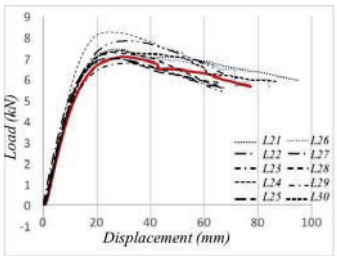

***Figure 8**. Load-displacement curves for Larch specimens with 3 faces reinforced*

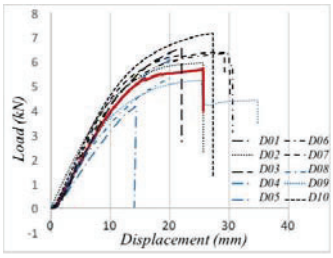

***Figure 9** Load-displacement curves for DF witness specimens*

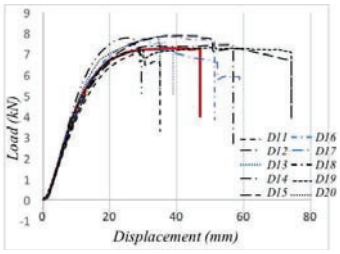

***Figure 10**. Load-displacement curves for DF specimens with 1 face reinforced*

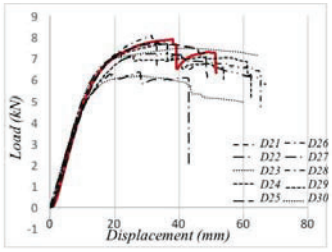

***Figure 11.** Load-displacement curves for Larch specimens with 3 faces reinforced*

In every figure, the curve in red represents the mean of all the others; the curves in blue represent the specimens that failed because of a knot. The mean curve has been sketched removing the knot failures cases because the tests are supposed to be conducted on clear specimens according to the Standards. The analysis of the curves leads to the determination of the evolution of the MOE, and the mode of rupture of the beams. In Figure 12 the curves for Larch highlight the mechanical behavior of a timber beam: an elastic part and a plastic part are observed.

The Elastic and linear part leads to the evaluation of the MOE[7]. Indeed, the graph equation in this first linear part is $F=k \cdot E \cdot u$ where u is the displacement, F the

measured load and ***k*** a constant. It is noticed that the slope increases significantly between the load-displacement curves of the reinforced specimens compared to the witness ones. Table 1 gives the average of all the recorded values during the tests. Those loads and displacement characteristics allow to explain the evolution of the mechanical behavior of the timber specimens. Both stiffness and ductility increase for the reinforced specimens compared to the witness ones.

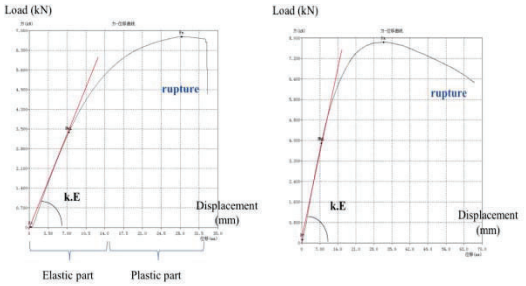

Figure 12. *Load-displacement curves of Larch witness sample – rupture in tension, and of Larch with 3 faces reinforced – rupture in compression*

Table 1. *Average experimental values for each specimen*

	Peak Load (kN)	Disp. at Peak Load (mm)	Load at Rupture (kN)	Disp.at Rupture (mm)
Witness DF	5,699	25,158	5,694	25,158
Witness Larch	6,548	27,874	5,855	34,559
1 CFRP DF	7,534	37,780	7,007	50,046
1 CFRP Larch	7,565	31,522	6,473	60,298
3 CFRP DF	7,356	33,325	6,286	63,819
3 CFRP Larch	7,287	27,816	6,046	74,267

3.3 LINEAR ANALYSIS OF THE MIXED SECTION

The MOE of the witness specimens was calculated with the equation of the second derivative of the deflection (Equation 1), and successive integrations gave the expression of the Modulus E_w (Equation 2).

$$E_w I_{Gz} y'' = M f_z(x) \quad (1)$$

$$E_w = -\frac{FL^3}{48 y_c I_{Gz}} \quad (2)$$

where y_c = the maximum deflection at mid-span (mm) , F = the peak load (kN), I_{Gz} = the section's moment of inertia (mm^4)
The computations lead to the following results:

$E_{w\ Douglas\ F}$ = 12 382 MPa

$E_{w\ Larch}$ = 11 925 MPa

The determination of the MOE of the mixed section (timber + epoxy resin + CFRP) is more complicated because the position of the center of gravity is modified as shown in Figure 13.

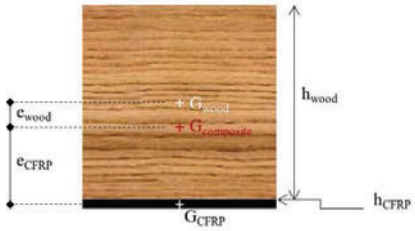

Figure 13. *Position of the new neutral axis within the reinforced specimens*

The bending stiffness is obtained with the theorem of Huygens (Equation 3); it will allow to be close to the reality and avoid the use of the glide factor γ pretending the bonding to be "perfect".

$$(EI)_{eff} = E_w I_w + E_w A_w e_w^2 + E_{CFRP} I_{CFRP} + E_{CFRP} A_{CFRP} e_{CFRP}^2 \quad (3)$$

The section of the CFRP is very low so the moment of inertia I_{CFRP} can be neglected faced to the wood moment of inertia I_w. The effective stiffness is easily calculated with the (Equation 3) and the modulus of elasticity shall be obtained by dividing this value by the effective moment of inertia of the section (Equation 4) when we neglect the proper moment of inertia of CFRP:

$$I_{eff} = I_w + A_w e_w^2 + A_{CFRP} e_{CFRP}^2 \quad (4)$$

The results are presented in Table 2. The comparison with the values of $E_{w\ Douglas\ F}$ and $E_{w\ Larch}$ obtained with the witness samples shows an increase of 47% of the MOE for both species.

Table 2*. Stiffness of the reinforced specimens*

	$(EI)_{eff}$ kN/mm2	I_{eff} mm4	$E_{w\ reinforced}$ MPa
DF	1.379E+7	7.536E+5	18 298
L	1.345E+7	7.635E+5	17 616

4 A NUMERICAL MODEL

4.1 Hypothesis

An elasto-plastic numerical model was introduced based on ABAQUS software.The dimensions used for the numerical modeling are 50×50×780 mm for the timber beam, and 50×1.5×780 mm for the CFRP reinforcement. C3D8R solid elements were used for the timber beam, and S4R shell elements for the reinforcement. The supports were fixed at 30 mm from the extremities of the samples, and the load applied at mid-span is located at 390 mm from each extremity. The wood plasticity model uses the Hill's stress

https://doi.org/10.52202/069179-0004

potential for anisotropic behavior[8]. (Equation 5) gives the Cauchy stress tensor used in this model:

$$\underline{\sigma} = \underline{\underline{\Lambda}} : \underline{\varepsilon}^{e} \quad (5)$$

This elastic law was used with the mechanical characteristics of Larch and Douglas Fir taken from the table 3[8]. The present model assumed that the behavior in the radial direction is equal to the one observed in the tangential direction. This is why the elasto-plastic model gets the following simplifications: $E_R = E_T$; $G_{RT} = G_{TR}$; $G_{LR} = G_{LT}$; $\nu_{RT} = \nu_{TR}$; $\nu_{LR} = \nu_{LT}$. The Hill's criterion was taken as yield criterion as follows, and also used as stress potential for anisotropic behaviour.

$$f(\underline{\sigma}) = \sqrt{H(\sigma_x - \sigma_y)^2 + G(\sigma_x - \sigma_z)^2 + F(\sigma_y - \sigma_z)^2 + 2N\tau_{xy}^2 + 2M\tau_{xz}^2 + 2L\tau_{yz}^2} - R - \sigma_{yield}$$

Table 3 *Material properties for wood*

Elasticity	E_L= 14.5 GPa E_R= 1.2 GPa E_T= 1.2 GPa	V_{LR} = 0.37 V_{LT} = 0.43 V_{RT} = 0.45	G_{LR} = 590 MPa G_{LT} = 590 MPa G_{RT} = 73 MPa
Plasticity	σ_{yield} = 40 MPa Q = 750 MPa b = 17	F = 0.35 G = 0.4 H = 0.6	L = 1.5 M = 1.5 N = 1.45

The CFRP material was considered as linear elastic orthotropic up to failure. E_L=110 (GPa), E_R = E_T=8.82 (GPa), V_{RT}=0.38, G_{LR} = G_{LT}=4.32GPa, G_{RT}=3.2GPa.
The surface-based cohesive behaviour was specified for modelling the adhesive interaction.
For the meshing of the timber beam and the CFRP sheet, 10 for the approximate global size for seed parts was taken.

4.2 Comparison with experiments

Figure 14-figure 17 show the displacements and stresses of the modelling witness sample and reinforced sample with lower face CFRP reinforcement.
The stresses modeled in the witness specimens confirm what was observed in the laboratory during the conduction of the experiments. The stretched fibers located in the lower part of the beam are the weakest and fail first. Besides, the modelling shows the location of the neutral axis: it has not been affected at all by the bending load. For the reinforced specimens, the distribution of stresses in the stretched area is much lower than in the witness beam. This explain the high number of specimens that failed in compression more than in tension. It is difficult to conclude on the modification of the displacements of the specimens, because if the load increases so does the maximum displacement. However, the displacement itself is limited because of the presence of the CFRP sheet which reinforce the wood. The experimental results highlight a global increase of the peak load and of the displacement at rupture for the reinforced specimens compared to the witness. A comparison of the load–deflection curves obtained from experiments and from FE analysis is made in Figure 18 for Larch specimens, and in Figure 19 for Douglas Fir specimens.

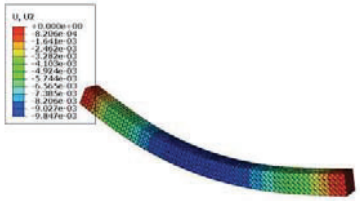

Figure 14*. Displacements obtained after the modelling of the witness sample*

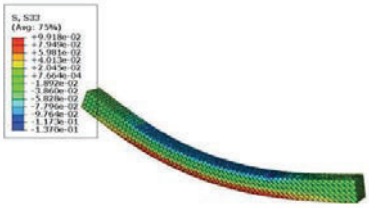

Figure 15. *Bending stresses obtained after the modelling of the witness sample*

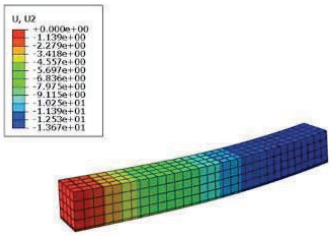

Figure 16*. Displacements obtained after the modelling of half a sample reinforced along its lower face*

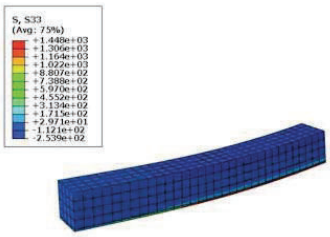

Figure 17*. Bending stresses obtained after the modelling of half a sample reinforced along its lower face*

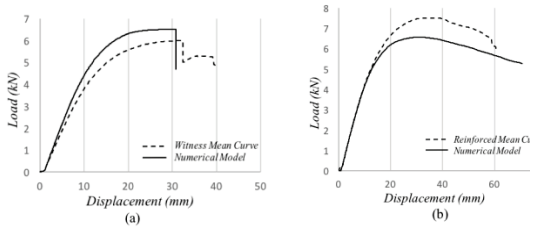

Figure 18*. Larch load–mid-span deflection curves: comparison between numerical and experimental data (a)-*

witness and (b)-reinforced specimens

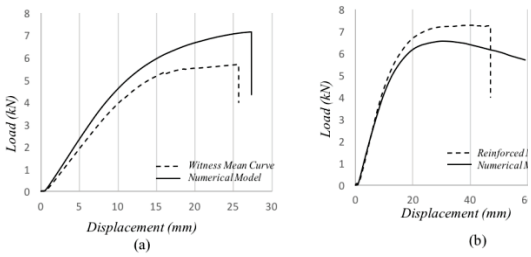

***Figure 19**. DF load–mid-span deflection curves: comparison between numerical and experimental data (a)-witness and (b)-reinforced specimens*

For the Larch's witness specimens, the behavior obtained with the FE analysis is linear up to a displacement of about 10 mm with a corresponding load that reached 4.5 kN, before entering in the plastic behavior. The witness mean curve has an elastic zone up to a displacement equal to 7.8 mm and a load of about 3.5 kN. Beyond those points the response became nonlinear and a discrepancy between predicted and experimental results was observed. The peak load is reached at rupture for the numerical model, and is about 6.5 kN for a maximum displacement of 30.4 mm. Whereas the experimental data lead to a peak load that does not correspond to the failure one, even if it is close to prediction of the FE model: 5.8 kN for a displacement of about 32 mm. However, the rupture occurs at the ultimate load of 5.3 kN with a displacement that reaches 39 mm. The comparison between the numerical and experimental data about reinforced specimens on the lower fibers also show similitudes in the elastic area and divergence in the plastic area. The behavior is linear up to a displacement of about 9.6 mm with a corresponding load of 4 kN. The plastic stage lasts longer in the FE simulation: ultimate displacement is equal to 73 mm for an ultimate load that reaches 5.3 kN. The experiments show a mean final displacement up to 58 mm with a corresponding load of 6.5 kN, and a rupture in both compression and tension (sudden drop of the load for constant displacement visible on the curve).

For the Douglas Fir's witness specimens, the FE analysis shows a linear behavior up to a displacement of about 9 mm with a corresponding load of 4.1 kN, before the plastic stage. The elastic zone of the mean curve goes up to a displacement of 10 mm with a load of about 3.8 kN. The rupture is similar between the experimental and the numerical results: it is sudden and typical of a tensile failure. The experimental rupture occurs for an ultimate load of about 5.4 kN and a maximum displacement of 25.5 mm, whereas the numerical model shows a rupture for a load equal to 7.2 kN and a displacement that reaches 27 mm. As for Larch specimens, the comparison between the numerical and experimental models shows similitude in the elastic area. The slopes of the curves are very close, and the behavior is linear up to a displacement of about 8 mm with a corresponding load of 3.2 kN. Once again, the plastic stage lasts longer for the FE simulation. The maximum displacement is about 60 mm and the ultimate load reaches 5.8 kN, whereas the plastic stage of the experimental results is shorter. The rupture mode is different because the curve shows a tensile rupture with a load that drops suddenly from 7 to 4 kN for a corresponding displacement of about 44 mm.

The comparison of the load-displacement curves of the reinforced specimens is surprising, because the peak load seams to decrease form the witness results to the reinforced scheme. This means that the numerical model is not close enough to the reality in the plastic area. The FE model shows an improvement of the ductility of the specimens because the final displacement increased a lot compared to the witness one. But the improvement of the specimens' stiffness is not obvious according to the numerical modelling. However, we can notice that the curves are close enough in the linear part to validate the numerical model as far as the elasticity of the wood is concerned.

5 CONCLUSIONS

The experiments conducted on the specimens of Larch and Douglas Fir and the numerical modelling allowed to reach the following conclusions:

(1) CFRP reinforcement increases the load carrying capacity of the specimens. The peak load of the Douglas Fir witness specimens is around 5.7 kN and reaches 7.5 kN for the reinforced specimens. For Larch witness specimens it is around 6.5 kN and reaches also 7.5 kN for the reinforced specimens. The MOE increased by 47 % for both Douglas Fir and Larch specimens with CFRP reinforcement.

(2) CFRP reinforcement improves the ductility of the timber specimens. The maximum displacement at rupture is much higher for the reinforced specimens than for the witness specimens.

(3) The U-shape reinforcement has no significant impact compared to the single one-layer reinforcement of the lower fibres as far as load carrying capacity is concerned, but significant impact compared to the single reinforcement of the lower fibres as far as ductility is concerned.

(4) The failure mode changes with reinforcement. Witness specimens fail in tension. Some specimens which had their 3 faces reinforced had their rupture in compression, others in compression coupled with tension, and few of them had their rupture at their defect's localization (knot).

(5) The Numerical model can be validated for the elastic behavior of the wood, but not for the plastic behavior. Even if the ductility is indeed improved, the maximal load carrying capacity decreases between the reinforced specimens and the witness which is the opposite observed during the experiments. The combination of the failure modes and the compressive failures both perpendicular and parallel to the grain can explain this difference.

https://doi.org/10.52202/069179-0004

6 DISSCUSION

Several improvements can be proposed in order to maximize the efficiency of the CFRP reinforcement.

(1) The experimental results showed that the U-wrapping of the beam with the Carbon fibers sheet delays the rupture by improving the ductility of the specimens, but does not improve the stiffness. Indeed, on the lateral faces only the wood fibers located below the neutral axis work in tension, the others are subjected to compression. For beams with bigger sections, the U-shape reinforcement could cover only half of the lateral face. This new reinforcement design would diminish the costs of the CFRP used for the reinforcement.
(2) The section of CFRP stayed constant during the whole experiment. An increase of the thickness of the carbon fibers sheets or the taping of several layers could improve the reinforcement. A study was led by Borri et al[4], where the efficiency of the reinforcements with one, two and three layers of CFRP were compared. Three sheets of CFRP resulted on a 60% increase of the flexural strength.
(3) The timber species has an impact on the testing results. Sometimes, CFRP reinforcements concern the renovation of old buildings built with oak or chestnuts. Those species have tyloses which can block pores. This feature allows the protection of wood against moisture so it can have an impact on the impregnation of the resin. Thus we obtain very thin adhesive film thicknesses, but it may not be quite adherent to the support. Besides for very thin film, the ambient humidity has an influence on the epoxy resin and may weaken it.

ACKNOWLEDGEMENT

The authors would like to thank the two companies who provided the materials for conducting the experiments Shanghai Yichang Carbon Fabric Materials Co., Ltd for the Carbon Fibers, and AONA Wood Structures for the timber specimens.

MICROWAVE TECHNOLOGY AND ITS APPLICATIONS TO WOOD TREATMENT AND MODIFICATION

Fernando Mascarenhas[1], Alfredo Dias[2], André Christoforo[3], Rogério Simões[4]

ABSTRACT: Humanity has utilized wood, a renewable resource, for a long time. To capitalize on all of the wood's advantages as a building, structural, and furnishing material, the wood industries and academics have continuously sought innovative approaches that lead to better and larger usage of wood. Microwave (MW) treatment is a technology that has gained increased popularity in modifying wood properties. It has been applied to improve the drying quality, increase fluid permeability, and enhance the treatability and impregnability of wood specimens. Therefore, this paper aims to present a summarized state of the art about MW treatment for wood modification and study the application of MW energy to drying wood samples of the Portuguese *Pinus Pinaster*, investigating the changes in the water uptake and compressive strength parallel to the grain of the MW-treated and control specimens. Based on the results, it was identified that there was an average energy consumption of 1233 MJ/m^3 and an average energy application of 3038 MJ/m^3. In addition, the water uptake of MW-treated samples increased by four times, and their compressive strength parallel to the grain was reduced by 19 % compared to the control samples.

KEYWORDS: Microwave treatment, Literature review, *Pinus pinaster*, Water uptake, Compressive strength.

1 INTRODUCTION

Wood is a natural material that has been used for many centuries for different purposes. Nevertheless, certain wood species have low permeability, which causes problems throughout the lumber manufacturing process, such as lengthy drying durations, material losses after drying, expensive drying procedures [1], and even difficulties in impregnating wood elements with preservative agents [2].

Because of this, wood industries and researchers have increasingly sought technologies, procedures, and innovations that address the limitations that wood might have and improve the use of wood in several fields, such as civil construction. Hence, wood modifications, either chemical, impregnation, or thermal, are modern technologies that have been changing the wood industry and research. The goal is to increase the performance of wood or wood-based products, resulting in gains in dimensional stability, improvements in mechanical properties, decay, and weathering resistance [3]–[5].

The use of microwave (MW) energy to dry, treat or modify wood species has been a promising technology with several possibilities of application. MW energy was first created for communication purposes, and then it started to be used for food heating in 1945/1946 [3,4]. It has also been used to heat materials such as wood [2]. MW are electromagnetic energies that interact with the molecules of the materials at different frequencies [6–8]. Because water molecules have a strongly polar structure, they can absorb MW energy and convert it into heat [11], [12]. The water molecule's angular geometry produces a hydrogen and oxygen atom–based dipole at the angle's bisector. When exposed to an electric field, the dipole will alter its orientation. The positive end of the dipole experiences a torque in the positive field direction, whereas the negative pole aligns with the positive field direction. If the field is made to alternate, the molecule will oscillate as it seeks to align with the current field direction [11]. Thus, this movement generates heat.

The use of MW energy in wood elements effectively reduces the drying time, improves its quality, and enhances permeability, contributing to increasing the preservative uptake [5,8–10].

Data from the Portuguese National Forest Inventory shows that maritime pine (*Pinus pinaster*) is the most common softwood in Portugal, representing 22% of the total [15]. Pine trees have rapid development and strong adaptation to varied environmental circumstances, so they are key raw resources that may satisfy some present market needs [16]. Because it has been utilized in construction as a raw material for furniture, poles, and posts, it is one of the most significant wood species in Portugal from an economic standpoint [17], [18]. It is also important to mention that in the case of Portuguese woods, only wild maritime pine appears in the European

standards with defined classification and testing procedures [19]. Hence, it is vital to comprehend all potential uses of this wood species for the wood sector, given the significance of this pine species in the economics and forestry of Portugal, as well as the rest of the Iberian Peninsula and other European areas, and the significance of forest sustainability [18], [20].

Given the importance of maritime pine for Portuguese construction and economy and the advantages that MW technology has for wood modification, this paper aims 1) to present the most relevant and recent studies regarding MW treatment for wood modification, pointing out the main usages and the scientific research possibilities, i.e., a brief literature review; 2) to analyze the improvement in water uptake (absorption) as an indirect way to analyze the improvement in the capability of being impregnated with preservative agents; and 3) to investigate the variations in the ultimate stress in compression parallel to the grain of wood samples with and without MW treatment of the Portuguese maritime pine.

2 MICROWAVE TREATMENT AND ITS MAIN APPLICATIONS – REVIEW

MW modification of wood is a new technology [5,11,12] with major applications for reducing wood drying time and improving fluid permeability [2]. When MW is applied, some parameters need to be adjusted to have different levels of MW wood modification: wood initial moisture content (IMC), MW power, frequency, energy supplied to the wood (intensity), and exposure time [5,8]. Wood industries have great concerns about the refractory species [21], which have low permeability and might show problems either during drying, impregnation, or retention of protective agents [10].

Conventional wood drying processes are time-consuming. Drying hardwood species might take long periods, and undesirable drying effects may emerge from it [10]. When MW wood drying is appropriately used, it can reduce the drying time and defects [2] and overcome the issue of hardwoods collapsing during drying [10].

In contrast to conventional wood drying, where heat is conducted from the outer layers towards the inner of the specimen through convection, conduction, and radiation, electromagnetic waves penetrate the entire volume of the sample in MW drying (treatment), promoting volumetric heat absorption by the wet wood [12], [23]. According to Sahin and Ay [23], energy is conveyed in the traditional drying heat process due to thermal gradients in the material; however, in microwave heating, electromagnetic energy is transformed into thermal energy rather than heat transmission. It produces rapid heating over the thickness of the material while also decreasing thermal gradients. Volumetric heating can also help to reduce drying times and conserve energy.

Wood is a biomaterial, so water plays an important role in it [21]. When MW energy hits the wood, the absorbed energy generates random vibrations of water molecules [13,14]. This motion raises the interior temperature of the wood, creating steam pressure that can quickly reach 600 kPa [10], [25], [26]. This increasing steam pressure damages the wood cell tissue to varied degrees [27]. Micro-structures that are prone to rupture include brittle ray cells, pit membranes in cell walls, and tyloses in arteries [28]. Variations in porosity and pore diameter distribution may result from changes in microstructure, opening up new channels for the easier passage of liquid. As a result, they affect crucial end-product qualities, such as permeability [28], [29] and absorption and retention of preservative agents [2].

The retention of acid copper chromate by MW-treated samples of *Eucalyptus tereticornis* increased by more than 375% after high-intensity MW treatment, from 2.03 kg/m^3 to 9.72 kg/m^3 [30]. Compared to wood samples without MW treatment, the absorption of Tanalith E in Spanish *Eucalyptus globulus* L. samples treated with MW increased by 148% [13].

After the MW treatment, Samani et al. [31] discovered a substantial improvement in the preservative retention and penetration of MW-treated wood specimens of Melia composita compared to the samples with no MW treatment. Compared to the control group, the retention capacity of *Pinus roxburghii* Sarg samples treated with MW was reported to be two times larger [32]. In addition, after submitting wood samples of Picea orientalis to an MW treatment with applied energy of 2158 MJ/m^3, Kol and Çayır [33] impregnated them with Tanalith E 8000. Their results showed that the retention rate increased by 61% compared to wood samples with MW treatment [33].

According to Wang et al. [34], MW treatment altered the chemical structures of cellulose, hemicellulose, and lignin, the three main constituents of wood. In contrast, lignin and cellulose were relatively stable. They only modified under limited circumstances, and hemicellulose sustained significant harm [34].

Both the physical and mechanical properties of wood are impacted by the microstructural changes that MW treatment causes to the wood cells. The damage in wood microstructure (and even macrostructure) increases when more MW energy is applied to the wood. Studies carried out by Weng et al. [27], [35], [36] using scanning electron microscopy (SEM) demonstrated that increased MW energy led to an increase in damage to wood microstructure. Numerous cavities were formed in the wood due to the high MW energies used, changing its porosity, permeability, strength, and flexibility [10]. The density of MW-treated samples tended to be lower than that of untreated samples, according to experimental research [10], [37], [38].

Several investigations have demonstrated that the values of modulus of rupture (MOR) and other strength parameters of MW-treated samples may decrease to varying degrees depending on the MW power and exposure period [10], [13], [21], [33], [38], [39]. According to Torgovnikov and Vinden [10], the degree of alteration that may be assigned to structural changes in wood following MW treatment – low, moderate, and high – depends on the MW treatment circumstances. The authors stated that there was no effect on the mechanical characteristics of wood and an increase in permeability of up to 1.5 times with low degrees of alteration. The moderate degree of alteration decreases the mechanical qualities of wood while increasing permeability 1,000 times. Finally, a high degree of modification greatly

increases permeability but greatly decreases mechanical properties [10].

Weng et al. [14] employed two MW powers, 15 and 20 kW, to treat wood samples of *Cunninghamia lanceolate* (Lamb.) Hook. The authors demonstrated that the damage to the wood microstructure was more severe under high MW treatment power (20 kW). For 20 kW, the produced macro-cracks were between 100 and 130 μm wide, while for 15 kW, they were between 1 and 25 μm wide. For 15 kW and 20 kW, the diameter of margo capillary holes in pit membranes increased by 23% and 55%, respectively. In addition, the results from the literature have demonstrated that the influence of the applied energy directly impacted the density and the mechanical properties of different wood species.

According to Torgovnikov and Vinden [10], samples with heartwood lost more strength than samples with only sapwood under the same MW applied energy, for example, to produce a modest degree of modification. This resulted in a slight change in the MOR. Mascarenhas et al. [40] also demonstrated a significant improvement in water uptake of small clear wood specimens of Portuguese maritime pine containing only heartwood compared to the samples containing only sapwood, demonstrating the necessity of providing the sapwood sample with more MW energy. This improvement in water uptake was demonstrated by drying wood samples with only sapwood and heartwood under the same MW parameters. In light of these results, it can be concluded that the density of the wood component was, in fact, a major parameter (that affects) the fluctuations in the MOR values following MW treatment.

According to Wang et al. [34], utilizing MW intensities (applied energy) ranging from 72 MJ/m^3 to 288 MJ/m^3, neither the cell architectures nor the cell wall morphology of any of the samples with an IMC of 40% changed substantially. On the other hand, the worst alterations to the cell wall structure were caused by MW treatments in wood samples with an IMC of 20% and applied energy of 288 MJ/m^3. As a result, the decline in the mechanical properties values of the wood samples treated with MW was closely related to the harm caused to the cell morphology.

He et al. [29] indicated that under the adopted MW treatment parameters, no significant influence was detected in the MOR values of wood samples with IMC over the fiber saturation point (FSP) (greater than 40%). Then, for these circumstances, the drop in mechanical characteristics during static bending tended to be less the greater the initial MC.

According to the results reported in the literature, the effects of MW treatment on strength and stiffness rely not only on the MW treatment parameters but also on the type of wood and IMC. Furthermore, it is challenging to impregnate wood with resins and preservatives. Wood components may be more easily impregnated with substances to boost biological and fire resistance because of their increased permeability due to MW treatment. They can even be used to create new wood-based products that are impregnated with polymers that have improved qualities [2], [10], [25].

3 MATERIALS AND METHODS

3.1 SAMPLE PREPARATION

Small clear heartwood specimens of the Portuguese maritime pine with 20 mm × 20 mm × 200 mm (radial × tangential × longitudinal) (Figure 1) from the Centre region of Portugal were obtained from commercial boards. The idea of using them is because they allow a safer comparison of results between different wood species [41], [42]. Small clear specimens also have better workability, are simple to obtain, economically attractive, rapid to condition, and straightforward in tests, for example, mechanical ones [43], [44].

In total, 24 specimens were used. They were divided into two groups, control (no MW-treated) and MW-treated, which were submitted to the MW treatment (MW drying). Table 1 shows the number of samples per group, their average initial moisture content (IMC), and standard deviation values.

Figure 1: *Small clear specimen of Maritime Pine*

Table 1: *Sample groups, their quantity, and IMC*

Group	Designation	Quantity of specimens	Average IMC (%)	Standard deviation (%)
HP_MW	Heartwood Pine – MW-treated	12	83.44	16.33
HP_Control	Heartwood Pine – Control	12	12.55	5.43

The wood samples submitted to the MW treatment were placed in a container of distilled water to preserve their "green" conditions so they would not lose water until the drying process began.

3.2 MICROWAVE TREATMENT

The MW treatment was carried out in a conventional MW device measuring 200 mm × 300 mm × 300 mm, at a frequency of 2.45 GHz, with a turntable that allowed a homogeneous distribution of the MW waves.

The wood samples were dried using full MW power of 800 W until they achieved an average final moisture content of 12 %. The MW treatment schedule is shown in Figure 2.

Figure 2: *MW treatment schedule*

https://doi.org/10.52202/069179-0005

As seen in Figure 3, four wood specimens were placed inside the MW oven during each MW drying cycle. The wood samples were exposed to continuous MW energy for 30 s, removed during a colling interval of 30 s to measure the samples' weight (and then to have the moisture content profile along the MW treatment process), and then placed again inside the MW oven.
The cooling intervals were necessary for measuring the weight of the specimens as well as for preventing overheating, which might seriously damage the wood. A similar approach was made by [11], [33], [45]. Oloyede and Groombridge [11] noticed that each succeeding MW exposure should have a larger penetration depth and that by cycling the drying process, the wood might be efficiently dried to any moisture content.

Figure 3: *Pine samples during the cooling interval*

The energy required to heat moist wood and vaporize the water in the wood, Q_w, was calculated according to equation (1) [46].

$$Q_w = \Delta T \cdot (c_1 \cdot m_1 + c_2 \cdot m_2) + \Delta m \cdot r \quad (1)$$

Where: Q_w is the energy required to heat moist wood and to vaporize the water in the wood, in kJ (kWs); ΔT is the temperature difference, in ºC; c_1 is the heat capacity of water, 4.18 kJ/kgºC; m_1 is the mass of water in the specimen, in kg; c_2 is the heat capacity of dry wood, 1.36 kJ/kgºC; m_1 is the mass of dry wood in the specimen, in kg; Δm is the mass of vaporized water, in kg; r is the heat of vaporization of water at 100ºC, 2250 kJ/kg.
The average effective power density consumed to dry the wood specimens is given by Equation (2) [46].

$$P_\delta = \frac{Q_w}{V.t} \quad (2)$$

Where: P_δ is the specific power density consumed to dry the wood specimens, in kW/m^3; V is the volume of wood specimen, in m^3; t is the drying time, in s.
The specific energy consumption during the process is given by Equation (3) [46].

$$E_{in} = \frac{P_\delta \cdot t}{1000} \quad (3)$$

Where:E_{in} is the specific energy consumption during the process, in MJ/m^3.

The specific energy supplied during the process is given by Equation (4) [33].

$$E_{out} = \frac{P \cdot t}{V \cdot 10^6} \quad (4)$$

Where:E_{out} is the specific energy supplied during the process, in MJ/m^3; P is the MW power supplied.
Finally, the overall MW efficiency, η, was calculated according to equation (5).

$$\eta = \frac{E_{in}}{E_{out}} \quad (5)$$

Once the MW treatment was completed, the mass percent loss (MPL) was calculated using equation (6):

$$MPL\ (\%) = \frac{M_f - M_i}{M_{od}} \times 100 \quad (6)$$

where MPL is the mass percentage loss, in %; M_f is the mass of the sample after the MW treatment, in grams; M_i is the mass of the samples before MW treatment, in grams; M_{od} is the oven-dry mass, in grams.

3.3 WATER UPTAKE

Both wood groups were impregnated with distilled water under constant pressure for 30 min. The water uptake (W) was measured using equation (7):

$$W\ (\%) = \frac{M_a - M_b}{M_{od}} \times 100 \quad (7)$$

where W is the water uptake, in %; M_a is the mass of the sample after the water impregnation at the instant in which it was measured, in g; M_b is the mass of the MW-treated samples before the impregnation, in g.

3.4 COMPRESSION STRENGTH PARALLEL TO THE GRAIN

The average ultimate stress in compression parallel to the grain at 12 % moisture content, $f_{c0,12\%}$, was evaluated according to ISO 13061-17 [47]. Wood specimens measuring 20 mm x 20 mm x 60 mm were used in this mechanical test. Before the compression tests, the wood samples were conditioned at a temperature of 20 °C ± 2 °C and 65 % ± 5 % of relative humidity for 14 days to achieve their equilibrium moisture content.

Figure 4: *Compression parallel to the grain test according to ISO 13061-17* [47]

3.5 STATISTICAL ANALYSIS

Pearson's correlation coefficient (r) measures the degree of linear correlation between two quantitative variables. This approach typically uses datasets with a normal distribution and an interval or continuous scale [48]. It can range from -1 to +1, presenting a low, moderate, or strong correlation, where a 0 value means that there is no correlation. It is calculated according to Equation 8:

$$r(X_i, Y_i) = \frac{cov(X_i, Y_i)}{\sqrt{var(X_i) \times var(Y_i)}} \quad (8)$$

Where: X_i and Y_i are the datasets of the MW-treated woods, $cov(X_i, Y_i)$ is the covariance, $var(\cdot)$ is the variance.

Simple linear regression models, which have one dependent variable (Y) and one independent variable (X), were used with Pearson's correlation coefficient to analyze the correlation between the $f_{c0,12\%}$ and the water uptake of the MW-treated wood samples. The general equation for a linear regression model is:

$$Y = b_0 + b_1 X \quad (9)$$

Where: Y is the dependent variable as output, X is the independent variable as input, b_1 is the regression coefficient, b_0 is the constant.

The analysis of variance (ANOVA), at a 5 % significance level, using Minitab Software (Version 18) [50], was applied to study the effectiveness of the MW treatment in improving the water uptake and the changes in the compressive strength of maritime pine wood samples. According to the ANOVA formulation, if p-values are smaller than the significance level (p-value ≤0,05), the samples (control group and MW-treated) can be considered different.

4 RESULTS AND DISCUSSION

4.1 MW DRYING

Once a total of 12 specimens were dried, and each treatment scheme was done with four specimens dried together, three rounds of drying were performed. Based on this, the average values of the MW drying (treatment) of the pine heartwood samples are shown in Table 2. The total time the wood samples were exposed to MW energy was, on average, 21 min, with a maximum of 27 min. The average effective power density, P_δ, to dry the wood specimens was 1005 kW/m^3, the average energy consumed, E_{in}, was 1233 MJ/m^3, and the average energy applied, E_{out}, was 3038 MJ/m^3, with an overall MW efficiency of 0.40 (average) and a maximum value of 0.46. According to [12], [46], the overall MW efficiency for MW ovens with industrial applications is approximately 0.50. Therefore, our results are in accordance with this value.

Table 2: *MW drying information*

Group	Average total MW exposure time (s)	P_δ (kW/m^3)	E_{in} (MJ/m^3)	E_{out} (MJ/m^3)	η
HP_MW	1260 (383)	1005 (131)	1233 (239)	3038 (958)	0.40 (0.05)

The values in brackets are the respective standard deviation.

In addition to this, Table 3 presents the average MPL and the amount of energy per MPL. The MPL average value was 67.17 %, ranging from 51.60 to 82.74 %. Based on these results, the consumed energy used to obtain 1 % of MPL was 17.78 MJ/m^3, i.e., it was consumed, on average, 17.78 MJ/m^3 to evaporate 1 % of the water from the wood samples. In addition, it was supplied 44.37 MJ/m^3, to have 1 % of MPL, which is in accordance with the previous results, such as the ones found by [33], [51], whose values ranged from 43.60 to 50.30 MJ/m^3.

Table 3: *Information about MPL after MW treatment*

Group	MPL (%)	$E_{in}/_{MPL}$ (MJ/m^3/%)	$E_{out}/_{MPL}$ (MJ/m^3/%)
HP_MW	67.17 (17.07)	17.78 (0.98)	44.37 (3.82)

The values in brackets are the respective standard deviation.

The average MW drying rate was 3.19 %/min, and the maximum was 6.31 %/min. Figure 5 shows the MW drying rates over the drying time. Drying small clear samples of another pine species, *Pinus banksiana*, applying an MW power of 800 W, Ouertani *et al*. [21] identified a maximum drying rate slightly higher than 6 %/min.

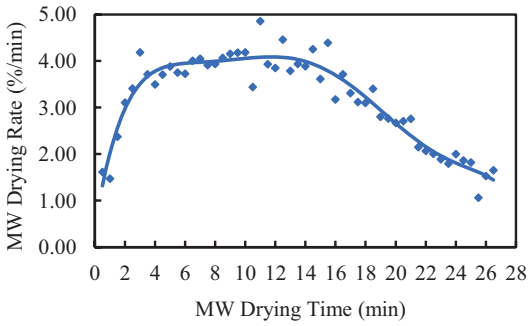

Figure 5: *MW drying rate*

Three stages can be seen in Figure 5. First, the drying rate increased, which may be interpreted as the time when a portion of the energy input was used to raise the temperature of both the water and the wood material from room temperature to around 100 ºC. After then, the drying rate remains relatively steady for the whole drying process. As the amount of free water in the wood approached zero, the drying rate decreased in the last stage.

https://doi.org/10.52202/069179-0005

4.2 WATER UPTAKE

The water absorption of the MW-treated and control wood specimens was measured through their water uptake, and the results can be seen in Figure 6. The average W of HP_MW was 42.57 % (stand. dev. of 16.69 %), and the average W of HP_Control was 10.32 % (stand. dev. of 3.63 %). Thus, the MW treatment significantly impacted the water uptake of MW-treated samples at a confidence level of 95%, i.e., it was almost six times higher.

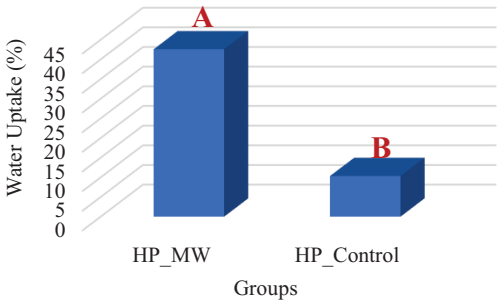

Figure 6: *Water uptake (W) of the wood samples (Values followed by the same letter do not differ significantly at α=0.05)*

According to EN 350 [52], the treatability, which is "the ease with which a wood can be penetrated by a liquid (for example, a wood preservative)" of maritime pine's heartwood, is considered extremely difficult to treat. This fact can be seen in the water uptake value of the wood control samples. Since the water uptake of the MW-treated samples increased, it might indicate that the permeability of the MW-treated sample enhanced, which may be beneficial for easier impregnating those heartwood pine samples with preservative chemicals.

4.3 COMPRESSION STRENGTH PARALLEL TO THE GRAIN

Compression is an important mechanical property in designing different elements, such as poles, trusses, and columns. The newest version of the Brazilian Timber Structures Code, ABNT NBR 7190-1 [53], uses compressive strength parallel to the grain to classify the batch strength.

The ultimate stress in compression parallel to the grain at 12 % moisture content, $f_{c0,12\%}$, of both wood groups is shown in Figure 7. The average $f_{c0,12\%}$ values for MW-treated and control groups were 61.94 MPa (minimum of 48.51 MPa, maximum of 78.41 MPa, and stand. dev. of 8.70 MPa) and 49.93 MPa (minimum of 36.82 MPa, maximum of 59.94 MPa, and stand. dev. of 7.68 MPa).

Studying the mechanical behavior of small clear samples of maritime pine, Santos [54] found that the average compressive strength of the specimens was 59 MPa.

Besides the compressive strength of studied MW-treated and control specimens being statistically different (at a confidence level of 95 %), the MW treatment of 3038 MJ/m^3 applied energy caused a decrease of approximately 19 % in the compressive strength of the specimens. Using an MW power of 925 W and applied energy of 2158 MJ/m^3, Kol and Çayır [33] identified a reduction of 4 % in $f_{c0,12\%}$ of MW-treated small clear sapwood samples of *Picea orientalis* (L). Link.

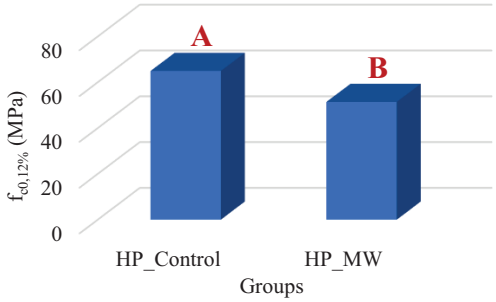

Figure 7: *Results of compression strength parallel to the grain, $f_{c0,12\%}$ (Values followed by the same letter do not differ significantly at α=0.05)*

Load-displacement curves in compression parallel to the grain of control and MW-treated samples are shown in Figure 8(a) and (b), respectively. Overall, both curves demonstrated an initial elastic domain almost up to the maximum applied force and, after that, a plastic behavior. As previously presented, the maximum average compressive stress of the MW-treated specimens is statistically lower than that of the control group specimens, which is also evident when analyzing Figure 8. The maximum average force of control samples was 26.2 kN with an average actuator displacement of 2.21 mm. On the other hand, the maximum average force of MW-treated samples was 21.1 kN with an average displacement of 1.65 mm.

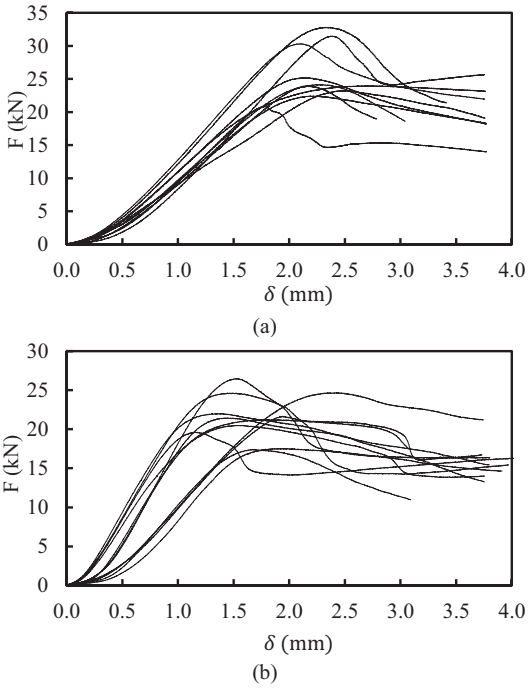

Figure 8: *Load-displacement curves of compression parallel to the grain of (a) control and (b) MW-treated groups (F=Force)*

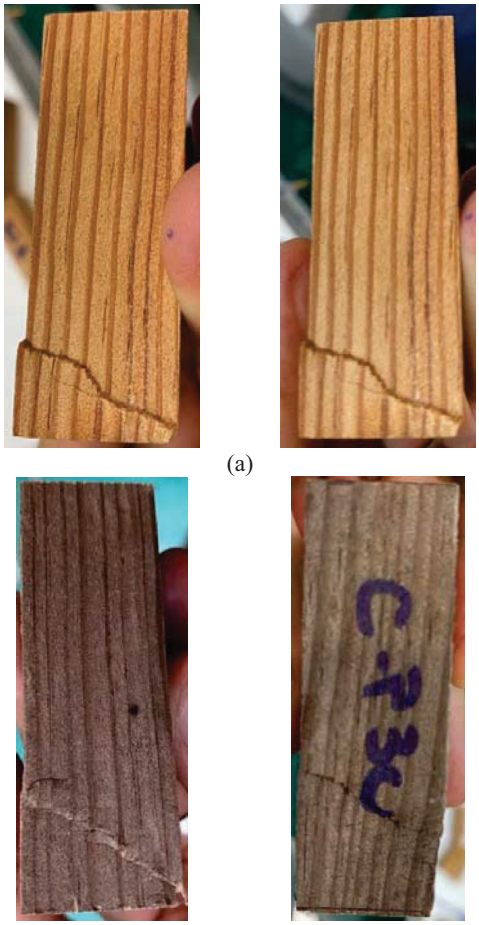
Figure 7 shows four wood samples of maritime pine, (a) two with no MW treatment and (b) two MW-tread. The most common type of failure in control and MW-treated samples was crushing-shearing, which are normal types of failure according to ASTM D143 [55].



(a)

(b)

Figure 9: *Compression failure mode of (a) control and (b) MW-treated samples*

It is important to explain that the darker color of the MW-treated sample is not because of the MW treatment. As previously explained, the specimens were kept in water to preserve their "green" condition. Therefore, this period that they were immersed in water contributed to the change in their color.

According to Benabou [56], the compressive properties of wood play a crucial role in this behavior. Wood, in particular, exhibits a typical failure pattern known as kink banding when compression parallel to the grain. It is a shear-type failure that occurs in many aligned-fiber composites and wood materials. Benabou [56] also stated that under the kink banding mechanism, three main stages could be recognized (Figures 8 and 10). To begin, incipient kinking occurs in limited areas, beginning with ray cells of wood dispersed throughout the material and causing the stress-strain curve to become non-linear. Fibre shearing and buckling is the softest kind of deformation at this stage. The peak stress occurs shortly after the commencement of nonlinearity and indicates the conclusion of incipient kinking. After that, the transient kinking occurs when the stress decreases from its peak to a steady condition. During this phase, the tiny zones of incipient kinking get bigger and unite to produce a single dominant band with a specific direction across the specimen. The fibers within the band are compressed and rotated at the same time. Fiber rotation increases until the final lock-up position is reached. Due to volumetric preservation considerations, no more deformation inside the band is feasible at this lock-up angle. Third, steady-state kinking happens after fiber lock-up and is caused by continually applied tension, also known as steady-state stress. The band broadens laterally into the surrounding material throughout this period [56].

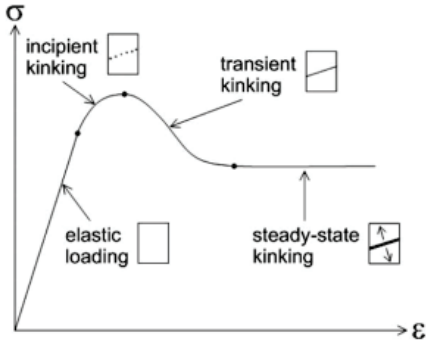


Figure 10: *Diagrammatic representation of the stress-strain crushing behavior of a wood specimen at various kinking stages (From Benabou* [56])

Figure 11 shows Pearson's correlation coefficient r and the p-values. First, the correlation between the ultimate stress in compression parallel to the grain at 12 % moisture content and the water absorption of the MW-treated specimens can be considered moderate to high and significant (p-value<0.05). It is a negative correlation, 0.639, which indicates that the higher the water uptake, the smaller the values of $f_{c0,12\%}$ were. This is easily understandable since a greater water retention capacity may indicate that more damage has occurred in the microstructure of the wood specimens, so this damage negatively affects the mechanical properties.

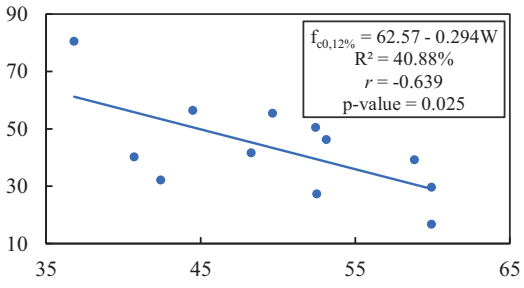

Figure 11: *Correlation analysis*

5 CONCLUSIONS

Microwave treatment or drying of wood is a modern technique with primary applications in wood drying and increasing the fluid permeability and the impregnation with preservative chemicals. When MW is used, the following main variables must be adjusted to achieve various degrees of MW wood modification and assure its efficiency: wood initial moisture content, MW power, frequency, applied energy (intensity), and exposure time.

Microwave treatments can expand the radius of pit membrane pores and even generate microscopic cracks inside the wood by altering the wood's microstructure (such as the pit and ray parenchyma cells). These effects may lead to increased permeability of wood, which is desirable for many wood species primarily to improve impregnability and retention of preservative chemicals and even to make novel wood-based composites.

Regarding the analysis impacts of the MW treatment on the samples of Portuguese maritime pine containing only heartwood, the following conclusions were drawn:

- With an average IMC of 83 %, there was an average energy consumption of 1233 MJ/m^3 and an average energy application of 3038 MJ/m^3. This gave an overall MW efficiency of 0.40 on average, with a maximum value of 0.46.
- The amount of consumed energy to dry 1 % water was around 18 %, and the amount of applied energy to dry 1 % water was approximately 44 %.
- The average MW drying rate was 3.19 %/min, and three stages were identified: a rapid increase of the drying rate after a constant period and then a decrease of the drying rate.
- An increase of about four times in the water uptake capability of the MW-treated samples compared to the control group was measured.
- A decrease of 19 % in the ultimate stress in compression parallel to the grain of the MW-treated specimens compared to the control group was identified.

Finally, based on the results of this study, MW treatment (drying) of Portuguese maritime pine presents interesting possibilities in increasing the absorption of preservative chemicals without causing significant reductions in the compressive strength parallel to the grain. Hence, fine adjustments in the MW treatment conditions might be made in order to maintain the improvement in the capability of absorbing fluids without causing severe reductions in the mechanical properties, which can be more extensively studied.

FUNDING

This work was financed by national funds through Foundation for Science and Technology – FCT, from Portugal, under grant agreement 2021.07636.BD, the FCT, the Ministry of Science, Technology and Higher Education (Portuguese: Ministério da Ciência, Tecnologia e Ensino Superior or MCTES), the Programa Operacional da Região Centro (CENTRO 2020), and the European Social Fund (Portuguese: Fundo Social Europeu or FSE).

ACKNOWLEDGEMENT

We are also thankful Institute for Sustainability and Innovation in Structural Engineering – ISISE Coimbra, the Department of Civil Engineering of the University of Coimbra, the Innovation and Competence Forest Centre – SerQ, and the Department of Chemistry, the Unit of Fiber Materials and Environmental Technologies (FibEnTech-UBI) of Universidade da Beira Interior, for all support provided in the development of this work.

STRUCTURAL PERFORMANCE, AND FAILURE MECHANISM, OF HARDWOOD CROSS LAMINATED TIMBER CONCRETE COMPOSITE UNDER SHEAR LOAD

Aamir Khokhar[1], David Bell[2], Roshan Dhonju[3]

ABSTRACT: The performance of Timber Concrete Composite(s) (TCC) is primarily governed by the type of connection used in connecting the constituent members together. This paper investigates the performance of various commonly used connections in a TCC. The main goal of this research is to identify which type of connection provides the optimal structural performance while also identifying the effects parameters such as inclination angle and penetration/notch depth have on the performance of connections. Shear tests on 40 hardwood CLT Concrete Composite specimens comprising of 5 connection configurations, utilising notched and screw connections were undertaken in accordance to BS EN 26891. The results showed that notched connections provided the most satisfactory structural performance in relation to load carrying capacity and stiffness, with the depth of the notch having a significant impact on the behaviour of the composite under load. In terms of timber screw connections, screws inclined at 45° yielded the best structural performance in relation to load carrying capacity and stiffness.

KEYWORDS: Hardwood, Cross laminated timber, Push-out test, Shear connectors, Slip modulus, Failure modes

1 INTRODUCTION

To date the study of Engineered Wood Products (EWP) such as CLT and Glulam has been widely undertaken. Such materials offer a means of building larger timber structures, due in part to their improved structural properties compared to sawn timber, yet much like traditional timber construction there is a boundary to their structural capabilities. As a result of this, an old building technology has seen a recent increase in academic and industrial research. Timber Concrete Composites (TCCs) are a composite material originally used to renovate old timber structures due to a global lack of steel [1]. Yet TCCs are currently being utilised as a material which can overcome the structural limitations of timber and indeed EWP construction. The benefits of TCCs are well documented, with improved structural, thermal and seismic performance compared to timber only construction [2,3], while also being faster to construct, and have a significantly lower global warming potential compared to conventional concrete and steel construction [4,5]. In recent years, there has been an increase in interest on the use of a TCC which uses an EWP as the timber member. The results from recent studies show that such composites can overcome the limitations associated with traditional mass timber construction [6]. Previous TCC research has shown that the most important element in such a system is the connection used, as using an ineffective connection can result in a large reduction in structural performance [7]. The limited research on EWP TCC has mainly been focused on the effectiveness of connections used in the composite [3,8]. These studies reported that the orientation of dowel, notched and glued connections can greatly influence the overall performance of the composite. Despite the benefits of TCCs, limitations to their widespread adoption exist and can be attributed to a lack of design and practical knowledge on the behaviour of connections [2,6]. Furthermore, guidance on the slip modulus for inclined screws and the behaviour of notched connections with various notch depths and screw inclinations has not yet been fully investigated [3,8,10].

Additionally, there has been no research investigating the suitability and performance of a hardwood CLT Concrete Composite, leaving a notable gap in the current published literature on Timber Concrete Composites. Using hardwood CLT can further increase the scope of timber construction while making TCCs even more competitive compared to traditional materials as a result of its improved structural properties. Therefore, the main objective of this work is to examine the structural performance of various types of connections used in a hardwood CLT Concrete Composite.

2. EXPERIMENTAL PROGRAMME

2.1 TESTING SUMMARY

A total of 40 specimens were tested, which comprised of two main connection categories, metal screw connections (S) and notched connections used in conjunction with screws (NS). Five different configurations of the (NS) and (S) connections commonly used in TCCs were adopted in this research. This included metal screw connections with various penetration depths (PD) and orientations (α) and notched connections cut to various PD coupled with screws at varying orientations. The PD for each of the (S) series specimens was based on the diameter of the screw, with d, being equal to the diameter (in this case d=5 mm). For the NS series the PD was measured as the depth from the top surface of the CLT as shown in Figure 1. Each (S) series specimen had a row of three (or six, if inclined screws were used) screws on each side of the CLT. Each (NS) series specimen had 2 notches and 2 screw (or 2 notches and 4 screws for the NS45 specimens) on either side of the CLT

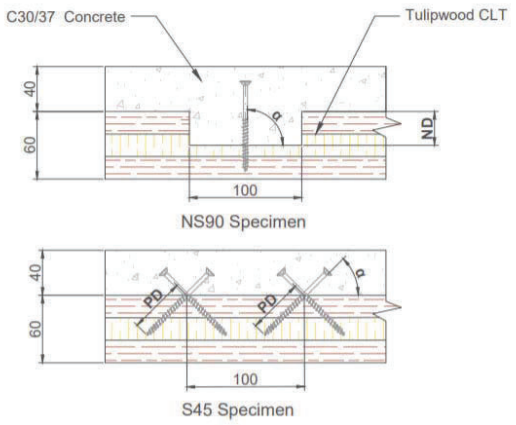

***Figure 1**: Type (NS) and (S) connection schematic*

Table 1 provides further details on the number of specimens and connection configurations. Each specimen consisted of a 60×140 mm CLT member with a height of 430 mm, connected to two 40×140 mm concrete members of the same height.

***Table 1:** Detail of test specimens*

Test code	Connection	Connection orientation (°)	Penetration depth/ Notch depth (mm)	Number of specimens
S90	screw	90		
			10d	2
			11d	2
S45	screw	45	9d	3

2.2 MATERIAL PROPERTIES

The Tulipwood (*Liriodendron tulipifera*) CLT used in this research was supplied by the American Hardwood Export Council (AHEC). This CLT was chosen as it offers increased structural performance compared to conventional European softwood CLT. Additionally, as mentioned previously, no published work has been undertaken investigating the effects of using a hardwood EWP in a TCC. The high strength to weight ratio of Tulipwood CLT makes it a very suitable choice for TCC fabrication, where weight plays a vital role in the effectiveness of the composite. Additionally, the increased density of this hardwood is expected to improve the load carrying capacity of the connections and thus the performance of the overall composite. The properties of the CLT used in this research has been previously determined in work undertaken by [11] and is shown in Table 2.

Two possible manufacturing options for concrete used in TCC construction exist. These are offsite concrete casting and in-situ casting. This research is focused on TCCs that are cast in-situ and as a result, in-situ concrete casting was used. The strength of concrete used in this research has been based on what is currently used as an industry standard in TCC design, which comprises of C30/37 concrete. The quantities of the constituents used in the concrete was calculated using a Building Research Establishment (BRE) concrete mix design. The properties of the concrete used can be seen in table 2.

https://doi.org/10.52202/069179-0006

***Table 2**: Mechanical properties of CLT, concrete and screws*

Material	Properties	Values	Units
CLT	Density (ρ)	485.79	kN/m^3
	Modulus of elasticity (E)	11010	N/mm^2
	Shear modulus (G)	196.57	N/mm^2
Concrete	Compressive strength ($f_{c,k}$)	36	N/mm^2
	Mean target strength ($f_{c,k}$)	43	N/mm^2
Screw	Tensile strength ($f_{tens,k}$)	7900	N
	Yield moment ($M_{y,k}$)	5909	N.mm
	Characteristic yield strength ($f_{y,k}$)	1000	N/mm^2
	Length (L)	80	mm
	Threaded length (B)	45	mm
	Diameter (D)	5	mm

5 x 80 mm *Spax* Windrox screws were used in this research. They have been chosen for their quality, availability and cost which according to [12] are important criteria to consider when choosing a suitable connection for a TCC. The screws are also corrosion resistant, which is a further benefit for use in this application [13]. The screws are partially threaded which offers high withdrawal strength, while the lack of threading near the head of the screw reduces the potential for concrete cracking to occur. The properties (provided by [14]) of the screws can be found in Table 2.

An important consideration in the design of a TCC is the spacing of the connectors. The spacing of the screw connections adopted in this work was calculated in accordance to EN 1995-1-1. The spacing for the notched connections is based upon the recommendations provided by [3] in addition to the size restraints of the specimens.

2.3 TESTING PROCEDURE

Each specimen was simply supported at their base. The supports elevated the specimens 50 mm above the ground providing sufficient space for the specimens to deform vertically. Horizontal movement was restrained by the self-weight of the specimens. The vertical slip between the timber and concrete members was measured and recorded using two Linear Variable Displacement Transducers (LVDT) each with a 50 mm maximum displacement. The LVDTs were fitted on the front and back of the specimens as shown in Figure 2. The specimens were tested in accordance to BS EN 26891. A F_{est} (maximum load) was established for each connection type, by testing a sacrificial specimen for each connection configuration. The test specimens were then loaded following the loading profile set out in BS EN 26891 as show in Figure 3. The specimens were tested in a Schenck Trebel Instron 5500 testing machine fitted with a 100 kN load cell.

***Figure 2:** S-Series specimen (left) and NS-Series Specimen (right) in testing apparatus*

3 RESULTS AND DISCUSSION

3.1 LOAD-SLIP RESPONSE

A simple and effective way of determining the structural behaviour of a TCC and the performance of the connections used, is by analysing the load-slip response of the specimens under shear load. This allows for the determination of the relative stiffness and slip modulus of connections and helps classify the type of failure that occurred. The load-slip response of the specimens was obtained by testing the specimens in accordance to BS EN 26891-1991. Figures 4 and 5 provide the load-slip response for the (S) series of specimens.

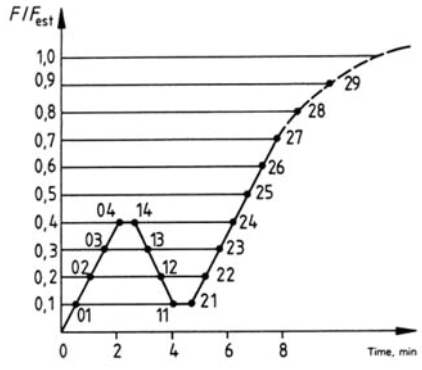

***Figure 3**: Loading procedure for slip modulus and maximum load, accordance of BS EN 26891-1991.*

https://doi.org/10.52202/069179-0006

3.1.1 Screw connections

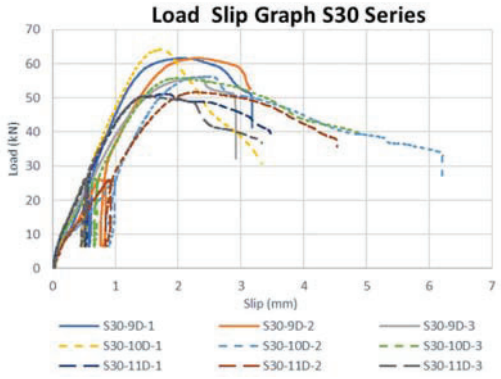

***Figure 4**: Load-slip Graph 30° screw orientation*

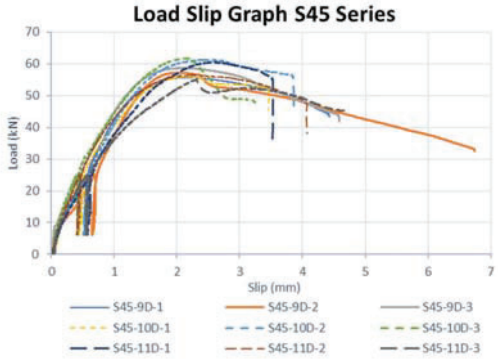

***Figure 5**: Load-slip Graph 45° screw orientation*

It can be observed in Figure 4 & 5, that the S30 and S45 specimens failed in a similar manner regardless of the screw orientation and penetration depth, with a plateau of load carrying capacity followed by the failure of the screws and sudden drop in load. Such failure is typical for screw connections in TCC [17]. In terms of structural performance, the S45 specimens showed a higher average maximum load than the S30 series. However, the S30 series displayed a greater initial stiffness as illustrated in Figure 4. As for penetration depths, 11D specimens, specifically for the S30 series, yielded the lowest load carrying capacity. This is as a result of the shallow orientation angle of the S30 screws and the thickness of concrete used in this research. The level arm produced by screws inserted at 30° provided less resistance to load, due to a reduced resistive contact surface compared to the S45 series. This is most evident when looking at the S30 11D specimens, which produced the lowest load carrying capacity out of the three penetration depths tested. The S30 11D specimens also failed at a lower Fmax and in a more brittle manner, compared to S45 inserted at a lower penetration depth. The resulting shallow angle of the screw in combination with the penetration depth did not allow for favourable deformation/settlement of the screw and as a result an increase brittle failure of the specimen was observed.

Specimens with perpendicular screws (S90) exhibited a more ductile behaviour and as a result a significantly lower Fmax than S30 and S45 specimens. This is shown when comparing Figure 6 to Figure 4 and 5. This outcome was expected, as previous work by [18] carried out on perpendicular connections in CLT Concrete Composites and TCCs has concluded the same findings. Similarly to the previous research carried out by [6], a penetration depth of 11D for S90 specimens resulted in a connection with increased stiffness and on average a greater load carrying capacity, in comparison to the other penetration depths tested. However, for both penetration depths tested, the large slip yielded from the S90 specimens under load showed that they exhibit the lowest levels of composite action, highlighting the structural limitations of this orientation of metal screw connections in CLT Concrete Composites.

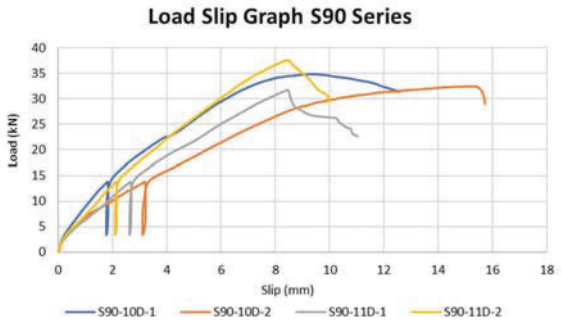

***Figure 6**: Load-slip Graph 90° screw orientation*

3.1.2 Notch connections

Similarly to the theory regarding penetration depth and connection stiffness for screw connections, an increase in notch depth is directly related to an increase in maximum load carrying capacity [8,10]. The main parameters which govern the behaviour of notched connections according to [3] are the geometry of the notch (primarily the notch depth) and whether or not a metal fastener is used in combination with the notch. However, according to [8,10] to date there has been little research investigating the effective number and orientations of screws used in combination with notched connections.

The results from this research show the effects a change in notch depth and orientation of screws used in tandem with notches have on the performance of notched connections in CLT Concrete Composites. NS specimens exhibited the greatest load carrying capacity and stiffness of out all specimen configurations tested, as shown in Table 3. For the NS45 specimens, a linear relationship

between Fmax and notch depth can be identified, with a clear increase in Fmax with an increase in notch depth. This ranges from a Fmax of 72.7 kN for a notch depth of 25 mm to a Fmax of 77.5 kN for a notch depth of 35 mm. Translating to an average increase of 3 percent in Fmax for every 5 mm increase in notch depth.

For the NS90 specimens, an increase in Fmax is noted between specimens NS90-25 and NS90-35 of 11.3 kN. However, unlike the NS45 specimens a further increase in notch depth to 35 mm does not result in an increase in maximum load. This difference in behaviour is likely a result of variance in the material used and not a result of the depth of the notch itself, as unlike screw connections, notched connections resist applied load through direct contact between the concrete and timber members. Thus, the performance of the composite is greatly dependant on the properties of said members. Additionally, the higher variance in results for the NS90, is also likely due to the manufacturing of the notch itself. As the notched specimens tested in this research were cut by hand, unlike the industry standard of using CNC machinery. Therefore, it is speculated that, despite the results shown in this research for the NS90 11D specimens, it is still believed that an increase of notch depth yields an increase in load carrying capacity. This interpretation is based on the results from the NS45 specimens and previous research by [3], [8] and [10] on notched connections in TCCs.

The depth of notched connections proved to have a significant influence on the performance of the connection, as an increase in notch depth provided greater ultimate load and lower slip modulus. This is shown in Figure 7 and 8. A similar relationship between notched depth and Fmax has also been recently reported by [10].

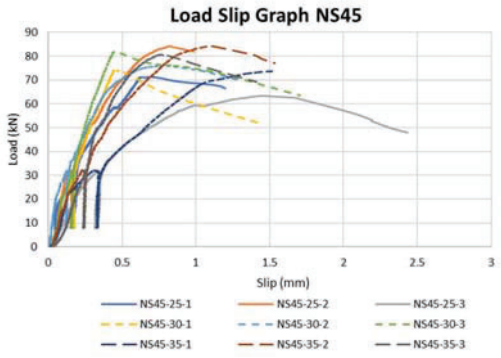

***Figure 7**: Load-slip graph NS45 specimens*

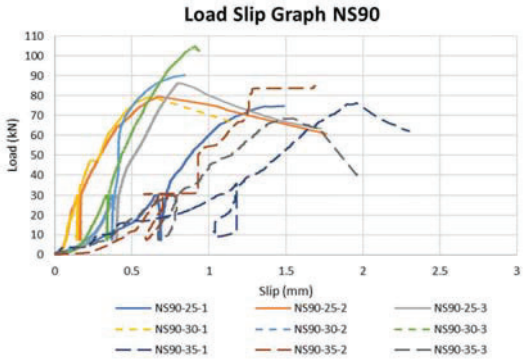

***Figure 8**: Load-slip graph NS90 specimens*

3.2 SLIP MODULUS

To calculate the slip modulus, displacements at 10, 40, 60 and 80 percent of the maximum load (F*est*) were obtained. Using these values, the initial slip modulus (Ki) and the Serviceability Slip modulus (Ks) were calculated according to BS EN 26891-1991.

***Table 3**: Maximum load and slip modulus results*

Connection type	Fmax	Slip at Fmax	Initial	Serviceability limit state
	(kN)	(mm)	Ki (kN/mm)	Ks Slip Modulus (kN/mm)
NS 45 25	72.9	0.99	151.0	161.5

S30 11D	51.1	1.89	43.1	34.3
Average	56.3	2.1	41.3	36.2

As shown in Table 3, the notched connections exhibited the greatest slip modulus compared to the other specimen configurations. This was expected as it was previously stated that notched connections offer the highest load resistance and lowest slip. In terms of comparing the slip modulus of the NS90 and NS45 connections, the slip modulus for NS45 specimens was 26.9 kN/mm higher on average than the NS90 specimens. This difference can be attributed to several factors ranging from material density, screw orientation and concrete properties. Therefore, in terms of notch connections, the NS45 specimen outperformed the NS90 specimens in terms of slip modulus, but further testing is required to validate this finding and establish which notch connection configuration yields the greatest structural performance.

https://doi.org/10.52202/069179-0006

For the S series connections both S30 and S45 specimens obtained a far greater slip modulus with up to 8 times the S90 values, ranging between 34.3 and 48.1 kN/mm respectively (as shown in Table 3). The low slip modulus of the S90 specimens shows good agreement with previous research on CLT Concrete Composites, as it was found that screws connected at 90° behave in a more ductile manner under load [2,5]. Furthermore, the slip modulus obtained for the S30 and S45 specimens also shows good agreement with the values obtained in previous research on CLT Glulam Concrete Composites which also tested the performance of inclined connections [2,5,18]. Additionally, similar results were found when correlating a relationship between the slip modulus and inclination of the connector. In the case of this research, S45 specimens showed a slightly higher slip moduli compared to S30 specimens, which is the opposite to what was found by [2]. However, it must be noted that [2] conducted tests on Glulam Concrete Composites and not CLT, which due to timber grain direction can potentially partially explain the discrepancies in results. Despite this, [5] tested screws with various inclinations inserted in CLT Concrete Composites and found that 30° specimens for any given penetration depth yields higher values of slip modulus than 45° specimens. Given the difference in slip modulus for inclined screws obtained in this research is low, the difference in findings between this paper and previous research can be associated with a large variance in the properties of the timber and connectors used. In spite of this, the results obtained from the BS EN 26891 testing shows good general agreement with previous research, whilst also highlighting key differences in slip modulus based on the type of connection, inclination and timber used.

3.2 FAILURE MODES

3.2.1 Johansen's failure modes

One way in which the load carrying capacity and failure of connections in timber structures can be predicted, is through a numerical approach known as the European Yield method or the Johansen's equations. This method is very effective for timber to timber connections, however, there has been no formal adaptation provided for connections in TCCs. Therefore, to classify the failure modes of TCCs, experimental work needs to be carried out. Previous research by [9, 6] has shown that only a handful of failure modes can occur in TCCs, this is due to the low possibility of connection embedment in the concrete member. The failure modes most likely to occur in TCCs are modes E and F.

3.2.2 S90 series

The S90 specimens deformed predictably, with the development of a plastic hinge associated with a mode E failure. The hinge occurred on the section of the screw located at the concrete-timber interface. Such deformation was also noted in previous research by [9] who tested screws oriented at 90° in CLT Concrete Composites. As clearly indicated from the slip modulus, Fmax and slip at Fmax, S90 series had the largest deformation out of all specimens tested. This resulted in large hinge development of the connector and embedment in the timber member. Differences in the magnitude of hinge development and timber embedment was noted for S90 specimens connected with varying penetration depths (as shown in Figure 9a). For S90-10D specimens a timber embedment of 13-15 mm was observed, compared to only 10–13 mm for S90-11D specimens. The difference in magnitude of failure is due to the connection performance in correlation to the connection's penetration depth, as shown in Table 3. The failure of the concrete members for all the S90 specimens showed typical and uniform failure. As recorded during testing, hairline fractures propagated at approximately 20 kN. These fractures occurred along the row of screws on the CLT member, which eventually fully developed and failed. This is shown below in Figure 9b. Such failure can be attributed to the deformation of the connector inside the concrete. It was found that penetration depth had little impact on whether cracking of the concrete member occurred. Rather the failure in the concrete member was related to the concrete thickness/cover adopted in the specimens.

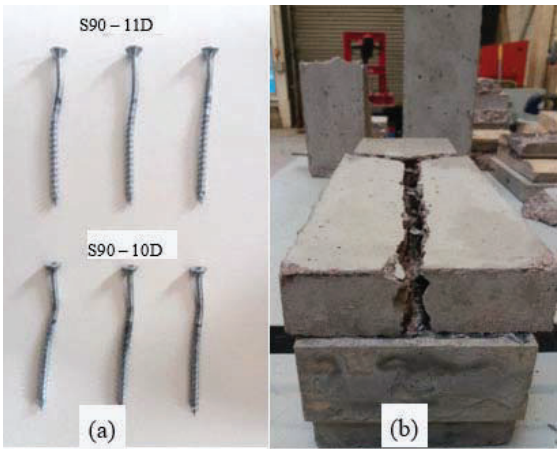

***Figure 9**: (a) S90 screw deformation (b) concrete failure S90 specimens*

3.2.3 S30 & S45 series

The deformation of screws for the S30 and S45 specimens differ to the deformation of the S90 specimens. This is due to their orientation, as when inclined, one screw is loaded in tension while the other is loaded in compression. As a result of the distribution of tensile and compressive forces, different yields can be identified, with the screws in tension showing very little deformation, while the screws in compression showing the development of a plastic hinge, as shown in Figures 10 and 11. According to [2] three failure modes of inclined screws should be examined in TCCs. These correspond to Johansen's failure modes A, E and F. From the examination of the inclined screws post testing, failure modes E and F were identified with two hinges being visible. It is important to note that the hinge development for the S30 specimens was not as visible compared to the S45 specimens at all

penetration depths. Evidently this provides insight into a reason for the lower S30 specimen loads, which was that the screws did not fully yield underload, thus loosing additional potential load bearing resistance.

A further area of interest with the failure of inclined screws is the concrete failure that occurred as a result of the applied load. For both S45 and S30 specimens the concrete members failed as a result of concrete punching failure (shown in Figure 10). This occurred just prior to and in most cases after the Fmax being reached. This type of failure was evident with almost all of the S45 specimens, regardless of their penetration depth. However, this concrete failure only occurred in S30 specimens with a penetration depth of 9D and 10D. It is believed that the lower inclination of the S30 specimens meant that they had increased concrete cover, thus requiring a far greater load to achieve the concrete punching failure. [2] Also noted a similar concrete failure in their research on inclined screws in Glulam Concrete Composites. [2] found that the failure is due to the displacement of screws inside the concrete member under load. It was found that the screws acting in tension, were responsible for this type of failure, as a result of the withdrawal of the screw while under load. Despite concrete punching failure only occurring at a force greater than Fmax, it would be recommended that either a minimum concrete thickness or a minimum penetration depth be adopted to mitigate this type of failure. In order to determine these values further testing on CLT Concrete Composites connected with inclined screws is advised.

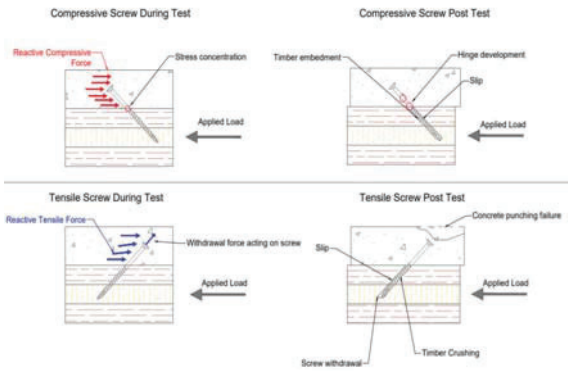

***Figure 10**: Failure process of S30/45 specimens*

***Figure 11**: Deformation of screws with 45° orientation*

3.2.4 NS45 & NS90 series

Unlike screw connections, the failure of notched connections cannot be classified using Johansen's equations. The failure mechanisms for notch connections are dependent on the strength of both the concrete and timber members, as the load is directly transferred from one material to another. It is therefore of critical importance that both members are sufficiently strong to ensure that premature failure of the section does not occur [19]. According to [8] and [16], the failure of notch connections can be caused by the following; (1) Failure of concrete in shear, (2) Crushing of concrete in compression in the notch, (3) Failure of the timber member in shear between two consecutive notches, (4) Failure of the timber member in crushing. From observations during the loading of the specimens both NS90 and NS45 specimens failed as a result of crack propagations originating at the concrete notches. After the development of the hairline cracks (1) at ≈ 40 kN (shown in Figure 12a), a loss of composite action was realised at ≈ 60 kN. After the failure of the concrete members, the load was then distributed to the CLT where the failure of the timber member between two notches (3) occurred (shown in Figure 12b) resulting in the sudden and brittle failure of the specimen. There were no obvious signs of timber crushing (4) on any of the specimens tested. This can be attributed to the high strength and density of the Tulipwood CLT and, additionally, to the grain direction of the CLT, as it varies, notches cut in CLT Concrete Composites can almost certainly be cut in the optimum grain orientation. According to [8] TCCs with notch connections made from Glulam exhibited large amounts of timber crushing and shearing (4) and (5) when they are cut in the transverse direction of the grain.

The difference in screw inclination proved to have little effect on the global failure, however, varying levels of uplift between the two types of notched connections was observed, with the NS45 specimens providing more restraint between the concrete and CLT members. Furthermore, the difference in screw deformation for the NS45 and NS90 specimens was negligible, with both specimens showing no sign of a plastic hinge. Therefore, it can be said that the effects of using inclined screws in tandem with notch connections has been seen to reduce the uplift between the concrete and timber members. To conclude the failure of the notched specimens tested in this research shows very good agreement with [8], [10] and [17]. This research also found that increasing the notch depth had no influence on the type of failure. Although it must be noted that in the case that hardwood CLT is used, and where a small timber section is adopted, a large notch depth > 35 mm could result in a significant loss of cross section, and thus in a reduction in overall strength. Therefore, further testing should be undertaken on inclined screws in TCC notched connections to determine the optimum notch depth.

4 CONCLUSION

4.1 INFLUENCE OF PARAMETERS

4.1.1 Penetration depth

For the S90 series, a penetration depth of 11D was found to provide the greatest maximum load at 34.6 kN. From the post testing examination of the screws, it was found that screws inserted at 11D showed less deformation compared to the 10D specimens. Furthermore, the 11D specimens exhibited a lower slip on average at all stages of loading. These results concur with previous research on CLT Concrete Composite connections by [6] and [9].

In terms of the inclined screws, S45 specimen showed a linear increase in Fmax for penetrations 9D and 10D. 11D penetration depths for S45 specimens, resulted in a Fmax marginally lower than the 10D specimens. Additionally, the S30 specimens exhibited a decrease in Fmax with an increase in penetration depth, with a drop of 13.28 percent from 9D to 11D. This contradicts findings by [2] and [5] who have found that for both inclinations of 30° and 45° an increase in penetration depth results in an increase in both Fmax and slip modulus. However, the penetration depths studied by [5] was increased in increments of 20 mm for each penetration depth, while the penetration depth studied in this research increased in increments of 5 mm. Furthermore, [2] investigated TCCs which used Glulam Concrete Composites as opposed to CLT. These differences in scale of penetration increase and materials used, could be the result of the variation between findings. Therefore, further testing should be undertaken to support the current findings.

4.1.2 Notch depth

It was found that a linear increase in notch depth provides an increase in structural performance for both NS45 and NS90 specimens. These results show good agreement with research conducted by [10], who also investigated the influence of notch depth on CLT Concrete Composites. It was also found that the governing parameters of notched connections was the strength of the concrete and timber members, with hardwood CLT offering potential increases in structural performance for notched connections opposed to softwood CLT. Additionally, it was found that almost no timber embedment was evident in any of the specimens. This differs to what was found by [8], where timber embedment was clearly identifiable. The reason for the difference in specimen condition is that, CLT is orthogonally bound. [8] stated that notches cut in the longitudinal grain orientation are superior to notches cut in the transverse direction. Thus, notches cut in Hardwood CLT, due to the orthogonal nature of CLT and increased density of the hardwood, may be more suitable than notches cut in alternative softwood timber members. To validate this claim further testing should be undertaken.

4.1.3 Screw inclination

Out of the three screw orientations tested, an orientation of 45° proved to be the most effective, in both load carrying capacity and slip modulus. This result contradicts current findings, which state that decreasing the inclination angle of screw connections will increase their structural performance [5,21]. The reason for the difference in findings can be attributed to several factors ranging from the types of screws used, concrete thickness and spacing adopted. However, in the case of this research, and as mentioned previously the S30 provided a lower Fmax due to premature failure in the concrete member, and as a result of the connections reduced load resisting lever arm due to its shallow insertion angle.

The inclination of screws in notched connections, proved to have a minor influence on the load carrying capacity of the connection. The NS90 specimens showed increased values for Fmax, however, they also exhibited a greater slip at Fmax and a reduced slip modulus compared to the NS45 specimens. The orientation of the screws used in NS specimens did, however, have an impact on the failure of the specimen, with the NS45 specimens showing less signs of uplift between the concrete and timber members of the composite compared to the NS90 specimens. A reduction in uplift between the members shows that the timber and concrete members are achieving a greater level of composite action, which is evident as the NS45 yielded a greater slip modulus than the NS90 specimens. This provides an insight into which screw orientations provides the greatest structural performance in a notch connection. However, further research into the inclination of screws used in notched connections in TCCs should be carried

https://doi.org/10.52202/069179-0006

out to verify these findings and expand on current research.

4.1.4 Failure modes

After examining the screws taken from the specimen's post testing, two clear failure modes were identified. Mode E and F failures from Johansen failure modes were exhibited. This shows good agreement with previous research and highlights that only certain Johansen failure modes can occur in TCCs. It was also noted that the failure modes were governed by the penetration depth of the connection, with 11D specimens exhibiting less deformation compared to the 9D specimens for inclinations of 30° and 90°. It was also found that the failure of the concrete member was greatly governed by the penetration depth and inclination of the screws with failures such as concrete punching being observed for the inclined screw, which was also noted in research by [2]. The concrete failure for notched specimens identified in this testing showed good agreement with [8] and [10]. However, it must be noted that the failure mode of connections in CLT Concrete Composites cannot be calculated and can only be accurately obtained via laboratory testing. This is a result of a lack of guidance in the design standards. Therefore, the development of a new or even a modified equation based on the existing Johansen's equation is recommended.

4.1.5 Recommendations for future research

From the lack of guidance in the current design standards, there is a noticeable gap not only for an accurate equation to calculate the slip modulus, but for improved guidance on obtaining the load carrying capacity and failure modes of TCCs. Therefore, work addressing these issues is encouraged. Additionally, as the knowledge of connections under conventional loading is being increasingly covered, it is recommended that connections in TCCs be tested under dynamic loading, to gain a better understanding of the behaviour of various connections under such types of loads and how this will affect the overall structural performance of the composite

SCALING STUDY ON VISCOUS DAMPING FOR GLULAM AND HYBRID GLULAM-FRP BEAMS

Tomas Bravo Tetlak[1], Joseph M. Gattas[2], Cristian Maluk[3]

ABSTRACT: Damping plays an important role in long-span, mass timber floors due to the relation it has to energy dissipation. Energy dissipation in these systems helps control how vibrations spread and whether its interaction with humans occupying the buildings causes discomfort or not. The present study focuses on the effect of scale on viscous damping in Glulam and fibre-reinforced Glulam beams. Twelve full-scale and thirteen small-scale equivalent Glulam beams (Australian Southern Pine) of two different depths were tested using the impact test method. Hybrid beams where manufactured with Fibre Reinforced Polymer (FRP) strips embedded at the interface between lamellas during manufacturing of test samples. Outcomes of this experimental study show that there is an effect of scale in viscous damping – small-scale beams experience a higher viscous damping when compared to equivalent full-scale beams, regardless of testing Glulam or Glulam-FRP beams.

KEYWORDS: Glulam, scale-effect, viscous damping, serviceability performance

1 INTRODUCTION

Timber has been a popular construction material for centuries, particularly for houses in lightweight frame structures. With the development of engineered wood products (EWPs) and adhesives, larger cross-sections, longer spans and improved structural properties have been made possible, allowing timber to compete with concrete and steel as a high-capacity building material [1]. During the last decade, mass timber buildings have rapidly gained prominence with projects all over the world, including Mjostartnet in Norway, HoHo Wien in Austria, T3 Minneapolis in the US, and Brock Commons in Canada. Australia has also contributed to the mass timber building industry with recent examples such as Daramu, International House, and 25 King St.

Timber-only floor and building systems are often limited by serviceability (static and dynamic) limitations. For taller buildings and longer spans, buildings have instead utilised hybrid-timber structural systems, such as timber concrete composites (TCC) or steel-timber composites (STC), by increasing mass and stiffness of the structural elements, as well as mechanical properties, Fibre reinforcement have also proven to be relevant in improving the timber elements properties [2].

The growing interest in studying EWPs and the surge of hybrid EWP elements to further improve their properties has led to many experimental studies to increase the knowledge of these novel systems. Most of these studies are focused on the mechanical properties of elements and structures, but for the serviceability checks required for long-span elements, variables such as natural frequencies, accelerations, damping, and stiffness are a key focus.

Many full-scale tests have been performed in long-span timber floors to study the dynamic behaviour of these systems, underlining the importance of the understanding of damping mechanisms in the context of long-span floors [3-8]. Although some standards, for example Eurocode 5 [9], indicate that vibration serviceability checks should focus on staying above the 8Hz threshold, studies indicate that increased damping can greatly improve the performance of a timber floor [4].

Testing for long-span floors and elements require large laboratory space, labour, and equipment to move and manipulate the specimens. This can be challenging when testing and can sometimes make full-scale testing difficult and cost prohibitive.

As an alternative evaluation method, down-scaled samples have been used to study and understand the equivalent full-scale performance of elements, particularly when full-scale testing is constrained by available space and budget [10]. Scaling factors are expected to make the small-scale and full-scale measurements and results related. Size effects in timber beams translate in a reduction of mechanical properties, such as strength [11]. It is known that shorter span elements present higher damping ratios [6], but no studies have been carried out to thoroughly investigate the effect of scale when determining the damping and serviceability performance of timber floors.

This work presents non-destructive testing of unreinforced and FRP-reinforced Glulam beams and scaled versions in a 1:2.14 ratio. Experimental data was analysed to obtain natural frequencies and compare material viscous damping scale factors obtained from small and large scales.

2 MATERIALS AND METHODS

2.1 SPECIMEN CONFIGURATION

Twelve full-scale and thirteen small-scale beams were tested for vibrations with cross sections and labels shown in **Error! Reference source not found.**. The full-scale beams consisted of five (G5, HG5) and seven lamella (G7, HG7) configurations with heights of 155mm and 217mm with a width of 86mm. HG5 samples had a positive reinforcement ratio of 1% and HG7 samples had both a negative and positive reinforcement ratio of 1.5%. Scaled samples were fabricated by scaling lamellas and reinforcement (scale was determined by the commercially available CFRP strip thicknesses).

Fabrication of beams included the lamination of timber beams in both scales and in-layer reinforcement as described by Bravo Tetlak, et al. [12], with the fabrication method developed by Zaben [13]. Table 1 shows the geometric properties of the full-scale and small-scale beams.

2.2 EXPERIMENTAL SETUP

Beams were tested in a free vibration setup. A schematic figure of the configuration is shown in Figure 2. The beams were instrumented with five accelerometers (Kistler 8630B5) placed evenly on the bottom face. The accelerometers were connected to a data acquisition system where accelerations were stored to be processed using modal analysis to estimate natural frequencies and damping, according to Hearmon [14] and Casiano [15], respectively. The beams were hit with a PCB 086B02 modal hammer also connected to the data acquisition system to measure force. The sampling rate was fixed to 2500Hz, allowing to identify frequencies of up to 1250Hz without accounting for Nyquist aliasing.

2.2 DAMPING COMPUTATION

According to Casiano [15] the half-power method can be used to estimate the damping values, where half of the amplitude of the power spectra at the peak (at $\frac{1}{\sqrt{2}}$ of the maximum amplitude, if using Fast-Fourier Transform FFT to obtain spectra), will yield f_u and f_l, the upper and lower frequencies at half-power. The ratio between the natural frequency of the mode, and the difference between f_u and f_l, yields the quality factor. Figure 3 shows a schematic explanation of the calculation of damping, for the case of an FFT-obtained spectrum.

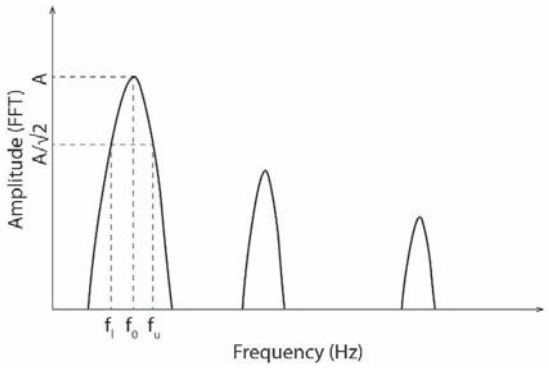

Figure 3. *Schematic representation of a frequency spectrum with the relevant parameters to estimate damping values.*

$$Q = \frac{f_0}{f_u - f_l} \quad (1)$$

If the damping values are expected to be less than 0.05 (5%), they can be estimated by [15]:

$$\xi = \frac{1}{2Q} = \frac{f_u - f_l}{2f_0} \quad (2)$$

2.3 SCALING OF SPECIMENS

According to Masaeli, et al. [16], it is assumed that, in static analysis, geometric properties and static parameters are proportional to the geometric scale. On the other hand, Carvalho [10] states that for scaled specimens, the scale factors should be derived depending on the force restoration mechanism. If the restoring forces are related to the elastic properties of the material only, scale factors should be deduced from geometric scaling and the Cauchy similitude (Equation (3)),

$$\text{Cauchy similitude: } Ca = \frac{\rho v^2}{E} \quad (3)$$

with equation parameters ρ, the specific mass, v the velocity and E, Modulus of Elasticity, as listed in Table 2.

If restoring forces are dependent on the material elastic properties and gravity loads, then the scaling factors must satisfy both the Cauchy similitude (Equation (3)) and Froud similitude (Equation (4)).

$$\text{Froude similitude: } Fr = \frac{v^2}{Lg} \quad (4)$$

with equation parameters v the velocity, L, length, and g, gravity, as listed in Table 2.

In this study, gravity loads do not play a significant role in the restoration loads, so only geometric parameters and Cauchy similitude are used to determine the theoretical scaling parameters, which are shown in Table 2.

Table 2. *Scale parameters derived from Cauchy similitude law. Adapted from [10, 17]*

Parameter	Symbol	Scale factor

3 RESULTS

3.1 GLULAM BEAMS

Natural frequencies up to the third mode are shown in Table 3 and acceleration spectra are presented in Figure 4, and were part of a broader study carried out by Bravo Tetlak, et al. [12].

https://doi.org/10.52202/069179-0007

Natural frequencies presented similar values between samples, with coefficients of variation of up to 2.4%. For each natural frequency, damping values were estimated using the half-power method. Values are presented in Table 4.

Damping values in Glulam were consistently in a range between 0.43% and 0.63% in every mode, except for outlier 0.86% in Mode 1 of small-scale G5 #2. It can be observed that the variability between samples and modes is 12.9%, by discarding the outlier, CoV reduces to 8.4%, with no specific trend regarding scale.

3.2 HYBRID FRP-GLULAM BEAMS

Natural frequencies up to the third mode are shown in Table 3 and acceleration spectra are presented in Figure 4, and were part of a broader study carried out by Bravo Tetlak, et al. [12].

Natural frequencies presented similar values between samples, with coefficients of variation of up to 1.6%. For each natural frequency, damping values were estimated using the half-power method. Values are presented in Table 4.

Damping values in Glulam were consistently in a range between 0.37% and 0.70% in every mode, except for outliers 0.94% in Mode 3 of small-scale HG5 #3. It can be observed that the variability between samples and modes is 18.9%, by discarding the outlier, CoV reduces to 13.8%, with no specific trend regarding scale.

4 DISCUSSION

4.1 SCALE TESTING EFFICACY IN GLULAM AND HYBRID-GLULAM BEAMS

Table 7 presents the experimental scaling factors of studied beams. While in most cases, a factor of less than 1.0 indicates small-scale samples presented a higher damping than their full-scale counterparts. HG7 for mode 1 and HG5 for mode 3 show higher average values for damping in full-scale. G7 and HG5 presented an average value of 1.0 for mode 2.

Table 7. *Average scale factors for damping of beams.*

Beam	Mode 1	Mode 2	Mode 3
G5 Average	0.83	0.93	1.09
G7 Average	0.86	1.00	-
HG5 Average	0.91	1.00	0.89
HG7 Average	1.09	0.95	-

Interestingly, if the outliers are removed from the analysis, the situation changes, as highlighted in Table 8. This indicates that more studies should be conducted to have higher statistical significance, and that there is no correlation observable between full-scale and small-scale tests that can be attributable to dynamic serviceability parameters, as consistent with that observed in Bravo Tetlak, et al. [12], and observed in Table 3 to Table 6.

Table 8. *Average scale factors for damping of beams without outliers (G5 small-scale, mode 1; HG5 small-scale, mode 3).*

Beam	Mode 1	Mode 2	Mode 3
G5 Average	1.02	0.93	1.09
G7 Average	0.86	1.00	-
HG5 Average	0.91	1.00	1.09
HG7 Average	1.09	0.95	-

4.2 GENERAL COMMENTS

Although the addition of CFRP increased the stiffness and natural frequencies of the beams, the damping parameters were not greatly affected, as observed in the studied set of beams.

The scattering of damping values for different modes in the studied beams shows no clear trend or correlation between scales, which can be a sign that scaled down elements can be studied under serviceability without accounting for size effect issues.

The ease testing of scaled down beams was greatly improved, when compared to full-scale testing, given the lighter and smaller sizes of the beams.

5 CONCLUSIONS

This work presented the damping characterisation of two sets of Glulam beams and two sets of carbon fibre reinforced hybrid-Glulam beams. Vibration tests were performed on full-scale and 1:2.14 scale beams and damping parameters were estimated from the accelerometers data acquired. The efficacy of scale testing was evaluated in the context of damping parameter calculations. The main findings can be summarised in the following:

- Downscaled versions of Glulam and hybrid-Glulam beams were significantly easier to test, compared to full-scale beams. This includes, use of laboratory space, freight, experimental set ups, and equipment demand.
- Damping of beams did not show a particular trend regarding scale, and values stayed in fairly determined boundaries, indicating no particular size effect in damping. Although more tests are required to determine if there is a statistical correlation.
- Small-scale samples presented two outlier cases in a Glulam beam, and a hybrid-Glulam beam at a higher mode. More tests should be carried out to understand if the phenomenon is common, or only a particular case in this analysis.

This study indicated that scaled down Glulam and hybrid-Glulam beams in terms of damping estimation is feasible, can yield similar results to full-scale beams and reduce the effort required for testing. In the context of long-span timber and hybrid-timber floor prototyping and testing, these results could lead to easier serviceability testing.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the financial support provided by the Australian Research Council Research Hub to Transform Future Tall Timber Buildings IH150100030. They are also grateful to Hyne Timber, for donation of material used in testing and prototyping.

The authors also wish to thank the technical staff at The University of Queensland for their valuable assistance, especially Stewart Matthews, Jason Van der Gevel, Chris Russ, and Van Thuan Nguyen. EXPERIMENTAL AND FINITE ELEMENT MODELLING (FEM) OF TIMBER-TIMBER COMPOSITE (TTC) UNDER HOGGING MOMENT

Mahmoud Wajdi Hammad[1], Hamid R ValiPour[2]

ABSTRACT: This study aims to investigate the structural behaviour of timber-timber composite (TTC) systems subject to hogging moment. A total of thirty-one TTC and six bare timber beam-to-column subassemblies (including fourteen replicates) were fabricated and tested to failure under hogging moment. The TTC beams were fabricated by connecting a cross laminated timber (CLT) slab to the top edge of a pair of laminated veneer lumber (LVL) or glued laminated timber (GLT) beams/joists. The effect of the CLT slab thickness, width, and orientation (i.e., loaded lengthwise or crosswise), column penetration in the CLT slab, bending moment to shear force ratio (span length), degree of shear interaction between the slabs and beams (controlled by the size of the shear connectors), and type of beams (LVL or GLT) on the structural performance of the TTC subassemblies were investigated experimentally. In addition, an analytical model was adopted for composite Timoshenko beams and modified to predict the stiffness and load carrying capacity of the TTC beams under hogging moment. Furthermore, 3-Dimentional Finite Element Models (FEM) have been developed and analysed for TTC structures subjected to hogging bending moments using ABAQUS.

KEYWORDS: Hogging moment, Timber-timber composite (TTC), Finite Element Modelling (FEM).

1 INTRODUCTION

Since sustainability in construction has become a major headline, the popularity of timber structures has grown significantly. The advancement in the manufacturing and treatment of large engineered wood panels (EWPs) such as cross laminated timber (CLT), glued laminated timber (GLT) and laminated veneer lumber (LVL) with improved durability, dimensional stability and resistance to variable environmental conditions has made it conceivable to plan and construct massive timber structures with performance on par with conventional steel and concrete structures, but with less detrimental impact on the environment [2, 3].

The application of lightweight TTC (i.e., LVL-CLT or GLT-CLT) floors, which are easy to assemble and conducive to prefabrication, seems to be a promising solution for the development of hybrid frames with continuous timber beams/slabs that can cover long spans with fewer columns or load bearing walls. Structural behaviour of timer composite floors (e.g., TTC and TCC) subjected to hogging bending moment remains largely unexplored. Preserving the continuity of CLT slabs and LVL/GLT beams across the columns can reduce the mid-span deflection, which is a major governing factor in designing the long-span TTC floors under service conditions. However, benchmark experimental data required for the accurate evaluation of the failure modes, stiffness, ductility, and load carrying capacity of continuous TTC beams (to column connection) under hogging moment are not available in the literature.

Thus, experiments were conducted to comprehensively study the structural behaviour of CLT-LVL and CLT-GLT composite beams subjected to hogging (negative) moment over the beam-to-column connection zone. In total, thirty-seven TTC and bare timber beam-to-column subassemblies were fabricated and tested under hogging moments.

Furthermore, in the 3-Dimentional Finite Element Models developed, nonlinear behaviour of the Engineered Wood Products (EWPs) such as Cross Laminated Timber (CLT), Laminated Veneer Lumber (LVL) and Glued Laminated Timber (GLT) were defined in a UMAT code using continuum damage mechanics modified by Gharib et al [4]. CLT was modelled using the layer wise approach, assigning parallel and perpendicular to the grain, which will be further discussed in this chapter. Meanwhile, the veneers and the lumber in the LVL and GLT were ignored respectively in ABAQUS, having LVL and GLT

[1] University of New South Wales (UNSW) Sydney, School of Civil and Environmental Engineering, mahmoud.hammad@unsw.edu.au

https://doi.org/10.52202/069179-0008

modelled as a single piece of timber. Steel was modelled using the standard user materials defined in ABAQUS.

The EC5 model is only applicable for timber composite beams/floors under sagging moments and hence there is a need for simple analytical model (like gamma-method) that can be used for stiffness and strength evaluation of timber composite subjected to hogging.

2 MATERIAL TESTING

2.1 ENGINEERED WOOD PRODUCTS (EWP)

The characteristic strength and mean elastic modulus values for C24(CLT), GLT(GL17) and LVL were taken from AS1720.1 [5] and the manufacturer's catalogue, respectively. Moreover, 4-point bending tests on 60 mm and 100 mm thick CLT panels (five identical strips of each thickness) were performed according to BS EN408 [6] to determine the mean global elastic modulus $E_{m,g}$ and bending strength f_b of the CLT panels. The mean global elastic moduli of the 60 mm and 100 mm thick CLT panels (lengthwise) were $E_{m,g}$= 11.3 GPa (CoV = 7.7%) and 9.7 GPa (CoV = 7.6%), respectively. The mean bending strength of the 60 mm and 100 mm thick CLT panels (lengthwise) were f_b = 37.5 MPa (CoV = 13.4%) and 31.9 MPa (CoV = 8.8%), respectively. The glulam (GL13) and LVL beams were manufactured from Radiata Pine in accordance with AS/NZS1328.1 [7] and AS4357.0 [8] requirements, respectively. The characteristic strength and mean elastic modulus of the GL13 and LVL respectively taken from AS1720.1 [5] and the manufacturer's catalogue are given in Table 3 1. The moisture content (MC) of the LVL and GL13 beams were measured by oven-dry method of AS/NZS 1080.1 [9]. The mean MC (obtained from five samples) of the LVL and GL13 are provided in **Table 1** and
Table 2. Bending tests were performed on three 85×336 mm GLT beams and the mean bending strength of GLT beams from the tests was $f_{b,mean}$= 49 MPa (CoV= 9%). The mean bending strength of the GL13 closely correlate with the mean bending strength of 45 MPa obtained from the samples taken from six Australian manufacturers of the glulam [10].

The mean bending strength of 200 mm deep LVL beams was $f_{b,mean}$= 66.5 MPa and it was obtained from the bending tests performed on two pairs of 3.0 m long bare LVL (200 mm deep) beam subassemblies. A size effect strength reduction factor of was considered according to the manufacturer's catalogue and the bending strength of 400 mm deep LVL beams was estimated to be $f_{b,mean}$= 59.7 MPa.

Table 1: *mean elastic modulus of C24 timber (used in manufacturing CLT panels), GLT and LVL beams.*

Timber type	Compressive strength (MPa)		Elastic moduli ‖ (GPa)	Shear moduli (GPa)	Moisture content (%)
	‖ to grain	⊥ to grain			
C24	21	2.5	11.0	0.69	11.6
GLT (GL17)	33	---	16.7	1.11	13.1
LVL	42	12	13.2	0.66	8.6

Table 2: *Characteristic strength (# Flexural strength for 200 mm deep LVL joists)*

Timber type	Bending strength (MPa)	Tensile strength ‖ (MPa)	Shear strength (MPa)
C24	24	14	4.0
GLT (GL17)	40	20	4.2
LVL	45#	30	4.6

2.2 DIGITAL IMAGE CORRELATION (DIC)

A digital image correlation (DIC) system was used during the bending tests on LVL (200 mm) beams to capture the strain field over the depth of the beams and accordingly establish the flexural strength and its corresponding strain. The contours of longitudinal strains ε_{xx} and the ε_{xx} strains at three points (i.e., farthest bottom, and top fibre and mid height of LVL) captured by the DIC are shown in Figure 3 1. At the peak load, the max. tensile strain (averaged at the farthest bottom fibre point P1) of the LVL was ε_{xx}=((0.00574+0.0058))/2=0.00577 (**Figure 1**). If a linear elastic behaviour for LVL is assumed, the tensile strength of the 200 mm deep LVL can be estimated from σ_{xx} = 0.00577×E = 0.00577×13200 = 76.2 MPa that confirms the bending strength of LVL.

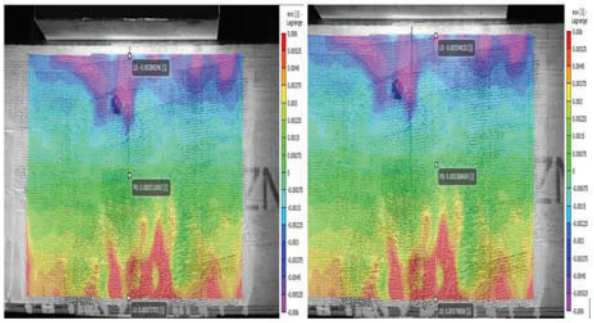

Figure 1: *Contours of ε_{xx} strains (DIC) at failure load of a bare LVL (200 mm) subassembly.*

https://doi.org/10.52202/069179-0008

2.3 SCREWS AND EPOXY (ADHESIVE)

Coach screws (KOP) 8 mm or 12 mm in nominal diameters with hexagonal heads manufactured in accordance with EN 14592 [11] were used as shear connectors in the TTC specimens. The KOP 8 mm screws were 160-200 mm, and the 12 mm screws were 160-220 mm in length **Figure 2**a [12]. The yield bending moment M y of 8 mm and 12 mm coach screws (i.e., KOP8 and KOP12) were obtained from 3-point bending tests in accordance with AS/NZS ISO 10984.1 [13], known as Method B. In total, five screws of each size were tested under 3-point bending with the screws spanning over 132 mm distance between the supports (**Figure 2**a) that satisfies the minimum span requirement of 11d and a minimum overhang of 2d as per AS/NZS ISO 10984.1 [13]. The sample load vs mid-span displacement obtained from the 3-point bending tests on KOP8 screws are plotted in **Figure 2**b. The intersection between the straight line offset 0.05d from the linear part of the graphs and the load-mid span displacement diagram is taken as the yield load F_y. The yield bending moment My of the coach screws was obtained from $My = F_y\, l / 4$, with l = 132 mm being the span length (**Figure 2**a). The mean yield bending moment of the KOP8 and KOP12 screws were My = 15.2 kNm (CoV = 10.6%) and 79.8 kNm (CoV = 9.5%), respectively. The yield strength σ_y of the screws was back calculated from the yield bending moment My, using $\sigma_y = M_y/S$, where S is the plastic section modulus. The plastic section modulus was calculated from $S = (1.1d_{in})3/6$, where d_{in} is diameter of the screw's cross-section excluding the threads and for KOP8 and KOP12 taken as 5.6 mm and 9 mm, respectively. The estimated mean yield strength of the KOP8 and KOP12 screws was σ_y = 442 MPa.

3 TTC SUBJECTED TO HOGGING MOMENT [1]

3.1 LOADING PROCEDURES

All the tests were performed according to the EN 26891 [14] loading protocol. All the specimens were loaded up to $0.4F_{est}$ over 2 minutes, then the load was kept constant for 30 seconds before the specimens were unloaded to $0.1F_{est}$ over 1.5 minutes (Figure 3a). At the end of the unloading stage, the load was kept at $0.1F_{est}$ for 30 seconds, before the specimen was reloaded to failure. The loading-unloading-reloading protocol of EN 26891 [14] was followed to eliminate (or minimise) the possible effects of internal friction between the CLT slab and LVL/GLT or test setup looseness on the structural behaviour of the specimens. The test was stopped once the applied (displacement-controlled) load dropped to 70% of the peak load (F_{max}), and accordingly the failure load was taken as the post-peak load corresponding to $0.7F_{max}$.

https://doi.org/10.52202/069179-0008

3.2 TTC subassemblies outline

Thirty-one TTC and six bare LVL or GLT beams representing the end span regions of a continuous timber/TTC floor (**Figure 4**) were fabricated and tested under hogging moment. The TTC and bare timber beams were either 2.0 m or 3.0 m long, which represent continuous TTC floors with span length in the range of L = 8-10 m, based on the assumption that the points of contraflexure are approximately located at cross-sections 0.125-0.15L away from the supporting columns. The TTC composites were benchmarked against the subassemblies with bare timber beams to determine contribution of the CLT slabs to the hogging moment and stiffness of the TTC beams/floors continuous across the columns.

3.3 MODES OF FAILURE

In total, seven distinctive failure modes, i.e., I to VII, including six primary (I-VI) and one secondary (VII) were observed in the tested specimens. Failure mode I was associated with the onset of tensile flexural cracks (fracture) in the outermost lamella of the CLT panels. Failure modes II and III were observed in TTC beams with CLT panels loaded crosswise (i.e., perpendicular to the outer lamellae of the CLT). In mode II, fracture of the lamella along the edge of the glue line and in mode III, tensile fracture (perpendicular to the grain) took place. Failure mode IV was observed in CLT slabs loaded lengthwise and it was associated with rolling shear failure in the second lamella, which was loaded perpendicular to the grain.

Failure mode V was associated with the fracture of the epoxy line at the interface between the CLT and LVL beam when the composite action between the slab and the beam was developed by the combination of the screw and epoxy. Mode VI was associated with the onset of tensile flexural cracks in the LVL/GLT beams, and in mode VII shear cracks developed along the LVL/GLT beams and reached the end of the beam well into the post-peak (softening) stage. Mode VI predominantly took place in conjunction with Modes I-III while mode VII was mostly observed in 2 m long TTC beams. In all specimens (except for S6, S7 and S10), failure mode VII was a secondary mode that occurred after the onset of a primary mode and during the post-peak stage of the behaviour. In specimens S6, S7 and S10, mode VII was the dominant (primary)

https://doi.org/10.52202/069179-0008

failure mode that took place before others. The longitudinal shear cracks (in mode VII) mostly propagated along the glue line of the GLT beams and the shear cracks were at the height where the screw tips were located. This resulted in the tip of the screw to slightly bend.

The load versus deflection evolution for specimens with 2 m and 3 m long TTC beams are plotted in Figure 5 and Figure 6, respectively. The mean peak load F_{peak} and the serviceability stiffness $K_{s,0.4}$ of the TTC specimens obtained from the load versus deflection results are summarised in Table 4. The service stiffness was taken as the slope of the line between the two points corresponding to $0.1F_{peak}$ and $0.4F_{peak}$ [14] on the load-deflection diagram.

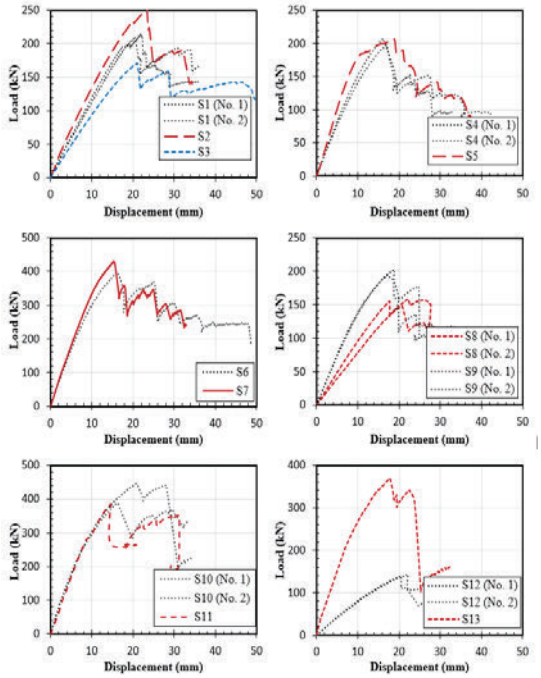

Figure 5 *Load versus deflection of the TTC subassemblies (group S, 2 m long TTC beams)*

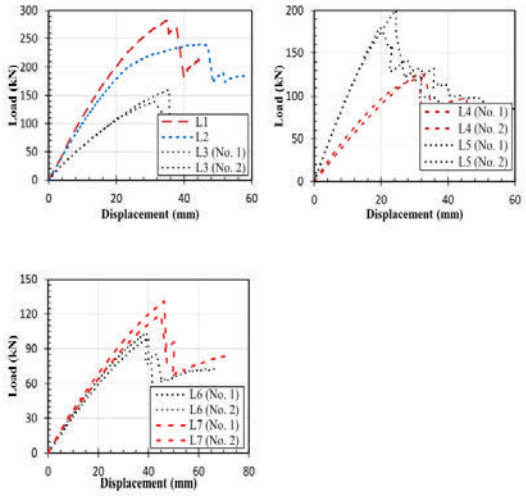

Figure 6 *Load versus deflection of the TTC subassemblies (group L, 3 m long TTC beams).*

3.4 EFFECT OF VARIOUS PARAMETERS

The width of the CLT slab and column penetration in the slab (resulting in the reduction of the slab area of up to 20%) had minor (less than 9%) influence on the stiffness and peak load. However, the CLT slab thickness (in the range of 60-100 mm) had a major (up to 48%) influence on the peak load and stiffness of the TTC beam subject to hogging moment. The size of shear connectors (degree of shear connection provided by 8-12 mm screws) and

https://doi.org/10.52202/069179-0008

orientation of the CLT slab had a moderate (max. 18-23%) influence on the load carrying capacity and stiffness of the samples. In the tested specimens, the stiffness and peak load of TTC specimens with lengthwise loaded CLT were up to 20% higher than the ones with CLT loaded crosswise.

3.5 ANALYTICAL RESULTS

The analytical model obtained from the solution to the Timoshenko composite beam was slightly more accurate than the *g*-method, especially for TTC beams with smaller shear span over cross-section depth ratio. But the *g*-method (EN 1995-1-1 [15]) is simpler, and more efficient and usable than the Timoshenko composite beam model. The comparison bar chart is shown in Figure 7.

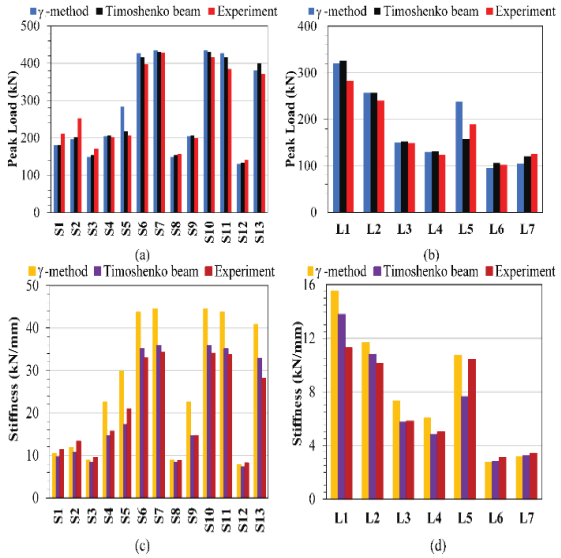

***Figure** 7 Comparison of (a-b) peak loads and (c-d) service stiffness values obtained from two analytical models and experimental results.*

For all specimens (except S5 and L5 with glued shear connections), the peak load analytically predicted by γ-method and Timoshenko beam model had close correlation with the experimental results. In the case of specimens S5 and L5, the gamma-method overestimated the peak load by 37.1% and 26.1%, respectively. The maximum difference between the peak load predicted by the Timoshenko beam model and the experimental peak load was less than 19.5% (observed in specimen S2). The service stiffness of the specimens (specially the S group with large cross-section depth over shear span ratio) predicted by the Timoshenko beam model was more accurate than the stiffness obtained from the γ-method as evident from the bar charts shown in Figure 7c-d.

4 FINITE ELEMENT MODELLING (FEM)

4.1 OVERVIEW

In the FE models, CLT panels were modelled using the layer-wise approach with mechanical properties assigned to parallel and perpendicular to the grain lamellae. However, the veneers and the lumbers in the LVL and GLT were not explicitly modelled, and LVL and GLT were treated as a single piece of timber. To enhance the computational efficiency and avoid numerical convergence/instability issues associated with stress concentration and fine meshes around the screw shear connectors, the shear connectors were modelled using nonlinear springs defined at the interface between slab and timber joists/beams. Apart from nonlinearities of steel, timber and concrete/grout, the geometrical non-linearity was also considered in the FE simulation, though effect of geometrical nonlinearity was deemed to be negligible.

The configuration and details of loading, boundary conditions and geometric outline of the TTC and TCC specimens modelled in ABAQUS are provided in Figure 8. To simplify the structure and increase speed of analyses without comprising the accuracy of the results, the steel column of the subassemblies was not modelled in the FE simulations. The load was applied to a stiff loading plate with a displacement rate consistent with the experiments. The supports of the timber composite beams were treated as an ideal pin and only the displacements in x, y, and z direction were fixed along the bottom centreline of the support plates accordingly (Figure 8). To prevent localised crushing and excessive deformation of the timber joists (loaded perpendicular to the grain), timber stiffeners were modelled underneath the loading plates (Figure 8). The stiffeners were assumed to be linear elastic materials with mechanical properties identical to timber joists/beams.

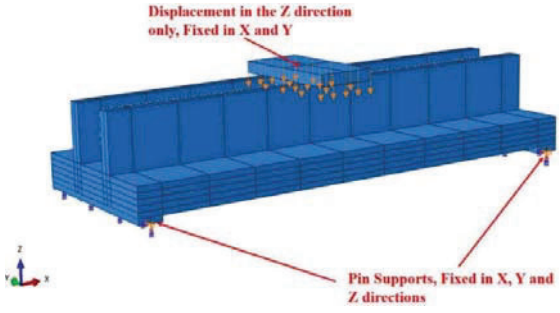

***Figure 8** Outline of the geometry, loading and support conditions considered in the FE model of TTC and TCC beams.*

4.2 MESH SIZE

The element used for modelling LVL, GLT, CLT, concrete slab, steel loading plate and support plates was a standard linear Hexagonal C3D8R (an 8-node linear brick) element with reduced integration and enhanced hour-glass control. The screws were modelled using a wedge 8-node linear brick (C3D8) element with full integration. The size and configuration of the FE mesh for the timber beams/slabs and screws are depicted in Figure 9 and the element size for each component is given in Table 5.

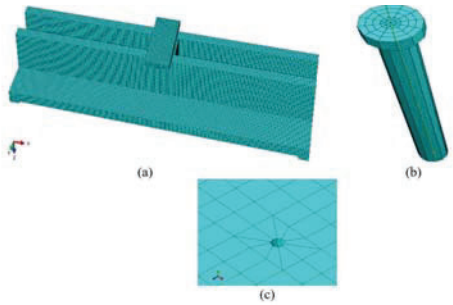

Figure 9 *FE mesh (a) entire TTC/TCC domain, (b) dowel and (c) domain around the hole.*

Table 5 *Mesh type and size for each respective element used in the TTC model.*

Structural component	Mesh type	Mesh size
CLT Slab	C3D8R	15
LVL	C3D8R	15
GLT	C3D8R	15
Stiffeners	C3D8R	15
Steel Load Plate	C3D8R	15
Steel Support plates	C3D8R	15
Dowel (KOP8 and KOP12 screws)	C3D8R	2

4.3 COMPARISON AND DISCREPANCIES

The FEM was adequately able to capture the results within close proximity. There was a slight discrepancy between the experimental GLT members and the FEM GLT. This can be attributed to rolling shear failure and stress localisation. Furthermore, some specimen was modelled with screws instead of line connectors. The results are summarised in Figure 10.

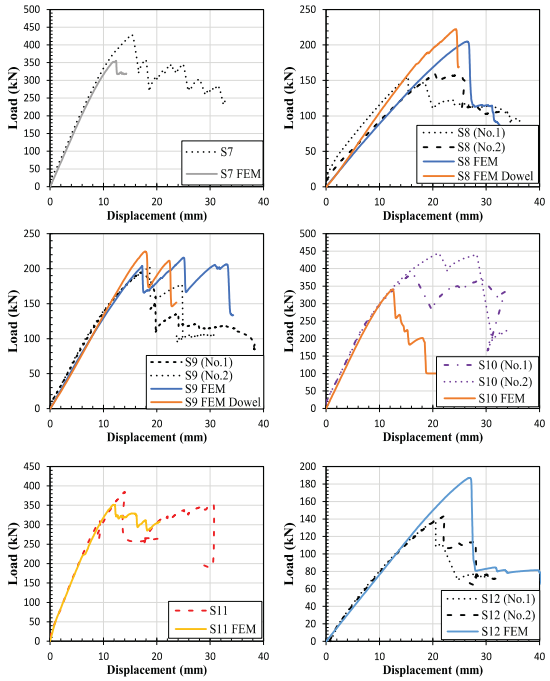

Figure 10 *experimental vs analytical Load vs displacement with line connectors and dowels.*

5 CONCLUSIONS

The purpose of this project was to investigate the structural performance of TTC and TCC systems through full scale laboratory experimentation, advanced numerical simulation, and development of analytical models. Emphasis was placed on structural behaviour of the TTC and TCC floors subjected to hogging moment.

- The dominant failure mode of TTC beams under hogging moment was brittle and it was associated with tensile flexural failure in the outermost lamellae of the CLT slabs combined with tensile flexural failure in the LVL/GLT joists. These modes were followed by rolling shear in the CLT slab, or shear failure of the LVL/GLT joists specially during the post-peak stage of the behaviour.
- The orientation of CLT slabs had some effect on the stiffness and load carrying capacity. In the tested specimens, the stiffness and peak load of TTC specimens with lengthwise loaded CLT were up to 20% higher than the ones with CLT loaded crosswise.
- Despite a 20% reduction in the cross-sectional area of the CLT slabs, because of the column penetration, the reduction in the stiffness and load carrying capacity was less than 9%.
- The size of screw shear connectors (8 and 12 mm) had a moderate (up to 18%) influence on the peak load and stiffness of the TTC under hogging moment. However, using the epoxy glue in conjunction with screws considerably increased stiffness of the TTC specimens. The joists glued to the CLT slabs with opening also prevented the crack initiation and propagation from

https://doi.org/10.52202/069179-0008

the corner of the penetration/opening and increased the peak load of the TTC accordingly.

- The analytical model obtained from the solution to the Timoshenko composite beam was slightly more accurate than the γ-method, especially for TTC beams with smaller shear span over cross-section depth ratio. But the γ-method is simpler, and more efficient and usable than the Timoshenko composite beam model.
- The nonlinear 3D FE models were able to capture the complex (combination of shear, tension parallel and perpendicular to the grain) failure modes of TTC and TCC beam to column subassemblies. Small difference was found between the results of two modelling strategies, i.e., explicit modelling of the screw shear connectors and implicit modelling of the she connectors with nonlinear springs/links.

ACKNOWLEDGEMENT

The Authors would like to thank UNSW Heavy Structure Lab (HSL) team for their efforts during the fabrication process of project.

QUASI-STATIC OUT-OF-PLANE TESTING OF REINFORCED CROSS-LAMINATED TIMBER

Eric Kjolsing[1], Mark Weaver[2], Marco Lo Ricco[3], Adam Senalik[4], Jason Cattelino[5], Jim Henjum[6], Russell Edgar[7], Edwin Nagy[8]

ABSTRACT:

There is an increasing desire to use wood products, which are environmentally sustainable, in protective design. Although cross-laminated timber (CLT) panels can be designed to mitigate blast threats, softwood CLT needs some form of reinforcement to defeat typical design basis ballistic threats. The inclusion of thin steel plates within a CLT panel's layup, which has previously been shown to be feasible from both a cost and ballistic performance perspective at small scale, could conceivably be used to transform CLT into both a blast and ballistic resistant panel. To evaluate the response of such a reinforced CLT (RCLT) panel at full scale, an analytical methodology was developed to predict the performance of RCLT panels to out-of-plane loading. The methodology was used to develop three unique RCLT layups that varied both the lumber grade and ply orientation to achieve targeted failure mechanisms. Twelve RCLT panels were fabricated and subjected to quasi-static four-point bending. Tested specimens showed high levels of ductility, excellent wood-to-steel adhesion, and significant post-peak load carrying capacity. Dynamic analyses indicate that the 7-ply RCLT panels perform better than unreinforced 7-ply and 9-ply CLT panels.

KEYWORDS: Cross-Laminated Timber, CLT, Reinforced CLT, RCLT, Enhanced CLT, Protective Design, Blast

1 INTRODUCTION

Buildings used by the U.S. Department of State (DOS) and U.S. Department of Defense (DOD) often must meet blast, ballistic resistance, and forced entry (FE) design requirements to mitigate the hazardous effects associated with terrorism [1]. Historically, DOS and DOD buildings exposed to these threats have been constructed using concrete and steel. A significant amount of testing has been performed to demonstrate the ability of these building materials to resist blast, ballistic, and FE threats. A relatively smaller number of tests have been performed on wood construction for similar threats. At least part of this stems from the relative difficulty of designing light-frame wood construction to resist these threats efficiently and economically. However, the emergence of mass timber construction, particularly cross-laminated timber (CLT), presents a sustainable, modular, and cost-effective alternative building material for high-security infrastructure. Recent blast testing of cross-laminated timber [2] has informed the development of design guidance in the United States [3]. Additional ballistic testing has shown the feasibility of incorporating thin steel plates within a CLT panel's layup to defeat typical design basis ballistic threats [4]. It is hypothesized that by detailing the ballistic reinforcing layers to act compositely with the wooden CLT panel, this reinforced CLT (RCLT) panel may also demonstrate improved blast performance.

2 OBJECTIVE

An analytical method was developed to estimate the resistance function (i.e., the out-of-plane (flatwise) load versus displacement relationship) of RCLT panels with arbitrary (user defined) layups. This methodology was used to select three distinct RCLT layups that were fabricated by SmartLam North America and subsequently tested under quasi-static out-of-plane loading at the University of Maine. The objectives of this effort were to (a) develop a viable methodology to predict the performance of RCLT panels to out-of-plane loading, (b) generate test data to validate the methodology, and (c) demonstrate the post-peak behavior of RCLT panels.

3 ANALYTICAL METHOD

An analysis methodology was developed to predict the out-of-plane bending resistance of RCLT panel designs. The methodology is similar to the shear analogy method used for standard CLT panels [3],[5],[6], but the relevant equations are modified to permit the inclusion of non-wood (e.g., steel) laminations. As a verification effort, the methodology was used to estimate the ASD design values for several standard CLT panels [7]. The comparison showed good agreement for most of the design values, with the methodology predicting an approximately 9% higher shear strength than published values. This difference was found to stem from different shear capacity equations used in the methodology [6] and by ANSI/APA PRG-320 [8]. The PRG-320 shear equation implicitly assumes a uniform wood cross section, resulting in the well-known equation for peak shear stress in a rectangular section, shown in Equation (1):

$$\tau = 1.5\frac{V}{A} \tag{1}$$

In contrast, the developed methodology based on the shear analogy method uses a shear flow calculation to estimate the shear capacity of the CLT/RCLT panels. Due to the alternating, orthogonal wood layers the shear stress through the panel thickness is non-parabolic, contrary to that assumed by Equation (1). The effect is that the shear flow calculation estimates a slightly lower peak shear stress demand in the panel for an applied unit shear, resulting in a larger estimate of the panel's shear force capacity. An analogy to the design of steel W-shapes is appropriate. The flanges in a steel W-shape drive the shear stress distribution in the web to be nearly uniform. Similarly, although to a lesser degree, the strongly oriented outer wood layers (in a CLT panel) and steel inserts (in an RCLT panel) result in a more uniform shear stress distribution through the panel thickness (relative to the parabolic shear stress distribution assumed in PRG-320), leading to a lower peak shear stress in the panel, and a larger shear force capacity of the panel.

4 TEST SPECIMENS

4.1 LAYUP SELECTION

The analysis methodology was used to select RCLT panel layups for quasi-static testing. Several dozen wood species and layups were considered. In each case the steel layers were placed near the exterior of the panel to maximize their contribution to bending strength and their effect on redistributing the shear stress through the panel. The steel layers were ASTM A1011 sheets with a specified minimum yield strength of 250 MPa. Based on the calculated capacity estimates and economy of material, three wood species/grades were selected: Spruce-Pine-Fir South (SPF-S) No.2, Southern Pine (SP) No.2, and 2400F-2.0E Southern Pine MSR (SP MSR). These three wood grades were oriented in three specific layups to target desired failure limit states.

Layup number 1 (Table 1) utilized SPF-S No.2 in each wood layer and acted as a baseline case (note that using SPF-S No.2 in an unreinforced CLT panel is a standard 'V4' grade CLT panel). SPF-S No.2 has a relatively low density, hardness, and toughness when compared to other wood species and thus served as a reasonable estimate for the lower bound case. The analysis methodology predicted layup number 1 would fail in rolling shear.

Layup number 2 (Table 2) utilized SP No.2 in each 0-degree layer (the major strength direction) and SP MSR in each 90-degree layer (the minor strength direction). SP provides a higher rolling shear capacity then SPF-S, which increases the overall shear capacity of the panel. The analysis methodology predicted the steel layers would yield nearly simultaneously with rupture of the outer wood layers.

Layup number 3 (Table 3) is similar to layup number 2, except the outer wood layers (wood plies 1 and 7) are oriented in the 90-degree (minor) direction. Changing the orientation of the outer layers only slightly changes the shear capacity of the panel but greatly reduces the panel's flexural capacity. Thus, the intent was a panel in which the steel plates would yield prior to either a wood flexural rupture or rolling shear failure. The analysis methodology predicted the steel layers would yield first, followed by rupture of the inner wood core.

Analogous unreinforced CLT panels (i.e., baseline cases) were not tested due to cost considerations.

4.2 SPECIMEN FABRICATION

For each of the three layups, four replicate specimens were fabricated by SmartLam North America (twelve specimens total). The fabrication process started by sandblasting the steel plates to remove oils and mill scale. The lumber was acclimated and processed according to normal CLT operations and PRG-320 requirements. Steel plates were placed by hand during the pressing operation to facilitate correct alignment. Adhesive, similar to that used for normal CLT production, was used. All specimens were approximately 1.22 m wide x 4.27 m long x 250 mm thick. Figure 1 shows the installation of the steel plates during the layup process. Figure 2 shows some of the finished panels.

5 TEST CONFIGURATION

The twelve RCLT specimens were tested at the University of Maine under quasi-static four-point bending. A schematic of the test setup is shown in Figure 3 with Figure 4 showing a corresponding isometric view of the actual test setup. For each test, a 1300-kN actuator loaded a steel spreader/cross I-beam which then loaded two steel W-shapes running orthogonal to the span length. The cross beam-to-W-shape connection was detailed to allow rotation of the W-shapes. The RCLT panels were supported on hollow structural sections (HSS) across the full width of the panels. The HSS sections were supported on concrete supports and were permitted to rotate. Between the W-shape-to-RCLT panel and RCLT panel-to-HSS section were lubricated sheets of high-density polyethylene (HDPE) to reduce frictional constraint of the RCLT panel. The test span length was 3.66 m. Three displacement gages recorded the midspan displacement while four video cameras oriented at the four panel corners (i.e., North-West, North-East, South-West, South-East) recorded the testing. The applied load was recorded via a calibrated load cell at the actuator. Testing was performed well beyond the maximum load carrying capacity of the panel.

Figure 4: *Test configuration*

6 TEST RESULTS

6.1 LAYUP NUMBER 1

Figure 5 shows the force-displacement curves of the four specimens. On average, the layup displayed a rolling shear failure near 465 kN with a corresponding deflection of 25 mm. There is a sharp drop in load carrying capacity after the rolling shear failure, but a significant residual capacity remains. This residual capacity is attributed to the two steel plates, each acting compositely with the immediately adjacent (intact) wood layers, and quasi-compositely with the other steel plate. This adds ductility to the system, even after a rolling shear failure has occurred. Figure 6 shows specimen 1 under various levels of loading. The images correspond to (A) the specimen just after a rolling shear failure, (B) midspan flexural (tension) rupture of the wood, and (C) the post-test state of the panel.

6.2 LAYUP NUMBER 2

Figure 7 shows the force-displacement curves of the four specimens. On average, the layup first displayed a flexural wood rupture near 750 kN with a corresponding deflection of 35 mm, and later, a rolling shear failure near 76 mm of displacement. Figure 8 shows specimen 1 under various levels of loading. The images correspond to (A) the onset of wood flexural rupture, (B) a rolling shear failure, and (C) the post-test state of the panel.

As seen in Figure 7, specimen 2 displayed significant load carrying capacity through 250 mm of displacement. Unlike the other three specimens, specimen 2 did not display a rolling shear failure. Instead, after the outer wood ply on the underside of the panel ruptured, the core of the panel displayed an adhesive bond failure between the tension steel and wood core, as well as a flexural rupture of the wood core layers near midspan. The significant drop in load carrying capacity (around 250 mm) is due to this bond failure eventually propagating to the support. The force-displacement curve for specimen 2 is an ideal outcome for blast design as the area under the curve represents significant energy dissipation potential. Figure 9 shows the failure sequence from the specimen 2 test.

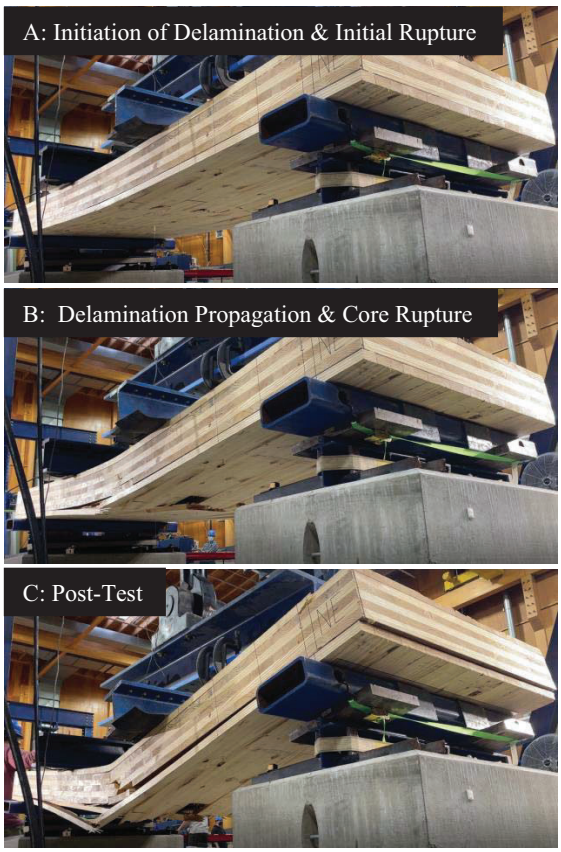

Figure 9: *Layup number 2, specimen 2, under loading*

6.3 LAYUP NUMBER 3

Figure 10 shows the force-displacement curves of the four specimens. On average, the layup displayed steel yielding behavior near 320 kN (23 mm corresponding displacement) and a rolling shear failure near 560 kN and 94 mm of displacement. Figure 11 shows specimen 1 under various levels of loading. The images correspond to (A) the specimen just before a rolling shear failure, (B) a rolling shear failure, and (C) the post-test state of the panel.

6.4 COMPARISON TO PRE-TEST ESTIMATES

Figure 12 compares pre-test estimates with average load-displacement curves obtained from testing. In all cases the pre-test initial stiffness underestimated the actual stiffness. The pre-test prediction for layup 1 was a rolling shear failure, which was observed in the actual test. The pre-test prediction for layup 2 was steel yielding followed by flexural rupture of the outer wood ply. The pre-test calculation erroneously assumed failure of the outer wood ply was an ultimate limit state, thus leading to the relatively brittle nature of the predicted force-displacement curve. In the actual test the outer ply ruptured, but significant ductility was observed before the final rolling shear failure was observed (the embedded steel plates carry considerable flexural load). The pre-test prediction for layup 3 was steel yielding followed by flexural rupture of the inner wood core. While the pre-test estimate accurately predicted the steel yielding, the ultimate strength and final limit state were inaccurately predicted. It is noted that the pre-test calculated shear strength was ~590 kN, which agrees with the observed peak shear strength of the panel.

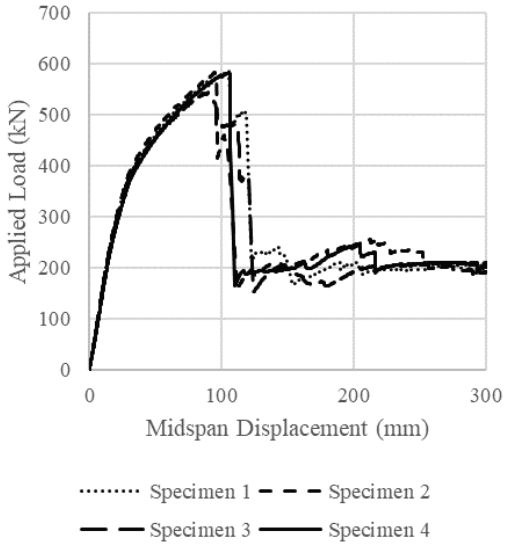

Figure 10: *Layup number 3 force-displacement curves*

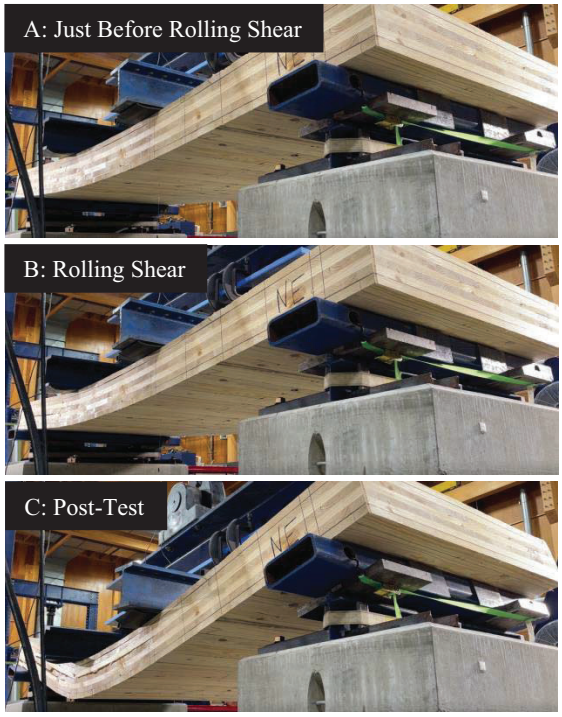

Figure 11: *Layup number 3, specimen 1, under loading*

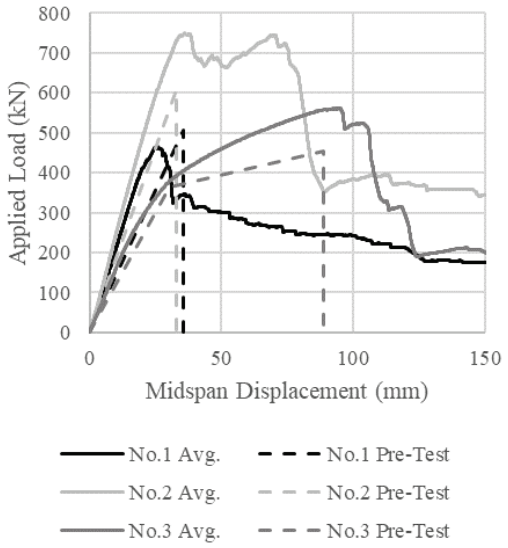

Figure 12: *Average force-displacement curves and pre-test predictions for the three layups*

6.5 POST-TEST ESTIMATES

Following the four-point RCLT panel bending tests, material tensile testing was performed on samples of the steel plates to improve the material properties used in the predictive analysis model. In addition, the analysis methodology was updated to include an incremental calculation approach, which accounts for damaged plies in the flexural calculations. Although still being developed, this updated methodology seems to better capture the evolution of flexural failures as degradation of load carrying capacity due to wood flexural rupture is now being captured, as shown in Figure 13.

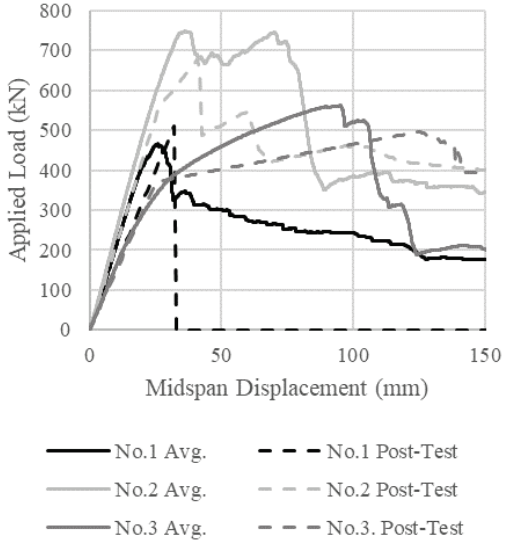

Figure 13: *Average force-displacement curves and updated methodology (post-test) predictions for the three layups*

7 DYNAMIC ANALYSIS

Following the test, calculations were performed to investigate the relative performance of these RCLT layups against unreinforced CLT layups under blast loading. Resistance curves were calculated for standard (unreinforced) CLT panels utilizing SP No.2 in 7-ply and 9-ply layups assuming a 3.66 m simply supported clear span. The layups assumed alternating 0 deg (strong) and 90 deg (weak) layers, with the exterior layers oriented in the 0 deg direction. Resistance functions for the three RCLT panels (layups 1, 2, and 3) were calculated with the updated methodology described in Section 6.5, using high-strain rate dynamic increase factors and assuming a uniform load distribution. The calculated resistance functions for all five panels are shown in Figure 14. The resistance function calculations predict: the two unreinforced CLT panels will display flexural failures near 105 kPa and 155 kPa; layup 1 will fail in shear near 165 kPa; layup 2 will demonstrate steel yielding near 180 kPa, followed by a shear failure near 215 kPa; layup 3 will demonstrate steel yielding near 130 kPa, and rupture of the wood core near 180 kPa. In all five cases the resistance function was set to perfectly plastic at the calculated ultimate resistance, generally following the approach in PDC-TR 18-02 [3].

Pressure-Impulse (P-I) diagrams were generated to compare the relative performance of the five panels. For each panel, a single-degree-of-freedom (SDOF) solver was used to determine the pressure-impulse combination that resulted in a specified ductility demand (i.e., μ = {maximum displacement / yield displacement} = 1, 2, 3, 4). The results are plotted in Figure 15 though Figure 18; note that the scales vary across the four figures. For each P-I curve, P-I combinations to the left or below the curve result in a smaller ductility demand while P-I combinations to the right or above the curve result in a greater ductility demand. Using Figure 15 as an example, the three RCLT panels are expected to sustain larger loads then the 7-ply CLT panel in the elastic range, while layup 2 is expected to sustain larger loads than both the 7-ply and 9-ply panels in the elastic range.

Although useful for comparison purposes, the P-I diagrams fail to account for the ductility capacity of the various panels. PDC-TR 18-02 defines ductility response limits for unreinforced CLT panels where, currently, ductility demands greater than 2 (i.e., $\mu \geq 2$) are expected to result in a 'Blowout' failure of unreinforced panels. On the other hand, Figure 13 indicates a ductility capacity for layup 3 of $\mu \sim 4$. Thus, if we compare the P-I diagrams of these three panels closer to their estimated limits of performance (see Figure 19), we see that layup 3 is expected to outperform both the 7-ply and 9-ply unreinforced CLT panels.

8 FUTURE EFFORTS

Several efforts are planned or ongoing to continue advancing the use of RCLT in protective design:

- Methodology Improvement (Ongoing). The methodology developed and utilized in this effort is being improved by implementing an incremental approach to calculating stiffness, flexural and shear capacities accounting for various damage mechanisms. The current version of the revised methodology provides better agreement with the test results presented herein (i.e., compare Figure 12 and Figure 13) and is planned to be included in a stand-alone software which calculates both CLT and RCLT resistance functions, as well as perform SDOF analyses.
- Weathering Study (Ongoing). Preliminary tests have shown the wood-to-steel adhesive bond not to be a limiting failure mechanism in RCLT panels. Both small-scale and large-scale weathering tests are ongoing to evaluate if temperature and moisture cycling degrades the adhesive bond and reduces the capacity of RCLT panels.
- Arena Blast Testing (Planned). Three RCLT layups will be subjected to arena blast testing. Two specimens will be fabricated for each layup, with one specimen subjected to six months of outdoor weathering prior to blast loading. Testing is scheduled for 2023.

9 CONCLUSIONS

This paper describes the development of a methodology to predict the performance of reinforced CLT (RCLT) panels, the manufacturing of full-scale RCLT panels, and quasi-static bending tests on those panels. The following general conclusions can be made from this work:

- The performance of RCLT panels can be well predicted. The methodology developed within this effort reasonably predicted the behavior of the RCLT panels selected. Future efforts include improving the methodology based on available test data.
- Full scale RCLT panels can be manufactured at an active CLT manufacturing facility. The cost to fabricate the RCLT panels is competitive with other protective solutions and would reasonably be expected to come down with wide-spread adoption of RCLT (e.g., automated vs. manual placement of the steel).
- Adhesive bond failure between the wood and steel layers was not typically observed, indicating that premature delamination failures at the embedded steel/lumber interface is not likely to compromise the out-of-plane resistance. Accelerated laboratory and short-term field weathering studies are currently ongoing to further evaluate the wood-to-steel adhesive bond.

https://doi.org/10.52202/069179-0009

- Rolling shear or delamination are the likely ultimate limit states for RCLT, although delamination was not typically observed. Because of the continuity, ductility, and capacity of the embedded steel plates, wood flexural rupture does not appear to cause a catastrophic panel failure. Further, even after a rolling shear failure RCLT demonstrates significant residual load carrying capacity.

ACKNOWLEDGEMENT

The work upon which this project was based was funded in part through a grant awarded by the U.S. Forest Service, Wood Innovations Grant (U.S. Federal Grant No. 21-DG-11052021-242). Additionally, the work was made possible with contributing funds provided by the Softwood Lumber Board and SmartLam. WoodWorks led the previous testing efforts to develop blast design guidance for mass timber construction. Testing was performed at the Advanced Structures & Composites Center at the University of Maine.

BALLISTIC TESTING OF CROSS-LAMINATED TIMBER LAYUPS TO FURTHER DEVELOP PROTECTIVE PANELS

Marco T. Lo Ricco[1], Mark K. Weaver[2], C. Adam Senalik[3], Jim Henjum[4], Jason Cattelino[5]

ABSTRACT: Though ballistic projectile penetration of wood has been studied for centuries, standard models overestimate the thickness of wood required to stop projectiles, often by a large margin. Adhesive lamination via contemporary manufacturing methods can produce mass timber panels of unprecedented thickness, yet industry standard layups of softwood cross-laminated timber (CLT) cannot stop projectiles traveling at velocities specified by current protective design requirements. To develop mass timber panels that comprehensively mitigate blast, ballistic, and forced entry threats, seven reinforced or hardened CLT layups were manufactured to compare their ballistic performance with that of a baseline 7-ply softwood CLT layup. Three calibers of ammunition were fired at each panel specimen, and entry and exit velocities were recorded with high-speed cameras. For projectiles that did not fully perforate the panel, the depth of penetration was determined by radiography. Four of the eight tested layups stopped all projectiles. Among the successful layups, three included embedded steel reinforcements. The other successful layup was made entirely of hardwood laminations. Steel-plate-reinforced softwood CLT proved the most cost-effective option.

KEY WORDS: cross-laminated timber, ballistic penetration, protective structures, reinforced CLT, hardwood CLT

1 INTRODUCTION

Blast and ballistic threats are two primary concerns in protective design. Past testing has demonstrated that mass timber can resist blast threats [1]. Although the ballistic performance of wood has been studied over the course of three centuries [2, 3], satisfactory resistance to ballistic threats remains unresolved. Approximately two decades ago, Smrž et al. [4] tested 55 mm (2-⅛ in.) thick wood plates under ballistic impacts from 7.62-mm bullet, spherical, and simulated fragment projectiles. The model developed from these experiments, however, is limited to 100 mm (3-⅞ in.) of thickness and adapted a unified theory of penetration that has proven accurate for metal alloys [5]. Whether this unified theory of penetration simulates perforation of wood materials as well remains an open question.

Two classic models of ballistic penetration, the Robins-Euler and Poncelet equations, originated during the eighteenth century when wood materials were common targets, and remain relevant in the mechanics of terminal ballistics [6]. Koene and Broekhius [7] applied these classic models to the penetration of 9-mm ammunition into solid wood blocks of various species and showed that the models reasonably fit the penetration depth data for metal-tipped bullets. The models, however, did not apply to polyethylene tipped bullets used in the tests. To ensure that bullets would be stopped by the wood blocks, impact velocities were limited, so whether the models need parameters for projectiles hitting the targets at much higher velocities remains unknown.

Protective design of U.S. government facilities commonly uses an empirically based model that correlates hardness, density, and thickness of wood to calculate the dimension required to stop a bullet or the residual velocity of a perforating bullet. According to equations and tabulated data in UFC 4-023-07 [8], an unrealistic 4.55 m (179 in.) thick panel of pine or 1.5 m (59 in.) thick panel of hickory would be required to stop a NATO M80 round fired at a velocity of 853 m/s (2800 ft/s). However, test programs that form the basis of these UFC 4-23-07 estimates predate innovations like cross-laminated timber (CLT).

Sanborn et al. [9] conducted one of the first published ballistics tests on CLT targets and found that UFC equations, among other models, overpredicted both (a) the thickness required to prevent perforation and (b) the exit velocities of spherical projectiles. Although the tested specimens outperformed conventional ballistic model estimates, Sanborn [10] anticipated that softwood CLT would need reinforcement to stop more realistic ballistic threats and tested several enhanced “eCLT” layups using steel, fiberglass, aramid, and ultra-high molecular weight polyethylene reinforcement layers. While several reinforcing options reduced penetration depth of spherical projectiles, mild steel was the least costly reinforcement.

2 OBJECTIVE

Wood's ballistic performance must be proven before governmental agencies and other institutions implementing protective design requirements can realize the sustainable and architectural benefits of mass timber construction. A feasibility study, therefore, was undertaken to investigate whether a CLT layup measuring 254 mm (10 in.) or less in thickness could stop ogive-nose bullets. To increase the ballistic resistance of softwood CLT layups and avoid the cost of exotic armoring materials, conventional steel sheets were incorporated into several layups. Other layups incorporated dense hardwoods, instead of steel reinforcement, to determine if wood panels without metal reinforcement could prevent ballistic perforation. The objective of the study was to demonstrate that CLT could meet ballistic protection requirements at a layup thickness and cost comparable to conventional reinforced concrete and steel protective options.

3 TESTING

3.1 SPECIMENS

The layups assessed in this study are schematically shown in Figure 1. All eight layups utilize seven layers of wood, with some layups utilizing up to four additional layers of embedded steel reinforcement. The layups are comprised of: (a) all softwood [to represent the control], (b) all hardwood, (c) alternating hardwood and softwood, (d) alternating interlocked grain hardwood and softwood, (e) thin steel plate reinforcement, (f) fine steel mesh reinforcement, (g) coarse steel mesh reinforcement, and (h) thick steel plate reinforcement.

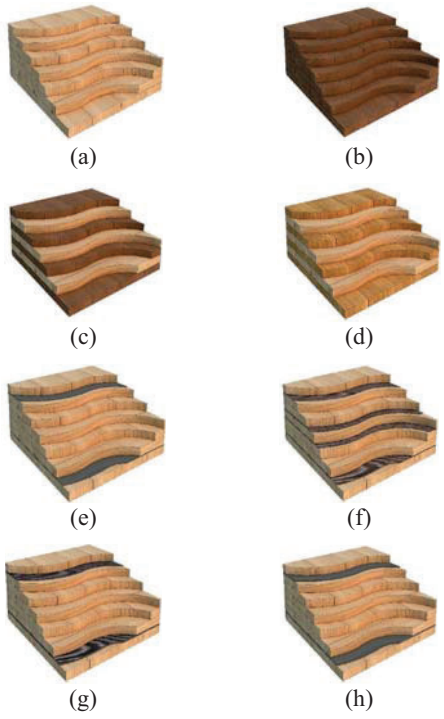

Figure 1: *Renderings of specimen layups.*

Layup (a) utilized Spruce-Pine-Fir, South (SPF-s), No. 2 Grade laminations of 35 mm (1.375 in.) nominal thickness, conforming to North American standards [11]. As the only standard CLT layup, this panel acted as a control that is representative of the ballistic resistance of unreinforced softwood CLT. Because Layup (a) had no hardwoods nor steel reinforcement, all other layups were compared and expected to outperform this control.

Layup (b) utilized laminations of shagbark hickory (Carya ovata) in select and better grades of 32 mm (1.250 in.) thickness. Shagbark hickory is selected as it is among the hardest and densest North American species, which is theorized to provide increased ballistic resistance when compared to softer and less-dense alternatives.

Layup (c) alternated hardwood (hickory) and softwood (SPF-s) layers, of respective 32- and 35-mm thickness, to assess whether contrasting combinations of hardness and density might outperform layups composed of a single species classification.

Layup (d) was similar to Layup (c) but substituted hickory with American sycamore (platanus occidentalis) to assess whether a hardwood with an interlocked grain microstructure might provide additional resistance. Previous tests indicated that sycamore has relatively high ballistic resistance relative to other woods [12].

Steel reinforcement is utilized in the four remaining layups, along with No. 2 SPF-s wood layers of 35-mm thickness. It was hypothesized that the hardness, density, and ductility of steel may sufficiently reinforce softwoods to prevent ballistic perforation. Past testing has shown that mild, low-carbon steel plates of 12.5 mm (0.5 in.) thickness are adequate in stopping the ammunition used in this study [13], so Layups (e) through (h) were limited to an embedded steel content equivalent to this thickness of steel plate or less. Two of the four layups utilize woven steel wire cloth while the other two layups utilize solid steel plates. Steel plates conform to ASTM A36 [14] with a minimum specified yield strength of 250 MPa (36 ksi), while the woven steel wire cloth conforms to ASTM E2016 [15]. The cold-drawn steel wires used in the woven steel cloth are uncoated and conform to the 1042 grade designation.

Layup (e) utilized steel plates of 3 mm (1/8 in.) thickness at the bond lines of the panel face laminations.

Layup (f) utilized finely woven steel wire cloth, with 47% open area and 1.6 mm (1/16 in.) wire diameter, at all bond-line interfaces except two. Although solid steel plates offer continuous coverage throughout the panel, woven steel cloth provides openings for adhesive contact between wood laminations, which may provide improved bond characteristics.

Layup (g) utilizes a coarsely woven steel wire cloth, with 27% open area and 3 mm (1/8 in.) wire diameter, at the bond lines of the panel face laminations.

Layup (h) utilizes 6 mm (1/4 in.) steel plates at the bond lines of the panel face laminations.

https://doi.org/10.52202/069179-0010

The thicknesses of the eight layups are similar but are all slightly different. Because softwoods and hardwoods are typically milled to different dimensions, Layup (b) made entirely of hardwoods results in the thinnest panel. The embedment of steel elements thickens Layups (e) through (h). While the eight layup thicknesses could have been held constant, practical considerations of lamella thickness are more representative of what the CLT industry would eventually produce. For each of the eight layups, a panel measuring approximately 915 mm (36 inches) square was pressed and subsequently cut into four 457 mm (18 in.) tiles. For the steel-reinforced panels, hardboard spacers are placed along the edges of embedded steel plates to make a path for saws to cut only through wood-based materials.

Of the four tiles produced from each panel layup, only three tiles were used as specimens for ballistics testing, so Table 1 provides panel thickness for each of the eight layups and three tiles used in ballistics tests. The resulting range of thickness is minus 22 mm (0.866 in.) and plus 14 mm (0.551 in.) relative to the baseline Layup (a) of 248 mm (9.75 in.) tile thickness.

Table 1: Panel thickness in mm

	Tile			
Layup	**1**	**2**	**3**	**Average**
(a)	248	248	248	248
(b)	227	225	225	226
(c)	235	235	233	234
(d)	232	232	232	232
(e)	252	251	254	252
(f)	259	259	260	259
(g)	262	262	262	262
(h)	257	257	257	257

25.4 mm = 1 inch.

Figure 2 plots the measured densities of the layups. Layup (b), the thinnest panel of Table 1 and made of shagbark hickory with a specific gravity reported as 0.72 [16], ranks as the densest panel. At the opposite end of the range, softwood Layup (a), made with a SPF-s of reported specific gravity of 0.36 [17], ranks as least dense.

Figure 3 plots the measured areal densities of the layups, calculated as the mass of each tile divided by the surface area. By this measure, Layup (h) has the highest areal density, while Layup (a) remains least dense. In other words, Layup (h) is the heaviest wall component among the tested layups because it has highest mass per square meter of exterior wall area. From a ballistics perspective, areal density provides the more useful measure, so both effective and areal density are reported here to highlight the distinction.

3.2 PROJECTILES

The test ammunition of Table 2 lists specified properties of the three NATO cartridges used is this ballistic study. A complete *round of ammunition* or *cartridge*, according to ballistics terminology [18], includes a bullet and cartridge case containing propellant and primer for ignition. The *bullet* is the only portion of the cartridge that is the *projectile* and has mass specified in units of *grains*. For enhanced aerodynamics and penetration of the projectile, the front end of bullets was ogive shaped. While levels of protection may vary for different facilities, the standard [13] used to evaluate this test program requires zero perforation for the projectiles impacting targets within the range of velocities specified in Table 2.

***Table 2:** Test Ammunition*

	Velocity (m/s)	
Cartridge	**Min.**	**Max.**
7.62 mm, M80, ball 147 gr.	823	853
5.56 mm, M193, ball, 55 gr.	955	986
5.56 mm, M855, ball, 63 gr.	899	930

1 m ≈ 3.28 ft; 1 grain ≈ 0.0647989 gram ≈ 0.00228571 oz.

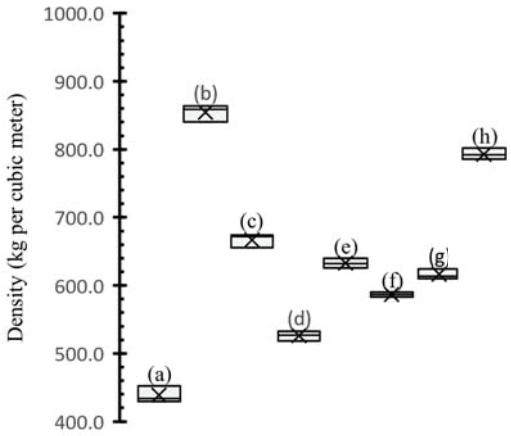

***Figure 2:** Effective density of layups used in ballistic testing.*

https://doi.org/10.52202/069179-0010

Based on previous softwood CLT tests which utilized spherical projectiles [9], it was expected that a softwood 7-ply CLT layup will not be able to stop ogive-nosed cartridges fired at standard rifle speeds as the ogive-nose typically penetrates materials more efficiently than spherical projectiles, because of simultaneous driving and drilling actions.

3.3 PROCEDURE

Of the four tiles produced for each layup, one tile underwent bond integrity testing while three underwent ballistic testing. The tiles undergoing bond integrity assessments were subjected to AITC T110 cyclic delamination tests [19] and physical prying with a weighted hammer and crowbar to qualitatively assess bond integrity. Ballistic resistance testing was conducted by a qualified laboratory (H.P. White Laboratory, Inc., Street, MD) during the spring of 2020 [20]. The cartridges listed in Table 2 were fired into each tile from a muzzle 6.1 m (20 ft) away from the strike face of the tile target. The shots were oriented in a triangular pattern to minimize the influence of previous shots. Velocity screens positioned relative to the muzzle at distances of 1.52 m (5 ft) and 4.57 m (15 ft) recorded the times projectiles passed, so that an initial velocity could be estimated at a position of 3.05 m (10 ft) along the trajectory. Impact velocities were determined from the velocity screen data and high-speed cameras recording video of impact with the target within the fixture pictured in Figure 4.

For projectiles that fully perforated the tiles, residual velocities were determined by high-speed video cameras tracking projectiles exiting the back face of the target from both top and side views, as shown in the example of Figure 5. For projectiles stopped within the tiles, their position was measured from the back (non-strike) face of the target by a qualified laboratory (MCQ Labs, Inc., Aberdeen, MD) using radiography, as shown in the example of Figure 6. The penetration depths shown in Figure 6 include both calculated (C) and measured (M) values given in the computed radiography report.

Figure 4: *CLT tile mounted in steel frame for ballistic testing viewed from back, non-strike face (foreground) and looking toward velocity screen (background).*

Figure 5: *Residual velocity video-recorded upon projectile exit.*

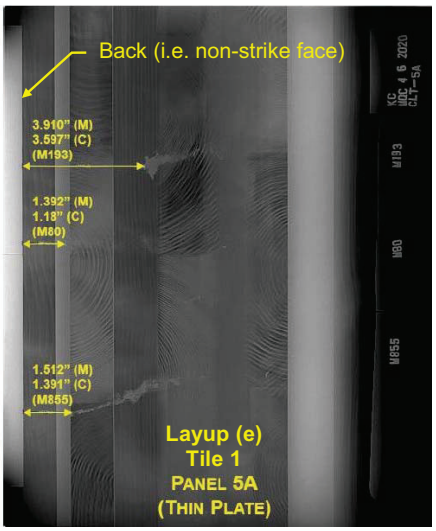

Figure 6: *Projectiles stopped from reaching exit face (datum).* 1 inch or 1.0" = 25.4 mm.

4 RESULTS

All nine projectiles fired at the Layup (a) tiles passed through the tiles (full perforation), while Layups (b), (e), (g) and (h), successfully stopped all projectiles from exiting the tiles (no perforations). Layups (c), (d) and (f) had multiple tiles perforated by M80 projectiles. Both Layups (c) and (f) stopped all shots of the M193 and M855 projectiles. Layup (d) failed to stop one of the M193 projectiles and all three shots of the M855 projectiles. Table 3 summarizes these results in terms of a binary pass-fail criterion. If panels stopped all the projectiles of a given cartridge type, it was deemed to pass. If at least one bullet passed through a panel and exited the back, non-strike face, the layup was deemed to fail. Regardless of the pass-fail determination, all targets were evaluated in more detail to estimate the energy absorbed by the CLT panels when shot with projectiles from each cartridge type.

https://doi.org/10.52202/069179-0010

Table 3: *Pass-fail results of ballistic perforation test.*

Layup	M80	M855	M193
(a)	FAIL	FAIL	FAIL
(b)	PASS	PASS	PASS
(c)	FAIL	PASS	PASS
(d)	FAIL	FAIL	FAIL
(e)	PASS	PASS	PASS
(f)	FAIL	PASS	PASS
(g)	PASS	PASS	PASS
(h)	PASS	PASS	PASS

PASS: Panel captured all bullets.

FAIL**:** One or more bullets exited the back face of panel.

Shaded: Layup failed to stop at least one bullet.

4.1 Perforated Targets

Figure 7 plots the striking velocity versus the residual velocity for projectiles associated with full penetration, where the M80 projectiles generally displayed the largest residual velocities. One residual velocity for the M80 round that breached Layup (c) could not be measured, though all three M80 projectiles exited the tiles. Since protective design is typically concerned with energy and a protective element's ability to dissipate energy, the recorded velocities of Figure 7 were converted to kinetic energy using the fundamental equation of one-half mass times velocity squared. For this calculation the mass of the bullet was assumed constant; (although this assumption cannot typically be made for ballistics traveling through hard or ductile materials, it is justified by video observations of the tests). Figure 8 plots the kinetic energy upon impact versus the residual kinetic energy for the projectiles associated with full penetration. The larger mass of the M80 projectiles results in a much larger striking kinetic energy then the M193 and M855 projectiles and, because the capacity of target tiles to absorb energy is finite, generally leads to a much larger residual kinetic energy.

To quantify the kinetic energy absorbed by each layup, the residual kinetic energy is subtracted from the striking kinetic energy. Figures 9, 10, and 11 show the differentiated kinetic energies for the M80, M193, and M855 projectiles, respectively. The total height of each bar chart represents the average striking kinetic energy on a specific layup. The light grey portion of the bar chart represents the energy absorbed by the impacted tile. The black portion of the bar chart represents the kinetic energy of the projectile after exiting the back of the tile.

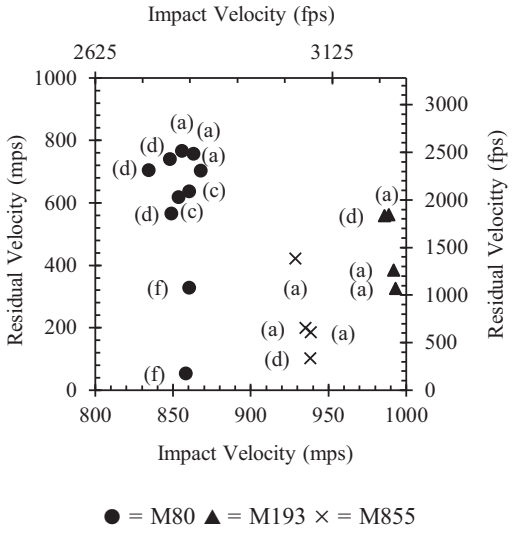

Figure 7: *Impact and residual velocities of projectiles breaching full thickness of panels.*

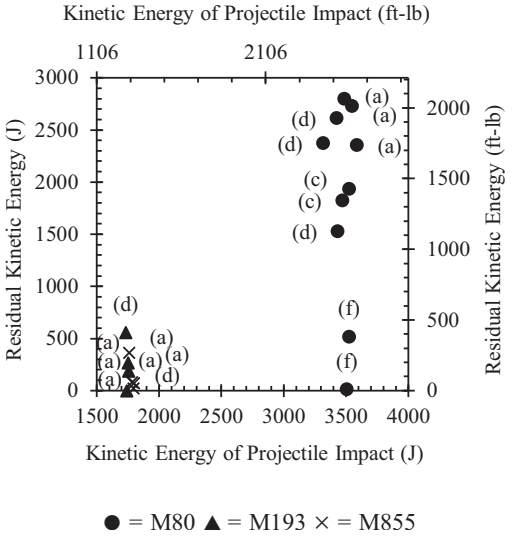

Figure 8: *Impact and residual kinetic energies of projectiles breaching full thickness of panels.*

Figure 9 shows that Layups (a), (c), and (d) absorbed less than half the kinetic energy of the striking M80 projectiles, in contrast to Layup (d) which absorbed nearly all projectile kinetic energy. Figures 10 and 11, plotted to the same y-axis scale as Figure 9, show that the M193 and M855 projectiles strike the tiles with approximately half the kinetic energy of the M80 projectiles. Though the full thickness of Layups (a) and (d) were breached by the M193 and M855 projectiles, Figures 10 and 11 show that nearly all the kinetic energy was absorbed by the tiles.

4.2 Embedded Projectiles

Table 4 provides the position of projectiles found within panel specimens, labelled as tiles, which were calculated using computed radiography. Blank entries of Table 4 indicate that no projectile of that ammunition type was found, supporting the penetration of full panel thickness observed during tests. The third M80 projectile into Layup (b) did not exit the panel but reached the back face and therefore was assigned a position of zero, to indicate near perforation.

Penetration depths of each projectile were calculated by subtracting position from total panel thickness, *t*. Because all shots were fired directly, with no oblique angles, the assume length of penetration of breached panels is the full thickness. Figure 12 shows the average depths projectile penetration alongside plots of average panel thickness for each layup. Projectile depths equal to panel thickness, *t*, indicate breaches. In panels that stopped bullets, the depth of penetration was generally proportional to the kinetic energy of the ammunition. Layup (h) reinforced with thick steel plates, however, presented an exception where the average depth of penetration of the M855 round exceeded the average penetration of the M80.

Table 4*: Positions of embedded projectiles measured from back face of panel.*

		Position from exit face		
		M80	**M193**	**M855**
Layup	**Tile**	**(mm)**	**(mm)**	**(mm)**
(a)	1	-	-	-
	2	-	-	-
	3	-	-	-
(b)	1	39	115	106
	2	40	148	111
	3	0	138	118
(c)	1	-	61	70
	2	-	95	94
	3	-	107	70
(d)	1	-	51	-
	2	-	22	-
	3	-	-	-
(e)	1	30	91	35
	2	44	85	61
	3	42	101	68
(f)	1	41	130	92
	2	-	127	96
	3	-	136	140
(g)	1	40	96	107
	2	45	108	89
	3	42	121	83

	2	100	143	75
	3	95	142	70

https://doi.org/10.52202/069179-0010

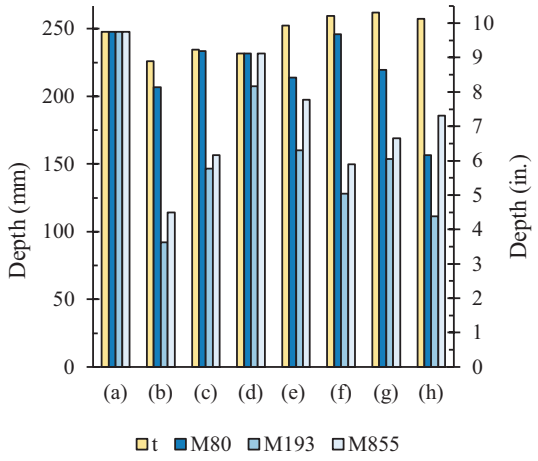

Figure 12: *Thickness and penetration depths of projectiles.*

4.3 Variation

Because all test ammunition was fired according to Table 2 specifications, with consistent velocities and mass, there was little variation in the striking kinetic energy. The coefficient of variation for the average striking kinetic energy of each tested layup given by Table 5 shows less than 2% variation in any given set of test ammunition. Variation of mass from the grain size specifications in Table 2 was neglected in the variation reported in Table 5, so the calculated variation is entirely attributable to the squared magnitude of velocity measured during testing.

Table 5: *Coefficients of variation for average kinetic energies of impact.*

Layup	M80 (%)	M193 (%)	M855 (%)
(a)	1.2	0.4	0.9
(b)	0.1	0.1	1.2
(c)	0.7	1.5	1.0
(d)	1.6	0.1	0.3
(e)	0.9	1.4	0.8
(f)	0.2	0.8	1.5
(g)	0.2	1.1	0.4
(h)	0.3	1.0	1.4

The coefficients of variation for averages of residual kinetic energy and penetration depth are respectively provided in Tables 5 and 6. Several factors account for the relatively high variation observed in the residual kinetic energy averages. First, the averages are based on a limited data set of three samples. In at least one instance, firing the M80 round into a Layup (c) panel, residual velocity could not be recorded, so results from two samples were averaged. In Layup (f), two M80 projectiles breached panels but one did not, which led to high variation in the average. With more tests, the effects of a limited number of samples would decrease. Second, woods have historically exhibited coefficients of variation greater than 20% for some mechanical properties [21]. The Spruce-Pine-Fir (South) commercial grouping further introduces variation by including 10 species [17]. Third, moisture content introduces additional variability that may affect results. In this study, ambient temperature and humidity readings were recorded and samples retained to verify that moisture content was typically 12% or less for each of the samples.

Table 5: *Coefficients of variation for average residual kinetic energies of breached layups.*

Layup	M80 (%)	M193 (%)	M855 (%)
(a)	7.4	47.6	78.9
(b)	-	-	-
(c)	2.9	-	-
(d)	21.4	141.4	48.2
(e)	-	-	-
(f)	135.9	-	-
(g)	-	-	-
(h)	-	-	-

The coefficients of variation for average depth of penetration listed in Table 6 range from approximately one to fifteen percent. For Layups (e) through (h) reinforced with steel, the variation is generally less than those of wood. For Layups (a), (c) and (d), the coefficients of variation are not reported for penetration values, because it is obvious that projectiles penetrated the full panel thickness. In these cases, the change in kinetic energy should be based on residual velocities with the variation reported in Table 5.

Table 6: *Coefficients of variation for average depth of penetration for layups with embedded projectiles.*

Layup	M80 (%)	M193 (%)	M855 (%)
(a)	-	-	-
(b)	14.0	15.5	4.7
(c)	-	13.8	7.2
(d)	-	10.0	-
(e)	3.1	3.3	7.0
(f)	7.9	2.7	14.0
(g)	1.1	6.7	6.1
(h)	3.3	4.2	1.5

4.4 Engineering model

Though variation poses challenges, it is possible to begin developing an engineering model from this limited data set. Ballistic modeling for wood has typically tried to correlate performance to fundamental properties of density, or specific gravity, and Janka hardness. Framing the problem in the context of energy is useful for the objective of stopping bullets. Although shape of the projectile is a factor in depth of penetration, the problem of armoring is largely dominated by kinetic energy delivered to an extremely localized scale. The challenge

https://doi.org/10.52202/069179-0010

lies in determining how much energy absorption wood may offer via breakage, friction, and other means of damping. The introduction of steel undoubtedly adds hardness, density, and ductility that enhances energy absorption of the panels.

For this data set, some additional steps may be taken to extract information that may be useful for engineering modeling. Resistance drilling studies [22] have developed models for distinguishing driving force, torque, and friction in correlation to density and Janka hardness. Via resistance drilling of retained samples, there may be a practical method to predict the ballistic performance based on the driving forces, torque, and friction measured near the ballistic perforations. Such studies have shown that numerous samples must be taken to develop statistical confidence in the models and obtain reasonable fit.

4.5 Costs and additional considerations

Among the four layups that stopped all test shots, the cost ranked in order from least to greatest is:

1. Layup (e), thin steel plates,
2. Layup (h), thick steel plates,
3. Layup (g), welded wire fabric
4. Layup (b), select shagbark hickory hardwood.

This ranking primarily factors the cost of raw materials and additional labor to produce the layups. Steel embedment requires preplanning of cuts and fastening zones, so that tools do not have to pass through wood and steel simultaneously. Despite this added fabrication planning, steel reinforcement facilitates use of economical and abundant softwoods in protective applications. Because protective panels must also resist blast effects and forced entry, the added ductility offered by the steel armoring enhances overall ductility and energy dissipation. Therefore, considering costs and enhancements to local and global ductility of panels, steel-reinforced softwood layups appear to be the most viable solution to develop and include in engineering models.

5 CONCLUSIONS

With either embedded steel reinforcement or an all hardwood CLT panel, it is possible to prevent ballistic perforation within a 254 mm (10 in.) panel thickness. One of the four successful CLT layups, however, stood out, because softwoods and thin steel plates are the most economical material options among those considered. Steel reinforcement, furthermore, provides ductility that may enhance the performance of panels in response to other hazards, such as blast, considered in protective design. For additional details of the ballistic tests described in this paper and other related testing, see the project report [20].

PREDICTING MODULUS OF RUPTURE OF HEAT-TREATED WOODS BY ARTIFICIAL NEURAL NETWORK COMBINED GENETIC ALGORITHM

Mehdi Nikoo[1], Reza Abbasi Malekabadi[2], Ghazanfarah Hafeez [3]

ABSTRACT: A total of 104 spruce and Larix gmelinii wood samples were employed to generate a reliable ANN-based model for estimating the Moment of Rupture (MOR) of heat-treated woods. Seventy percent of the samples were used for training, while the remaining thirty percent were used for testing phases of the data set. The Feed Forward network with five topologies was used, including heat treatment at various temperatures, durations, and relative humidity as input parameters. The weights of the artificial neural network are optimized by employing a genetic algorithm. The model's accuracy is assessed by comparing results with the particle swarm optimization-based neural network model. The study concluded that the genetic algorithm-based ANN model performed better by yielding results with reduced error.

KEYWORDS: Modulus of Rupture (MOR), Heat-Treated Woods, Artificial Neural Networks, Genetic Algorithm, Particle Swarm Optimization

1 INTRODUCTION

While timber is a distinctive, renewable, and sustainable construction material, it is biodegradable, mainly in open-air applications. Modifying timber's physical and mechanical properties improves its durability, preventing degrading agents. Wood modification methods are an evolving fashion and an eco-friendly substitute of chemicals for wood preservation procedures. During heat treatment processes, the wood is heated and modified in various atmospheres [1]. The material's structural performance and durability depend on numerous properties of heat-treated wood. Heat treatment dramatically lowers the wood's water absorption, equilibrium moisture content, and wettability, increasing its dimensional stability and biological endurance. Additionally, changes in the various characteristics of heat-treated wood affect the wood's performance in its application area.

Fernandez et al. (2012) determined the MOR and MOE of structural plywood using an artificial neural network and verified the results through the Multiple Linear Regression (MLR) model. The study considered thickness, moisture content, and density as the input variables for determining MOR and MOE. The results showed that the ANN model with three hidden layers has higher accuracy than the MLR model [2].

Yapıcı et al. (2012) employed Fuzzy Logic Classifier to determine the MOR and MOE of the heat-treated chestnut woods. The authors found that the developed model can calculate the MOR and MOE parameters of the test specimens with an accuracy of 92.64% and 90.35%, respectively, emphasizing its implementation in the wood industry manufacturing stages [3].

Yang et al. (2015) modified wood at high temperatures and under steam pressure. They created an ANN model to determine the mechanical properties of wood, considering temperature, time, and relative humidity as input parameters. The proposed ANN-based model yielded MOR and MOE values with reasonable accuracy [4].

Jiang et al. (2021) performed non-destructive testing of bamboo-based wood. The authors considered a duo Artificial Neural Network (ANN) and support vector machine (SVM) models to determine the MOR and MOE parameters. The outcomes of the study demonstrated that the SVM model with correlation coefficients of 0.90, 0.93, and 0.95 in the training, validation, and testing stages possesses higher accuracy than the ANN model [5].

The current study investigates the MOR of heat-treated woods employing Feed-Forward networks on the selected dataset. A genetic algorithm is used to optimize the weights of ANNs, followed by selecting the best-performed model among all samples of the same type. The proposed model is compared with the Particle Swarm Optimization (PSO) algorithm to evaluate its accuracy.

2 BACKGROUND

2.1 ARTIFICIAL NEURAL NETWORKS (ANN)

An artificial neural network (ANN) is a data model that can be taught from past experiences while implementing the outcomes to new data [6,7]. ANN is fabricated with neurons that work simultaneously to resolve a problem locally. Neural networks learn through typical computations describing the intrinsic mechanisms of the dataset in a reduced human brain-like manner. This study uses the Feed-Forward model comprising more than three layers, including input, hidden and output.

[1] Department of Building, Civil and Environmental Engineering, Concordia University, Montréal, Canada, mehdi.nikoo@mail.concordia.ca

[2] Department of Building, Civil and Environmental Engineering, Concordia University, Montréal, Canada, reza.abbasimalekabadi@mail.concordia.ca

[3] Department of Building, Civil and Environmental Engineering, Concordia University, Montréal, Canada, ghazanfarah.hafeez@concordia.ca

https://doi.org/10.52202/069179-0011

Each layer carries a set of nodes known as neurons connected to the layer above it. Weights, biases, and an activation function that can be continuous, linear, or nonlinear frame the neurons in the hidden and output layers. Once the structure is framed for Feed-Forward training, several procedures will be implemented to optimize the weight and bias levels. The study employs, The Levenberg Marquardt technique for distributing the error to yield the best fit with the least error [8,9].

2.2 GENETIC ALGORITHM (GA)

GA is thoroughly described considering biological concepts, including genetics and evolution. An individual is a candidate solution (typically a parameter vector), and a gene is a component of an individual, while a population is a collection of candidate solutions. An algorithm iteration is generally referred to as a generation, as such, a candidate solution or parent is modified in some way to generate a new candidate solution or child, followed by the algorithm's execution [10]. The standard GA algorithm comprises three genetic operators, including selection, crossover, and mutation. The selection operator is used to pick parents during each generation. The individuals with higher fitness levels have a greater chance of selecting the operator, followed by producing additional individuals or children [10].

3 METHODS AND MATERIALS

3.1 DATASET

In this study, the required data set is extracted from past studies [4,11]. In all, 104 samples of heat-treated woods were studied. The Feed-Forward network, considering temperature, time, and relative humidity as input parameters, was implemented on the dataset to determine the MOR of heat-treated wood. The statistical properties of the input and output parameters are shown in Table 1. While Figures 1 and 2 illustrate the box normal plot and histogram of the MOR parameter, indicating the cluster of MOR values between 60 to 70 MPa.

Table 1:*Input and output parameters in heat-treated wood* [4,11]

Num	Parameter	Unit	Type	MIN	MAX
1	Temperature	°C	Input	120	210
2	Time	hrs	Input	0.5	9
3	Relative Humidity	%	Input	0	100
4	Modulus of Rupture	MPa	Output	45.1	78.2

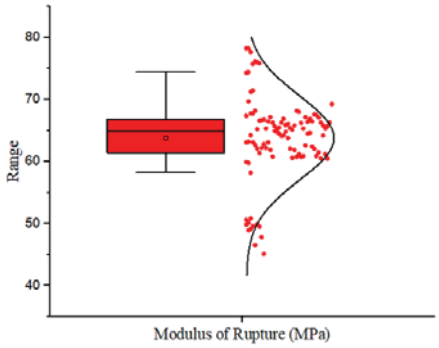

Figure 1: *Box normal plot of experimental data for MOR*

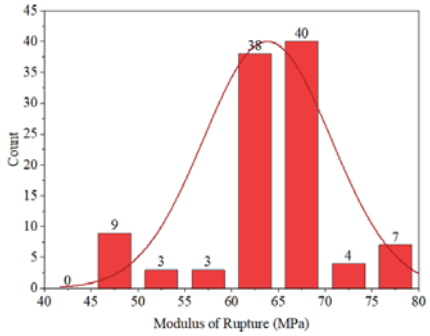

Figure 2: *MOR plot for experimental data histogram*

3.2 ANN MODEL COMBINED WITH GENETIC ALGORITHM

Of 104, 73 samples (70%) were used for training, and the remaining 31 (30%) contributed to testing the data. Two-layer neural networks with different transfer functions suggested the various topologies, as presented in Table 2. The weights and biases of the models were reduced by employing a genetic algorithm. Table 3 displays various properties of the genetic algorithm.

Table 2: *Different topologies used in ANNs*

No	Topology	Hidden and Output Activations
1	3-4-3-1	PURELIN-PURELIN-PURELIN
2	3-4-2-1	POSLIN-POSLIN-PURELIN
3	3-3-4-1	LOGSIG-LOGSIG-PURELIN
4	3-3-3-1	POSLIN-POSLIN-PURELIN
5	3-3-2-1	TANSIG-TANSIG-PURELIN

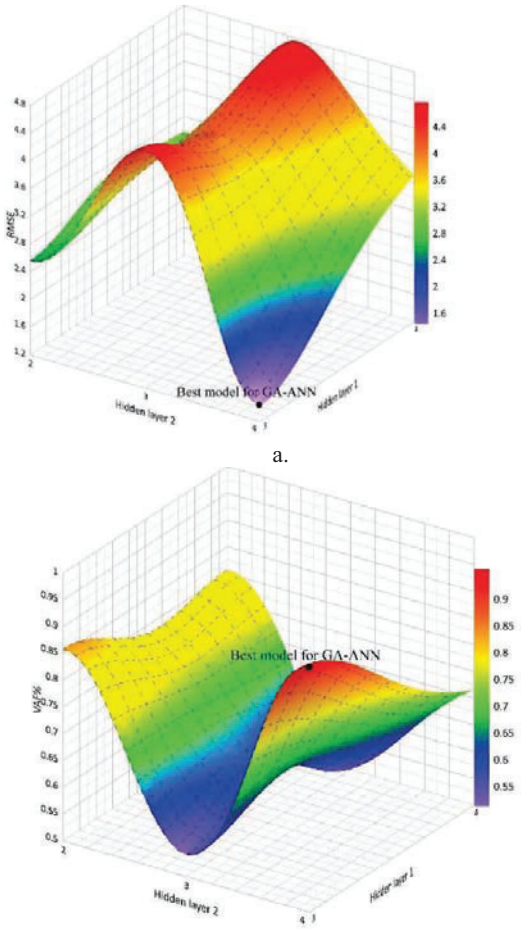
Table 3: *Genetic algorithm (GA) parameters* [12]

Parameter	Value	Parameter	Value
Crossover (%)	50	Max generations	150
Crossover method	single point	Recombination (%)	15
Lower bound	-1	Selection Mode	1
Upper bound	+1	Population Size	150

Table 4 presents the output of five GA based models, GA-ANN, created to determine the MOR of the heat-treated wood samples. Five different topologies, as illustrated in

https://doi.org/10.52202/069179-0011

Figure 3, were evaluated on the measures of Variance Account Factor (VAF) and Root Mean Squared Error (RMSE) values. The results indicated that the network with the GA-ANN 2L topology (3-4) design achieved the lowest RMSE error rates and the highest VAF percent when estimating the output parameters.



a.

b.

Figure 3: *Statistical values for the proposed topologies in all data: a) RMSE, b) VAF%*

Further, as presented in Table 4, the Feed-Forward network with a GA-ANN 2L topology (3-4) has the lowest value of the RMSE index in the training (1.28) and testing (1.75) phases. Additionally, the model with the same topology maintained the highest VAF value in the training (96%) and the testing (94%) phases indicating the least error among other topologies of the same algorithm. The GA-ANN 2L network topology (3-4) is shown in Figure 4.

Table 4: *Statistics of ANNs combined with the genetic algorithm (GA) for the MOR parameter*

Model Name	Hidden layer 1	Hidden layer 2	Train		Test		All	
			RMSE	VAF%	RMSE	VAF%	RMSE	VAF%
GA-ANN 2L(4-3)	4	3	4.59	51	5.15	46	4.76	51
GA-ANN 2L(4-2)	4	2	2.95	80	3.04	81	2.98	81
GA-ANN 2L(3-4)	3	4	1.28	96	1.75	94	1.43	96
GA-ANN 2L(3-3)	3	3	4.37	56	5.18	47	4.63	54
GA-ANN 2L(3-2)	3	2	2.78	82	1.95	92	2.56	86

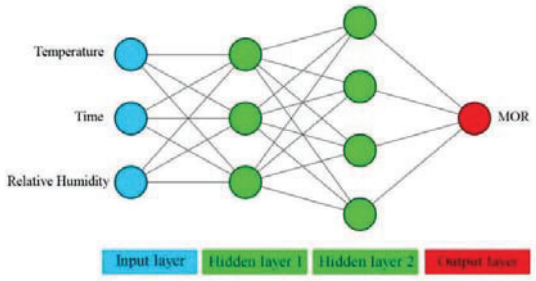


Figure 4: *The architecture of the ANN with the 3-3-4-1 topology*

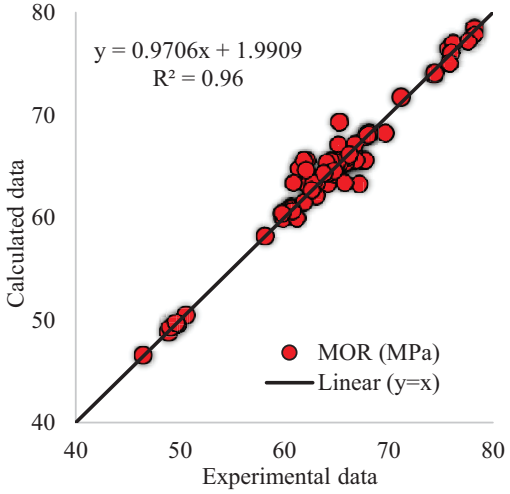
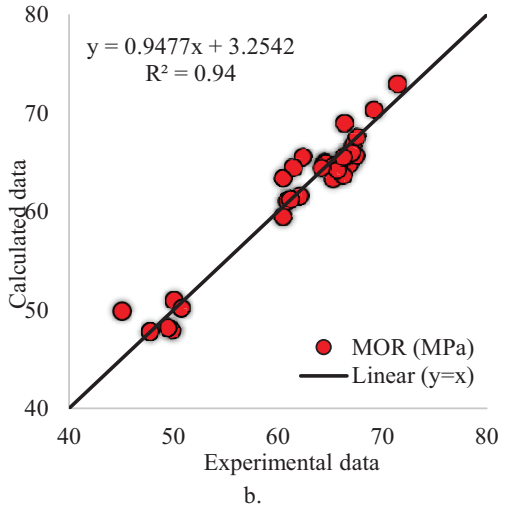
Figure 5 illustrates the best performance of GA-ANN 2L (3-4), as depicted in the calculated values versus their experimental counterparts in the testing and training phases. The model's projected values fall in the vicinity of the line *(y=x)*, indicating the model's accuracy. Further, the R^2 value for the training and testing phases are found as 0.96 and 0.94, respectively, demonstrating the accuracy of the proposed model.



a.



b.

Figure 5: *Experimental vs. predicted values of MOR for the GA-ANN 2L(3-4) model: a) training, b) testing*

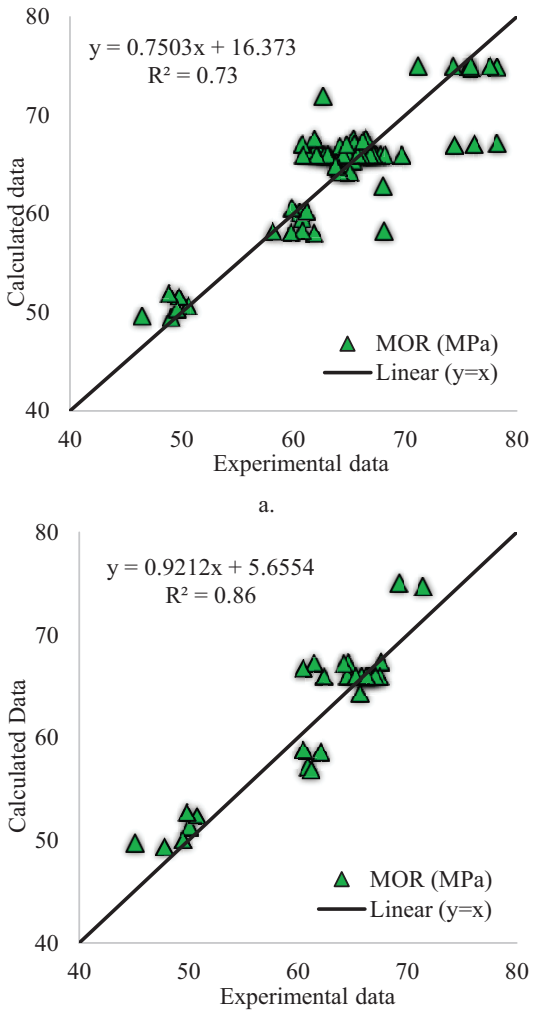
3.3 ANN MODEL COMBINED WITH PARTICLE SWARM OPTIMIZATION

The study employs a PSO-optimized ANN to calculate the MOR variable. Similar to GA based models, five topologies presented in Table 2 were used, creating various models for estimating the output parameters.

The models with PSO-ANN 2L(4-2) topology best calculated the required parameter (MOR), as indicated in Table 5 and Figure 6. The testing and training outputs for VAF and RMSE indicators confirm the lowest error rate of the model compared to the experimental data. Also, as indicated in the figure, the R^2 values of the training and testing phases are found to be 0.73 and 0.86, respectively, indicating the model's appropriate accuracy.

Table 5: *Statistics of ANNs combined with the Particle Swarm Optimization algorithm for the MOR parameter*

Topology	Hidden layer 1	Hidden layer 2	Train		Test		All	
			RMSE	VAF%	RMSE	VAF%	RMSE	VAF%
PSO-ANN 2L(4-2)	4	2	3.43	73	2.79	85	3.25	77



a.

b.

Figure 6: *Experimental vs. predicted values of MOR for the PSO-ANN 2L(4-2) model: a) training, b) testing*

3.4 SELECTION OF THE BEST MODEL

Finally, the best-performed GA-ANN and PSO-ANN models are compared on equal measures for all the datasets. Figure 7 illustrates the comparative normal distribution of the best-performed models with their experimental counterparts. As displayed in the figure, the normal distribution of GA-ANN is closer to the experimental data than the PSO-ANN model indicating the higher accuracy of the GA-ANN model. The comparison of the two models, illustrated in Figure 8, confirms the relatively higher accuracy of the GA-ANN model over the PSO-ANN model.

https://doi.org/10.52202/069179-0011

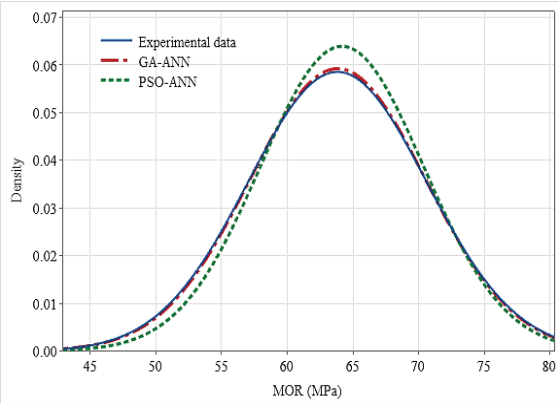


Figure 7: *Normal distribution of experimental data and GA-ANN and PSO-ANN models*

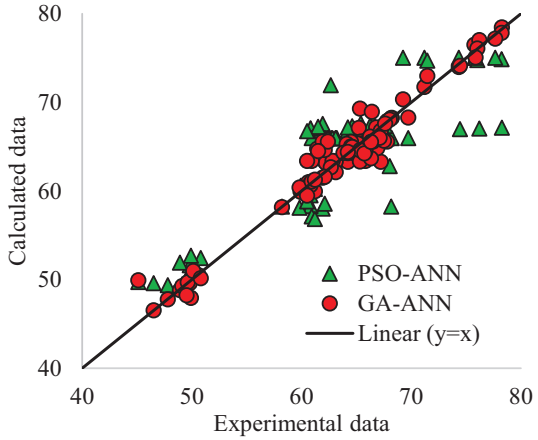

Figure 8: *Experimental vs. predicted values of MOR for different models*

4 CONCLUSION

A total of 104 experimental results obtained from spruce and Larix gmelinii woods were used to determine the MOR of the heat-treated woods. Artificial neural networks were optimized by employing genetic algorithms and particle swarm optimization to analyze the considered dataset. The analyses of the results suggested the better performance of GA-ANN over PSO-ANN for determining the modulus of rupture of the heat-treated woods.

TENSION-LOADED CONNECTIONS WITH WOOD DOWELS

Matthias Brieden[1]; Max Braun[2], Werner Seim[3]

ABSTRACT: Wood dowels carry tremendous opportunities concerning their application as fasteners and connection elements. Aspects such as sustainability and homogeneous recyclability can be addressed very well by using them to an increasing degree. Although they have been quite common for carpenters for hundreds of years, several characteristics need to be clarified systematically from an engineering point of view.
In this context, results and further investigations are presented within this paper. The load-bearing behaviour of beech dowels under tension force is subject to pull-out and shear testing. Both the inclination angle and the penetration length as major parameters are varied. The interrelation between the inclination, failure loading and ductility of wood dowels is not linear. This finding should be considered when designing and dimensioning new segmented cross-sections.

KEYWORDS: wood dowel, fastener, pull-out test, shear test, inclined connection

1 INTRODUCTION

1.1 HISTORIC AND CURRENT APPLICATIONS

Connections with wooden fasteners are one of the oldest techniques for connecting load-bearing elements. This type of pin-shaped fastener has often been found in historical structures. There, they serve to secure the position of carpenter's joints and transfer connection forces. In this application, the dowel connection is subjected to shear and tension forces [1] [2].
After having been replaced by steel fasteners in recent decades, wood dowels are now back in focus, even outside the rehabilitation of cultural heritage [3] [4]. Wood dowels could be a viable alternative, especially where the use of steel fasteners is critical. Their usage in salt silos, where metal fasteners would be exposed to chemical attack or the amount of electrically conductive material is to be reduced, offers several advantages. In addition, wood dowels have the same favourable properties in case of fire as structural timber. [5]

1.2 FUTURE PROSPECTS

A new aspect is the increasing potential of digital manufacturing methods. Complicated joint geometries are no longer a challenge, which means that, together with the geometry, the performance of wood dowels can be optimally utilised. In this context, the use of robotically manufactured composite components with wood dowels is being researched at the University of Kassel.
It has become clear through the planning and production on a prototype basis that questions regarding the load-bearing behaviour of wood dowels cannot be completely clarified by the relevant literature. The combination especially of tension and shear load has not been studied previously.

2 TEST SERIES 1

2.1 GENERAL INFORMATION

The main focus of the experimental investigations within the first test series is on evaluating the influence of the inclination angle of the fasteners. Therefore, pull-out and shear tests are conducted for different set-ups.
In order to get some statistical background for the research, each single test is repeated five times. Two different material combinations are additionally considered for the pull-out testing. Together with the four angles selected – α = 0°, 15°, 30° or 45° – this leads to 40 pull-out and 20 shear tests.
Both the diameter ($d_{fastener}$ = 10 mm) and the length ($\ell_{fastener}$ = 70 mm) of the wooden dowels are constant for test series 1. The penetration lengths $t_{h,1} = t_1$ and $t_{h,2} = t_e$ correspond to each particular set-up and are dependent on the specific test.
Regarding the style of presenting the experimental results, the single test results are marked as "X", the coloured columns represent the bandwidths and range, and the dotted lines show the mean values as well as the 5 % quantile in the following diagrams.
In the case where single values are identified as outliers, they are displayed as "X", and are not considered for the columns.
Outliers are identified according to the following rules. Results lower than 50 % of the mean value of the three medium results and higher than 150 % of the mean value of the three medium results are treated as outliers and, therefore, neglected.
As an example, the steps of this methodical approach are described for the results Series 1 – Pull-out test – max Force – LVL/LVL – α = 0° (see Figure 5). The single test results are given in Table 1.

https://doi.org/10.52202/069179-0012

Table 1: *Pull-out test – exemplary results for laminated veneer lumber (LVL)/LVL – α = 0°*

	test number				
	1	2	3	4	5
F_{max} [N]	268	677	466	347	357

As the data in Table 1 show, the minimal and maximal failure load measured occur for test $n = 1$ and $n = 2$. Neglecting these two results, the mean value of the remaining three tests produces ${F_{outlier}}^{mean} = 0.390$ kN, see (1).

$$ {F_{outlier}}^{mean} = (466 + 347 + 357)/3 = 390\ N \quad (1) $$

The upper and the lower limit can be calculated as ${F_{outlier}}^{upp} = 0.585$ kN and ${F_{outlier}}^{low} = 0.195$ kN, see (2) and (3).

$$ {F_{outlier}}^{upp} = 1{,}5 \cdot 390 = 585\ N \quad (2) $$

$$ {F_{outlier}}^{low} = 0{,}5 \cdot 390 = 195\ N \quad (3) $$

Comparing these values with the experimental results, test $n = 2$ ($F_{max} = 0.677$ kN) exceeds the bandwidth and is, therefore, identified as an outlier.

Out of the remaining four results, the mean value, the variance and the coefficient of variation (COV) can be determined as ${F_{max}}^{mean} = 0.359$ kN, $\sigma = 81.40$ and COV = 0.23, respectively, see (4) to (6).

$$ {F_{max}}^{mean} = (268 + 466 + 347 + 357)/4 = 359\ N \quad (4) $$

$$ \sigma^2 = 1/3 \cdot [(268 - 359)^2 + (466 - 359)^2 + (347 - 359)^2 + (357 - 359)^2] \quad (5) $$

$$ \sigma = 81.40 $$

$$ COV = \sigma / {F_{max}}^{mean} = 81{,}40/359 = 0.23 \quad (6) $$

Moreover the 5 % quantile can be calculated as ${F_{max}}^{5\%} = 0.280$ kN, see (7).

$$ 1 + (n-1) \cdot p = 1 + (4-1) \cdot 0.05 = 1.15 $$

quantile is between the smallest (268 N) and second smallest (347 N) result

$$ {F_{max}}^{5\%} = 268 + (347 - 268) \cdot (1.15 - 1.00) = 280\ N \quad (7) $$

2.2 PULL-OUT TESTS

2.2.1 Set-up

In order to study the load-bearing behaviour of connections with beech dowels under tension forces, a modified pull-out test for fasteners has been applied, which enables one to assess the tension resistance of different arrangements of fasteners.

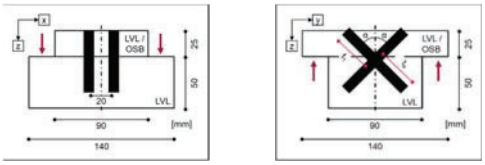

Figure 1: *Pull-out test – Test set-up*

Each pull-out test contains two wooden specimens that are connected by a pair of dowels in various geometric positions. The set-up can be seen in Figure 1.

The load protocol is chosen according to EN 26891 [6]: firstly, an estimated failure loading needs to be selected. The initial loading level is set at 40 % of this estimated failure loading – the strain is increased until this level and then kept constant for 30 seconds. After that, the strain is released to 10 % of the estimated failure loading and then again kept constant at this level. Finally, the strain is increased until the specimen fails – the failure loading has been reached.

2.2.2 Parameters

Forty pull-out tests were conducted with laminated veneer lumber (LVL) and oriented strand board (OSB) to be connected with four different inclinations of the dowels.

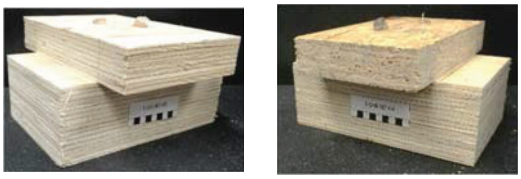

Figure 2: *Pull-out test – Specimen, wood dowels, inclination 30°, left LVL/LVL, right OSB/LVL*

An LVL specimen with wood dowels arranged with an angle of $\alpha = 30°$ can be seen in Figure 2. Figure 3 shows the situation during manufacturing for $\alpha = 30°$.

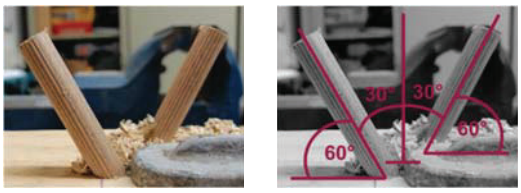

Figure 3: *Pull-out test – Detail, wood dowels, inclination 30° (pretesting)*

Variations considered

The test setting with vertically oriented dowels represents the most inappropriate case, where methodically, no forces straight orthogonally to the specimen surface can be transmitted. The pull-out resistance results because of friction between the specimen and the cylindrical surface of the dowels.

The second limit case considered occurs by tilting the dowels for $\alpha = 45°$. In this constellation, both vertical and horizonal forces are transmitted in addition to friction; moreover, tension and bending within dowels occur.

Intermediate tests with $\alpha = 15°$ and 30° were conducted to evaluate the influence of different angles.

Material and geometrical specifications

The bottom part of the specimens has a thickness of 50 mm and is always made of LVL. By contrast, the material of the upper layer is varied between LVL and

https://doi.org/10.52202/069179-0012

OSB, both with a thickness of 25 mm. Additional data concerning the dimensions of the specimen can be found in Figure 1.
The fasteners are made of beech and have a corrugated cylindrical surface. The diameter is 10 mm, and the dowel holes are predrilled with a diameter of 9.5 mm. The penetration lengths can be calculated for the individual situation.

2.2.3 Results

The F-t diagram and the corresponding F-u diagram are illustrated for one particular variation – OSB/LVL, inclination 15° – in Figure 4. These curves are exemplary for the whole pull-out testing campaign.

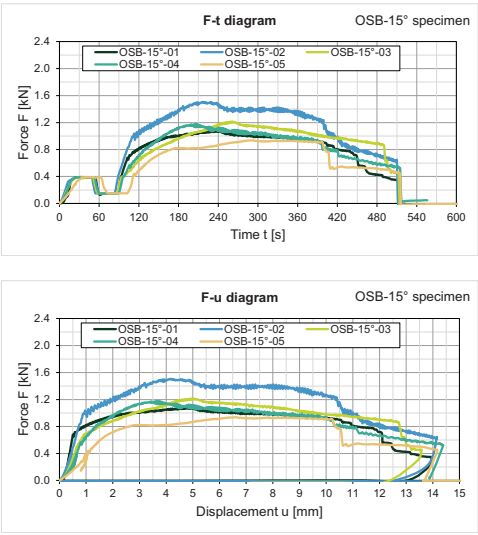

Figure 4: *Pull-out test – Exemplary test date*

All results which are presented in the following refer to "Two Fasteners in One Shear Plane with a Crossed ('X') Arrangement". This note can be found in the upper right-hand corner of the diagrams.

Failure loading and failure mode

Results of the pull-out tests are displayed in Figure 5 and Figure 6. The diagrams show the maximal tension force as a function of the installation angle.

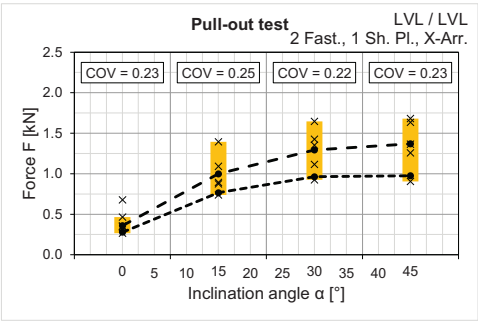

Figure 5: *Series 1 – Pull-out test – max Force – LVL/LVL*

One "0° test" is neglected in Figure 5, because of a faulty load protocol. Figure 6 shows that the maximal tension force fell below significantly for two of the five "0° tests". They are also neglected.

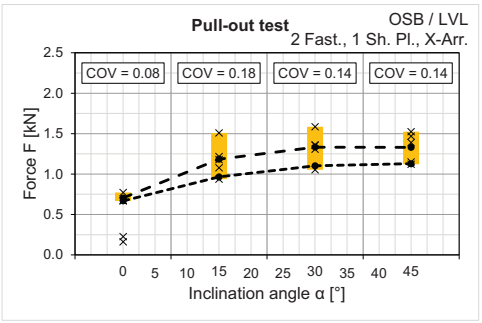

Figure 6: *Series 1 – Pull-out test – max Force – OSB/LVL*

The tension resistance rises considerably in relation to the vertical arrangement if the fasteners are tilted only about $\alpha = 15°$. Additional tilting improves the tension resistance in the following, but the increase is no longer as significant.
Both combinations considered – LVL/LVL and OSB/LVL – reach a similar level of failure loadings.

Slip modulus

In addition, the stiffnesses are also determined. Two different slip moduli (K_{init} and K_{re}) are determined corresponding to the specifications of the load protocol (initial load to 40 % of the estimated failure loading; relief to 10 % of the estimated failure loading; reload until the failure loading is reached). The gradient between 5 % and 35 % of the estimated failure loading is calculated for the initial slip modulus. The gradient in the force-displacement curve is determined between 10 % and 50 % of the failure loading to get the slip modulus of the reloading section.

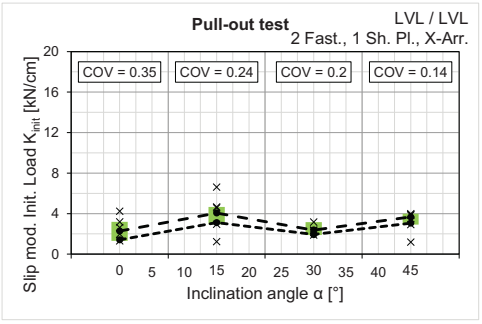

Figure 7: *Series 1 – Pull-out test – Slip modulus init. loading – LVL/LVL*

The results in Figure 7 to Figure 10 illustrate the particular slip moduli again as a function of the inclination angle. The style of the diagrams matches the ones already presented. Once more, the outliers are displayed as mentioned earlier, but are not considered for the further course of the discussion.

https://doi.org/10.52202/069179-0012

As seen in Figure 7 and Figure 8, no clear correlation between the slip modulus and inclination angle can be found. While K_{init} can be recognised as constant for the LVL/LVL specimen, a nearly linear increasing graph can be found for the OSB/LVL tests.
Concerning the different material combinations, it can be assumed that the OSB variation leads to higher slip moduli in contrast to the LVL variation.

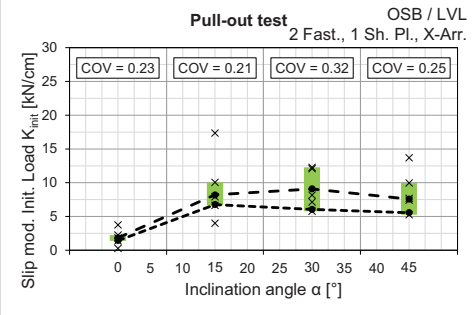

Figure 8: *Series 1 – Pull-out test – Slip modulus init. loading – OSB/LVL*

Figure 9 and Figure 10 show the slip moduli for the reloading section of the test series conducted. In this case, it can be seen even more clearly that no straight dependence occurs. The OSB/LVL tests in Figure 10 differ significantly due to the inclination angle.

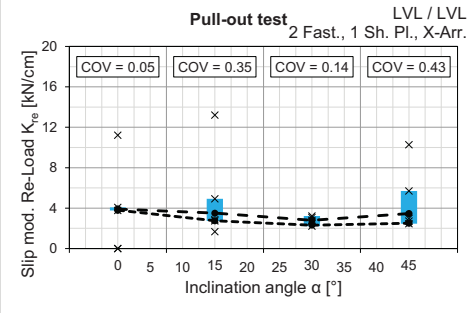

Figure 9: *Series 1 – Pull-out test – Slip modulus reloading – LVL/LVL*

Comparing the LVL and the OSB tests, higher slip moduli can again be determined for the latter.

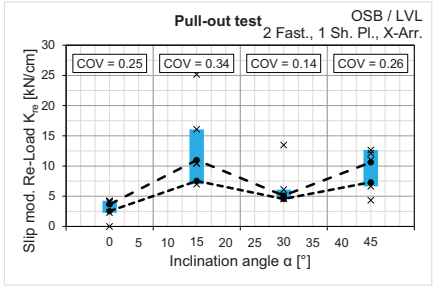

Figure 10: *Series 1 – Pull-out test – Slip modulus reloading – OSB/LVL*

2.3 SHEAR TESTS

2.3.1 Set-up

In order to evaluate the performance of the beech dowels under shear loading, several experimental tests were conducted. The test set-up is shown in Figure 11.

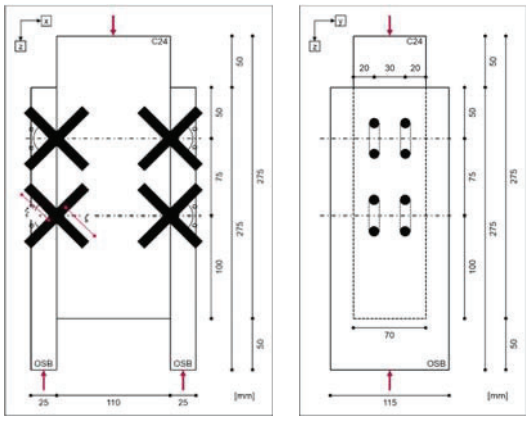

Figure 11: *Shear test – Test set-up*

Specimens with OSB elements and one C24 element are constructed for the investigations. The connection between the OSB panels and the C24 part is realised with eight wooden dowels. The fasteners are inclined with different angles, similar to those applied for the pull-out tests.
The middle parts have dimensions of 110 x 70 x 275 mm, while the panels are 25 x115 x 275 mm.
The load protocol is again chosen according to EN 26891 [6]. For more information, see 2.2.1.

2.3.2 Parameters

There are a total number of 20 shear tests in series 1. In terms of material specifications, only the combination of OSB panels with a C24 beam is considered. Again, four different angles are investigated.

Figure 12: *Shear test – Specimen and test set-up*

https://doi.org/10.52202/069179-0012

Figure 12 and Figure 13 show a specimen, the test set-up and some selected details.
Five tests are performed for each of the four different angles – α = 0°, 15° 30° and 45°.

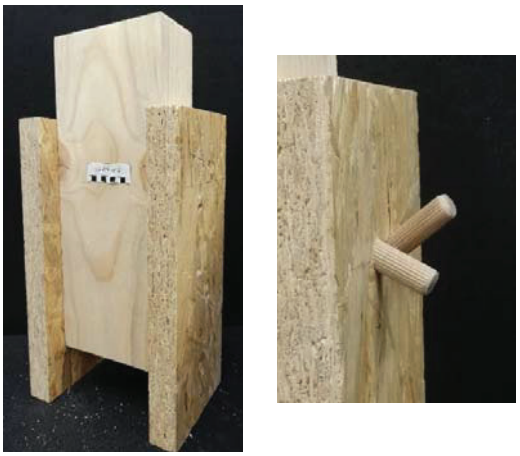

Figure 13: *Shear test – Specimen, detail, wood dowels, inclination 45°*

The diameter of the fasteners is again set at 10 mm, and the dowel holes are predrilled with a diameter of 9.5 mm. The penetration lengths correspond with the length of the fasteners of 70 mm and the particular set-up.
Details concerning the dimensions of the specimen can be found in 2.3.1.

2.3.3 Results

Figure 14 shows an example of the set-up with α = 15°; the values measured compiled as both an F-t and a F-u diagram. The current curves are valid for two fasteners with one shear plane.

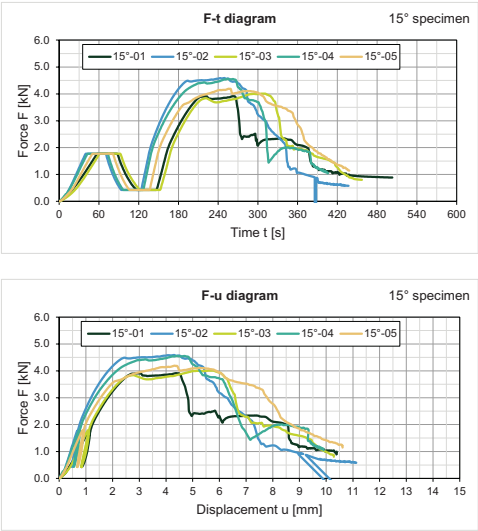

Figure 14: *Series 1 – Shear test – Exemplary test results*

All results presented in the further course refer to “Four Fasteners in Two Shear Planes with a Crossed (‘X’) Arrangement”. This note can be found in the upper right-hand corner of the diagrams.
See 2.2.3 for the style and layout of the results.

Failure loading and failure mode

The maximal loads as a function of the inclination angle can be seen in Figure 15. A rather clear correlation can be found. The maximum force decreases as the angle increases.

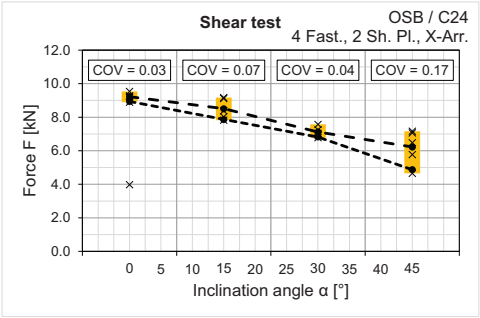

Figure 15: *Series 1 – Shear test – max Force – OSB/C24*

In this case, the cross-wise arrangement of the dowels – see detail in Figure 13 – indicates the course of the test results. Regarding α = 0°, each dowel is loaded in the same way, while for other angles, only one out of two dowels contribute to the load-bearing capacity.

Slip modulus

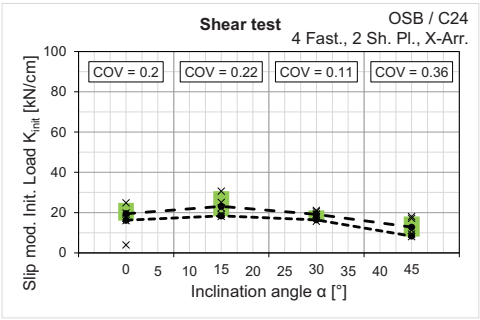

Figure 16: *Series 1 – Shear test – Slip modulus init. loading – OSB/C24*

In addition to the failure loadings, the slip moduli are also determined. The results – firstly, for the initial loading section, secondly, for the reloading section – can be found in the diagrams in Figure 16 and Figure 17.

https://doi.org/10.52202/069179-0012

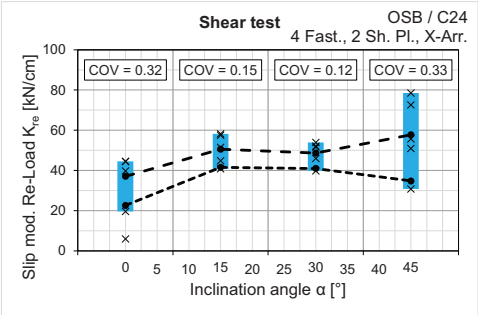

Figure 17: *Series 1 – Shear test – Slip modulus reloading – OSB/C24*

As the experimental results indicate, both slip moduli are more or less independent of the inclination angle. This may be due to the ambiguous effect of the different arrangements of the fasteners – on the one hand, tilting the dowels improves the load-bearing capacity, but, on the other hand, the pairwise opposing orientation reduces the load-bearing capacity.

While K_{init} slightly decreases with an increasing angle (Figure 16), K_{re} tends to increase in this course (Figure 17). The initial slip modulus is generally less than half of the slip modulus for the reloading.

3 TEST SERIES 2

3.1 GENERAL INFORMATION

The main focus in the second test series is on evaluating the influence of different penetration lengths of the dowels. As has already been conducted within test series 1, pull-out and shearing test are performed. This time, as a secondary parameter, the inclination angle is varied for only two values – pull-out tests are done for α = 15° and 30°, whereas shearing tests are conducted for α = 0° and 30°.

Five specimens were tested for each parameter combination. The material specifications are point, with OSB and C24 as materials for all investigations. A total of 30 pull-out and 30 shear tests were conducted.

The diameter ($d_{fastener}$ = 10 mm) of the wooden dowels constant, while the particular length for test series 2 corresponds with the penetration length of each set-up.

3.2 PULL-OUT TESTS

3.2.1 Set-up

The set-up for the pull-out test in the second test series complies with that in series 1. Details can be found in 2.2.1.

Similar to the first test series, the dimensions of the specimens are 90 x 140 x 50 mm for the lower element (C24) and 140 x 90 x 25 mm for the upper element (OSB).

3.2.2 Parameters

The penetration length in the lower timber element (C24) is given in relation to the thickness of the upper timber element (OSB). With t_1 = 25 mm and t_e / t_1 = 1.0, 1.5 and 2.0, the particular values are t_e = 25.0, 37.5 and 50.0 mm. The total length of the fasteners are $\ell_{fastener}$ = 50.0, 62.5 and 75.0 mm.

3.2.3 Results

Due to the corresponding testing conditions, the remarks given in 2.2.3 hold as well.

Failure loading and failure mode

The results of the experimental tests are illustrated in Figure 18. Here, the diagrams show the maximum force over the penetration length.

It can be seen that the penetration length has no significant influence on the failure loading. A clear effect cannot be found because of the statistical deviation. As a trend, it can be assumed that the rising penetration length leads to a higher failure loading.

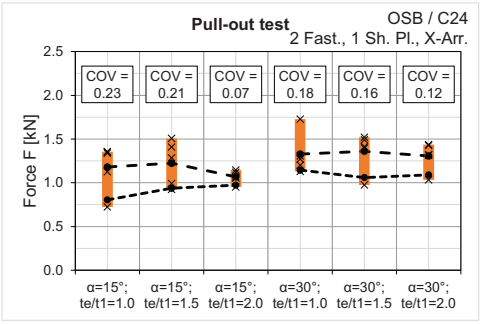

Figure 18: *Series 2 – Pull-out test – max Force – OSB/C24*

Slip modulus

In addition, the two slip moduli discussed already are also determined. Figure 19 and Figure 20 show the corresponding results.

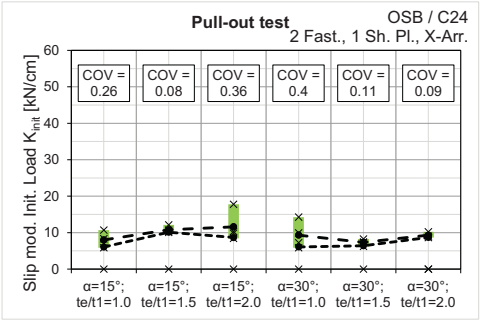

Figure 19: *Series 2 – Pull-out test – Slip modulus init. loading – OSB/C24*

Regarding the initial load section, the slip modulus is almost constant and, thus, not influenced by the penetration length (see Figure 19).

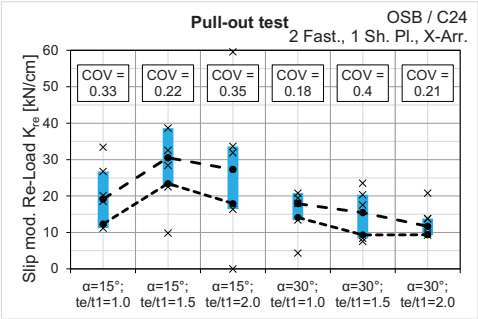

Figure 20: *Series 2 – Pull-out test – Slip modulus reloading – OSB/C24*

By contrast, although the slip modulus for the reloading section (see Figure 20) is obviously affected by the penetration length, a direct correlation cannot be found.

3.3 SHEAR TESTS

3.3.1 Set-up

The test set-up for the shear tests of the second test series is the same as test series 1. Further information can be found in 2.3.1.

3.3.2 Parameters

The main focus of the pull-out tests presented previously is on the influence of different penetration lengths. The particular lengths investigated are t_e = 25.0, 37.5 and 50.0 mm. Moreover, two inclination angles are considered: α = 0° and 30°.

3.3.3 Results

See 2.3.3 for the layout and more details about the following diagrams.

Failure loading and failure mode

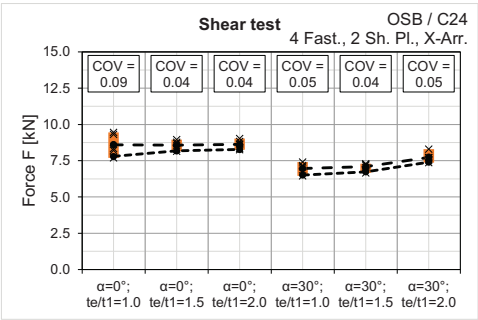

Figure 21: *Series 2 – Shear test – max Force – OSB/C24*

Figure 21 contains the maximal failure loadings determined experimentally for the different set-ups considered. It can be seen that there is only a slight effect of the penetration length. Regarding the inclination angle, the results presented show a decreasing trend when increasing the tilting.

Slip modulus

Figure 22 and Figure 23 show the slip moduli which are determined for the initial and the reloading section. The results indicate that at least K_{init} is not significantly influenced by the penetration lengths. No clear trend is obvious.

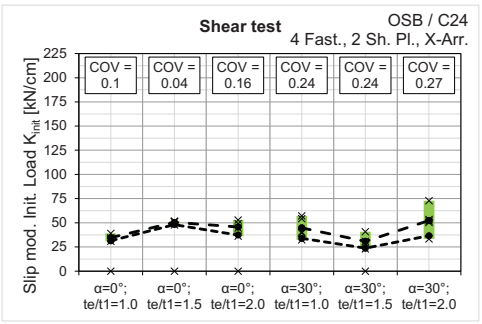

Figure 22: *Series 2 – Shear test – Slip modulus init. loading – OSB/C24*

Concerning K_{re}, on the one hand, there seems to be a corresponding correlation for α = 0°, however, on the other hand, no clear effect can be proved for α = 30°.

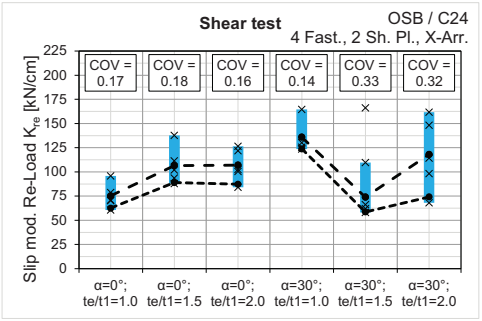

Figure 23: *Series 2 – Shear test – Slip modulus reloading – OSB/C24*

4 DISCUSSION AND INTERPRETATION

4.1 PULL-OUT TESTS

The results of the pull-out tests are summarised in Table 2, Table 3 and Table 4; the tables contain the mean value and the 5 % quantile of each particular configuration. Normal distribution was assumed and the quantiles have been calculated as given in (7).

Table 2: *Pull-out test – max Force*

Configuration			*n [-]*	*F [kN]* mean value	*F [kN]* 5 % quantile
Series 1	LVL/LVL	α=0°	4	0.359	0.280
		α=15°	5	0.999	0.765
		α=30°	5	1.294	0.964
		α=45°	5	1.370	0.976

https://doi.org/10.52202/069179-0012

	OSB/LVL			α=0°	3	0.705	0.669
				α=15°	5	1.184	0.966
				α=30°	5	1.333	1.104
				α=45°	5	1.332	1.128
Series 2	OSB/C24	t_e/t_1	1.0	α=15°	5	1.180	0.805
				α=30°	5	1.227	1.141
			1.5	α=15°	5	1.224	0.937
				α=30°	5	1.360	1.060
			2.0	α=15°	5	1.068	0.973
				α=30°	5	1.306	1.090

Comparing the results of both test series, it can be outlined that the failure loadings in series 2 fit in well to the ones of series 1. The increase of the inclination angle leads to a higher load-bearing capacity, whereby the effect flattens with increasing angles. Table 2 indicates that a clear effect of the different material combinations cannot be found. Thereby, the failure of the specimen seems to be caused by the fasteners themselves.

Table 3: *Pull-out test – Slip modulus init. loading*

Configuration					*n [-]*	*K_{init} [kN/cm]* mean value	5 % quantile
Series 1	LVL/LVL			α=0°	4	2.28	1.42
				α=15°	3	4.02	3.12
				α=30°	5	2.38	1.94
				α=45°	4	3.68	3.06
	OSB/LVL			α=0°	3	1.84	1.45
				α=15°	4	8.21	6.78
				α=30°	5	9.10	6.07
				α=45°	4	7.59	5.58
Series 2	OSB/C24	t_e/t_1	1.0	α=15°	4	7.98	6.04
				α=30°	4	9.32	6.07
			1.5	α=15°	4	10.78	10.11
				α=30°	4	7.31	6.39
			2.0	α=15°	4	11.58	8.64
				α=30°	3	9.29	8.66

By contrast, it can be detected that the two slip moduli and, with it, the deformation of the specimen, are influenced by the different materials. Table 3 and Table 4 show that the slip moduli of the LVL tests are lower than the other ones for most configurations. The results of series 2 especially indicate that the material combination has a large impact on the performance.

Table 4: *Pull-out test – Slip modulus reloading*

Configuration					*n [-]*	*K_{re} [kN/cm]* mean value	5 % quantile
Series 1	LVL/LVL			α=0°	2	3.92	3.79
				α=15°	3	3.51	2.76
				α=30°	5	2.80	2.32
				α=45°	4	3.47	2.51
	OSB/LVL			α=0°	4	3.66	2.53
				α=15°	4	11.01	7.53
				α=30°	4	5.12	4.58
				α=45°	4	10.62	7.62
Series 2	OSB/C24	t_e/t_1	1.0	α=15°	4	19.17	12.31
				α=30°	4	17.92	14.10
			1.5	α=15°	4	30.53	23.41
				α=30°	3	15.45	9.32
			2.0	α=15°	3	27.30	17.94
				α=30°	4	11.68	9.37

4.2 SHEAR TESTS

Table 5, Table 6 and Table 7 summarise the results of the shear tests of both series. The mean values determined and the corresponding quantiles are given for each configuration.

Table 5: *Shear test – max Force*

Configuration					*n [-]*	*F [kN]* mean value	5 % quantile
Series 1	OSB/C24			α=0°	4	9.232	8.942
				α=15°	5	8.504	7.864
				α=30°	5	7.119	6.819
				α=45°	5	6.227	4.877
Series 2	OSB/C24	t_e/t_1	1.0	α=0°	5	8.600	7.796
				α=30°	5	6.964	6.508
			1.5	α=0°	5	8.574	8.177
				α=30°	5	7.083	6.733
			2.0	α=0°	5	8.618	8.269
				α=30°	5	7.729	7.396

On the one hand, it can be seen that the results of both test series for the failure loadings (Table 5) are very close.

Table 6: *Shear test – Slip modulus init. loading*

Configuration					*n [-]*	*K_{init} [kN/cm]* mean value	5 % quantile
Series 1	OSB/C24			α=0°	4	19.50	16.21
				α=15°	5	23.11	18.38
				α=30°	5	19.15	16.41
				α=45°	5	12.81	8.36
Series 2	OSB/C24	t_e/t_1	1.0	α=0°	4	34.52	31.40

		α=30°	5	44.74	33.83
	1.5	α=0°	4	50.37	48.18
		α=30°	4	30.74	23.74
	2.0	α=0°	4	45.65	37.40
		α=30°	5	52.33	36.63

Table 7: *Shear test – Slip modulus reloading*

Configuration				*n [-]*	*K_{re} [kN/cm]* mean value	5 % quantile
Series 1	OSB/C24		α=0°	4	37.09	22.62
			α=15°	5	50.57	41.57
			α=30°	5	48.69	41.00
			α=45°	5	57.73	34.82
Series 2	OSB/C24	t_e/t_l 1.0	α=0°	5	75.26	62.58
			α=30°	4	135.96	123.90
		1.5	α=0°	5	106.54	89.03
			α=30°	4	74.00	58.62
		2.0	α=0°	5	107.06	87.33
			α=30°	5	118.16	74.16

Due to the slip moduli, on the other hand, the results indicate a significant deviation between the two test series. In this context, it has to be emphasised that the evaluation of the data is of great importance. The particular way of determining the gradients (initial and reloading section) of the load-displacement curves must be considered.
In addition, the effect of the different penetration lengths shows no clear tendency. More testing with other specifications is necessary in order to evaluate this effect.

5 CONCLUSIONS AND OUTLOOK

The results presented lead to a better understanding of connections with wood dowels under tension and shear. Wood dowels are easy to use, flexible, sustainable and represent a promising alternative not only in the restoration sector but also for new constructions.
More investigations concerning doweled connections under shear and tension will be carried out to understand the load-bearing behaviour of these fasteners and, thus, to expand the application area.
As an additional approach, other geometrical and material specifications – different diameters, wider range of penetration lengths, alternative arrangements of the fasteners – will be investigated.
As a consequence of the research approach, further application areas for wooden dowels and similar fasteners should be found. This will lead to a more sustainable and appropriate use of wooden construction elements.

ACKNOWLEDGEMENT

The results presented were achieved within the DFG research project “Additive robotic assembly techniques for timber construction – Computational design and integrated structural joining methods”. This project is funded by “Deutsche Forschungsgemeinschaft”. The work would not have been possible without this support.
The authors would like to thank the funding agencies, the colleagues named in the bibliography and the representatives of the companies involved in the project as well as the associated project committees for their contributions.

MECHANICAL PROPERTIES OF GLUE LAMINATED TIMBER BY SMALL SIZE TREE SPECIES (CASE STUDY OF OKINAWAN FOREST)

Juan Jose Castro[1], Shogo Omi[2]

ABSTRACT: Local islanders have used Okinawan forest products for construction since ancient times. However, the present state is that the local forest trees have only a tiny diameter of 30 to 40 cm and 4 to 5 m in length on average. Because of that limited size, the timbers do not meet the size requirements for building construction, thus, they have been used only for low added value products. Therefore, to utilize those local timbers more valued products, the authors have proposed the glue laminated timber technique, which enables larger sections of structural elements to be used for building construction. This study selected four types of local timber to elaborate solid type and glue laminated timber type specimens to examine their applicability. The test consists of bending and fiber longitudinal compression tests to assess the mechanical properties of the Okinawan timbers. The results showed that the mechanical properties, such as strength and modulus of elasticity of solid and glue laminated timber, were equal to or stronger than solid timber. In addition, the mechanical properties of those timbers tested in this study were even stronger compared to extensively used timbers in Japan, such as Cedar and Japanese Cypress.

KEYWORDS: small size timber, glue laminated timber, bending strength, compression strength, modulus of elasticity

1 INTRODUCTION

With a sub-tropical climate, Okinawa Prefecture is home to many tree species not found elsewhere on Japanese islands. Several of these species have long been used for local large scale public buildings such as Shuri Castle and traditional private houses, shipbuilding, etc. However, the social and political shift to present modern Japan in the late 19th century caused the destruction of local forests. Due to this change, people started to consume timbers intensively, but the implant project of wood had not been executed properly. This poor forest preservation has continued over the years. Consequently, Okinawan sub-tropical woods recently have limited resources of trees, such as a tiny diameter of 30 to 40 cm and 4 to 5 m in length on average. Thus, it is known that the size of Okinawan solid wood is limited and too small for structural building materials, as shown in Figure 1[1].

Figure 1: *Lumber in Okinawan Islands*

Since the market of Okinawan timber is small as explained above, most local timbers are utilized for small products.

Among the total lumber processed, as shown in Figure 2, 35% is for chips for livestock bedding, 35% is for fuel wood, and the remaining 30% is used for lumber elements. Among the last item, the main products processed are furniture, accessories, and other elements with small demand for timber volume.

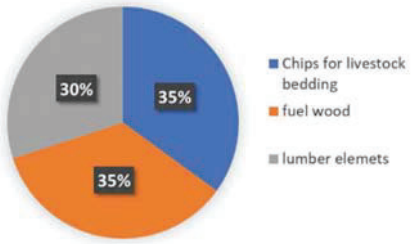

Figure 2: *Use of the Okinawan lumber*

The characteristic of the lumber produced in Okinawan islands such as Ryukyumatsu (Pinus luchuensis), Itajii (Castanopsis sieboldii), Iju (Schima wallichii) and Inumaki (Podocarpus macrophyllus) is that they have in average a density of 0.6 gr/cm^3[1]. This density is higher than the Cedar (0.34 gr/cm^3) and Japanese Cypress (0.42 gr/cm^3), which are more prevalent lumber in the Japanese timber industry. However, since Okinawan timber's mechanical properties are not standardized as the other

[1] Juan Jose Castro, Faculty of Engineering, University of the Ryukyus, 1 Senbaru, Nishihara, Okinawa, 903-02313, Japan, castro@tec.u-ryukyu.ac.jp

https://doi.org/10.52202/069179-0013

species, they can not be used as structural elements for building construction due to the lack of technical information.

In this study, we would like to consider using this timber as a higher value-added structural material for construction. Therefore, we have proposed using small-sized Okinawan lumber for glue laminated timber (GLT), enabling high-quality structural elements with large sections with fewer defects.

The research focuses on whether the mechanical properties of the Okinawan timber can be improved by using GLT and comparing them with the Cedar and Japanese Cypress values. Also, this paper proposes a reference strength value to be used in the structural design.

In this paper, full-scale specimens of solid wood and glued laminated timber from Okinawa Prefecture were prepared and tested in bending and compression to assess their mechanical properties.

2 METHOD

2.1 MATERIAL AND SPECIMENS

Four tree species were selected for this study, Ryukyumatsu (Pinus luchuensis), Itajii (Castanopsis sieboldii), Iju (Schima wallichii), and Inumaki (Podocarpus macrophyllus). The timber was obtained from the Kunigami-village, Okinawa Prefecture's forestry cooperative, and was used to make solid and glue laminated timber specimens.

The specimens were manufactured following the Japan Housing and Wood Technology Center (HOWTEC) regulations[2]. Figure 3 shows the dimension of the specimens. Three solid and six GLT specimens were tested from each tree species, as shown in Table 1.

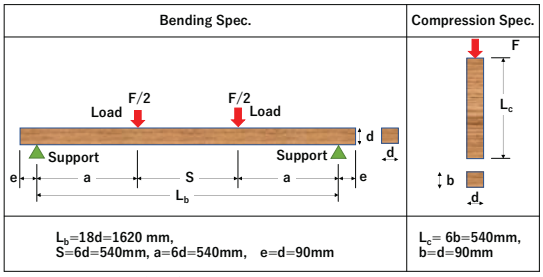

Figure 3: *Details of specimens*

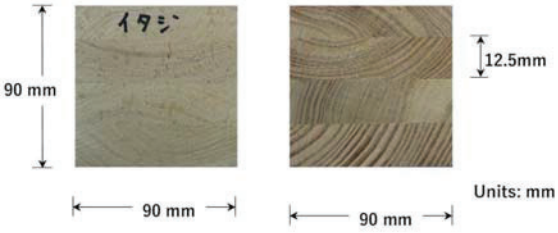
Table 1: Specimens List

Test	Timber Type	Solid		GLT	
		Size (mm)	No. of Spec.	Size (mm)	No. of Spec.
Bending Spec.	Ryukyumatsu	90x90x1800	3	90x90x1800	6
	Itajii	90x90x1800	3	90x90x1800	6
	Iju	90x90x1800	3	90x90x1800	6
	Inumaki	90x90x1800	1	80x80x1600	1
Comp. Spec.	Ryukyumatsu	90x90x540	3	90x90x540	6
	Itajii	90x90x540	3	90x90x540	6
	Iju	90x90x540	3	90x90x540	6
	Inumaki	90x90x540	1	80x80x480	1

The glued laminated wood specimens were made of four layers of lamina boards, which were finger-jointed and glued together with water based polymer isocyanate adhesive, as shown in Figure 4. Also, Figure 5 shows the details of the finger joints.



(a) Solid *(b) GLT*

Figure 4: *Section of specimens*

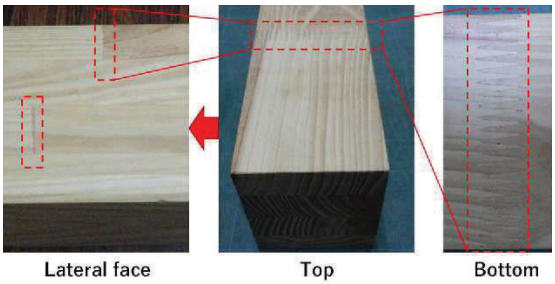


Figure 5: *Detail of the finger joint*

2.2 EXPERIMENTAL METHODOLOGY

In this test, bending and longitudinal compression tests were conducted on solid and glued laminated timbers following the Manual for Strength Testing of Structural Timbers[1]. The testing machine was a universal testing machine (Shimadzu Corporation, UH-FC, maximum capacity 2000 kN) at the experimental testing laboratory of the Faculty of Engineering, University of the Ryukyus. The loading rate was constant displacement so that the time to reach maximum load was at least one minute. The density and moisture content of all specimens were determined before testing. For moisture contents calculations, pieces cut from each specimen were placed in an oven from 101°C to 105°C until the quasi constant weight was obtained.

1) Bending Test

The loading system for the bending test is shown in Figure 6. This test determines the bending strength MOR_b and the bending modulus of elasticity MOE_b. The bending test was performed using the four points load method to have pure bending between the applied loads.

The load cell attached to the testing machine and the displacement transducer installed on the specimen were used to record the bending loads and deflections at the center of the span. A jig was attached to the neutral axis at the center of the specimen to measure the deflection.

https://doi.org/10.52202/069179-0013

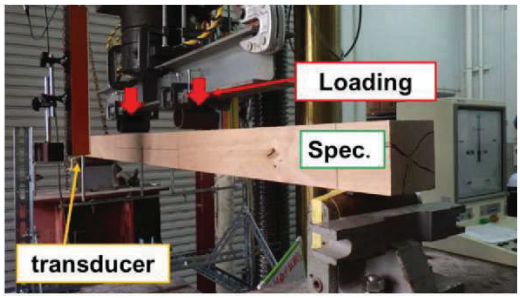

Figure 6: *Bending Test*

The displacements on both sides were measured with a displacement transducer (SDP-3000), and the average value was taken. Using the values measured in the test, MOR_b and MOE_b were calculated from the following equations (1) and (2) [2].

$$MOR_b = \frac{aP_m}{2Z} \quad (1)$$

$$MOE_b = \frac{a(3L^3 - 4a^2)(F_2 - F_1)}{48(w_2 - w_1)} \quad (2)$$

Where MOR_b=bending strength (N/mm^2), MOE_b= modulus of elasticity (N/mm^2), a = distance between the two supports (mm), P_m=maximum load, a=distance between loading points and support, Z= section modulus (mm^3), ΔP= increment of load at the elastic range (N), I=moment of inertia (mm^4), F_1-F_2= Incremental load on the straight line portion of the load-deformation curve F_1=Pm /10 、 F_2=4P_m/10 [N], w_2-w_1= Incremental deformation corresponding to F_2-F_1 (mm).

2) Compression test

The loading system for the longitudinal compression test is shown in Figure 7. This test determines the longitudinal compressive strength MOR_c and the longitudinal compressive modulus of elasticity MOE_c.

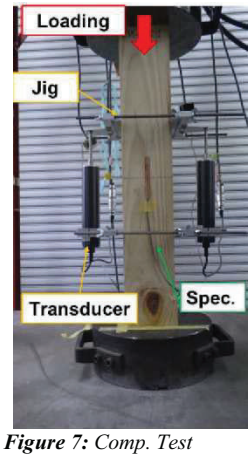

Figure 7: *Comp. Test*

The specimens were loaded using a universal testing machine with a spherically seated load head, allowing the application of uniform compressive load without creating bending stresses. The compression strains were measured by placing a jig located at the center of the specimen (l = 200 [mm]) with a displacement transducer (CDP-50). This jig was located 170 mm from both ends of the specimens. Using the values measured in the test, MOR_c and MOE_c were calculated from the following equations (3) and (4).

$$MOR_c = \frac{P_c}{A} \quad (3)$$

$$MOE_c = \frac{l(F_2 - F_1)}{A(w_2 - w_1)} \quad (4)$$

Where MOR_c=compression strength (N/mm^2), MOE_c= modulus of elasticity (N/mm^2), A = section of the specimen (mm), P_c=maximum load, l = test length (200mm), F1-F2= Incremental load on the straight line portion of the load-deformation curve F_1=Pm /10, F_2=4P_m/10 [N], w_2-w_1=Incremental deformation corresponding to F_2-F_1 (mm).

3 RESULTS

3.1 BENDING TEST

The strength-deflection curves for bending specimens are shown in Figure 8. The maximum strength value of the GLT specimens tended to be higher than that of the solid timber. In this study, the solid specimens showed a bigger deflection capacity before the failure than GLT ones. For example, solid specimens RM-S-B2 and RM-S-B3 showed deflection values greater than 50 mm, while GLT specimens showed deflection values around 35 mm.

The GLT specimens of Ryukyumatsu showed quite a similar trend in bending tests.

Specimens of Itaji and Iju showed similar bending behavior. The solid ones presented more significant deflections before failure than the GLT specimens.

In the case of Inumaki, there were no differences between solid and GLT specimens because of the limited number of samples.

Table 2 summarizes the bending test results. As the table shows, the bending strength values of GLT specimens were about 1.0 to 1.4 times higher than solid ones. The bending modulus of elasticity of GLT specimens was approximately 1.1 to 1.5 times higher than solid ones.

The measured water contents varied from 10 to 25 % depending on the period that passed since the tree was cut off. The difference between the solid and GLT specimens within the same kind of timber ranged ±5%, and then it was assumed to be no influence on the bending strength results.

Concerning the failure patterns, three types were observed. In some specimens, the failure occurs at the bottom face of specimens, as shown in Figure 9 (a), where the higher bending stresses occur.

https://doi.org/10.52202/069179-0013

In other cases, the failure starts from knots located at the lateral face, as shown in Figure 9 (b). In this particular case, several lateral face knots influenced the failure.
On the other hand, the failure of GLT specimens tended to occur from the finger joints, as shown in Figure 9 (c), especially those located at the bottom face between load points where the maximum bending stresses occur.

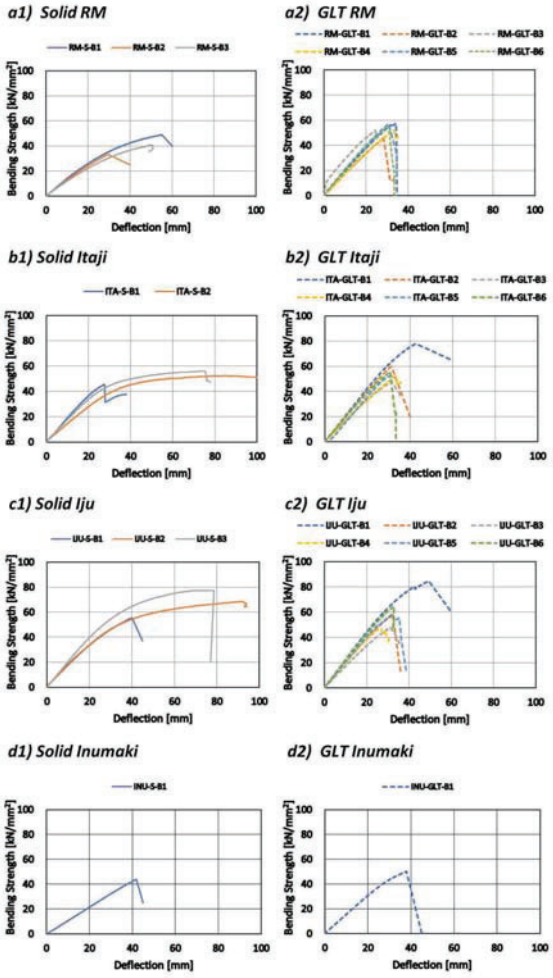

Figure 8: *Bending strength vs. deflection*

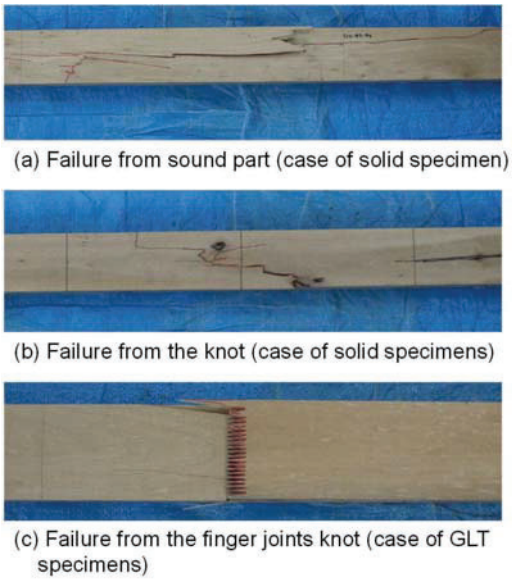
Table 2: *Bending Test Results*

Timber	Type	No of Spec.	Density (kg/m³)	WC (%)	Max Load (kN)	Bending Strength (N/ mm²)	Bending Elastic Modulus (kN/ mm²)
Ryukyumatsu	Solid	3	571.1 (24.9)	16.6 (1.3)	18.4 (2.9)	41.0 (6.4)	7.8 (0.6)
	GLT	6	681.5 (9.9)	20.8 (0.6)	24.2 (1.7)	53.8 (3.8)	11.6 (0.7)
Itajii	Solid	3	818.7 (57.7)	24.1 (2.3)	23.1 (2.0)	51.3 (4.3)	10.4 (1.3)
	GLT	6	732.3 (11.3)	18.2 (1.1)	26.4 (4.4)	58.7 (9.9)	12.1 (1.3)
Iju	Solid	3	643.1 (23.4)	10.7 (0.3)	30.2 (4.4)	67.1 (8.9)	11.3 (1.0)
	GLT	4	639.8 (10.8)	16.5 (1.1)	31.1 (5.2)	69.1 (9.7)	13.1 (0.6)
Inumaki	Solid	1	485.9 (-)	21.2 (-)	15.7 (-)	34.9 (-)	5.3 (-)
	GLT	1	559.0 (-)	25.2 (-)	17.7 (-)	49.8 (-)	7.6 (-)



(a) Failure from sound part (case of solid specimen)

(b) Failure from the knot (case of solid specimens)

(c) Failure from the finger joints knot (case of GLT specimens)

Figure 9: *Failure Pattern*

Even though the failure of the GLT specimens occurred at the bottom due to the finger joints, all these specimens showed higher bending strength than their solid specimens counterparts. Therefore it is possible to infer that the finger joints do not influence the maximum strength values.

3.2 COMPRESSION TEST

The results of the longitudinal compression test are shown in Figure 10. The maximum compression strength value of GLT specimens was higher than that of the solid timber except for Inumaki specimens.
The solid and GLT specimens of Ryukyumatsu showed strength strain curves behavior proportionally. In both cases, some specimens showed bigger deformation capacity while others failed shortly after reaching the maximum strength. Also, the GLT specimens of Ryukyumatsu showed similar behavior in the initial stage at the elastic range.
It seems reasonable to suppose that a bigger strain means a larger deformation capacity without collapse. The solid specimens of Itaji showed more deformation capacity than the specimens of Iju. However, this group presented bigger compressive strengths.
The GLT specimens of Itaji and Iju have similar strength and deformation capacity trends. In this sense, solid and GLT specimens of Inumaki showed quite similar behaviors.
Table 3 summarizes the compression test results. As the table shows, the compression strength values of GLT specimens were about 2.2 times higher than solid ones.
The compression bending modulus of elasticity of GLT specimens was approximately 1.6 times higher than solid ones.
The specimen water contents were measured just after the experiment and varied from 10 to 22 % depending on the period since the tree was cut off. The difference between the solid and GLT specimens within the same kind of

https://doi.org/10.52202/069179-0013

timber ranged ±5%, and then it was assumed to be no influence on the bending strength results.

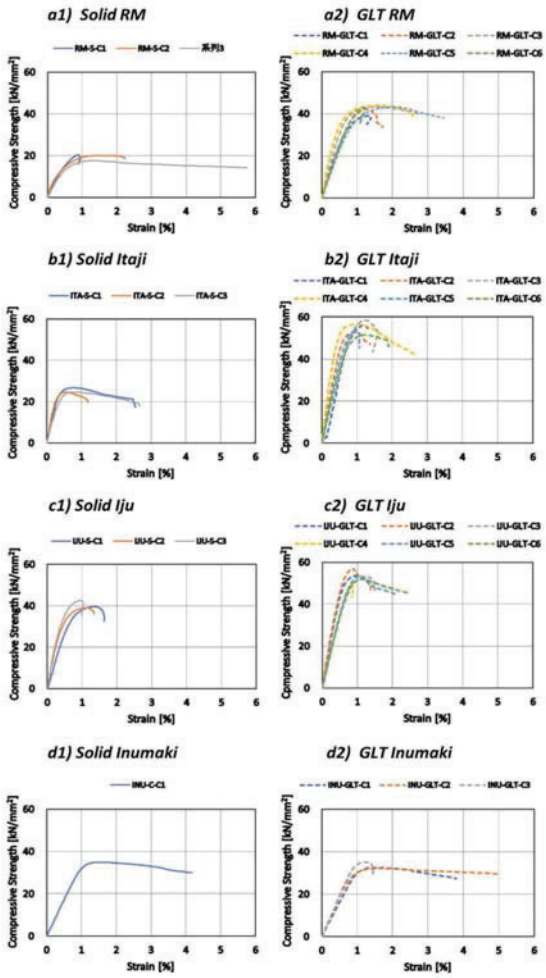


Figure 10: *Compression strength vs strain*

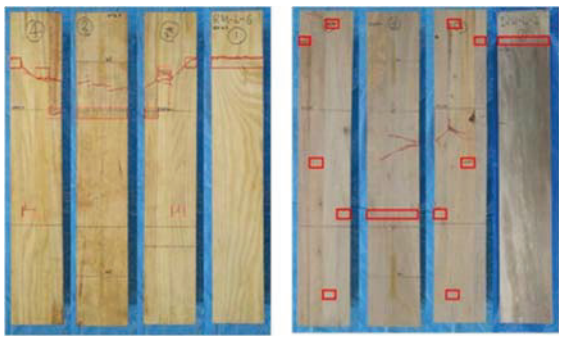
Table 3: *Compression Test Results*

Timber	Type	No of Spec.	Density (kg/m³)	WC (%)	Max Load (kN)	Comp. Strength (N/ mm²)	Comp. Elastic Modulus (kN/ mm²)
Ryukyumatsu	Solid	3	548.7 (13.1)	14.8 (0.4)	155.3 (10.9)	19.2 (1.3)	7.3 (0.9)
	GLT	6	665.7 (20.8)	14.0 (2.2)	343.3 (12.9)	42.4 (1.6)	11.6 (2.7)
Itajii	Solid	3	870.3 (20.5)	14.1 (2.3)	198.0 (16.0)	24.4 (2.0)	14.0 (0.8)
	GLT	6	731.6 (16.5)	22.4 (4.3)	442.9 (20.3)	54.7 (2.5)	18.1 (4.4)
Iju	Solid	3	711.8 (7.5)	10.7 (0.3)	327.0 (12.9)	40.4 (1.6)	16.0 (3.1)
	GLT	6	653.1 (12.4)	19.5 (0.4)	430.5 (16.9)	53.1 (2.1)	16.0 (2.8)
Inumaki	Solid	1	541.8 (-)	21.2 (-)	282.6 (-)	34.9 (-)	7.0 (-)
	GLT	3	571.8 (3.1)	19.5 (0.4)	212.8 (8.3)	33.3 (1.3)	7.2 (0.5)

Each value indicates the mean value, the numbers in parentheses indicate the standard deviation, and the symbol (-) are not calculable.

Concerning the failure patterns of GLT, two types were observed. In some specimens, the failure occurs at the finger joint, as shown in Figure 11 (a). In another case, the failure occurs in the specimens' middle part with no influence of finger joints, as shown in Figure 11 (b).



(a) Failure on finger joint (b) Failure on the middle part

Figure 11: *Failure pattern of compression specimens*

4 STANDARD MATERIAL STRENGTH

Cedar and Japanese Cypress are extensively used for building construction in Japan. Those timbers have authorized standards, so the authors compared the mechanical properties of Okinawan timbers with them. The test results proved clearly that Okinawan timbers are strong enough to be applied to structural building elements.

The reference strength F can be obtained from Equations (5) and (6). The coefficient K for obtaining the 5% lower limit at the 75% confidence level is the value shown in Tables 4 and 5, depending on the number of specimens. Based on this, the reference strength in bending of glued laminated wood in this study was calculated and compared with the reference strength of ungraded timber described by the Architectural Institute of Japan[5].

$$ {}_0F = \bar{x} - K \times s.d. \qquad (5) $$

$$ F = Kt \times {}_0F \qquad (6) $$

Where:

${}_0F$: is the Reference Strength Characteristic Value

$\bar{x}$: average value (average experimental value)

K: Value based on the number of specimens (coefficient for obtaining the lower 5% limit at the 75% confidence level)

$s.d.$: Standard deviation

Kt: Deterioration Effect Factor (In this case, it is considered the timber has no deterioration, therefore Kt is taken a 1)

Table 4: *Bending standard material strength*

Timber	Type	Bending Strength (N/ mm²) MOR	S.D.	Bending Standard Strength F_b
Ryukyumatsu	Solid	41.0	6.4	20.9
	GLT	53.8	3.8	44.9
Itajii	Solid	51.3	4.3	37.6
	GLT	58.7	9.9	35.6
Iju	Solid	67.1	8.9	39.0
	GLT	63.6	11.7	36.3
Inumaki	Solid	34.9	-	34.9
	GLT	49.8	-	49.8

https://doi.org/10.52202/069179-0013

Table 5: *Compression standard material strength*

Timber	Type	Comp. Strength MOR (N/ mm²)	S.D.	Comp. Standard Strength F_c (N/ mm²)
Ryukyumatsu	Solid	19.2	1.3	14.9
	GLT	42.4	1.6	38.7
Itajii	Solid	24.4	2.0	18.2
	GLT	54.7	2.5	49.8
Iju	Solid	40.4	1.6	35.3
	GLT	53.1	2.1	48.3
Inumaki	Solid	33.3	1.3	29.2
	GLT	19.2	1.3	14.9

Table 6: *Compression standard material strength*[5]

Tree Species			Standard Strength (N/mm²)	
			Bending	Comp.
Conifer	Category I	Pine	28.2	22.2
	Category II	Larch, Cypress	26.7	20.7
	Category III	Hemlock	25.2	19.2
	Category IV	Fir, Cedar	22.2	17.7
Hardwood	Category I	oak	38.4	27.0
	Category II	Chestnut, Zelkova	29.4	21.0

Although a small number of timber specimens for all four Okinawan timbers ranged from three to six specimens each except Inumaki, the result of the GLT bending test showed 1.4 times stronger than the standard bending strength of Cedar on average. Compared with another standard value of Japanese Cypress, the GLT performed even 1.7 times higher on average. On the other hand, concerning a longitudinal compression test, the GLT showed twice as strong as Cedar and Japanese Cypress. All those results encourage using the Okinawan GLT for building structural elements, as shown in Table 6. However, the number of specimens was limited, as mentioned above. More importantly, the data was dispersed for Itajii and Ijyu, which authors cannot find a particular reason to explain within this study.

In addition, in comparing solid timbers and the GLT, the GLT appeared to be higher figures in the bending and longitudinal compression tests, with a few exceptions.

5 DISCUSSIONS AND CONCLUSIONS

The results showed that the GLT of four kinds of Okinawan timbers, Ryukyumatsu, Itajii, Ijyu, and Inumaki, were stronger regarding the mechanical properties for both bending and compression tests compared to the same kinds of solid timbers. The material difference between GLT and solid timbers is noticeable because, naturally, the solid ones have knots and defects on the surface of timbers, whereas GLT does not. Therefore, it seems reasonable to suppose that this higher strength is due to the absence of knots and defects in timbers(GLT) when they are glue-laminated.

Here is one concern about the use of GLT for building construction. Using glue, some people are concerned about the strength of the adhesive and the part of the joints. However, our test results proved enough strength of timbers in bending and compression with finger joints. There is considerable validity to the test results, though it should not be pushed too far. For instance, further research should be included the deterioration of glue in the long term and /or to consider some different types of finger joints.

Historically Okinawan timbers had been limited and highly valued for building construction; however, recently, they have not been used for other reasons. One reason is that there is no technical endorsement of mechanical properties, and another is the small size in length and diameter. Thus, the Okinawan timber industry has shrunk over the years. If the GLT method is introduced as effective timber utilization, the Okinawan timbers can be used for structural building elements in this situation. Consequently, local industry and the economy can be boosted simultaneously.

From the viewpoint of industry activation, it should be considered in several aspects carefully. One is the production systems, and another is the market, in other words, the balance of demand and supply in the local economy and society. Additionally, since the growth rate of overall Okinawan timbers is low, the availability tends to be naturally limited.

In terms of GLT production in Okinawa, as explained before, the material supply itself is limited, so lucrative market sales cannot be expected in straight forward. For this reason, these Okinawan timbers, Ryukyumatsu, Itajii, Iju, and Inumaki, should be treated as least valued timbers so that the GLT processing system should not be prepared for a massive production system. Instead, after using solid Okinawan timbers for public historical and traditional wooden buildings, denominated as important cultural properties, the rest of the timber should be processed for the GLT production system for better-respected utilization. There is a general agreement that GLT production would work supportively instead of mainly in the timber industry. GLT production works even in a small but feasible industry in the local economy and society.

From the contrary viewpoint of industrialization, the authors considered the GLT production system might expand the effective timber use. Eventually, the system helps the sustainable circle of forest conservation, plantation, and utilization. It is expected that the loss of small timbers will be reduced remarkably because those timbers used to be assumed as residuals would convert into even stronger timber products by the GLT technique. At the same time, the consumption of timbers and the surplus of timbers would be managed under more controlled conditions because timber stock can be integrated as GLT products.

In conclusion, GLT of Okinawan timbers can be reliable for building structural elements.

EXPERIMENTAL INVESTIGATION ON THE IN-PLANE PERFORMANCE OF NAIL-LAMINATED TIMBER FLOORS

Zhaozhuo Gan[1], Minjuan He[2], Zheng Li[3], Xiaofeng Sun[4]

ABSTRACT: Nail-laminated timber (NLT) can be used as structural floors to transfer lateral force. However, the research on the in-plane performance of NLT floors is still insufficient. This paper presents the results of an experimental investigation on the in-plane performance of NLT floors. Three NLT floor configurations, a total of nine specimens, considering different sheathing nail spacings and orient strand board (OSB) sheathing fibre orientations, were subjected to fully reversed cyclic loading. Sheathing nail and lamina nail failure were observed as main failure mode during the cyclic loading. Sheathing orientation was noticed to have impact on the NLT floor deformation pattern. Equivalent energy elastic-plastic curves were obtained from each specimen group, from which the elastic shear stiffness, yielding load and displacement, ductility ratio, and shear strength were calculated. Secant stiffness and dissipated energy were also extracted from hysteresis loops. The comparison indicates that arranging OSB fibre perpendicular to lamina axis could significantly increase the elastic shear stiffness and ductility ratio of NLT floor, and a tightened sheathing nail spacing (i.e., 75 and 150 mm at the edge and centre, respectively) could provide higher elastic shear stiffness, shear strength, ductility, and improve energy dissipation capacity.

KEYWORDS: Timber structure, Nail-laminated timber, Timber floor, In-plane performance

1 INTRODUCTION

With its architectural aesthetics and structural reliability, timber structure has been increasingly accepted by both architects and structural engineers, and widely applied in recent years. Nail-laminated timber (NLT) is one of the mass timber products, which is constructed by nailing laminas side-by-side. NLT has been applied in timber decks and floors [1]. The existing research on NLT mostly focus on its bending performance. Derikvand et al. [2] investigated the modulus of elastic (MOE) of NLT constructed by fast grown eucalypt. The result shows that the overall MOE is higher than the MOE of most individual laminas, proving its ability to make good use of low-grade timber when properly arranged. Herberg [3] indicated that NLT could reach a similar MOE and flexural strength as solid timber, but with a relatively lower manufacturing cost. Other relevant research includes the nail connection in-between the laminas [4], push-out performance [5] and bending performance [6,7] of NLT-concrete composite floor. Moreover, a novel nail-cross-laminated timber (NCLT) was brought up to combine the advantages of both NLT and cross-laminated timber (CLT) [8,9].

Nevertheless, floor system not only transfers vertical loads using its bending performance, but also transfers lateral forces using its in-plane stiffness and bearing capacity. Tena-Colunga and Abrams [10] analysed the influence of timber floor on unreinforced masonry (URM) buildings. Results point out that the maximum horizontal acceleration of floors and walls increases as the in-plane stiffness of timber floor decreases. Similarly, Tamagnone et al. [11] analysed the influence of floor stiffness on the rocking behaviour of a CLT wall. Results show that the out-of-plane flexural stiffness of the floor is negligible to the CLT wall rocking behaviour, while the in-plane stiffness has a significant impact. Furtherly, Mendes [12] performed shaking table test on two URM buildings, one of which had the connection between timber floors and structure strengthened. Test results show that the damage index, which is defined as a function of natural frequency, of the strengthened URM building is 54% lower than the one of the original URM building. Moreover, the maximum horizontal displacement and maximum inter-storey displacement of the strengthened one is 20% and 31% lower than the original one, respectively. These test and/or analysis results indicate that the in-plane performance of floor system could play a critical role at seismic performance of the over-all structure.

Therefore, research on the in-plane performance of various timber floors have been widely investigated. Mirra et al. [13] studied the in-plane response of the traditional and retrofitted timber floor in Dutch, which is similar to those used in light-frame structure. Results show that the loading direction plays an important role on the in-plane response of a traditional flexible floor. An

additional plywood sheathing panel can achieve a significant improvement in strength, stiffness, and energy dissipation. The deformation pattern was also observed to transform from mainly flexural to shear-related after retrofit. D'Arenzo et al. [14] developed a simplified equivalent frame model to predict the in-plane flexibility of CLT floor and validated using a planar finite element model. The model novelty included the effect of the floor-to-wall connection. Results show that connection to the supporting walls redistributes the bending moment but does not significantly affect the shear deformations between panels. Li et al. [15] studied the in-plane behaviour of timber-steel hybrid floor experimentally and numerically. Results indicate that shear deformation contributed up to 90% of the total in-plane deformation of the hybrid floor. The overall behaviour of the floor showed an obvious nonlinearity due to the screwed wood-steel connections. A numerical model was also developed to predict the behaviour of this hybrid floor. Newcombe et al. [16] conducted an in-plane experimental test of a timber-concrete composite floor. Results indicate that composite floor shows a high elastic stiffness compared to the connection between the floor and structure, and the composite floor can be modelled as single-degree-of-freedom in structural analysis.

To summarize the existing literatures, the in-plane performance of structural timber floors is critical to the seismic response of the overall structure. Research on the in-plane performance of various timber floors have been widely investigated. However, despite that there have been some applications of NLT floors, the research on its in-plane performance is still insufficient. This paper presents an experimental investigation on the in-plane performance of NLT floors. An in-plane shearing test of NLT floors is designed and carried out. Different sheathing nail spacings and orient strand board (OSB) sheathing fibre orientations were considered. Failure modes were observed. Equivalent energy elastic-plastic based in-plane performance characteristics, as well as energy dissipation capacity were extracted from the test.

2 TEST SET-UP

2.1 SPECIMEN DESIGN

A total of nine specimens at three different configurations, three specimen per configuration, were fabricated and tested. Comparing to control group, different sheathing nail spacings and OSB fibre orientations were considered in the remaining groups, respectively. The number of specimens was determined based on previous research considering the material deviation of timber, which also satisfied the requirement of American standard ASTM E2126-19. The three tested configurations are listed in Table 1, and detailed dimensions of specimens in the first group are shown in Figure 1. All tested specimens have an area of 2440 mm × 2440 mm and a thickness of 152 mm. Each specimen was constructed with a 140 mm thick NLT panel and a 12 mm thick OSB sheathing panel. The NLT panel was constructed by nailing roughly 61 pieces of 2440 mm long laminas side-by-side using nail gun. The nailing pattern of nail connections in-between the laminas followed the one described by Derikvand et al. [2], which is a staggered pattern with a nominal nail spacing of 135 mm per row, and a row spacing of 100 mm.

Table 1: *Overview of tested configurations*

Group	OSB nail spacing*	OSB fibre orientation**	Number of specimens
A-V	Spacing A	Vertical	3
B-V	Spacing B	Vertical	3
A-H	Spacing A	Horizontal	3

*: For OSB nail spacing, spacing A refers to an edge spacing of 150 mm and a centre spacing of 300 mm; spacing B refers to an edge spacing of 75 mm and a centre spacing of 150 mm.
**: For OSB fibre orientation, the horizontal is defined to be aligned with the direction of the lamina axial in NLT.

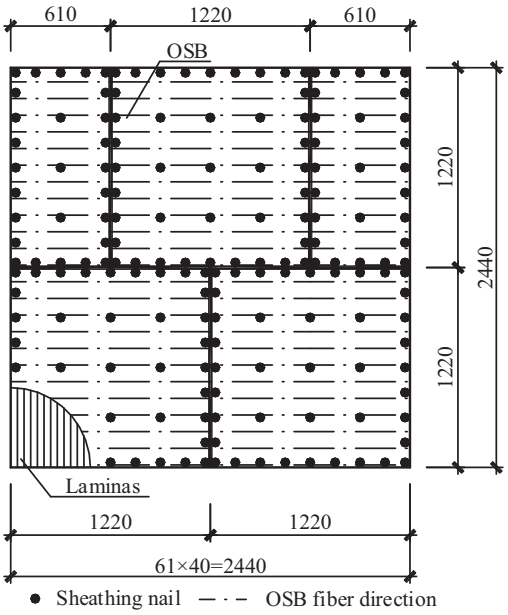

Figure 1: *Dimensions (in mm) of tested group A-V.*

2.2 MATERIAL

The materials used in the tests are listed as follows:

(1) Spruce-pine-fir (SPF) lamina, with a cross section of 40 mm × 140 mm (nominal 2″ × 6″), No. 2 and better grade according to Canadian National Lumber Grades Authority (NLGA) were used to construct NLT panels. Moisture content of each NLT specimen was measured using a moistures meter before testing, and the average value was 9.5%, with a coefficient of variation (CoV) of 10.6%. The density of SPF was evaluated after the test according to American code ASTM D143-22, and the average value was 462 kg/m^3, with a CoV of 5.4%.

(2) OSB with a thickness of 12 mm (APA rated 15/32) were used as sheathing material above the NLT.

(3) 3.3 mm × 83 mm smooth shank strip nails were used to construct NLT and to fasten OSB sheathing to the NLT panel. The tested yield strength according to American standard ASTM F1575-21 is 851 MPa with a CoV of 4.6%.

https://doi.org/10.52202/069179-0014

2.3 TEST SETUP AND LOADING PROTOCAL

Figure 2 illustrated the test set-up. In a practical application, both ends of NLT floor is usually connected to the supporting steel or timber beam using self-tapping screws (STSs). In this test, to represent its real-life boundary condition, the NLT floor specimens was securely connected to the top-and-bottom steel beams using STSs. A load distribution beam was used to apply loading force to the trisection point of specimen. The load distribution beam was then connected to a hydraulic actuator with 300 kN capacity and a stroke length of ±250 mm.

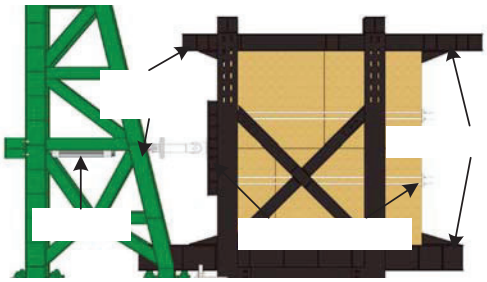

Figure 2: *Test set-up*

The cyclic loading protocol was established according to the CUREE method described in American standard ASTM E2126-19. The reference deformation Δ is determined as 70 mm by conducting a preliminary numerical analysis. The cyclic loading pattern is shown in Figure 3.

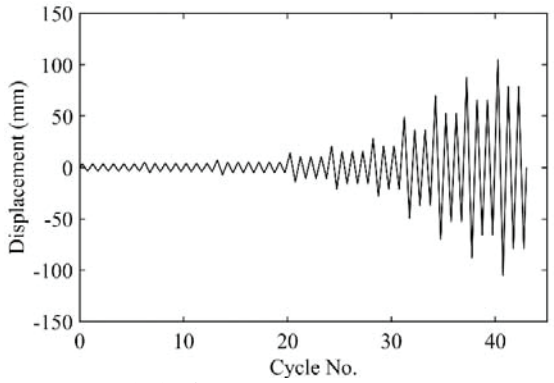

Figure 3: *Cyclic loading pattern.*

A total of 22 linear variable differential transformers (LVDTs) were attached to the specimen to acquire necessary displacement. As shown in Figure 4, LVDT 1-14 were evenly placed at the loading edges to acquire lateral deformation, LVDT 15-18 were placed at the trisection point of a loading edge to acquire shear deformation, and LVDT 19-22 were placed at the corners to acquire rotational deformation.

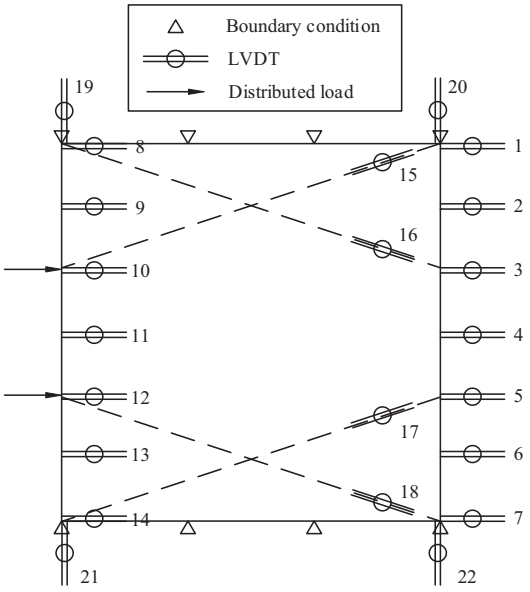

Figure 4: *Layout of LVDTs.*

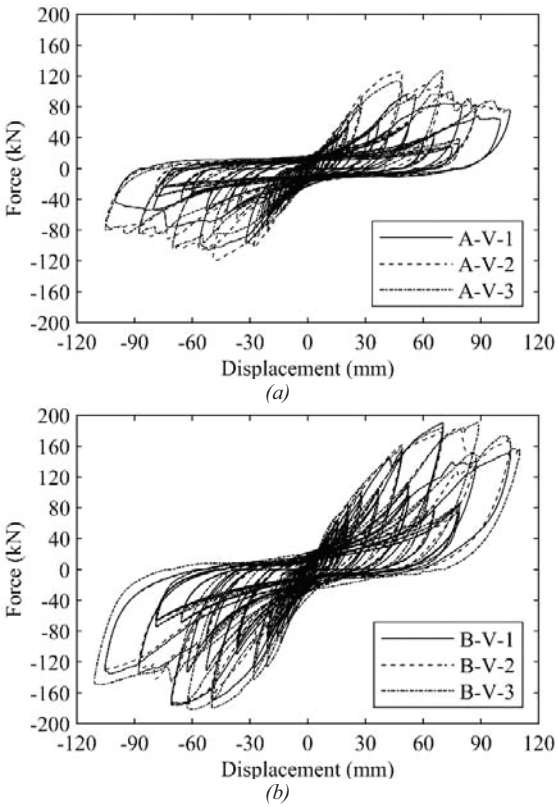
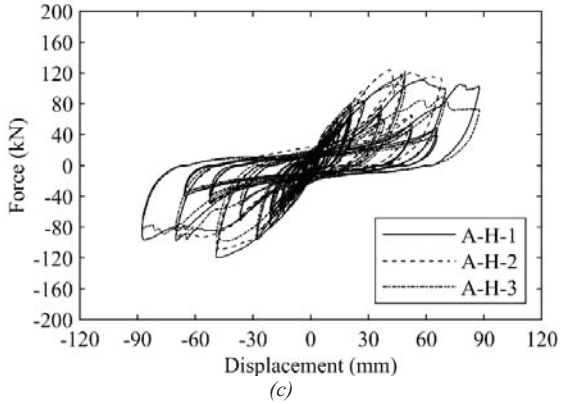
3 RESULTS AND DISCUSSIONS

3.1 LOADING CURVES



https://doi.org/10.52202/069179-0014



(c)

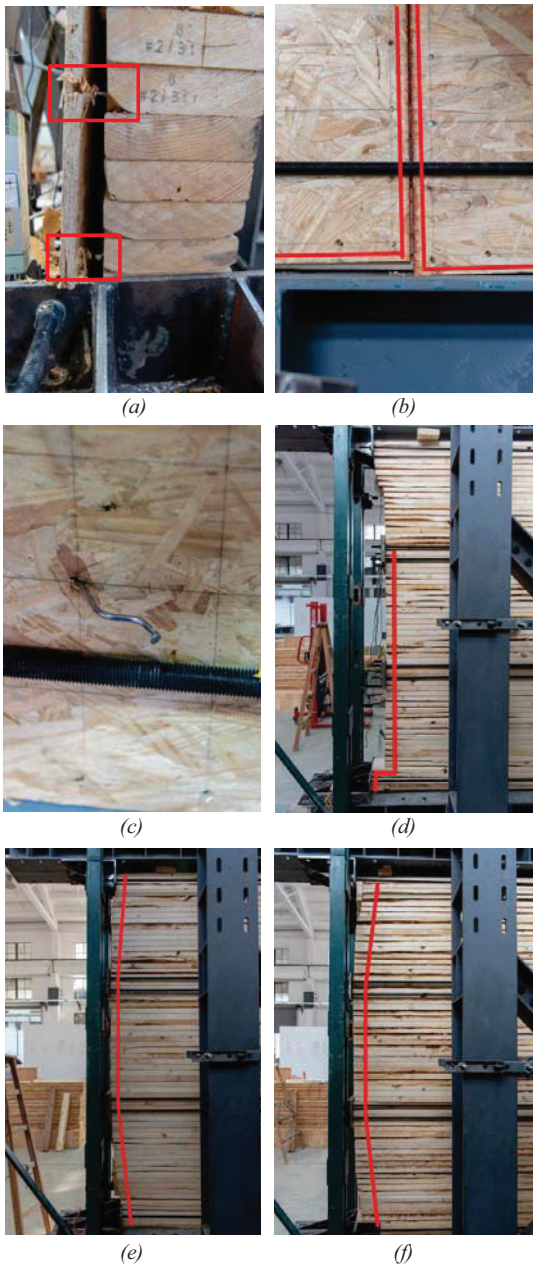
Figure 5: *Hysteresis loops of (a) group A-H, (b) group B-V, and (c) group A-V.*

Using the applied force from actuator as the force, and the average value of midspan displacement (LVDT 4/11) as the displacement, the force-displacement curves of tested specimens are shown in Figure 5. From the hysteresis loops, all specimens showed similar strength/stiffness degradation and pinching effect, due to the damage accumulation of nail connections, both in-between laminas and between lamina and OSB.

3.2 FAILURE MODES

The main failure modes observed were similar in all groups of specimens. During the loading process, sheathing nail embedment failure at the corners of sheathing panel (Figure 6(a)) was first noticed around cycle No. 20. Dislocation of adjacent sheathing panel (Figure 6(b)) was also observed at the peak of each cycle thereafter. As the loading displacement increases, beginning from roughly cycle No. 32, most sheathing nails were either embedded or withdrawn (Figure 6(c)). Finally, at around cycle No. 40, the failure of nail connection in-between laminas occurred (Figure 6(d)) and the floor lost its most capacity.

It's worth to mention that though all specimens showed the similar failure pattern, the difference of sheathing nail spacing did have impact on the deformation pattern of the floor. For the relatively larger nail spacing, which is an edge spacing of 150 mm and a centre spacing of 300 mm, the floor exhibited mostly shear deformation, as shown in Figure 6(e). While for the relatively smaller nail spacing, which is an edge spacing of 75 mm and a centre spacing of 150 mm, the floor exhibited a shear and flexural combined deformation, as shown in Figure 6(f). This difference is mainly due to that the tighten sheathing nail spacing enables the sheathing to coordinate the deformation of laminas. This thereafter led to the floor deformation pattern transform from shear controlled to shear and flexural combined.



(a) (b) (c) (d) (e) (f)

Figure 6: *Failure modes of (a) sheathing nail embedment, (b) sheathing dislocation, (c) sheathing nail withdraw, (d) lamina nail failure, (e) floor shear and flexural combined deformation of relatively larger sheathing nail spacing (group A-V), and (f) floor shear deformation of relatively smaller sheathing nail spacing (group B-V).*

3.3 PERFORMANCE CHARACTERISTICS

Based on the averaged envelope curve of each group obtained from the test, equivalent energy elastic-plastic (EEEP) curve was calculated according to American standard ASTM E2126-19. The following performance characteristics were extracted from EEEP curve:

(1) Elastic shear stiffness $k_e=0.4P_{peak}/\Delta_e$, where P_{peak} is the maximum load in the envelope curve, and Δ_e is the displacement at $0.4P_{peak}$.

https://doi.org/10.52202/069179-0014

(2) Yielding load P_{yield} and yielding displacement Δ_{yield}, in which the enclosure area under EEEP curve equals to the one under envelope curve.
(3) Ductility ratio $D=\Delta_u/\Delta_{yield}$, where Δ_u is the displacement at ultimate load.
(4) Shear strength $R_d=P_{yield}/2B$, where B is the width of the floor.

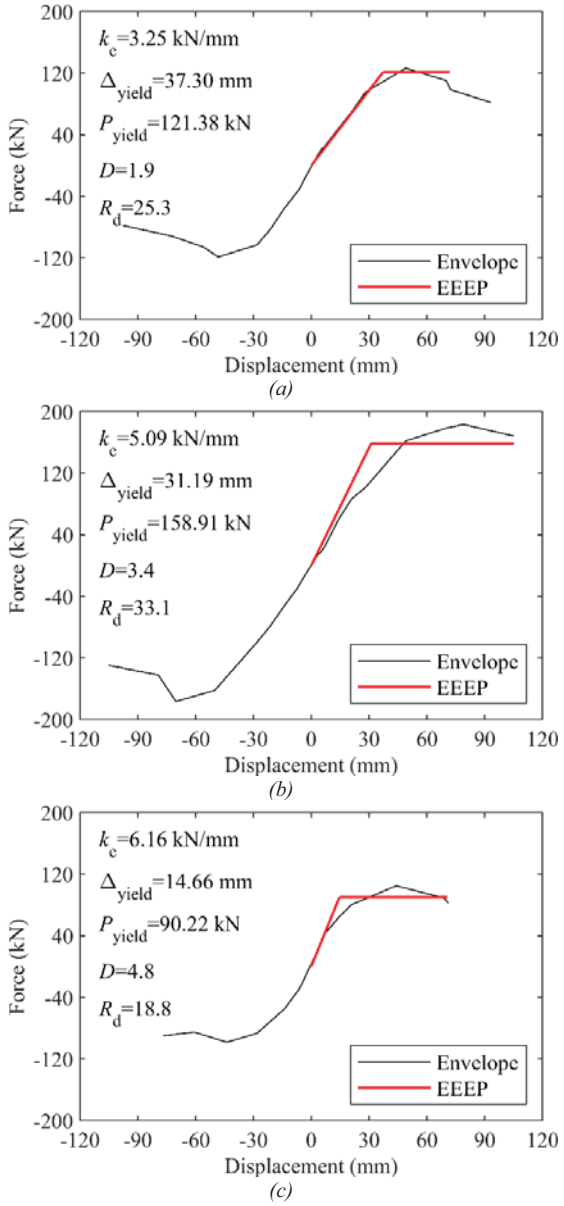


Figure 7: *EEEP analysis result of (a) group A-V, (b) group B-V, and (c) group A-H.*

Figure 7 shows the EEEP results of the three tested groups. In-between the tested groups, the EEEP analysis results indicate that reducing sheathing nail spacing by 50% could increase elastic shear stiffness, ductility ratio, and shear strength of the NLT floor by 56.6%, 78.9% and 30.8%, respectively. And by switching the OSB fibre orientation from aligning lamina axis to perpendicular, the elastic shear stiffness and ductility ratio increased by 89.5% and 152.6%, respectively, with no significant change on shear strength.

Similar to the discussion on the different floor deformation pattern, the EEEP analysis result also confirmed that the tighten sheathing nail spacing brought significant higher elastic shear stiffness, thereafter, led to a shear and flexural combined deformation patter.

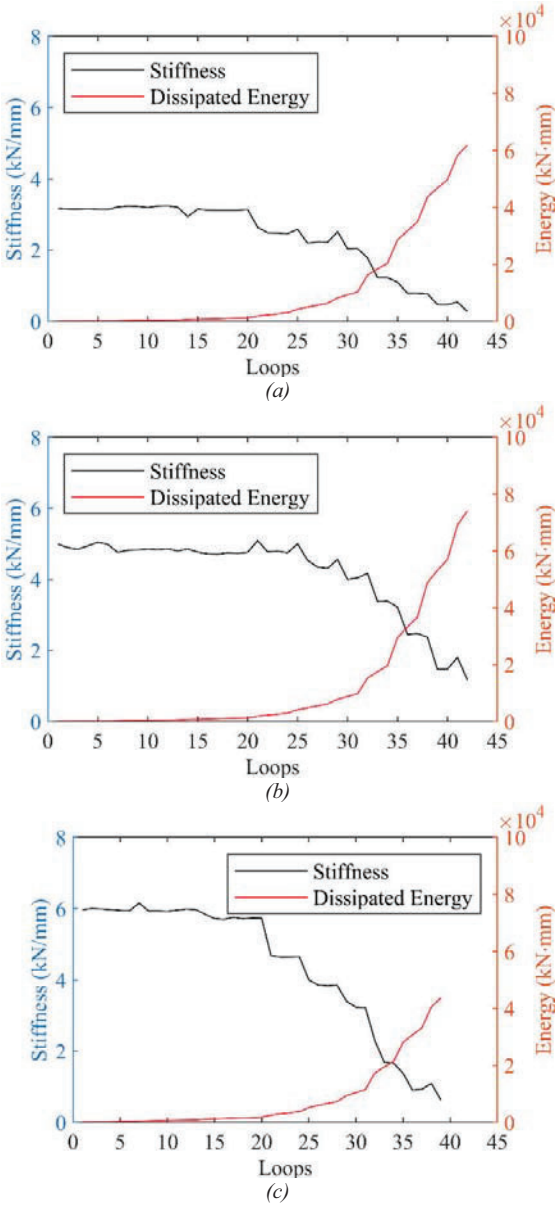

Figure 8: *Secant stiffness and cumulative dissipated energy per hysteresis loop of (a) group A-V, (b) group B-V, and (c) group A-H.*

Furthermore, the secant stiffness, calculated according to Chinese standard JGJ/T 101-2015, and cumulative dissipated energy was extracted from each hysteresis loop and shown in Figure 8. It can be noticed that the floors are basically linear elastic before cycle No. 20. Both reducing sheathing nail spacing and arranging OSB fibre

https://doi.org/10.52202/069179-0014

perpendicular to lamina axis can increase initial elastic shear stiffness significantly. Moreover, the energy dissipation capacity is mainly controlled by sheathing nail spacing, or rather the quantity of nail connections, since the energy dissipation is mostly contributed by the embedment and/or the withdrawn of nail connections, both in-between laminas and between lamina and OSB sheathing.

4 CONCLUSIONS

This paper presents an experimental investigation on the in-plane performance of NLT floor. Failure modes were observed, and performance characteristics were obtained.

(1) For failure modes, sheathing nail spacing and OSB fibre orientation didn't change the failure pattern, which is from the failure of sheathing nail connections to the failure of lamina nail connections.
(2) The sheathing nail spacing did have impact on the floor deformation pattern. That is, tightening sheathing nail spacing transforms the deformation pattern of NLT floor from shear controlled to shear and flexural combined.
(3) Placing OSB fibre perpendicular to lamina axis could induce a stiffness and ductility increasement of 89.5% and 152.6%, respectively, compared to parallel to lamina axis. Elastic shear stiffness could also be further improved by reducing sheathing nail spacing.
(4) The energy dissipation capacity is mainly controlled by the sheathing nail spacing, or rather the quantity of nail connections.

In conclusion, in design of a NLT floor, in order to obtain an optimal performance, the results indicate that the sheathing nail spacing and sheathing material orientation should be carefully decided. Nevertheless, a more detailed and parametrical numerical analysis could be carried out to determine an optimal sheathing nail arrangement, and to provide a detailed design method.

World Conference on Timber Engineering Oslo 2023

AN EXPLORATORY STUDY ON MIXED-MODE FRACTURE AND STRAIN DISTRIBUTION NEAR A CRACK TIP OF ADHESIVELY-LAMINATED WOOD SPECIMENS USING THE MODIFIED ARCON FIXTURE AND DIGITAL IMAGE CORRELATION

Zizhen Gao[1], Meng Gong[2], Ling Li[3], Mohsen Mohammadi[4]

ABSTRACT: Glue-laminated lumber-based mass timber products, such as glue-laminated timber (GLT), have been widely used in construction. This study was aimed at understanding the mixed mode fracture behaviour of a bond-line of GLT using the modified Arcon fixture and digital image correlation (DIC) technique. The laminated wood specimens used were made of white spruce (*Picea glauca*), as the laminations, and structural adhesives, say emulsion polymer isocyanates (EPI) and polyurethanes (PUR). The modified Arcan fixture was employed to implement mixed mode stress conditions at different angles. The effects of adhesive type on the mixed mode fracture behaviour of a bond-line of laminated wood specimens were examined. In addition, the strain distribution near the crack tip of a bond-line was illustrated using the DIC system. The results showed that the critical mode I and mode II stress intensity factors, K_{Ic} and K_{IIc}, were 0.48 MPa√m and 0.72 MPa√m for the specimens made of white spruce and EPI, respectively, while those were 0.73 MPa√m and 0.90 MPa√m for the specimens made of white spruce and PUR, respectively. In addition, the mixed mode fracture criteria for the EPI and PUR bond-lines were proposed, resulting in a good correlation with the experimental data.

KEYWORDS: Glue-laminated specimen, Bond-line, Mixed mode fracture, Arcan test, Digital image correlation

1 INTRODUCTION

Adhesively bonding represents the most common joining technique in modern engineered wood products (EWPs). Lumber-based mass timber products are commonly made with an adhesive(s), such as glue-laminated timber (GLT) and cross-laminated timber (CLT), which have been widely used in construction [1, 2]. In these adhesively laminated products, the mechanical performance of a bond-line(s) plays a critical role in the structural behaviour of a wood product, and furthermore governs the safety and durability of a timber structure. Therefore, understanding of the mechanical performance of a bond-line(s) is of great importance in use of these mass timber products. Fracture characterized as the formation of new surfaces in wood is one of the most important properties mass timber products. It should be emphasized that the bond joints usually are subjected to mixed-mode loading [3]. Therefore, a deep understanding of the fracture behaviour of an adhesively bonded joint under a given load, in particularly under mixed-mode loading conditions, is no doubt required.

There are many studies in the measurement of mixed mode fracture toughness of EWPs. *Mall* et al. investigated the mixed mode fracture toughness of eastern red spruce (*Pieca rubens*) using the single edge notch and centre crack specimens, in a nominal equilibrium moisture content of 12% (±1%), with various crack inclinations in the tangential-longitudinal (TL) plane of wood [4]. Their results indicated that there was a definite interaction between two failure stress intensity factors (K_I and K_{II}) during the mixed mode fracture in wood [4]. *Jernkvist* tested the mixed mode fracture performance of Norway spruce (*Picea abies*), with moisture content of 12.2%, in the radial-longitudinal (RL) plane of wood and derived a criterion for predicting the mixed mode fracture toughness of wood [5, 6]. Their results showed that onset of mixed mode fracture could be predicted with a simple fracture criterion in the crack system [5, 6]. *Moura* et al. obtained a mixed mode fracture criterion for the maritime pine (*Pinus pinaster*), for the moisture content of 12.3%, based on the critical fracture energy from a modified mixed mode bending test [7]. The mixed mode fracture toughness (K_c) of a bond-line of phenol resorcinol formaldehyde (PRF) resin and a one-component polyurethane (PUR) adhesive with European beech (*Fagus sylvatica*) wood adherends at the relative humidities (RH) of 50%, 65%, and 95% of the surrounding air were examined by *Ammann* et al. [8]. Their results indicated that K_c of the specimens made of either adhesive increased with increasing shear stresses, and the PUR bond-line generally showed a lower K_c than the PRF one in dry climate [8]. It is well known that the fracture energy under mode-II loading is different from that under mode-I loading in adhesively bonded joints [9].

[4] Mohsen Mohammadi, University of New Brunswick, Canada, mohsen.mohammadi@unb.ca

https://doi.org/10.52202/069179-0015

For the situation under the mixed-mode loading, there is an interaction between the two fracture modes, requiring to find a relationship between mode-I and mode-II stress intensity factors [4-6, 9].

The Arcan test was first proposed by *Arcan* et al. [10] with an attempt to produce uniform plane stress state in the test section of a specimen. The Arcan testing configuration has been proved very successful for testing and evaluating mixed mode fracture performance of different materials, including wood, plastic, composites and mental [8, 9, 11, 12]. One of the advantages of the Arcan test is that it allows mode I, mode II, and almost any combination of mode-I and mode-II loading to be tested with the same test specimen configuration [9].

Digital image correlation (DIC) technique is a popular non-contact method for measuring the distribution of displacement and strain on the surface of a specimen under loading [13]. As the development of DIC method and computer technology, researchers have widely employed it to evaluate the fracture performance of a material [14, 15].

This study was aimed at understanding the mixed mode fracture behaviour of a bond-line of laminated solid wood products with help of a modified Arcan testing setup and a DIC system.

2 FRACTURE MECHANICS

There are three types of cracks, termed Modes I, II, and III as illustrated in Fig. 1 [16]. The Linear Elastic Fracture Mechanics (LEFM) is deemed to be a useful tool for investigating the cracks in wood and wood products. The strain energy release rate (G) and stress intensity factor (K) are two main indexes for evaluating the fracture behavior of a material [16].

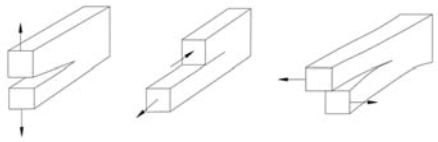

Figure 1: *Three fracture modes: (a) Mode I – Tension; (b) Mode II – In-plane shear; (c) Mode III – Out-of-plane shear.*

K_I and K_{II} for through the thickness edge crack in a finite body subjected to uniform stress at edges are given in Eqs. 1 and 2 [17]:

$$K_I = \sigma\sqrt{\pi a} f_1\left(\frac{a}{w}\right) \quad (1)$$

$$K_{II} = \sigma\sqrt{\pi a} f_2\left(\frac{a}{w}\right) \quad (2)$$

K_I and K_{II} for such stress condition in a Arcan specimen can be calculated using Eqs. 3 and 4 [11, 12]:

$$K_I = f_I\left(\frac{a}{w}\right)\frac{P}{wt}\sqrt{\pi a} \quad (3)$$

$$K_{II} = f_{II}\left(\frac{a}{w}\right)\frac{P}{wt}\sqrt{\pi a} \quad (4)$$

Where, P is the critical load on the specimen for crack propagation; t is the thickness; w is the width, and a is the initial crack length.

3 MATERIALS AND METHOD

3.1 MATERIALS

White spruce (*Picea glauca*) lumber of a thickness of 38mm was obtained from a sawmill in New Brunswick, Canada, which were stored in a conditioning chamber with a relative humidity (RH) of 65% and a temperature of 20 C° for two months. The physical properties of the lumber used after conditioning were tested in a separate study by the authors, which are given in Table 1. Two types of adhesives were used, two-component emulsion polymer isocyanates (EPI) and one-component polyurethanes (PUR), which were obtained from Ashland Inc. and Lepage Inc. respectively.

Table 1: *Elasticity and physical properties of lumbers*

Property	Mean (COV)
Density (g/cm^3)	0.38 (5.24%)
MC (%)	13.73 (1.13%)
E_L (MPa)	9932 (9.10%)
E_R (MPa)	517 (14.67%)
E_T (MPa)	221 (12.14%)
v_{LR}	0.41 (16.7%)
v_{LT}	0.51 (10.52%)

3.2 SPECIMENS

The EPI and PUR specimens were made using EPI and PUR as the adhesives with a spread rate of 220 g/m^2, respectively, while white spruce lumber was used as the adherend for both EPI and PUR specimens. The specimens used were processed to have a butterfly shape, Figure 2, to fit the modified Arcan fixture. An initial crack with a length of 10 mm was carefully made by placing a 0.1-mm-thick Teflon sheet between laminations after spreading adhesives. A speckle pattern with high contrast was applied to the surface of the specimens for DIC analysis, and the speckle size was 0.2 mm.

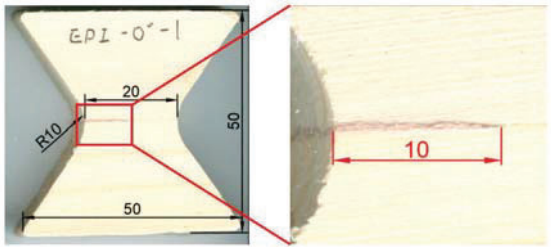

Figure 2: *The specimen used for Arcan test*

https://doi.org/10.52202/069179-0015

3.3 TESTING METHOD

The mixed mode fracture criteria of a bond-line were determined using the butterfly-shape specimens. To achieve this, seven angles were used in the modified Arcan fixture to generate the mixed mode stress conditions, Figure 3, ranging from 0 (Mode I) to 90 (Mode II) degrees with an interval of 15 degrees.

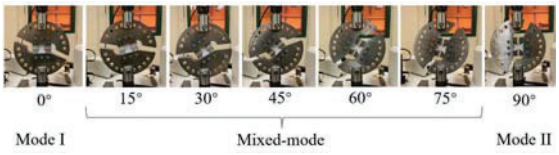

Figure 3: *Experimental setups of the Arcan fixture at seven angles.*

Two cameras were set up in the front of a specimen to capture the images from the DIC system, Figure 4. The image logging frequency of two cameras was set at 2Hz (2 images per second), which was the same as the data logging frequency of the mechanical testing machine. The load was applied at a rate of 0.5mm/min and the fracture loads were recorded. All the tests were carried out using an Instron testing machine (Model: 3367). A 3D-DIC system and software by the Correlated Solutions was used to analyse the images and calculate the strain distribution.

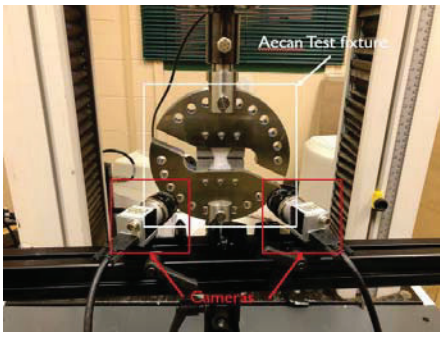

Figure 4: *Testing setup mounted with a DIC system.*

4 RESULTS AND DISCUSSION

Figure 5 gives the critical load (P_c) of EPI and PUR specimens loaded at different angles. It can be found that the P_c of PUR specimens are overall higher than those of EPI ones. For both EPI and PUR specimens, with the loading angle increasing, the P_c increases. The P_c under pure shear stress has the highest value. It is worth to note that, as airdry wood can be approximately treated as an elastic material, the process of crack propagation is usually instantaneous. Therefore, the peak load was recorded as the P_c in this study.

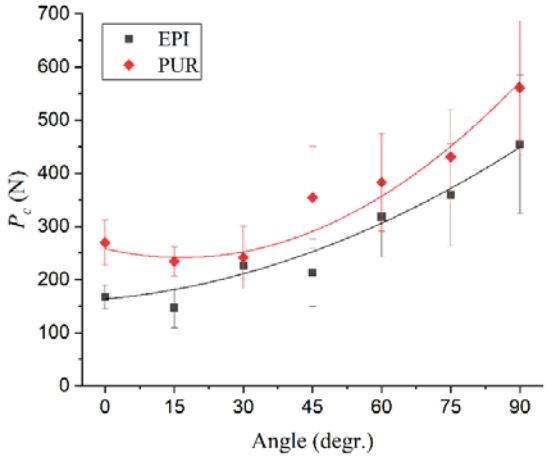

Figure 5: *Critical Loads at different angles.*

The critical strain distribution along a bond line means the strain distribution at the point at which a crack starts propagating. The critical strain distributions of EPI and PUR specimens are plotted in Figures 6 and 7, respectively. The results showed that the average tensile strain (ε_c) of both EPI and PUR specimens decreased with the loading angle increasing, while the average shear strain (γ_c) increased. In addition, for both EPI and PUR specimens, tensile strain is more concentrated at the crack tip than shear strain. Figure 8 gives the relationship between the critical tensile strain and critical shear strain at crack tips. It can be found that both critical tensile strain and shear strain of PUR specimens are overall larger than those of EPI specimens, which reflects the difference in P_c between these two types of specimens. Moreover, Figure 8 shows that with increasing the loading angle, the changes in tensile strain and shear strain are not linear, suggesting that the mixed mode facture criterion of a bond-line is a critical index for predicting the fracture of an adhesively-laminated wood product subjected to a mixed loading condition. In addition, under the pure tension or shear loading, both ε_c and γ_c of PUR specimens are about 42% higher than that of EPI specimens.

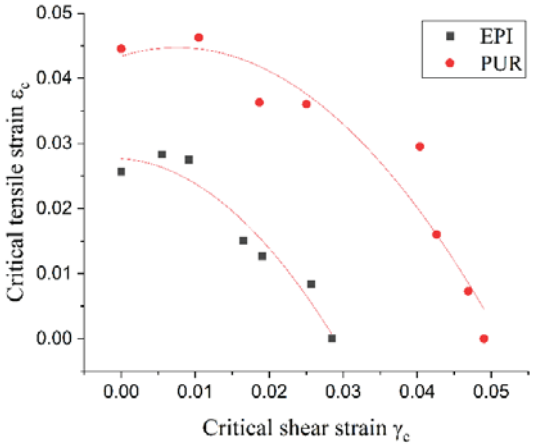

Figure 8: *Relationship between the critical tensile strain and shear strain at the crack tips of two-type specimens.*

According to Equations (3) and (4), the K_I and K_{II} represent the strength of the stress singularity that occurs at a sharp crack tip. The K_I or K_{II} is a function of the specimen geometry, applied load and crack length. The nondimensional stress intensity factors (e.g., geometrical factors, *f(a/w)*) of the modified Arcan specimens for mode I and mode II can be obtained by the finite element analysis (FEA) [18, 19], Figure 9. The geometrical factor functions for Mode I and Mode II fracture were determined in this study by using the least square fitting method, which are given in Equation (5) and (6).

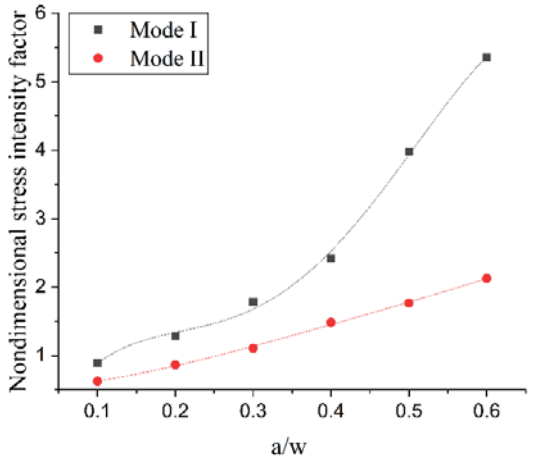

Figure 9: *Non-dimensional stress intensity factors for Mode I and Mode II fracture of the specimens tested using the modified Arcan fixture.*

$$f_I\left(\frac{a}{w}\right) = -237.04\left(\frac{a}{w}\right)^4 + 339.84\left(\frac{a}{w}\right)^3 - 150.15\left(\frac{a}{w}\right)^2 + 29.33\left(\frac{a}{w}\right) - 0.863 \quad (5)$$

$$f_{II}\left(\frac{a}{w}\right) = 7.42\left(\frac{a}{w}\right)^4 - 13.17\left(\frac{a}{w}\right)^3 + 9.26\left(\frac{a}{w}\right)^2 + 0.25\left(\frac{a}{w}\right) + 0.5223 \quad (6)$$

https://doi.org/10.52202/069179-0015

Tables 2 and 3 summarize the results of failure stress intensity factors K_I and K_{II}, obtained from all specimens at different loading angles. The critical mode I and mode II stress intensity factors, K_{Ic} and K_{IIc}, for EPI specimens are 0.48 MPa√m and 0.72 MPa√m, respectively, while those for specimens are 0.73 MPa√m and 0.90 MPa√m. The fracture mechanics parameters of the bond-lines of both EPI and PUR specimens made with white spruce have not yet been reported. However, the K_{Ic} and K_{IIc} in this study are comparable with the results from *Ammann's* study, in which the K_{Ic} and K_{IIc} of the bond-lines of the specimens made of PUR adhesive and European beech wood were 0.75 MPa√m and 1.85 MPa√m, respectively [8]. In addition, K_{Ic} and KI_{Ic} of the specimens made of solid Norway spruce wood, which were reported by *Jernkvist* [6], were 0.58 MPa√m and 1.52 MPa√m, respectively.

Table 2: *Failure stress intensity factors K_I and K_{II} of EPI.*

Angle	K_I (MPa√m)		K_{II} (MPa√m)

90	0.00	0.00	0.90	0.17

To examine the interaction between K_I and K_{II} of EPI and PUR specimens under different loading angles, all the data are plotted in Figure 10. This figure indicates that the trend of relationship between K_I and K_{II}, which defines the tensile stress and shear stress distributions near a crack tip, is similar to that between ε_c and γ_c.

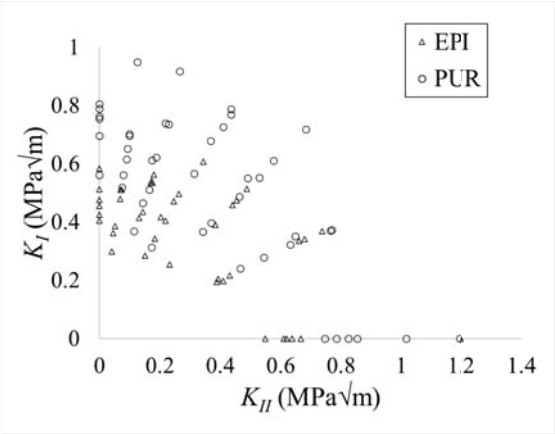

Figure 10: *Relationship between K_I and K_{II}.*

For the situation under a mixed-mode loading, there is an interaction between the two fracture modes, calling for investigating the relationship between K_I and K_{II} [20]. The mixed fracture criterion is generally proposed in Equation (7) [6]:

$$\frac{K_I}{K_{Ic}} + \left|\frac{K_{II}}{K_{IIc}}\right|^n = 1 \quad (7)$$

The subject of the mixed mode fracture in wood-based materials was first studied by *Wu* [21], who found that Equation (7) could well describe the interaction between K_I and K_{II} of balsa wood (*Ochroma pyranidale*) when n=2. *Mall* et al. [4] compared several mixed mode fracture criteria and discovered that *Wu*'s criterion was also applicable to eastern red spruce (*Pieca rubens*). *Jernkvist* found, using the least square fitting method based on their experimental data, that Equation (7) could be used as the fracture criterion of Norway spruce when n=2.2 [6]. The values of n in Equation (7) for the fracture of EPI bond line and PUR bond line could be obtained using the least square fitting method according to the data in Tables 2 and 3, and Figure 11. The fitting parameters are given in Table 4. The n values of the mixed mode fracture criterion for EPI and PUR are found to be 1.89 and 2.93, respectively, suggesting that the mixed mode fracture criterion of EPI bond line is similar to the clear softwood specimens such as red eastern spruce and Norway spruce [4, 6].

	EPI specimen	PUR specimens
n	2.93	1.89
R-square	0.966	0.977
p-value	<0.0001	<0.0001

Figures 12 and 13 show the typical failure modes of EPI and PUR specimens. It was found that the crack propagation paths were similar between specimens, i.e., the crack propagation started from a crack tip and grew along the fibre direction of wood near a bond-line. Despite the crack propagation started from the glue-line, the crack path was totally along the clear wood, which means that, for both EPI and PUR specimens, the wood failure percentage were 100%.

5 CONCLUSIONS

In this study, a modified Arcan testing setup equipped with a 3D-DIC system were employed to examine the mixed fracture properties of a bond-line of the wood products bonded with EPI and PUR adhesives. The strain distributions and critical strains of each specimen were obtained using the DIC system. Based on experimental observations, data analysis and above discussion, the conclusions could be drawn as follows:

(1) Under the pure tension or shear loading, both ε_c and γ_c of PUR specimens were 42% higher than those of EPI ones, and tensile strain was more concentrated at the crack tip than shear strain.

(2) The K_{Ic} and K_{IIc} of the bond-line of EPI specimens were 0.48 MPa√m and 0.72 MPa√m, respectively, while those for PUR specimens were 0.73 MPa√m and 0.90 MPa√m, respectively.

(3) The n of the mixed mode fracture criterion for EPI and PUR specimens were 1.89 and 2.93, respectively.

GREEN OAK BUILDING WITH HIGH-TECH METHODS, PART 2: LOG BENDING TESTS FOR DETERMINATION OF STRENGTH AND STIFFNESS

**Kay-Uwe Schober[1], Beate Hörnel-Metzger[2], Maximilian Leonhard Müller[3]
Nicolas Hofmann[4], Franka Brüchert[5], Udo H. Sauter[6]**

ABSTRACT: The green oak building research project deals with small-diameter oak logs as sustainable construction material for timber truss structures. The basis for structural use and design are the specific mechanical properties and the knowledge of performance influencing factors like wood defects, moisture content and density distribution. In a first step, the characterisation of the raw material itself has been done by quality assessment, followed by the determination of strength and stiffness parameters as input for the parametric design process and a prototype building as proof of concept. This paper summarises the experimental investigations on strength and stiffness of naturally dried green oak logs. The laboratory tests were supplemented by non-destructive data acquisition of the geometry, moisture, and density distribution along the full length and over the entire surface. The results show that strength and stiffness properties are affected by growth conditions, especially the moisture content and drying behaviour of green oak. The obtained results were in line with similar tests on softwood logs and other studies comparing destructive and non-destructive mechanical characterisation methods for roundwood. The preliminary results of the green oak research project indicate that small-diameter oak logs (≤ 250 mm) appear suitable for load-bearing timber structures.

KEYWORDS: small-diameter logs, roundwood, bending strength, visual grading, oak, *Quercus petraea* (Matt.) Liebl.

1 INTRODUCTION

In Germany, only half of the annual increment of oak wood from forests is used. Especially small-diameter oaks (≤ 250 mm) are currently either not used or only used as firewood. But they also sequester carbon dioxide and this much longer compared to firewood which is an added benefit for the forest owner. To exploit these opportunities, the green oak building research project aims on making small-diameter oak logs available as sustainable construction material, e.g., for columns and frameworks and in agricultural buildings, like barns. For this purpose, the mechanical properties of the logs need to be determined, due to insufficient knowledge and investigations, especially for small-diameter oak logs as natural resource in the building sector. This requires exploring the characteristics and factors influencing the structural performance and serviceability of green oak logs, like wood defects, moisture content (MC), density distribution and others, which are part of the subsequent presented investigations.

Part one of the Green Oak Building project deals with the characterisation of the raw material [1]. This topic was the main task of the forestry research partner FVA, located in Freiburg on the edge of the Black Forest, while the determination of strength and stiffness has been done in Mainz, Rhineland-Palatinate. The research results of both interdependent investigations on small-diameter oak logs (*Quercus petraea*) shall serve to upgrade the potential of this currently in Germany unemployed forestry resource as a local source building material for rural areas.

Based on the findings carried out in Freiburg and Mainz an approach was specified to derive the most suitable log as a structural member in wooden buildings dependent on its specific dimensions, actions, load scenarios, structural behaviour and design requirements. The buildings itself will be formed by the “perfect log” for its specified position in the structure by parametric analysis and design subject to the raw material database and the structural member database. Drawbacks of the idea to use the yet unpopular assortment of green small-diameter oak logs are their high moisture content, the low drying rate and the high distortion along the centreline, making any sort of standardized grading impossible. Additionally, the high moisture content is affecting the mechanical properties negative and can lead to additional crack development. It is questionable whether the visual grading and property assignment system for round timbers adequately assesses the potential quality of these logs for structural use.

2 BACKGROUND

Nowadays, logs used as round and sawn round timber beams are graded by visual examination with properties assigned by testing procedures defined in standards, e.g. [2]-[6] in the Americas or [7] in the European Union. Allowable properties for round timber beams and struts are derived using strength ratios for limiting defects as specified in grading rules and clear wood strength values. And the visual quality evaluation sort into categories for assignment of design properties. The characteristics of green oak (*Quercus petraea*) logs or in general unsawn hard woods prevented the further development of grading standards and industrial applications for round wood.

A major European study by RANTA-MAUNUS investigated the application of round wood in the building sector with experimental studies on round and sawn timber to compare both cross-section types with each other [8]. 1400 specimens, composed of different softwood species, such as Scots pine (*Pinus sylvestris)* and Norway spruce (*Picea abies)*, were tested in this study at an average MC of 16% to determine bending, compression and tension strength properties parallel to grain. The bending tests were conducted with the logs simply supported and loaded symmetrically at the 1/3-point of the span and tested at a span-to-depth ratio of 18:1. The modulus of elasticity (MOE) values were calculated using the average diameter of the log and the modulus of rupture (MOR) values were calculated using the diameter near failure. Furthermore, short column compression tests were conducted using an unsupported free span of six times the log diameter, with the compression MOE calculated using deformation measured over a span of four times the diameter. The research results have shown higher strength values for round wood compared to sawn timber made from the same logs. The bending strengths for roundwood have been observed with even double the value of sawn timber. Similar studies have been carried out and published in the following years mostly by American and European researchers, e.g. [9], [10], [11], [12] and others.

The studies confirmed the potential of round wood as building material while grading and design rules for round wood elements are still missing. In contrast to the above outlined research to determine material properties by testing under usual moisture conditions around 15% MC or to grade logs for design purposes, the impact of a much higher moisture content near or above fibre saturation in green and naturally dried logs along with a much lower drying rate played a significant role in this joint research.

Figure 1: *Debarked small-diameter oak logs for testing.*

3 MATERIAL AND METHODS

210 oak logs (*Quercus petraea* (Matt.) Liebl.) with a length of five meters and an average mid diameter of about 25 cm were cut from one 90 years old stand in Rhineland-Palatinate. The trees have developed from stump sprouts. The logs were divided into three subsamples ($n = 70$, each) to facilitate the measuring process. Subsample 1 (cut 1) and subsample 2 (cut 2) underwent the complete measurement programme in non-destructive and destructive testing for material characterisation [1]. From these subsamples, 80 logs were debarked (Figure 1), 30 logs were edged on two sides and 30 logs were edged on four sides. Debarking was executed for faster drying and edging for a simplified construction geometry. The remaining logs were assigned for construction of the demonstration hall and excluded from this characterization due to a shorter test program without destructive measurements.

At the test facility, each log was weighed and measured, and the slope of grain was recorded. The logs were oriented with the round side down for the sawn round logs and the load was applied to the flattened surface as they would typically occur. A similar handling has been implemented for the unsawn round wood (Figure 2). The experimental program consisted of 4-point-bending tests following DIN EN 14251 [7], which specifies the requirements to obtain mechanical properties of round timber from laboratory tests under controlled air conditions (20°C, 65% rH). Table 1 gives an overview of selected specimen dimensions. Due to different shape and diameters at tip and butt and distortions, special support devices for this test series have been custom made to address the irregular and for each specimen different geometries and shapes of the log sections.

Figure 2: *Natural and load-induced distortion of test specimen.*

To investigate the influence of wood defects, such as knots (Figure 3), different parameters have been investigated and recorded for each specimen: i) The position of the knot along the longitudinal axis of the log (x-axis), ii) the position of the knot along the height in loading direction (y-axis), defined in cylindrical coordinates by the radial distance and the azimuthal angle. To simplify the observation and speed up the lab test documentation, the azimuthal angle was recorded as knot position clockwise, defining ninety degrees or a quarter section to three hours like on a clock-face (Table 1) with later-on conversion in the cylindrical coordinate system.

https://doi.org/10.52202/069179-0016

iii) The knot radius (size), iv) the knot diving angle (inclination), and if possible, v) the knot length. The largest knot in the log (max knot) had some influence on both strength and stiffness prediction, but it was less correlated with these properties than was the sum of the knots in each cross section (knot sum). The correlation of the sum of the knots divided by the diameter of the cross section was like the correlation of the knot sum alone.

Table 1. *Exemplary summary of specimen span and sections.*

Log No.	vertical diameter d_v [cm] butt	mid-span	tip	knot position clockwise [h]	span [cm]
803	18.58	17.69	17.40	5:00	334.80

858	30.00	28.20	27.20	6:00	460.00

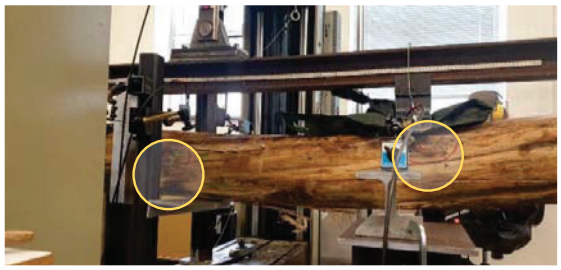

Figure 3: *Wood defects were recorded before flexural testing.*

Depending on the nominal diameter d_{nom}, the span was set-up as defined by the test standard [7] to (18 ± 1) d_{nom}, including loading and measuring points (Figure 4), while d_{nom} has been calculated as an average value of the vertical and for bending tests more influencing diameter. The different values have been measured in vertical and horizontal direction separate for each log at the two supports (tip and butt side), near loading at (6.5 ± 1) d_{nom} from the specimen support and additional in the middle of the span. The 4-point-bending tests were derived by application of hysteresis with peaks of deflections at around 30% of the calculated average maximum stress level.

All tests were carried out by continuous measurements of time, deflections, and forces. First, non-destructive evaluation measurement was taken on each log while it was simply supported at the ends. The specimen (diameters vary from 20 cm to 30 cm, Table 1) were loaded up to a third of the failure load according to a preliminary design, then unloaded and the MOE was determined from measuring the incremental deformation 60 s after the first load level was applied. The deflections at midspan, near loading and at the supports were obtained with a linear variable displacement transducer (LVDT) to the nearest 0.0025 mm and the highest deflections in 100 mm to 200 mm range were recorded by laser sensors with different measuring ranges. The load-deflection plots were obtained for each specimen to calculate the MOR and static MOE depending on the wood defects, the species and overall quality.

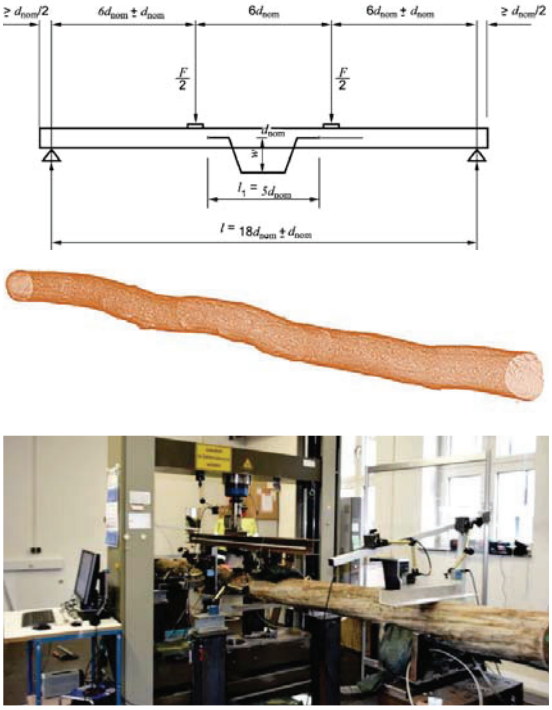

Figure 4: *Standard test arrangement with span-to-depth ratio 18:1 [7]; DiShape surface model of log no. 862 and lab view on log no. 862 waiting for action.*

After testing, a 50 mm thick section of each specimen has been removed from an area close to the location of failure to determine moisture content and the specific gravity (SG), as well as destructive investigations of geometry, oven-dry kiln density and moisture content in the defined section (failure location), [1]. The MC was measured in 2 cm and 4 cm depth at 0°/90°/180°/270° location (GANN Hydromette® CH 17). Then, the surface envelope of each log has been digital recorded from the images to calculate the cross-section data, e.g., diameter, section area, circumference, moment of inertia, etc. (Figure 5).

The lab tests were supplemented by non-destructive data acquisition of the geometry and raw wood density distribution along the full log length by MiCROTEC CT Log and DiShape, see Figure 4 middle and ref. [1]. The computed tomography scans and reconstructs the internal features of the log digitally and allow the assessment of the material in real time where size and position of internal wood defects can be accurately described in all three dimensions. The further use of the test outcome for design processes and material strength classification highly benefits from this technology and the accompanying research results and investigations.

Moment of inertia X: 292,666,326 mm⁴ *Area: 59,384.48 mm²*
Moment of inertia Y: 272,328,664 mm⁴ *Circumference: 883.73 mm*

Figure 5: *Section view of log no. 862 with special support construction (left) and digitalized cross-section (right) with corresponding section data.*

The MOR was calculated according to the round log testing standard [7], eq. (1), using the horizontal and vertical diameter (d_h ; d_v) at the point of failure, the maximum load (F_{max}), and the distance between the load head and nearest support (a).

$$\mathrm{MOR} = f_{m,0} = \frac{16\, F_{\max}\, a}{\pi\, d_h\, d_v^{\,2}} \tag{1}$$

The MOE was determined from measuring the incremental deformation and applied load linear regression, eq. (2), in a specific load range (F_1 ; F_2) corresponding to the elastic range of structural response (0.1 F_{max} ; 0.4 F_{max}) and the corresponding deflections (w_1 ; w_2). The coefficient of determination was greater than 0.99 for all series. The moment of inertia I_{cal} has been calculated from the digital sections as described before (see also Figure 5) and the span ℓ is defined by the distance of the supports.

$$\mathrm{MOE} = E_{m,0} = \frac{a\left(3\,\ell^2 - 4\,a^2\right)}{48\, I_{cal}} \cdot \frac{(F_2 - F_1)}{(\mathrm{w}_2 - w_1)} \tag{2}$$

The green oaks had an average moisture content of ca. 70% after felling, drying within 20 months to 35% at the time of testing, which is still above the FSP of approximately 25% MC for oak wood [13]. The moisture content at the time of destructive testing has been determined from the 50 mm sawn-collected section where failure occurred by regular weighing and measurement of the dry mass. For better comparison of the different specimen and considered that the findings of this research shall serve for green oak log building application guidelines, the elastic properties were standardized by moisture for indoor climate.

Normative indoor climate in the Eurocode 5 service class system is characterized by a material moisture content corresponding to a temperature of 20°C and a relative humidity of 65% in the surrounding air exceeding it only a few weeks per year. The design code itself and the assumptions serve in general for timber buildings in softwood, where in service class 1 (SC 1) the average moisture content of 12% is reached quite fast and will be not exceeded in most cases. This process takes much longer for hardwoods, such as naturally dried oak. All test results have been evaluated, considering the moisture content at time of testing is above or near fibre saturation. The slow drying process is not affecting the material properties, respectively the MOE, until the FSP is reached. The changing behaviour and moisture dependency of the MOE below FSP until SC 1 conditions $T = 20°C$, rH = 65%, $u = 12\%$, have been taken into account according to related research, e.g. [14], and eq. (3) with $u_1 \le u_2 \le$ FSP.

$$E_2 = E_1\left[1 - 0.016\left(u_2 - u_1\right)\right] \tag{3}$$

The test series of subsample 1 (cut 1) and subsample 2 (cut 2) have been evaluated statistically and design values have been derived for material properties, respective MOE, and MOR, to complete the characterisation of the raw material [1] done the forestry research partner FVA in Freiburg, Germany. The evaluation was following the "Design assisted by testing" guidelines of Eurocode – Basis of structural design, DIN EN 1990:2021-10 Annex D [15] with X_d as the design value of the specific property, s_x^2 the variance and V_x as the COV of X.

$$X_d = \eta_d / \gamma_m \cdot m_x \cdot \left(1 - k_n \cdot V_x\right) \tag{D.1}$$

$$s_x^2 = \frac{1}{n-1}\sum\nolimits_1^n \left(x_i - m_x\right)^2 \tag{D.2}$$

$$V_x = s_x / m_x \tag{D.3}$$

4 RESULTS AND DISCUSSION

The deflection of the log specimens was measured at mid-span and the positions of the loading rollers with two sensors under path-controlled loading. Figure 6 show the typical load-deflection behaviour including the observed local failure as small stepwise decreases in load before ultimate failure occurs.

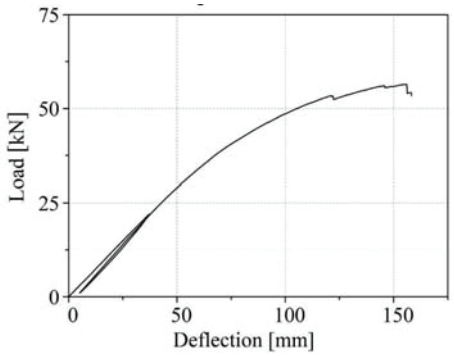

Figure 6: *Typical load-deflection relationship (hysteresis)*

The statistical evaluation has been done for cut 1 and cut 2 separately for the unsawn roundwood specimen, excluding the sawn roundwood in this stage of data interpretation. Table 2 show the results for all unsawn logs (cut 1 and 2) derived from testing as mean values of MOR and MOE, the characteristic and 5%-quantile values calculated from the statistical distribution over all samples and the influence of the moisture content when shifting the MC to normative indoor climate conditions.

https://doi.org/10.52202/069179-0016

The calculated MOE from testing ranged from 4,360 MPa to 32,956 MPa with an average of 11,026 MPa by scattering results and a coefficient of variation of 48.4%. The calculated MOR show a much better distribution in the range of 27.40 MPa to 103.77 MPa with an average value of 60.10 MPa, COV = 22.4% (Table 2).

Table 2. *Statistical evaluation of n = 71 log tests.*

	MOR (u_{test})		MOE (u_{test})	MOE (u_{12})
	[MPa]		[MPa]	[MPa]
mean	60.1	mean	11,026	13,500
char.	36.8	5%-Q	1,799	3,289

MOR(u_{test})	$f_{m,0,mean}$	MOR mean value at time of testing
	$f_{m,0,k}$	MOR characteristic value
MOE(u_{test})	$E_{m,0,mean}$	MOE mean value at time of testing
	$E_{m12,0}$	MOE mean value at calc. 12% MC
MOE(u_{12})	$E_{m,0,05}$	MOE 5%-Quantile from test series
	$E_{m12,0,05}$	MOE 5%-Quantile at calc. 12% MC

The statistical evaluation of all samples and subsamples shows that both, modulus of elasticity and modulus of rupture are normal distributed over the number of all samples. Figure 7 show the distribution of the MOR per example. The variation of around 22% for the fibre parallel bending strength is line with similar tests executed on softwood logs, [11], [12].

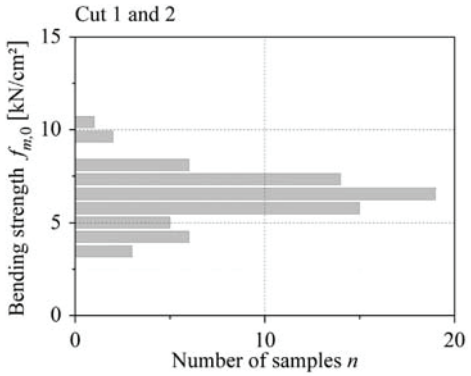

Figure 7: *Distribution of MOR for all samples.*

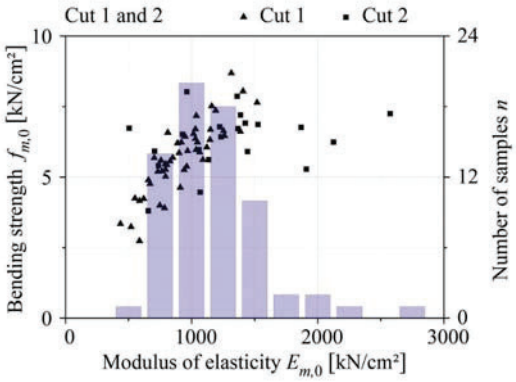

Figure 8. *Relation between MOE and MOR for all samples.*

Including the MOE in the evaluation, a linear regression dependency can be observed. Some specimens from cut 2 contribute a much higher MOE by medium strength in contrast to the rest of specimen (Figure 8). The mean MOE obtained by destructive tests appears 18% lower than the dynamic MOE measurement done in Freiburg [1]. This is also described in other research reports on comparison of destructive and non-destructive characterisation of material properties of wood.

Further investigations have been done relating the wood density and the moisture content to the mechanical properties tested. Fresh sawn or wet oak has a density of around 1,200 kg/m³ and a MC around 70%. To be in line with the test standards, the moisture content has been decreased over 18 months from the time of felling (December 2019 for cut 1) by natural drying. At the time of testing the MC was still over the FSP. To investigate further dependencies the MC have been reduced to 10-12% equilibrium humidity in service class 1 with the corresponding density ρ_{12} around 720 kg/m³. The kiln-dry density to the MOR relationship (Figure 9) and the kiln-dry density to the MOE relationship (Figure 10) could be confirmed as linear. The moisture content of the logs showed a good correlation with the modulus of elasticity and the bending strength. For further investigations, the relevant material properties have been also calculated for SC 1 conditions (u = 12%), as the MC at the time of testing was above FSP for all specimens.

5 CONCLUSIONS

The results of the research done show that small-diameter oak logs appear suitable for load-bearing structures. This could be a significant addition to the existing range of application, since those logs have no further use due to curvature, knot distribution or diameter. The work done is a first step towards sustainable applications of small-diameter oak as structural timber, using modern classification methods within the framework of forest management. The results are not perfect, but promising to go the next steps in roundwood classification to ensure a long-lasting and high-quality raw material for construction and the necessary increase in stocks of climate-resilient hardwood assortments in the coming decades.

A good correlation between flexural strength and stiffness could be observed in the first test series, basis for developing a grading system for round timbers. In the second batch only a few specimen delivered high stiffness values resulting in a high COV and scattering results. A follow-up study is needed in which logs of at least two nearby sites are sorted and then tested to confirm the flexural properties. Additional information is also needed on the compressive strength of lower diameter logs to quantify the relationship between compressive and bending material strength. These investigations have been started with destructive testing recently and will be expanded by studies of the effects of changing moisture content in logs on strength and stiffness as an aid for further classification and quality control issues.

The investigations done in Freiburg and Mainz have shown, that the more efficient team work and the use of digital and modern destructive and non-destructive applications and methods are beneficial to predict the material properties of irregular-shaped individual logs. Apart from shape and properties distribution along the trunk, the influence of knots is known and investigations on the sample assortment of this study have started already. Innovative machine learning procedures applied to computed tomography scans can help to reconstruct knots and other internal wood defects and shall serve for a better strength prediction of small-diameter hardwoods in the future.

ACKNOWLEDGEMENT

The project receives funding via the Waldklimafonds (WKF) funded by the German Federal Ministry of Food and Agriculture (BMEL) and Federal Ministry for the Environment, Nature Conservation, Nuclear Safety and Consumer Protection (BMUV) administrated by the Agency for Renewable Resources (FNR) under grant agreement No. 2218WK18D3. The authors would like to thank all employees of the National Material Testing Authority (MPA) in Mainz, going the extra mile for this project during the corona pandemic and Maximilian Leonhard Müller for his engagement and support in evaluating the experimental results.

EXPERIMENTAL STUDY ON IN-PLANE SHEAR PERFORMANCE OF CROSS-LAMINATED TIMBER

Kaito Yamagata[1], Ryo Inoue[2], Takuro Mori[3]

ABSTRACT: The in-plane shear performance of CLT using the asymmetric four-point bending test method was conducted to examine the test conditions. The parameters of specimens were the span, the height, the layups and the loading direction. As a result, it was found that the bending failure occurred when the span ratio was 1.25 times. This suggests that shear failure may occur reliably below the span ratio was 1.0 times. The shear strength was increased when loaded with the same lamina at the span ratio of less than 0.5 times. Therefore, it is recommended that the span ratio was 0.5 to 1.0 times to adapt for CLT in-plane shear testing method. The shear strength and the percentage of perpendicular layers were positively correlated, suggesting that shear strength may be estimated in a simplified manner. The diagonal measurement of shear modulus is considered to be the easier way to calculate the shear modulus, as it does not require any concern for the grain direction. The shear modulus values ranged from half to four times higher than the design values in Japan. A comparison of the shear strength and shear modulus between values in the reference using other testing methods and the experimental values in this study shows a tendency to show different values. This may be due to the different shear section areas of the specimens depending on the test method and the different restraint conditions.

KEYWORDS: Shear performance, Cross-laminated timber, Asymmetric four-point bending test

1 INTRODUCTION

Currently, the utilization of wood is promoted around the world since the environmental problem became serious. To increase the utilization of timber in buildings, the tall and large-scale wooden buildings are getting important. CLT is attracting attention because it has high shear performance and the usage ability of a large amount of wood. Therefore, CLT is used at walls and floors in wooden large structures. If CLT is used as earthquake-proof walls, the horizontal force applies at the in-plane direction of CLT panel. As the structure becomes larger, the in-plane shear force increase. Therefore, it is important to understand the in-plane shear performance of CLT.

However, the method for evaluating the in-plane shear performance of CLT is not established. We focused on the asymmetric four-point bending test method as shown in Figure 1 from among multiple test methods[1)-4)], because the method has the advantage that the stress control of bending and shear is easy. The span of the method for lumber and glulam is set by Japan Housing and Wood Technology Center (HOWTEC)[5)]. There are also existing studies using this test method for lumber[6),7)], glulam[8)] and MDF[9)], but there are almost no studies using it for CLT have been found[10)]. Therefore, it is not established about CLT, so it needs to investigate to adapt on CLT. Particularly with regard to the in-plane direction of CLT, appropriate test methods are difficult to implement, as bending and embedment failures may occur.

In this study, it was investigated the in-plane shear performance of CLT; the parameters of the targets are the loading span, loading direction and specimen's height. In addition, shear deformation is measured using three different measurement methods, and the simplest and most suitable measurement method is investigated. This study aims to propose the test method and measurement method of in-plane shear for CLT.

2 OUTLINE OF EXPERIMENT

Table 1 shows the specifications of the specimens. As shown in Figure 2, specimen's layups were set to 3 layers 3 plies, 4 layers 4 plies, 5 layers 5 plies. 4 layers 4 plies CLT is not standard used layups, but was used to study the differences in deformation under the same stress, as the front and back sides have different the grain directions. All specimens were made of *Japanese Cedar* (*Sugi*). The 3 layers 3 plies and 5 layers 5 plies have two load directions which are in major axis and minor axis against in-plane bending.

As shown in Figure 1, the testing method was the asymmetric four-point bending test method, the supporting and loading spans were 1 to 2 times as specimen's height. And the span of between supporting and loading span minus loading plate width (S-w_p), divided by specimen's height(d) is called span ratio. Here, it was named the major and the minor axis as shown in

Table 1: *List of specimens*

Layups	width×height (mm)	{Span(S) – Width of plate(w_p)} / height(d) ratio	Loading direction	Density (kg/m^3)	Moisture (%)	Number of specimens
3 layers 3 plies	90×240	0.5	Major	410±50	11.9±1.1	Each 6 Total 12
		0.75	Minor			
4 layers 4 plies	120×240	0.5・0.75・1.0		438±36	11.6±0.7	Each 6 Total 18
5 layers 5 plies	150×120 150×360	0.25・0.5・0.75・1.0・1.25	Major	463±24	10.1±0.6	Each 3 Total 60
		0.5・0.75・1.0・1.25・1.5	Minor			

Figure 3. The major axis outer laminae are grain perpendicular to the loading direction, and the minor axis outer laminae are grain parallel to the loading direction. The width of the loading and supporting plate were set to 3/4 of the specimen's height for the major axis, and 1/2 for minor axis and 4 layers 4 plies in consideration of the compression stress. The loading rate was 1 mm/min and the load was applied until the load dropped to 0.8 P_{max} after the maximum load was reached.

The 4 layers 4 plies have different grain directions on the front and back side. Here, they were named the pe side and pa side as shown in Figure 4. The sides were determined in the loading direction and grain direction. As shown in Figure 5, the shear strain was measured by three ways. The shear modulus values calculated by each measurement methods are called as G_h, G_v and G_d respectively.

3 RESULTS AND DISCUSSIONS

3.1 FAILURE MODES

The mainly failure phenomenon are shown in Figures 6 to 8. As shown in Figure 6, bending failure occurred in a part of the span ratio 1.25*d* and 1.5*d*. Shear failure occurred in the parallel layer as shown in Figures 7 and 8. Mode I failures were common on the major axis and pe side, while Mode III failures were common on the minor side and pa side as shown in Figure 9[11]. In the shear failure specimens, there was no difference in the failure phenomenon depending on the span ratio. Bending failure may occur if the span ratio is 1.25*d* or more, therefore the span ratio must be set to less than 1.0*d*.

3.2 SHEAR STRENGTH

The relationship between the span ratio and shear strength is shown in Figure 10. The reference value, which is the CLT Construction Manual in Japan (CLT-Manual-J)[12], is also shown in Figure 10. The value of the major axis was higher than that of the minor axis regardless of the span. In addition, the effect of specimen's height was small and the shear strength showed almost the same value in the minor axis of 120mm and 360mm. The experimental value was approximately 1.09 to 3.01 times that of the reference value. In the 120mm specimens, some high values were shown in a small span ratio. In this case, the specimen's height is small, the shear area is also short and there had only one vertical lamina in the shear area as shown in Figure 11. Therefore, the loads were applied to each end of one lamina, and the high struts occurred on one lamina as the vertical compression. Thus, it is necessary to consider the test conditions so that the lamina boundary is within the shear section. For larger heights, a size of 240mm is considered appropriate as the increased volume makes testing more difficult. A span ratio of 0.5 to 1.0d is considered a desirable span ratio, where bending failure does not occur and the same lamina is less likely to be loaded. In terms of layups, the major axis was higher than the minor axis in 3 layers 3 plies and 5 layers 5 plies. The factor was considered to be the proportion of perpendicular layers in the total layer thickness.

The relationship between the percentage of perpendicular layers and shear strength is shown in Figure 12. Mode I to III indicate the shear strength of each mode as determined by the shear reference strength calculation formula in the CLT Manual J[12].The calculation formulas for Mode I～III are shown in Equation(1).

$$F_s = min\left\{\begin{array}{c} f_{v,lam} \\ f_{v,lam90}\cdot\dfrac{t_{net}}{t_{gross}} \\ \dfrac{b\cdot n_{ca}}{2t_{gross}}\cdot\dfrac{1}{\dfrac{1}{f_{v,tor}}\cdot\left(1-\dfrac{1}{m^2}\right)+\dfrac{2}{f_R}\cdot\left(\dfrac{1}{m}-\dfrac{1}{m^2}\right)} \end{array}\right. \quad (1)$$

$f_{v,lam}$:Shear strength of parallel to the grain
$f_{v,lam90}$:Shear strength of perpendicular to the grain
t_{net} :Thickness of perpendicular to the grain
t_{gross} :Thickness of the CLT
b :Width of lamina
n_{ca} :Number of perpendicular bonded layers of CLT
$f_{v,tor}$:Torsional shear strength of the intersecting surfaces of two perpendicular bonded lamina
m :Lowest value out of the number of lamina in each layer in the width direction
f_R :Rolling shear strength

Figure 12 shows that the percentage of perpendicular layers and the experimental values are positively correlated, with a transition close to mode II. The approximate equation y=10x for the proportion of perpendicular layers x, suggesting the possibility of a simple shear strength estimate. Mode II is a failure caused by shear deformation the perpendicular lamina at the edge, but the failure was observed in this study. The calculation formula, experimental values and failure properties show different fracture mode tendencies. The factor is considered to be influenced by the test method and is an issue for further study. The range of perpendicular layer percentages in this study includes the Japanese Agricultural Standard (JAS)[13] for CLTs other than 5 layers 7plies. Further studies should be conducted on 3 layers 4 plies, where the proportion of perpendicular layers is 50% the same as with 4 layers 4 plies. In addition, 5 layers 7 plies should also be considered in the further studies. Figure 14 shows the relationship between shear strength and air-dry density, and Figure 15 shows the relationship between shear strength and moisture content calculated by the oven-dry testing. The approximate straight line, approximate equation and coefficient of determination are shown respectively. Neither showed much correlation and the results were almost unchanged. The slope of the approximate line and the value of the coefficient of determination also indicate that there is no correlation between density and moisture content and shear strength in the results of this study.

3.3 DIRECTIONS OF SHEAR MODULUS

Figure 16 shows the shear modulus for the pa side and pe side of 4 layers 4 plies for each measurement method. As the 4 layers 4 plies has different grain directions on the front and back, it was thought possible to study the differences in deformation due to the grain direction under the same stress.

The vertical and horizontal axes are the pe side and pa side, respectively. In G_h shown on the left, the pa side showed higher values than the pa side. In contrast, the pe side showed higher values for G_v shown on the middle. On the side with high values, the measurement direction was perpendicular to the grain direction on each surface as shown in Figure 17. Therefore, the horizontal and vertical measurement should be measured parallel to the grain. In G_d shown on the right, the shear modulus showed 500-1000N/mm^2 with small differences in each side. This is due to the fact that the diagonal measurement has a wider measurement range and can measure deformations in any direction. Therefore, diagonal measurement is less affected by the grain direction and is considered to be an easier measurement method. It is also considered a simple measurement method, as it does not require any concern for the direction of the grain.

3.4 SHEAR MODULUS

The relationships between the span ratio and shear modulus by each measurement methods in Figures 18-20. The legend is the same as in Figure 10. The values indicated in the CLT-Manual-J[12] are called reference values and are compared. The horizontal and vertical measurement methods in the previous section showed high values for the values measured in perpendicular to the grain direction. Therefore, for G_h and G_v in the 4 layers 4 plies, the values measured on the side parallel to the grain direction were used. For G_d, the difference between the values of the two sides was small, so the average value of the two sides was used. Figures 18-20 show that the values for the 4 layers 4 plies were higher than the reference values, ranging from 500-1000 N/mm^2 for all measurement methods. The horizontal measurement method showed a wide range of values, with a particularly large variation in the minor axis. Specimen height had no effect on the shear modulus. For span ratio, a negative correlation is observed for G_v and G_d, suggesting that bending deformation is affected. However, G_v and G_d are

https://doi.org/10.52202/069179-0017

considered to be suitable measurement method for shear deformation, as they show a smaller range of values than G_h. And they are closer to be reference value. In particular, G_d is considered to be a more suitable measurement method because its highest value is around 1000 N/mm^2 and it is easy to measure as mentioned above. A reason for the different variation in values is the difference in the measurement range. G_h is measured at the center of the specimen, whereas G_v and G_d are measured at over a wider area (including more lamina boundaries in parallel and perpendicular layers) between the inner supporting and loading points. Therefore, it is considered that the inclusion of the deformation of the entire CLT is a factor. These results suggest that the shear modulus is negatively correlated with the span ratio, that over test conditions have little influence. And that the diagonal measurement method is close to the reference value and stable because it is measured over a wide range.

3.5 COMPARE WITH OTHER TESTING

Figures 21 and 22 show a comparison with experimental values and reference values for full-scale horizontal loading testing[14)-15)], which are often used as in-plane shear testing for CLT. Only data from the same tree species used in this study were used in the reference. The shear modulus is based on values of diagonal measurement.

In the relationship between shear strength and the percentage of perpendicular layers shown in Figure 21, the values in the reference show a sideways trend that differs from the values in this study. The results of the 3 layers 3 plies (33%) in this study and the reference are also close. However, for the other layups, the divergence of the values according to the test method is greater, with an average difference of approximately 2.3 times the value for the percentage of perpendicular layers of 66%.

In the relationship between shear modulus and the percentage of perpendicular layers shown in Figure 22, the reference values show a slightly negative correlation, whereas the values of this study show a positive correlation. Specimens with 50% of perpendicular layers showed close values regardless of the test method and layups.

Thus, a comparison of the shear strength and shear modulus between values in the reference values using other test methods and the experimental values in this study shows a tendency to show different values. This may be due to the different shear section areas of the specimens depending on the test method and the different restraint conditions. The differences in performance between test methods are a subject for further study.

4 CONCLUSIONS

The asymmetric four-point bending test was conducted on CLT to investigate the effects of layups, span ratio, height and loading direction on shear strength and shear modulus. For shear strength, it was found that the height and span ratio did not have a significant effect. The results for the 4 layers 4 plies showed values around the major and minor axis of 5 layers 5 plies. The difference in between 3 layers 3 plies depending on the loading direction suggests that

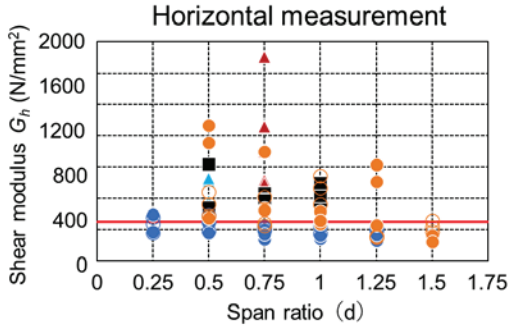

Figure 18: *Relationship between span and shear modulus G_h*

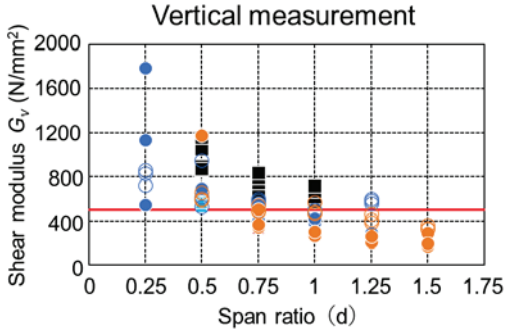

Figure 19: *Relationship between span and shear modulus G_v*

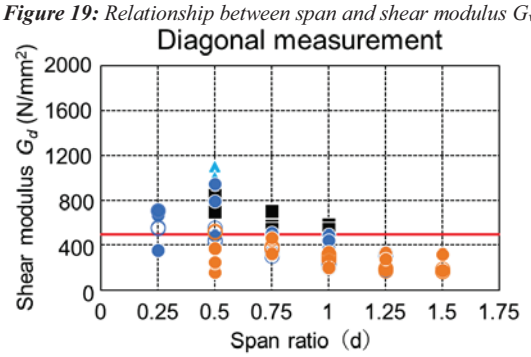

Figure 20: *Relationship between span and shear modulus G_d*

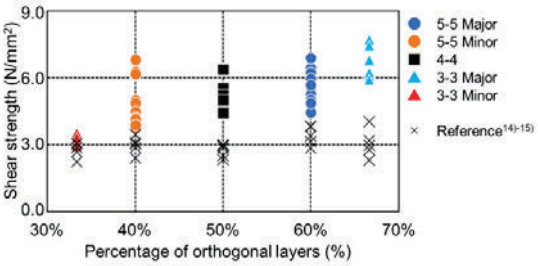

Figure 21: *Comparison with experimental values and reference values of shear strength*

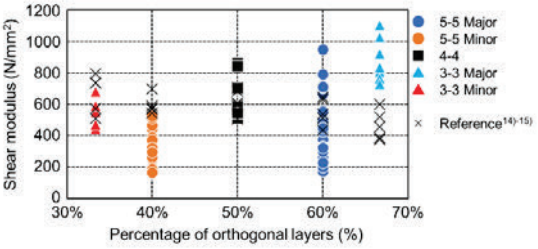

Figure 22: *Comparison with experimental values and reference values of shear modulus*

the percentage of perpendicular layers in the overall thickness may have an effect on shear strength. For shear modulus, the measurement in the diagonal direction (Gd) showed the least variation. In addition, it showed values close to those in the CLT-Manual-J[12] and is considered to be less affected by the grain direction. Based on these results, the method is considered to be an appropriate method for measuring deformation.
Based on the above results, it is considered that the appropriate test conditions are;

- The specimen's height should be 240 mm or more (two or more lamina in the direction of height)
- The span ratio should be in the range of 0.5-1.0*d*, avoiding bending failure and loading with the same lamina
- The layups are influenced by the percentage of perpendicular layers
- The shear strength is positively correlated with the percentage of perpendicular layers, suggesting that shear strength could be estimated in a simplified manner
- The measurement method is recommended because it is easier to measure in the diagonal direction.

Future research should include experiments on specimens with different proportions of perpendicular layers to investigate the relationship with shear strength and failure modes.

ACKNOWLEDGEMENT

We would like to thank all the students in the laboratory for their cooperation in conducting the experiment. Part of this study was based on the Architectural Institute of Japan Chugoku Branch Incentive Research Grants 2022. We would like to express our gratitude for all support.

SHEAR TESTS ON FULL-SCALE EUROPEAN ASH GLUED LAMINATED TIMBER BEAMS

Pedro Palma [1] , René Steiger [2] , Thomas Strahm [3] , and Ernst Gehri [4]

ABSTRACT: The influence of volume effects on the shear strength and stiffness of glued-laminated timber (GLT) made from European ash (*Fraxinus excelsior* L.) was assessed based on a comprehensive experimental campaign. The experiments were performed on full-scale GLT beams with rectangular cross sections $b \times h$ = 120 × 480 - 800 mm^2, shear lengths L_v = 720 - 1500 mm, and shear length/height ratios $\alpha = L_v/h$ = 1.2 - 2.5. The influence of the test configuration (3-point bending and asymmetric 4-point bending) was also assessed. The obtained shear strengths of European ash GLT had mean values $f_{v,mean}$ = 10.2 (CoV_{fv} = 14%) and 12.2 N·mm^{-2} (CoV_{fv} = 15%), for the 3-point and asymmetric 4-point bending test configurations. The shear strength showed some size dependency, with k = 0.2-0.4 for a strength modification factor $(h/600)^{-k}$ as a function of the beam height h.

1 INTRODUCTION

1.1 BACKGROUND

The determination of shear properties, namely shear modulus G and shear strength f_v, is a decade-long discussion [1–8]. In the ongoing revision of EN 1995-1-1:2004 *Eurocode 5* [9], the determination of shear strength has also been under active discussion, namely regarding conversion factors required to convert results from small-scale tests into values that represent the behaviour of the material in a structure. As pointed out, e.g., by Ehrhart et al. [10], the main issues in the determination of the shear strength parallel to the grain are the: i) influence of perpendicular-to-the-grain stresses; ii) influence of volume- and geometry related parameters and; iii) the incidence of unrelated failure modes.

Regarding the influence of perpendicular-to-the-grain stresses, the presence of tensile perpendicular-to-the-grain tensile stresses reduces the shear strength, whereas the presence of low perpendicular-to-the-grain compressive stresses increases (or at least it does not decrease) the shear strength [11,12]. Most of these tests, however, were carried out on small clear specimens [13]. The incidence of unrelated failure modes, namely in bending and compression perpendicular-to-the-grain arises mostly in tests on large-scale specimens and is due to the test and load-application configurations. Finally, the influence of volume-related parameters arises from shear being a brittle failure mode and, therefore, dependent on the theoretical higher probability of a strength-reducing feature occurring in a larger stressed volume [8].

1.2 FULL-SCALE BEAM TESTS

Previous studies have concluded that realistic values of shear strength cannot be based on tests on small-scale specimens, such as those prescribed by EN 408:2010 [14], but should instead be based on full-scale beam tests [5,15–18]. Shear failures are brittle and, therefore, the shear strength depends on the stressed volume. In this cases, it is common to relate the strength to a reference volume V_{ref} (or dimension) in the form of a power law $(V/V_{ref})^{-k}$. Stress states of pure shear are difficult to materialise experimentally and hardly occur in real structures, therefore the test configurations should mostly aim to represent the conditions to which the material is subjected in reality. As already mentioned, an issue with using bending tests to determine the shear strength has been the high number of bending failures that tend to occur. To overcome this, beams with I-shaped cross sections have been used and at a certain point they were even included in the draft amendment to EN 408:2007/prA1:2007 [19], even though they were finally not adopted. The main shortcomings of these beams are the bigger preparation effort, a more complicated calculation of shear stresses and shear modulus, and stress concentrations in the web-flange transition.

Gehri [17] proposed the test configuration in Figure 1. This configuration comprises a simple three-point bending test and a beam with rectangular cross-section, allowing for an easy determination of shear strength and shear modulus. To ensure that the shear stresses are as constant as possible over the entire shear field, without significant perpendicular-to-the-grain stresses, the applied forces are introduced using glued-in rods (GiRs),

namely the GSA® system developed by *neue Holzbau* AG, and not through "conventional" compressive perpendicular-to-the-grain stresses [7]. Since the shear strength of hardwood is higher than that of softwood glued laminated timber (GLT), the requirements for the load-transfer system are also higher, otherwise the shear strength of hardwood could not be captured experimentally. The shear fields proposed by Gehri [17] have a ratio $\alpha = L_v/h = 1.75$, avoiding the

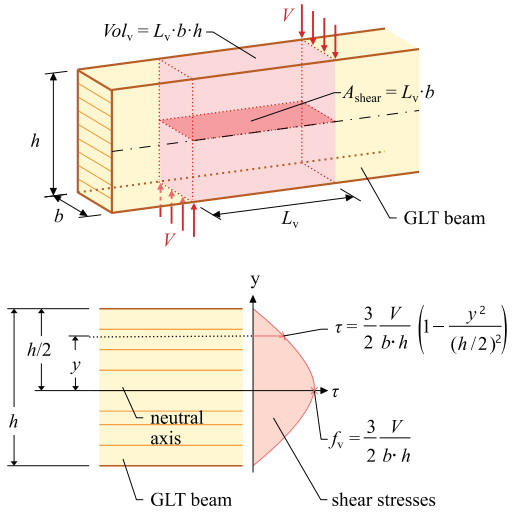

Figure 3: *Geometric parameters and distribution of shear stresses.*

bending failures that come with high values of α and still remaining within the classical beam theory with $\alpha > 1.5$. Ehrhart et al. [10] performed shear tests on beams with an I-shaped cross section under an asymmetric four-point bending configuration, based on a test configuration developed by Basler et al. [20], (Figure 2). In comparison with 3-point bending tests, this configuration allows for longer shear fields for the same beam height and bending moment, which gives the possibility to study the influence of the various geometric parameters over broader ranges. For structural engineering practice, the values of shear strength must be adjusted for the actual climatic and loading conditions and geometry of the structural member. It is therefore of interest to study the influence of geometric parameters on the shear strength (Figure 3), namely those that are easily available to the designer, since the shear strength of GLT is not correlated (or slightly negatively correlated) to the strength classes (EN 14080:2013) [21]. The most straightforward parameter is the beam height h, since the volume under the higher shear stresses around the neutral axis is correlated to the beam height. The shear length L_v is also a parameter of interest, since it is proportional to the shear crack area (Figure 3). In addition, the volume of the shear field Vol_v is a relevant parameter (Figure 3), but it is not always easy to determine, since it depends on the loading configuration and might be disturbed by perpendicular-to-the-grain stresses. Therefore, test configurations should ensure that shear stresses are as constant as possible over the entire shear field, without significant perpendicular-to-the-grain stresses. This is possible if the applied forces are introduced using GiRs, as mentioned above and described in detail by Steiger and Gehri [7].

1.3 OBJECTIVES AND SCOPE

The objectives of the study presented in this paper were to:

- obtain knowledge on the influence of the member size (geometrical parameters) and of the test configuration on the shear strength of hardwood (European ash) GLT and of a small sample of softwood (Norway spruce);
- develop tests methods for the experimental determination of the shear stiffness and strength parallel to the grain of GLT beams for research (where it is important to obtain only shear failures and it is possible to implement more complicated test set-ups) and for GLT production (where simple test set-ups are required);
- define the reference dimensions for cross-sections that meet the requirements for the two abovementioned fields of application;
- propose simple relationships to account for size effects in design standards (SIA 265:2021 and EN 1995-1-1:2004).

The experimental research presented in this paper was conducted on full-scale glued laminated timber (GLT) beams made of European ash (*Fraxinus excelsior* L.). For comparison purposes, tests were also performed on GLT made of Norway spruce (*Picea abies* (L.) H. Karst.).

2 EXPERIMENTAL RESEARCH

2.1 THREE-POINT BENDING TESTS ON ASH GLT

2.1.1 Materials and methods

The 3-point bending tests on European ash (*Fraxinus excelsior* L.) GLT beams (Figure 4 and Table 1) were performed at the Structural Engineering Research Lab of Empa (Switzerland). The test specimens were made from European ash GLT of strength class GL48c "special", with T33 laminations and three T50 outer laminations, without finger joints, in the tension zone. The mean density of the test specimens was $\rho_{mean} = 640$ kg·m^{-3} (coefficient of variation $CoV_\rho = 3\%$) at an average moisture content $\omega_{mean} = 10\%$. The load-application zones were reinforced with GiRs (GSA® system).

The tests were performed under force control. The shear modulus G was determined based on the shear field method, with square measurement fields with side lengths $h/2$. The shear strength f_v was calculated as $f_v = 3/2 \cdot F/(b \cdot h)$.

2.1.2 Results

The results of the 3-point bending tests on European ash GLT are presented in Table 2 and Figure 5. The mean shear modulus was $G_{mean} = 1162$ N·mm^{-2} ($CoV_G = 6\%$) and showed no size dependency. The global mean shear strength was $f_{v,mean} = 10.2$ N·mm^{-2} ($CoV_{fv} = 14\%$). Some size-dependency of the shear strength can be observed at the mean-value level, but the scatter of the results makes it less clear than for the equivalent Norway spruce GLT beams. The shear strength can be described as a function of the beam height h by

$$f_v = 34 \cdot h^{-0.19} = 10.2 \left(\frac{600}{h}\right)^{0.19}. \quad (1)$$

The position of the longitudinal shear cracks in the beam height was above the neutral axis in approximately 70% of the tests and below the neutral axis in approximately 30% of the tests [22].

For beam heights $h = 480$ and 600 mm, the shear cracks occurred within 25% of the beam height above the neutral axis (i.e. in the zone under longitudinal compressive stresses), which corresponds to shear stresses higher than $0.75 \cdot \tau_{max}$, with $\tau_{max} = 1.5 \cdot V/(b \cdot h)$. For the three beams with height $h = 800$ mm, the shear cracks occurred within 15 and 20% of the beam height above and below the neutral

https://doi.org/10.52202/069179-0018

axis, respectively, which corresponds to shear stresses higher than $0.84 \cdot \tau_{max}$, with $\tau_{max} = 1.5 \cdot V/(b \cdot h)$. The mean maximum bending stresses reached when the shear failures occurred were $\sigma_{m,max,mean} = 70.9$ N·mm^{-2} ($CoV_{\sigma max} = 15\%$) and no bending failures happened.

2.2 ASYMETRIC 4-POINT BENDING TESTS ON EUROPEAN ASH GLT

2.2.1 Materials and methods

The asymmetric 4-point bending tests on European ash (*Fraxinus excelsior* L.) GLT beams were also performed at the Structural Engineering Research Lab of Empa. The test specimens (Figure 6 and Table 3) were made from ash GLT of strength class GL40c, except test specimens ES-2.5, which were made from ash GLT of strength class GL48c "special", with T33 inner laminations and three T50 outer laminations, without finger joints, in the tension zones. The mean density of the test specimens was $\rho_{mean} = 664$ kg·m^{-3} ($CoV_{\rho} = 3\%$) at an average moisture content $\omega_{mean} = 10\%$. The load-application zones were reinforced with GiRs (GSA® system).

The tests were performed under force control. This test configuration was more difficult to implement, namely because both reaction forces (supports 1 and 2) had to be measured and vertical displacements of both load-application points had to be the same, to ensure symmetry of applied loads and support reactions. The shear modulus G was determined based on the shear field method, with square measurement fields with side lengths $h/2$. The shear strength f_v was calculated as $f_v = 3/2 \cdot (F_1\text{-}F_2)/(b \cdot h)$ (see Figure 6).

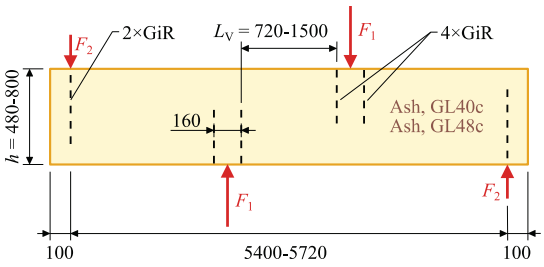

Figure 6: *Asymmetric 4-point bending tests on European ash GLT: geometry of test specimens and test configuration (dimensions in mm, drawing not to scale).*

Table 3: *Three point bending tests on European ash GLT: geometry of test specimens and test configuration.*

Test configuration	Cross-section			Shear field

ES-3.3 (n=3)	120	800	1280	1.6	153600	0.123

2.2.2 Results

The results of the asymmetric 4-point bending tests on European ash GLT are presented in Table 4 and Figure 7. The mean shear modulus was $G_{mean} = 1120$ N·mm^{-2} ($CoV_G = 6\%$) and showed no size dependency. The global mean shear strength was $f_{v,mean} = 12.2$ N·mm^{-2} ($CoV_{fv} = 15\%$). Some size-dependency of the shear strength can be observed at the mean-value level, but the scatter of the results makes it less clear than for the equivalent Norway spruce GLT beams. The shear strength can be described as a function of the beam height h by

$$f_v = 34 \cdot h^{-0.37} = 12.2 \left(\frac{600}{h}\right)^{0.37}. \quad (2)$$

The position of the longitudinal shear cracks in the beam height was above the neutral axis in approximately 60% of the tests and below the neutral axis in approximately 40% of the tests [22]. All but one shear crack occurred within ±20% of the beam height from the neutral axis, which corresponds to shear stresses higher than $0.84 \cdot \tau_{max}$, with $\tau_{max} = 1.5 \cdot V/(b \cdot h)$

The mean maximum bending stresses reached when the shear failures occurred were $\sigma_{m,max,mean} = 47.3$ N·mm^{-2} ($CoV_{\sigma max} = 29\%$) and no bending failures happened.

3 DISCUSSION AND CONCLUSIONS

3.1 TEST CONFIGURATIONS

From a production quality-control point of view, e.g. to check if a specified or declared material property (which in effect means a system value linked to a controlled procedure) is met, the simpler 3-point bending test configuration is adequate. The asymmetric 4-point bending test allows for a broader range of geometric parameters, namely higher $\alpha = L_v/h$ ratios, given the higher shear forces for the same bending moment. It is better suited to study the shear behaviour of timber beams but it is also significantly more complicated to perform. Reinforcement with GiRs is necessary to ensure a uniform shear field and to apply the required forces perpendicular to the grain, in particular for hardwood GLT.

3.2 Reference size of test specimens

The test results showed that it is possible to test beams with cross-sectional dimensions of up to 160×800 mm^2 for Norway spruce GLT and 120×800 mm^2 for European ash GLT, but the applied forces are quite high (up to 550 and 1150 kN, respectively). Since the bending properties

are given for a reference beam height $h = 600$ mm (e.g. EN 14080:2013 [21], SIA 265:2021 [23]), it makes sense to adopt this dimension as the reference height, i.e. $h_{ref} = 600$ mm, also for the shear properties.

3.3 Shear modulus *G*

The shear modulus showed no size dependency. The stiffness of the tension and compression diagonals in the shear fields showed, however, some dependency on the ratio $\alpha = L_v/h$. The obtained mean values were $G_{mean} = 1162$ (CoV 6%) and 1120 N·mm^{-2} (CoV 6%), for the 3-point and asymmetric 4-point bending tests, respectively. This is in good agreement with the value $G_{mean} = 1000$ N·mm^{-2} specified in the publication Lignatec 33/2021 [24], which had been issued recently in Switzerland, to disseminate results from research projects on the use of hardwood in design practice.

3.4 Shear strength f_v

The obtained shear strengths of European ash GLT had mean values $f_{v,mean} = 10.2$ (CoV 14%) and 12.2 N·mm^{-2} (CoV 15%), for the 3-point and asymmetric 4-point bending tests, respectively (Figure 8 and Table 5). For Norway spruce, the corresponding value determined in 3-point bending tests was $f_{v,mean} = 4.0$ N·mm^{-2} ($CoV_{fv} = 19\%$) [22]. The test configuration showed a marked influence on the shear strength and on the position of the failures cracks. Failure cracks in the 4-point bending tests were evenly distributed within $\pm 0.2 \cdot h$ from the neutral axis, whereas in the 3-point bending tests the failure cracks occurred mostly within $0.25 \cdot h$ above the neutral axis.

The shear strength also showed some size dependency (obtained strength modification factors are presented in Figure 9), even though not as evident as in the preliminary tests on Norway spruce GLT. The exponent k of the strength modification factor $(h/600)^{-k}$ for the 3- and asymmetric 4-point bending tests is $k = 0.19$ and 0.37, respectively. The latter is close to the value $k = 0.4$ proposed by Ehrhart et. al. [10] for European beech (*Fagus sylvatica*) GLT, but that was based on 3-point bending tests on beams with I-shaped cross sections and $h_{web} < 240$ mm. The publication Lignatec 33/2021 [24] specifies a value of $k = 0.25$ for beech and ash GLT, which is approximately the average of the k values determined in the 3– and asymmetric 4-point bending tests. The same publication, for European beech and European ash, also specifies a conservative reference design shear strength $f_{v,d} = 3.2$ N·mm^{-2} for $h = 600$ mm and all strength classes.

3.5 Size effects in design standards

In Eurocode 5 (EN 1995-1-1:2004 [9]), the design shear strength is based on the characteristic 5th-percentile values derived from tests according to EN 408:2010 [14] and prescribed, e.g. for softwood GLT, in EN 14080:2013 [21] as $f_{v,g,k} = 3.5$ N·mm^{-2} for all strength classes. As already mentioned, the strength values derived from EN 408:2010 [14] are not adequate for typical structural applications and hence, a strength modification factor k_{cr} was introduced already in the first Amendment to Eurocode 5 (EN 1995-1-1:2004/A1:2008) [25]. This modification factor was supposed to account for the negative influence of "cracks" and the recommended value was $k_{cr} = 0.67$. Since it was a "nationally determined parameter", countries were able to set their own values of k_{cr}, which led to widely varying approaches. During the systematic reviews of EN 1995-1-1 *Eurocode 5*, there were many comments and requests regarding clarification and harmonisation of k_{cr}, namely to discretise it into more well-defined factors accounting for the influence of specific parameters on the shear strength. A revision of the verification of shear strength is ongoing within Working Group 3 of CEN/TC 250/SC 5 *Eurocode 5: Design of timber structures*. The latest draft of the revised verifications [26] includes a modification factor $k_{h,v}$ to account for the effect of size on the shear strength of softwood GLT that is a function of $(600/h)^{-0.2}$, i.e. sets $k_{h,v} = 0.2$ as proposed by Brandner et. al. [8] (based on 3-point bending tests on spruce beams with I-shaped cross sections and $h_{web} < 300$ mm). That value is in good agreement with the value $k = 0.19$ determined in the 3-point bending tests on ash GLT. In the latest draft of prEN 1995-1-1 [26], the influence of cracks on the shear strength may still be accounted for by means of a specific factor k_{var}.

STRUCTURAL USE OF CUT-OFFS FROM CLT-PRODUCTION – THREE EXAMPLES THAT UTILIZE THE UNIQUE PROPERTIES

Johan Vessby[1], Mikael Perstorper[2], Florian DeMonte[3], Jacob Eriksson[4]

ABSTRACT: Production of CLT-panels typically results in 5-10% cut-offs due to window and door openings. CLT-boards can be made by slicing these cut-offs and finger-jointing them. It is worthwhile from economic and climatic aspects to find applications for such boards as building products with long service life. It is preferred to find uses where the premium transverse properties are utilized. This paper present three novel ideas for re-use of cut-offs from CLT. (a) The re-use as REX laminations in CLT production is a smart concept that minimize waste in an economical way. (b) By using finger-jointed CLT-boards as horizontal rails in timber frame buildings, the problems with over-load and deformations in multi-storey houses are minimized. (c) The capacity of glulam beams to carry concentrated loads is greatly enhanced by integrating CLT-boards as laminations.

KEYWORDS: CLT, REX lamination, perpendicular to grain, re-use, rails, glulam, concentrated load

1. INTRODUCTION

The background to this study is the urge to find smart use for cut-offs from CLT-production, see Figure 1. Due to window and door openings and waste due to non-rectangular shapes of the CLT-panels, 5-10% of all produced CLT material is typically chipped to become biofuel. The idea here is to slice these cut-offs and finger-joint them to CLT-boards with arbitrary length so that these boards have every second layer oriented with the longitudinal direction along the length direction of the board and the other, referred to as "cross-layer", perpendicular to that direction. The cross-layers gives the CLT-boards superior stiffness and strength properties when loaded perpendicular to their length direction since every second layer is then loaded in parallel to the fiber direction, see Figure 1.

It is worthwhile from economic and climatic aspects to find applications for such boards as building products with long service life. It is also favorable to find uses where the premium transverse properties are desired, beneficial and fully utilized.

In this paper, three concepts of re-use of cut-offs are presented and discussed, see Figure 1 (b-d):

a) Re-use as REX lamination in CLT made by Stora Enso
b) CLT-boards as rails in timber frame structures
c) CLT-boards as integrated glulam laminations to enhance capacity for concentrated load

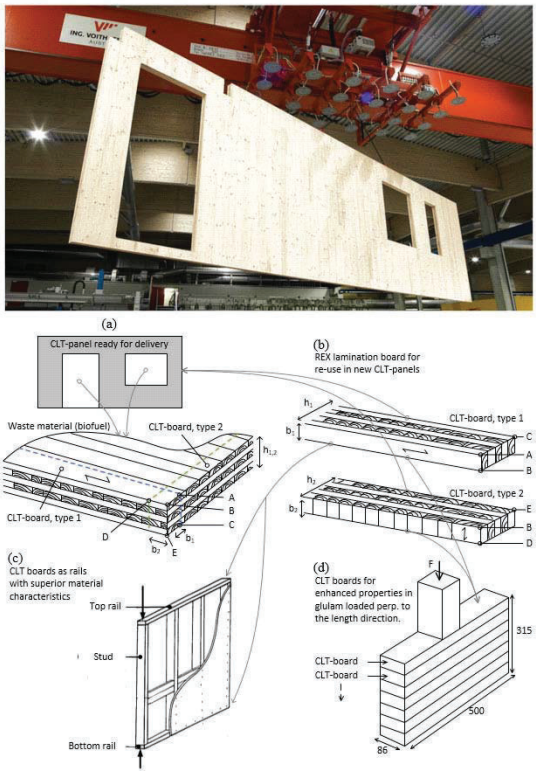

Figure 1: *(a) Waste material from CLT-panels sliced into CLT-boards and used for b) re-use in new CLT-panels c) rails in timber structures and d) to enhance performance locally in glulam beams.*

2. RE-USE OF CUT-OFFS AS REX LAMINATION IN CLT

Stora Enso has developed the idea to finger joint slices of the cut-offs and reuse them as transverse layers of floor and roof slabs in CLT production. The properties of this so-called REX laminations are defined in a European Technical Approval (ETA-14/0349) [1], see Figure 2 (a). The effective E-modulus of the REX lamination depends on the proportion of end-grain, which varies between 20-40 %. However, the E-modulus has been set conservatively to E_{REX} = 6 800 MPa for all laminations type REX.

The properties of the longitudinal layers remain unchanged, which means that the difference in mechanical properties between standard CLT slabs and CLT slabs with REX transverse layers is limited. CLT panels with transverse layers made of REX lamination can significantly limit the carbon footprint by reducing the need for virgin material for producing a panel. CLT with transverse layers of REX lamella have on several occasions been produced in a production line at one of Stora Ensos pulps and used successfully in projects. A stack of five CLT-panels with REX lamellas are shown in Figure 2 (b).

3. CLT-BOARDS AS SUPERIOR RAILS IN TIMBER FRAME STRUCTURES

In multi-storey timber frame buildings the horizontal rails are often a weak point and the accumulated vertical deformations occasionally become problematic. Extra wall studs are at times needed to distribute the load onto a larger area on the rail and thus decrease the stress. By using CLT-boards as rails this problem is minimized thanks to the superior transverse properties. Since every other layer in a CLT-board has the fiber direction in the direction perpendicular to the length direction of the rail and in parallel to the stud, it can carry a much higher perpendicular load compared to structural timber.

Tests of the transverse properties were carried out on 50+50 CLT-boards cut from 5-ply (5·20 mm) CLT wall panels from the Stora Enso mill in Gruvön, Sweden, and on 15 specimens with similar dimensions using structural timber of quality C24. The boards were planed to the standard size 45·95 mm^2 and blocks were cut for the test following EN 408 [2]. In Figure 3 (a) and (b) the cross section of one of the tested specimens is shown together with the setup used for loading. The setup was designed

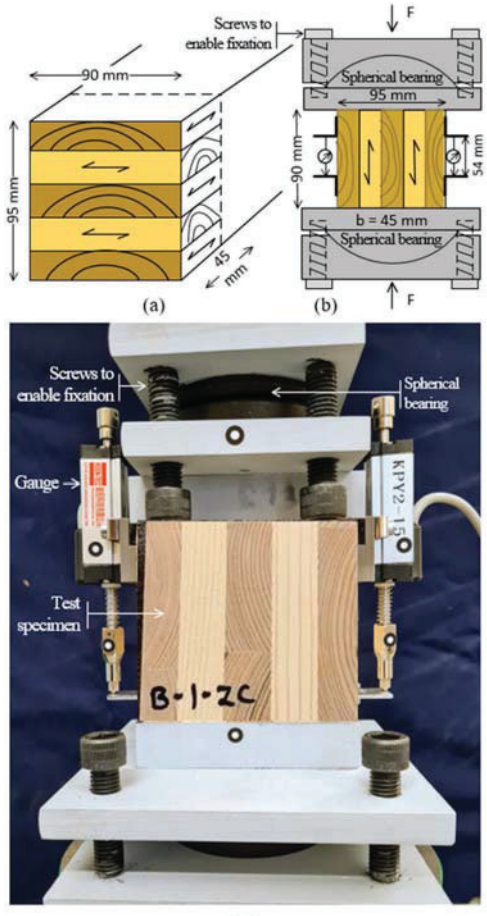

Figure 3: *Test specimen and setup used for testing the stiffness and strength.*

https://doi.org/10.52202/069179-0019

so that a spherical bearing was placed between two steel plates on top of the specimen and below the specimen respectively. Once a pre-load, being 0.2 kN, was applied any further rotation was prevented by means of four screws between the two steel plates fixing the configuration in desired position. The load was thereafter applied under displacement control at a constant displacement of 3 mm/min until a total of at least 2.5 mm. The vertical relative displacement was measured by means of two gauges placed centrically with respect to the height, one on each side of the specimen, measuring the variation in length between the two attachment points on each side being originally 54 mm apart. The data collected was used for calculating the stiffness and the strength of the material tested.

According to the EN 408 [2] the stiffness of the material is to be calculated as

$$E_{c.90} = \frac{(F_{40} - F_{10})h_0}{(w_{40} - w_{10})bl} \quad (1)$$

where F_{10} and F_{40} are the loads at 10 and 40 % of the compressive strength $F_{c.90.max}$ respectively, h_0 is thevertical distance between the measuring points w_{10} and w_{40} the deformation corresponding to the 10 and 40 % load levels and finally b and l the cross-section dimensions of the specimen. The strength of the test specimens was calculated as

$$f_{c.90} = \frac{F_{c.90.max}}{bl} \quad (2)$$

with obvious similar notations. A selection of results from the performed test series are presented in Table 1. Within parenthesis are the variation expressed as a percentage of the average. Since the moisture content was different in the specimens the result presented is compensated in line with the standard [2] to match M.C. = 12 %.

ν_{lr} = 0.05	ν_{lr} = 0.05	ν_{lr} = 0.4

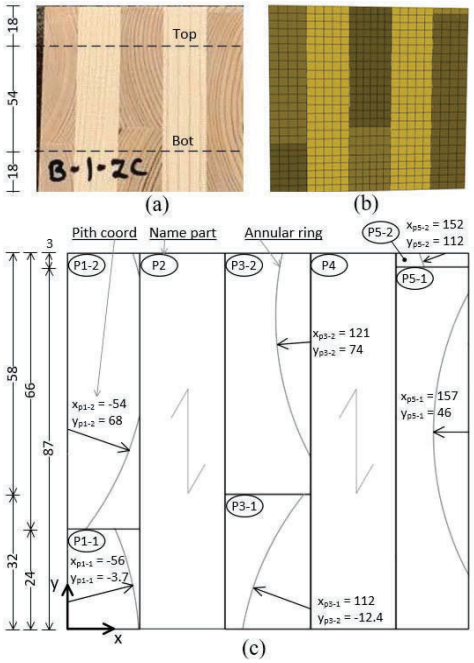

Figure 4: *Pith location for the boards in a selected specimen analysed by use of FEM.*

This way of evaluating the stiffness and the strength for material loaded perpendicular to the grain has been used successfully under long time, but as it turns out it is quite challenging to use for analysis of the CLT-boards due to their variable stiffness in various parts of the material. This will be addressed and exemplified by use of three selected specimens, one of each type tested, in the following. Such analysis is made possible due to the use of a Digital Image Correlation (DIC) system utilized for some of the specimens tested as a complement to the gauges previously described.

One of the tested specimens, of the sort with two layers with fibres in parallel to the loading direction, were analysed by means of the finite element method. The elastic analysis was performed so that the orthotropic material used followed the cylindrical coordinate system defined by the pith of each of the annular rings (assumed circular) in the visible cross sections of the boards, see Figure 4 (a) and (c). The mesh, with second order elements with reduced integration, used to analyse the

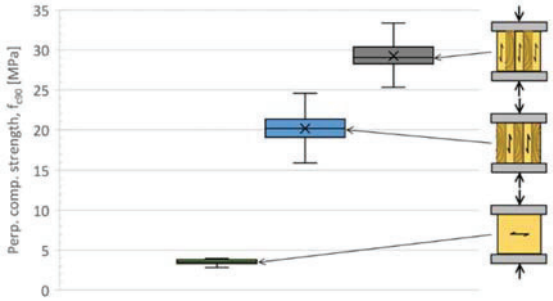

Figure 5: *Perpendicular compression strength f_{c90} of 5-ply CLT-boards compared with standard C24-timber.*

https://doi.org/10.52202/069179-0019

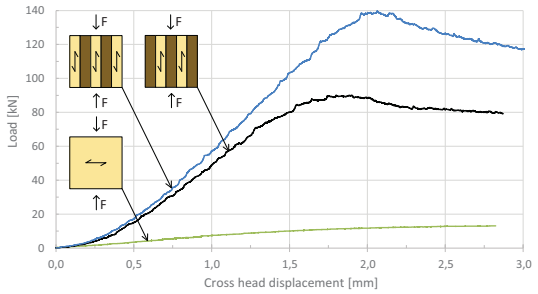

Figure 6: *Load displacement curves for three typical test specimens, one of each type tested, i.e. three parallel layers, two parallel layers and structural timber.*

loading of the specimen is illustrated in Figure 4 (b), each of the parts defined coded with a specific nuance of the brownish colour.

The tests of the perpendicular compression strength showed that a CLT-board had a capacity of 5-8 times the capacity of a standard C24 timber, depending on the proportion of transverse cross layers, see Figure 5. For the case with three layers in parallel with the load direction, corresponding to 57.4 % of the cross-section area, the average of the 50 specimens was calculated to $f_{c90.3par}$ = 29 MPa, see Figure 5. For the other case with two layers in parallel with the stud length direction, corresponding to 42.6 % of the cross-section area, the average strength was calculated to $f_{c90.2par}$ = 20 MPa. Finally, for the tested specimens of structural timber, quality C24, the strength was calculated to $f_{c90.C24}$ = 3.5 MPa on average. The results indicate the considerable potential for making use of the products in loading situations where timber is loaded perpendicular to the length direction of the board, e.g. in rails in prefabricated planar of module building elements.

Yet another property worth pointing out is the post peak behaviour. The load displacement curves for one representative test specimen of each type is shown in Figure 6. For the two CLT-boards the post peak load is falling, but there is no sudden considerable loss in load bearing capacity representing a fatal collapse. Rather, a plateau is reached and the material exhibit plastic behaviour at a load corresponding to the peak load reduced by 10-15 %.

Finally, the curves in the figure indicates a considerably higher stiffness in the CLT-boards compared to the structural timber. At this stage however it should be noted that the horizontal scale in the graph represents the cross head movement rather than the individual or average values of the two gauges installed on each side of the specimen. This means that any boundary effect along the top or bottom loading surfaces

Table 3: *Stiffness's and strength values for three specimens, one of each type tested.*

	Structural timber, C24	Two layers par.	Three layers par.
$E_{c.90}$	160 MPa	1.49 GPa	1.86 GPa
$f_{c.90}$	3.11 MPa	21.1 MPa	32.7 MPa

respectively will be included in the curves. Accepting this the stiffnesses equated by use of (1) can be calculated to values presented in Table 3.

The explanation to why the cross head displacement is used rather than values from the gauges is revealed by the results from the DIC. In Figure 7 (a) the test specimen with two layers having their longitudinal direction in parallel to the loading direction (and with the partitioning and annular rings according to Figure 4) is shown at peak load ($F_{c.90.max}$ = 89.6 kN) and with an overlay of strains in vertical direction at that given load level. It is evident from the strain concentrations at some specific localizations that local properties such as variations in stiffness, inclined fibres or a glue line between two layers of boards, will affect the properties of the specimen. To further investigate this the vertical displacement is plotted at the peak load along two lines, referred to as "top" and "bot" in Figure 7 (a). The result is presented in subfigure (c) and the relative distances between the two ("top" and "bot") lines is in turn shown in subfigure (d).

Not only are these results shown for the specimen described, but also for two other specimens, one from structural timber and one with three layers oriented with their fibres parallel to the loading directions. These results are shown in the two same graphs. Finally, subfigure (e) and (f) show the same thing but at 30 % load level compared to the peak load. The relative difference in vertical displacement between the "top" and the "bot" lines clearly indicates the challenges associated with the measuring technic often utilized to perform measurements used to calculate the stiffness $E_{c.90}$. The subfigures (d) and (f) show that in particular for the CLT boards, the relative length between the two lines is varying considerably over the section. This applies for peak load (c) and (d) as well as within the typical range used to calculate the stiffness, e.g. 30 % of the peak load, see subfigures (e) and (f). Based on this it is recommended simply to use the cross head displacement for the calculation of the stiffness values in case of CLT-boards. This will give conservative stiffness values in general.

At last Figure 7(b) shows results from the FE-simulation performed for the selected and previously discussed specimen with two layers with their fibres in parallel to the loading direction. Displacements are magnified by a factor 5 and maximum stresses $\sigma_{yy} \approx 58$ MPa are obtained in the two layers oriented with their fibres in the y direction.

4. CLT-BOARDS AS INTEGRATED GLULAM LAMINATIONS

When designing glulam beams with long spans there are occasionally critical design issues related to stress levels perpendicular to the fibers involved. According to the Eurocode [3] the design compressive stress in the contact area perpendicular to the grain $\sigma_{c,90,d}$ for a single supported or continuous beam should be less than the design compressive strength perpendicular to the grain, $f_{c,90,d}$, multiplied by a correction factor $k_{c,90}$ so that

https://doi.org/10.52202/069179-0019

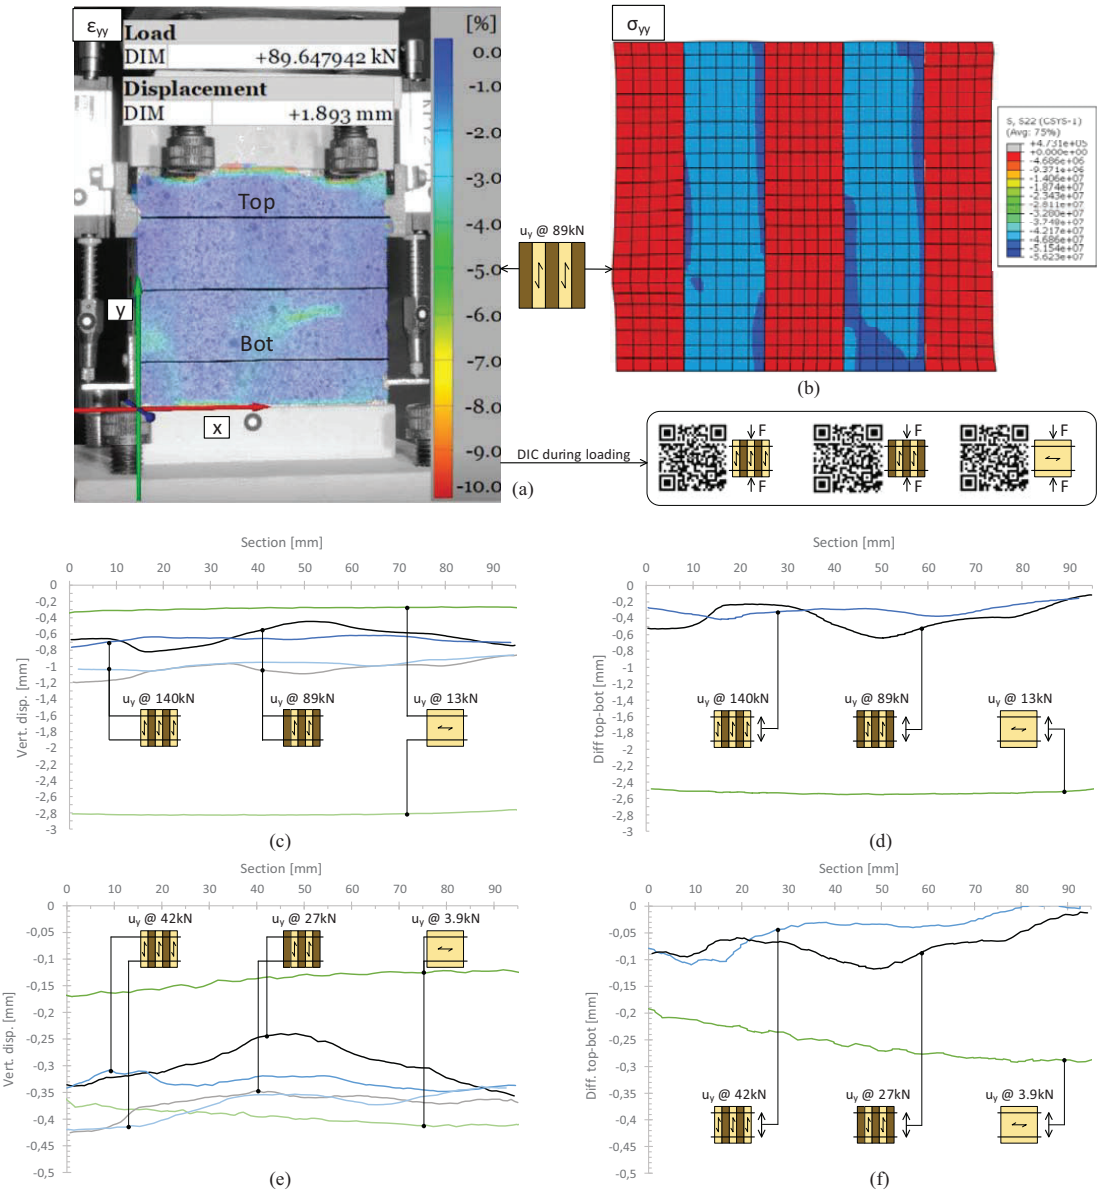

Figure 7: *Results from a) DIC during loading of specimen with two layers with longitudinal direction in parallel to the loading direction and b) results from stress component σ_{yy} from FEM-simulations of the same specimen and vertical displacement of reference lines at c) and d) peak load and e) and f) at 30 % of peak load.*

$$\frac{F_{c,90,d}}{A} = \sigma_{c,90,d} \leq k_{c,90} \cdot f_{c,90,d} \qquad (3)$$

For a beam with a depth $h > 2{,}5\ b$ resting on a support closer than $h/3$ to the beam end or on internal supports respectively the factor k_{90} is obtained as

$$k_{c,90} = (2.38 - \frac{l}{250})(1 + \frac{h}{12l}) \qquad (4)$$

$$k_{c,90} = (2.38 - \frac{l}{250})(1 + \frac{h}{6l}) \qquad (5)$$

where l is the contact length between column and beam. For a reference continuous beam 86 · 315 mm in cross-section being supported internally by a column with full beam width and l = 90 mm the design load can be calculated to $F_{c,90,d}$ = 47 kN (γ_M = 1.25, k_{mod} = 0.8).

The phenomenon with high stresses perpendicular to the fibers in the vicinity of supports has been the subject for several research studies [4, 5] and various suggestions have been made how to address the issue. These suggestions include to increase the contact length l (and thus the contact area) e.g. by placing a stiff and strong steel plate between the beam and the column, see Figure 8(b), to fasten long self-tapping screws into the beam so

https://doi.org/10.52202/069179-0019

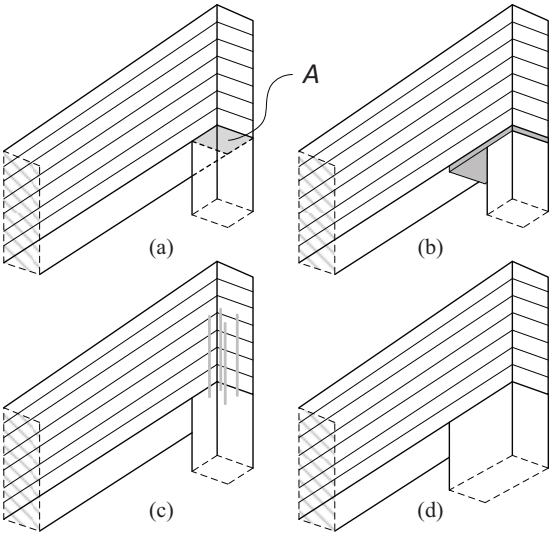

Figure 8: *a) Area loaded perpendicular to grain b) example of steel plate in the contact area between column and beam c) screws for distribution of the load and d) increased column area.*

that the forces are distributed into the beam [6], Figure 8(c), or to simply by increased dimensions of the column, see Figure 8(d).

In the current study another method is suggested to increase the stiffness and strength for a glulam beam loaded perpendicular to the grain in the support area. 1, 2 or 3 of the lamellas in the glulam beam located closest to the column are substituted by CLT-boards from a five layer CLT-panel. These are of type 1, see Figure 1, so that two of their layers are oriented with their longitudinal fiber direction in parallel to the length direction of the column. The CLT-boards were glued to the GLT beam by use of a polyurethane glue and cured for 4 hours under a constant pressure corresponding to 0.5 MPa. An example of an end support and an internal support for a glulam beam when 1 lamella is exchanged locally to a CLT-board is illustrated in Figure 9. Note that the CLT-board is finger jointed to the conventional lamella and that it might also include a finger joint itself.

Modified glulam beams with the dimensions according to Figure 1d were loaded under displacement control to a 15 mm piston displacement. In addition to the beams enhanced by 1, 2 or 3 CLT-lamellas, a reference glulam beam (GLT) without CLT-lamellas was included in the test series as well as a GLT-beam with a 12 mm thick steel plate being 86 · 200 mm in dimensions placed centrally in between the column and the GLT-beam. For each of the five types of setups, A-E, five specimens were tested. An illustration of the setup for the experimental test is shown in Figure 10, see also [7].

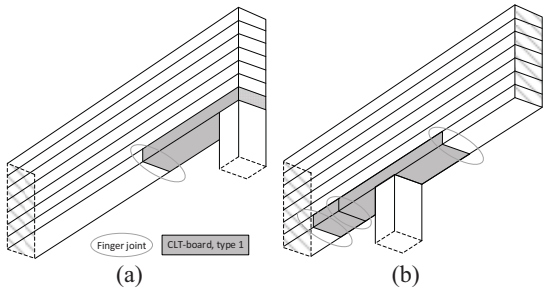

Figure 9: *Illustration of the concept for obtaining increased stiffness and load bearing capacity in a GLT beam for a) end support and b) internal support.*

The average load-displacement curves for the five specimens per setup, shown in Figure 11, indicates a surprisingly high increase in stiffness and strength when 1, 2 or 3 CLT laminations are built into the glulam compared to the reference conventional GLT-beam. It can be noted that the maximum applied load was slightly higher for the case with a distributing steel plate compared to that with a setup including one lamella made out of a CLT-board. However that load-level was obtain at substantial displacements, e.g. larger than 8 mm.

In Table 4 the stiffness, k, and the maximum applied force, F_{max}, is showed as an average of the five tested specimens in each setup. The stiffness is obtained as

$$k = \frac{0.4F_{max} - 0.2F_{max}}{u_{0.4Fmax} - u_{0.2Fmax}} \qquad (6)$$

were F_{max} is the maximum applied load and u_x is the displacement at 40 and 20 % of that load respectively. In addition to the stiffness and maximum load the table shows each of the two normalized against the reference GLT beam E, i.e. the quota k_x/k_E and $F_{max.X}/F_{max.E}$. It is striking that by use of three CLT-lamellas the stiffness can be increased by 98 % and the maximum applied load may be 132 % higher compared to the reference beam E.

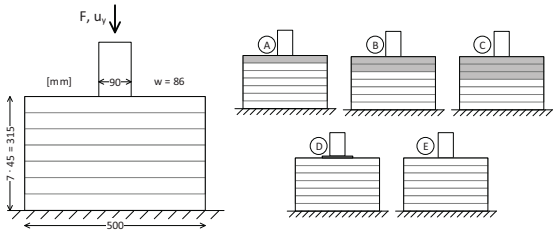

Figure 10: *Geometry and load cases for each setup and illustration of the five different setups, A-C with included CLT-boards, D with a steel plate and E with a pure GLT-beam as a reference.*

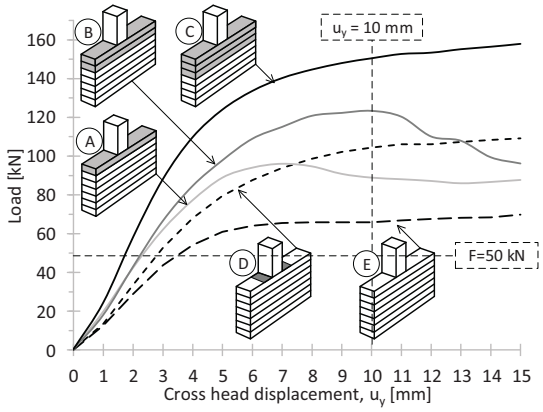

Figure 11: *Average load-displacement curves from experimental tests of 1, 2 and 3 CLT laminations in the beam and GLT beam with and without steel plate.*

Finally the piston displacement u_y at the design load $F_{c.90.d}$= 47 kN is given in the table. The displacement of the reference beam E is almost double that of the beam with three CLT-boards at that load.

For at least one of the specimens in each setup digital image correlation (DIC) was used for taking stereoscopic pictures during the loading event. In Figure 12 strains in vertical direction (ε_y) are shown at a load F = 50 kN and at a piston displacement u_y = 10 mm respectively. The black horizontal lines in the photos of the GLT indicates the centre of each lamella. Note that the scale for the strains are the same in all subfigures. Red colour indicates larger strains and blue is representing small strains and the total span for the scale is $0 \leq \varepsilon_y \leq 0.01$. For each setup a 20 sec film sequence showing the whole load event can be found if the qr-code at the right is followed and there a scale with the strains is included. One result worth noting is the relatively small strains in the CLT-boards. From the photos in the figure this is particularly clear for setup B and C. This is explained by the high stiffness in the CLT-boards achieved by the lamellas oriented in parallel to the load direction.

Table 4: *Stiffness and maximum applied force for the tested setups.*

Setup	k [kN/mm]	F_{max} [kN]	k/k_E	$F_{max}/F_{max.E}$	u_y@ $F_{c.90.d}$ [mm]
A	23.1	96.8	1.35	1.39	2.22

5. CONCLUSIONS

In this paper, three concepts of re-use of cut-offs from CLT are presented.

a) The re-use of cut-offs as REX laminations in CLT production is a smart concept that minimize waste in an economical way.
b) By using finger-jointed CLT-boards as horizontal rails in timber frame buildings, the problems with high local compression perpendicular to the grains and large vertical deformations in multi-storey houses are minimized.
c) The capacity of glulam beams to carry concentrated loads is greatly enhanced by locally integrating CLT-boards as laminations.

EXPERIMENTAL STUDY ON CHARACTERISTIC VALUES OF PARTIAL COMPRESSION PERPENDICULAR TO THE GRAIN OF HARDWOOD WITH EDGE DISTANCE ORTHOGONAL TO THE LONGITUDINAL DIRECTION

Hiroto Suesada[1], Kohta Miyamoto[2]

ABSTRACT: The use of hardwoods for wooden joints is advantageous because of their higher density and superior structural performance compared to softwoods, which are generally used as construction materials in buildings. However, the effects of the dimensions of the hardwood specimens and wood species on the partial compression performance perpendicular to the grain are unclear. In this study, we conducted partial compression tests perpendicular to the grain of hardwoods clarify the effect of edge distance that is orthogonal to the longitudinal direction and wood species on the characteristic values. The tendencies of the relationships between the partial compression performance perpendicular to the grain and the edge distance perpendicular to the grain of hardwoods were found to be similar to those of softwoods. The effect of wood species on characteristic values needs to be examined in more detail.

KEYWORDS: Hardwood, Partial compression perpendicular to the grain, Edge distance in two directions

1 INTRODUCTION

The compression performance of wood perpendicular to the grain was considerably lower than that of wood parallel to the grain. Partial compressive deformation perpendicular to the grain is one of the primary causes of deformation of wooden joints.

In Japan, most planted forests are in the mature and utilisation stages [1]. In addition, the environmental advantages of wooden buildings have led to an increase in the number of mid-rise and large-scale non-residential wooden buildings. These buildings require higher structural performance than low-rise buildings.

Some hardwood species have a higher density and superior compression performance perpendicular to the grain compared with softwoods, which are generally used as construction materials in buildings. Therefore, it is advantageous to utilise such hardwoods in wooden joints. The estimation of the performance of hardwoods is essential for their utilisation as structural materials but not yet for the partial compression performance of hardwoods perpendicular to the grain. Furthermore, the effects of the dimensions of the hardwood specimens and wood species on the partial compression performance perpendicular to the grain is unclear.

Previously, the relationships between the partial compression performance perpendicular to the grain and the edge distance in the longitudinal direction were determined [2]. In this study, partial compression tests perpendicular to the grain were conducted to clarify the effect of the edge distance orthogonal to the longitudinal direction and wood species on the characteristic values.

2 MATERIALS AND METHODS

2.1 TEST SPECIMENS

Table 1 presents the specifications of the test specimens. Eight hardwood species were used as test specimens. Itayakaede (IT, *Acer mono Maxim.*), Udaikamba (UD, *Betula maximowicziana*), and Buna (BN, *Fagus crenata*) are diffuse-porous woods. Shirakashi (SR, *Quercus myrsinifolia*) is radial-porous wood. Kuri (KR, *Castanea crenata*), Keyaki (KY, *Zelkova serrata*), Yachidamo (YC, *Fraxinus mandshurica*), and Mizunara (MZ, *Quercus crispula Blume*) are ring-porous woods.

The height of each sample was fixed at 40 mm. Specimens with three different widths (w) (40, 60 and 80 mm) and two different lengths (l) (40 and 120 mm) were

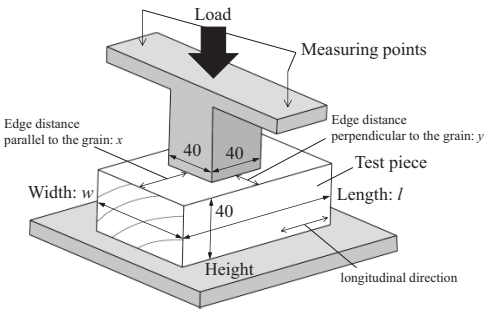

***Figure 1**: Schematic of partial compression test perpendicular to the grain (dimensions in mm)*

***Table 1**: Specification of the test specimens*

wood species	length (mm)	width (mm)	n [a)]	ρ [b, c)] (kg/m^3)	MC [c, d)] (%)
Itayakaede (IT, *Acer mono Maxim.*)	40 / 120	40 / 60 / 80	6	734 ± 32.8	10.9 ± 0.89
Shirakashi (SR, *Quercus myrsinifolia*)	40 / 120	40 / 60 / 80	3	890 ± 59.5	12.6 ± 0.20
Udaikamba (UD, *Betula maximowicziana*)	40 / 120	40 / 60 / 80	4	707 ± 71.9	12.1 ± 0.72
Kuri (KR, *Castanea crenata*)	40 / 120	40 / 60 / 80	6	575 ± 73.7	13.9 ± 0.88
Keyaki (KY, *Zelkova serrata*)	40 / 120	40 / 60 / 80	6	747 ± 67.7	12.2 ± 1.93
Yachidamo (YC, *Fraxinus mandshurica*)	40 / 120	40 / 60 / 80	6	571 ± 80.4	13.3 ± 0.48
Mizunara (MZ, *Quercus crispula Blume*)	40 / 120	40 / 60 / 80	6	732 ± 59.7	12.4 ± 0.91
Buna (BN, *Fagus crenata*)	40 / 120	40 / 60 / 80	6	687 ± 17.8	12.9 ± 0.31

Notes: a) Number of specimens, b) Density, c) The values mean Average ± Standard variation, d) Moisture content

made. Thus, each wood specimen had 6 dimensional specifications, which are indicated by a four-digit number. For example, 4040 represents a width of 40 mm and a length of 40 mm, whereas 6120 represents a width of 60 mm and a length of 120 mm. For each species, six specimens of different widths and lengths were obtained from a single piece of wood in the longitudinal direction.

2.2 COMPRESSION TEST PERPENDICULAR TO THE GRAIN

Figure 1 shows a schematic of the partial compression test perpendicular to the grain. The tests were conducted according to Japanese Industrial Standards (JIS) Z 2101 [3]. Figure 1 shows that the centre of the specimen was loaded with a metal bearing plate with a length and width of 40 mm. Therefore, the edge distances parallel (x) and perpendicular (y) to the grain were represented by $(l-40)/2$ and $(w-40)/2$, respectively. Accordingly, x is 0 mm (4040, 6040, 8040) and 40 mm (4120, 6120, 8120), and y is 0 mm (4040, 4120), 10 mm (6040, 6120) and 20 mm (8040, 8120). When both x and y were 0 mm (4040), the tests were full-area compression tests perpendicular to the grain tests.

A tensile and compression testing machine (MAEKAWA MFG. CO., LTD. A-300-B4) was used for loading.

Vertical displacements of the bearing metal plate were measured at two points using displacement transducers (Tokyo Measuring Instruments Laboratory Co., Ltd., CDP-25), and the average value was considered as the test displacement. The ratio of the displacement to height was considered as the test strain. The load was measured using a testing machine. The load divided by the loading area (1,600 mm^2) was considered as the test stress.

The method of calculating the characteristic values was the same as that used in a previous study [2]. The elastic stiffness (E_e), plastic stiffness (E_p), yield stress (σ_y), and yield strain (ε_y) were calculated from the stress–strain curves. E_e was calculated following Inayama's study [4] and E_p, σ_y and ε_y were calculated following Fujita's study [5].

3 RESULTS AND DISCUSSION

3.1 DIFFERENCE IN STRESS-STRAIN CURVE DUE TO POROUS STRUCTURES

Figure 2 shows examples of stress-strain curves of the compression test perpendicular to the grain for diffuse-porous wood (Itayakaede) and ring-porous wood (Keyaki), each taken from the same piece, for each dimensional specification. In diffuse-porous wood, the stiffness gradually decreases after the yield point. The stiffness decreased more clearly in ring-porous wood than in diffuse-porous wood at the yield point. In the specification without the edge distance (4040), the load increased and decreased repeatedly after the yield point. This behaviour may be due to the sequential failure of vessels in the pore zone of ring-porous wood. The load increase/decrease behaviours were milder for the specifications with edge distance than for those without edge distance. Such behaviour was less apparent for the specifications with an edge distance parallel to the grain (4120, 6120, and 8120). The edge distance is considered to constrain the fracture of the vessels in the pore zone. For the edge distance perpendicular to the grain, shear failure occurred at the edge of the loading area, which may have weakened this effect compared with the edge distance parallel to the grain. The other diffuse-porous and radial-porous wood specimens showed similar trends to the example of diffuse-porous wood, and the other ring-porous wood specimens showed trends similar to those of ring-porous wood.

Notes: a) Elastic stiffness, b) The values mean Average (Standard deviation), c) Plastic stiffness, d) Yield stress, e) Yield strain, size shows dimensional specifications

3.2 RESULTS OF COMPRESSION TESTS

Table 2 shows the mean values and standard deviations of E_e, E_p, σ_y and ε_y. The mean values of E_e, E_p and σ_y were higher for partial compression than for full-area compression for all the species. For the edge distance perpendicular to the grain, the values tended to be higher with increasing edge distance; however, little differences were noted between 6120 and 8120. The mean values of ε_y were higher for specimens without an edge distance parallel to the grain than for those with an edge distance parallel to the grain.

The coefficients of variation for E_e and E_p were 0.49–54.8% and 2.77–245% respectively. E_e for Kuri and Mizunara were particularly high. E_p for Kuri and Yachidamo were particularly high. Ring-porous wood tended to show a higher variation than diffuse- and radial-porous wood. Ring-porous wood is considered more affected by the annual ring angle than diffuse- and radial-porous wood because of the fracture of vessels in the pore zone. There is also the possibility of the influence of an increase/decrease in the load on the stress-strain curve after the yield point.

3.3 RELATIONSHIP BETWEEN THE CHARACTERISTIC VALUES AND DENSITY

Figure 3 shows the relationship between E_e and the density of each specimen. Figure 4 shows the relationship between σ_y and density for each dimensional specification. Figures 3 and 4 represent the regression line calculated for

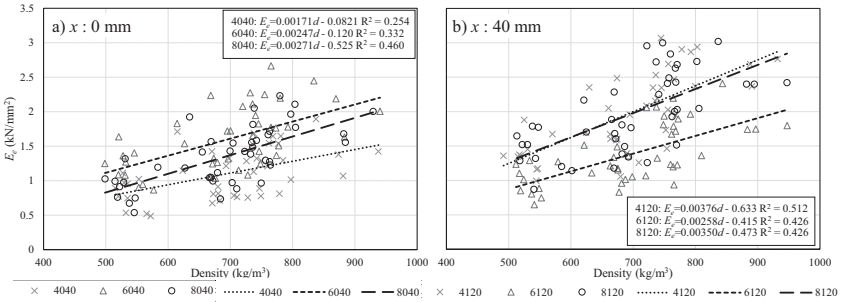

***Figure 3**: Relationship between E_e and density (d) of each specimen.*

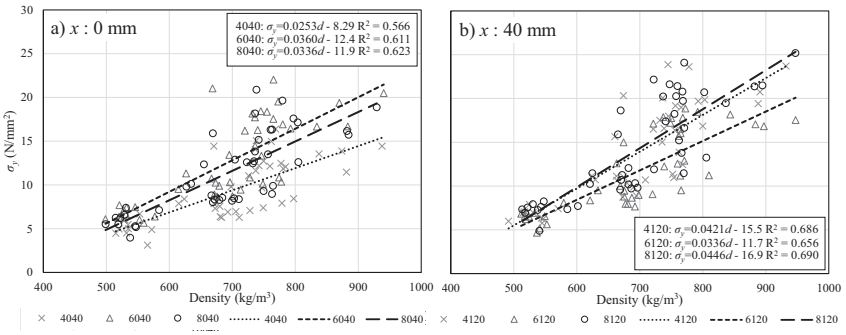

***Figure 4**: Relationship between σ_y and density (d) of each specimen.*

https://doi.org/10.52202/069179-0020

each dimensional specification for the relationships between E_e and density and σ_y and density.

For E_e and σ_y, a significant positive correlation was observed ($p < 0.01$) with density for all dimensional specifications. In both cases, the correlation was stronger in the specifications with edge distance than in those without it. A possible explanation for this is that the effect of factors other than density, such as the annual ring angle, was less affected by the partial compression specifications because the deformation was constrained by the edge distance. For σ_y, the correlation was stronger than that for E_e for all dimensional specifications. The effect of density may have been greater for σ_y than for E_e, while the effects of other factors may have been relatively less.

3.4 EFFECT OF EDGE DISTANCE ON INCREASE RATIOS OF CHARACTERISTIC VALUES

Figure 5 shows the relationship between the increase ratios of E_e and σ_y and the edge distance perpendicular to the grains. The increase ratios of E_e and σ_y are defined as the average of the ratio of the characteristic value of a specimen to that of the full compression specimen without both edge distances being prepared from the same material.

As shown in Figure 5, the increase ratios of E_e and σ_y were higher for the partial compression specimens than for the full compression specimens. Irrespective of the edge distance parallel to the grain (0 mm or 40 mm), the increase ratios of E_e and σ_y tended to increase with increase in the edge distance perpendicular to the grain. In contrast, at an edge distance perpendicular to the grain longer than 10 mm, the increase ratios of E_e and σ_y increased only slightly or remained constant depending on the wood species. It is suggested that the effect of the edge distance parallel to the grain on the improvement in the characteristic values converged. These trends agree with a previous study on softwood reported by Inayama [4].

3.5 DIFFERENCES IN INCREASE RATIONS BY WOOD SPECIESE

As shown in Figure 5, the increase ratios of E_e and σ_y tended to be higher for Shirakashi and Udaikamba and lower for Yachidamo compared to other species. These results suggest that there are differences among the wood species. However, further studies are needed to clarify the effects of the annual ring angles and other factors.

3.6 RELATIONSHIPS BETWEEN CHARACTERISTIC VALUES

Figures 6 and 7 show the relationships between E_e and E_p and σ_y and ε_y, respectively, and indicate that both relationships are significantly positively correlated. However, the relationships between σ_y and ε_y had a smaller correlation coefficient than E_e and E_p and were not strongly correlated. Figure 7 shows that the plots for each tree species fell within certain ranges, and the all ranges appeared to be different from the regression line for all specimens. Therefore, although a positive correlation was observed for all specimens, the relationship may be different for each tree species.

Table 3 summarizes the linear regression equations calculated for each tree species, the dimensional specifications for the relationships between E_e and E_p, σ_y and ε_y, and their coefficients of determination. For the relationship between E_e and E_p, significant positive correlations were found for all tree species and dimensional specifications. Therefore, there is a positive

correlation between elastic stiffness and plastic stiffness in the compression strength of wood perpendicular to the grain, regardless of the wood species and dimensional specifications. For the dimensional specifications, the slope and coefficient of determination of the linear regression equation were the smallest for the full-area compression specification (4040), and each value increased with an increasing edge distance perpendicular to the grain. In addition, they tended to be even larger for specifications with the edge distance parallel to the grain. The slope is because the plastic stiffness is close to zero for the full-area compression specification (4040) and the stiffness increases with increasing the edge distance. The coefficient of determination is due to the constraining effect of the edge distance on the deformation and fracture of the specimens, which reduces the variation between the elastic and plastic stiffnesses. In the relationship between σ_y and ε_y, significant positive correlations were found for each dimensional specification; however, significant negative correlations were found for many wood species. Previous studies on softwoods [4] and hardwoods [2] have shown that for the same species, loading area dimensions and specimen height, relationships between σ_y and ε_y are inversely related. This may also be true for the results of this study, as the relationship is not clear but is close to inversely proportional when the same wood species, loading area dimensions, and specimen height are held constant. However, the relationship between σ_y and ε_y was significantly positively correlated for each dimensional specification. Although the coefficient of determination was smaller than that in the relationship between E_e and E_p, the slope and coefficient of determination in the relationship between σ_y and ε_y were similar to those in the relationship between E_e and E_p. These results suggest that there is a positive correlation between σ_y and ε_y for dimensional specifications regardless of the species.

4 CONCLUSIONS

The aim of this study was to investigate the effect of edge distance orthogonal to the longitudinal direction and wood species on the compression performance of hardwoods perpendicular to the grain.

The results of this study are as follows.

(1) The behaviour of the stress-strain curve after the yield point might differ depending on the porous structure.

(2) With respect to the edge distance parallel to the grain, the variation in the elastic stiffness and yield stress can be

https://doi.org/10.52202/069179-0020

reduced by constraining the deformation and fracture with the edge distance perpendicular to the grain.
(3) The elastic stiffness and yield stress are significantly correlated with density, and specifications with an edge distance perpendicular, parallel, or both to the grain have a stronger correlation than those without it.
(4) The effect of the edge distance perpendicular to the grain on the increase ratio of elastic stiffness and yield stress tends to be similar to that of softwood [4] and may vary between wood species.
(5) The relationships between elastic stiffness and plastic stiffness, yield stress and yield strain tend to be similar to those for softwood.
These results support the conclusions of a previous study in which hardwoods were able to estimate the same degree of denting performance as softwoods [4]. However, some species showed greater variability in their characteristic values, particularly in ring-porous wood. More detailed studies are needed on the effects of different species, especially on the porous structure, and on the effects of the annual ring inclination angle.

COMPARISON BETWEEN ACTUAL AND EQUIVALENT CRACK RESISTANCE R-CURVES FOR TIMBER AND TIMBER BOND UNDER MODE-II FRACTURE

Shaikh Atikur Rahman[1], Mahmud Ashraf[2] Mahbube Subhani[3]

ABSTRACT: This paper focuses on Mode-II fracture behaviour of solid timber and timber adhesive bond using end notched flexure (ENF) test. Mode-II strain energy release rates are obtained using three different data reduction methods known as compliance calibration (CC), direct beam theory (DBT) and corrected beam theory (CBT) that require actual crack length monitoring. At the same time, the compliance-based beam method (CBBM) is evaluated without the need for actual crack length measurements by considering an equivalent crack length. In both cases, the Mode-II strain energy release rates (G_{II}) obtained for the timber adhesive bond interface was found to be approximately 20% higher compared to timber fracture. The strain energy release rates calculated from actual crack and equivalent crack length values show similar trends in resistance curves. However, initial strain energy release rate (G_{II0}) and critical strain energy rate (G_{IIC}) for Mode-II significantly varies in actual crack methods than the equivalent crack method.

1 INTRODUCTION

Currently, all design guidelines for timber and engineered timber products (ETPs) are based on the maximum elastic stress and stiffness criteria for strength analysis. However, it fails to attain the material's post-elastic plastic behaviour and localised failure owing to defects like cracks or delamination [1]. In the stress/stiffness method, the structural component is considered as a continuous homogenous material, which is not relevant to naturally grown materials such as timber. Those defects are often considered using a strength reduction factor in a conventional stress/stiffness design technique, which is very conservative for real-life structure.

To overcome such limitations, fracture mechanics-based design approach in timber structure could be a rational alternative. Fracture mechanics is often utilised in material testing on samples with well-defined characteristics [2]. It is, however, rarely employed in engineering design with structural elements of arbitrary shape. Fracture characterisation of softwood timber is essential, especially for the design of various timber joints, notches, holes, and connections. Timber failure can cause catastrophe as they lead to highly brittle failure produced by tension and shear acting perpendicular to grain direction of timber [1, 3, 4].

Material fracture characterisation is therefore vital in giving accurate fracture characteristics such as the critical strain energy release rate, $G_{I/IIc}$, which is defined as the material's resistance to crack propagation. Furthermore, using experimental $G_{I/IIc}$, the current design approach for brittle splitting failure prediction of connections loaded perpendicular to the grain (critical failure mode in timber structures) defined in Eurocode 5 (EC5). A new fracture based design approach is currently used in a few design standards only for certain connection designs [3]. To ensure safe and effective application of timber and ETPs, a comprehensive fracture-based design approach is necessary. Comprehensive knowledge of the fracture properties of solid timber and timber adhesive bond is a prerequisite to develop fracture-based design approach. Fracture behaviour of timber has recently gained momentum and fracture mechanics based numerical models has been shown to provide a superior mechanical rupture description than traditional strength-based techniques. The ability to consider the material non-linearity beyond the fracture tip, the limited stress capacity, and the material's non-linear stress-deformation performance at the crack tip can be address by non-liner fracture mechanics (NLFM) [3]. This may be accomplished by a variety of methods, the most straightforward of which is to characterise the material's fracture behaviour using

crack resistance R-curve or stress deformation relation that incorporates material softening, generally referred to as σ-w curve. Continuum damage mechanics (CDM) or cohesive zone (CZM) based material modelling in finite element (FE) simulation have been shown to capture fracture behaviour of timber [5].

Two methods are typically used to identify the material fracture resistance, i.e., the stress intensity factor approach and the strain energy-based approach. The energy-based technique is used in this study since it is more suited to orthotropic materials like timber, and the derivation of the main equation is less dependent on sample geometry [3]. Timber is strong if load is applied in parallel to grain direction while very weak against perpendicular to grain loading. Timber parallel longitudinal fibre is strong and acts like reinforcement against any displacement. Thus, Parallel loading to the grain direction normally involves with longitudinal fibre breaking in LR and LT fracture plane which has significantly higher crack resistance than any other plane of timber. On the other hand, fibre has lots of gaps, faults and has less crack resistance while crack propagating along longitudinal direction in RL and TL plane. Therefore, crack plane RL and TL is one of the weakest crack planes of timber and widely seen in end notch, circular, rectangular holes and various timber connections [6]. Additionally, adhesives are used in most of the engineered timber products (ETPs) and timber connections. Failure of timber adhesive bond can be highly brittle and catastrophic like timber fracture due to perpendicular loading. Due to the softness of timber material, timber bond delamination shows combination of bond fracture and timber splitting along the longitudinal direction. Therefore, it is important to identify pure bond delamination resistance and timber resistance along the bond interface, which is usually the longitudinal direction of timber.

This paper presents Mode-II fracture behaviour of timber and timber adhesive bond using end notched flexure (ENF) test. In the last decades, methods to evaluate fracture energies (strain energy release rates in Mode-II (G_{II})) have been developed using simple analytical methods as well as complex compliance-based beam methods (CBBM) [1]. Crack resistance curves, commonly known as R-curves, are generated from the evolution of fracture energy release rate in relation to the crack length. Due to the complexities of monitoring actual crack length, an equivalent crack method is widely used for different modes of fracture tests. It is worth noting that fracture theories were mostly developed for fibre reinforced composites and there are significant gaps in their application for natural bio composite materials such as timber and ETP. Lack of specific guidelines and standards on timber fracture tests, R-curves generated only from the load-displacement behaviour may sometime lead to wrong projection of strain energy release rate due to inconsistent specimen size and testing procedure. Equivalent crack method has advantage for ENF test, but it also requires proper validation from actual crack length monitoring during test. Using digital image corelation (DIC) system in crack detection and crack length measurement will remove complexities of traditional crack identification techniques and increase the accuracy and robustness of actual crack method. This study presents a detailed comparison between actual and equivalent crack resistance R-curves to highlight the potential as well as the challenges associated with the equivalent crack method. This study also compare the Mode-II fracture behaviour of solid timber and timber adhesive bond.

2 MATERIALS AND METHODS

Samples required for ENF testing were produced from the Australian softwood timber species Radiata pine. The prepared timber specimens were maintained in a chamber at 20°C and 65% relative humidity until the moisture content reached equilibrium. Before the test, the density of each specimen was tested, and the average density was determined to be 580(±44) kg/m3. The average moisture content for all samples was 10.8(±0.94) percent. Figure 1 depicts a schematic of an ENF sample for solid timber. ENF timber samples have cross-sections of 20 mm×20 mm, and 500 mm long. The span length was kept at 460 mm to ensure smooth and steady fracture propagation, as previously reported by De Moura, et al. [7]. Carlsson, et al. [8] proposed that the initial fracture length (a_0) should be more than 0.7L to enable steady crack propagation. The first crack length (a_0) was taken as 162 mm long, greater than 0.7L, where L is half the specimen span length (= 230 mm). It is difficult to maintain smooth straight initial crack line using handheld saw blade and table saw machine does not have blades thinner than 0.80 mm. Therefore, to keep the initial notch width as small as feasible, a 162 mm notch was cut using a 0.80 mm blade of a table saw machine. The following notch was then cut using a handheld saw blade, and the width of the last 20 mm notch was kept 0.50 mm. Timber adhesive bond samples were made by bonding two different timber boards with 20 mm width and 10 mm height to ensure the same cross section (20 mm×20 mm) as solid timber samples. Glue specifications were used to maintain the bond curing time, moisture content, and relative humidity.

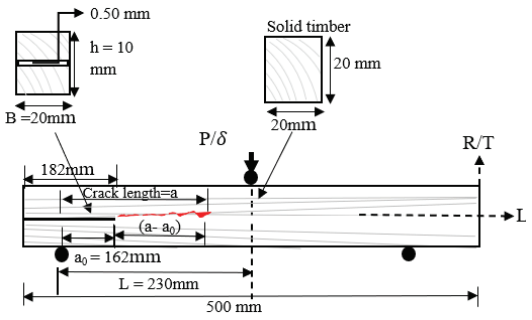

Figure 1: *Geometric dimensions and set-up of ENF solid timber specimen.*

Polyurethane based adhesive HB S309 PURBOND was used for timber adhesive bond. A schematic overview

https://doi.org/10.52202/069179-0021

and test set-up of the ENF test is shown in Figure 2. The timber adhesive bond specimen has same dimension as solid timber of 500 (l) × 20 (b) ×20 (t) mm. A thin plastic tape with a thickness of 0.1 mm was placed between two timber beam joints along 182 mm length to make an initial notch. This thin plastic produced a 0.1 mm gap at the initial notch, and remaining length of the sample were bonded properly. This method was implemented to protect timber fibres from damaging due to mechanical cutting.

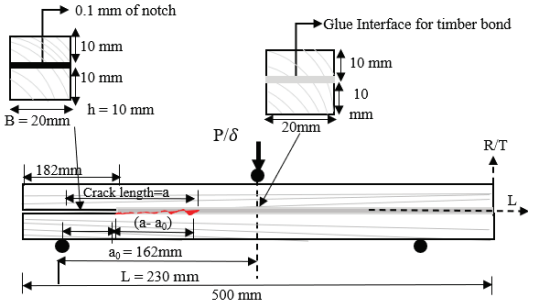

Figure 2: *Schematic overview and set-up of ENF timber adhesive bond test*

The test was conducted using a 10 KN Instron load frame with a displacement control of 5 mm/min. All the test was captured by the digital image corelation (DIC) to identify the crack and monitor the crack propagation length. DIC was calibrated and verified prior to test commencement with known displacement from Instron load frame. The Instron load frame and DIC system were ensured to have the same frequency so that both data can merge. The displacement (δ) was measured at the load application point and a continuous crack growth length (a) was measured by DIC. The testing set-up was identical in timber and timber bond fracture tests.

2.1 DATA REDUCTION METHODS

A bending load (p) is applied at the mid span for ENF test, causing Mode-II fracture propagation over the length of the test (L-a_0). Instron load frame was used to determine the applied load (p) and displacement (δ) at the loading point while continuous crack propagation length (a-a_0) is obtained by DIC. The basic formula to calculate strain energy release rate was introduce by Irwin-Kies [2]. The formula is based on compliance C, which is determined from load and displacement, as shown in Eq. (1)

$$G_{II} = \frac{P^2}{2B}\frac{dC}{da} \qquad (1)$$

Several data reduction schemes exist to calculate the evolution of Mode-II strain energy release rates [9]. Mode-II data reduction techniques are classified into two types: actual crack identification methods and equivalent crack methods. ASTM-D7905 [10] (Standard test method for fibre-reinforced polymer) suggested to use compliance calibration (CC), direct beam theory (DBT) and corrected beam theory (CBT) method based on actual crack monitoring. The accuracy and robustness of those methods largely depend on precision in monitoring actual crack length. Several investigations were carried out in the absence of a rigors technique for measuring crack length, resulting in a broad range of timber fracture energy[8, 11]. With the help of DIC system crack identification and monitoring can be more appealing than conventional methods. According to the compliance calibration (CC) method, strain energy release rate is determined using Eq (2).

$$G_{IIc} = \frac{3ma^2P^2}{2B} \qquad (2)$$

where m is the coefficient of CC obtained from the slope of compliance (C) verses crack length cube (a^3); B is the specimen width. Therefore, CC is not only dependent on load and crack length but also rely on experimental calibration by compliance. A simplified beam theory known as direct beam theory (DBT) evaluates Mode-II fracture energy directly from load, displacement and other constant geometric values. However, DBT does not implement any experimental data reduction scheme. The load head displacement from ENF test is comparatively higher than other testing method like compact shear test (CS) and tapered end notched flexure TENF [7]. Due to those issues DBT may overestimate the fracture energy than other method. DBT is also based on actual crack monitoring. DBT method can be expressed as shown in Eq (3):

$$G_{IIc} = \frac{9a^2P\delta}{2B(2L^3 + 3a^3)} \qquad (3)$$

To address the limitation of DBT, a correction factor of introducing flexural modulus is added to the fracture energy calculation. This corrected method is known as corrected beam theory (CBT) also a classical method based on actual crack monitoring [9]. In CBT, G_{IIC} is determined from Eq 4.

$$G_{IIc} = \frac{9a^2P^2}{2B^2h^3E_f} \qquad (4)$$

where E_f is calculated using Eq (5) and initial compliance (C_0) determined from the ratio of displacement and load.

$$E_f = \frac{L^3}{4Bh^3C_0} \qquad (5)$$

All aforementioned methods (CC, DBT, CBT) depend on accurate measurement of the actual crack length during test. The compliance-based beam method (CBBM) [12], which is based on Timoshenko beam theory, can predict G_{II} using the load-displacement data [9] without actual crack measurements. CBBM determines G_{II} following Eq (6) to (10).

$$G_{IIc} = \frac{9P^2{a_{eq}}^2}{16B^2h^3E_f} \qquad (6)$$

$$C = \frac{3a^3 + 2L^3}{8Bh^3E_{f(CBBM)}} + \frac{3L}{10BhG_{LR}} \qquad (7)$$

where $E_{f(CBBM)}$ is the flexural modulus; $I = 8Bh3$ /12 is the second moment of area and G_{LR} is the shear modulus in longitudinal-radial plane. Initial elastic compliance C_0 and initial crack length a_0 are used to calculate corrected

https://doi.org/10.52202/069179-0021

flexure modulus $E_{f(CBBM)}$ using Equation (8)

$$E_{f(CBBM)} = \frac{3a_0^3 + 2L^3}{12I}\left(C_0 - \frac{3L}{5G_{LR}A}\right)^{-1} \quad (8)$$

To get an equivalent crack length at each point, the experimental compliance C should be replaced by a corrected compliance C_C. An equivalent crack length a_{eq} and the corrected compliance C_C can be determined using Equation (9):

$$a_{eq} = \left[\frac{C_C}{C_{0C}}a_0^3 + \frac{2}{3}\left(\frac{C_C}{C_{0C}} - 1\right)L^3\right]^{1/3} \quad (9)$$

Where $C_C = C - \frac{3L}{5AG_{LR}}$ and $C_{0C} = C_0 - \frac{3L}{5AG_{LR}}$

Once a_{eq} is determined, equation (9) can be modified as G_{II} using Equation (10)

$$G_{II} = \frac{9P^2}{16B^2h^3E_f}\left[\frac{C_C}{C_{0C}}a_0^3 + \frac{2}{3}\left(\frac{C_C}{C_{0C}} - 1\right)L^3\right]^{2/3} \quad (10)$$

CBBM also depends on of the shear modulus in the longitudinal-radial plane G_{LR} but its effect in G_{II} calculation has been reported to be insignificant [13].

3 RESULTS AND DISCUSSION

Figures 3 and 4 illustrate the load versus displacement curves of ENF Mode-II fracture tests on solid timber and timber adhesive bond. The elastic part of the load-displacement curve is linear and has a constant initial slope prior to development of fracture. However, immediately after fracture initiation, the load curve drops to a lower magnitude for both solid timber and timber adhesive bond.

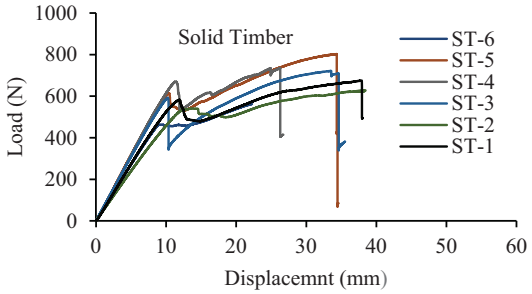

Figure 3: *Load vs Displacement from ENF test on sawn timber*

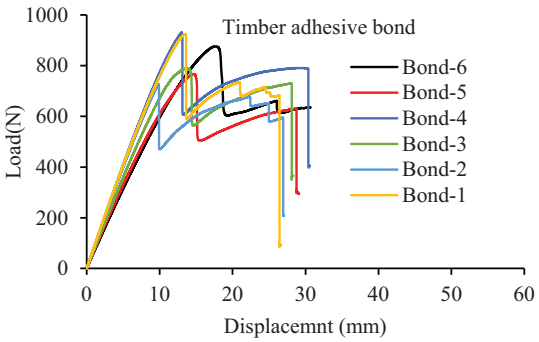

Figure 4: *Load vs Displacement from ENF on timber adhesive bond*

The post-elastic component of the load-displacement response was highly non-linear and showed variations between samples. Most critically, the post elastic section of the load-displacement curve did not follow linear elastic fracture mechanics (LEFM). To address the Mode-II fracture behaviour of solid timber and timber adhesive bond, advanced nonlinear fracture mechanics-based FEM analysis techniques such as cohesive zone model (CZM) or continuum damaged mechanics (CDM) would be required. It is also obvious from the load-displacement response that, after crack initiation, the timber and timber adhesive bond displayed strain hardening response, which finally led to ductile failure showing better structural response when compared with Mode-I fractures observed in timber [14]. The in-plane shear fracture in RL and TL plane showed slightly ductile failure than tensile fracture. In contrast to solid timber, timber adhesive bond fracture demonstrated higher stiffness and strength.

Crack propagation due to Mode-II loading is typically known as in-plane shear crack. Pure Mode-II shear crack developed due to horizontal movement of two cracked surfaces is characterised by a very thin crack line, which is extremely difficult to visualise using naked eye. The current study, hence, used DIC to identify and monitor exact crack length. Mode-II ENF sample of both solid timber and timber-adhesive bond developed ultra-thin cracks as shown in Figure 5. It is worth noting that unlike Mode-I fracture due to direct tension, the timber and timber adhesive fracture process and crack growth in Mode II was more gradual and consistent.

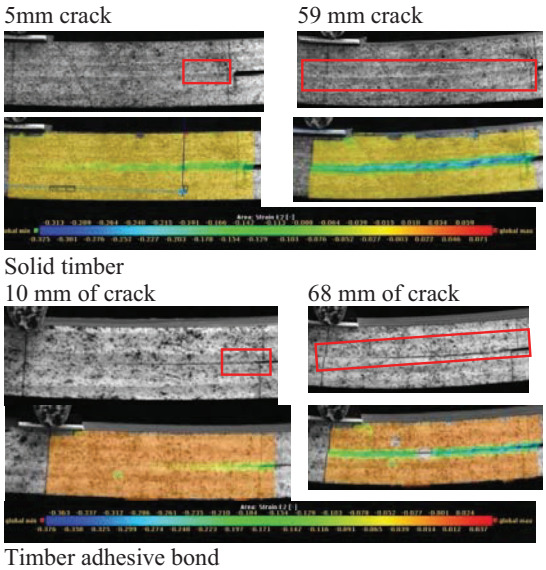

Figure 5: *Illustration of crack development in solid timber and timber adhesive bond*

3.1 CRACK RESISTANCE R-CURVE

The development of the strain energy release rate (G_{II}) as a function of the crack length is commonly known as R-curve. The area immediately around the crack tip, where

https://doi.org/10.52202/069179-0021

different toughening and softening processes due to many microcracks, cracks-branching, and fibre-bridging, occur, is known as the fracture process zone (FPZ). These non-linear events should be included in R-curve as they have obvious impact on how crack propagates through timber and timber adhesive bond. Since the critical fracture energy (G_c) is determined by the plateau value of these curves, the R-curve is a valuable tool for quantifying the critical fracture energy in the effect of the FPZ. Shape and pattern of R-curve depends on the material's crack resisatnce property. Material crack resistance can have three different shapes as rising R-curve, flat R-curve and falling R-curve [11]. For example Mode-I crack resistance R-curve for timber in RL plane show falling R-curve [14]. A simplified scematic of those three type of R-curves are illustrated in Figure 6. The shape and pattern of R-curve is a important material behaviour to catagorise the type of structural failure due to fracture. The material having falling R-curve (where fracture energy gradually or suddenly decrease with the increase of crack length) causes more catstropic and brittle failure of the structure. With a rising R cuve, material's crack resistance increases after the crack initiation or propagation to a point when G_c is greater than G_0. The specific plane of a maerial with rising R-curve will offer more ductile fracture behaviour than the plane with a falling R-curve.

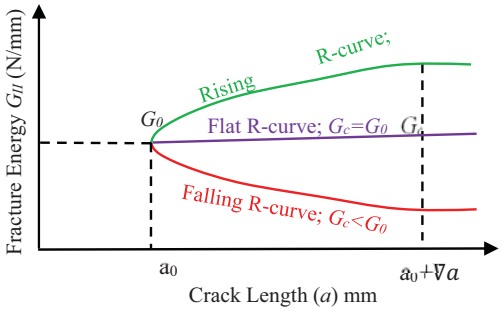

Figure 6: *Schematic of different R- curve patterns*

To develop crack resistance R-curve for solid timber and timber adhesive bond, all data reduction methods including actual crack method and equivalent crack method were applied. A typical comparison among all data reduction methods for solid timber and timber adhesive bond are shown in Figure 7 and Figure 8. The shape of the R-curve for both solid timber and timber adhesive bond are rising, i.e. crack resistance increase as the crack length propagates showing ductile failure. The governing equation of fracture energy (G_{II}) clearly depends on load, displacement, and corresponding crack length, and hence, hardening or softening responses of load-displacement curve are directly reflected in the corresponding R-curve.

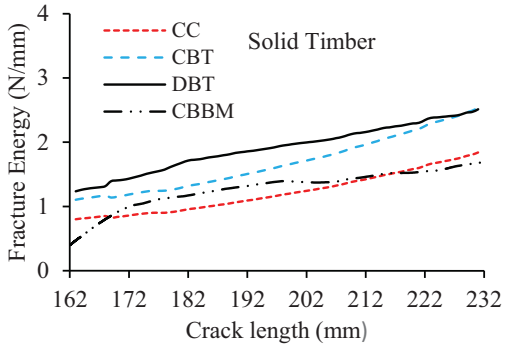

Figure 7: *R-curve for solid timber*

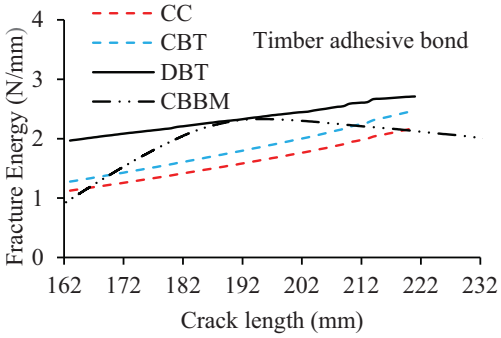

Figure 8: *R-curve for timber adhesive bond*

3.2 COMPARISON BETWEEN ACTUAL AND EQUIVALENT R-CURVE

R-curves were developed following actual crack methods as CC, CBT and DBT, and all three methods showed similar trends as shown in Figure 7 and Figure 8. However, DBT overestimate the fracture energy than other methods. DBT was simplified beam theory directly formed from load and load head displacement. It is also important to note that DBT does not implement any data reduction scheme which cause wrong prediction of fracture energy. Compliance calibration (CC) and corrected beam theory (CBT) showed well prediction of Mode-II fracture energy, although CBT prediction is higher than CC. In contrast, the fracture energy at crack initiation from CBBM is much lower than those obtained from CC, DBT and CBT. This raises a fundamental issue of identifying crack initiation point for the equivalent crack method. It is worth noting that in Figure 8, the actual crack length from (CC, DBT and CBT) culminated at 222 mm, but the equivalent crack from CBBM goes to the full length of 232 mm as the equivalent crack method cannot differentiate whether the crack was developed due to fracture or specimen damaged due to other material issues such as natural defects, and faulty notch width. In equivalent crack method, fracture energy release rate (G_{II}) is only calculated from load and displacement values, and hence validation with actual crack length measurement is essential. Despite some limitations and shortcomings,

https://doi.org/10.52202/069179-0021

CBBM remarkably produced consistent and stable R-curve after the crack initiation. CBBM produced excellent plateau shape in R-curve which signifies the stable energy release rate, known as critical strain energy release rate. The advantages of using CBBM are obvious as the technique does not require any sophisticated equipment such as travelling microscope and DIC system. The critical fracture energy determined using CBBM technique may be used in advanced structural analysis once the fundamental behaviour of the material is validated against classical techniques, i.e., CC/CBT. A comparison of G_{II} obtained from three different data reduction methods for solid timber and timber adhesive bond are summarised in Table 1 and Table 2. Considering the results obtained from six identical solid timber samples, the average fracture energy (G_{II}) from CC, CBT and CBBM are 1.32 N/mm, 1.41 N/mm, and 1.20 N/mm respectively. CBT produce 6.81% higher fracture energy than CC and 17.5% higher than CBBM.

Table 1: *ENF test result on Solid timber (ST)*

Test	Max Load (*N*)	Actual crack monitoring		Equivalent crack method
		CC (*N/mm*) (G_{IIc})	CBT (*N/mm*) (G_{IIc})	CBBM (*N/mm*) (G_{IIc})
ST-1	594.90	1.26	1.34	1.28
ST-2	539.84	1.21	1.30	1.32
ST-3	588.23	1.24	1.34	1.20
ST-4	528.62	1.18	1.27	1.04
ST-5	669.31	1.54	1.63	1.27
ST-6	608.90	1.50	1.59	1.07
Mean	**588.3**	**1.32**	**1.41**	**1.20**
COV%	8	11	11	9

The average Mode-II fracture energy for timber adhesive bond using CC, CBT and CBBM are 1.56N/mm, 1.69N/mm and 1.72N/mm individually. For timber adhesive bond equivalent crack method (CBBM) produced higher fracture energy than CC and CBT. During the crack development process, timber-adhesive bonded specimens experienced higher load than those for solid timber samples (as shown in Figure 3 and Figure 4) resulting in higher compliance (C_0 and C), which eventually contribute to flexural modulus (E_f) and fracture energy (G_{II}) (see the Eq(7-(10).

Table 2: *ENF test results on Timber adhesive bond*

Test	Max Load (*N*)	Actual crack monitoring		Equivalent crack method
		CC (*N/mm*) (G_{IIc})	CBT (*N/mm*) (G_{IIc})	CBBM (*N/mm*) (G_{IIc})
Bond-1	922.01	1.50	1.54	1.83
Bond-2	719.62	1.50	1.69	1.05
Bond-3	787.82	1.68	1.79	1.80
Bond-4	926.34	1.91	2.00	2.00
Bond-5	762.09	1.26	1.38	1.56
Bond-6	875.21	1.56	1.79	2.12
Mean	**832.1**	**1.56**	**1.69**	**1.72**
CV%	10	13	12	22

3.3 COMPARISON BETWEEN SOLID TIMBER AND TIMBER ADHESIVE BOND CRACK RESISTANCE

Results shown in Table 1 and Table 2 indicates that timber-adhesive bond would require more energy to fracture when compared to an equivalent sawn timber. With the same testing configurations, average crack initiation load was almost 42% high in timber bond than that for solid timber, and fracture energy from CC method was 18% high in timber bond than solid timber. An overall response of R-curve for all timber and timber-adhesive bond specimens obtained from CC (as a representative classical method) and CBBM are shown in Figure 9-Figure 12. Crack resistance R-curves for solid timber and timber adhesive bond followed rising R-curve. However, CBBM method for timber adhesive bond showed slightly flat curve after a significant length of crack propagation.

4 DISCUSSION

This paper put emphasis on quantifying crack resistance of solid timber and timber adhesive bond under Mode-II fracture using two different techniques, i.e., actual crack method and equivalent crack method. A comparison shown in Table 3 were conducted between Mode-I and Mode-II fracture energy values for various timber species (results in bold are taken from the current study). Mode-II fracture energy for radiata pine was found to be 1.32 N/mm, which is consistent with other Mode II energy levels published in the literature.

Mode-I fracture energy values [5, 12-14] for radiata pine and other species are also shown in Table 3, which shows that Mode-II fracture energy of radiata pine is almost three time higher than its Mode-I fracture energy. This implies that that in case of mixed mode loading, timber structure will be vulnerable to Mode-I cracking. However, in cases where in-plane shear is dominant such as various holes in timber beams for service lines and in various joints, Mode II failure will trigger eventually splitting failure. Since that Mode II fracture in timber and timber adhesive bonding is more ductile than Mode I failure, a combined failure would be structurally preferable to the more catastrophic Mode I failure alone. A typical comparison between Mode-I and Mode-II R-curves is shown in Figure 13, in which R-curve for Mode-I is taken from [14]. Figure 13 clearly demonstrates the distinct difference in R-curves between Mode II and Mode I, with the former gradually rising in contrast to the latter showing a plateau as crack propagates.

This comparison reiterates the fact that Mode II timber failure shows resistance to cracking and is more ductile than Mode I failure. Additionally, timber fracture energy is compared with those of carbon fiber/epoxy composite laminates in Table 3. It is interesting to see that despite being a natural fibre, timber's resistance to fracture in Mode II is only 35% less than that of carbon fiber/epoxy composite [15].

***Table 3:** Comparison of energy with different material and different timber species*

Mode-I Fracture Species	G_{Ic} (N/mm)	Mode-II Fracture Species	G_{IIc}(N/mm)
Radiata pine[14]	0.48	**Radiata pine**	**1.20-1.41**
Timber adhesive bond[16]	0.48	**Timber adhesive bond**	**1.56-1.72**
spruce[6]	0.30	Eucalyptus globulus[17]	1.54
European beech[6]	0.46	Radiata pine[18]	1.27
CF/EP composite[15]	0.68	CF/EP composite [15]	1.92

This study also examined the difference in fracture behaviour between timber fracture and glue delamination. A thin plastic tape with 0.1 mm thickness was used in ENF bond samples which produced pure bond delamination along the glue line. Although solid timber and timber adhesive bond indicated similar behaviour, timber adhesive bond showed higher stiffness, strength but was less ductile and less stable than solid timber; this clearly highlights the importance of recognition of glue lamination in engineered timber structures.

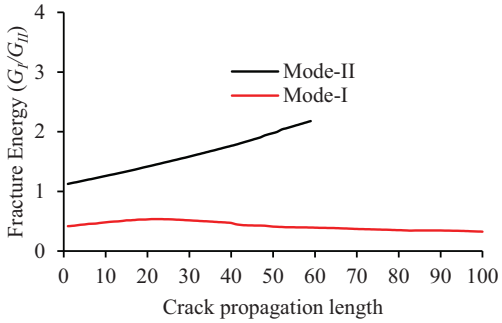

***Figure 13**: R-curves of timber in Mode-I and Mode-II*

https://doi.org/10.52202/069179-0021

In practice, however, glue delamination in softwood timber-adhesive joints is often ignored in both numerical and theoretical analysis of timber structures. Ignoring the glue delamination behaviour in engineered timber products may result in an incorrect prediction of resistance. Fracture properties presented in the current study should be useful in developing reliable numerical models for timber and ETPs such as cross-laminated timber (CLT), glue laminated timber (GLT), glulam etc.

5 CONCLUSION

The current research presents Mode II fracture behaviour of solid timber and timber adhesive bond utilising different data reduction strategies that are based on actual as well as equivalent crack length. In terms of Mode-II crack resistance R-curves, there were notable variations between the real crack method and the equivalent crack method.

Compliance calibration (CC) and corrected beam theory (CBT) methods produced reliable results for Mode-II fracture energy. While DBT fails to offer superior outcomes on Mode-II fracture energy. The equivalent crack method CBBM method showed outstanding response of crack resistance R-curve after crack initiation. However, CBBM suffered to identify the reliable fracture energy at crack initiation point.

A realistic comparison of Mode-II fracture properties between timber and timber adhesive bond were executed. Comparison result shows timber adhesive bond require greater fracture energy to initiate crack in bond line than solid timber. A new technique of creating initial notch without cutting or damaging timber fibre were introduce which produce pure glue delamination and guaranteed stable crack propagation across the glue line.

Digital image correlation (DIC) has been utilised effectively in timber fracture identification and crack length monitoring. Outputs from DIC could be important for cohesive zone modelling and continuum damaged based material modelling to evaluate timber and timber adhesive bond fracture. Finite element models, in conjunction with experimental findings, will give a strong solution for a wide range of difficult circumstances in wood joints and connections.

MODE I TESTS OF NORWAY SPRUCE USING SEN-TPB: DETAILED ANALYSIS OF THE CRACK LENGTH DETERMINED USING OPTICAL METHOD

Martin Hataj[1], Jiří Kunecký[2], Michal Kloiber[3]

ABSTRACT: The paper deals with characterization of fracture properties of Norway spruce using SEN-TPB test. Although the matter is not new, methods of processing the results are relatively recent. The article focuses on determination of crack length using DIC, however, the core of the work is the algorithm which determines the crack length based on the correlated point data. Results of optical measurement are compared to compliance-based analytical formulas. Altogether 18 experiments in radial orientation have been made. Samples used for determination of the strain energy release rate were 60 mm in width and 120 mm in height. Wider specimens have been used to employ the orientation of anatomical directions of the tested timber. Two cameras were used to track cracks on both sides. The algorithm works well, although interesting questions arise, especially when we look at the crack length determination algorithm and its failure criteria.

KEYWORDS: SEN-TPB, Norway spruce, digital image correlation, strain energy release rate, crack length

1 INTRODUCTION

Energy-based methods, especially cohesive zone modelling or LEFM provide us with solutions for problems, which are problematic to solve using standard stress-based approaches. Such methods are crucially dependent on proper material properties characterization, especially strain energy release rate [1]. This quantity is, however, highly dependent on mode (or combination of modes) under which the material is loaded. This article deals with mode I, as it is the most common and easiest one to perform. There is a lot of literature about mode I testing and Norway spruce (as a typical softwood) which is also an advantage, since one can easily compare the results to the previously published values. In all quasi-brittle materials, including timber, there exists some kind of size effect [2], which has to be taken into account. That is also the reason why authors did not choose narrow and rather low sample size used in the previously published works [3,4]. Of course, for proper size effect description there is a need of many more experiments and configurations, nevertheless, just repetition of what has been done was not preferred. Also, it is clear that the orientation of anatomical directions of wood is important. The article shows result of radial direction of timber.

Digital image correlation is a method, which is highly suitable to study timber engineering problems, since relatively low values of stiffness of wood allows for good precision of results. Its drawbacks are, of course, that the abundant number of data have to be understood and reinterpreted. This was the most important part of the work, how to get the crack length using experimental data only. Although in the literature there exists a plethora of algorithms [7-9], there is missing an easy criterion to recognize the presence of a crack. Since we see in optical solution relative distance or deformation of two points, it is relatively tricky to say the threshold value to be used to evaluate the crack length properly.

The strain energy release rate is a quantity, which is usually computed using one of the compliance-based methods. Its advantage is that is does not require complicated tracking of crack length. In the literature e.g. Dourado et al. [1,3], the processing of the data is based on compliance change of the whole specimen, which looks robust, however, it has to be taken into account, that the procedure itself is not purely experimental, since it incorporates also an analytical model, which needs material properties to be inserted and which are only assessed using the initial compliance, which is often tricky due to nonlinearities present in the beginning of the experiment. Another question arises, that the algorithm uses complicated computation of equivalent crack length, which one is complicated to understand and which has to be solved numerically. Last, there is a coefficient k representing the influence of SRR width, which is based on a separate numerical model, thus producing values, which are not directly related to the measured values. Although all criticisms are possible, still it is very robust method.

During processing the data and the results the authors have noticed, that the processing of the data is not just a research task, but that it can be educational not only for the authors themselves, but that it is a nice example to help understand the complicated nature of fracture mechanics and eqLEFM especially [2, 6]. Such an approach, where all nonlinear behavior is directly related to a virtual equivalent crack is the simplification, which allows to construct a R-curve and makes understandable the complicated phenomena appearing near crack tip, mainly micro-cracking and fiber-bridging, but also plasticity etc. All the nonlinearities are present in the optical measurement.

2 METHODS

2.1 Samples

The work followed the methods well described in [3], called SEN-TPB, which is basically a three-point bending with glued-in (PVA based dispersions of one-component adhesive) middle part (see Figure 1), where the orientation of grain is rotated 90° to the original one. Dimensions of the samples were chosen 60 mm width and 120 mm height, length 840 mm. In this scale we have already the problem of annual rings, which have slightly rounded shape. This problem can add additional noise to the data. The studied timber was dried using a special protocol in order to simulate conditions present in construction timber: the green wood dried for three months in the forest after harvest and later dried artificially for 14 days to reach the final MC of 12% abs. This could be the way how to let the internal stresses induced by drying at a level commonly found in standard structural timber. The density of the specimens was measured in the range between 429 and 529 kg/m^3 with an average value of 477 kg/m^3.

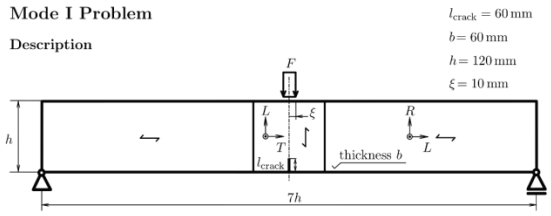

Figure 1: *Description of SEN-TPB test used in the article*

2.2 Loading

The force application was made using a steel plate to spread the loading and avoid shear loading due to misalignment; the supports were made using steel plates and valves to assure free move and omit embedment. When testing a component, usually in the first loading stage one experiences few peaks due to loading all the possible interfaces which are present. This actually happened also here and that was the reason to use curve fitting to the measured force. The test was driven using displacement control, this is important to understand the R-curve. The loading speed was chosen to cause damage in 8-10 minutes.

During the load test, the universal testing machine Galdabini Quasar 100 was used, equipped with a load cell with a range of 10 kN. The outputs from the test machine were processed by the Labtest test software. Furthermore, the DEWE2602 measuring center was used, which is designed to measure the static and dynamic behavior of monitored objects. The microcomputer built into the central unit automatically balances the connected sensors, calibrates the amplifier, and operates the individual measured points in the measurement mode. For each sensor, its constant K is entered, so that the measured values are then directly reported in the exact physical units of the monitored quantities. During the described test, the control panel was controlled by a computer and the DeweSoft program. For all samples, the load value of the joint and the corresponding deflection and path during the initiation and opening of the crack were monitored. Deflection and path during crack initiation and opening were measured by inductive LVDT sensors Micro-epsilon, type DTA-5G-CA throughout the duration of the load test, located on both sides of the test specimen. The average value of these LVDT sensors was used to evaluate the data.

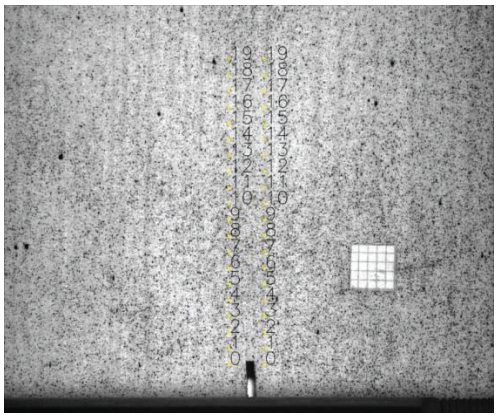

Figure 2: *20 points whose relative displacement was used as an input to the algorithm*

2.3 Compliance-based evaluation

Results were evaluated according to Dourado et al. [3]:

$$E_{Tf} = \left(\frac{L_2^3 - L_1^3}{bH^3} + \frac{L^3 - L_2^3}{b(H - ka_0)^3}\right)\left(\frac{C_0}{2} - \frac{L_1^3}{E_L bH^3}\right)^{-1} \quad (1)$$

where E_{Tf} = corrected value of the flexural modulus, L_1 = lateral arm length (distance between support and nearest glued surface, L_2 = distance between middle of span and support minus side of rectangular SRR – stress relief region (ka), L = distance between middle of span and support, C_0 = initial value of corresponding measured specimen compliance; b = specimen width, H = specimen hight, k = non-dimensional parameter (authors used k = 0,86), a_0 = initial value of the crack length, E_L = the Young's modulus on the longitudinal direction.

https://doi.org/10.52202/069179-0022

$$a_e = \frac{1}{k}\left\{H - \left[\left(\frac{C}{2} - \frac{L_1^3}{E_L b H^3} - \frac{L_2^3 - L_1^3}{E_{Tf} b H^3}\right)^{-1} \frac{L^3 - L_2^3}{E_{Tf} b}\right]^{1/3}\right\} \quad (2)$$

Where a_e = the equivalent crack length, C = specimen compliance (C = δ/P), δ = Castigliano theorem, P = load.

Fracture energy can be obtained by means of the Irwin–Kies equation:

$$G_I = \frac{P^2}{2b}\frac{dC}{da} \quad (3)$$

Equation of the specimen compliance:

$$C = 2\left(\frac{L_1^3}{E_L b H^3} + \frac{L_2^3 - L_1^3}{E_T b H^3} + \frac{L^3 - L_2^3}{E_T b (H - ka)^3}\right) \quad (4)$$

Where E_T = the Young modulus on the transverse direction.

applied to Eq. (3), which leads to:

$$G_I = \frac{3P^2}{b^2}\frac{(L^3 - L_2^3)k}{E_{Tf}(H - ka_e)^4} \quad (5)$$

The initial compliance was set usually between 0.15 and 0.35 times F_{max}. To avoid peaks the curves (force, displacement) were smoothed using moving average filter.

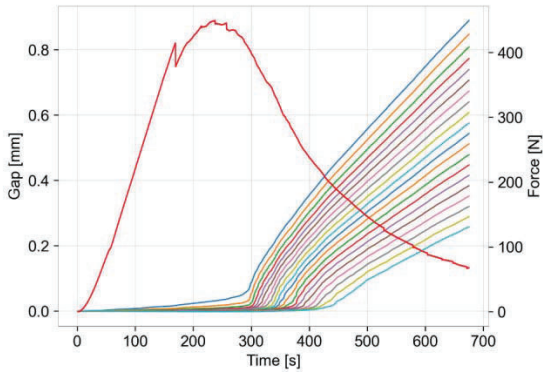

Figure 4: *20 pairs of points (0-9) and their relative displacement show the nonlinear behaviour; measured force in red*

2.4 Optical measurement

The whole test has been recorded with two Basler acA2440-20gm cameras from both sides with a frame rate at 1 Hz and a telecentric lens having 55 mm focal length. The cameras were synchronized using IP protocol and triggered using software trigger from the computer. The camera region of interest was set to not only the crack itself, but also a relatively long path has been recorded using the cameras (see Fig. 2). To ensure we know the ratio (size) of a pixel in distance units, a millimeter scale was glued onto the sample. Synchronization between the optical measurement and loading was made using minimization of error afterwards between the curves of optical displacement in y-direction and displacement measured. Pattern was applied using acryl black and white colors and an airbrush (Revell Masterclass), to meet the standard criterion (3-4 pixels/speckle).

The DIC part consisted of a) tracking several pairs of points (see Figure 2 and 3) using DICe correlation engine [10] and b) based on the data we introduced an algorithm to get the crack length distance.

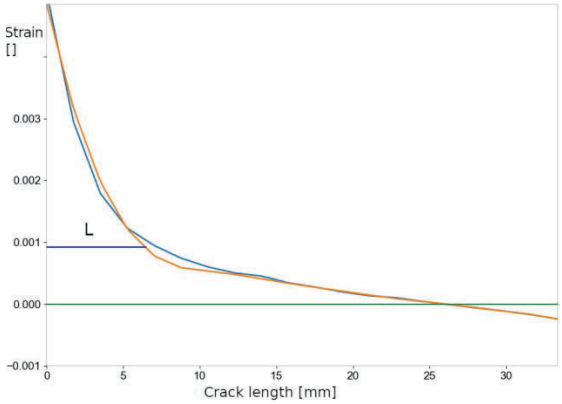

Figure 5: *Crack length determination, crack axis is now the horizontal one. L is the length determined when strain is equal 0.925e-3. Blue is the original data, orange curve is interpolated using polynomial.*

2.4.1 Crack length algorithm

The basic idea of eqLEFM: if there is some nonlinearity (change of compliance) present in the force-displacement curve, it means some length of virtual or equivalent crack is produced; we do not know exactly what happens in the region, however, we look at solution of equation:

$$U = 2\left[\int_0^{L_1} \frac{M_f^2}{2E_L I} dx + \int_{L_1}^{L_2} \frac{M_f^2}{2E_T I} dx + \int_{L_2}^{L} \frac{M_f^2}{2E_T I_{ST}} dx\right] \quad (6)$$

Where U = strain energy due to bending, M_f = the bending moment ($M_f = Px/2$), I = the second moment of area of the entire section (height H), I_{ST} = the second moment of area of the effective section in the SRR (height of H - ka).

$$I = \frac{bH^3}{12} \quad (7)$$

$$I_{ST} = \frac{b(H - ka)^3}{12} \quad (8)$$

Using Castigliano theorem:

$$\delta = \frac{\partial U}{\partial P} \quad (9)$$

We can evaluate compliance (4) and using (3) also G_I. This solution means in fact, that every change in the whole system will lead to change of equivalent crack length,

although it is not still apparent or visible. This is, however, not possible in direct experimental way – the FPZ region and nonlinearity at the crack tip do not allow for this. The biggest disadvantage is, that the most important parameter we want to assess, the resistance to crack growth at the ultimate load (G_c) is in this nonlinear region, not in the one, where the crack is already visible by naked eye, where the curve of loading already turns down.
The algorithm used for evaluation of the optical measurement cannot follow the same approach, however, it can try to do similar technology – recognize the crack as a threshold value of linear behavior between a pair of correlated points. In steps:

1. In each moment (time) we can plot the point difference divided by their original distance (see Fig. 2 and 5)
2. Stabilize the curve (in each step the curve is moving a bit) - smooth it using a curve (here we used piecewise cubic Hermite interpolating polynomial)
3. Threshold strain value can be computed according to EN 338-2016 [11] using ratio between $E_{m,90,mean}/f_{t,90,k}$ yielding 0.925e-3
4. Interpolate the point on the curve and read the actual crack length (here another criterion is added, that it happens after the first onset of nonlinear region).
5. Compute this on both sides and average the result – $a_{eopt}=a_{eoptL}+a_{eoptR}$

All the above-mentioned steps were programmed using Numpy/Scipy Python libraries.
Now when the length of crack in time is ascertained, we can do the final assessment of the optical measurement using the classic Irwin-Kies equation shown in Eq. (3). Numerically it yields:

$$G_I = \frac{P^2}{2b}\frac{\Delta C}{\Delta a_{eopt}} = \frac{P^2}{2b}\frac{\Delta \frac{u}{P}}{\Delta a_{eopt}} \qquad (10)$$

where u is the measured deflection of the sample under load P, b is the sample width and a_{eopt} is the optically measured length of crack. Note the presence of derivatives which always leads to scattered results. That is why the quantities are first smoothed using splines.

3 RESULTS

The results are summarized in Tab. 1. The values show the ones assessed using compliance-based methods (first two columns) and its graphical interpretation can be seen in Fig. 6. In the table also 5% percentile is computed, taking into account normal distribution of the results (which is in fact not absolutely ensured).
The energy denoted G_C (in some literature denoted G_{IC}, or $G_{I(PU)}$) is the resistance to crack growth at the limit load. In contrast, the critical energy release rate G_f, which takes on higher values.
A comparison of the results of compliance-based evaluation and optical measurement can be seen in Tab. 1. The authors state the value of the resistance to crack growth at the limit load in the case of optical measurement G_{copt}. The results of these two methods show good agreement for some specimens. However, the optical method generally shows higher energy values. In some cases, the difference between the results of these two methods is up to twofold.
Quantile values of energy obtained from compliance-based evaluation in comparison optical measurement show good agreement.

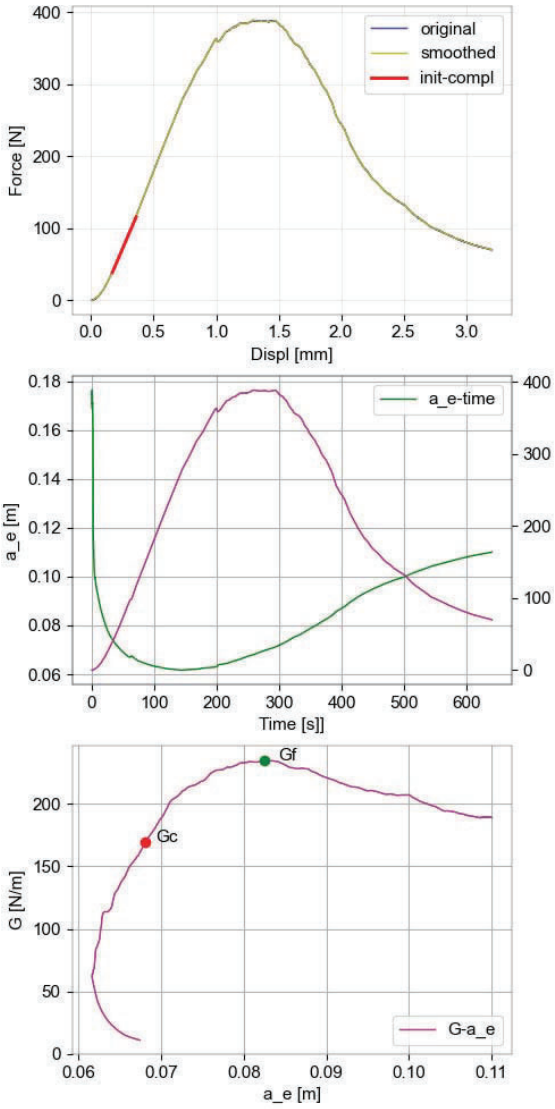

Figure 6: *Compliance-based method result of one sample: force-displacement curve with initial compliance shown in red (top), assessment of a_e (middle) and results in the form of a graph (bottom)*

It is also possible to compare the presented results with those already published, e.g., Dourado et al. [12]. It should be mentioned that the article presents the energy values of the specimens, which were calculated using the triangular stress relief region. Such a computation, to our best

https://doi.org/10.52202/069179-0022

knowledge and experience, shows similar results. The wood used to produce test specimens is the same - *Picea abies* L. The cross sections of the specimens are different (40/140 and 60/210 mm). Dourado reports a lower average wood density of 417 kg/m3 and average value of resistances to crack growth at the limit load G_c are 118 N/m for profile 40/140 mm and 106 N/m for 60/210 mm. The critical energy release rates G_f are 152 N/m (40/140 mm) and 156 N/m (60/210 mm). The published results are lower than the results in Tab. 1, more consistent with quantile values.

Table 1: *Results of the analysis*

Specimen	G_c [N/m]	G_f [N/m]	$G_c$opt [N/m]
R_007	172	238	169
R_008	184	300	264
R_009	215	258	240
R_010	171	227	270
R_011	130	211	278
R_012	170	235	185
R_013	174	229	162
R_014	167	245	219
R_015	148	217	222
R_016	144	180	211
R_017	175	241	301
R_018	156	221	288
$G_{I,mean}$	**167,2**	**233,5**	**234,1**
stdev	21,6	28,8	47,0
var.coef	0,13	0,12	0,20
$G_{I,k}$	**124,0**	**176,0**	**140,1**

It is good to discuss and mention some of the drawbacks of the method. First, of course, the threshold criterion plays an important role in the whole process. Here the authors used tabular data. Nevertheless, the nonlinear region (see Fig. 5) in the curve changes well with this criterion and looks like a reasonable one. Optical measurement is dependent on the way of smoothing the experimental data curves. The authors found that the experimental measurement does not provide a smooth flow of data. The final energy values are very sensitive precisely to the method of data smoothing.

On the other hand, the advantage of optical measurement is complete independence from other material characteristics (E_L and E_T) and also from the theory. To be exact, in compliance-based method the measured values are inserted into a very complicated model that nobody can understand directly. This is not the problem when considering the optical measurement, where the physics of the problem is clear.

Another problem is the crack length determination from two cameras. To date most SEN-TPB tests have been done without optical measurement or rather on narrower samples using DIC from one side. This is a nice contribution of the article. Actually, the difference in crack lengths on both sides was very often very high. The relatively higher values can be also attributed to the influence of this feature.

Last it should be pointed out that Dourado et al. [12] showed much lower density of timber tested, and here the authors see the biggest influence. However, the effect of different geometry of the sample could be also an important parameter.

4 CONCLUSIONS

The article summarizes the comparison of two different methods for obtaining resistance to crack growth at the maximum load. Specifically, it is a comparison of the results of compliance-based evaluation and optical measurement. The experimental work followed the methods SEN-TPB, which is basically a three-point bending with glued-in middle part, where the orientation of grain is rotated 90° to the original one.

The presented results were compared with those already published. The published results are lower than the results in this paper and are more like quantile values. It should be mentioned that the shape of the stress relief region (SRR) used in the calculation is different, but influence is not big. The cross-sections and average wood density of the samples are also different.

The quality of optical measurement results is very sensitive to the method of smoothing the experimental data curves. On the other hand, the advantage of optical measurement is complete independence from other material characteristics.

BAMBOO GRIDSHELL: FROM THE MATERIAL TO THE STRUCTURE

Esti Nurdiah[1], Tsung-Hsien Wang[2], Wen-Shao Chang[3]

ABSTRACT: The majority of gridshell structures are built using timber lath and steel. only few are made from bamboo. Constructing a gridshell structure using bamboo is challenging because the anatomy, physical and mechanical properties affect the ability of bamboo culm to be bent. This paper aims to investigate the utilisation of bamboo for gridshell structures by examining bamboo as the material, the elements, and the whole gridshell structure. The experiments were conducted in three stages: testing material properties, examining bending capacity, and constructing a full-scale model of gridshell structure. The bamboo species used in the experiments was *Gigantochloa apus*, a species that is commonly found in Indonesia. The experiments showed that full-culm bamboo had a limitation on the depth of curvature, which then affected the height of gridshell, the form, and the structure.

KEYWORDS: bamboo, bamboo gridshell, material properties, bending capacity, form, structure.

1 INTRODUCTION

The construction sector has contributed significantly to global carbon dioxide (CO_2) emissions, and the use of environmentally friendly materials is highly promoted to maintain the sustainability of our planet [1]. Bamboo is one of the building materials widely known as a sustainable material. The sustainability aspect of bamboo has been researched, and findings have shown the capability of bamboo in sequestering carbon, reducing CO_2 emission, contributing to carbon storage, conserving water, controlling erosion and conserving energy, making a significant contribution to controlling climate change issues [2]–[4]. Moreover, bamboo is a fast-growing plant that can be harvested in 3 to 5 years, which makes bamboo an important replacement material for wood in terms of supply and demand [5]. Regarding workability, bamboo provides flexible and uncomplicated methods to work with, whether utilised as structures, such as portal frames, trusses and building envelopes, or as non-structural elements, such as walls and floors[6].

Gridshell structure is considered an efficient structure because it needs fewer materials than a solid surface shell structure, and is capable of enveloping a large span space [7]. Gridshell structure can be defined as a double-curvature shell built of grids instead of the usual solid surface [8]. In terms of construction methods, strained gridshell produce form by assembling the initial flat grid consisting of continuous members, which is lifted until the designated form is achieved. The curve is shaped by actively bending members; thus, the structural elements can be called active bending [9]. Gridshell built through this method also can be called 'elastic gridshell' which refers to the materiality and construction process [10].

Choosing a suitable material for elastic gridshell requires considering two important aspects. First, the material should have a sufficiently low modulus of elasticity (MOE) to minimise bending moments resulting during the shaping process. However, high MOE is needed to provide adequate global buckling stiffness. Second, materials with higher ultimate stresses can resist significant bending moments and adopt a lower radius of curvature; thus, they are suitable for achieving a strong curvature shape [11]. Bamboo has high flexibility and strength, making it capable of being employed as an active bending structure [12]–[14]. However, there is limited information about the degree to which the bamboo can be bent, especially for the utilisation in gridshell structures.

Literature on the construction and erection methods of bamboo gridshell is limited compared to timber gridshell. Rockwood's research [14] investigated the form finding and construction of bamboo gridshell. The form-finding process was through physical models, and the construction used very small-diameter bamboo. The experiments found that buckling and splitting were significant challenges in achieving desirable curvature, and some bamboo poles snap and break during the bending process. It also showed that despite bamboo being flexible, bending the material is challenging. Meanwhile, the ZBC pavilion designed by CUHK team showed the process of realising a bamboo gridshell designed through computational form-finding and modelling. During the construction, amendments were performed in response to the natural behaviour of bending bamboo which showed the discrepancy between the simulated model and the real material [15].

Therefore, some challenging questions need to be answered, such as the bending capacity of bamboo and

https://doi.org/10.52202/069179-0023

bending methods that influence the depth of curvature and, hence, affect the maximum height of gridshell. Regarding the construction, there are some gridshell construction issues; whether the erection methods for timber gridshell are suitable for bamboo gridshell; whether gridshell as-design can be directly realised as-built.

This paper aims to investigate the utilisation of bamboo for gridshell structures from the material to the structure system. The paper discusses bamboo as the material by testing the material properties, as an element of the structure by investigating the bending capacity, and the whole structure system by erecting a full-scale model of bamboo gridshell.

2 MATERIAL AND METHODS

2.1 MATERIAL SELECTION

The experiment used the bamboo species *Gigantochloa apus* from Indonesia, known by the local name *bambu tali*. *Bambu tali* is readily available in most areas and cultivated in lowlands and highlands. It is known by local people for its flexibility and has been used for building construction. The features have a relatively small diameter with medium wall thickness (Figure 1). Thinner wall bamboo with a larger diameter would break easily during the bending process, while big diameter and thick wall bamboo would be hard to bend. Meanwhile, a very small-diameter bamboo was not selected because this research aimed to utilise bamboo for large-span gridshell. Bamboo with a very small diameter certainly has more flexibility, but its strength is questionable. Thus, *G. apus* was selected in consideration of its dimensions and wall thickness, and when the structure would need more than one layer, multiple layers of *G. apus* might not create a thick surface for the gridshell.

The experiment used full-culm bamboo aged 3-4 years and 5-7 cm in diameter. The age was considered the optimum age for bamboo for construction purposes. The bamboo was brought from a supplier in Magelang, Central Java province in Indonesia.

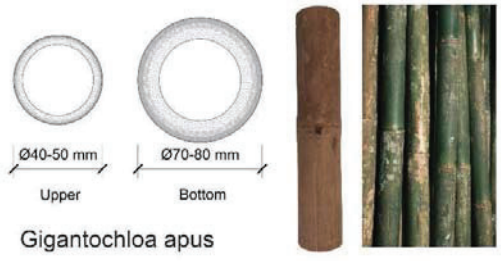

Figure 1: *Bamboo species Gigantochloa apus for the experiments.*

2.2 MATERIAL TEST

The material tests were carried out in accordance with BS ISO 22157:2019 tensile parallel to the fibres [16]. The specimens were taken from 20 bamboo culms with a length of six meters and extracted from three parts within the culm: upper, middle, and bottom. In total, 60 specimens were tested. For the tensile test, the bamboo had been treated by soaking in the boric borax solution for two weeks, then aired-dried and stored for at least six months before the testing.

The mechanical tests were carried out using JTM Universal Testing Machine with a maximum capacity of 30 Ton. The ultimate load at failure (F_{ult}) and displacement (Δ) were recorded, and the cross-section of the specimens (A) was measured from the specimen width (b) and wall thickness (δ) to calculate the strength. The formula used to determine the tensile strength was as follows:

$$\sigma_t = \frac{F_{ult}}{A} \quad (1)$$

2.3 TEST ON THE DEPTH OF CURVATURE

To design a bamboo gridshell, it is crucial to identify the maximum depth of curvature that can be reached by a bamboo culm. Whilst bamboo can be bent, due to its anatomy, there was a limitation in actively bending the bamboo. The bending capability and capacity of bamboo would determine the final geometry, apex height, and could be a consideration in determining the suitable erection method. To determine the depth of curvature, the tests were carried out in the laboratory through a bending test, and at the construction site by bending the bamboo on-site.

The first test on bending parallel to the fibres was conducted in accordance with BS ISO 22157:2019 [16]. The load was given continuously using Enerpac hydraulic jack, and a load cell was installed to record the load (F) and ultimate load (F_{ult}). To measure the displacement (Δ), three laser meters were positioned at the centre, left and right sides (Figure 2). The measurement taken for calculation were clear span (L), shear span (a), outside diameter of bamboo (D), and wall thickness (δ). Seven bamboo poles with a clear span of 3.60 meters were tested.

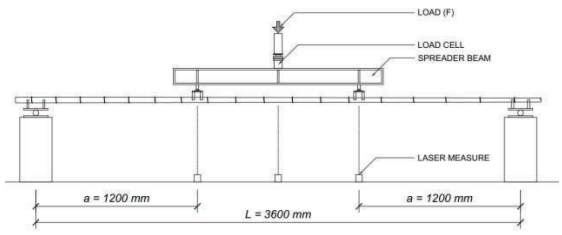

Figure 2: *Bending test set-up*

The formula used to calculate the bending moment (M_{ult}), bending strength parallel to the fibres (f_m) and tangent bending stiffness ($E_m.I_B$) were as follows:

$$M_{ult} = \frac{F_{ult} \times a}{2} \quad (2)$$

https://doi.org/10.52202/069179-0023

$$f_{m,0} = \frac{M_{ult} \times D}{2 \times I_B} \quad (3)$$

$$E_m \cdot I_B = \frac{(F_{60} - F_{20})a(3L^2 - 4a^2)}{48(\Delta_{60} - \Delta_{20})} \quad (4)$$

The apparent modulus of elasticity (E_m) was determined by dividing the tangent bending stiffnees (E_m I_B) by the second moment of area (I_B)

$$E_m = \frac{4(F_{60} - F_{20}) \cdot a(3L^2 - 4a^2)}{3\pi(\Delta_{60} - \Delta_{20}) \cdot [D^4 - (D - 2\delta)^4]} \quad (5)$$

The second test on the depth of curvature was done on the construction site by setting up bamboo poles with scaffolding and bending the bamboo manually. A set of bamboo poles was laid on two sets of scaffolding, a rope was tied at the middle of the poles, and two ropes were tied at the left and side parts. The ropes were knotted in a certain way that made them capable of being shortened by twisting a short blade installed in the middle. Alternatively, ratchet straps can also be used as a replacement for the ropes (Figure 3). The heat from a gas torch was applied to soften the bamboo's fibres in attempt to make the bamboo culm more flexible and add depth of curvature. Water was continuously applied to prevent the culm from overheating and getting burnt.

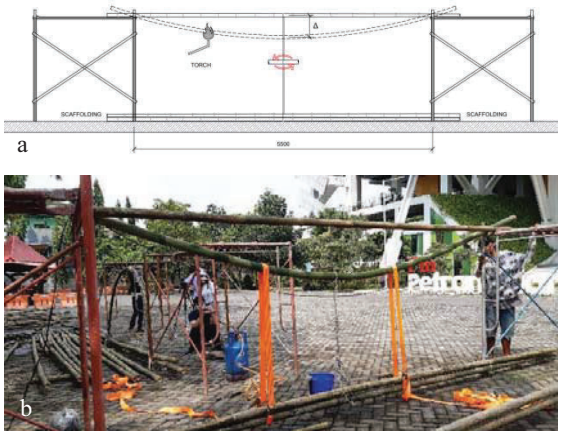

Figure 3: *Setting up of bending test on the construction site*

2.4 CONSTRUCTION METHOD

The full-scale model was built inside the campus area of Petra Christian University in Surabaya, Indonesia. Construction was carried out by building a full-scale model made from bamboo culms with a span dimension 10.80 m x 10.80 m. The entire process needed six days to complete a full-scale bamboo gridshell. The construction was done by hiring five construction workers with experience constructing bamboo buildings. However, even though they had long experience with bamboo, it was their first time constructing a bamboo gridshell.
Adjustments were made to the gridshell design and the erection method following the findings from the tests on the depth of curvature. The initial plan was to move the anchor inward and pull up the lattice. However, during several pre-construction testing events, it was hard to bend the whole culm of *bambu tali* by pushing the two tips inward. The bamboo tended to swing and return to its original shape, which would be dangerous for the workers; they could get hurt and thrown if the bamboo swung back to its original shape. Therefore, it was decided to lay the members one by one using scaffolding, then slowly pull down the members and tie them to the other members and boundary (Figure 4).

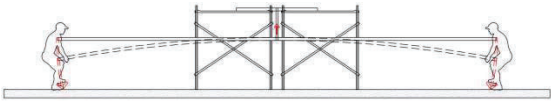

Figure 4: *Illustration of bending method to erect the bamboo gridshell*

The gridshell structure was erected by bending each member and utilising scaffolding. The two main arches at the centre were assembled and erected first, followed by other members. The connections were tied using ropes to allow rotation during the erection process. Later, the connections to the boundary were fixed using nuts and bolts.

3 DISCUSSION

3.1 TENSILE STRENGTH OF BAMBOO

A summary of the tensile test results can be seen in Table 1. The tensile strength of bamboo was particularly high but not evenly distributed within the culm, and the variation within the upper, middle, and bottom was quite significant. From the test, the highest strength was found in the upper section, with an average of 301.67 N/mm^2. Meanwhile, the middle section had an average of 289.61 N/mm^2, and the bottom section was 255.69N/mm^2.

Table 1. Summary of tensile test result

Specimens		δ (mm)	A (mm^2)	F_{ult} (kN)	σ_t (N/mm^2)
Bottom	Max	11.90	40.10	9.89	327.40
	Min	6.30	15.75	3.77	176.38
	Ave	8.42	26.23	6.52	255.69
	Stdev	1.50	7.23	1.45	40.95
Middle	Max	9.14	23.31	6.18	367.44
	Min	5.40	14.50	3.51	205.14
	Ave	6.66	17.26	4.96	289.61
	Stdev	0.85	2.20	0.78	48.24
Upper	Max	6.07	16.39	5.54	345.34
	Min	4.70	12.69	3.10	215.13
	Ave	5.30	14.05	4.32	307.67
	Stdev	0.36	0.94	0.56	31.87

The results showed good performance of bamboo in tensile, especially at the upper part. The difference between the upper and bottom sections was significantly high at 51.98 N/mm^2. The tensile test results showed that an increase in wall thickness resulted in a decrease in

tensile strength, which caused by the composition of fibres and lignin within the culm wall.

3.2 BENDING TEST OF BAMBOO

Results from the bending test are summarised in Table 2. The average bending strength parallels to the fibre (f_m) was 71.02 N/mm2, with the minimum being 41.04 N/mm2 and the maximum reaching 100.80 N/mm^2. The results were not significantly different from the previous research for *G. apus* [17], which found the modulus of rupture (MOR) of *G. apus* ranged between 376.5 kg/cm^2 (36.92 N/mm^2) and 965.6 kg/cm^2 (94.69 N/mm^2) with an average of 686.7 kg/cm^2 (67.34 N/mm^2). While the modulus of elasticity (E_m) from the experiment was found as 22,277 N/mm^2 on average. The specimens with an average culm diameter between 68.21 mm to 83.38 mm had variation in flexural rigidity with an average of 2.56E+10 Nmm^2.

Table 2. Summary of bending test result

Speci-mens	D (mm)	Δ_{max} (mm)	f_m (N/mm^2)	E_m (N/mm^2)	$E_m.I_B$ (Nmm^2)

The characteristics of failure observed during the bending test were due to compression and buckling (Figure 5), which can be seen from the crushing and splitting in the compression area. While from all specimens, no damage was found in the tension area. Previous research [17] on the flexural properties of *G. apus* showed the failure were shear and compression, and similarly, no failure in tension area and mode were found. Hence, the result presented the compression strength of the bamboo, which was significantly smaller than the tensile strength shown in Tabel 1. The failure characteristics also showed buckling in the compression area, in which the fibres were wrinkling at the top. The failure also happened due to load concentration at the saddle. The stress concentrated at one point, which caused the breaking located at the saddle.

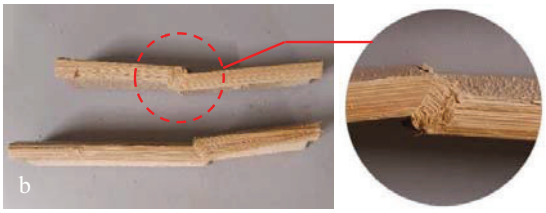

Figure 5: *Failures due to bending*

Similar failure characteristics were obtained through the bending test on the construction site using bamboo six metres in length. Failure modes recorded during the experiments were identified as splitting and fibres crushing within the uppermost area of the culm, which was the compression area. Buckling also occurred and caused sudden collapse during the bending process (Figure 6. a).

The application of heat by torching the bamboo added flexibility to the fibres and allowed the culm to reach deeper curvature. However, the heating process did not eliminate the limitation, and there was a maximum depth of curvature that the culms could reach. In the experiments, the bamboo culms were able to reach deeper curvature compared to the culms without heating; but when the culms were cooled down, they suddenly broke without any loads applied (Figure 6. c). It showed that the fibres returned to the original length and stiffness after removing the heat and showed buckling characteristics. Thus, applying heat to add the depth of curvature did not significantly help in reaching deeper curvature. Actively bending bamboo culms can only produce narrow curvature.

Figure 6: *Failures due to bending test on the construction site*

The tests on the depth of curvature resulted in a major revision to the initial design of the full-scale model. The initial design of gridshell form was based on the basic form of a simple gridshell structure (Figure 7). The form had been used by Labonnote [18] and Dyvik [19] and was based on form-finding from Pone [20]. The form finding

https://doi.org/10.52202/069179-0023

was done in Rhinoceros using plug-ins Grasshopper and Kangaroo. The initial construction plan was to build gridshell form by constructing a flat lattice and moving the anchor inward to create maximum curvature and form the gridshell surface.

Based on the experiments, the initial plan could not be realised. It was not possible to bend a whole culm bamboo into the expected depth of curvature based on the initial design. As can be seen in Figure 7, middle members had narrow curvature, but members near the boundary had deeper curvature. The depth cannot be formed and certainly would result in buckling and breaking. Therefore, the initial design was revised, and several adjustments were added concerning the bending capacity of bamboo.

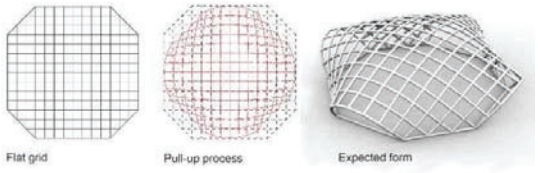

Figure 7: *Initial design of bamboo gridshell*

The adjustments involved lowering the apex height and increasing the span from 8.40 m x 8.40 m to 10.80 m x 10.80 m (Figure 8) to gain higher curvature. Following the result of bending tests, the maximum curvature a bamboo culm or pole could achieve was limited. Thus, by increasing the span, it was expected that the depth of curvature would also be increased, and the maximum apex height could be determined.

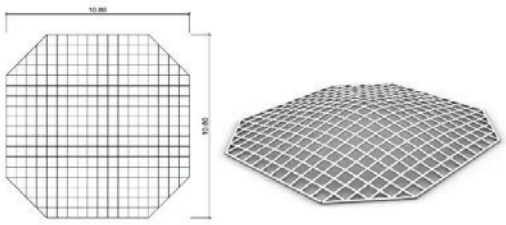

Figure 8: *Final design of bamboo gridshell for the experiment.*

3.3 CONSTRUCTION PROCESS OF BAMBOO GRIDSHELL

Methods of bending the bamboo to reach the maximum possible curvature and form a lattice structure became a crucial part of this construction stage. Based on their experience and craftsmanship, the workers preferred to employ slicing methods to create bamboo arches. Slicing methods provided a quick and easy technique; however, only small strips of the culm were left to bear the loads. The strength would be greatly reduced, and the deeper the curvature, the more slicing would be needed. Therefore, in this research, it was decided to actively bend the bamboo culm and use the heating method to help raise the curvature's depth

The span dimension of the full-scale model was 10.80 m x 10.80 m, and the mesh grids were 0.60 m x 0.60 m. Eight bamboo poles were assembled to form the boundary structure, which had an octagon shape. Around 120 bamboo culms, including those used for the depth of curvature test, were prepared for the construction. The model consisted of 34 long members to construct the surface. As the shortest members for the surface was 7.2 meters, two bamboo culms were joined into one long pole and cut according to the length. No joinery to lengthen the poles were needed for the boundary since the members' length did not exceed 6 meters.

The construction process began with the erecting of the first arch as the centre arch, which played a significant role in defining the maximum height of curvature or the apex of gridshell. Two sets of scaffolding were assembled, and a bamboo pole was strung across the centre to form the first arch (Figure 4 and Figure 9). Two workers held the tips of the bamboo pole and carefully pulled down the tips until they reached the ground. The bamboo was raised to its greatest possible height without snapping. After six poles were tested, it was determined to lift the arch to a height of 1.20 m, which could potentially break the bamboo poles. The height was considered narrow compared to the potential reach of timber gridshells. Afterwards, the arch was tied to a horisontal beam to hold the curvature (Figure 9).

Figure 9: *Erection process of the centre arch*

The second arch was erected perpendicular to the first arch by constructing another two sets of scaffolding, tying the centre of the second pole to the first arch, then carefully lowering the tips to the ground and tying the arch to straight poles, following a similar procedure as the previous arch (Figure 10). After constructing two major arches, the boundary was created. Then, other members were set one by one on top of the major arches and then carefully lowered and tied to the boundary. Throughout the assembly process, short poles were installed under the connectors as supports to maintain the curvature. To ensure that the connection could rotate during assembly, each connection was secured using ropes that permit rotation (Figure 11).

https://doi.org/10.52202/069179-0023

Figure 10: *Assembly process*

Figure 11: *The connections and the temporary supports*

After the members had assembled, the bamboo was heated by torching the culms. Water was regularly applied during heating to prevent the bamboo culms from overheating and cracking (Figure 12.b). The structure was then raised using a chain block. However, the outcome of attempts to increase the height of the apex was insignificant. The apex only raised around 3-5 cm during the process. In the last stage, nuts and bolts were used to secure the connection between the lattice and the boundary. Then, all supports were removed, resulting in the lattice independently forming the whole curvature of the gridshell.

Figure 12: *Heating and pulling the gridshell using chain block to add height*

Once all supports were removed, the gridshell structure quickly lost a certain height, and the final apex height only reached 1.12 m. It was recorded that when the supports were removed, the lattice members pressed against the boundary beams. The bamboo culm showed a tendency to swing back to its original shape, and the boundaries were crucial in holding the form.

During the construction, many bamboo culms failed and broke. Several causes of the failures were buckling and splitting, and some failures occurred at the connections. Buckling happened during the bending process, which has been discussed in section 3.2. However, when the curvatures were getting narrow near the boundary, the occurrence of buckling was not found. The critical failure resulting from bending was at the highest curvature area. Splitting was recorded to occur mainly at the boundary. The pressure from lattice members to the boundary increased the stress, and the beams started to split (Figure 13.a). The pressure also affected the connections between lattice members and boundary. One connection was heavily damaged and broke (Figure 13.b). The connection had been fixed using nuts and bolts, and thus, it no longer could move. On the other hand, fixing the connections was necessary to hold the curvature when the supports were removed. Otherwise, the gridshell would lose its height, and the bamboo would swing back to its original shape.

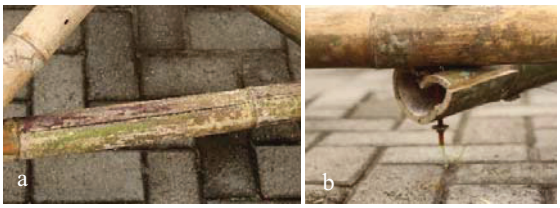

Figure 13: *Failures in the construction: a. due to splitting; b. due to breaking*

4 CONCLUSION

The experiments showed that the choice of bamboo as material influenced the final gridshell design and the construction method. As a material, bamboo has high tensile strength. However, limitation in bending significantly impacted its flexibility. Majority of failures in bending, both during the depth of curvature test and construction, was caused by fibres wrinkling in compression area, splitting, and buckling.

The bending limitation affected the depth of curvature of bamboo arches and the apex height of bamboo gridshell. The apex height produced by the full-culm bamboo was narrow, especially compared to the apex height that a timber gridshell can reach. The maximum depth of curvature or apex height in this study was compared to the span at a ratio of 1:9.64. Hence, designing a bamboo gridshell should take into account the maximum depth of curvature, and the curvature would have to be narrow if the gridshell were entirely made of full-culm bamboo.

The boundaries structure was crucial in keeping the curvature shape, particularly in holding the bamboo culm from returning to its original shape. Therefore, the connection between the lattice members and the boundaries should be considered to prevent breaking, in which, can cause the collapse to the whole structure system. Further analysis of stress distribution in boundaries and alternatives of suitable connections will surely be necessary for future research.

PRELIMINARY INVESTIGATION ON SAFETY PERFORMANCE OF CLT WALL PANELS UNDER IMPACT AND SUSPENSION TESTS

Gabriela Lotufo Oliveira[1], Fabiana Lopes de Oliveira[2]

ABSTRACT: Cross-Laminated Timber (CLT) panels are a relatively new construction element of the international construction industry. In Brazil, the manufacture of this technology started about ten years ago. The use of this innovative construction element in the country is still limited. For this reason, many of those who are first introduced to the material express several doubts regarding its applicability. Thus, this paper sought to analyse this type of panel in terms of safety performance, as this is the fundamental requirement of any building and one of the essential premises to guarantee its stability, as well as the safety of the user. The proposed verification was carried out according to the Brazilian technical standard ABNT NBR 15575:2013 – Residential Buildings – Performance. For this, the following laboratory tests were carried out in one specimen of CLT wall panel: soft body impact, hard body impact and determination of the resistance of the panel to the demands of suspended parts. At the end, it was found that the panels tested met the minimum requirements and criteria established by the studied standard.

KEYWORDS: Cross-Laminated Timber (CLT), safety performance, wooden structure, prefabricated structure, engineered wood.

1 INTRODUCTION

CLT panels are prefabricated structural timber panels, that can be used as floor or roof slabs, and internal or external walls, with or without structural function. As the name describes (Cross-Laminated Timber), they are composed of layers of solid wood glued perpendicularly to each other. Initially developed in the 1990s in Europe, they started to be manufactured in Brazil about ten years ago by a national manufacturer located in São Paulo state. The first Brazilian CLT structure was fabricated and assembled in 2012. Between this first example and 2018, as pointed by [1], more than 30 constructions were built in the country, most of them being single-family homes.

The use of this innovative construction element in Brazil is still limited. For this reason, many of those who are first introduced to the material express several doubts regarding its applicability. Thus, the study of the panels' performance is imperative. Additionally, considering the predominant residential use of CLT in Brazil, it is essential that the requirements established by the technical standard "ABNT NBR 15575:2013 – Residential Buildings – Performance" [2] are properly met by this new technology.

Therefore, this paper aims to analyse CLT wall panels in terms of safety performance, which is considered the fundamental requirement of any building as well as one of the essential premises to guarantee its stability and the safety of the user.

The basis for this study was the standard "ABNT NBR 15575: 2013 Part 2: Requirements" for structural systems, which presents the requirements that must be met by the construction to guarantee minimum building performance. Most of those presented requirements can be verified through the project's analysis, which varies according to each building. One of them, however, can be checked through laboratory tests, which is item 7.4 – Soft and hard body impacts.

In addition, since CLT panels may be applicable for structural walls, one must also verify its conformity with "ABNT NBR 15575:2013 Part 4: Requirements for internal and external vertical sealing systems – VVIE". In this part of the standard the item which can be verified through laboratory test was item 7.3 – Load requests from suspended parts acting on internal and external sealing systems.

Hence, for the proper determination of the safety performance of CLT buildings, the tests were carried out between September and October 2017 in one specimen of CLT wall panel. The results obtained were compared to the performance requirements established by the ABNT NBR 15575:2013, which are classified as minimum (M), intermediate (I) or superior (S).

2 CONTEXT

As seen previously, CLT panels are of European origin. According to [3], this technology started to be developed in Switzerland, in the cities of Zurich and Lausanne, during the early 1990s. However, CLT, as it is currently known, is the result of a research that started in 1990 in Austria and involved a partnership between a wood-based systems' manufacturer and Graz University.

Since its development, the use of CLT panels has increased significantly, including the growth in the number of tall buildings that incorporate this innovative building technology along with other mass timber products, such as Glued-Laminated Timber (Glulam). As pointed by [4], almost 200 mass timber buildings with five storeys or more were developed between 2004 and 2019 around the globe. Over 80% of those are located in Europe. In North America, the implementation of CLT panels is still recent, although this is the region that concentrates most of mass timber tall buildings, after Europe [4] [5].

In Europe, the first standard that regulates CLT panels, EN 16351, was published in 2015. It addresses performance features, in addition to establishing minimum requirements for the manufacture of panels, whether straight or curved. It applies to panels made with at least three orthogonal layers, which can also have up to three successive layers glued in parallel, in the case of panels with at least four layers [6].

The American standard ANSI/APA PRG 320, which establishes rules for the manufacture and characterization of the CLT produced in the United States and Canada defines Cross-Laminated Timber as a prefabricated engineered wood product consisting of at least three layers of solid sawn wood or Structural Composite Lumber (SCL), glued with structural adhesive. The thickness of each layer must be a minimum of 16 mm and a maximum of 51 mm, resulting in panels up to 508 mm thick [7].

As indicated by [4], the cross configuration of the layers enables the distribution of loads in a bidirectional way, allowing to achieve high strength and stiffness capacities. Thus, the main innovation is the production of panel elements, which function as self-supporting walls or slabs.

The sizes of CLT panels vary according to the manufacturer, reaching dimensions of up to 2.95 m x 24.00 m [3]. Transport regulations, however, can also impose dimensional limitations on these construction elements. As highlighted by [8], the common dimensions are lengths of up to 18.00 m, reaching 30.00 m, and maximum widths of 3.00 m, reaching up to 4.80 m, with maximum thicknesses between 300 and 400 mm.

In national production, according to [1], the panels are manufactured with maximum dimensions of 12.00 x 3.00 m, with thicknesses varying between 60 mm and 250 mm. The author also mentions that the Brazilian construction process can be divided into three parts: raw material, manufacture of panels and assembly of the building. Each has its own internal phases. The raw material, after extraction, may or may not receive preservative treatment to prevent the attack of deteriorating organisms, such as fungi or insects. The manufacture, in turn, begins with visual screening of the lamellas, passing through the splicing of these, the assembly and pressing of the panel and the cutting and machining of the pressed panel. The assembly of the building includes logistics, that is, the transportation of the construction elements to the construction site, as well as the movement and connection of the parts, the execution of the building installation and facade [1].

Regarding the assembly of CLT buildings in Brazil, [1] reports that the panels are fixed together, or in other building systems, such as concrete slabs, metal beams, among others, by means of self-tapping screws or metal connectors. In the joints formed between two CLT elements, being parallel or perpendicular to each other, a line of weather-resistant silicone sealant is applied. The screws used in Brazil are manufactured by an Italian company specialized in connectors for wooden structures, the Rothoblaas®. They are used both in simple connections, as well as in more complex ones, that is, when the fixation occurs by means of metallic connectors.

In Brazil, as beforementioned, the production of CLT panels is even more recent than in North America, dating back to 2012. There are no multi storey buildings in the country yet.

However, the use of CLT panels is expected to increase soon. One of the reasons for that is the recent publication of the reviewed national standard for timber structures, that occurred in the second semester of 2022. This document, which regulates wood structures in Brazil, was going through a revision process since 2002. Among many important changes that were incorporated in its latest version was the mention of CLT panels and the introduction of five tests methods for panels that are produced in the country [9].

Even though, as any other construction technology, when used for residential purposes, CLT panels must also meet the criteria established by the technical standard "ABNT NBR 15575:2013 – Residential Buildings – Performance", which is also known by the denomination of "Performance Standard".

3 MATERIALS AND METHODS

To verify the safety performance of a CLT wall panel produced by the first Brazilian Manufacturer, the following laboratory tests were carried out: Soft body impacts, Hard body impacts, and Load requests from suspended parts acting on internal and external sealing systems.

For the three tests mentioned, a single sample was used, which was 80 mm thick (three layers panel, with 20 mm thick external layers and 40 mm thick internal layer), 4000 mm wide and 2700 mm height. It consisted of two CLT panels: the first one measuring 3000 mm wide and the second one 1000 mm wide (Figure 1). Such thickness is the most commonly used in CLT panels to build walls in Brazil.

https://doi.org/10.52202/069179-0024

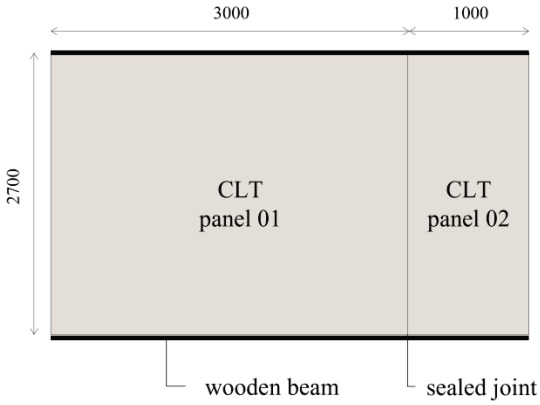

Figure 1: *Design of the specimen carried out to verify the safety performance of the CLT panel. Measures in millimetres (without scale)*

The panels were produced using a vacuum press, with lamellas of *Pinus taeda* wood that were glued with polyurethane structural adhesive. The grade and strength class of each layer was not provided. For more information about the production process of this manufacturer see [1], that describes the production process in detail.

In order to verify the performance of the system also at the point of attachment between the two panels, a joint in the panel was made. The fixation between the two panels occurred through Rothoblaas® VGZ7140 screws fastened with an angle of 45º in relation to the faces of the panels. The joint between the two panels received an application of silicone sealant weather resistant.

The specimen was fixed at its lower and upper edges in a pre-existing porch, composed of two metal beams filled with concrete (Figure 2). For this fixation, in order to replicate a real connection between CLT elements and concrete foundations, a wooden beam was adopted, which was fixed to the concrete sleeper by means of anchor bolts. An EPDM tape was positioned above the beam. The panels were fixed to the beam using Rothoblaas® VGZ7140 screws fastened with an angle of 45º in relation to the faces of the panels.

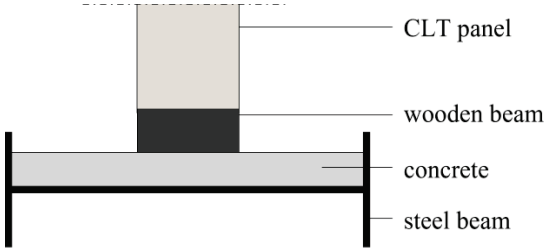

Figure 2: *Schematic detail of the lower fixation of the specimen carried out to verify the safety performance of the CLT panel. Measures in millimetres (without scale)*

3.1 SUSPENDED PARTS TEST

The first test carried out was the requirement Load requests from suspended parts acting on internal and external sealing systems. The method adopted for this test is set out in Annex A of the ABNT NBR 15575:2013 Part 4 [2]. The purpose of this test is to analyse the resistance of CLT panels to the demands caused by fixing suspended parts, such as cabinets, shelves, washbasins, hydrants, pictures and others. The application of the load on the panel, to verify its resistance, is carried out by means of a standardized shelving bracket.

Two tests of this type were performed, each one using different screws for fixing the shelving bracket. In the first, Rothoblaas® HBS 660 screws and, in the second, conventional screws for MDF in size 4.5 x 60 mm were used. The first screw is not produced in Brazil and, therefore, it is more difficult and expensive to acquire. That was the reason for conducting this test with a second screw, which is considerably more common and can be found in all regions of the country.

The load was applied to the shelving bracket at 50 N levels and without blows, according to the standard, with an interval of 3 minutes between the positioning of each level (Figure 3). The maximum load considered in the test had to be maintained after a period of 24 hours.

Figure 3: *Suspended parts test in progress*

3.2 HARD BODY IMPACT TEST

For the second test, which consisted of verifying the resistance of wall panels to hard body impacts, the method adopted is set out in Annex B of the ABNT NBR 15575:2013 Part 4 [2]. In this test, structural components under hard body impacts must not be broken or pierced under any impact energy, but the occurrence of cracks, chipping and other damages (impacts of use) can be tolerated. The test was carried out with the pendular release, at rest, of a body of known mass, at a specified height. The body consisted of steel balls of two types: a small hard body of 0.5 kg and a big hard body of 1 kg.

These bodies were suspended by a cable and released in a pendular motion, generating impact energies that are

https://doi.org/10.52202/069179-0024

indicated in the standard, until reaching the specimen (Figure 4). The impacts were applied at different random points, that is, each impact had to occur at a different point, without repeating. The standard in question establishes as impact energy 10 J and 20 J, for the big body, and 2.5 J and 3.75 J for the small body. To mark the point of impact on the panel, a carbon paper was used and fixed with self-adhesive tape on the specimen.

Figure 4: *Hard body impact test in progress. The picture shows the moment before the hard body is abandoned.*

3.3 SOFT BODY IMPACT TEST

The last test consisted of measuring the resistance of the panels to soft body impacts, according to the test method which is indicated in the ABNT NBR 11675:2016 Modulated internal light partitions – Verification of resistance to impacts [10]. For this purpose, a cylindrical leather bag was used as a soft body. It measured approximately 350 mm in diameter and 900 mm high and contained dry sand and sawdust inside, with a total weight of (400 ± 4) N (equivalent to about 40 kg). In addition, the measurement of the horizontal displacement of the panel was carried out by means of a depth calliper with a resolution equal to or less than 0.1 mm.

As the standard describes, the test begins with the suspension of the leather bag, through a steel wire, so that the projection of its centre of mass on the surface of the specimen coincides with the point where the impact must be applied. The device for the graphic record of the displacements of the panel must be installed in a position coincident with the centre of mass of the leather bag, on the face of the specimen opposite to that which will suffer the direct impact. The cylindrical leather bag is then abandoned in a pendular motion and must reach the specimen with the energies that are specified in the standard: 120 J, 180 J, 240 J, 360 J, 480 J, 720 J and 960 J (Figure 5).

After each impact, the specimen undergoes visual inspection. The instantaneous horizontal displacement (dh) and the residual horizontal displacement (dhr) of the panel are determined for each impact using the depth calliper. Five minutes after the application of each impact, one can register the residual displacement of the panel and, then, the device's graph paper is moved to record the displacements graphically in order to apply the following impact [10].

Figure 5: *Soft body impact test in progress. The picture shows the moment after the leather bag is abandoned.*

The test performed on the CLT panels followed the procedures described above and provided for the mentioned standard. Two points were determined where the impact was applied, the first being in the centre of the CLT Panel 01, with a width of 3000 mm and the second located at the joint between the two panels. For each point, an impact was made for every energy specified in the standard, registering the horizontal displacement by means of the depth calliper (Figure 6).

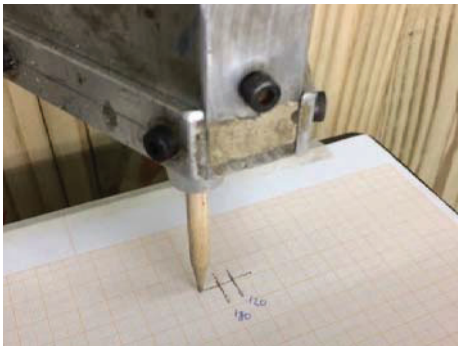

Figure 6: *Soft body impact test in progress. The picture shows the measurement of the instantaneous horizontal displacement (dh) and the residual horizontal displacement (dhr) of the panel by the depth calliper.*

4 RESULTS

4.1 SUSPENDED PARTS TEST

The first test aimed to verify the resistance of the panel to load requests from suspended parts acting on internal and external sealing systems. As a result, loads of 80 kgf and 100 kgf were kept in the shelving bracket for 24 hours, for both screws that were tested, without any kind of damage or instantaneous or residual horizontal displacements in the panel.

4.2 HARD BODY IMPACT TEST

When verifying the resistance of the wall panel to hard body impacts, the panel was tested only with energy of 3.75 J, for the small body, and 20 J, for the big body. It

was decided not to test the lowest energies, for, since the panel did not suffer damage with the highest energies, neither would it suffer with lower energies. Due to the impacts made, dents with small depths were observed. However, there was no rupture, piercing, and occurrence of cracks, chipping or other damages. The dents' depths verified in each impact are shown in Table 1.

Table 1: *Depth of the dents verified in each hard body impact.*

Impact nº.	Depth of dent (mm)	
	Impact of 3.75 J	Impact of 20 J
1	0.6	1.3
2	0.6	1.7
3	1.0	1.1
4	0.7	1.6
5	0.2	1.2
6	0.3	2.5
7	0.7	2.1
8	1.4	1.6
9	0.6	0.8
10	0.2	0.6

4.3 SOFT BODY IMPACT TEST

In the last test (soft body impacts) at the two points of impact and for all energies tested, there was no occurrence of ruin and piercing or surface flaws, such as dents, cracks, chipping, detachments and breakdowns. However, there was a small instantaneous horizontal displacement in the panels, which was recorded by the depth calliper. This displacement, for each point and impact energy, is shown in Table 2.

Table 2: *Displacements verified in each soft body impact.*

Energy (J)	Impact on the joint		Impact at the center of the specimen	
	Instantaneous displacement – dh (mm)	Residual displacement – dhr (mm)	Instantaneous displacement – dh (mm)	Residual displacement – dhr (mm)
120	8	0	6	0
180	9	0	7	0
240	11	0	9	0
360	13	0	12	0
480	14	1	13	1
720	18	0	16	0
960	22	1	18	1

5 DISCUSSION

5.1 SUSPENDED PARTS TEST

Regarding load requests from suspended parts acting on the CLT panel, the test was paused when the tested screws reached the load limit established by the ABNT NBR 15575:2013 for intermediate performance level (Annex F of the ABNT NBR 15575-4:2013) [2], that is 1.0 kN (equivalent to 100 kgf). In both cases, no cracks, detachments or instantaneous or residual horizontal displacements were identified. However, it is possible that the screws could withstand a load even greater than the value reached. Thus, it is not possible to say whether they would achieve intermediate or higher performance in this regard.

5.2 HARD BODY IMPACT TEST

In order to verify the wall panel's resistance to hard body impacts, as established by the ABNT NBR 15575:2013 [2], the minimum performance level for energies of 2.5 J and 10 J requires no failure in the structural element, although dents with any depth are allowed. For energies of 3.75 J and 20 J, surface flaws such as dents, cracks, chipping and disintegration are allowed. Ruins and piercing cannot occur. For 3.75 J energy, to reach the intermediate or higher performance level, the standard determines as the maximum depth allowed for the dent 5 mm and 2 mm, respectively.

In this test, as mentioned above, there was no rupture, piercing, cracking, chipping or other damage in any of the cases. While for dents, as seen in Table 1, the maximum depth obtained in the energy impact of 3.75 J was 1.4 mm. Consequently, regarding the panel's resistance to hard body impacts the higher performance level was reached, according to the criteria established in the ABNT NBR 15575: 2013 [2].

5.3 SOFT BODY IMPACT TEST

The analysis of the results obtained with soft body tests applied the performance criteria presented in Annex F of the ABNT NBR 15575:2013 Part 4 [2] for all CLT possible uses, which are: internal walls with and without structural function, external walls (facades) of single-story houses with structural function and external walls of single-story houses without structural function. In the last case, only the criteria for light seals were analysed, that is, with a density less than 60 kg/m², considering that the tested panel (80 mm thick and an average density of 550 kg/m³), by having a mass of approximately 44 kg/m², falls into this category.

Whereas the absence of ruins, piercing or any other failure, it is necessary to check the horizontal displacements caused by the impacts. The method that must be used to calculate the displacements, as presented by the mentioned criteria, are presented in Table 3.

Thus, it was calculated the maximum instantaneous and residual displacements that were allowed in each situation. These displacements were compared to the maximum values established by the Performance Standard, which determines three performance levels: minimum (M), intermediate (I) and superior (S).

Table 4 shows the calculated values and the actual values that were measured during the test for each impact point. It can be seen from the results presented in Table 4, that practically all the actual displacements measured, whether

https://doi.org/10.52202/069179-0024

instantaneous or residual, were lower than the values that were calculated with the equations presented by the ABNT NBR 15575-4:2013 [2] and in Table 3.

It is also interesting to analyse the use of "external walls of single-story houses with a structural function – external impact (external public access)". For this use and for the impact energy of the soft body of 240 J, the instantaneous displacement limit must be less than or equal to h/250. As mentioned, the specimen was 2700 mm high and, therefore, according to the equation, the dh limit is 10.8 mm. In this case, the 11 mm value measured for the instantaneous displacement would be higher than the calculated limit of 10.8 mm. However, considering the accuracy of the 1 mm depth calliper, and not 0.1 mm, as provided by the standard, it is not possible to say, for sure, that the actual displacement was, in fact, below the established limit. Thus, it was considered that the measured value would be equivalent to the one calculated, rounding the limit from 10.8 mm to 11 mm, by proximity.

Thereafter, it is possible to verify that, if used as an internal wall with or without structural function, CLT panels similar to the specimen from this study could reach the level of higher performance according to the resistance to soft body impacts. Also, as external structural walls of single-story houses, the level of performance that was achieved in this analysed requirement is also higher. Finally, CLT panels just like the one tested, when working as walls of a single-story house, without structural function, would also achieve the level of higher performance.

Table 3: *Compilation of the limitation of horizontal displacements presented in Annex F of the ABNT NBR 15575:2013 Part 4 for all possibilities of uses for CLT elements.*

Vertical seal type	**Impact energy (J)**	**Limitation of horizontal displacements**	**Performance Level**		
			M	**I**	**S**
Internal with structural function	**120**	d_h <= h/250; d_{hr} <= h/1250	X		
Internal without structural function	**120**	d_h <= h/125; d_{hr} <= h/625		X	X
	60	d_h <= h/125; d_{hr} <= h/625	X		
External of single-story houses, with structural function – External impact	**240**	d_h <= h/250; d_{hr} <= h/1250	X	X	X
External of single-story houses, with structural function – Internal impact	**120**	d_h <= h/250; d_{hr} <= h/1250	X	X	X
External of single-story houses, without structural function – External impact	**120**	d_h <= h/62.5; d_{hr} <= h/312.5	X		

Table 4: *Compilation of the results found for the horizontal displacements of the tested panel.*

Vertical seal type	**Impact energy (J)**	**Calculate displacement (mm)**	**Actual displacement (mm)**	
			Ponto A	**Ponto B**
Internal with structural function	**120**	d_h <= 10.8; d_{hr} <= 2.16	d_h = 8; d_{hr} = 0	d_h = 6; d_{hr} = 0
Internal without structural function	**120**	d_h <= 21.6; d_{hr} <= 4.32	d_h = 8; d_{hr} = 0	d_h = 6; d_{hr} = 0
	60	d_h <= 21.6; d_{hr} <= 4.32	- -	- -
External of single-story houses, with structural function – External impact	**240**	d_h <= 10.8; d_{hr} <= 2.16	d_h = 11; d_{hr} = 0	d_h = 9; d_{hr} = 0
External of single-story houses, with structural function – Internal impact	**120**	d_h <= 10.8; d_{hr} <= 2.16	d_h = 8; d_{hr} = 0	d_h = 6; d_{hr} = 0

6 CONCLUSIONS

The present work sought to verify the safety performance of CLT panels manufactured in Brazil according to the criteria established by the Performance Standard, ABNT NBR 15575:2013. To this end, the following laboratory tests were carried out: Hard body impacts and Load requests from suspended parts acting on internal and external sealing systems. The tests' results were compared with the minimum requirements and criteria established in the ABNT NBR 15575:2013, in order to verify their compliance.

The authors are aware that the study tested only one specimen of one producer. Therefore, the results cannot ensure that all Brazilian CLT panels have adequate performance according to national standards. There are a great number of other standards in Brazil and, also, other requirements in ABNT NBR 15575:2013 that must be achieved by this technology. It must be highlighted, further, that the performance analysis of the element in question should encompass other requirements not included by this study, such as thermal or acoustic comfort.

Moreover, since the latest publication of the reviewed Brazilian standard for timber structures and the introduction of tests methods for CLT panels that are produced in the country, it is also expected for the national production of CLT panels to meet those recent requirements. Therefore, it was not intended, in this work, to exhaust the studies on the use of CLT panels in Brazil.

Finally, it appears that CLT panels present themselves as an extremely promising option for the global and Brazilian construction industry. Certainly, as the demand to CLT panels in the national construction business increases, just like it has occurred in other countries, new challenges, and therefore new solutions, will be faced, and shall be overcome. Thus, the present study aims to be one unassuming step towards the actual and permanent implementation of this technology nationally.

ENABLE THE USE OF MASS TIMBER PRODUCTS FOR NON-RESIDENTIAL BUILDINGS IN HIGH VELOCITY HURRICANE ZONES

Sovanroth Ou[1], Michael Stoner[2], Weichiang Pang[3]

ABSTRACT: The wind design requirements for all regions designated as wind-borne debris regions are governed by the International Building Code (IBC). In Florida, stricter requirements apply to regions with high hurricane wind speeds, referred to as High Velocity Hurricane Zones (HVHZ). For non-residential buildings, the building products for the entire building envelope must be evaluated and meet the requirements of Section 1626 in the Florida Building Code (FBC). While there are construction assemblies deemed to comply with these requirements. Cross-Laminated Timber (CLT) is yet proven to be qualified. The goal of this project is to enable the use of CLT in HVHZ through experimental testing including windborne debris impact and cyclic pressure testing. The experimental results show that 3-ply CLT with a thickness of approximately 105 mm (4.125 in) satisfactorily passed all tests conducted with very little damage indicating that CLT is suitable for applications in HVHZ.

KEYWORDS: Cross-Laminated Timber, High Velocity Hurricane Zones, Debris Impact Test, Cyclic Wind Pressure Loading Test

1 INTRODUCTION

After Hurricane Andrew ripped through Florida in 1992, it exposed shortcomings of the current building codes. In September 1992, the Federal Emergency Management Agency's (FEMA) Federal Insurance Administration (FIA) assessed buildings' damages caused by Hurricane Andrew (FIA, 1992). It was observed that the damages differ significantly between neighbourhoods of proximity which were mainly due to the construction details and building products for the building envelope, shown in Figure 1.1. As a result, the FBC published the first version of enhanced wind provisions in 2001. Additionally, it was further enhanced following the damages due by Hurricanes Charley, Frances, Jeanne, Katrina, and Wilma in 2004 and 2005. Similar to Hurricane Andrew, FEMA's Mitigation Assessment Team's (MAT) building damage assessment caused by Hurricane Katrina showed excessive building envelope damage which was due to inadequate wind resistance and damage from windborne debris impact (FEMA, 2006). "In part, the building envelope failure problem is due to lack of high-wind design guides for envelope assemblies and various types of rooftop equipment.", says MAT. The most recent FBC requires the entire building envelope to be impact resistant in HVHZ. Studies, conducted by Bridwell et al. in 2013 and Falk et al. in 2015, show the ability of 5-ply CLT to resist a 6.8 kg (15 lb) 2x4 lumber missile with a velocity of approximately 44.7 m/s (100 mph) with minimal damage. In 2020, the capacity of 3-ply CLT to resist debris impact loads was investigated at Clemson University and showed that there is a 26% probability of failure for missiles expected in an EF-2 tornado (50 m/s – 60 m/s) and a 54% probability of failure in an EF-5 tornado (89+ m/s) (Stoner, 2020). In addition, recent experiments conducted at the Forest Products Laboratory (FPL) have shown that a 4-ply CLT wall, a 3-ply CLT roof, and a 4-ply CLT door can meet the requirements of ICC-500, the standard for the design and construction of storm shelters published jointly by the International Code Council (ICC) and the National Storm Shelter Association (NSSA) (Falk et al., 2019). While the ICC-500 and the HVHZ standard share some similarities, the specifications for the two necessary experiments, debris impact and cyclic wind pressure loading tests, are different for HVHZ.

Figure 1.1: *Building performance difference between manufactured homes (outlined in the center) and conventional residential buildings (lower left) (FIA, 1992).*

There are several construction assemblies listed in Section 1626.4 of FBC, which have been proven to meet HVHZ requirements, including exterior concrete masonry walls, exterior wood-frame walls, and exterior reinforced concrete elements. This project presents the experimental test results, explaining the performance of CLT under HVHZ testing criteria. The main objective of this project is to qualify PRG-320 compliance CLT panels for HVHZ standards.

2 EXPERIMENTAL TESTING

To qualify CLT for HVHZ, debris impact test and cyclic wind pressure loading test must be conducted in compliance with Section 1626 of FBC, Testing Application Standard (TAS) 201-94, and TAS 203-94. CLT panels will be deemed to comply with HVHZ standards if three test specimens reject missile impacts without penetration and resist the cyclic pressure loading with no crack forming longer than 127 mm (5 in) and 1.6 mm (1/16 in) wide through which air can pass during cyclic wind pressure loading test.

2.1 DEBRIS IMPACT TEST

A total of three CLT test specimens will be tested in compliance with Section 1626 of FBC and TAS 201-94. In accordance with FBC's Section 1626, the test specimens must undergo large missile and small missile impact tests. However, it is specified in TAS 201-94 that any specimen that passes the large missile impact test with no opening that a 4.8 mm (3/16 in) sphere can pass through need not be tested for the small missile impact test. From preliminary testing, it was observed that CLT can resist the large missile without opening, therefore it is concluded that the small missile impact test is not necessary for this project. Figure 2.1 shows the test setup for the large missile tests while Figure 2.2.a shows a high-speed camera used to calibrate the missile velocity at a frame rate of 2000 fps. The description of the large missile impact test is summarized in Table 2.1. The missile is propelled using a 33-gallon compressed air tank, shown in Figure 2.2.b.

Table 2.1: *A summary description of a large missile impact test*

Missile	2" x 4" #2 surface dry Southern Pine 4 kg (9 lb)
Missile Velocity	24.4 m/s (80 ft/s or 54.5 mph)
Target	Within a 127 mm (5 in) radius circle having its center on the midpoint of the test specimen Within a 127 mm (5 in) radius circle in a corner having its center at 152.4 mm (6 in) away from supporting members
Test Specimen	1.2 m x 2.4 m (4-ft x 8-ft) PRG-320 compliance CLT panel
Fail Criterion	Openings ≥ 4.8 mm (3/16 in) (Exemption for small missile test)

2.2 CYCLIC WIND PRESSURE LOADING TEST

Following the debris impact test, the CLT specimens go through the cyclic wind pressure loading test in conformity with Section 1626 of FBC and TAS 203-94. The assumptions for wind loads are determined using the Directional Procedure in ASCE 7-22, shown in Table 2.2. Additionally, the loading schedule for the cyclic test is shown in Table 2.3. Figure 2.3 shows the test setup for the cyclic pressure loading test.

Table 2.2: *Assumptions for wind loads*

Exposure Category	C
Building Height, H, m (ft)	18.3 (60)
Design Wind Speed, V, m/s (mph)	89.4 (200)
Directionality Factor, K_d	0.85
Exposure Coefficient, K_z	1.13
Topographic Factor, K_{zt}	1.00
Ground Elevation Factor, K_e	1.00
Gust Factor, G	0.85
Ultimate Design Load, P, kPa (psf)	5.79 (121)
Max. Cyclic Pressure, $P_{max,}$ kPa (psf)	3.5 (73)

Table 2.3: *Loading schedule for cyclic test*

Number of Cycles	Minimum Pressure kPa (psf)	Maximum Pressure kPa (psf)
600	0 (0)	1.77 (37)
70	0 (0)	2.11 (44)
1	0 (0)	4.55 (95)

Figure 2.3: *Test setup for cyclic pressure loading test*

The cyclic pressure protocol was achieved using a large fan which was connected to a bi-polar valve shown in Figure 2.4. The location and control of the valve allowed for air to be forced into the chamber (positive pressure) or taken out of the chamber (negative pressure). For all tests in this study, negative pressures were achieved through the calibration of the pressure to the location of the bi-polar valve. Positive pressures were avoided to test the

https://doi.org/10.52202/069179-0025

panel independent of the connection between the panel and the supporting elements. Prior to each test, calibration of the relationship between the location of the bi-polar valve and the pressure was performed. An example of this calibration is shown in Figure 2.5 and was dependent on the seal between the CLT panel and the pressure chamber.

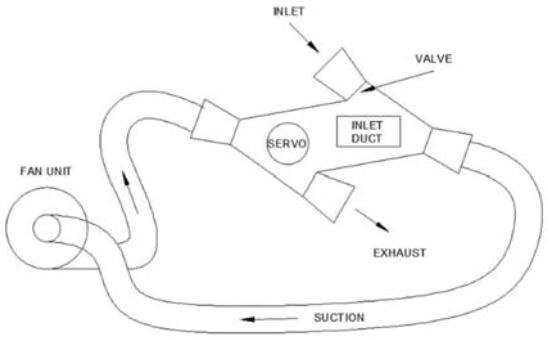

Figure 2.4: *Pressure controlled with a bi-polar valve*

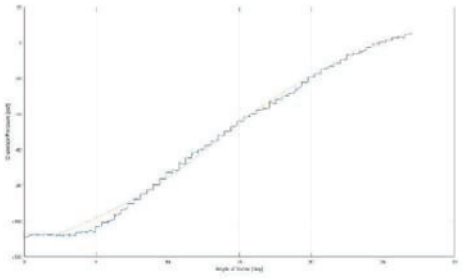

Figure 2.5: *Calibration curve, shown in yellow*

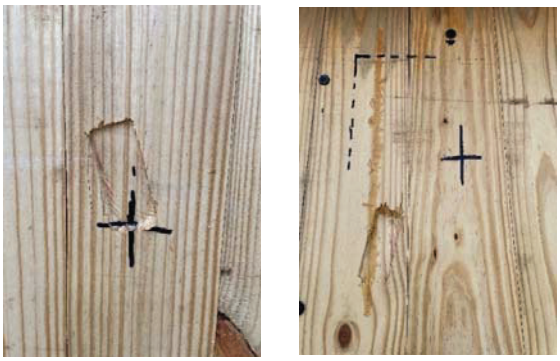
3 TEST RESULT

3.1 LARGE MISSILE IMPACT TEST

A CLT panel specimen was tested for the large missile. It received two impacts at the center and corner 152.4 mm (6 in) away from supporting members, shown in Figure 2.4. Table 2.4 shows the summary result of missile indentation for the test while Figure 2.4 shows their corresponding pictures. There were indentations of 6.35 mm (0.25 in) and 12.7 mm (0.5 in) at the center and corner, respectively. This corresponds to 6% and 12% of the CLT panel thickness (105 mm or 4.125 in), respectively which are minimal damages to the panel.

Table 2.4: *A summary result for missile indentation*

Impact Location	Missile Weight kg (lb)	Missile Length m (in)	Missile Speed m/s (mph)	Indentation Depth mm (in)
Center	4 (9)	2.17 (85.25)	29.5 (66)	6.35 (0.25)
Corner	4 (9)	2.17 (85.25)	31.7 (71)	12.7 (0.50)



(a) Center (b) Corner

Figure 2.4: *Missile penetration depth of large missile test*

3.2 CYCLIC WIND PRESSURE TEST

A specimen was tested for cyclic wind pressure loading test with the loading schedule, shown in Table 2.3. The maximum deflection was measured to be 2.845 mm (0.112 in) throughout all three loading cycles with a permanent deformation of 0.686 mm (0.027 in). No crack or opening formed during or after the experimental test. Figures 3.1, 3.2, and 3.3 show the pressure loads and deflection for several cycles of the three loading cycles respectively (Table 2.3). The CLT specimen remains elastic during the cyclic test, as shown in Figure 3.4.

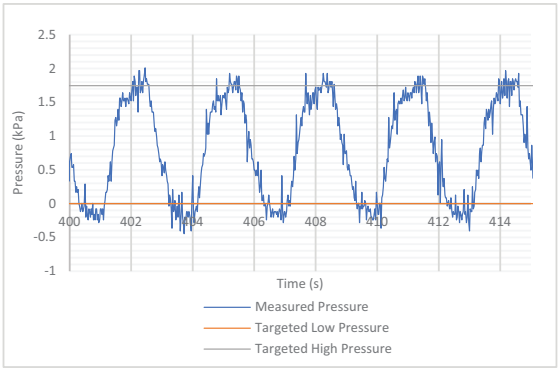


Figure 3.1.a: *Measured pressure for 5 cycles of 0-1.77 kPa*

https://doi.org/10.52202/069179-0025

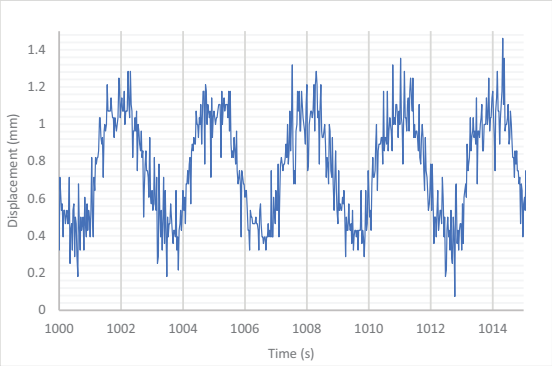

Figure 3.1.b: *Measured deflection for 5 cycles of 0-1.77 kPa*

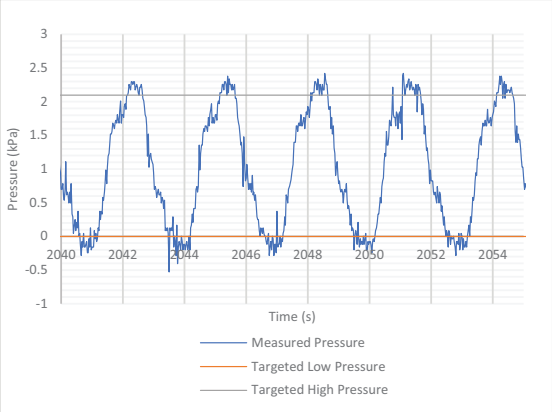

Figure 3.2.a: *Measured pressure for 5 cycles of 0-2.11 kPa*

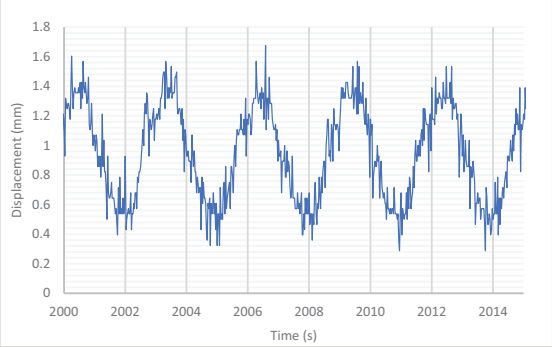

Figure 3.2.b: *Measured displacement for 5 cycles of 0-2.11 kPa*

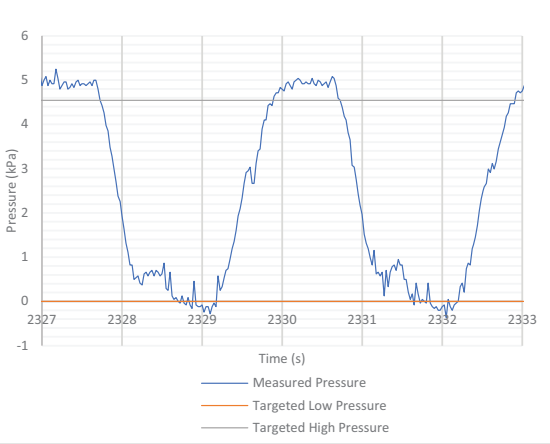

Figure 3.3.a: *Measured pressure for 5 cycles of 0-4.55 kPa*

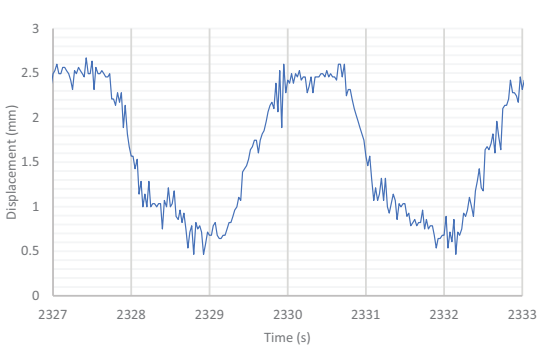

Figure 3.3.b: *Measured displacement for 5 cycles of 0-4.55 kPa*

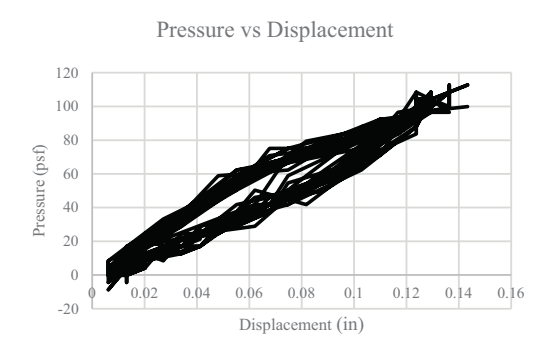

Figure 3.4: *Result from the preliminary test*

The measured pressures in the chamber were consistent with the targets outlined in Table 2.3. Deviation of the pressures from the target value was limited to 11% for the testing shown. Such deviation was the result of the pressure cycles which approached 0 Pa as they had the potential to interrupt the seal. Efforts were made to minimize deviation through the testing protocol such as

https://doi.org/10.52202/069179-0025

placing a plastic film over the panel and using clamps around the panel edges to ensure that if a positive pressure was experienced by the panel, it would not cause the panel to lift off the test chamber.

Overall, the results of the experimental testing indicate little damage to the CLT panel from the debris impact and cyclic pressure. Additional testing could be performed to determine the point at which 3-ply CLT panels would begin to experience more significant damage from such events.

4 CONCLUSIONS AND FUTURE WORK

As part of this study, the 3-ply CLT test specimen underwent debris impact and cyclic wind pressure loading test in accordance with FBC requirements. The results of the two tests indicate that 3-ply CLT can withstand such impacts and pressure testing with little to no permanent damage. It is recommended that CLT be included as a qualified construction assembly listed in FBC 1626.4. Moving forward, two additional CLT specimens will be tested, and a test report will be drafted, describing the performance of CLT under the HVHZ condition. This report will aim to serve as support for engineers and contractors seeking to implement CLT as a construction material in HVHZ.

BENDING BEHAVIOUR OF GLT-STEEL BEAM CONNECTED BY INCLINED SCREWS

Sung-Jun Pang[1], Kyung-Sun Ahn[2], Gwang-Ryul Lee[3], Min-Jeong Kim[4], Jae-Won Oh[5], Jung-Kwon Oh[6]

ABSTRACT: In this study, a glued-laminated timber (GLT) was reinforced with a steel plate and inclined screws, and its bending performance was analyzed. In a total of 8 GLTs, 3 GLTs were not reinforced (control group) and 5 GLTs were reinforced with steel plates (comparison group). The size of GLT was 80 mm (width) × 120 mm (thickness) × 2400 mm (length). The GLT in the comparison group, a steel plate (SPHC-P, yield strength: 227 MPa, modulus of elasticity 166.33 GPa) was installed with screws (Ø9x160mm, 45°). The deflection and load of specimens were measured by a third-point bending test to derive their bending stiffness and load-carrying capacities. As a result of the experiment, all specimens in the control group showed brittle tensile failure, but all specimens of the comparison group showed ductile behavior and maintained a load-bearing capacity of about 30 kN. After the compression failure of the GLT, there was no damage to the screw connection while the steel plate was extended. Therefore, the screw connection sufficiently supported the shear force generated between GLT and steel plate, and the steel plate reinforcement completely changed the GLT behavior.

KEYWORDS: Glued-laminated timber (GLT), Steel, Screw, Beam, Bending behavior

1 INTRODUCTION

Glued-laminated timber (GLT) and steel are structural building materials used in dry construction and recyclable. Both materials are cut or drilled in the factory using CNC cutting machines, so the machining precision is high and the machining error is small.

Several hybrid beams have been developed with GLT and steels. When the GLT are reinforced by steel, the bending performance of the GLT beam is improved and the deviation is reduced (André, Alan, 2006). Generally, the two meterals are glued with an adhesive, but it is not easy to maintain the adhesive performance enough to resist a large external force.

In this study, a new GLT and steel composite beam was designed which were mechanically joined using screws instead of bonding. The bending performance and failure modes of the mechanically connected GLT and steel beams were analyzed.

2 MATERIALS AND METHODS

2.1 SPECIMENS

Figure 1 shows the cross section of GLT and the combination of lamina. One lamina grade (E9) was used, and the modulus of elasticity (MOE) of that grade was greater than 9 GPa. The size of GLT was 80 mm (width) × 120 mm (thickness) × 2400 mm (length).
For GLT-steel beam specimens, a steel plate (SPHC-P, yield strength: 227 MPa, modulus of elasticity 166.33 GPa) was installed with screws (Ø9x160mm, 45°).

2.2 BENDING TEST

The deflection and load resistance of specimens were measured by a third-point bending test to derive their bending stiffness and load-carrying capacities (Figure 2).

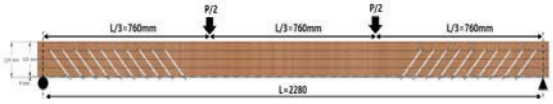

Figure 2: *Cross section of GLT and GLT-steel specimen*

Figure 3 shows the total thickness, neutral axis, and maximum load resistance of the specimen according to the thickness of the steel plate reinforcing the GLT. When GLT was reinforced with a steel thickness of 3 mm or less, the maximum load of the beam was governed by the tensile failure of the steel plate. However, when GLT was reinforced with a steel thickness of 4 mm or more, the maximum load of the beam was governed by compression failure of wood. Thus, in this study, when GLT was reinforced with a 4mm thick steel plate, it was checked whether or not compression failure of wood occurred.

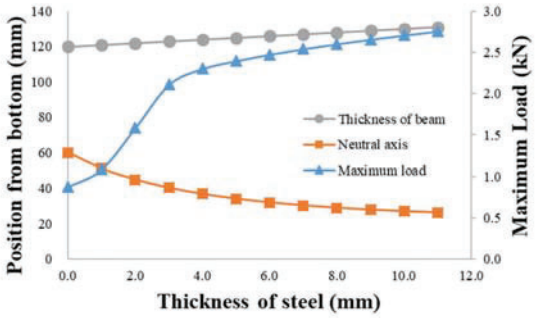

Figure 3: *Thickness of beam, neutral axis, and maximum load resistance by steel plate thickness*

3 RESULTS AND DISCUSSION

Figure 4 shows the failure mode of the non-reinforced GLT specimen. All specimens were broken around the knot in the tensile zone. At the time of failure, the load resistance dropped sharply as shown in Fig. 5. This brittle failure is a typical failure mode of GLT or wood in bending tests.

In the case of non-reinforced GLT, the bending stiffness was about 0.16×10^{12} N/mm^2 and the maximum load was 28.2 kN, which was determined by brittle failure.

Figure 4: *Failure mode of the non-reinforced GLT specimens*

https://doi.org/10.52202/069179-0026

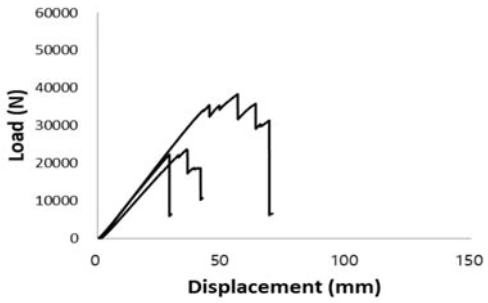

Figure 5: *Load-displacement curve of the non-reinforced GLT specimens (three specimens)*

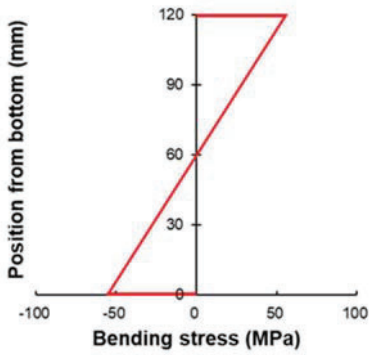

Figure 6: *Bending stress distribution of non-reinforced GLT specimens at the maximum bending moment*

Figures 7 through 9 show the failure mechanism of the reinforced GLT specimens. In two of the five specimens, tensile failure occurred first at the finger joint (Fig. 7a) or knot (Fig. 8a) of GLT. The finger-joint and knots are the main factors causing the strength reduction (Pang et al. 2011, 2018, 2021; Pang and Jeong 2019). Unlike the non-reinforced GLT, compression failure occurred at the top of the GLT (Fig. 7b and Fig. 8b) and large deformation occurred (Fig. 7c and Fig. 8c).

In three of the five specimens, compressive failure occurred first at the top of the GLT (Fig. 9a). After that, tensile failure occurred at the knot, but the tensile failure of the specimens did not lead to rapid brittle failure. The specimens showed ductile behavior due to the elongation of the steel plate. The elongation of the steel plate shows that the screw connection sufficiently supported the shear force between GLT and the steel plate.

(a) Tensile failure at finger joint of GLT

(b) Compression failure on top of GLT

(c) Tensile Large deformation

Figure 7: *Fracture mechanism of reinforced GLT in which tension failure (finger joint) of GLT occurs firs*

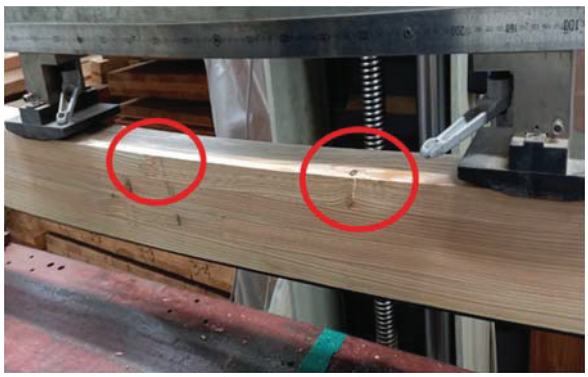
(b) Compression failure on top of GLT

(c) Large deformation

Figure 8: *Fracture mechanism of reinforced GLT in which tension failure (knot) of GLT occurs first*



(a) Compression failure on top of GLT

(b) Tension failure on bottom of GLT

(c) Large deformation

Figure 9: *Fracture mechanism of reinforced GLT in which compression failure of GLT occurs first*

Figure 10 shows the load-displacement curve of the reinforced GLT specimens. Unlike the non-reinforced GLT, the reinforced GLT did not lose its load-carrying capacity significantly after the initial failure and maintained a load-carrying capacity of approximately 30 kN. The maximum load-carrying capacity was higher in the case where the compression failure occurred first (48 kN to 51 kN) than in the case where the tensile failure occurred first (32 to 38 kN). This shows that the tensile part (bottom of GLT) contributes to the load-carrying capacity of the reinforced GLT until the tensile failure occurred. The bending stiffness was also improved by about 64% from 0.161 to 0.265 $\times 10^{12}$ N/mm^2 by the reinforcement, and the coefficient of variation decreased from 0.056 to 0.03.

There was no screw damage while the steel was extending. This means that the screw connection supported the shear force generated between the wood and the steel plate.

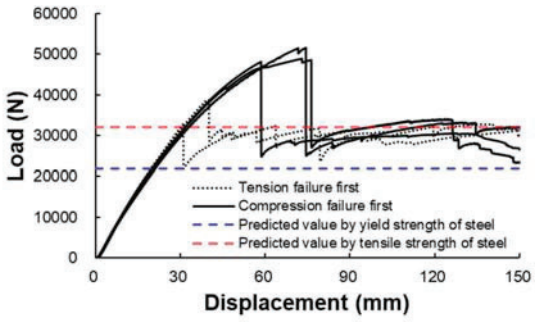


Figure 10: *Load-displacement curve of the GLT specimens reinforced with a 4mm thick steel plate (five specimens)*

https://doi.org/10.52202/069179-0026

As mentioned above, the reinforced GLT beam continuously supported a load of about 30 kN while undergoing large deformation. Figure 11 shows the bending stress distribution of reinforced GLT by elastic analysis (Eq. 1). The maximum bending stress acting on the steel plate (466.3 MPa, Fig. 11(a)) exceeds the yield strength of the used steel plate (227 MPa). This means that the steel plate was in a plastic state, and plastic analysis is required.

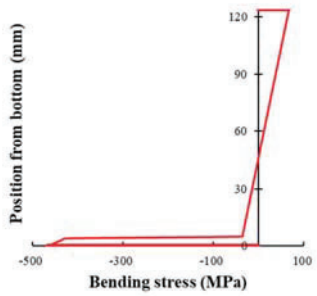
$$\sigma_{bending} = E_i \cdot \varepsilon_i \quad (1)$$

where $\sigma_{bending}$ is the bending stress in the elastic analysis (MPa), E_i is the elastic modulus of *i* material (MPa), and ε_i is the strain of *i* material.

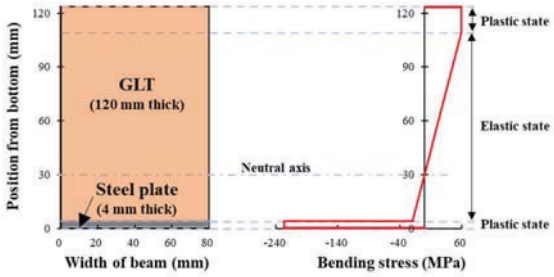
Figure 11(b) shows the bending stress distribution of reinforced GLT considering the plasticity of the GLT and steel. The maximum bending moment of the reinforced GLT can be predicted by Eq. 2. Equation 2 consists of three terms. The first term is the plastic bending moment in GLT, the second term is the elastic bending moment in GLT, and the third term is the plastic bending moment of the steel plate. In the compression test of wood, the load-displacement curve shows a ductile behavior in which the strength decreases slowly as the wood wrinkles after the maximum load (Pang and Jeong 2018). For plastic analysis of reinforced GLT, the load-displacement curve of GLT in compressive stress was idealized as an elastic-plastic curve. Among the reported experimental data (Pang and Jeong 2018; Park *et al*. 2010), the compressive strength (58.8 MPa) of wood with similar elastic modulus in the same species was regarded as the yield strength of GLT,

$$M_{max} = \int_{c_1-h_{c,GLT}}^{c_1} \sigma_{c,GLT} \cdot y \, dA + \int_{c_2-t_{steel}}^{c_1-h_{c,GLT}} E_{GLT} \cdot \varepsilon_{GLT} \cdot y \, dA + \int_{c_2-t_{steel}}^{c_2} f_y \cdot y \, dA \quad (2)$$

where M_{max} is the maximum bending moment (kN·m), c_1 is the distance between the top surface and the neutral axis of the composite section (mm), $h_{c,GLT}$ is the height of the compressive zone in GLT (mm), $\sigma_{c,GLT}$ is the compressive strength of GLT (MPa), y is the distance from the neutral axis of the composite section (mm), c_2 is the distance between the bottom surface and the neutral axis of the composite section (mm), t_{steel} is the thickness of steel plate (MPa), E_{GLT} is the elastic modulus of GLT (MPa), ε_{GLT} is the strain of GLT, and f_y is the yield strength of steel plate (MPa).



(a) Elastic analysis (bending stress exceeds the yield strength (227 MPa) of the steel)



(b) Elastic-plastic analysis

Figure 11: *Bending stress distribution of the reinforced GLT specimen at the maximum bending moment*

Figure 12 shows the bending stress distribution of the reinforced GLT when the steel and timber in compressive zone reach plastic state. The compressive force acting on the upper part of the GLT and the tensile force by the steel plate are equal. Thus, the height of the compressive zone in the reinforced GLT can be calculated by Eq. 3. Figures 12 (a) and (b) show when the maximum stress of steel reached the yield strength (227 MPa) and the tensile strength (345 MPa) of the steel plate, respectively. When the maximum stress of the steel from yield strength to maximum tensile strength increased the height of the compressive zone in the reinforced GLT also increased.

The bending moment and the load-carrying capacity of the reinforced GLT can be predicted by Eq. 4, and Eq. 5, respectively. The predicted load-carrying capacity of reinforced GLT was 21,845 N by applying yield strength of steel (227 MPa) and 32,035 N by applying yield strength of steel (345 MPa). Figure 10 shows the load-carrying capacity predicted by Eq. 5 together with the experimentally measured load-displacement curve. The load capacity predicted by the tensile strength of the steel was similar to the maximum load capacities at the plastic condition of the test specimens. This indicates that the steel plate almost reached its maximum tensile strength. In addition, all of the load capacities of the test specimens were higher than the load predicted by the yield strength of steel. Therefore, the bending moment of GLT reinforced by steel plate can be safely designed with the yield strength of steel.

https://doi.org/10.52202/069179-0026

$$h_{c,GLT} = \frac{f_y \cdot t_{steel}}{\sigma_{c,GLT}} \quad (3)$$

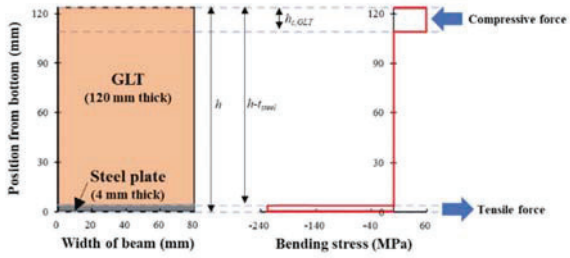
$h_{c,GLT}$ is the the height of the compressive zone in GLT (mm), f_y is the yield or tensile strength of steel plate (MPa), t_{steel} is the thickness of steel plate (MPa), and $\sigma_{c,GLT}$ is the compressive strength of GLT (MPa).

$$M_{predict} = f_y \cdot w \cdot t_{steel} \cdot (h - \frac{t_{steel}}{2} - \frac{h_{c,GLT}}{2}) \quad (4)$$

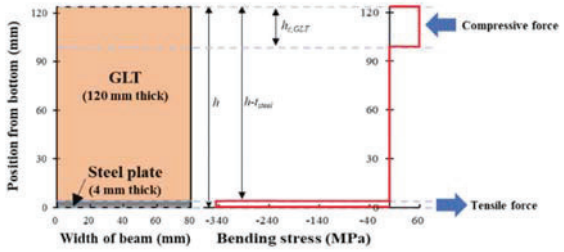
where $M_{predict}$ is the predicted bending moment (kN·m), f_y is the yield or tensile strength of steel plate (MPa), w is the width of steel plate (mm), t_{steel} is the thickness of steel plate (mm), h is the height of reinforced GLT (mm), and $h_{c,GLT}$ is the height of compressive zone in GLT (mm).

$$P_{predict} = \frac{M_{predict}}{L_e} \cdot 2 \quad (5)$$

where $P_{predict}$ is the predicted load-carrying capacity of reinforecd GLT (kN), $M_{predict}$ is the predicted bending moment (kN·m), and L_e is the the distance between the load position and support position (mm).



(a) Bending stress distribution at the yield strength (227 MPa) of the steel plate



(a) Bending stress distribution at the tensile strength (345 MPa) of the steel plate

Figure 12: *Bending stress distribution of the reinforced GLT specimens at the plastic state*

4 CONCLUSIONS

1. The load resistance of non-reinforced GLT decreased to zero after brittle failure in the tensile side of the GLT. However, the reinforced GLT specimen showed ductile behavior even after GLT failure and maintained a load resistance of about 30 kN during large deformation. The bending stiffness was also improved by about 64% from 0.161 to 0.265 by the reinforcement.
2. The prediction model for the load-carrying capacity of the reinforced GLT was developed based on the compressive strength of wood and the yield strength of steel. The experimentally measured load capacity of the beam was higher than the load predicted load capacity. Therefore, the load and bending moment of the reinforced GLT can be designed with the compressive strength of wood and yield strength of steel.
3. The GLT and steel plate were mechanically connected using only inclined screws without the use of any adhesives. The resistance of the screw sufficiently supported the shear forces so that the steel plate can perform plastic behavior after yielding. This study shows the possibility of non-adhesive composite beam, and additional research to optimize the mechanical connection is needed.

THE PRODUCTION OF ADHESIVE-FREE CROSS-LAMINATED TIMBER (CLT) PANEL USING PRODUCTS GENERATED BY THE SUSTAINABLE FOREST MANAGEMENT OF THE AMAZONIAN OLD GROWTH FOREST

Marcos Cesar M. Pereira[1], Adma M. D. Higuchi[2], Geraldo Lira[3], Yago P. Souza[4], Estevão V. C. M. Paula[5], Antonio A. Dias[6], Niro Higuchi[7]

ABSTRACT: The dowel cross-lamella timber (DCLT) is a type of adhesive free construction system which uses wooden dowels as connectors between the lamella layers. The use of wood in construction is environmentally friendly because it is the only building material of renewable origin. This is true only if the wood comes from sustainable forest management plans. In this sense, This work aims to study physical and mechanical characteristics of four species in the Amazon Forest of sustained forest management, use these species for the production of dowels and to determine the rigidity of the connection. The species was Pau Rainha (*Brosimum Rubescens*), Matá Matá Amarelo (*Eschweilera Wachenheimi*), Cardeiro (*Scleronema micranthum)* and Breu Vermelho (*Protium altsonii*). Tests of compressive strength, shear, and density were performed according to the Brazilian Standard of Wooden Structures parameters and slip modulus was obtained by a test developed specifically for this purpose. Among the four wood species studied for use as a connecting element (dowel), only the Pau Rainha wood (*B. Rubescens*) and Matá Matá Amarelo (*E. Wachenheimi*) obtained good results. Mata Mata Amarelo did not get the best results, but in the criterion of abundance, that is, number of tree individuals per m² in the rain forest, it has advantages over the Pau Rainha. Thus, it is possible to apply the concept of sustainable forest management and rationally use this tree species.

KEYWORDS: Dowels, DCLT, Amazon Wood, Mass Timber, Hard Wood

1 INTRODUCTION

1.1 DCLT PANEL

Engineered wood market is expected to gain a market value of USD 4,9 million by 2030[1]. CLT panels are engineered timber products that have been standing out in the construction market mainly on the European continent, where they have been developed. However, for its production structural weather-resistant adhesives and a large hydraulic press are required to glue the panel layers together, which entails a high-cost production and makes recycling very difficult. The DCLT, on the other hand, uses dowels as a bonding agent to the lamellas disposed at 90° between themselves (Figure 1) and do not require neither the use of adhesive nor the press, reducing the process' costs and improving the environmental performance of the product [2]. The efficiency of the bonding is ensured by the moisture content variation between the oven dried dowels (48h at 100°C) and the lamellas [3].

In this process, it loses water impregnated in the wood cells, and consequently reduces its volume, facilitating the dowel insertion into the hole. After being placed in the hole, the dowel regains moisture from the environment, making its volume return to its original size, so that the dowel locks within the hole, providing a more efficient connection when compared to a dowel inserted without this drying process.

Figure 1: *a) Dowels fabrication; b) Panel lay-up; c) Edges compressions; d) Drilling of holes; e) Dowel hammering; f) Final panels.*

Similar panels were developed in United Kingdom using densified wood by a hot-pressing process to give greater densities dowels. The results were promising inclusive with the fabrication and assembly of a prototype of a construction [4].
In Brazil there are hundreds of high-density tree species (> 1000 kg / m³) that can be used to produce dowels without the need for densification process. Many of these have no commercial value and, as a result, are little or no exploited. Thus, selective logging is concentrated on a few specific species [5, 6].
European experience shows that it is possible to manage forest resources (timber) to fabricate structural elements from small to large civil works, without degrading or destroying forests and the environment (sustainably). The implementation of sustainable forest management (SFM) is the best alternative to sustainably assure supply of hardwood in Tropical forests.
Typically, SFM in rainforest, such as the Amazon, is based on selective logging of specific species. Specifically, maintain a sustained income regime, whilst conduction natural regeneration of the forest, over a certain period, without compromising his natural structure and its initial capital [7].

1.2 STIFFNESS OF CONNECTIONS

In the DCLT panel the connection's stiffness is given by the mechanical connection between the dowel and the wood layers.
The deformation between two or more members that are connected results from elastic and non-elastic deformation in the connecting members and the fasteners. To describe this behaviour that Eurocode 5 calls a slip module, which refers to of Slope of the Load-Deformation Curve [8].

2 OBJECTIVE

In this work were studied physical and mechanical characteristics of four Amazonian hard wood tree species to determine its suitability to compose a DCLT panel.

3 MATERIALS AND METHODS

3.1 MATERIALS

Some species of trees with higher incidences in the Amazon Forest per unit area were chosen for the dowel tests.
Pequiarana wood (*Caryocar glabrum)* was chosen as lamellas for all specimens tested, while dowels were made of *Eschweilera wachenheimii* (Matá Matá Amarelo), *Scleronema micranthum* (Cardeiro), *Brosimum rubescens* (Pau-Rainha) and *Protium altsonii* (Breu Vermelho).

In this study no characterization tests of Pequiarana wood (*Caryocar glabrum*) were performed. However, data from the literature present the following physical and mechanical characteristics [9, 10]:

- Density = 690 kg/m³;
- Parallel compression stiffness ($f_{c0,m}$) = 59,8 MPa;
- Shear Stiffness ($f_{v0,m}$) = 14,42 MPa
- Bending stiffness ($f_{b0,m}$) = 103 MPa

The trees were obtained from the Tropical Silviculture Experimental Station (EEST) under the management of the Forest Management Laboratory (LMF) of the National Institute of Amazon Research (INPA) of Manaus, Brazil. Figure 2 presents its location.

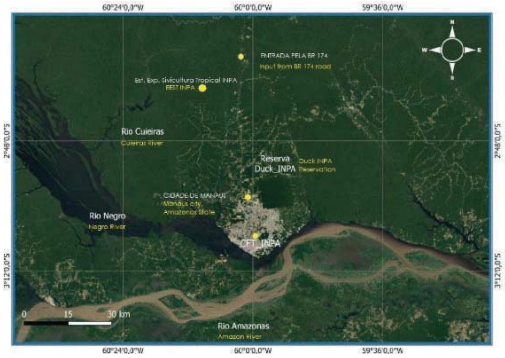

Figure 2: *Location map of Experimental Station of Tropical Silviculture (EEST), from INPA .*

3.2 METHODS

Tests to determine compressive strength resistance, shear and density parameters were performed according to the Brazilian Standard of Wooden Structures NBR 7190 part 3 - Test Methods for characterization of defect-free specimens for timber of native forests [11]. The connection slip modulus (Kser) was obtained by the test proposed by Pereira *et.al*. [3] (Fig. 3).

https://doi.org/10.52202/069179-0027

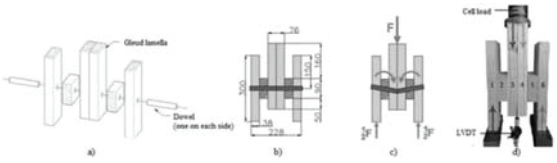

Figure 3: *a) Assembly scheme; b) Specimen measurements (mm); c) Static layout and d) Real model during the test.*

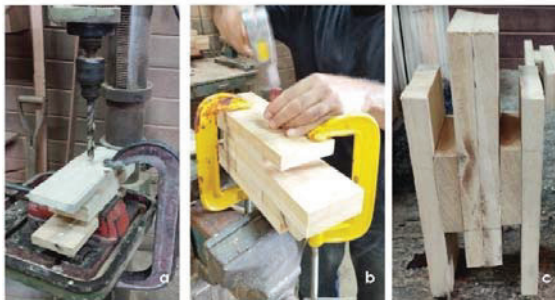

Figure 4: *a) Positioning of the lamellas and drilling; b) Placement of dowels in the holes; c) Test Specimen*

The slip modulus determination test has been proposed simulating the forces applied to the dowels during the use of the panel in bi-supported bending, as shown in Figure 5. In this purpose, the dowel bonding is submitted to a compressive force parallel to the lamellas and perpendicular to the dowel.

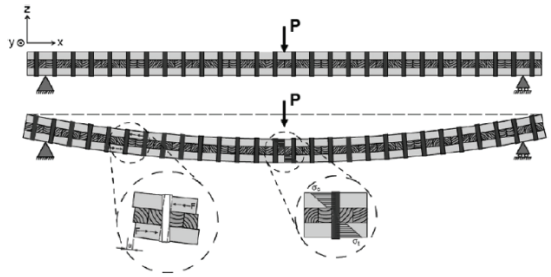

Figure 5: *Y-axis bending of the 3-layer slab, highlighting of the shear and bending forces in the panel.*

The calculations for obeying the value of the slip module were made using the methods described in the European Norm EN 26891:1991, ISO 10984/2009 and in Brazilian standard ABNT 7190-7/2022. The methodology of ISO and EN are equal. European norms and the Brazilian norm have methodology similar but the calculation method is different, as shown in figure 06 and equations 1 and 2.

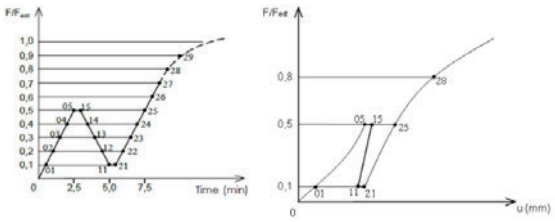

Figure 6*: Form of loading application during testing (left); Force diagram versus connection slip (right).*

For the Brazilian norm, k_{ser} is calculated for equation 1.

$$K_{ser} = \frac{0{,}5 \cdot F_{est}}{\frac{5}{4}(u_{05} - u_{01})} \quad (1)$$

Where F_{est} is a force estimated for rupture, u_{05} is displacement for 50% of force, and u_{01} is displacement for 10% of force.

For European Norm EN 26891and ISO 10984, k_{ser} is calculated for equation 2.

$$K_{ser} = \frac{F_{04}}{\frac{4}{3}(u_{04} - u_{01})} \quad (2)$$

Where F_{04} is the force of 40% of rupture force, u_{04} is displacement for 40% of force, and u_{01} is displacement for 10% of force.

4 RESULTS

The results obtained for the tests performed are presented in the following items.

4.1 COMPRESSIVE STRENGTH TEST

The results of compressive strength test parallel to the fibres and the Modulus of Elasticity in Compression of the analysed woods are presented in Table 1.

Table 1: *Compression and MOE in Compression parallel to the fibres*

Popular name	Matá Matá Amarelo	Breu Vermelho	Pau-Rainha	Cardeiro
Scientific Name	*Eschweilera wachenheimii*	*Protium altsonii*	*Brosimum rubescens*	*Scleronema micranthum*
$f_{c0,med}$ *(MPa)*	56.23	51.78	109.65	37.12
$f_{c0,k}$ *(MPa)*	58.95	48.16	120.0	38.76
St. Desv.	2.32	5.38	1.50	0.91
$E_{c0,med}$ *(MPa)*	12661	-	16243.74	6785
$E_{c0,k}$ *(MPa)*	14578	-	16523.44	5729
St. Desv.	1275	-	1653.25	7425

4.2 SHEAR TESTS

The results of shear tests of the analysed woods are presented in Table 2.

Table 2: *Shear stiffness results for the species*

Popular name	Matá Matá Amarelo	Breu Vermelho	Pau-Rainha	Cardeiro
Scientific Name	*Eschweilera wachenheimii*	*Protium altsonii*	*Brosimum rubescens*	*Scleronema micranthum*

Density med. (kg/m³)	810	605	910	590
St. Desv.	2.1	2.51	3.12	0.54

4.4 CONNECTION SLIP MODULUS TESTS

Figure 7 illustrates the *Pequiarana* wood specimen connected with *Pau rainha* dowel's during a binding test to determine the slip module. It is possible to observe that the cross layer was breaking by shear. This behaviour is similar to rolling shear in the ordinary CLT.

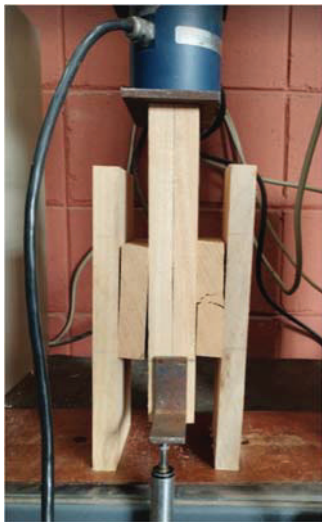

Figure 7: *Cross -sectional layer broke through shear*

Figures 8, 9 and 10 show the results of the connection sliding tests, of which the values used to calculate the K_{SER} were obtained, according to the European Standard and the Brazilian Standard of Wood Structures.

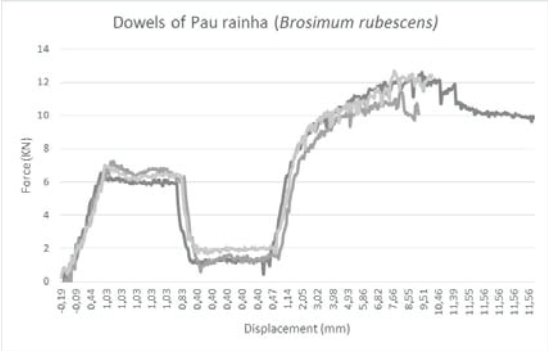

Figure 8: *Chart illustrating the force versus displacement during testing of the specimens using Pau rainha Dowel's.*

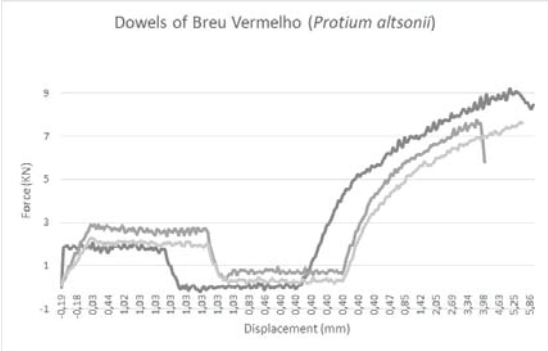

Figure 9: *Chart illustrating the force versus displacement during testing of the specimens using Breu vermelho Dowel's.*

https://doi.org/10.52202/069179-0027

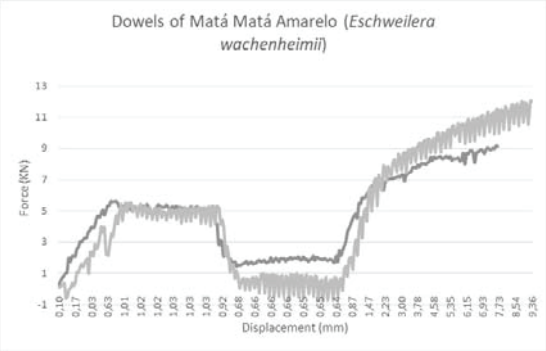

Figure 10: *Chart illustrating the force versus displacement during testing of the specimens using Matá Matá Amarelo Dowel's.*

The table 4 presents the values of the k_{ser} obtained using the calculations described in European and ISO standards and the Brazilian norm, for the tests performed.

Table 4: *Kser values for Brazilian and European Norms*

Wood of dowel (Ø16 mm)		$K_{ser,med}$ [N/mm]	
Popular Name	Scientific name	ABNT 7190-7/2022	ISO 10984 & EN 26891
Pau Rainha	*B. rubescens*	2061	3133
Breu Vermelho	*P. Altsonii*	1607	1216
Matá Matá Amarelo	*E. wachenheimii*	1754	807

The figure 11 presents some dowels after the test to determine the connection slip module.

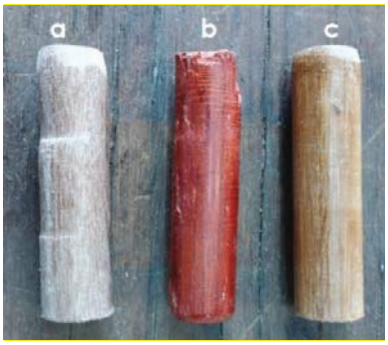

Figure 11: *Some dowels after slip test. a) Breu Vermelho; b) Pau rainha; c) Matá Matá Amarelo*

4.5 ANALYTIC CALCULUS

The analytical calculation of Slip Modulus was performed in accordance with the method described in the European Standard of wood structures - Eurocode 5, and in the current version of the Brazilian Standard of wood structures (NBR 7190/2022), which are equivalent [12, 13].

Equation 3 presents the analytical calculation to estimate the connection slip modulus. According to the standards, if the characteristic density of the joint members is different ($\rho_{k,1}$ and $\rho_{k,2}$), then calculating the stiffness may be taken as presented in equation 4.

$$K_{ser} = \rho_{med}{}^{1,5} \cdot \frac{d}{23} \quad (3)$$

Where ρ_{med} is the average specific density in kg/m³, given by multiplication of the apparent density characteristic by the value 1.20; d is the effective diameter of the dowel, expressed in millimetres (mm).

$$\rho_{med} = \sqrt{\rho_{k1} \cdot \rho_{k2}} \quad (4)$$

Where ρ_{k1} and ρ_{k2} are the density values of woods 1 e 2.

The Table 4 presented results for analytical values for the species studied.

Wood	Density ρ_k (Kg/m³)	Density ρ_{med} (Kg/m³)	Kser (N/mm)
Pequiarana	*690*	-	-
Breu vermelho	605	646	11425
Pau rainha	910	792	15517
Mata Mata Amarelo	810	748	14220
Cardeiro	590	638	11212

5 DISCUSSION

5.1 PHYSICAL AND MECHANICAL PROPERTIES OF WOOD

Through the characterization tests it was possible to conclude that the Pau Rainha (*B. rubescens)* obtained the highest values of the physical and mechanical properties, reaching a 120 MPa in parallel compression ($f_{c0,k}$). The Matá Matá Amarelo (*E. wachenheimii*) species also obtained good values for use in dowels, because the Brazilian standard recommends use of wood from class D60 for dowels. The value obtained for parallel compression ($f_{c0,k}$) by Matá Matá Amarelo did not exceed 60 MPa but was very close. The other two species, Breu Vermelho (*P. Altsonii*) and Cardeiro (*Scleronema micranthum*) obtained the lowest values, with parallel compression ($f_{c0,k}$) 48 and 38 MPa, responsively.

The Cardeiro species was excluded from the tests as a connection element because besides low mechanical resistance, it has traumatic channels, an anatomical feature that increases wood fending during machining.

Differences in perpendicular and parallel resistances the fibres of the three species studied can be seen in the image of the dowels after the test to determine the slip module, (Figure 11). It is clear that the Breu Vermelho scare has been compressed perpendicular to fibres while those of

Matá Matá Amarelo and Pau Rainha this compression was not evident.

5.2 SLIP MODULE TEST

The results of the rigidity tests of the connection according to the parameters of the Brazilian standard showed that Pau Rainha (*B. Rubescens*) obtained the highest value of k_{ser}, followed by Matá Matá Amarelo (*E. Wachenheimi*) and finally the Breu Vermelho wood (*P. Altsonii*). These results are aligned with the values of the physical and mechanical properties presented in tables 1, 2 and 3, where the Pau Rainha (*B. Rubescens*) presents the highest values of resistance and rigidity to compression parallel to fibres, resistance to shear and density, followed by Matá Matá Amarelo (*E. Wachenheimi*) and finally the Breu Vermelho wood (*P. Altsonii*).

The results of binding rigidity tests according to the parameters of EN26891 and ISO 10984 did not show the same behaviour. In the comparison between the values obtained by the method of calculating the Brazilian standard and the EN26891 and ISO 10984, the values range from 30 to 200%.

5.3 ANALYTIC CALCULUS RESULTS

The results of the analytical calculation indicated in Eurocode 5 and the Brazilian Standard of Wood Structures did not converge for the values obtained for the connection slip test. Other authors estimate k_{ser} using other relationships that also take into account the density of the wood and the dowel diameter, but with different equation [2]. New calculations using these other equations will be performed to obtain an analytical equation more consistent with the use of the dowelled connection in cross -lamella panels.

6 CONCLUSION

Among the four wood species studied for use as a connecting element (dowel), only the Pau Rainha wood (*B. Rubescens*) and Matá Matá Amarelo (*E. Wachenheimi*) obtained good results. Mata Mata Amarelo did not get the best results, but in the criterion of abundance, that is, number of tree individuals per m² in the rain forest, it has advantages over the Pau Rainha. Thus, it is possible to apply the concept of sustainable forest management and rationally use this tree species.

The preparation of cross-lamelas wood panels using high density wood caves from the Amazon rainforest presents itself as an alternative for the use of little-known species and great abundance in the forest. New studies are being conducted to validate these results, varying the diameter of the dowels and the lamellas woods.

AN EXPERIMENTAL INVESTIGATION OF FAILURE MODES IN SHORT SPAN FRP REINFORCED GLULAM BEAMS

Catherine Shrimpton[1], Serena Siciliano[2], Herry Chen[3], Yannick Vetter[4], Daniel Lacroix[5]

ABSTRACT: Although the Canadian bridge code has provisions for fibre-reinforced polymer (FRP) timber stringers, the lack of tools and limited understanding of the structural behaviour prevents widespread adoption, specifically for glulam beams. Thus, an experimental investigation examining the effects of FRP reinforcement configurations on short span glulam beams was undertaken. A total of fourteen glulam beams were tested to failure under four-point bending with five of them being unreinforced and the remaining nine reinforced with two or four layers of simple tension and U-shaped tension FRP reinforcement. In comparison to the unreinforced beams, FRP reinforced beams were observed to have an increase in maximum load with a lower maximum displacement. Although the addition of FRP reinforcement contributed to an increase in strength and stiffness, the primary failure mode changed from pure flexure, as found in the unreinforced beams, to longitudinal shear, tension perpendicular-to-grain or a combination of brittle failure modes. The brittle failure modes can be attributed to insufficient development lengths, the low shear span to depth ratio, and the inherent low shear strength of the tested glulam. These factors need to be considered in future models to accurately predict the structural behaviour of short span glulam beams in flexure.

KEYWORDS: fibre-reinforced polymers, glulam, timber, shear failure, flexural failure

1 INTRODUCTION

1.1 BACKGROUND

The resurgence of timber within the construction industry has been heavily influenced by the development and commercialization of mass timber products, such as glued-laminated timber (glulam) and cross-laminated timber (CLT). Significant research efforts have thus been undertaken in Canada and internationally to investigate the performance of different mass timber products. As a result, significant updates to the newest editions of the National Building Code of Canada [1] and International Building Code [2] have been implemented allowing for the construction of encapsulated mass timber buildings up to 12- and 18-storeys, respectively.

Despite the significant progress towards the development of design provisions and guides, one area that has not been fully investigated is the behaviour of glulam beams reinforced with fibre-reinforced polymers (FRPs). To this date, there are no design guidelines in the CSA O86 "Engineering Design in Wood" [3] nor the CSA S6 "Canadian Highway Bridge Design Code" [4] for glulam beams reinforced with FRPs. Although there are design provisions in the CSA S6 for timber stringers reinforced with FRP fabric and bars, the increased strength is tied to a minimum reinforcement ratio being met, thereby resulting in an increased strength of one grade category (e.g., from No.1/No.2 to Select Structural).

The overarching aim of the current research program at the University of Waterloo is to provide designers with guidance in the detailing of FRP-reinforced wood members in addition to providing tools to understand and predict their structural behaviour. Within the scope of the current paper, traditional FRP reinforcement methods on the performance of short span glulam beams are investigated and discussed.

1.2 PREVIOUS RESEARCH

Several types of FRPs exist and can be applied to wood (e.g., sawn timber, glulam) to strengthen deficient structural members, retrofit against extreme hazards (e.g., earthquakes, blast loading), or to use as a hybrid product in a new design. Common FRP types include glass FRP (GFRP), carbon FRP (CFRP), aramid FRP (AFRP), or basalt FRP (BFRP). These types can be installed through external bonding of FRP sheets [e.g., 5–7] or insertion of FRP bars or plates into the members [e.g., 8,9].

In general, whether in the form of sheets or bars, FRP generally contributes to an overall increase in stiffness

and strength with an upper limit of 3% of reinforcement to wood area. Vetter et al. [10] conducted an analytical study on the effects of the material wood properties on the flexural behaviour of FRP-reinforced glulam. In the study, three different cross-section sizes, two reinforcement schemes (i.e., simple tension, and U-shaped up to mid-depth), six different number of FRP layers provided (i.e., 0, 1, 2, 3, 5, 7), and three different ratios of tension-to-compression moduli (i.e., 2:1, 1:1, 0.5:1) were investigated for a total of 99 simulations. The tensile-to-compressive wood strength ratio was observed to significantly affect the increases in moment resistance when the wood in tension is significantly weaker than in compression (i.e., 0.5:1), with increases in moment resistance of 1.95. In comparison, for the case where the wood in tension is significantly stronger than that in compression (i.e., 2:1), a maximum moment resistance increase of 1.19 was observed. This observation is in line with the literature that the contribution of the FRP is most evident for weaker specimens [6].

Although the previous research provides a good insight on the behaviour of FRP-reinforced glulam beams, the material model used in Vetter et al. [10] assumed a flexural response and an infinitely rigid bond between the FRP and omitted FRP delamination and longitudinal shear failure in the wood.

1.3 OBJECTIVES

The primary aim of the research is to investigate the behaviour of both unreinforced and FRP reinforced glulam beams, in order to understand the limitations of reinforcement configurations on the flexural behaviour of glulam beams. This paper presents the findings of the research program, specifically the effects that FRP reinforcement has on the failure modes of short span glulam beams.

2 EXPERIMENTAL PROGRAM

2.1 DESCRIPTION OF SPECIMANS AND MATERIALS

The experimental program investigated the behaviour of fourteen unreinforced and FRP-reinforced 69 mm x 100 mm x 1355 mm 20f-EX glulam beams under four-point bending. Upon receipt of the glulam, it was observed that the specimens had minor deformities (e.g., uneven edges, inconsistent laminate widths, splits) which were removed by use of a planer and jointer to a final 69 mm x 100 mm cross-section. The specimen lengths, and clear span, were determined in accordance with ASTM D198 “Standard Test Methods of Static Tests of Lumber in Structural Sizes” [11]. According to the standard, a minimum shear span to depth ratio (a/d) of 4 allows for the evaluation of flexural properties. Therefore, shear and clear spans of 400 mm and 1,200 mm were chosen with beams having a total length of 1,355 mm. Prior to testing, the specimens were conditioned to an average moisture content of 11.4% (CoV 0.11). using a humidity chamber. The average density of the beams was determined to be 442 kg/m3 with a coefficient of variation of 0.06.

Of the fourteen specimens, five were unreinforced and nine were reinforced with glass FRP (GFRP). Five beams were reinforced with simple tension reinforcement and four with U-shaped reinforcement extending to mid-depth (Figure 1).

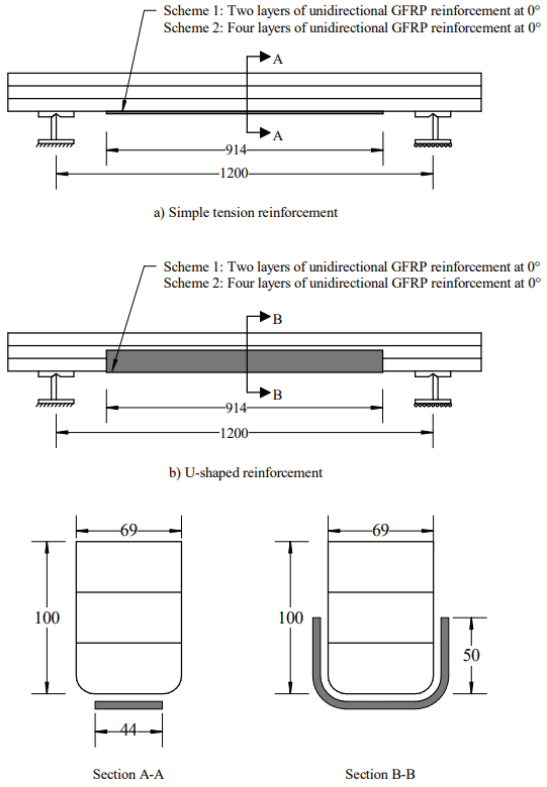

Figure 1: *Reinforcement Configurations*

All reinforced specimens were provided with either two or four layers of unidirectional GRFP reinforcement at 0°.The glulam tension laminate corners were routed using a corner round over bit (12.7 mm radius) prior to the application of the GFRP to prevent stress concentrations in the FRP extending beyond the bottom face. The application face(s) of the beams were wire brushed using a grinder to roughen the surface, providing an ideal interface for the bond between the FRP fabric and the glulam. The glulam FRP application face(s) were then coated with a layer of the epoxy resin mixture. The GFRP fabric was initially saturated with the epoxy resin followed by placing the FRP sheets onto the epoxy coated glulam beam surfaces. A summary of the test matrix is shown in Table 1.

https://doi.org/10.52202/069179-0028

Table 1: *Test Matrix Summary*

Specimen Number	Specimen Type	Reinforcement Configuration
G-1 - G-5	Unreinforced	-
GS_2-1 – GS_2-3	Reinforced	Simple Tension, 2 Layers
GS_4-1 – GS_4-2	Reinforced	Simple Tension, 4 Layers
GU_2-1 – GU_2 -2	Reinforced	U-Shaped, 2 Layers
GU_4-1 – GU_4 -2	Reinforced	U-Shaped, 4 Layers

2.2 DESCRIPTION OF TEST SETUP

A total of fourteen glulam beams were tested under static four-point bending, in accordance with ASTM D198-21a "Standard Test Methods of Static Tests of Lumber in Structural Sizes" [11]. Simply supported boundary conditions were provided through the use of an anchored pin and roller system.

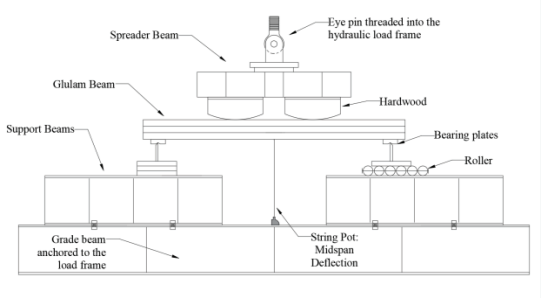

Figure 2: *Flexural Test Set Up*

A 500 kN hydraulic load frame with a load cell connected to the actuator was used to load all bending tests. The unreinforced and reinforced beams were loaded in displacement control until failure, with loading protocols ranging from 3.5 mm/min to 10 mm/min to ensure ultimate failure within five to ten minutes [11]. During the tests, a data acquisition system recorded the data. The applied load and midspan deflection were measured using the load cell in the test frame and a wire (i.e., string pot) respectively. Furthermore, the strains of the wood and FRP were recorded at midspan using strain gauges. Before testing the weights, moisture readings and visual observation of the specimens were recorded.

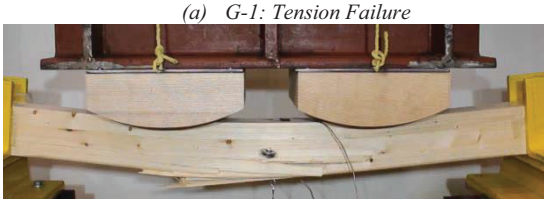
3 EXPERIMENTAL RESULTS

3.1 FAILURE MODES

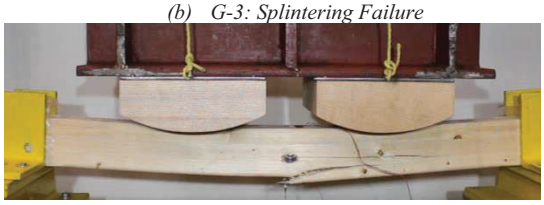
A total of five unreinforced and nine FRP-reinforced glulam beams were tested to failure. The observed failure modes in the unreinforced glulam beams consisted of simple tension and splintering (Figures 3a and 3b), as well as cross-grain tension in one specimen (Figure 3c).

For the simple tension reinforcement configuration with two layers and four layers, the failure mode changed from a flexure failure to one that is dominated by longitudinal shear and stress concentrations. Figure 4 shows a representative failure progression where a longitudinal shear failure first occurred followed by a failure of the wood where the simple tension reinforcement ended (GS_2-2, GS_2-3, GS_4-1). For all three beams, FRP debonding on the tension face or tensile failure of the FRP were not observed. This observation conflicts with other studies that reported debonding of the FRP caused by a flexural failure of the wood material on the tension side pushing on the FRP laminations [12–15].

(a) G-1: Tension Failure



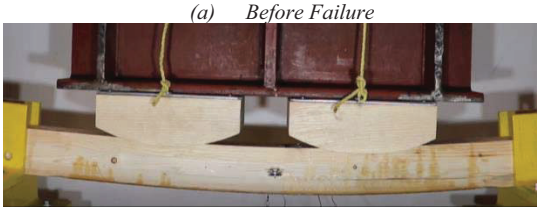
(b) G-3: Splintering Failure



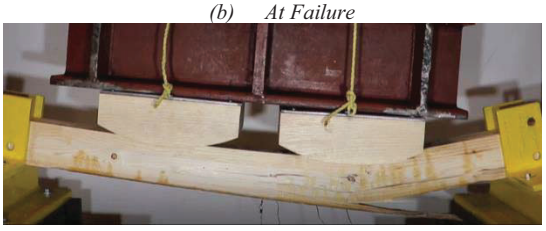
(c) G-4: Cross-grain Failure

Figure 3: *Failure Modes of Unreinforced Specimens*

(a) Before Failure



(b) At Failure



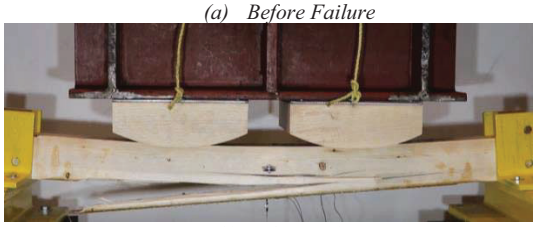
(c) After Failure

Figure 4: *Representative failure of longitudinal shear dominated failure modes in simple tension reinforcement (GS_2-2)*

https://doi.org/10.52202/069179-0028

A second failure mode was observed for specimens reinforced with simple tension reinforcement where failure was observed to occur at the ends of the simple tension GFRP strips causing horizontal shear and tension perpendicular to grain stresses (GS_2-1, GS_4-2). The bond between the reinforcement and the wood remained intact, followed by the propagation of the failure throughout the wood.

(a) Before Failure

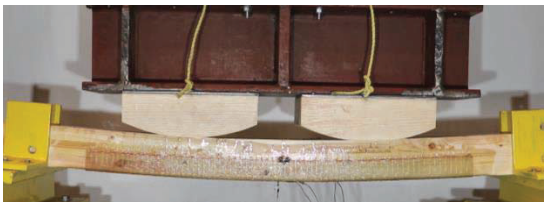


(b) After Failure

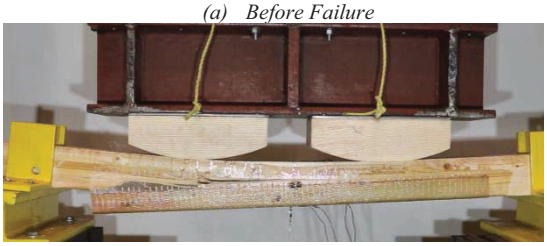
Figure 5: *Representative Failure of Tension Perpendicular-To-Grain Dominated Failure for Specimens with Simple Tension Reinforcement (GS_4-2)*

The conflicting failures modes observed for the configuration of simple tension reinforcement glulam beams can be attributed to a combination of factors including: 1. Insufficient development length of the reinforcement, 2. Lower bound shear span to depth ratio (a/d), and 3. Shear strength of glulam. The simple tension reinforcement configuration appears to have provided insufficient development length causing stress concentrations between the supports and end of FRP reinforcement, ultimately leading to an initial failure mode dominated by tension perpendicular-to-grain. In comparison to Lacroix and Doudak [12] for which the FRP reinforcement ended 82.5mm from the centre of the supports, the FRP reinforcement in the current study was terminated 143mm from the centre of supports. Furthermore, while the shear span to depth ratio (a/d) was within the recommended range in the standard [11] with a value of 4:1, it was at the lower end, thus even providing minimum reinforcement shifted the failure mode from flexure to one that is predominantly dominated by longitudinal shear. This can also be attributed to the fact that the glulam in the current study had a lower shear strength, thus only minimal reinforcement was required to alter the primary failure mechanism as Lacroix and Doudak had an a/d ratio of 3.85:1 [12], but did not observe the failure modes reported herein.

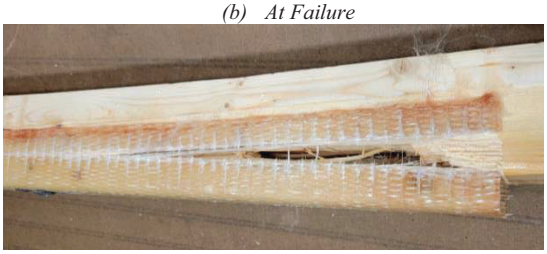
For all but one specimen, the U-shaped tension reinforcement eliminated the horizontal longitudinal shear failure as shown in Figure 6. All three specimens (GU_2-1, GU_2-2, GU_4-2) failed due to stress concentration at the end of the FRP reinforcement resulting in debonding of the FRP. Nonetheless, shear stresses are clearly evident as indicated by the splitting of the FRP. This failure mode in the FRP is to be expected due to the use of unidirectional FRP, thus there are no FRP fibres aligned with the depth of the beam. The addition of the reinforcement resulted in a primary failure mode of sudden brash failure at the end of the FRP reinforcement combined with horizontal shear failure of both the wood and FRP reinforcement on the side faces, rather than flexural failure as observed in the unreinforced specimens (Figure 6c). The change in failure mode was expected since the additional reinforcement provided some shear reinforcement.



(a) Before Failure



(b) At Failure



(c) Close Up of Back-Side Failure

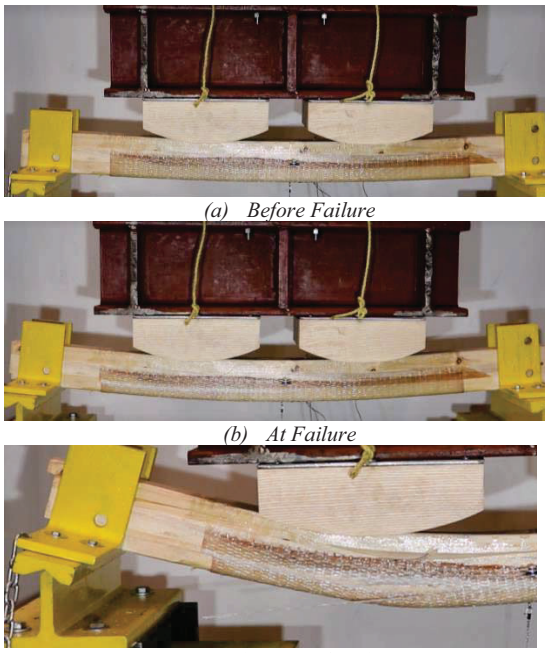
Figure 6: *Representative Failure of Tension Perpendicular-To-Grain Dominated Failure for Specimens with U-Shaped Tension Reinforcement (GU_2-1)*

The second failure mode observed for the specimens reinforced with U-shaped tension reinforcement is one that is dominated by a longitudinal shear failure as shown in Figure 7. GU_4-1 failed in horizontal shear at the support with the failure propagating throughout the beam, accompanied with splitting of the FRP reinforcement. Debonding of the FRP was not observed even at large displacement (Fig. 7c).

In general, the failure modes of the unreinforced and reinforced specimens were observed to be different. For all unreinforced specimens, wood tension-dominated failures were observed. This failure mode was not the primary failure mode observed in reinforced specimens as the increase in the woods tensile strength provided by a minimum 2% reinforcement ratio proved to be significant enough to cause the failure mode to change from flexure

https://doi.org/10.52202/069179-0028

to shear for simple tension and U-shaped reinforced specimens.



(a) Before Failure

(b) At Failure

(c) Close Up of Failure

Figure 7: *Representative Failure of Longitudinal Shear Dominated Failure Mode for U-Shaped Tension Reinforcement (GU_4-1)*

3.2 ANALYSIS OF EXPERIMENTAL RESULTS

In this section, key parameters describing the behaviour of the unreinforced and FRP-reinforced specimens are presented, including: the maximum applied load (P_{max}), displacement at the maximum applied load (Δ_{Pmax}), and the initial stiffness defined as the slope from 10 to 40% of load-displacement curve. The results are summarized in Table 2-3 and Figures 8-10. The flexural response of the unreinforced beams is summarized in Table 2 whereas the individual load-displacement curves as well as the average curve are presented in Figure 8.

Table 2: *Unreinforced Beam Flexural Test Results*

Specimen Number	P_{max} (kN)	Δ_{Pmax} (mm)	K (N/mm)
G-1	27.9	26.4	1620
G-2	30.8	29.3	1541
G-3	36.8	24.3	1731
G-4	36.8	23.3	2107
G-5	31.9	29.8	1510
Average	32.8	26.6	1702
Std. Dev.	3.5	2.6	216
CoV	0.11	0.10	0.13

The load-displacement curve of the unreinforced beams is observed to behave in a linear fashion with some level of softening caused by compression yielding prior to the wood tensile failure. Since glulam beams consist of different laminates glue-pressed together, the variability and location of naturally occurring defects often leads to wood tensile failures occurring prior to reaching the maximum compression resistance of the laminates.

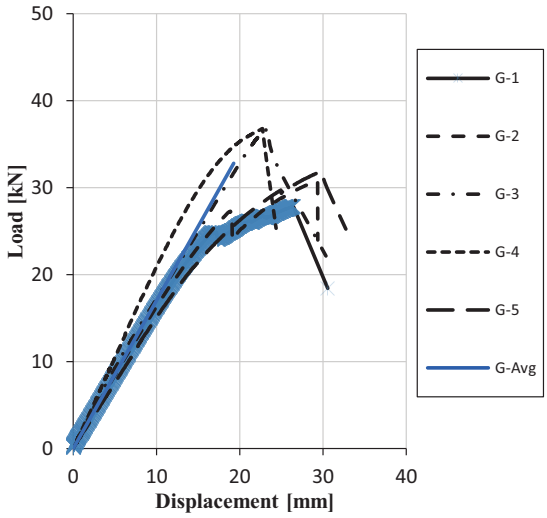


Figure 8: *Load – Displacement Curves of G-Specimens*

The flexural performance of the reinforced beams is summarized in Table 3. The majority of the reinforced specimens showed an increase in the maximum load (P_{max}) and stiffness (K). The provided FRP reinforcement contributed to stiffening of the beams, allowing for greater loads to be sustained. Therefore, leading to a combination of horizontal shear failures and tension perpendicular-to-grain as opposed to that of flexure for the unreinforced beams. As all reinforced beams failed in either shear, delamination, or a combination of alternative failure modes, rather than tensile flexural (e.g., splintering, cross-grain) this is an indication that an increase in tensile strength from the FRP reinforcement schemes can lead to an alternate failure mode. The reinforcement prevented failure of wood tensile fibres observed during the unreinforced beam tests, ultimately increasing the shear stresses in the specimens. This resulted in alterative brittle failures beyond tensile flexural failures observed in the unreinforced beams.

Table 3: *Reinforced Beam Flexural Test Results*

Specimen Number	P max (kN)	Δ_{Pmax} (mm)	K (N/mm)
GS_2-1	32.1	12.8	2544
GS_2-2	35.2	24.1	1783
GS_2-3	36.8	19.5	2082
Average	34.7	18.8	2137

GU_4-2	46.9	19.5	2844
Average	46.8	27.3	2552

https://doi.org/10.52202/069179-0028

3.2.1 GS Specimens

The addition of two unidirectional GFRP sheets applied longitudinally (GS) increased the capacity and stiffness of the beams on average by a factor of 1.06 and 1.26, respectively. With four unidirectional GFRP sheets, the capacity and stiffness increased by an average factor of 1.44 and 1.46, respectively. However, on average the GS_2 beams failed at a maximum displacement of 0.72 times less than that achieved in the unreinforced beam tests, whereas the GS_4 beams showed an increase of 1.02 times the displacement of unreinforced beams. Relative to the unreinforced beams, the displacement at maximum loads did not increase proportionally (Figure 9).

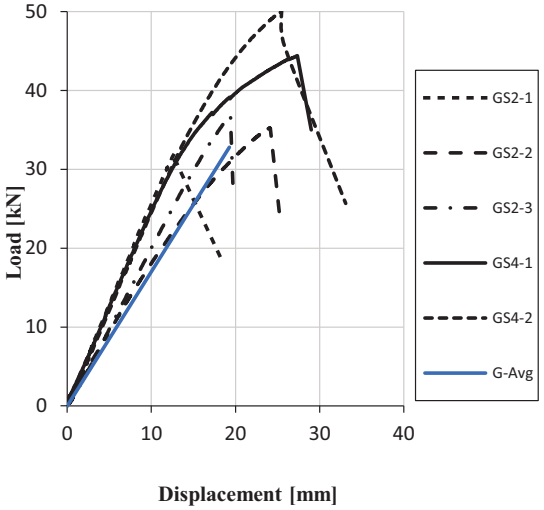

Figure 9: *Load – Displacement Curves GS Specimens*

The significant difference in the change of resistance versus the change of maximum displacement observed in GS can be attributed to a change in failure mode. The addition of simple tension reinforcement altered the failure mode from a wood tension failure in flexure to a horizontal shear failure or stress concentration failure located where the simple tension FRP reinforcement sheets were terminated. The FRP was shown to effectively increase the bending stiffness and reinforced the wood fibres, allowing for the specimens to support greater loads at smaller displacements. The reinforcement provided did not allow for further increase in the beams' bending performance by causing it to fail in a brittle manner (i.e., shear, tension perpendicular-to-grain).

3.2.2 GU Specimens

For beams reinforced with two layers of U-shaped reinforcement (GU), the average resistance and stiffness increased by 1.26 and 1.25 respectively, when compared to the unreinforced beams. For four layers, the average resistance and stiffness increased by 1.43 and 1.50, respectively. Similar to the GS beams, the increases in maximum load and maximum displacement were not proportional. When compared to the unreinforced beams, a decrease of 0.03 times the displacement was observed for the GU_2 beams, whereas a slight increase of 1.05 was observed for the GU_4 beams.

When comparing the effect of U-shaped reinforcement (GU) to the simple tension configuration (GS), the overall flexural behaviour of the specimens is similar. The specimens reinforced with 2 and 4 layers of U-shaped reinforcement (GU) were observed to have an increase in maximum resistance by an average of 1.26 and 1.43, respectively relative to the unreinforced beams.

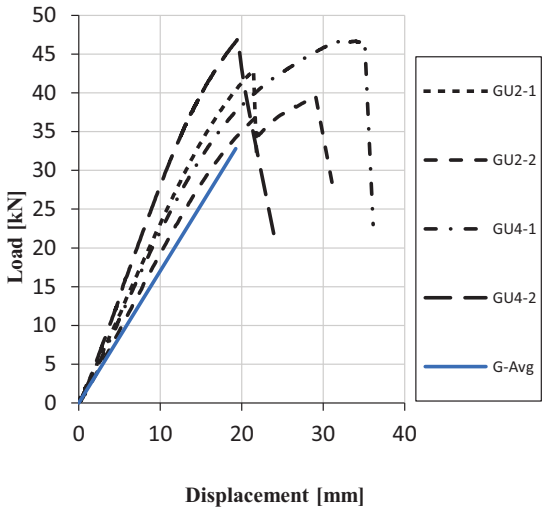

Figure 10: *Load – Displacement Curves GU Specimens*

4 CONCLUSIONS

The current research program investigated the effects of simple tension and U-shaped tension FRP reinforcement on the performance of short span glulam beams. It was observed that while the addition of FRP reinforcement to glulam beams contributed to an increased strength and stiffness when compared to the unreinforced glulam beams; that alternate failure modes consisting of longitudinal shear, tension perpendicular to grain, or a combination of rather than flexure were observed. The alternate brittle failure modes can be attributed to insufficient development lengths, the low shear span to depth ratio, and the inherent low shear strength of the tested glulam. The conflicting failure modes reported herein when compared with the literature [12] indicate that further investigation into the development length of the FRP reinforcement and the corresponding shear concentration at the start and end of FRP reinforcement should be undertaken for the development of future models.

Overall, specimens with two layers of FRP reinforcement increased in capacity by 1.06 to 1.26 for simple and U-shaped configurations respectively. For specimens with four layers of reinforcement, the capacity increased by 1.26 to 1.43, respectively. Similarly, the beams had an observed stiffness increase of 1.25 to 1.26 for two layered configurations, and 1.46 to 1.50 for four layered

https://doi.org/10.52202/069179-0028

configurations. Additionally, the increase in the resistance at a lower maximum displacement of the GS and GU specimens relative to the unreinforced beams indicate benefits attributed to specific FRP reinforcement schemes. While the main objective of the reinforcement is to increase the ultimate capacity of the beam at locations of large bending stresses, to remain effective, the reinforcement is required to be adequately anchored or bonded, to allow the transfer of stresses.

DAMAGE MODEL FOR A BIOSSOURCED HETEROGENEOUS MATERIAL: APPLICATION TO TIMBER

Amal Rebhi[1], **Myriam Chaplain**[2], **Jean-Luc Coureau**[3], **Cedric Perez** [4]

ABSTRACT: The purpose of this study is to investigate the damage mechanisms of timber, by developing a numerical model based on the concept of damage mechanics. The first stage of this work is to study the existing damage models used for quasi-brittle materials and then propose a fitting to timber. Then a new model is proposed which allows to take into account the orthotropy of timber, the local variation of the mechanical properties due to heterogeneity induced by the defects of timber and the behaviour of timber according to the mode of loading in relation to the longitudinal axis of the grain. Finally, the model calibration is carried out through different experimental tests: fracture characterisation tests in mode I and II and bending tests integrating the heterogeneity of timber.

Keywords: Numerical model, damage mechanics, fracture, timber, quasi-brittle, ductility.

1 INTRODUCTION

To achieve the goals of sustainable development, the use of renewable materials is a response to the climate change. Timber has many advantages allowing it to be more attractive than materials used mainly in the field of construction (steel and concrete). Indeed, it is the only one totally renewable, natural and biological building material. Due to its advantages, research is focusing on improving its mechanical characterization. This means that researchers are focused on better understanding the mechanical properties of wood and finding ways to optimize its performance in terms of strength, stiffness and durability.

The design of wood structures is carried out according to the Eurocode 5 standard to guarantee their durability. It essentially implies a macroscopic characterization of the timber which is regarded as a homogenous material integrating the intrinsic its variability by semi-probabilistic analyses. In fact, wood is a highly anisotropic material, its properties are highly variable and are sensitive to loading types and environmental conditions in relation with the moisture content of the material.

Its mechanical behaviour is strongly influenced by the singularities (like knots) and also by the mode of solicitation with respect to the orthotropy directions. In fact, the bending failure tests show that the fracture is due, in more than 90% of the cases, to the presence of knots and the corresponding deviation of the grain slope. The influence of these defects has been the subject of several studies [1, 4, 6, 7, 10, 11] which show that most of the mechanical properties are lower in sections with knots than free defect wood. Longitudinal tension strength is the most affected property, followed by bending strength, compressive strength parallel to the grain and elasticity modulus. This reduction is due to a stress concentration caused by the presence of knots and the change in the orientation of the local frame along the fibres, thus changing the complacency matrix as a function of the grain slope. In view of this material complexity due to the variation of its mechanical properties, the development of mathematical laws presents an interesting challenge to establish reliable predictive models.

In order to improve the mechanical grading of timber and to limit qualification tests. New numerical approaches need to be developed to study its mechanical behaviour at failure, considering the anisotropy and the influence of its heterogeneities induced mainly by knots.

The majority of existing approaches are based on failure criteria associated with elastic behaviour [1, 3, 9...]. they used elastic failure criteria such as the Tsai-Hill criterion and the Tsai-WU criteria. The load that corresponds to the initiation of damage is determined, but these models are not able to correctly predict the strength and describe the shape of the post-peak portion of the load-displacement curve.

The simulation of timber behaviour requires a model that takes into account the defects of wood, the variation of the grain slope and that integrates the damage of the quasi-brittle anisotropic material to predict the initiation and the progressive damage up to the failure. This work is part of this framework, we propose a new non-linear approach based on the Mechanics of Continuous Damage (MCD) to predict the mechanical behaviour of timber.

MCD is a non-linear elastic approach that was developed in 1958 by Rabotnov and Kachanov [8] to study creep rupture and was subsequently used by several researchers to describe metal damage and failure. This

concept is part of the thermodynamics of irreversible processes [9]. It has become a promising tool for describing material degradation. The damage is presented by scalar or tensorial variables depending on the objective to be achieved during the modelling. In our case, the damage is anisotropic and several variables are defined according to each type of stress (tension, compression or shear). The MCD is based on the concept of effective constraints which consists in associating to the damaged real space a fictional space for which the material is healthy (Figure 1). New quantities are defined in this space which must be related to the real quantities according to the principle of equivalence used (principle of equivalence in strain, principle of equivalence in stress or principle of equivalence in energy) [13].
Stress increments are calculated as a function of strain increments via an effective stiffness matrix determined as a function of the initial stiffness matrix and damage variables.
Validation of the approach is carried out in two stages. The purpose of the initial modelling is to verify the model parameters by applying it to mode I and II fracture tests on Maritime Pine wooden (free defects) specimens. Then the model is applying to study the bending behaviour of timber beams, integrating the local variation of mechanical properties due to defects.

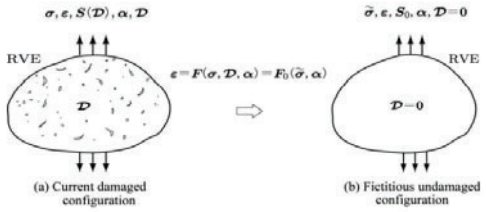

Figure 1: *Assumption of mechanical equivalence and effective stress [13]*

2 DEVELOPMENT OF THE BEHAVIOUR LAW

Before introducing the model, it is necessary to define some indices used for the wood material. Because of its mode of growth, the wood is characterized according to its three natural directions: longitudinal (L, axis of the tree), radial (R) and tangential (T) and its three planes: radial (LR), tangential (LT) and transverse (RT) (Figure 2)

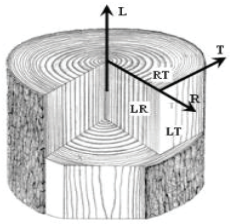

Figure 2: *orthotropy of wood [12]*

In the elastic field, the behaviour is determined by the generalized Hooke's law (Equation (1)), which shows the symmetrical elastic flexibility matrix, the components of this matrix are modified during loading according to the evolution of the damage variables.

$$\begin{bmatrix}\varepsilon_{RR}\\ \varepsilon_{TT}\\ \varepsilon_{LL}\\ \tau_{TL}\\ \tau_{LR}\\ \tau_{RT}\end{bmatrix} = \begin{bmatrix} \frac{1}{E_R} & \frac{-\vartheta_{RT}}{E_T} & \frac{-\vartheta_{RL}}{E_L} & 0 & 0 & 0\\ \frac{-\vartheta_{TR}}{E_T} & \frac{1}{E_T} & \frac{-\vartheta_{TL}}{E_L} & 0 & 0 & 0\\ \frac{-\vartheta_{LR}}{E_R} & \frac{-\vartheta_{LT}}{E_T} & \frac{1}{E_L} & 0 & 0 & 0\\ 0 & 0 & 0 & \frac{1}{G_{TL}} & 0 & 0\\ 0 & 0 & 0 & 0 & \frac{1}{G_{RL}} & 0\\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{RT}} \end{bmatrix} \cdot \begin{bmatrix}\sigma_{RR}\\ \sigma_{TT}\\ \sigma_{LL}\\ \sigma_{TL}\\ \sigma_{LR}\\ \sigma_{RT}\end{bmatrix} \quad (1)$$

2.1 Initiation and evolution of damage

Existing damage laws developed for isotropic materials are generally applied even if the damage is anisotropic.
The proposed method to implement a damage model for an orthotropic material is based on laws often used for quasi-brittle isotropic materials [5]. These are adapted according to the mechanical and geometric characteristics of wood. In addition, the model must have a ductile behaviour relative to the compressive stresses.
For a complete description of timber as an orthotropic material, different strain and stress-based failure criteria have been defined in tension and compression (Figure 3).
Wood has a quasi-brittle behaviour in tension and shear and a ductile behaviour in compression.

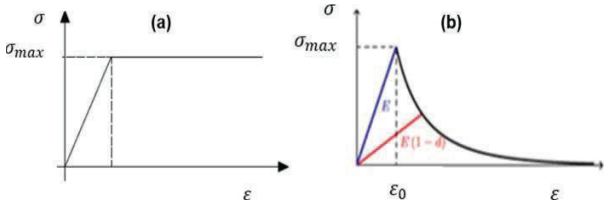

Figure 3: *Stress-strain: (a) ductile behaviour curve in compression, (b) softening behaviour in tension*

2.1.1 Tension behaviour

In tension parallel to the grain direction ($\sigma_L > 0$), damage initiation is governed by strain in the longitudinal direction ($\varepsilon_{t,L}$) and the elastic limit of tensile strain ($\varepsilon_{dt,L}$), the damage criterion ($F_{t,L}$) is given by the Equation (1):

$$F_{t,L} = \frac{\varepsilon_{t,L}}{\varepsilon_{dt,L}} - 1 \quad (2)$$

In tension perpendicular to the grain direction (σ_n>0) (n=R or T), damage is caused by tensile stresses (σ_n) and/or shear stresses (σ_{Ln} and σ_{RT}), the damage criterion in both directions perpendicular ($F_{t,n}$) is given by the Equation (2):

$$F_{t,n} = \frac{{\sigma_n}^2}{{f_{t,R/T}}^2} + \frac{{\sigma_{Ln}}^2}{{f_{Ln}}^2} + \frac{{\sigma_{RT}}^2}{{f_{RT}}^2} - 1 \qquad (3)$$

with $f_{t,n}$, f_{Ln}, f_{RT} are respectively the elastic limit of tensile stress in n direction (n=R or T), the maximum shear stresses in Ln plane and the maximum shear stresses in RT plane.

In order to take into account, the quasi-brittle behaviour of wood in tension as well as the parameters relating to failure, we are interested in existing laws on the damage of isotropic materials such as the Fichant and Mazars law. These laws use fracture energy and strains as the main parameters for predicting material behaviour.
In this quasi-brittle case, damage variables ($d_{t,n}$) have an exponential shape determined through the following relationship based on the Fichant law [5]:

$$\begin{cases} d_{t,n} = 1 - \frac{\varepsilon_{dt,n}}{\varepsilon_{t,n}} \exp\left(B_n\left(\varepsilon_{dt,n} - \varepsilon_{t,n}\right)\right) & if\ F_{t,n} > 0 \\ d_{t,n} = 0 & if\ F_{t,n} \le 0 \\ 0 \le d_{t,n} \le 1 \end{cases} \qquad (4)$$

with $F_{t,n}$ is the damage initialisation criterion, $\varepsilon_{dt,n}$ is the elastic limit in tension in the direction n (n=L, R, T), $\varepsilon_{t,n}$ is the tensile strain in the direction n at the current time increment and B_n is a damage parameters depending on the elastic modulus, strain limit, cracking energy in n direction ($G_{f,n}$) and finite element size (h) by the following relation :

$$B_n = \frac{hE_n\varepsilon_{dt,n}}{G_{f,n} - \frac{1}{2}hE_n(\varepsilon_{dt,n})^2} \qquad (5)$$

2.1.2 Compressive behaviour

For compressive strains parallel or perpendicular to the grain direction, timber has a ductile behaviour, in this case the damage is controlled by the compression deformations, the damage criterion ($F_{c,n}$) is given by the Equation (4):

$$F_{c,n} = \left|\frac{\varepsilon_{c,n}}{\varepsilon_{dc,n}}\right| - 1 \qquad (6)$$

with $\varepsilon_{dc,n}$ is the compression threshold deformation in the direction n and $\varepsilon_{c,n}$ is the deformation at time t.
The evolution of the damage variable ($d_{c,n}$) is determined from the following relationship:

$$\begin{cases} d_{c,n} = 1 - \frac{1}{F_{c,n}} & if\ F_{t,n} > 0 \\ d_{c,n} = 0 & if\ F_{t,n} \le 0 \\ 0 \le d_{c,n} \le 1 \end{cases} \qquad (7)$$

Wood has a quasi-brittle shear behaviour, which is in the proposed approach, related to its tensile and compressive behaviour. For example, a failure parallel to the LR plane can be caused by a tension perpendicular to the mode I, a shear (mode II) or a combination of both. Therefore, it is not possible to define separate failure modes for each direction of stress, a coupling is proposed. Therefore, shear damage is determined by the tensile and compression damage.
Finally, there are six damage variables, three in tension ($d_{t,n}$) and three in compression ($d_{c,n}$) (n=R, T or L).
Using Macaulay's mathematical operator to differentiate damage variables that are activated by the same stress component, but are sensitive to the sign of the component, i.e. tensile or compressive stresses.
So in each direction of orthotropy the damage variable is given by the following relation:

$$D_n = d_{t,n}\frac{\langle\sigma_n\rangle}{|\sigma_n|} + d_{c,n}\frac{\langle-\sigma_n\rangle}{|\sigma_n|};\ \text{with}\ \langle a\rangle = \frac{a+|a|}{2} \qquad (8)$$

We can define the diagonal tensor which represents the orthotropic damage due to the reduction of the effective bearing surface:

$$D = \begin{bmatrix} D_R & 0 & 0 \\ 0 & D_T & 0 \\ 0 & 0 & D_L \end{bmatrix} \qquad (9)$$

3 NUMERICAL SIMULATION OF FAULTLESS WOOD MECHANICAL BEHAVIOUR

In order to carry out the validation of the developed model, the experimental results of Perez [15] in mode I and II on perfect Maritime pine specimens are compared to the numerical results. The geometry of the specimen and the proposed limit conditions for the three experimental configurations (mode I and II) are shown in Figure 4. First, we used the mean experimental elastic and mechanical properties and mean experimental cracking energies.

Table 1: *Elastic and mechanical model parameters*

Parameter	Value
E_L (MPa)	10900
E_T(MPa)	1050
ϑ_{LT}	0.43
ϑ_{TR}	0.39
ϑ_{LR}	0.32
G_{LT} (MPa)	1030
$f_{t,L}$(MPa)	68
$f_{t,T}$(MPa)	3
$f_{c,L}$(MPa)	38
$f_{c,T}$(MPa)	4
$G_{f,I}$(J/m²) (Mode I cracking energy)	550
$G_{f,II}$(J/m²) (Mode I cracking energy)	1739

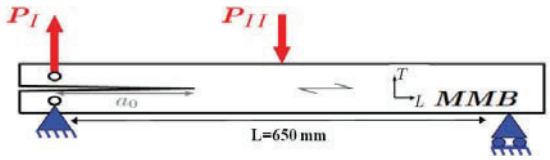

Figure 4: *Mode I DCB test (for* $\boldsymbol{P_{II} = 0}$*) and Mode II test (for* $\boldsymbol{P_I = 0}$*) (same specimen size for all tow failure modes)*

https://doi.org/10.52202/069179-0029

The numerical results are compared with the experimental ones by analysing the load-displacement curves and the corresponding resistance curves to verify the cracking energies declared in the model. The resistance curves (R-curve) are determined from the load-displacement curves and on the basis of the equivalent elastic fracture mechanics (MLER*eq*). They provide an estimate of the fracture properties and also information on the extent of the fracture development zone. Bazant and Kazemi [2] introduced the notion of equivalent elastic crack length (a_{eq}) in their expression of MLER*eq*. This approach defines the equivalent elastic crack length to that which, in a perfect elastic model, produces the same complacency as the actual crack with its development zone. Furthermore, the increase in complacency depends only on the extent of the potential fracture zone (FPZ) or the progression of the macro-crack with its development zone. On this basis, the crack propagation resistance can be estimated using the following equation proposed by Morel et al. (2005) [14].

$$G_R(a) = \frac{P^2}{2b}\frac{d\lambda(a)}{da} \qquad (10)$$

with λ(a) is the compliance such that λ(a) = δ(a)/P(a) with δ(a) and P(a) are the displacement and load for an equivalent elastic crack length a The equivalent elastic crack length is numerically determined from a linear elastic finite element model.

The R-curve for a quasi-brittle material can be divided into two zones. The first regime corresponds to the expansion of the elaboration zone until it reaches its critical size. The second regime is the plateau, which occurs when the macro-crack propagates in auto-similarity with its zone of development. The plateau value of the R-curve supplies the critical resistance to crack propagation, which is the cracking energy declared in the model to describe the mechanical behaviour of the material.

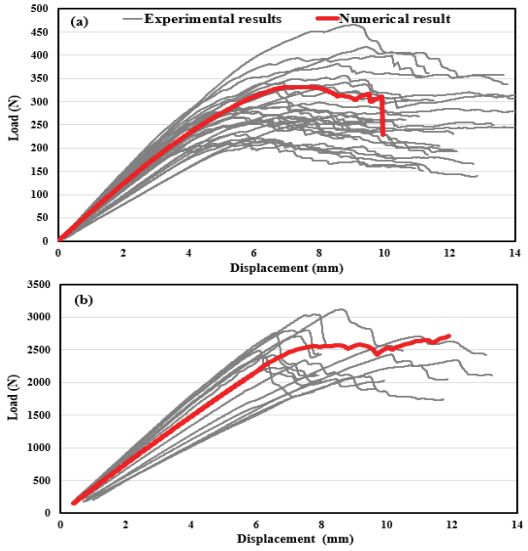

Figure 5: *Load -displacement curves: (a) mode I; (b) mode II; (c) mixed mode*

Using the average elastic and fracture properties of Perez, we observe a good agreement of the model in mode I and II (Figures 5 and 7).

Then, to verify each test, we performed a curve-to-curve comparison using the failure properties of each test (test 1: G_{fI}=400 J/m² ; test 2 : G_{fI}=520 J/m² ; test 3: G_{fI}=690 J/m²). The Figure 6 shows a comparison between experimental and numerical results for three tests performed in mode I.

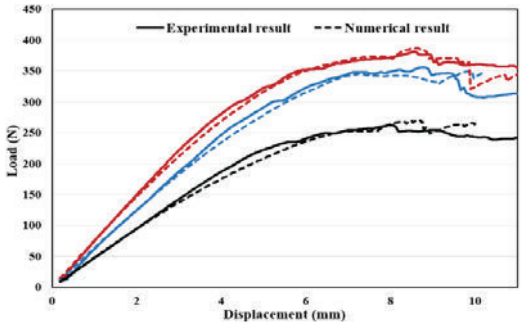

Figure 6: *Curve to curve comparison between numerical and experimental result (Mode I Mode II Mixed Mode colours)*

The numerical and experimental results are close and agree significantly, the numerical methods are reliable and can be used to predict the experimental results with some accuracy.

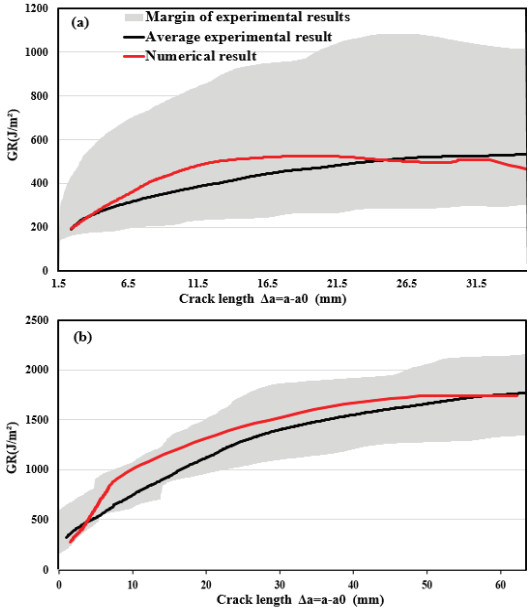

Figure 7: *Resistance curves: (a) mode I; (b) mode*

4 NUMERICAL SIMULATION OF THE MECHANICAL BEHAVIOUR OF HETEROGENEOUS WOOD

The model is then tested on heterogeneous wood by under bending tests. Eleven beams were tested in three-

point bending of 1200 mm length and a section of 100×50 mm².
Before the test, the variation of the grain slope and the geometric parameters of the knots is obtained experimentally and is taken into account in the modelling to determine the local elastic and fracture properties of the wood. The measurement of the grain slope is performed by a device named Xyloprofile. It is based on the projection of a line of laser points perpendicular to the longitudinal axes of the wood and by moving the beam longitudinally, it is possible to measure the fibre angle every 5 mm (Figure 8).

Figure 8: *Xyloprofile wood scan and measurement of the wire slope variation*

The modelling of the grain slope is performed from a numerical procedure that is able to read the experimental data of the slope as a function of the coordinates of each point of the beam and interpolate it in the mesh to build the field of variation of the slope. Then, the local elastic and mechanical parameters are determined by pass matrices calculated as a function of the slope value in each mesh element (Figure 9).

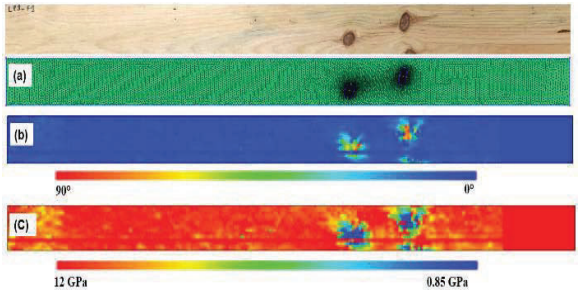

Figure 9: *Numerical modelling of grain slope: (a) mesh by EF, (b) variation of the grain angle in each point of the mesh, (b) variation of the longitudinal modulus of elasticity as a function of the grain slope*

Once we have all the necessary information on the variation of fibre inclination in the surfaces of each beam, on the position of knots and their geometry, the beams are then tested in three-point bending to determine their actual behaviour in the event of failure (Figure 10).

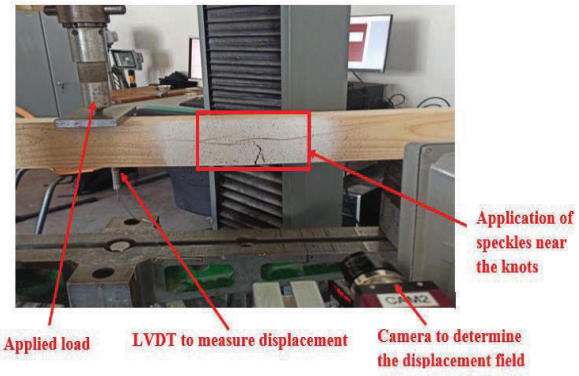

Figure 10: *three-point bending test*

Numerical modelling (2D) of these beams is performed using the average mechanical properties of perfect wood and experimental data of the slope variation. Then the failure stress is determined by taking the average of the numerical results found for the two load of the beam. The figure (Figure 11) shows the load-displacement curves found experimentally and by numerical simulation, as well as the cracking pattern at the fracture time of the three-points bending beams.

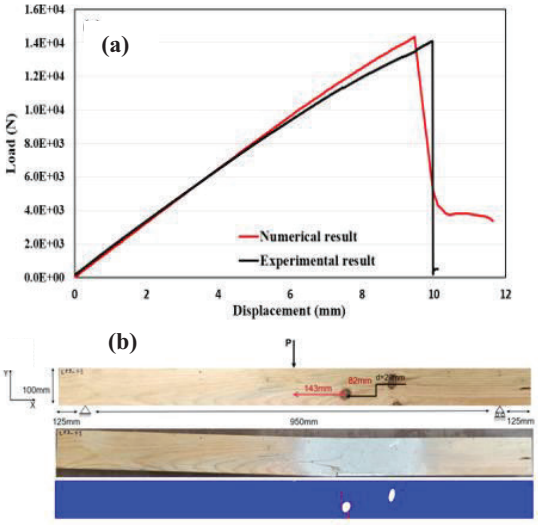

Figure 11: *Comparison between numerical and experimental results for a heterogeneous wood beam subjected to bending loading: (a) prediction of breaking load, (b) fracture facies.*

With the data of the variation of the grain slopes and the average mechanical properties of the perfect wood, we found a good correlation between the numerical and experimental results of the breaking load and displacement which corresponds to the breaking stress (Figure12).

https://doi.org/10.52202/069179-0029

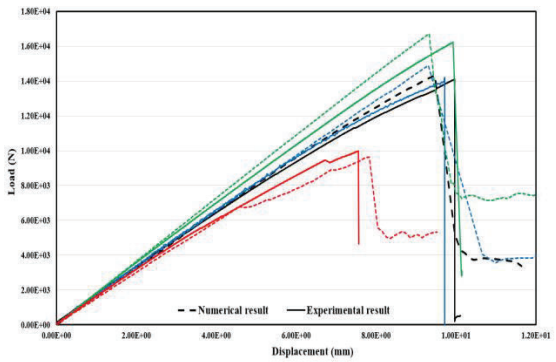

Figure 12: *Comparison between experimentally and numerically obtained fracture loads for four test cases*

In order to determine the displacement and strain fields that occur near the knots, a non-contact measurement method based on digital image correlation (2D) is used. This method allows for local observation of the material behaviour on the pre-nodal surface during the test. This can be very useful in understanding how the wood reacts to applied load and how the knots affect the stability of the structure in general. The results are then used to validate the developed numerical model by comparing the experimental and numerical deformation field values for the same loading times.

The Figure 13 shows the displacement fields (ε_{xx}) obtained from numerical modelling and by image correlation for the same imposed displacement. Comparing the two methods, it can be seen that the strain distribution is very similar around the knots. Furthermore, the strain values obtained from both methods are close in scale.

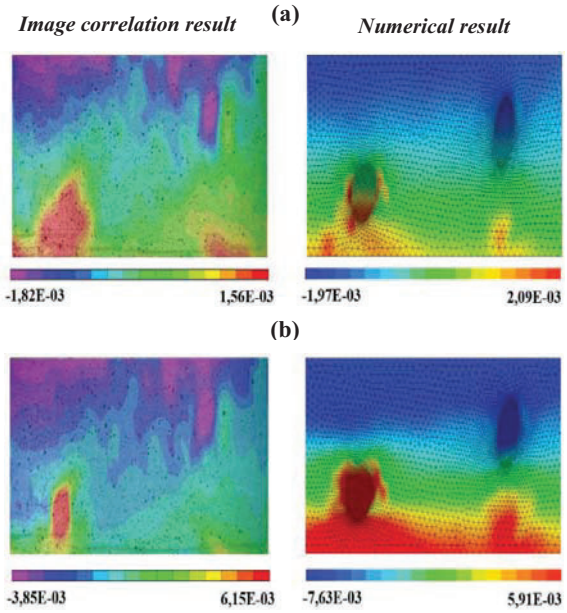

Figure 13: *Comparison between the displacement field obtained by numerical modelling and by image correlation: (a) ID= 3 mm; (b) ID = 6 mm (ID= imposed displacement)*

5 CONCLUSIONS

In this work, an anisotropic damage model for wood has been developed. The proposed model is able to model the fracture behaviour of wood with its heterogeneities, by implementing the damage criteria of wood according to the loading mode: a softening behaviour of wood in tension and shear and a ductile behaviour in compression. The satisfactory agreement obtained between the simulation results and the experimental results confirms the validity of the approach and the damage model proposed for the experimental conditions considered in this work. The integration of this mechanical model is a way of improvement. The next work consists in studying different timber species.

NUMERICAL EXAMINATION OF THE BEHAVIOUR OF DOWEL LAMINATED TIMBER ELEMENTS UTILISING COMPRESSED WOOD DOWELS

Conan O'Ceallaigh[1], Annette M. Harte[2], Patrick J. McGetrick[3]

ABSTRACT: This study examines the use of finite element software to model the failure behaviour of a dowel laminated timber (DLT) beam which is connected with the use of modified or compressed wood dowels. The numerical model is validated against experimental results and a parametric study is carried out to further examine the influence of dowel diameter and dowel spacing on the load-displacement behaviour of the DLT beams. The numerical model is shown to accurately simulate the ultimate failure load and the stiffness of the DLT beams. The influence of dowel diameter and dowel spacing are presented. The results demonstrate that DLT technology can be used to further improve the environmental performance of timber construction by replacing the use of adhesive which is commonly used when manufacturing laminated engineered wood products.

KEYWORDS: Compressed wood dowels; Dowel Laminated Timber (DLT); Engineered Wood Products (EWPs); Foundation zone, Numerical modelling; Parametric study

1 INTRODUCTION

In recent years, there has been an increased focus on the environmental impacts of construction and a movement towards more sustainable construction products. Dowel Laminated Timber (DLT) products are one such Engineered Wood Product (EWP) that can carry significant structural loads with a limited carbon footprint. The DLT process typically involves the use of hardwood dowels positioned within drilled holes to form a tight fit connection between adjacent laminations as shown in Figure 1. The use of such technology has been successfully utilised to form DLT panels and beams using a variety of different timber species [1–3]. This technology ultimately reduces the use of adhesives in EWPs and further improves the environmental credentials. The efficiency of the connection is reduced when compared to adhesively bonded EWPs and as such, it is important to understand the parameters that affect the strength and stiffness of such connections and the ultimate strength and stiffness of the developed DLT product.

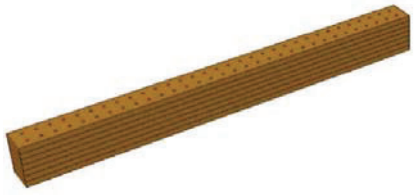

Figure 1: *Typical dowel laminated timber (DLT) beam connected with hardwood timber dowels.*

In this study, the use of compressed timber dowels is explored as a potential alternative to hardwood dowels. Compressed wood (CW) dowels are made from softwoods, which are compressed under heat and pressure which enhances their structural properties, and have been shown to have excellent properties when used in timber connections [4,5]. DLT members are manufactured and tested in accordance with EN 408 [6] to determine their ultimate failure behaviour and stiffness. The experimental results are utilised to validate a numerical model, which is then used in a parametric study to examine the influence of dowel diameter and dowel spacing on the structural response of the DLT members.

2 DOWEL LAMINATED TIMBER

2.1 INTRODUCTION

The use of dowel laminated technology has been the subject of a number of studies in recent years as an alternative to glued laminating technology to further improve the environmental performance of EWPs [1–3,7–12]. There have been significant advances in this technology and a number of commercial products are available and in use in several large timber structures across the world [1,13]. The DLT members utilised in this study were manufactured in the Timber Engineering Research Group (TERG) laboratory at the University of Galway. The timber substrate used is Sitka spruce, grown in Ireland, which is characterised as a fast-grown timber with a C16 structural grade. The CW dowels are

https://doi.org/10.52202/069179-0030

manufactured from Sitka spruce which has undergone a process known as thermo-mechanical compression which reduces the void space within the lumen between the cell walls increasing the density significantly and improving many structural properties of the timber. These are dicussed further in the following sections.

2.2 TIMBER & COMPRESSED WOOD DOWELS

For the purpose of this study, Sitka spruce, grown in Ireland, is the primary material under investigation. From a structural point of view, this species commonly achieves a structural grade of C16 due to the climatic conditions in which it grows. The standard EN 338 [17] provides a mean value of 8000 MPa for the elastic modulus of C16 timber in the longitudinal direction which is used as the primary substrate for the DLT members in this study. Typically, hardwood dowels have been used in the manufacture of DLT products, however, in this study, CW dowels are used. CW is a type of modified wood material that has been shown to have superior structural properties to natural timber and has proved to be an environmentally friendly alternative to metallic fasteners in timber connections [4,19–22]. The CW used in this study was produced by a process of thermo-mechanical compression of sitka spruce softwood timber to increase its density, strength, stiffness, hardness and to reduce its porosity [23,24].

CW in the form of dowels has demonstrated good properties when tested in shear and when compared with other standard hardwood dowels [24]. The modification process requires the application of pressure at a specific temperature. As the temperature of the timber increases, it may be easily compressed reducing the void space between the cell walls, increasing the density significantly and improving many structural properties of the timber. As the density of the timber is increased, a proportional improvement in stiffness, yield load and maximum load is expected. However, in contrast, the plastic modulus has been shown to decrease in some species [25]. The CW, with enhanced structural properties compared to standard hardwood dowel, also has a spring-back or shape-recovery property that means it will expand over time resulting in a tight fit connection that may be a beneficial characteristic in many structural timber engineering applications, particularly DLT beams and panels [26].

2.3 BEAM GEOMETRY

The beam geometry under investigation in this study is presented in Figure 2. The beam comprises three Sitka spruce timber laminations measuring 1140 mm in length and a cross-section of 20 mm x 60 mm. The three timber laminations are combined to form a final cross-section of 60 mm x 60 mm and a length of 1140 mm. The specimen geometry was chosen based on the criteria for the bending test specified in EN 408 [6]. The manufactured DLT members in Figure 2 are manufactured using CW dowels with a diameter of 10 mm and the dowel spacing of 100 mm. A total of 3 DLT members were manufactured with the same dimensions, dowel diameter and dowel spacing.

Figure 2: *Manufactured DLT members utilising 10mm diameter dowels and the dowel spacing of 100mm.*

3 EXPERIMENTAL TESTING

The DLT timber specimens were subjected to experimental testing under four-point bending in accordance with EN 408 [6]. This test standard specifies four-point bending over a test span of 18 times the specimen depth. As a result, the test specimen is supported over a test span of 1080 mm with point loads at 360 mm from each support. Steel plates (60 mm x 30 mm x 10 mm) are positioned at the support points and load points as specified by EN 408 [6]. As seen in Figure 3, the midspan of each beam is represented by a red dotted line and it is at this location that the global vertical displacement of the beam is determined for a given load until failure occurs. This is also the line of symmetry used when modelling the DLT member using finite element software discussed later.

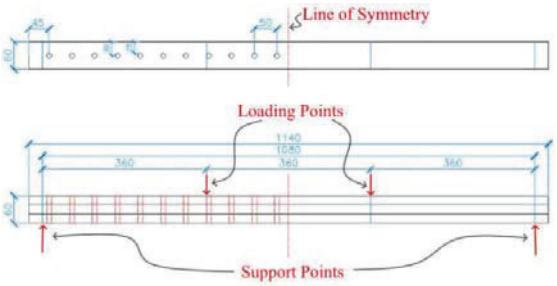

Figure 3: *DLT geometry for the 10mm diameter dowels and the dowel spacing of 50mm (DLT-D10-S50). Dimensions in mm.*

The load-displacement behaviour of each DLT member can be seen in Figure 4. It can be seen that the load-displacement behaviour of each DLT member is relatively similar and is characterised as linear elastic until brittle failure occurs. There are a series of small instances of failure whereby the load drops and is recovered until the ultimate failure occurs. In Figure 4, a line indicated as 'Glulam' represents the theoretical stiffness of a glued laminated beam with an elastic modulus of 9200 N/mm^2 to allow for comparison with the stiffness of the DLT members. It is clear that the stiffness of the DLT members is much less than that of the glued laminated member.

https://doi.org/10.52202/069179-0030

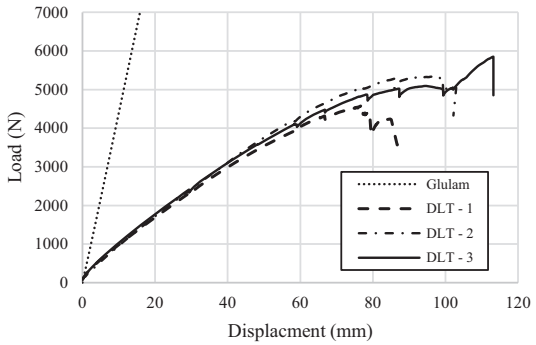

Figure 4: *Load-displacement behaviour of the DLT members*

A summary of the results is presented in Table 1. The results show that significant loads can be achieved for such DLT members connected solely with CW dowels. The maximum load (F_{max}) ranged from 4.57 – 5.85 kN with a mean value of 5.26 kN and a standard deviation of 0.6 kN. The corresponding ultimate displacement ranged from 76.6 - 113.2 mm with a mean value of 94.5 mm and a standard deviation of 18.3 mm. This magnitude of deflection indicates that the stiffness of the DLT members is relatively low. This is clear from the load-displacement curves presented in Figure 4 where the DLT members can be compared to an equivalent glued laminated member of similar dimensions. The only difference is the efficiency of the connection between the laminations of the elements. The adhesive used in glued laminated beams is quite efficient at transferring load between laminations and results in a fully composite beam. The dowels in the DLT are less efficient at transferring this load and as a result, reduced stiffness is observed.

The stiffness results from the tests are presented in Table 1. The stiffness ranges from 1520 – 1588 N/mm^2 with a mean value of 1548 N/mm^2 and a standard deviation of 35.3 N/mm^2. It should be noted that these results are also dependent on the dowel diameter and spacing used and there is a significant opportunity to optimise the dowel configuration to improve the strength and stiffness.

Table 1: *Experimental results of testing on DLT members*

Member	F_{max} (kN)	U_{max} (mm)	Stiffness (N/mm^2)
DLT-1	4.57	76.6	1520
DLT-2	5.34	93.8	1588
DLT-3	5.85	113.2	1537
Mean	5.26	94.5	1548
Std. Dev.	0.6	18.3	35.3

The typical failure behaviour of the DLT beams is shown in Figure 5. The most significant failure behaviour observed was a brittle failure of the timber along the bottom tensile laminate of the DLT beams. This occurred under the load point between the shear-free region of the beam. It is also clear from Figure 5 that significant interlaminar slip occurred in each beam between the load points and the support points. This can be seen at the end of the beam where a stepped profile can be observed.

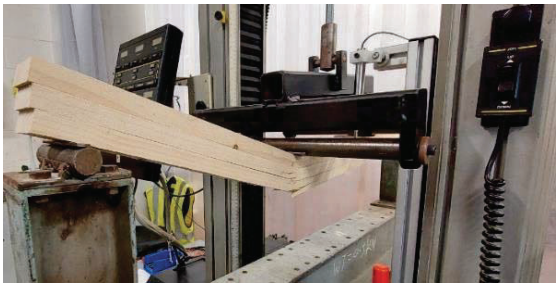

Figure 5: *Failure behaviour of DLT member (DLT - 2)*

To further examine this interlaminar slip, each specimen was split along the middle of the beam through the axis of the dowels to observe the behaviour at the dowel-timber interaction post-failure. An example of this can be seen in Figure 6. It is clear that significant dowel-timber embedment has occurred, particularly in the high-shear areas of each beam.

Figure 6: *Interlaminar slip, stepped profile and dowel-timber embedment.*

4 FINITE ELEMENT MODEL

4.1 MODEL DEVELOPMENT

A three-dimensional finite element model is developed, incorporating a UMAT subroutine to determine the total strain and associated damage experienced in DLT timber members when subjected to a structural load. The model is validated based on the results of the experimental test. As seen in Figure 7, the model utilises half symmetry to reduce the number of elements and computational time to solve the model. A symmetry boundary condition at the midspan is used to achieve this.

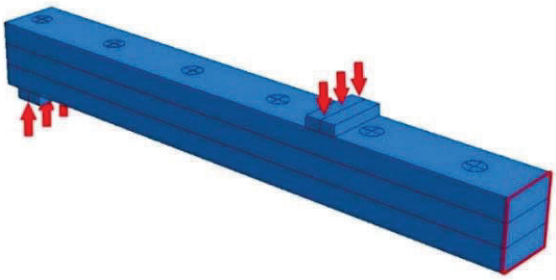

Figure 7: *Numerical model geometry subjected to four-point bending utilising half symmetry (DLT-D20-S100).*

4.2 FINITE ELEMENT FORMULATION

In this section, the constitutive model used to simulate the failure behaviour of Sitka spruce DLT members fastened with CW dowels is presented. As part of the development of the three-dimensional model, a UMAT subroutine has

https://doi.org/10.52202/069179-0030

been developed to simulate the damage experienced in timber elements when subjected to stress under loading. The elastic component of the timber, CW dowels and steel plates follows the generalised Hooke's law. The material behaviour of the timber and CW dowels are assumed to be orthotropic with a stronger and stiffer response along the fibre direction and reduced properties perpendicular to the grain. The material properties for both the timber and CW are presented in Table 2. For simplicity, the radial and tangential directions of the timber are considered equal in this model. The subscript '*L*' and '*T*' represent the longitudinal and transverse materials directions for timber. E_L and E_T represent the elastic modulus in the longitudinal or parallel to the grain direction and the transverse or perpendicular to the grain direction, respectively. G_{LT} and G_{TT} are the shear moduli and v_{LT} and v_{TT} are the Poisson's ratios.

Similar to the elastic properties, the strength characteristics are also assumed to be directionally dependent. The values are presented in Table 2 with superscripts '*t*' and '*c*' which refer to the tension and compression, respectively. For example, $\sigma_L{}^t$ represents the value of the longitudinal failure stress when loaded in tension. The shear failure stress, τ_{LT} is also presented.

$$f_L = \sqrt{\frac{\varepsilon_{11}^t}{\varepsilon_{11}^c}(\varepsilon_{11})^2 + \left(\varepsilon_{11}^t - \frac{(\varepsilon_{11}^t)^2}{\varepsilon_{11}^c}\right)\varepsilon_{11}} > \varepsilon_{11}^t \qquad (1)$$

where

$$\varepsilon_{11}^t = \sigma_L^t/_{C_{11}};\ \varepsilon_{11}^c = \sigma_L^c/_{C_{11}} \qquad (2)$$

where *Cij* are the components of the elastic matrix in the undamaged state. When Eq. (1) is satisfied, the damage variable d_L is determined according to Eq. (3).

$$d_L = 1 - \frac{\varepsilon_{11}^t}{f_L} e^{(-C_{11}\varepsilon_{11}^t(f_L - \varepsilon_{11}^t)L_c/G_L)} \qquad (3)$$

where L_C and G_L are the characteristic element length and the fracture energy, respectively.

The corresponding equations for the perpendicular to the grain direction are produced similarly in Eqs. (4), (5) and (6),

$$f_T = \sqrt{\frac{\varepsilon_{22}^t}{\varepsilon_{22}^c}(\varepsilon_{22})^2 + \left(\varepsilon_{22}^t - \frac{(\varepsilon_{22}^t)^2}{\varepsilon_{22}^c}\right)\varepsilon_{22} + \left(\frac{\varepsilon_{22}^t}{\varepsilon_{12}^\tau}\right)^2(\varepsilon_{12})^2} > \varepsilon_{22}^t \qquad (4)$$

where

$$\varepsilon_{22}^t = \sigma_T^t/_{C_{22}};\quad \varepsilon_{22}^c = \sigma_T^c/_{C_{22}};\quad \varepsilon_{12}^\tau = \tau_{LT}^t/_{C_{44}} \qquad (5)$$

When Eq. (4) is satisfied, the damage variable d_T is determined according to Eq. (6).

$$d_T = 1 - \frac{\varepsilon_{22}^t}{f_T} e^{(-C_{22}\varepsilon_{22}^t(f_T - \varepsilon_{22}^t)L_c/G_T)} \qquad (6)$$

The occurrence of damage is established when the elastic matrix is updated to form an effective elasticity matrix (C_d) which has terms reduced by including the two damage variables d_L and d_T as shown in Eq. (7).

$$C_d = \begin{bmatrix} (1-d_L)C_{11} & (1-d_L)(1-d_T)C_{12} & (1-d_L)C_{13} & 0 & 0 & 0 \\ & (1-d_T)C_{22} & (1-d_T)C_{23} & 0 & 0 & 0 \\ & & C_{33} & 0 & 0 & 0 \\ & Symmetric & & (1-d_L)(1-d_T)C_{44} & 0 & 0 \\ & & & & C55 & 0 \\ & & & & & C66 \end{bmatrix} \qquad (7)$$

G_T and G_L represent the fracture energies in the transverse and longitudinal directions, respectively and to improve convergence, a viscosity parameter, η is utilised in the user subroutine to regularise the damage variables and control the rate of damage.

The damage initiation criteria utilised in this model are based on the Hashin damage model which has been utilised in a series of studies to determine the failure behaviour of timber elements [27–31]. The damage initiation criteria are expressed in terms of strains and are treated differently for tension and compression strains however, one affects the other and if the strains are significant and cause partial or full damage (damage variable greater than zero) both tensile and compressive responses are affected. For example, damage in the longitudinal direction is initiated when the following criterion is achieved.

In the user subroutine, the stresses are then updated according to Eq. (8)

$$\sigma = C_d : \varepsilon \qquad (8)$$

The differentiation of the above equation is used to determine the Jacobian matrix as presented in Eq. (9).

$$\frac{\partial\sigma}{\delta\varepsilon} = C_d + \frac{\delta C_d}{\delta\varepsilon} : \varepsilon = C_d + \left(\frac{\delta C_d}{\delta d_T} : \varepsilon\right)\left(\frac{\delta d_T}{\delta f_T}\frac{\delta f_T}{\delta\varepsilon}\right) + \left(\frac{\delta C_d}{\delta d_L} : \varepsilon\right)\left(\frac{\delta d_L}{\delta f_L}\frac{\delta f_L}{\delta\varepsilon}\right) \qquad (9)$$

Furthermore, to improve the convergence, a viscosity parameter, η is utilised in the user subroutine to regularise the damage variables and control the rate of damage using the following Eqs (10) and (11).

$$\dot{d}_L^r = \frac{1}{\eta}(d_L - d_L^r) \qquad (10)$$

$$\dot{d}_T^r = \frac{1}{\eta}(d_T - d_T^r) \qquad (11)$$

where all parameters are as presented before but the superscript '*r*' indicates regularised and the accent '˙' indicates rate. The regularised damage variable is updated for each time step in the analysis.

https://doi.org/10.52202/069179-0030

4.3 MATERIAL DATA

The material data used in this model for the timber and the CW dowels are presented in Table 2. The steel plates are modelled as linear elastic material with an elastic modulus of 210 GPa and a Poisson's ratio of 0.3. The timber material is modelled as an orthotropic elastic material in Abaqus FEA software. The Sitka spruce material tested experimentally by O'Ceallaigh et al. [14–16] was graded to strength class C16. The standard EN 338 [17] provides a mean value of 8000 MPa for the elastic modulus of C16 timber in the longitudinal direction. The tangential elastic moduli (radial and tangential) directions were not measured experimentally; however, Bodig & Jayne [18] expressed a general relationship between the elastic modulus, E and shear modulus, G in the three material directions. Although these ratios are not without their inaccuracies, they are widely accepted for modelling the orthotropic properties of timber. The CW material properties presented in Table 2 are based on findings by O'Ceallaigh et al. [5,23]. Furthermore, a foundation zone was implemented within a 5 mm area surrounding each dowel home which accounts for reduced properties in this area. This approach is based on the foundation model proposed by Hong [32] which aims to account for the imperfect contact between the hole and fastener and also the reduction in strength due to the damage due to drilling to accommodate the CW dowels. Similar to Hong [32], both stiffness and yield properties are reduced. In this study, both stiffness and yield properties of timber are reduced to 20% [23].

Table 2: *FEM UMAT Material properties*

Property	Timber	CW Dowels	Unit
E_L	8000	13440	MPa
E_T	663	1075	MPa
G_{LT}	659	960	MPa
G_{TT}	66	96	MPa
ν_{LT}	0.038	0.48	-
ν_{TT}	0.558	0.35	-
σ_L^t	36	110.5	MPa
σ_L^c	40	110.5	MPa
σ_T^t	6	68	MPa
σ_T^c	9.6	68	MPa
τ_{LT}	6.9	5.9	MPa
G_T	10	30	N/mm
G_L	12	60	N/mm
η	0.0001	0.0001	-

The definition of the symbols and the notation has been presented in Section 0.

4.4 PARAMETRIC STUDY

In this study, Sitka spruce timber grown in Ireland is used as the primary structural material and the influence of a series of design parameters, namely, dowel diameter and dowel spacing, on the structural behaviour of a DLT beam is investigated. As part of the parametric study, three dowel diameters, 10 mm, 15 mm and 20 mm and three dowel spacing distances of 50 mm, 75 mm and 100 mm will be examined using a numerical model, once validated, to determine the structural behaviour. The naming convention of each specimen is presented in **Error! Reference source not found.**.

Table 3: *Numerical models and design parameters*

Numerical model Specimen	Dowel Diameter (mm)	Dowel Spacing (mm)
DLT-D10-S50	10	50
DLT-D15-S50	15	50
DLT-D20-S50	20	50
DLT-D10-S75	10	75
DLT-D15-S75	15	75
DLT-D20-S75	20	75
DLT-D10-S100	10	100
DLT-D15-S100	15	100
DLT-D20-S100	20	100

5 NUMERICAL RESULTS

The numerical model has been developed to simulate the load-displacement response with failure modes comprising a combination of dowel bending, dowel-timber embedment and tensile fracture of the bottom tensile laminate. This section presents the validation of the developed model against experimental results presented in Section 3 and then presents the parameter study investigating the influence of dowel diameter and spacing.

5.1 MODEL VALIDATION

The results of the numerical model are presented and compared to the experimental results in Figure 8. It can be seen that the numerically determined stiffness of the DLT beam matches that of the experimentally tested specimens. Typically, the simulated load-displacement behaviour of the DLT is in agreement with that observed experimentally, with linear elastic behaviour followed by a significant drop in the load-carrying capacity of the element.

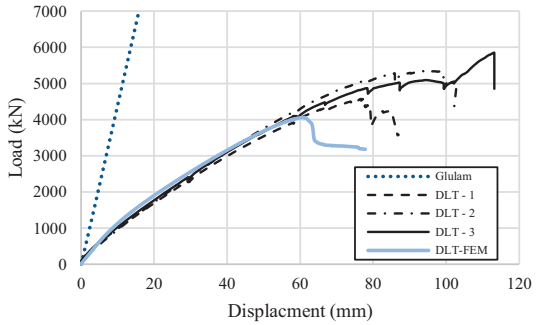

Figure 8. *Load-displacement behaviour of the 10 mm diameter dowel series*

Table 4: *Experimental results vs numerical model*

Member	F_{max} (kN)	U_{max} (mm)	Stiffness (N/mm^2)
DLT-1	4.57	76.6	1520
DLT-2	5.34	93.8	1588
DLT-3	5.85	113.2	1537
Mean	5.26	94.5	1548
DLT-FEM	4.06	61.03	1814.71
Perc. Diff.	26%	43%	16%

https://doi.org/10.52202/069179-0030

The maximum load, maximum displacement and stiffness of each beam are compared to the numerically simulated results in Table 4. The results show that the results are that conservative predictions are given for the maximum load and maximum displacement with percentage differences of 26% and 43%, respectively. In the case of stiffness, the numerically simulated results over-predict the stiffness that was observed experimentally. It is noted that the model does not provide a brittle rupture of the beam as was observed experimentally, and instead, the material that was damaged reduces in stiffness which mimics the failure of the material. This occurred experimentally in the tensile face of the DLT and was predicted in the zone in the numerical model. Furthermore, the damage observed in the dowels (Figure 6) and the stepped profile numerical model (Figure 9) were accurately captured by the model.

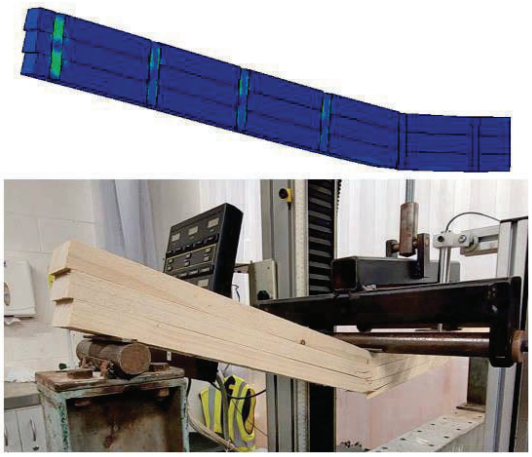

Figure 9: *FE vs experimental, tensile failure of bottom tensile laminate, and stepped profile from interlaminar slip.*

The model has demonstrated the ability to examine the local failure behaviour of the dowel/timber interaction with dowel bending and embedment at the dowel-timber interface and the load-displacement behaviour is in agreement with the experimental results.

5.2 PARAMETRIC STUDY RESULTS

In this section, the results of the numerical parametric study of the DLT specimens are presented. The load-displacement behaviour simulated by the numerical model is presented along with the maximum load (F_{max}) from each model, the displacement at maximum load (U_{max}) and the stiffness. The stiffness is determined on the linear proportion of the graph between 10% and 40% of the maximum load. These results are presented in Table 5 and the corresponding load-displacement graphs and presented in Figure 10, Figure 11, and Figure 12. In all cases, the numerically simulated curves are characterised by linear elastic behaviour until failure which comprised a combination of dowel bending, dowel-timber embedment and tensile fracture of the bottom tensile laminate.

Table 5: *Numerical model results*

Numerical Model Specimen	F_{max} (N)	U_{max} (mm)	Stiffness (N/mm^2)
DLT-D10-S50	4752	65.8	2292
DLT-D15-S50	4770	44.2	2913
DLT-D20-S50	3830	43.7	2503
DLT-D10-S75	4494	68.2	1984
DLT-D15-S75	4503	48.4	2731
DLT-D20-S75	3537	48.5	2395
DLT-D10-S100	4057	61.0	1815
DLT-D15-S100	4163	39.9	2705
DLT-D20-S100	3250	47.6	2338

The results presented in Figure 10, Figure 11, and Figure 12 are associated with DLT members with dowel diameters of 10 mm, 15 mm and 20 mm dowels, respectively. In each figure, a line indicated as 'Glulam' represents the theoretical stiffness of a glued beam with an elastic modulus of 9200 N/mm^2 to allow for comparison with the stiffness of the DLT members. In Figure 10, the influence of spacing on DLT members with a diameter of 10 mm can be observed and it is clear that decreasing the spacing between the 10 mm dowels has a positive impact on strength and stiffness. Reducing the spacing from 100 mm to 50 mm results in an increase in strength and stiffness of 17% and 26%, respectively.

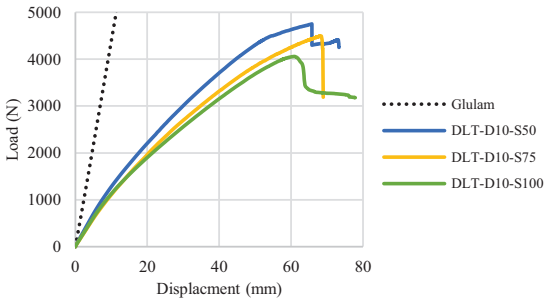

Figure 10. *Numerical load-displacement curves for specimens with 10 mm diameter dowels (D-10 Series).*

When the dowel diameter is increased to 15 mm, as seen in Figure 11, an improvement in strength and stiffness was observed for each dowel spacing studied. The influence of dowel spacing was not as significant as was observed for the 10 mm dowels with increases of 14% and 7% in strength and stiffness, respectively.

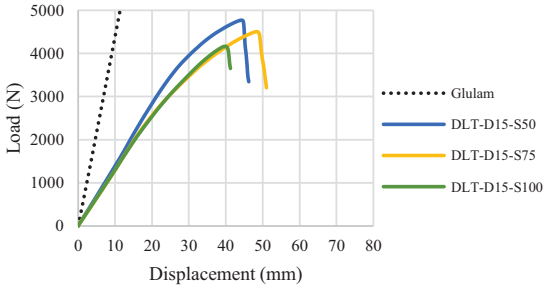

Figure 11. *Numerical load-displacement curves for specimens with 15 mm diameter dowels (D-15 Series).*

https://doi.org/10.52202/069179-0030

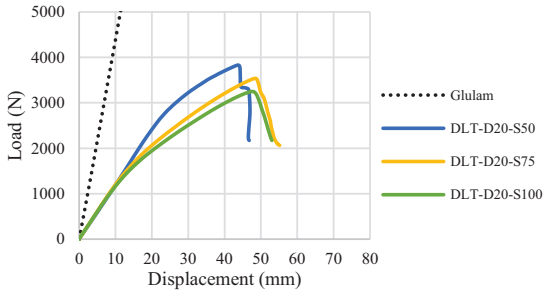

Figure 12. *Numerical simulated load-displacement curves for specimens with 20 mm diameter dowels (D-20 Series).*

Finally, for the 20 mm dowels, presented in Figure 12, contrasting load-displacement behaviour was observed. Increasing the dowel diameter to 20 mm has a negative influence on strength and stiffness. The results indicate that load-displacement behaviour is governed by the timber substrate with limited dowel/timber interaction and further studies should examine the effect for larger cross-sections.

The influence of dowel spacing for all specimens studied can be seen in Figure 13 and Figure 14. In Figure 13, it can be seen that the 50 mm spacing provided the highest loads for the 10 mm and 15 mm dowel diameters but this was not the case for the 20 mm dowels. This may be an issue with reduced edge distances and may not be the case for larger cross-sections.

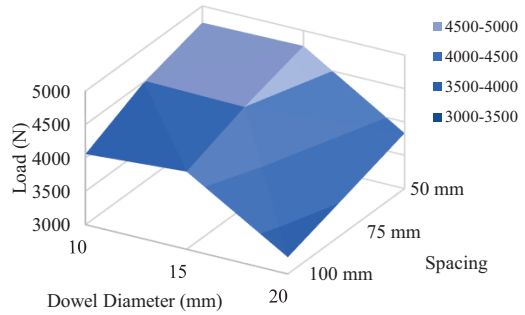

Figure 13. *The influence of dowel diameter and dowel spacing on maximum load (F_{max}).*

In Figure 14, the influence of dowel diameter and spacing on the observed stiffness for all specimens studied can be seen. It is clear that as the dowel diameter is increased from 10 mm to 15 mm, there was a positive influence on the stiffness of the DLT beam. The maximum stiffness was observed for the 15 mm CW dowels with a spacing of 50 mm. The stiffness of the 20 mm dowels did not perform as expected. While there was a positive increase in stiffness when increasing the dowel diameter from 10 mm to 15 mm, reduced stiffness was observed for dowel diameters of 20 mm, regardless of dowel spacing. The results of the numerical model indicated that the timber substrate was subjected to relatively high stress concentration adjacent to the dowel holes in the tension zone of the DLT members. This would indicate that the edge spacing criterion needs to be further examined.

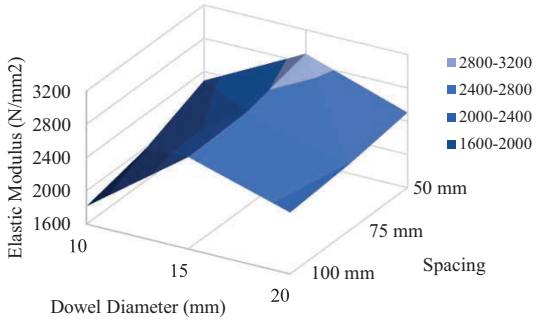

Figure 14. *The influence of dowel diameter and dowel spacing on elastic modulus.*

6 CONCLUSIONS

The feasibility of manufacturing DLT elements from Irish-grown Sitka spruce connected with CW dowels has been examined through experimental testing. A series of experimental tests have demonstrated relatively similar load-displacement behaviour in all specimens for the given dowel diameter (10 mm) and spacing (100 mm). The results have demonstrated that significant loads can be achieved through dowel laminating technology using Irish-grown timber which creates a value-added product with improved environmental credentials compared to adhesively bonded wood products. It is noted that the use of dowels instead of adhesive results in reduced capacity and stiffness for equivalent section sizes but this work has contributed to a better understanding of the behaviour for safe design in the future. There is also a significant opportunity to further refine the design and optimise this for increased structural capacity and stiffness.

A numerical model is presented and has been validated against the experimental results. The results show that the numerical model shows good agreement with the experimental results and the failure modes have also been adequately simulated by the numerical model. A parametric study has been carried out and the numerical results of DLT members connected using CW dowels have been presented for dowel diameters of 10 mm, 15 mm, and 20 mm with spacings arrangements of 50 mm, 75 mm and 100 mm. Typically, increasing the dowel diameter and reducing the dowel spacing have a positive influence on the strength and stiffness of the DLT members. This was not the case for the 20 mm dowels examined in this study and is believed to be due to edge spacing criteria which required further attention.

ACKNOWLEDGEMENT

The authors would like to express their gratitude for the support and funding of the Department of Agriculture, Food and the Marine's Competitive Research Funding Programmes, Project Ref: 2019R471 (MODCONS).

BONDING OF FIRE-RETARDANT TREATED SPRUCE LAMELLAE FOR USE IN CROSS LAMINATED TIMBER (CLT)

Karl-Christian Mahnert[1], Stine Lønbro Bertelsen[2]

ABSTRACT: This paper presents results from bond line testing to investigate the influence of fire-retardant (FR) treatment on the bondability of spruce, tested in glued laminated timber (GLT) specimens as requested by standards for testing of the actual adhesive systems, and specimens of cross-laminated timber (CLT) produced under laboratory conditions to investigate a product bonded with the adhesives. One MUF- and two PUR adhesives were chosen for the investigations, selected on the basis of their use in CLT-production today as this product was the main focus. They were tested in five different material combinations: lamellae with high uptake of fire-retardant against lamellae with high uptake of fire-retardant, high uptake against untreated lamellae, low uptake against low uptake, low uptake against untreated lamellae and untreated against untreated lamellae.
All 22 GLT specimens fulfilled the requirements for resistance to delamination according to EN 302-2:2017/EN 301:2017. The requirements for compressive shear strength according to EN 14080:2013 were fulfilled by all 24 specimens cut from the GLT samples.
73 of 75 CLT specimens fulfilled the requirements for resistance to delamination according to EN 16351:2021.
The results do not show any influence of the FR treatment on the bondability of the FR treated spruce lamellae. Potential explanations for this might be that a) the adhesives are fully compatible with the FR, or b) the FR-treated wood was removed by the slight planing of the lamellae prior to bonding, leaving untreated but insufficiently planed surfaces for bonding.

KEYWORDS: Fire-retardant, fire-retardant impregnated spruce, B-s1,d0, CLT, shear strength, delamination

1 INTRODUCTION

The objective of this work is to look into the possibility of using commercially available fire retardant (FR) treated wood in the outer layers of Cross Laminated Timber (CLT) panels for interior use in order to achieve reaction-to-fire class B-s1,d0.

CLT is often used in walls, often covered in gypsum boards to achieve the necessary reaction-to-fire classification. Alternatively, the wooden surface can be treated with a FR after installing the element in the building to maintain the wooden surface. But this is found to be time consuming, and the possibility of receiving the element with the right properties from the factory would be more efficient.
CLT produced in Norway consists exclusively of spruce wood, the outer lamellae usually fulfil the requirements of strength class C24 [1]. Therefore, this raw material has been used in this study.

1.1 APPROACH

Several types of fire retardants and their application processes were screened to select the most suitable one for application in CLT-production. The aim is to make the treated layer a part of the panel and avoid adding extra thickness, maintaining the same properties of the panel except for the improved fire properties.
The different types of fire retardants – paint/varnish and impregnation – and some of the challenges by using each type in different processes, were identified and discussed, focusing on those adding the treatment before leaving the production facility.
The different processes were mainly divided into "before-" and "after pressing" of the panel. Discussions about the various challenges led to one process chosen for further investigations – to add FR impregnated spruce lamellae to the production line of CLT before pressing of the panels. A such panel would consist of untreated wood in the middle layers and only FR impregnation in the surface layer(s), as reaction-to-fire is mainly affected by the surface properties of the panel.

A potential reduction of mechanical properties of the FR treated lamellae and issues linked to the hygroscopicity of the FR were ignored in this initial study, as well as the challenge about maintaining the fire properties after transportation and construction, where possible damage to the surface can be expected to have an impact on the reaction-to-fire properties.

https://doi.org/10.52202/069179-0031

Two questions were raised to the chosen solution: 1) Is it possible to FR impregnate C24 spruce and obtain a B-s1,d0 classification? 2) Is it possible to bond FR impregnated spruce and ensure adequate attachment of treated lamellae? These two questions were investigated, and the results are presented in this paper.

1.2 STATE OF THE ART

1.2.1 Fire-retardant impregnation of spruce

Spruce is difficult to impregnate due to the blockage of the fluid pathways in the wood due to aspiration (irreversible closure) of up to 75 % of the bordered latewood pits during drying of the wood [3], relatively small ray size and high percentage of heartwood which is impermeable to impregnation [4]. Biotechnological attempts to increase the permeability of spruce have been developed on laboratory scale [5, 6], but are not yet commercialised.

As a consequence, a pressure impregnation will only penetrate the outer millimetres of spruce, an area prone to be removed during machining. Therefore, the surface of the treated lamellae cannot be machined [7], if necessary, only lightly sanded to maintain the improved reaction-to-fire classification.

Screening the market for FR treated wood showed that spruce lamellae treated with 5.7% (arto/arto, weight percent gain calculated based on dry matter) FirePRO® and coated fulfilled the required classification [2]. The purpose for coating of the wood is to protect the surface of the wood from high relative humidity which is known to cause migration of the hygroscopic components of the FR which often results in discoloration and loss of FR over time. This aspect was neglected in this study because the interior surface of the CLT-panels is usually not exposed to relative humidity exceeding 60% (Service class 1). Following recommendations by the treater, desired uptake in this case is set to 6.5%.
With this, the first of the two questions was answered.

1.2.2 Bonding of fire-retardant treated wood

Bonding of fire-retardant treated wood, mostly veneers for plywood, has been done on at commercial scale since 1954 [8]. [9] investigated the influence of monoammonium phosphate, diammonium phosphate, ammonium sulphate, ammonium sulfamate, borax and boric acid on adhesives urea-formaldehyde (UF) and phenol-formaldehyde (PF) adhesives used in plywood production. Impregnation of veneers with borax and boric acid gave severe embrittlement rendering the use of a mechanic glue spreader not feasible. Black reports that it was these two treatments which caused most of the problems in achieving good bonds. He ascribes the difficulties to the low pH of borax and the high pH of boric acid. However, all fire-retardant treatments reduced the water resistance of the adhesives. [9] states that it is difficult to qualify the influence of the fire-retardant treatments on the performance of PF due to the variability of their chemical composition and complexity of their curing reaction.
[8] summarizes results from trials including veneers impregnated with monoammonium phosphate, diammonium phosphate, ammonium sulphate, borax, boric acid, zinc chloride and chromated zinc chlorate bonded with various glues and adhesives. The author recommends phenol, resorcinol and combinations of these two resin types for all treatments. Melamine, fortified urea and urea adhesives are recommended for a treatment combining boric acid and borax. [10] conducted bonding trials with solid wood from Douglas fir and Western Hemlock impregnated with a mixture of ammonium sulfate, zinc chloride, boric acid and sodium dichromate. The surfaces were slightly planed before bonding of the members with a resorcinol resin (PRF) and a paraformaldehyde hardener (type A) and a resorcinol adhesive and a hardener with 54% formaldehyde content (type B). The shear strength of the bond lines of all samples made from treated wood were lower than the shear strength of the samples made from untreated wood. Schaeffer identified chemical interaction between the fire-retardant salts and the adhesives as reasons for the reduced bond strength: Ammonium sulphate, zinc chloride and sodium dichromate showed increased rate of gelation, boric acid was found to slightly retard the rate of gelation of a resorcinol-resin adhesive. However, also changes in the wood surface affect the adhesion properties of wood. [11] investigated the influence of natural weathering on the tensile shear strength of Desmodur-vinyl trie ketonol acetate bond lines between pieces of Scots pine and Oriental beech that had been dip-treated with borax and boric acid. Without natural weathering, the reduction of tensile shear strength was higher for boric acid compared to borax for both wood species. After four years of outdoor exposure, the Oriental beech samples treated with fire retardant showed higher tensile shear strength than the untreated controls, the values for the borax-treated samples were higher than those for the samples treated with boric acid. In case of the Scots pine samples, the borax treated samples showed lower tensile shear strength compared to the controls and the samples treated with boric acid.
[12] investigated the influence of diammonium phosphate and sodium silicate on the adhesion properties of impregnated birch veneer. The former increased the glue bond strength measure by ABES, the latter showed unchanged or slightly reduced glue bond strength for 15% and 30% concentration in the impregnation solution. [13] consider using lamellae impregnated with a fire-retardant for CLT-production problematic because of the reduced bondability of fire-retardant treated wood and issues linked to the disposal of planer shavings from fire-retardant treated wood. Investigations of potential alternatives to planing, hot pressure treatment, chemical treatment with a confidential substance and plasma treatment showed that planing provided bond lines with highest shear strength and wood failure percentage. The adhesive systems used were PRF and polyurethane (PUR).

2 MATERIAL AND METHODS

2.1 PRODUCTION OF TEST SAMPLES

Lamellae and fire-retardant treatment

Lamellae of spruce (*Picea abies* L.) graded C24 were fire-retardant treated with FirePRO®, a fire-retardant containing Borax and boric acid, in a commercial treatment process.

The uptake of FR for each lamella was compared to the desired uptake to ensure reaction to fire-class B-s1,d0 according to product certificate of constancy of performance [2] (Figure 1, Figure 2). The lamellae with a deviation of -10% to +35% from the desired uptake were sorted out for other tests. The rest of the lamellae were divided into two groups; High uptake (H) (40–62.5 kg dry fire retardant/m^3 wood) and low uptake (L) (17.5–26.8 kg dry fire retardant/m^3 wood) and were used for preparation of the samples for bondability testing. Machining of the impregnated surfaces was kept to a minimum to remove as little fire retardant as possible from the face of the lamellae intended for bonding, but still provide favourable surfaces for bonding.

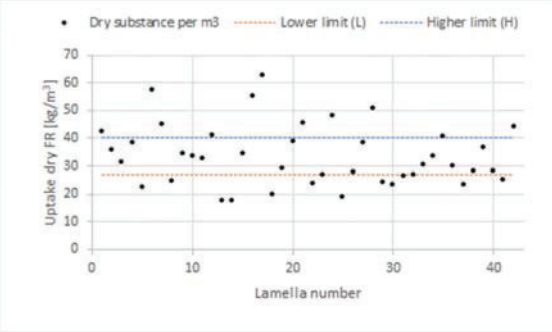

***Figure 1**: Distribution of impregnation liquid uptake in the lamellae (lamella no. 1-43).*

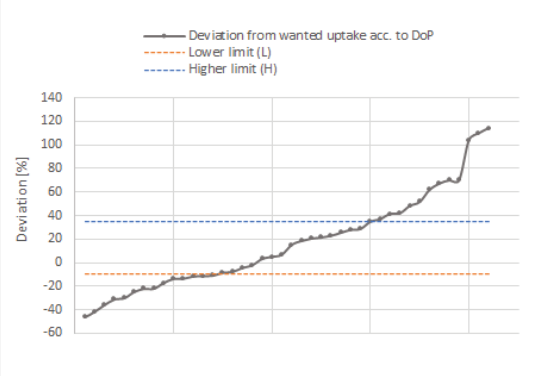

***Figure 2:** Distribution of dry substance uptake in the impregnated lamellae in relation to the desired uptake. 0% deviation marks the desired uptake, corresponding to 6,5% dry substance of the total weight after impregnation.*

Samples for testing of bondability

Glued laminated timber (GLT) samples were produced as described in EN 14080 [15] with the following combinations of treatments: L-U, H-U, L-L (L) and H-H (H) (illustration in Figure 3). With regard to CLT-testing, samples with the following combinations of treatments were assembled: L-U and H-U (illustration in Figure 4). For both GLT and CLT, reference samples of untreated lamellae (U) were assembled. Three different state-of-the-art adhesive systems for use in CLT were used: a 2-component MUF-system and two different 1-component PUR-systems.

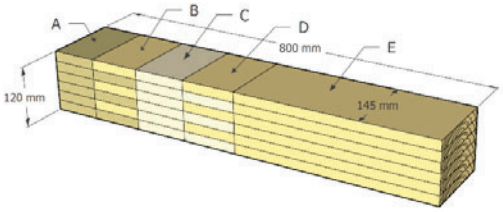

***Figure 3.** Illustration of the beams produced for adhesive testing. Each combination is partly shown, A (H) – B (HU) – C (L) – D (LU) – E (U).*

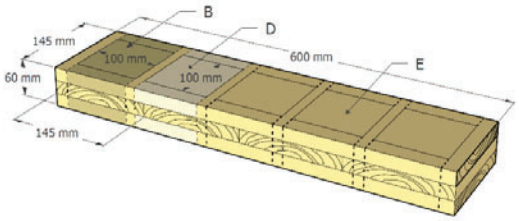

***Figure 4.** Illustration of the beams produced for product testing of small CLT specimens. Two beams were produced per combination B (HU), D (LU) and E (U) with the different adhesive systems. The marked areas illustrate the five specimens that are cut from each beam for testing of resistance to delamination, measuring 100 x 100 x 60 mm^3.*

2.2 TESTING BONDABILITY

The investigations of the material's bondability was divided into adhesive- and product testing. Adhesive testing covers testing of resistance to delamination of glulam samples according to EN 302-2 [14] and testing of compressive shear strength according to EN 14080 Annex D [15] on GLT as requested for testing of the actual adhesive systems.

Delamination was tested on two specimens per combination of treatment and adhesive with five bond lines per specimen (Figure 3). Compressive shear strength (CSS) was tested on two specimens per combination with five bond lines per specimen (Figure 3).

As the focus of the study is on CLT, product testing on CLT samples was conducted according to EN 16351 Annex A [16]. The standard requires maximum 40%

https://doi.org/10.52202/069179-0031

opening per individual bond line and an average of 10% opening of the sum of all bond lines. If a specimen exceeds these requirements, the bond areas are to be opened to quantify the wood failure percentage which may not be less than 50% for the individual bond area and not less than 70% for the total bond area per specimen.
In this study we evaluate the conformity of the bondings with the requirements defined in EN 16351. Additionally, we use the average opening of the bond lines in each specimen for further analyses.
The test was performed on five specimens per CLT-element, each specimen contained two bond lines (Figure 4).

3 RESULTS AND DISCUSSION

3.1 RESISTANCE TO DELAMINATION

The requirements for resistance to delamination of GLT according to EN 301 [17] were fulfilled by 22 of 24 specimens (Table 1). The evenly one-sided distribution of the delaminated areas on the samples produced from GLT.9 (6.2 and 6.4% delamination) (Figure 5) indicates deviation in thickness as reason for the failure of the specimens rather than the fire-retardant treatment. The results are therefore rejected.

***Table 1**: Delamination in GLT-specimens according to EN 302-2 in % of total bond line length, requirement: ≤ 5 % (Spec.= specimen).*

Sample	Adhesive and treatment	Delamination [%]	
		Spec. 1	Spec.2

GLT.R3	3/PUR U	0.7	1.9

N* Results rejected due to planing error

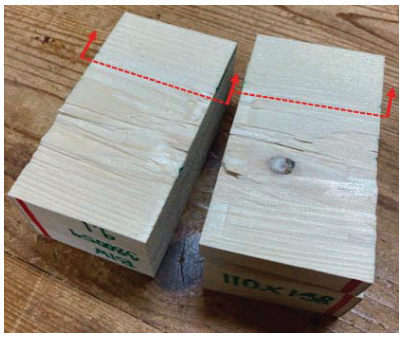

***Figure 5:** Evenly one-sided delamination on specimen GLT.9.1*

The average delamination of the visible bond line length per CLT element is compiled in Table 2. The specimens that did not fulfil the requirement were opened for further investigation of wood failure percentage in the glue line surface (results are found in Table 3).
Five specimens (Table 3) were rejected due to knots or resin pockets in the bond area and are therefore not included in all further analyses. Besides from these, two specimens did not fulfil the requirements given in EN 16351 (CLT3.1 and CLT10.1). The delamination of all remaining specimens was below the requirement of max. 30% of the bond area.

The delamination of the CLT-specimen was significantly higher than the delamination of the GLT-specimen (Figure 6). This is due to the higher stress on the bond line between cross-laminated lamellae in CLT compared to parallel laminated lamellae in GLT.

3.2 COMPRESSIVE SHEAR STRENGTH

The compressive shear strength (CSS) of all 24 specimens fulfilled the requirements for shear strength according to EN 14080:2013 Annex D, the average results are shown in Table 4. The specimens showed wood failure only. Results from specimens with knots in the shear area are excluded from further analyses.

GLT.7	3/PUR HU	8.9	0.9
GLT.8	3/PUR L	8.7	1.2
GLT.9	3/PUR LU	8.3	0.8
GLT.R3	3/PUR U	8.3	0.7

3.3 INFLUENCE OF FIRE-RETARDANT TREATMENT ON OVERALL BONDABILITY

The delamination results of both GLT and CLT samples do not indicate any influence of the treatment intensity on the delamination of the respective specimen (Figure 7), only the delamination of treatment LU was significantly different from the remaining treatments. This difference can be ascribed to the CLT specimens 4.2 (40.9% delamination of bond line) and 4.3 (42.0 % delamination of bond line). Both specimens, however, fulfil the requirement of ≥70% wood failure in bond area according to EN 16351 (Table 3).
The latter are decisive for the significant difference between the delamination results for CLT-specimen from treatment LU and UU (Figure 8). The delamination results for the GLT-specimen from the different treatments do not differ significantly (Figure 9).

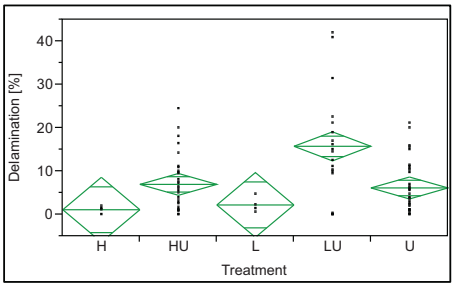

Figure 7: *Influence of treatment on the bond line delamination [%] of GLT and CLT samples.*

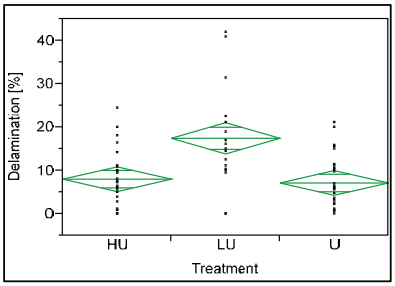

Figure 8: *Delamination of bond line of CLT samples based on the treatment.*

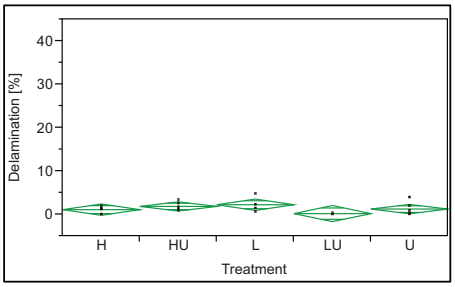

https://doi.org/10.52202/069179-0031

Figure 9: *Delamination of GLT samples based on the treatments.*

The compressive shear strength (CSS) of the GLT samples (Figure 10) did not differ significantly between the treatments. Thus, an influence of the treatment on the bondability was not found here either.

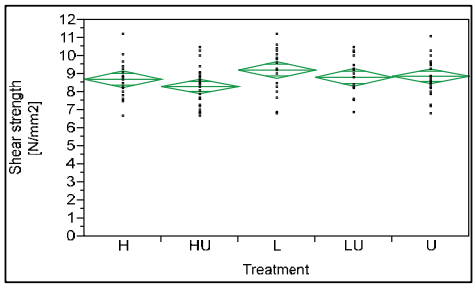

Figure 10: *Compressive shear strength of the bond lines in the GLT samples based on their treatments.*

3.4 INFLUENCE OF ADHESIVE

No significant differences between adhesives were found for the

- overall delamination (Figure 11),
- overall delamination as function of the treatment,
- delamination of CLT and GLT and
- delamination as function of the treatment within the specimens from CLT and GLT.

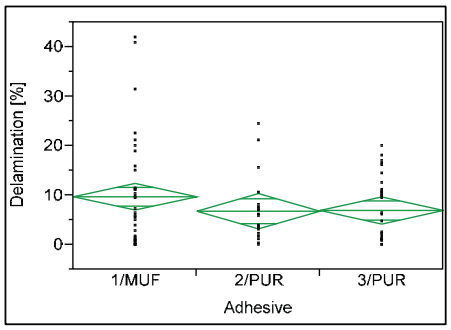

Figure 11*: Delamination in bond lines found in GLT and CLT samples as function of the adhesive.*

The compressive shear strength (CSS) of the bond lines of 1/MUF was significantly higher than the CCS of bond lines with 2/PUR (Figure 12), the same was observed for all treatments.
This is surprising as the delamination in the bond lines bonded with the different adhesives did not differ significantly. Additionally, bonding with 3/PUR yielded higher CSS than bonding with 2/PUR. Thus, the authors assume a combination of locally uneven uptake of FR or uneven planing with resulting local deviations in bond quality as explanation because incompatibility between PUR-adhesives and the FR can be excluded.

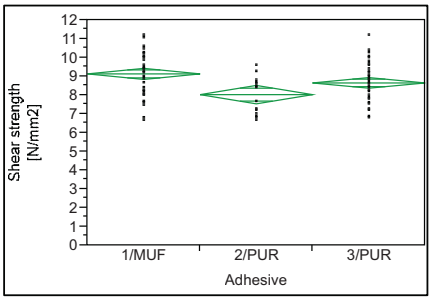

Figure 12*: Compressive shear strength as function of the adhesive*

4 CONCLUSIONS

The study did not show any influence of the fire-retardant treatment on the bondability of the spruce lamellae. This might be due to two reasons: Either the adhesives applied are fully compatible with the fire-retardant, or the fire-retardant has been removed from surfaces to be bonded during sample preparation.
The manufacturer of the impregnated material used in this study, as well as literature, advises against machining of fire-retardant treated wood as this will remove some of the impregnated surface [18, 19]. This is valid for all fire-retardant treated wood, but especially for refractory wood species such as spruce. Before this background, planing was limited to an absolute minimum, leading to wood surfaces of lower quality than usually accepted for bonding activities.
The combination of these two factors leads to the conclusion that the results from the current study do not represent the full bonding potential of the investigated adhesives and the fire-retardant treated wood.
Further investigations should be conducted where the planed surfaces are carefully re-treated with FR prior to bonding.

ABSTRACT: In this study, a novel notched connection has been developed made of Korean Larch structural plywood for timber-concrete composite (TCC) slabs to improve their bending performance in non-residential buildings. The use of TCC for non-residential buildings has become increasingly popular as horizontal members such as beams and slabs in such structures have been designed to have longer spans to create more space. Because the TCC system can provide greater stiffness to horizontal members, TCC slabs or beams have advantages for application in non-residential building members. The notched connection design in this study divided a sheet of structural plywood into several units and fastened them with timber flanges using nails. Insulations were inserted between connections to create an even concrete layer, and concrete was cast. The bending performance of TCC specimens was then evaluated through tests, with the results compared to the performance of other slabs estimated with the gamma method. The study found that the new notched connection significantly improved the effective bending stiffness of TCC slabs, which could lead to the wider adoption of TCC in non-residential building design.

KEYWORDS: Timber-concrete composite, TPC slab, Notch connection, Plywood segment, Double shear test, Full-scale bending test

1 INTRODUCTION

According to statistical data from The Ministry of Land, Infrastructure, and Transport in South Korea, most buildings have been constructed in recent years for commercial, industrial, or public purposes called non-residential buildings. In general, Horizontal members (beam and slab) in non-residential buildings are designed to have long spans to make more space. Timber-concrete composite (TCC) is a suitable material to apply to non-residential buildings since its effective bending stiffness (EI_{eff}) is high because of concrete topping. EI_{eff} of TCC is decided by not only material properties; but the performance of the shear connection between timber and concrete. The composite efficiency is decided with connection efficiency derived from the stiffness of the shear connection. Numerous types of shear connections have been investigated by past research [1]. Among these, a notched connection which is made by grooving in timber showed higher stiffness than metal connections [2]. However, the notched connection is difficult to process. Also, the loss of cross-section in timber can reduce bending capacity, so the increase of stiffness by lengthening or grooving deeper can be limited [3]. Therefore, the performance of TCC with traditional notched connections can be improved by increasing the amount of timber or concrete, but it is thought to be inefficient from the engineering point of view. In this study, a notched connection made of Korean Larch structural plywood was designed. A sheet of structural plywood was divided into several units and they are fastened with timber flanges using nails. After insulations are inserted between connections to make the concrete layer level even, concrete is cast. With this processing, TCC specimens were prepared to evaluate the bending performance. Test results were compared with the performance of other slabs which is estimated with the γ-method.

2 Materials and Method

2.1 CONSTITUENT ELEMENTS

TPC slab has three main components: Finger-jointed lumber, normal concrete and plywood segments.
Considering the properties of wood in South Korea, it is possible to achieve a depth of up to 140 mm. In a longitudinal direction, 6,210 mm length was obtained by finger-joint (24 mm × 140 mm × 6,210 mm - width × depth × length). The thickness of the concrete layer was set at 75 mm to satisfy the minimum cover thickness of the reinforcing bars if reinforcement is required by arranging reinforcing bars in the concrete layer, depending on the requirements. The mechanical properties of elements are specified in Table 1,2,3 and it was used to estimate the structural performance of TPC composite slab with the γ-method.

Table 1: *Mechanical properties of concrete*

Elements	F_c (MPa)	E (MPa)
Ready-mixed concrete	27	26,701

Table 2: *Mechanical properties of finger-jointed lumber*

Elements	F_t (MPa)	E (MPa)
Korean Larch lumber	13.5	10,000

2.2 DESCRIPTION OF THE COMPOSITE SYSTEM

Since wood fastened with plywood segments by nails (Figure 1). The spacing, edge and end distance of nails followed Nail-laminated timber design & construction guide and Eurocode 5 [4], [5]. In the compressive zone, ready-mixed concrete was topped on the timber-plywood panel and it was connected mechanically by notches, and the plywood segments were aligned in a line with 240 mm spacing.

2.3 DOUBLE SHEAR TEST

The slip modulus value is one of the main parameters in the γ-method estimation. It can be derived from by push-out test, and the test procedure has followed EN 26891 in most research [6]. To derive the slip modulus value, the double shear test was conducted as shown in Figure 3. The two types of test specimens were prepared to evaluate the slip modulus value of notches in the concrete layer and nails in the timber layer. Using LVDT, the relative slip of plywood segments between concrete and timber was measured. The slip modulus value can be derived from the load-slip curve. It can be used to calculate the connection efficiency factor (γ), and EI_{eff}. In the load-slip curve, the slip modulus values of the serviceability limit state (K_{SLS}) and the ultimate limit state (K_{ULS}) can be classified with the load level. K_{SLS} refers to the secant modulus of the load-slip curve between two specific points, namely 10% and 40% of F_{max} and K_{ULS}. K_{SLS} is utilized in determining the connection efficiency factor and EI_{eff} at the

https://doi.org/10.52202/069179-0032

serviceability limit state, while K_{ULS} is used to predict the load-carrying capacity of TCC

$$K_{SLS} = \frac{0.4F_{max} - 0.1F_{max}}{0.4v_{max} - 0.1v_{max}} \quad (1)$$

$$K_{ULS} = \frac{0.8F_{max} - 0.1F_{max}}{0.8v_{max} - 0.1v_{max}} \quad (2)$$

Where, K_{SLS} = the slip modulus value in the serviceability limit state, K_{ULT} = the slip modulus value in the ultimate limit state, F_{max} = The maximum load observed in the load-slip curve during double shear tests, v_{max} = The slip value corresponding to the point of maximum load.

2.4 FULL-SCALE BENDING TEST

The bending performance, including moment resistance (M) and EI_{eff} of TPC slabs, were measured through experiments with 10 specimens. The dimensions of the slab components are illustrated in the figure below, with a length of 6,210 mm and a span of 6,000 mm. In the longitudinal direction, the plywood segments are aligned. Figure 4C illustrates that plywood segments (b) function as shear connectors between layers. The plywood segments located at the midpoint of the span were aligned to ensure equal spacing of connections. the dimension of plywood was specified. Using a universal test machine, the load was applied to one-third of the TPC slab at a rate of 10 mm/min. Moment resistance was determined by the load at which failure occurred, while EI_{eff} was calculated by measuring the deformation at the centre of the span using a wire displacement sensor. The loading rate was 10 mm/min.

$$M = \frac{P_{max}a}{2} \quad (3)$$

Where, M = moment resistance, P = maximum load, a = the distance from support to the loading point.

$$EI_{eff} = \frac{a}{24}\frac{\Delta P}{\Delta v}(3l^2 - 4a^2) \quad (4)$$

Where, EI_{eff} = experimental effective bending stiffness, a = the distance from support to the loading point, ΔP = load increment, Δv = vertical deformation increment, l = length of the specimen.

2.5 GAMMA METHOD PREDICTION

The design of TPC was validated by comparing the bending performance of the TPC slab, as measured experimentally, with the predicted bending performance calculated using the equations specified in Eurocode 5. The slip modulus value used in the prediction equation was obtained from the value measured during a double shear test. It should be noted that the physical properties of plywood were not reflected in the equations since the plywood segments were not connected with each other.

$$EI_{eff,est} = E_1I_1 + \gamma_1E_1A_1{a_1}^2 + E_3I_3 + \gamma_3E_3A_3{a_3}^2 \quad (5)$$

Where, $EI_{eff,est}$ = estimated EI_{eff} of a specimen, E_i = elastic modulus, I_i = the moment of inertia, γ_i = connection efficiency factor, A_i = the cross-section of elements, a_i = the distance from neutral axis to centroid of elements, i = the number of elements (1- concrete, 3-timber)

$$M_{i,est} = \frac{f_i}{\gamma_iE_ia_i + 0.5E_ih_i} \times EI_{eff,est} \quad (6)$$

Where, $M_{i,est}$ = estimated moment resistance of elements, E_i = elastic modulus, h_i = the depth of elements,

The moment resistance of the TPC slab was determined based on the minimum moment resistance of its constituent elements, namely the compressive strength of concrete and the tensile strength of finger-jointed lumber.

https://doi.org/10.52202/069179-0032

3 RESULT & DISCUSSION

3.1 RESULT

3.1.1 DOUBLE SHEAR TEST

The slip modulus values for the nails and notches were determined experimentally by double shear tests, and these data were subsequently used to predict the bending performance of TPC slabs which have similar geometry to specimens in full-scale bending tests.

3.1.2 FULL-SCALE BENDING TEST

Based on the full-scale bending test, the primary failure mode of the TPC slab was identified as the tensile failure of the finger-jointed lumber. Additionally, some shear cracks were observed in the concrete layer; however, they were not considered critical to the load-carrying capacity of the TPC slab. A 2-parameter Weibull distribution was estimated using 10 datasets (Full data fitting), from which the 5% lower percentile value of the TPC slab's load-carrying capacity was calculated. The EI_{eff} was determined as the mean value of 10 datasets. (Figure 5).

Table 3: *Double shear test results*

Connection	$K_{0.4}$ (kN/mm)	$K_{0.8}$ (kN/mm)	v_{max} (mm)	F_{est}* (kN)
Notch in concrete	35.93	22.03	1.53	66.21

3.2 DISCUSSION

3.2.1 COMPARISON OF EXPERIMENTAL VALUE WITH PREDICTION

To assess the feasibility of the connection system, the bending performance of the TPC slabs measured experimental test was compared with the predicted values using the γ-method. The comparison showed that a conservative design of the TPC slab using the system is possible (Table 4). It was considered that plywood segments just serve as connections, but the observed error in comparison was attributed to the partial compression of the upper part caused by the rotation of the plywood during the experiment. This will be investigated in future research to enhance design efficiency.

Table 4: *Comparison measurement with estimation*

Test specimen	M (kN·m)	EI_{eff} (kN·m²)
Full-scale test	45.935	16,514
γ-method prediction	27.458	10,231

3.2.2 COMPARISON OF TPC SLAB WITH OTHER TCC SLABS

In order to evaluate the structural benefits of the TPC slab, a comparison was made with the structural performance of the TCC slab using other joints as proposed in the existing literature. However, it should be noted that objective comparison of different TCC slabs is challenging as they differ in not only the slip modulus of the joint used, but also the slab dimensions, physical

https://doi.org/10.52202/069179-0032

properties of the components, and longitudinal and width directions of the joint arrangement. To address this challenge, the bending performance of TCC slabs was calculated according to the following criteria. Firstly, assuming that the slab introduced in each paper was designed and optimized, the mechanical properties of elements and joint arrangement of the slab specimen were maintained. Secondly, the structural performance of each slab was compared using MOE and MOR values. The MOR and MOE values were calculated assuming a rectangular cross-section of the slab made up of a single material. As shown in Table 5, the load-bearing capacity of the TPC slab was lower than other TCC slabs. The reason why the MOR value is lower in this particular TCC slab is due to the arrangement of plywood segments instead of using timber laminae that resist tensile force. As a result, the tensile layer in the cross-section of the slab was lost to the same extent as the area where the plywood was placed, leading to a decrease in the load-bearing capacity. On the other hand, the EI_{eff} stiffness was found to be superior to that of other slabs. Through γ-method prediction, it is expected that the design of spans ranging from 8 m to 11 m can be possible with 1.2 m width, achieving the project's objective to apply the slab with long spans to buildings for using as non-residential purposes.

4 CONCLUSIONS

While the application of TCC systems has advantages in response to the increasing demand for non-residential construction in the market, various shear connections that connect timber and concrete have been developed, considering their performance and workability. This paper presents the development of a notch connection using structural plywood made of Korean larch species and an evaluation of the structural performance of the TCC slab. Also, the investigation was carried out to measure the actual bending performance and predict it using the gamma method on specimens of the same geometry. It was observed that the actual measured value exceeded the predicted value, confirming the possibility of the connection design through the gamma method. A comparison of the developed slab with other shear connections revealed that the effective bending stiffness of the former was superior to that of other TCC slabs. Considering that the structural capacity of building member with long span is determined by deflection, it is believed that this will confer structural advantages. However, future research is needed to evaluate the structural behavior of TPC slabs, including the improvement of load-bearing capacity and the efficiency of the prediction model.

ACKNOWLEDGEMENT

This study was conducted with the support of the 'R&D Program for Forest Science Technology (Project No. 2020224B10-2222-AC02)' provided by the Korea Forest Service.

MEASURING FIRE SAFETY PERFORMANCE: A COMPARATIVE EXPERIMENTAL STUDY ON DOVETAIL MASSIVE WOODEN BOARD ELEMENTS AND CROSS-LAMINATED TIMBER

Hüseyin Emre Ilgın[1], Markku Karjalainen[2], Mikko Malaska[3], Mika Alanen[4]

ABSTRACT: Adhesives and metal connectors play a critical role in the content of engineered wood products (EWPs). Though, the usage of adhesives can create challenges in terms of sustainability and recyclability because of toxic gas emissions. Metal fasteners are also critical to EWPs, but adversely affect end-of-life disposal, reusability, and recyclability. There is an alternative that is entirely pure wood, dovetail massive wooden board elements (DMWBEs) without adhesive and metal fasteners. In this paper, an experimental comparative fire-resistance study with cross-laminated timber (CLT) was conducted. Model scale test samples of 200 mm thickness, 950 mm width, and 950 mm length for CLT and DMWBE were tested in vertical position according to EN 1363-1. The charring performance of the DMWBE was found to be very similar to solid timber the charring rate being only slightly higher than that of solid timber. The char front was located in the third of the five lamella layers, but no flames or hot gases were observed on the unexposed side. With the tested lamella thickness, dovetail detail was able to effectively prevent the char fall-off. CLT specimens had a clear increase in the charring rate value due to the char fall-off of the first lamellae layer.

KEYWORDS: dovetail massive wooden board elements, CLT, fire safety, char depth, charring rate

1 INTRODUCTION

Owing to its numerous technical benefits e.g., uniform strength, stiffness, dimensional stability, and ecological properties, EWPs have been gradually used in the building sector as a construction material since the 1990s. They are getting more and more competitive in tall building construction [1] as in the 87-meter-high Ascent in Milwaukee (Figure 1) and the 85-meter-high Mjøstårnet in Brumunddal (Figure 2).

***Figure 1**: Ascent*
(Photo courtesy of Thornton Tomasetti)

***Figure 2**: Mjøstårnet*

Adhesives and metal connectors, with the regulation of the building sector, are frequently utilized as a connection in EWPs for modern wooden structures substituting traditional timber-to-timber assemblies. In this sense, adhesive bonding is among the essential parameters, and adhesives play a crucial role in EWPs, particularly by assisting to preserve the timber, enabling the building to be robust and light, and preventing shrinkage and expansion by natural humidity. But the usage of adhesives can create problems in terms of sustainability, recyclability, and broader ecological effect because of toxic gas emissions including VOC and formaldehyde during their lifetime [2]. Furthermore, in spite of

[2] Markku Karjalainen, Tampere University, Finland, markku.karjalainen@tuni.fi
[3] Mikko Malaska, Tampere University, Finland, mikko.malaska@tuni.fi
[4] Mika Alanen, Tampere University, Finland, mika.alanen@tuni.fi

https://doi.org/10.52202/069179-0033

continuing developments in this study field, important questions remain about environmentally friendly bio-based adhesives. Metal fasteners are also critical to EWPs, but adversely affect end-of-life disposal, reusability, and recyclability [3].

There is an alternative that is entirely pure wood, dovetail massive wooden board elements without adhesive and metal fasteners (Figure 3). To date, many types of research have been conducted on the technical characteristics of timber with numerous construction solutions based on the usage of EWPs in the literature. However, there is limited research on DMWBEs, and the literature about DMWBE is based on quite a few structural analyses of connection details rather than even assessing the performance of load-bearing elements such as floor slabs [4,5]. This precludes our understanding of the potential of DMWBE, particularly in terms of environmental effects and recyclability [6].

Figure 3*: Dovetail wall connection*

This study examines dovetail massive wood board elements. They are made of wood lamellae connected using one of the oldest joint techniques. This manufacturing technology offers an adhesive- and metal-connector-free solution from which no harmful chemicals are released [7]. As this is a new solution, very limited information is available on the technical and structural performance and more research is needed in some areas e.g., dimensional stability [8,9]. Within the scope of the DoMWoB project *(Dovetailed Massive Wood Board Elements for Multi-Story Buildings)* (see Acknowledgment), technical performance tests (fire resistance, structural performance, moisture transfer resistance, airtightness, and sound insulation tests) were planned to develop DMWBE for the international market as a replacement for traditional EWPs.

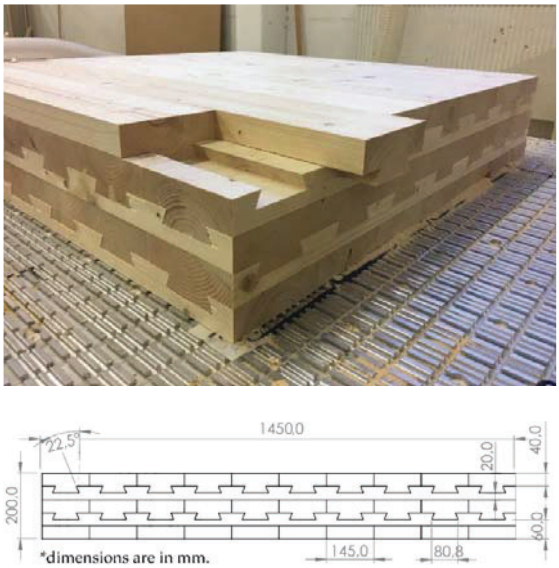

Figure 4*: DMWBE prototype as fire resistance test specimen*

An ongoing research project at Tampere University is aiming to investigate the performance of DMWBE structures at normal temperatures and when exposed to standard fire conditions. In this paper, an experimental comparative fire-resistance study with CLT was conducted as one of the important stages of evaluation of DMWBE's technical performance within the scope of the DoMWoB project. Model scale test samples of 200 mm thickness, 950 mm width, and 950 mm length for CLT and DMWBE (Figure 4) were tested according to EN 1363-1 [10] in vertical position.

The basic charring rate of a solid timber member made of pine or spruce is typically defined as 0,65 mm/min [11]. For CLT structures the charring rate values depend on many different parameters. The rate values are typically higher than that of solid wood as all the adhesives used are not able to prevent heat delamination and char layer fall-off when the char depth passes the bond lines between laminations. In DMWBE structure no adhesive is used and dovetail detail is used to prevent premature char fall-off.

In this research two fire tests have been conducted on DMWBE and CLT specimens with similar lamellae thicknesses. The study aimed to investigate if the dovetail detail can prevent the delamination of the DMWBE structure during a fire and how well the DMWBE structure maintains integrity and prevents the passage of flames and hot gasses through during the test. Also, charring rate estimates based on the temperatures measured inside the specimens were determined. The results and observations were compared with the results of the CLT specimens manufactured using a polyurethane adhesive. These experimental tests and the main conclusions were introduced in this paper.

https://doi.org/10.52202/069179-0033

2 FIRE TESTS

This section describes the fire test performed on DMWBE and CLT panels at the Fire Laboratory of Tampere University, considering char depth and charring rate.

2.1 TEST SPECIMENS

2.1.1 Dovetail test specimens

DMWBEs were produced at Vocational College Lapland (Ammattiopisto Lappia), Kemi, Finland [12]. A 5-axis CNC machine (Figure 5) with NUM operating system and compatible SOLIDWORKS computer application was used to manufacture the two test specimens. CNC post-processor methodology was employed, creating a unique integrated environment for the individual steps of finishing, toolpath optimization, and G-code simulation for manufacturing [13]. The moisture content of dovetail boards at the time of manufacture was between 10-12%. On the other hand, the relatively long production time due to the lack of a mass production line and the need for different types of tools such as blades and the removal of dust were the main challenges encountered during production.

***Figure 5**: 5-axis CNC machine used in DMWBE manufacturing at Vocational College Lapland (Kemi, Finland)*

To explore the fire resistance of DMWBE, two separate boards were manufactured. Each board was produced 200 mm thick, 1015 mm wide, and 1450 mm long (Figure 6), then cut into dimensions 200 mm thick, 950 mm wide, and 950 mm long. The boards were manufactured from Norway Spruce with C24 PS strength class. The moisture content of the test specimens at the time of the test was 10,3 %.

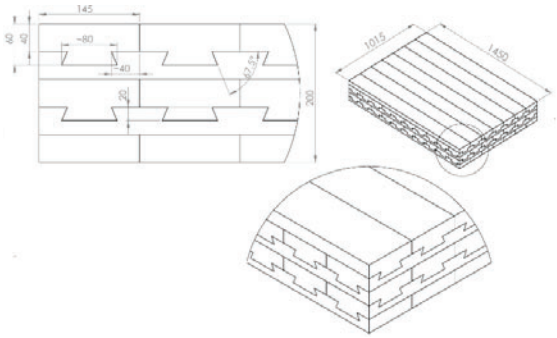

***Figure 6**: DMWBE test sample production drawings*

2.1.2 CLT test specimens

CLT panels were manufactured at CLT Plant Oy in Finland [14] for comparison with DMWBE. To explore the fire resistance of CLT, two separate panels were tested, and each test was performed on a panel 200 mm thick, 950 mm wide, and 950 mm long (Figure 7) as in DMWBE. The dimensions of a lamella were 145 mm by 40 mm. The adhesive used in CLT panels was M1 class polyurethane adhesive and lamellas supplied by Kiilto Oy (Tampere, Finland), where the adhesive was applied to all four faces of a lamella. The boards were manufactured from Norway Spruce with C24 PS strength class.

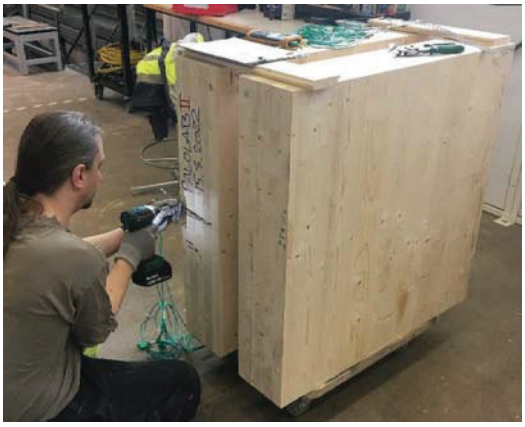

***Figure 7**: Preparation of CLT specimens for fire resistance test at Tampere University Fire Laboratory (Tampere, Finland)*

3 TEST SET-UP

In each test, two specimens of similar construction were mounted to supporting construction, made of aerated concrete blocks, in vertical position, as shown in Figure 8. The specimens were installed with their outer lamella layers in vertical direction.

https://doi.org/10.52202/069179-0033

***Figure 8**: Specimens mounted to supporting construction made of aerated concrete blocks. (Unexposed side)*

The tests were conducted according to EN 1363-1 (2020). During the test, furnace temperature, specimen temperatures, oxygen content within the furnace, and pressure differences between the furnace and test hall were monitored. The pressure was set to 20 Pa at the level of the specimen's top edge. The oxygen concentration in the middle of the furnace chamber was measured using a Dräger EM200-E multi-gas detector.

The char depth and charring rate assessments were based on temperatures measured inside the specimens during the test. Since the main aim of these tests was to observe the performance of the new non-adhesive construction in fire conditions and to investigate if the dovetail detail can restrict the delamination of the panels, it was considered that temperature measurements at main lamella interfaces only provide sufficient information. In a specimen, five thermocouples were used to monitor temperatures on one interface between two lamella layers. Schematic diagrams of the placement of the thermocouples in DMWBE and CLT elements are shown in Figure 9. In the vertical section of the slab, these thermocouples overlapped with the other thermocouples at different lamella interfaces. Shielded 3 mm diameter Type-K thermocouples were installed into 3,5 mm diameter holes drilled from the side face of the specimen and 150 mm along the interface between the layers.

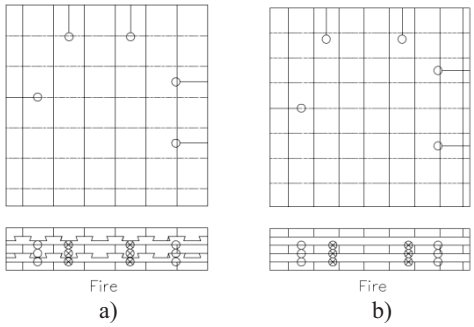

***Figure 9**: Elevation and cross-section of the CLT specimens and positions of the in-depth thermocouples: a) DMWBE and b) CLT panels.*

4 TEST RESULTS

Both tests were terminated, and the burners were shut off 140 min after the commencement of the test. The furnace temperature followed the standard temperature-time curve [10]. In both tests, the oxygen content in the furnace chamber was around 5 % during the first 60 minutes as seen in Figure 10. This is when the first lamella layer had charred through. In the case of DMWBE, the oxygen content decreases steadily thereafter, being approximately 2,5 % at 120 minutes. In the case of CLT, the oxygen content drops down to zero very rapidly at 65 minutes and remains for 15 minutes at this low level. Visual observations through the furnace camera showed that at the same time, large areas of the first lamellae layer fell off. After this, the content quickly increased again to 4 % and remained at this level until 117 minutes, after which the concentration decreased again to zero. This corresponded well with the visual observations of the falling off the second lamella layer.

The observations showed that both of the panel products were able to prevent the passage of flames and hot gases through the structures. In all the specimens, the char front was located in the third lamella layer at the end of the test, i.e. at 140 minutes.

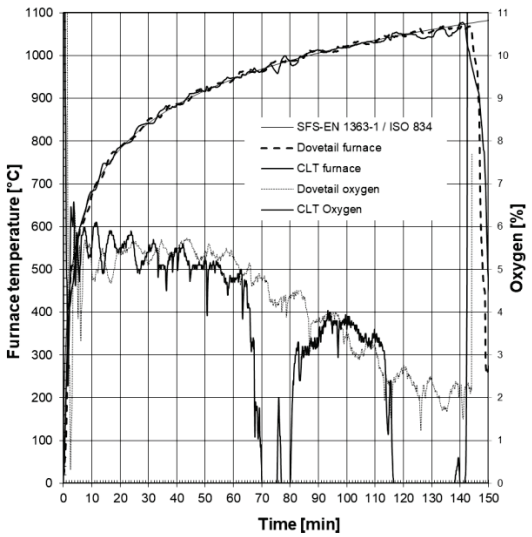

***Figure 10**: Furnace temperatures and oxygen concentrations measured during the fire tests.*

The char depths of the panel product were based on temperatures measured inside the specimen during the test; the charring temperature of the wood is considered to be 300 °C. Figure 11 illustrates the mean charring depths interpreted for the DMWBE and CLT panels. Also, the charring depth development based on the design charring rate of 0,65 mm/min for solid timber is shown in Figure 11. The results showed that the charring performance of the DMWBE panels corresponds well to the charring performance of solid wood, while the charring rate of the CLT panels starts to increase due to the char fall-off of the first lamella layer at 60 minutes. As the tests were terminated before the char front had reached 120 mm at

https://doi.org/10.52202/069179-0033

any thermocouple location, the mean charring depths can be determined only up to the point, when the temperature of a thermocouple at 80 mm first exceeds 300 °C. This is why the curve representing the mean charring depth for the CLT panel stops at 86 minutes.

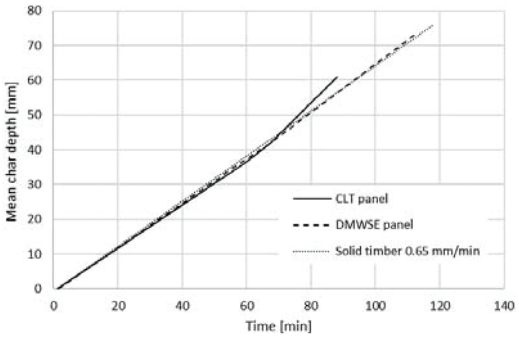

***Figure 11**: Mean charing depths for DMWBE and CLT panels. For comparison, charring depth development based on the design charring rate of 0,65 mm/min for solid timber is shown.*

Based on the test results the dovetail structure was able to limit the delamination of the unloaded DMWBE panel during the fire exposure. The estimated average charring rates determined between the exposed face and 40 mm and between 40 mm and 80 mm were 0,65 mm/min and 0,70 mm/min, respectively. The rate values were only slightly higher than that of solid timber. In the first layer, charring rates ranged from 0,57 mm/min to 0,70 mm/min, and in the second layer from 0,52 mm/min to 0,83 mm/min. Figure 12 shows the charred dovetail geometry after the test. In the structure tested, the panels were made of 60 mm thick lamellae. The charring performance can be very different and the charring rates are higher if thinner lamellae are used. In the case of the CLT panel, the charring rate of the first lamella layer was 0,62 mm/min, but when the charring progressed into the second lamella layer, the rate increased to 0,93 mm/min due to the char fall-off. This can be seen in Figure 11, as the curve representing CLT starts to deviate at this point from the curves of solid timber and DMWSE. In the CLT panel, charring rates for the first layer ranged from 0,57 mm/min to 0,69 mm/min, and in the second layer from 0,78 mm/min to 1,36 mm/min.

Uncertainties related to the accuracy of the position of the thermocouples and the thermal disturbance errors induced by shielded thermocouples were not analyzed in this research.

***Figure 12**: Remaining lamella layers and the dovetail structure of DMWBE at the end of the test.*

5 CONCLUSIONS

Two fire tests were conducted on DMWBE and CLT specimens with similar lamellae thicknesses to investigate the integrity and thermal insulation properties and charring of the adhesive-free DMWBE structure during a fire. The results and observations were compared with the results of a CLT panel of similar lamellae thickness manufactured using a polyurethane adhesive. The charring performance of the dovetail construction was found to be very similar to solid timber the charring rate being only slightly higher than that of solid timber. At the end of the test, the char front was located in the third of the five lamella layers but no flames or hot gases were observed on the unexposed side. With the tested lamella thickness, dovetail detail was able to effectively prevent the char fall-off. CLT specimens had a clear increase in the charring rate value due to the char fall-off of the first lamellae layer.

LABORATORY INVESTIGATION OF CROSS-LAMINATED DECKS FOR BRIDGE APPLICATIONS

Justin M. Dahlberg[1], James P. Wacker[2], Douglas R. Rammer[3]

ABSTRACT: The use of cross-laminated timber (CLT) has gained popularity during the past decade in North America, with many advances stemming from completed research and construction projects located in other countries. In particular, CLT has been utilized in vertical construction projects where many of its inherent features have been maximized. Despite these advances, the use of CLT in bridge structures has been limited and CLT has not been adopted into governing bridge design codes.

This paper reports the results and conclusions of the laboratory investigation of the feasibility of CLT as a primary structural material for highway bridge deck applications. Two common timber bridge superstructure systems are used in the United States: (1) longitudinal deck panels spanning the bridge abutments, and (2) transverse deck panels across the bridge width supported by longitudinal girders. The subject of this paper is the longitudinal CLT bridge deck system, which was tested under service loading to determine the structural behavior under static loading.

KEYWORDS: Cross-Laminated Timber, Bridge, Laboratory Investigation, Longitudinal Deck

1 INTRODUCTION

The use of cross-laminated timber (CLT) has gained popularity during the past decade, with many advances stemming from completed research and construction projects located in Europe. In particular, CLT has been utilized in vertical construction projects where many of its inherent features have been maximized. To name a few, CLT is prefabricated, relatively lightweight, dimensionally stable, and environmentally sustainable. North American design resources and standards have been developed for CLT in the form of PRG 320 [1], CLT Handbook [2], and the National Design Specification (NDS) [3] but these effectively limit the use of CLT to indoor applications where the moisture content can be maintained below 16%. The use of CLT in bridge structures has been limited and the adoption of CLT into governing bridge design codes has been slow-going.

CLT shows promise as a complementary or alternative construction material in bridge decks, and additional research evaluating the structural performance of these decks would further guide the appropriate use in bridge projects. This paper provides a summary of research conducted to characterize the structural characteristics of CLT bridge decks subjected to typical traffic loads.

CLT was first introduced in Europe in the 1990s to provide a potential alternative to more commonly used building materials such as concrete, masonry, and steel. Since that time, CLT and its production and distribution have vastly improved allowing for rapid growth and use. The building industry, in particular, has seen hundreds of projects completed using CLT, with mid-rise and high-rise buildings constituting the bulk of these projects.

The use of CLT for bridge projects has been very limited with very few in North America and none in the United States. In fact, there have been only a few notable bridge projects to incorporate CLT including the Mistissini Bridge located in Quebec, Canada, constructed in 2014 [4] and the Maicasagi Bridge located north of Quebec constructed in 2011 [5]. Both were long span bridges and the CLT was composite with other materials. Regardless, in each case, CLT was selected for its locally sourced material and shorter lead time compared with more commonly used materials. Both of these projects were considered a success and provide an example of CLT capabilities. Despite this fact, CLT is rarely considered for use in bridge applications, even with several inherent advantages. Additional research and proof of concept is

https://doi.org/10.52202/069179-0034

required to help make CLT a viable bridge construction material to be used by designers and engineers.

CLT is not currently recognized in the American Association of State Highway and Transportation Officials (AASHTO) load and resistance factor design (LRFD) bridge design specifications (BDS) [6]. Glue-laminated timber has been recognized by AASHTO for use in treated bridge structures for several decades. The inherent similarities between each bridge type along with continued proof-of-concept research should provide supporting data for CLT viability and acceptance by AASHTO in the bridge industry.

2 RESEARCH METHODS

2.1 PRE-TEST INVESTIGATION

The research team conducted a literature review of bridge designs using CLT in the United States, Canada, and European countries where CLT technology has been more quickly advanced and implemented. A review of deck materials, including species, size, and layup, was conducted. Additionally, the viability of CLT with respect to economics, strength, and serviceability was reviewed. Existing details for CLT from any available bridge plans and vertical construction were reviewed for viability and adoption to bridge structure use. CLT manufacturers were surveyed to identify the capabilities of pressure treatment facilities and assess the size limits of CLT panels that can be singly pressure treated.

CLT panels consist of an odd number of layers of flatwise lumber boards or structural composite boards stacked crosswise (typically at 90 degrees) and glued together under pressure. Modern CLT initially resulted from industry–academia joint research efforts in Austria in the middle 1990s. The use of CLT increased significantly in Europe in the early 2000s, partially driven by the green building movement and better efficiencies, product approvals, and improved marketing and distribution channels.

While this product is well established in Europe, the work toward the implementation of CLT products and systems has only recently begun in the United States and Canada. The U.S. edition of the CLT Handbook [2] and first CLT performance standard, PRG 320 [1] were published in 2013 with the intent to assist the U.S. building design and construction industry. The CLT Handbook [2] describes only glued CLT; nonglued CLT products are outside the scope of the publication. In 2015, CLT design procedures were introduced in the National Design Specification for Wood Construction, and in 2021, the International Building Code (IBC) [7] incorporated a new class of wood building materials, mass timber, which included CLT. The IBC also limited the construction of mass timber structures to 18 stories high

A cross section of a CLT element has at least three glued layers of boards placed orthogonally, each layer in an alternating orientation to the neighboring layers. Thickness of individual lumber pieces varies from 16 to 51 mm, and the minimum width is 1.75 times the thickness in the major strength direction and 3.5 times the thickness in the minor strength direction. Lumber laminations are visually graded or machine stress rated and dried to 12% moisture content. Panel sizes vary by manufacturer, and typical widths are 0.6, 1.2, 2.4, and 3 m while length can be up to 18 m and thickness can be up to 508 mm [1].

CLT provides relatively high in-plane and out-of-plane strength and stiffness properties, giving it two-way action capabilities similar to a reinforced concrete slab. The 'reinforcement' effect provided by the cross-lamination in CLT also considerably increases the splitting resistance of CLT for certain types of connection systems. Likewise, for floor and roof systems, the outer layers run parallel to the major span direction to maximize the flexural load capacity.

In North America, CLT design values are developed in accordance with the ANSI/APA PRG 320 [1] standard and qualified by an approved agency in accordance with the qualification and mechanical test requirements specified in the standard. PRG-320 Annex A contains seven layups to give the manufacture a means to validate calculations but these are not required layups. Rather, they are representative of what could be manufactured. Each manufacturer is free to develop and certify their own layup configuration.

2.2 PRESSURE TREATMENT

Similar to other timber bridge types, protection of CLT panels for exterior use is essential for long-term serviceability. The ability to pressure-treat full panels is limited by current manufacturer capabilities. Common chamber sizes in the United States would effectively limit the panel sizes to no wider than 2.1 m. Furthermore, pressure treating individual members to be used in a final CLT configuration is disadvantaged by the overall cost. The researchers understand that CLT panel protection measures are critical to their overall acceptance. Further research is recommended to identify best options to protect CLT panels from outdoor elements.

2.3 LABORATORY TESTING

At the Iowa State University structures laboratory, the project team conducted load tests using CLT panels in two configurations. The first configuration was a longitudinal deck panel superstructure system. It used two 314-mm-deep x 2.48-m-wide, 9-lam-layup (Figure 1), single-span panels, which spanned 7.62 m longitudinally between two deck concrete blocks serving as abutments (Figure 2). The second configuration was a transverse deck panel superstructure system. It used three 175-mm-deep x 2.49-m-wide, 5-lam-layup panels spanning transversely across longitudinal steel simply supported W-shape girders. For both bridge configurations tested, untreated Douglas-fir (*Pseudotsuga menziesii*) lumber was utilized for all layers in the CLT bridge deck panels. In the direction of the

https://doi.org/10.52202/069179-0034

primary span, select-structural graded lumber was used. For the corresponding orthogonal layers, lumber was graded for #2 and better. For brevity, this paper will focus on the 9-lam, longitudinal deck panel configuration, testing, and results.

Figure 1 *CLT Panel for Load Testing*

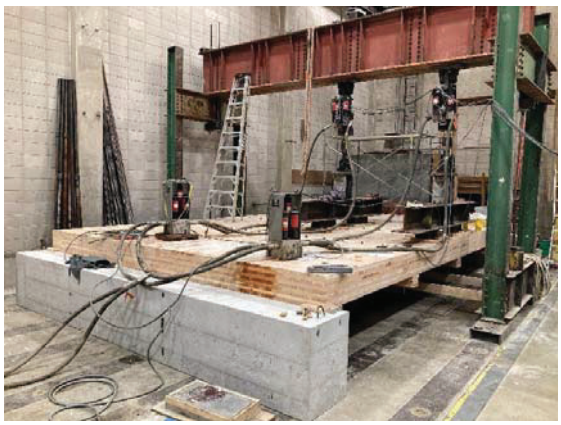

Figure 2 *Longitudinal Panel Test Configuration*

The configuration of the laboratory test setup included two equal-width panels set side-by-side spanning longitudinally as shown in Figure 3. The total width of the CLT deck was 4.88 m. This width constitutes approximately half of an actual in-service bridge. Three built-up spreader beams made up of five 38-mm x 191-mm boards connected with screws and measuring 191 x 216 mm in total were connected to the underside of the deck using 19-mm threaded thru-rods spaced at 305 mm on center, which is consistent with current AASHTO specifications.

Each of the panels were joined along their edge using a shiplap joint, which is a commonly fabricated joint used in the vertical construction industry and in nail-laminated timber bridge deck panels (Figure 4). The overlap width measured 76 mm, and the joint was stitched together using screws in the configuration shown in Figure 5. The vertical screws used were ASSY VG CYL 8 x 300 mm, and the inclined screws used were ASSY VG CSK 10 x 400 mm. This screw configuration was used because inclined screws tend to produce a stiffer connection with higher load capacities.

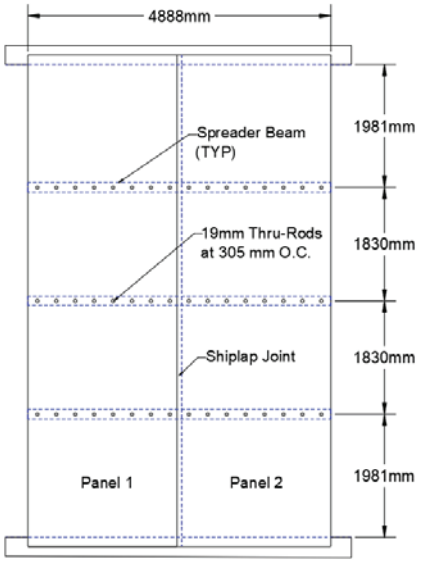

Figure 3 *Plan View of Longitudinal Deck Panel Configuration*

Figure 4 *Shiplap Connection used for Longitudinal Panel Deck*

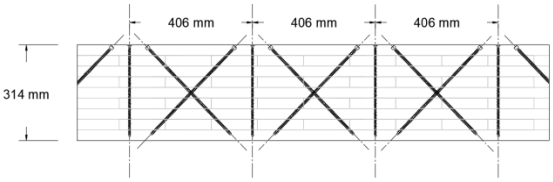

Figure 5 *Screw Pattern along Longitudinal Panel Shiplap Joint*

The tests were completed using typical highway service loads to simulate highway vehicle traffic. The panels were subjected to four load cases (LC), which simulated the rear tandem axle of a dump truck by placing loads at four specific locations as shown in Figure 6. The load, axle configuration, and tire spacing are consistent with the HL-93 AASHTO vehicular live loading design tandem. The locations were selected to maximize the shear and bending reactions within the panels and to determine how the applied force was distributed transversely across the panels, with a specific interest in how the longitudinal joint affected load distribution. The maximum applied load was 111 kN per axle, or 56 kN per tire location.

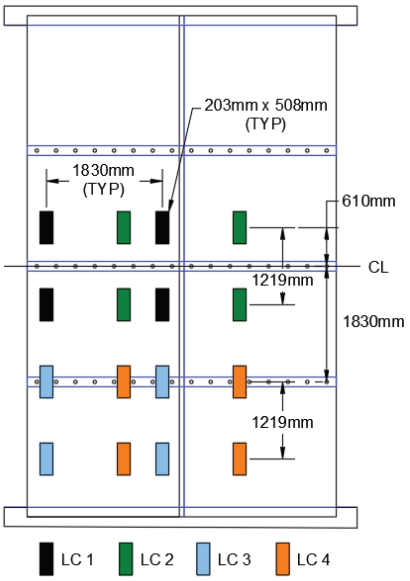

Figure 6 *Location of Rear-Axle Tandems for each Load Case*

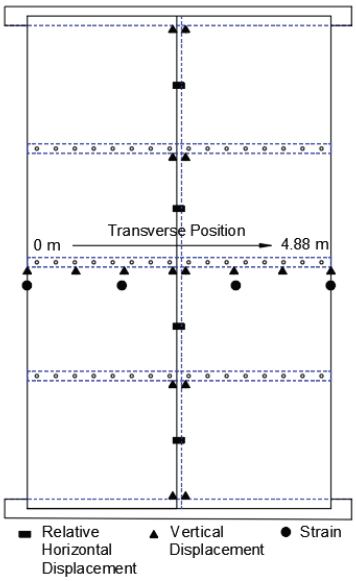

Figure 7 *Deflection and Strain Gage Placement*

2.4 DATA ACQUISITION

Strain and deflection gages were used to gather data for the purposes of structural characterization and comparison.

A series of deflection gages were placed transversely at midspan and along the longitudinal joint to capture the vertical deflection. Additional deflection gages were placed horizontally along the longitudinal joint to capture any relative movement or joint opening between the two panels.

Strain gages were placed at the top and bottom of the panel edges. During the manufacturing process, because of the overall panel width specifications, the outermost longitudinal boards were only 10 mm wide. This portion of the uppermost and lowest laminations was removed to allow the strain gage to engage the first full-width board. Top and bottom strain gages were also placed at approximately 1500 mm from each panel edge. The gage locations are shown in Figure 7.

At one of the panel edges (0-m transverse position), additional strain gages were placed on each of the longitudinal laminations. These gages were intended to determine the strain profile of the panel when loaded.

One horizontal displacement gage was placed at the lowermost transverse lamination to determine if any gapping occurs between individual members. The gages on the edge of panel are shown in Figure 8 and Figure 9.

3 CLT PANEL EVALUTION

3.1 STRUCTURAL CHARACTERIZATION

Photographs of the reaction frame and load position for each load case location are shown in Figure 10 through Figure 13. Plots of the corresponding strain and deflection behaviour at midspan at the time of maximum load for each of the four load cases are represented in Figure 14 through Figure 17.

For Load Case 1, Figure 15 indicates that when the entirety of the load was placed on Panel 1, the deflection was greatest at the panel edge with approximately 39 mm of deflection. This corresponds to a span-to-deflection ratio (L/D) of 197. The deflection values linearly decreased relative to the transverse position until the minimum value of 1.3 mm was measured at the opposing panel edge. The strain values ranged between 545 and 572 microstrain in compression and tension, respectively, at the panel edge with a relatively linear strain profile through the depth of the panel as indicated by the five strain gages positioned on the longitudinal laminations at the zero position (Figure 9). The strain profile at the panel edge was linear throughout the full load range. The peak strain value of 648 microstrain was measured in compression at the top of the panel at the first interior position. Assuming a modulus of elasticity of 11.7 GPa for select structural Douglas-fir, the corresponding maximum stress is 7.6 MPa.

For Load Case 2, when the load was equally positioned on each panel, Figure 15 indicates fairly symmetric behaviour of the panels under peak load. The deflection was greatest at the longitudinal joint with a measured value of 21.7 mm. This corresponds to an L/D value of 351. The deflection values uniformly decreased from the longitudinal joint to the panel edges but did not significantly decrease overall. A similar behaviour was observed in the strain values. Peak strain values of 401 and 392 microstrain were measured at the interior positions at the top of the panels corresponding to stress values of 4.7 and 4.6 MPa, respectively. The strain values decreased slightly at the panel edges similar to the behaviour observed in the deflection data. As with Load Case 1, the strain profile as indicated by the strain gage series at the panel edge was fairly linear indicating linear strain behaviour.

For Load Case 3, the load was positioned in the same transverse position as Load Case 1 entirely on Panel 1 but near the endspan. The results presented in Figure 16 indicate many similarities in the overall deflection and strain trends among each of these load cases. The deflection was greatest at the panel edge (20.5 mm) with linearly decreasing values corresponding to the transverse position. The deflection on the opposing panel edge was nearly 0 mm. The strain values at midspan are understandably less than the measured values when the load was positioned at midspan. However, it should be noted that the pattern of relative strain magnitudes when comparing adjacent strain locations is similar between Load Cases 1 and 3. The peak strain value is observed at the first interior strain position. The strain profile observed at the panel edge grouping of strain gages further indicates linear behaviour.

For Load Case 4, the load was positioned symmetrically on each panel as with Load Case 2 but near the endspan. The results presented in Figure 17 indicate very similar deflection and strain behaviour as that in Load Case 2, albeit smaller magnitudes due to the longitudinal load position. The deflection was greatest at the longitudinal joint (11.5 mm) and gradually and minimally decreased with distance from the joint toward the panel edge (9.1 to 9.5 mm). Strain magnitudes were also nearly symmetric with respect to the longitudinal joint. Furthermore, the strain profile at the panel edge indicated linear behaviour.

3.2 EQUIVALENT STRIP WIDTH

Load distribution characteristics for each load case can be quantified by calculating the equivalent strip width (ESW). Calculation of the ESW using measured data is typically achieved by 1) numerically integrating the area under the moment distribution curve, and 2) dividing the summation by the estimated maximum moment. However, when assuming uniform stiffness of the panels, deflection data can be used instead (Equation 1).

$$ESW = \frac{\sum_{i=1}^{n}(deflection_i \times d_i)}{deflection_{max}} \quad (1)$$

where, n is the total number of deflection sensors, $deflection_i$ is the deflection reading of the i-th sensor, $deflection_{max}$ is the maximum deflection measured by the sensors, and d_i is the spacing of adjacent deflection gages. The ESW results for each load case are listed in Table 1.

Table 1: *Equivalent Strip Width*

Load Case	ESW (m)
1	2.48
2	4.30
3	2.50
4	4.40

It is evident that when the load is positioned on both panels rather than on one panel only, the ESW is approximately 70% greater indicating that a greater width of the bridge is engaged in the load resistance. The transverse load distribution is significantly less when the load is entirely on one panel despite the uniformity of the deflection trend. A stiffer spreader beam may aid the transverse load distribution characteristics. As a means of comparison, ESW values calculated using deflection data from recently completed load tests of in-service, longitudinal nail-laminated bridge decks range from 1.8 to 4.2 m [8]. It can be observed that the ESW values calculated from the CLT tests and nail-laminated bridge decks, which traditionally have one-way action, are similar.

4 SUMMARY AND CONCLUSIONS

Cross-laminated timber panels have gained popularity in recent history and have been widely used in the vertical construction industry. Despite this fact, there have been few instances where CLT panels have been used for bridge deck applications in North America. The impediments to using them are not dissimilar to the use of other timber structures in exterior environments. The ability to pressure-treat full panels is limited by current manufacturer capabilities. Furthermore, pressure-treating individual members to be used in a final CLT configuration is disadvantaged by the overall cost. Further research is recommended to identify best options to protect CLT panels from outdoor elements.

CLT has been used in ways that maximize many of its inherent features. CLT is prefabricated, relatively lightweight, dimensionally stable, and environmentally sustainable. North American design resources and standards have been developed for CLT in the form of PRG 320 [1], CLT Handbook [2], and the National Design Specification (NDS) [3], but these effectively limit the use of CLT to indoor applications where the moisture content can be maintained below 16%. The use of CLT in bridge structures has been limited, and the adoption of CLT into governing design codes has been slow-going.

During this study, two nontreated, longitudinal CLT panels were subjected to highway-type service loads to characterize their structural performance and behaviour. The panels were made up of two grades of Douglas-fir, select structural for longitudinal layers and No. 2 for transverse layers, and were connected together using a shiplap joint, screws, and spreader beams. The simply supported, single-span panels were equipped with deflection and strain gages placed at various locations on the structure to quantify the performance under load. Four load cases were used to place the loads at distinctive locations at midspan and near the end span. In two cases, the entirety of the load was applied to only one panel, whereas in the other two cases the load was equally applied to both panels.

The equivalent strip width (ESW) was calculated for each load case. It was observed that when a single panel was loaded (Load Cases 1 and 3), the ESW decreased by about 40% when compared with the ESW when both panels were simultaneously loaded (Load Cases 2 and 4). This phenomenon is similar to the ESWs observed during in-service, slab-type timber bridge tests previously completed by this research team. Improvements to the transverse load distribution characteristics of longitudinal CLT panel bridges decks would benefit the design and rating of these bridges.

Because of their structural characteristics, CLT panels lend themselves well to being used for highway bridge structures. The data prove their performance to be uniform and predictable. Strain profiles through the depth of the panel indicate the panel remains linear through the full load range. The data also prove the performance to be within the prescribed guidance by the AASHTO Load and Resistance Factor Design [6] for timber bridge structures with the exception of the recommended deflection limits of L/425. This recommended limit is to aid the bridge deck serviceability, not to set limits for structural adequacy. The performance of overlay wearing surfaces are most sensitive to higher deflection magnitudes, which can result in maintenance costs for the bridge owner. An increase in the panel depth, improved transverse load distribution, or shorter span lengths can simply reduce the panel deflection.

ACKNOWLEDGEMENTS

Partial funding for this laboratory project was provided by the U.S. Department of Agriculture, Forest Service, Forest Products Laboratory. The CLT panels used in the project were manufactured by SmartLam North America. Threaded fasteners along the longitudinal joint were from MTC solutions.

COMPRESSIVE STIFFNESS PARALLEL TO GRAIN IN TIMBER

Marina Totsuka[1], Robert Jockwer[2], Kenji Aoki[3], Masahiro Inayama[4]

ABSTRACT: This paper describes results and analysis of experiments of compressive stiffness parallel to grain of glulam, with the focus on the damage zones near loading plates and joints. To investigate the influence factors of physical properties and the mechanism of the damage zone near the loading plates or the joints, compression tests on 90 specimens were performed. As a result, it was observed that damage zones exist near the loading plates and the joints. The Young's modulus of the damage zone was approximately 2% of that of a common longitudinal modulus of elasticity. The lengths of the damage zone of wood-wood joints are larger than that of wood-steel joints. The length of the damage zone and its scatter increase as the width of the cross-section increases. In the specimens, the lengths of the damage zone were 0.7~4.7mm. Therefore, the length of the damage zone has a size effect of the cross-sectional area and depends on the processing accuracy on the contact surface. The size effect was evaluated by the strongest link model and the evaluation method of the compressive stiffness parallel to the grain was proposed.

KEYWORDS: Glulam, Damage zone, Compression parallel to grain, Joints, Connections, Timber

1 INTRODUCTION

In connections of timber buildings, the deformations under compression parallel to the grain are often ignored since the deformations under compression perpendicular to the grain are bigger than the deformations under compression parallel to the grain due to the anisotropy of wood. However, in high-rise timber buildings, we may need to consider the deformation under compression parallel to the grain as well [1].

The heterogeneity of the strains in members loaded in compression parallel to the grain of clear specimens was reported in papers [2, 3] (Choi et al. and Dahl and Malo). In compression parallel to the grain, it is observed that the largest strains are allocated near the loading plates [4] (Zink et al.), which create a zone often called the "damage zone" as shown in Fig. 1. The zone between these damage zones is referred to as the "middle zone". Xavier et al. [5] and Brabec et al. [6] investigated the behaviour of the damage zones, e.g. the length and the modulus of elasticity, in small clear specimens. In addition, Totsuka et al. [7] reported the heterogeneity of the strains of large-sawn-timber specimens and showed the possibility that the length of the damage zone increases with increasing widths of the loaded area and the length of the damage zone does not change when the full height of the specimens increases. However, there is no evaluation method of the damage zone and the behaviour of the damage zones in glulam specimens remains unsolved so far.

In this present work, the compressive stiffness parallel to the grain of glulam was investigated. The aims of this work are as follows:

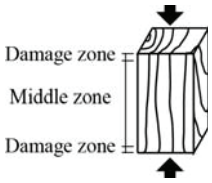

Figure 1: *Explanation of damage zone and middle zone*

(1) to clarify the influence factors of physical properties in the damage zone.
(2) to propose an evaluation method of compressive stiffness parallel to the grain.

2 EXPERIMENTAL WORK [8]

2.1 SPECIMENS AND TEST METHODS

Table 1 shows an overview of the test series of glulam specimens. The specimens were made from glulam of Norway Spruce (*Picea abies*) of quality GL30h according to SS-EN 14080:2013 [9], and Japanese cedar (*Cryptomeria japonica*) of quality E65-F255 and Japanese cypress (*Chamaecyparis obtusa*) of quality E95-F315 according to JAS (Japanese Agricultural Standards) [10]. The thickness of the glulam laminae was 42 mm for Norway Spruce and 30 mm for Japanese cedar and Japanese cypress. The width of the glulam laminae was the same as the specimen width. A total of 90 specimens were prepared by manufacturing 6 or 4 specimens per series. The test parameters are the size of the specimens and the type of joints (Fig.2). The specimens of series 20-3sSp had a 9mm steel plate. The specimens had typical wood characteristics, adhesive layers, and finger joints, however, the specimens of series 2.5-1Sp, 2.5-1Ce, and

2.5-1Cy did not exhibit visual defects (knots and cracks) and did not have adhesive layers and finger joints.
The compression tests of the specimens were carried out with an in-line 3000 kN load cell and a spherically seated loading-head, an in-line displacement transducer under displacement control at a rate of 1 mm/min. The deformations and local strains were measured by the digital image correlation (DIC) system [11].

2.2 TEST RESULTS AND DISCUSSION

2.2.1 Compressive stiffness parallel to the grain

According to the equilibrium and linear elastic constitutive equations, the following closed-form solution can be obtained for the identification of the longitudinal modulus of elasticity:

Table 1: *Test series.*

Series	Species	#	Specimen size [mm]		Joint type
			A	*H*	
2.5-1Sp	Norway spruce	6	25×25	100	-
10-1Sp			100×100	100	-
20-1Sp			200×200	100	-
20-05Sp			200×200	50	-
20-3Sp			200×200	300	-
20-3bSp		4	200×200	300	Butt(Parallel)
20-3bxSp			200×200	300	Butt(Cross)
20-3sSp			200×200	300	Steel plate
2.5-1Ce	Japanese cedar	6	25×25	100	-
10-1Ce			100×100	100	-
20-1Ce			200×200	100	-
20-2Ce			200×200	200	-
2.5-1Cy	Japanese cypress	6	25×25	100	-
10-1Cy			100×100	100	-
20-1Cy			200×200	100	-
20-2Cy			200×200	200	-

CV [%]	13	9	16	18	5	9	10	11

Note: CV is coefficient of variation.

$$E_{\mathrm{L}} = \frac{P}{A\varepsilon_1} \quad (1)$$

Where P is the applied compression load, A is the cross-sectional area (the loaded area), and ε_1 is the linear strain, from $0.2P_{\max}$ to $0.4\ P_{\max}$, along the longitudinal direction. In this study, two types of the E_L were calculated:
(1) the longitudinal modulus of elasticity in full height ($E_{L,f}$) using the ε_1 by the displacement transducers,
(2) the longitudinal modulus of elasticity in the middle zone ($E_{L,m}$) using the ε_1 in the middle zone measured by the DIC.
Table 2 shows the statistics of the specimens. The values of $E_{L,m,}$ were independent of the dimensions (height and width) of the specimens and the joint types. The mean values of $E_{L,m}$ were close to the literature values (7350 N/mm^2 for cedar and 11700 N/mm^2 for spruce[12], but no literature value for cypress) and considered to be equivalent to Young's modulus measured with a strain gauge or displacement meter attached to the middle of the test specimen. The mean values of $E_{L,m}$ of series 20-1Ce and 20-1Cy were bigger than those of the other series. The reason for this is unknown and further consideration will be needed to yield any findings about it.
Fig. 3 presents the influence of the heights and the widths of the loaded area on the values of $E_{L,f}$. The test results of solid timber of cedar [7] are also shown in Fig. 3 These values indicate mean values of the specimens with a cross-sectional area of 200×200 mm and 30×30 - 90×90 mm [7] for the influence of the heights and with a height of 100 mm and 30 - 90 mm [7] for the influence of the widths of the loaded area. The $E_{L,f}$ had an increasing trend as the height increased. This can be explained by the fact that the lengths of the damage zone do not change when the full height of the specimens increases. The $E_{L,f}$ had an increasing trend as the width of the loaded area decreased in the spruce-specimens and solid timber. This can be explained by the increasing lengths of the damage zone with the increase of the widths of the loaded area. However, the $E_{L,f}$ did not have an increasing trend in the cedar- and cypress-specimens. To clarify the mechanism of the damage zone, the damage zones were analysed in the following.

2.2.2 Strain field characterization and length of the damage zone

Fig. 4 shows an example of the deformation field of the longitudinal strain at 20% and 40% of the maximum load (P_{max}) of the series 10-1Sp by DIC. A damage zone near the loading plates or the joints and the middle zone can be recognized. The strain in the damage zone had a gradual distribution along with the height and exponentially increase as the distance from the loading plate or the joint

decreased. The phenomenon of the damage zone near the loading plates is in agreement with the observations made by Brabec [6]. The maximum strain is dependent on the load, but the length of the damage zone at 20% of the P_{max} was almost the same as that at 40% of the P_{max}.

Fig. 5 shows the longitudinal strain curves at 20% of the P_{max} of the specimens by DIC. The length of the damage zone seemed to be independent of the height, but the length of the damage zone increases as the loaded area increases. A detailed discussion of the length of the damage zone is provided in Fig.6-8. Fig. 5 (f)(g)(h) shows the longitudinal strain curves of wood-wood joints and wood-steel joints. The damage zones were also observed near the wood-wood joints and wood-steel joints, as well as near the loading plates.

Where the damage zone was defined at a strain ε_1 of -0.2% and less at 20% of P_{max}, the average lengths of the damage zone were 0.9 mm in 2.5-1Ce, 0.7 mm in 2.5-1Cy, 1.1 mm in 2.5-1Sp, 0.7 mm in 10-1Ce, 0.9 mm in 10-1Cy, 2.3 mm in 10-1Sp, 1.3 mm of the cedar- specimens with 200 mm, 1.0 mm of the cypress-specimens with 200 mm, and 4.7 mm of the spruce specimens with 200 mm width. Positive correlations were suggested between the length of damage zone and the width of the cross-section with correlation coefficients of +0.52 for the cedar-specimens, +0.41 for the cypress-specimens and +0.81 for the spruce-specimens. The length of the damage zone and its scatter increase as the width of the cross-section increases. This trend was especially remarkable in the spruce specimens. It was probably because the spruce specimens were processed on a different machine and the processing of the spruce specimens was rougher than that of the cedar- and cypress-specimens. The cedar- and cypress-specimens were processed on the same machine. The surface roughness of the contacted area is likely to increase as the cross-sectional area of the specimens increase. In other words, the length of the damage zone may depend on the accuracy of the processing machine. On the other hand, lower or negligible correlations between the length of the damage zone and the height of the specimen were indicated with correlation coefficients of +0.24 for the cedar-specimens, +0.46 for the cypress-specimens and +0.17 for the spruce-specimens in Fig.7. The length of the

3 EVALUATION METHOD OF COMPRESSIVE STIFFNESS

3.1 MODEL OF DEFORMATION DUE TO COMPRESSION PARALLEL TO GRAIN

A simple analytical spring model is used to evaluate the deformation of a specimen compressed parallel to the grain as shown in Fig. 9. If the Young's modulus is assumed to be constant in the damage zone, the specimen is modelled by two types of springs, and the stiffness at full height, K_f, is expressed by the following equations:

$$K_f = \frac{1}{\frac{2}{K_d} + \frac{1}{K_m}} = \frac{1}{\frac{2x}{0.02E_{L,m}A} + \frac{H-2x}{E_{L,m}A}} \quad (2)$$

where $E_{L.m}$ is the Young's modulus in the middle zone; A is the loaded area; H is the full height of the specimen; and x is the damage zone length.

In the previous study, Totsuka et al. [7] indicated that spreading effects in the compression parallel to the grain are small enough to be ignored for compressive stiffness. Therefore, the stiffness of specimens of partial compression are evaluated as the stiffness of specimens without margins.

3.2 DAMAGE ZONE LENGTH

The damage zone was considered to occur on the cut RT surface as shown in Fig. 10. The strongest link model was used to evaluate that the damage zone length and its scatter increased as the loaded area increased. The strongest link model [13] is the opposite of the weakest link model [14], in which a certain property (in this study, the damage zone length) is determined by the strongest (longest) element, as shown in Fig. 11. The probability $\boldsymbol{F_x}(x)$ that the length y of an element in a unit area is less than or equal to the length x is assumed to be a two-parameter Weibull distribution with the following equation:

$$\boldsymbol{F_x}(x) = 1 - e^{-\left(\frac{x}{x_0}\right)^m}, \quad (3)$$

where x_0 and m are the material parameters that define the magnitude and scatter in strength. In the model shown in Fig. 11, if all element lengths y are less than or equal to length x, the damage zone length is x. Therefore, when there are n elements, the probability $\boldsymbol{F_x}(x)$ that all element lengths y are less than or equal to x is expressed by the cumulative distribution function, given by the following equation:

$$\boldsymbol{F_x}(x) = \left(1 - e^{-\left(\frac{x}{x_0}\right)^m}\right)^n \quad (4)$$

For a specimen of a loaded area A, n can be replaced by A. Therefore, the probability $\boldsymbol{F_x}(x)$ is expressed by the following equation:

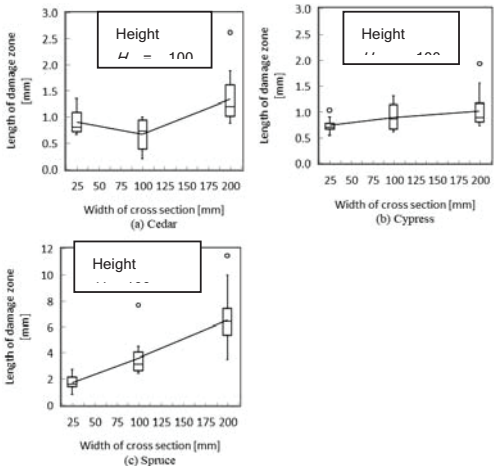

Figure 6: *Length of damage zone of specimens of varying widths of cross-section*

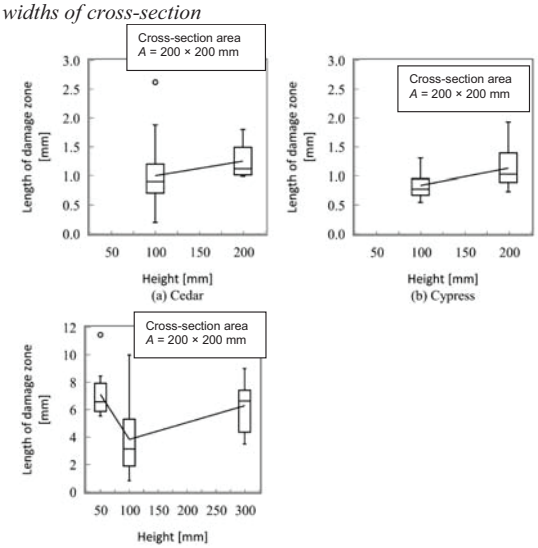

Figure 7: *Length of damage zone of specimens of varying heights*

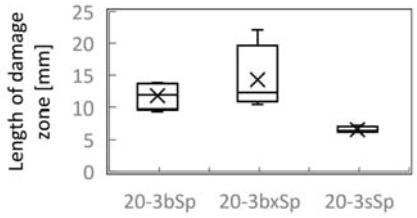

Figure 8: *Length of damage zone of specimens with wood-wood joints and wood-steel joints.*

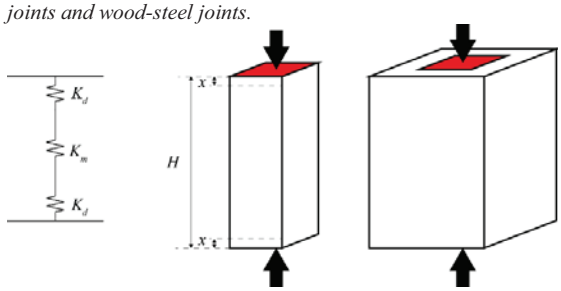

Figure 9: *Spring model of specimen compressed parallel to grain.*

https://doi.org/10.52202/069179-0035

$$\boldsymbol{F_x}(x) = \left(1 - e^{-\left(\frac{x}{x_0}\right)^m}\right)^A \quad (5)$$

Fig. 12 shows the cumulative probability distribution of the damage zone length obtained from the experiments and Eq. 5 with the material parameters, which are close to the experimental value. The solid line in the figure represents the experimental value, and the dashed line represents Eq. 5. The cumulative probability distributions of the experimental results can be successfully represented by the distributions of the strongest link model in Eq. 5, although the agreement was not perfect owing to the small number of specimens. Therefore, the size effect on the damage zone length can be explained by the strongest link model using the Weibull distribution.

In the strongest link model, the relationship between the damage zone lengths with loaded areas A_1 and A_2 can be as follows:

$$\boldsymbol{F_x}(x)^{\frac{1}{A}} = 1 - e^{-\left(\frac{x}{x_0}\right)^m} \quad (6)$$

$$1 - \boldsymbol{F_x}(x)^{\frac{1}{A}} = e^{-\left(\frac{x}{x_0}\right)^m} \quad (7)$$

$$\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A}}\right) = -\left(\frac{x}{x_0}\right)^m \quad (8)$$

$$\left(-\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A}}\right)\right)^{\frac{1}{m}} = \frac{x}{x_0} \quad (9)$$

If m, x_0, and $\boldsymbol{F_x}(x)$ are equal in the loaded areas A_1 and A_2, the relationship between the damage zone lengths x_1 and x_2 of the specimen with loaded areas A_1 and A_2 is as follows:

$$\frac{x_1}{x_2} = \left(\frac{\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A_1}}\right)}{\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A_2}}\right)}\right)^{\frac{1}{m}} = \left(\frac{\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A_1}}\right)}{\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A_2}}\right)}\right)^{k} \quad (10)$$

Where k is the size effect parameter. Fig. 13 shows the experimental results and approximate curves for Eq. 10 with the test of a 25 mm square section as the benchmark specimen (x_2 and A_2) when the cumulative probability is 50%. The size effect parameter k was 0.62 for cedar, 0.42 for cypress, and 3.12 for spruce specimens. The size effect parameter k of the strongest link model was similar to that of the weakest link model, indicating that the larger the parameter k, the larger the size effect.

3.3 YOUNG'S MODULUS OF DAMAGE ZONE

The experimental value of the Young's modulus of the damage zone in Table 3 was calculated using Eq. 2 with the experimental data (mean value) in Table 2. The Young's modulus of the damage zone was 128-464 N/mm² for the spruce, 61-574 N/mm² for the cedar, and 98-491 N/mm² for the cypress specimens. The Young's modulus of the damage zone was higher for Japanese cypress than for cedar, even though the two specimens were processed by the same machine. Fig. 14 shows the ratio of the Young's modulus of the damage zone to the Young's modulus of the middle zone. No correlation was found between this ratio and wood species or dimensions of the specimen. The mean values of the Young's modulus ratios were 2.1% for the spruce, 2.4% for the cedar, and 1.5% for the cypress specimens, respectively. Therefore, the Young's modulus of the damage zone is considered to be approximately 2% of the Young's modulus of the middle zone.

https://doi.org/10.52202/069179-0035

3.4 EXPERIMENTAL RESULTS AND CALCULATED RESULTS

The stiffness of the compression parallel to the grain can be evaluated using the following equations:

$$K_f = \frac{1}{\frac{2}{K_d} + \frac{1}{K_m}} = \frac{1}{\frac{2x}{0.02E_{L,m}A} + \frac{H-2x}{E_{L,m}A}} \quad (11)$$

$$x = \left(\frac{\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A}}\right)}{\ln\left(1 - \boldsymbol{F_x}(x)^{\frac{1}{A_s}}\right)} \right)^{k} x_s \quad (12)$$

To shorten x, the size effect parameter should be small, and machining that does not increase the surface roughness significantly is recommended. Since a specimen with a smaller loaded area is less susceptible to the effects of machining accuracy, it is recommended that the benchmark specimen have a loaded area as small as possible (in this study, an ASTM 143 specimen, R25×T25×L100 mm, was used). The cumulative probability should be set to 50%, considering that the mean value is typically used as the stiffness of the joint in timber buildings. If the loaded area of the benchmark specimen is 25 mm square and the cumulative probability is 50%, Eq. 12 becomes:

$$x = \left(\frac{\ln\left(1 - 0.5^{\frac{1}{A}}\right)}{-6.8} \right)^{k} x_s \quad (13)$$

Fig. 15 shows the value calculated using Eq. 11 and 13 along with the experimental values of the stiffness K_f. The parameters k and x_s inserted in Eq. 13 were 3.12 and 0.86 for spruce specimens, 0.62 and 0.89 for cedar specimens, and 0.42 and 1.01 for cypress specimens, as shown in Fig. 13. The calculated values are considered to be satisfactorily close to the experimental values.

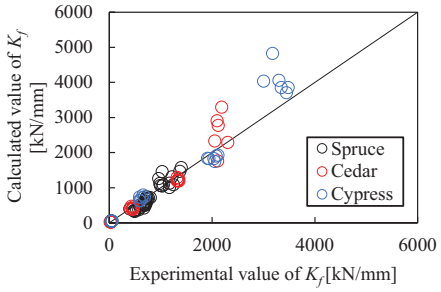

Figure 15: *Calculated value and experimental value of compressive stiffness parallel to the grain*

4 CONCLUSIONS

The properties of the damage zone of timber compressed parallel to the grain were studied using experimental results and computational models. The damage zone length and its scatter increased as the loaded area increased. No correlation was found between the ratio of the Young's modulus of the damage zone to the Young's modulus of the middle zone and the wood species or dimensions. The Young's modulus of the damage zone was approximately 2% of that of the middle zone. In addition, an evaluation method for the damage zone length is proposed using the strongest link model to consider the size effect of the damage zone length. The Young's modulus and damage zone length evaluation methods obtained above were used to evaluate the stiffness of the specimens compressed parallel to the grain. The proposed method could evaluate the experimental values reasonably well.

In the future, the proposed method for the damage zone can be applied to a variety of timber connections.

COMPARISON OF THE DEGREE OF INFLUENCE OF VARIOUS CONDITIONS ON THE BEARING CAPACITY OF WOOD-BASED PANELS

Ryutaro Sudo[1], Kenji Aoki[1],

ABSTRACT: Bearing property is important for the design of the connection. There are few studies about the bearing property of the wood-based panels. First, the tensile bearing test of the wood-based panels: Plywood and OSB of strong and weak axial specification, was conducted based on the comprehensive parameters. Test parameters were set as dowel insertion position, size of pilot hole and dowel diameter. The correlation between parameters and the mechanical characteristics: failure behavior, ductility, yield stress and maximum stress, was verified. To verify how much each parameter effect on maximum stress, standardized multiple regression analysis was conducted. These results provide insights into the failure behavior and stress distribution, supporting certain assumptions: (1) PW and OSB is deformed dominantly in-plane and out-of-plane respectively; (2) the relative stress spread range is decreased with the larger diameter of the dowel; (3) the stress spread range is widened by load step; and (4) the bearing stress is spread vertically and horizontally in strong and weak specification respectively, also verified in this section. A detailed investigation was performed using DIC and CT scanning techniques to shed light on the stress distribution and fracture processes. Three load steps were configured and subjected to cyclic loading. Verification and comparison were carried out for each specification, layer, and step, providing a clearer understanding of the stress distribution and fracture processes. These results are consistent with the conclusions drawn from the comprehensive testing.

1 INTRODUCTION

The structural properties of wood structures are greatly affected by the property of joints. Their behavior depends on the characteristics when the circular joints are embedding into the material, the bearing properties. There have been many studies on the bearing properties of timber[1)2)]. On the other hand, though studies on the bearing capacity of wood-based panels include Sekino et al.'s study on particle board[3)] and Ogawa et al.'s study on the bearing capacity of plywood[4)], there are only a few studies that have comprehensively examined the parameters and considered how the various conditions affect the bearing properties and how the degree of influence varies depending on the type of panels. The underlying mechanism of fracture remains elusive, which represents a crucial foundation for the development of theoretical equations for determining characteristic values.

The primary objective of this report is to systematically investigate the degree to which various conditions exert an influence on mechanical properties under the bearing stress of plywood (PW) and oriented strand board (OSB) through comprehensive testing. Additionally, the process of stress spread, and fracture was clarified by utilizing digital image correlation (DIC) and computed tomography (CT) scanning techniques.

2 STUDY BASED ON EXHAUSTIVE PARAMETERS

2.1 Material and method

The panels to be tested were 5-ply cedar PW[5)] and OSB[6)] for structural use. Since PW and OSB were orthotropy material, the test was conducted in both strong and weak axes. In addition, a trailing "-s" (e.g., PW-s) indicates a strong axial specification, whereas a trailing "-w" (e.g., PW-w) indicates a weak axial specification. Their thickness was 9mm. The detail properties of the panels are shown in Table 1. Other parameters were set as dowel diameter *d* (5.2 and 12mm), position (A~G), as shown in Figure

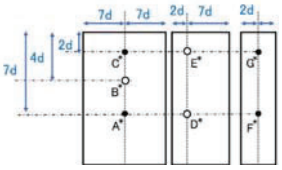

Figure 1: *Parameters of bearing tests. * Name of Position. Tests of 4 kinds of ph were conducted at place of black circle. Tests of 2 kinds of ph (0, 1d) were conducted at place of white circle.*

1, the size of the pilot hole *ph* (0, 1/3, 2/3 and 1 time to the diameter). Figure 1 also shows the combination of the position and *ph*. As a dowel (*d*=5.2mm), N150 nail (defined by JIS[7]) was used and, as the other dowel (*d*=12mm), a custom-made dowel was used, as shown in Figure 2. Number of the specimen were six per a specification.

Figure 2: *Schematic of 12mm pin.*

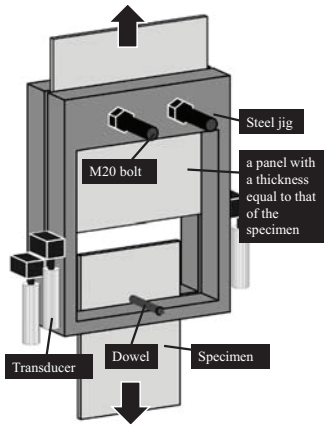

Figure 3: *Setting of bearing test.*

Bearing test was conducted as shown in Figure 3, applying shear force by sandwiching with a pair of steel plates with a rectangular hole. This jig was designed to enable to observe of the failure process and to eliminate depth clearance. The monotonical tensile load was applied to the specimen at 3~4mm/min (*d*=5.2mm) or at 6~7mm/min (*d*=12mm.). After the test, bending deformation of the dowel was not observed.

2.2 RESULT AND DISCUSSION

2.2.1 Failure mode

Two failure modes were observed as follows. One was shear failure at the area above dowel, as shown in Figure 4. It was named as "ESF (end shear failure)". The Other was tensile failure at the area next to the dowel, as shown in Figure 5. It was named as "STF (Side tension failure)". ESF was ductile failure, whereas STF was brittle failure. STF occurred only when the dowel position was D~G. The STF resembled a simple tensile failure, and it did not differ significantly among the panel types. Meanwhile, the ESF showed some differences among the panel types. Figure 6 shows a summary of the fracture progression during the test and the failure appearance of each panel after the test. In this figure, all parameters except the panel type are standardized uniformed (dowel position: A, *d*: 12 mm, *ph*: 1).

Note: *Ave. means average, and S. D. means standard deviation. Three mechanical tests were conducted according to ASTM D 1037 [8].*

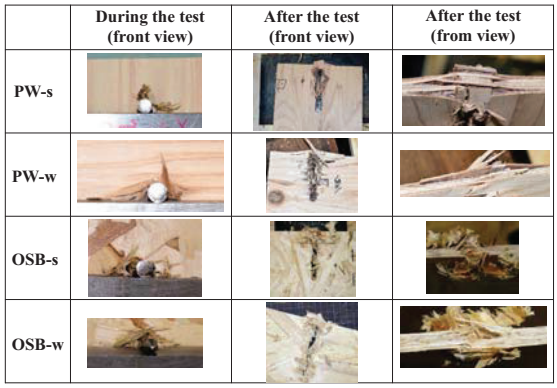

Figure 6: *Comparison of ESF behavior among panel types.*

The ESF mode exhibited two types of failure behavior: a crack on the surface of the panel generated by in-plane tensile or shear stress, termed "in-plane failure," and a peeled surface divided into several layers. The peeled surface failure is generated by the Poisson effect of the compressive stress immediately above the dowel and is termed "out-of-plane failure."

Although these two types of failure behavior generally occurred simultaneously, it was possible to identify the dominant failure behavior for each panel type.

After the test was completed, vertical and horizontal crack lines were observed in PW-s and PW-w, respectively. Although the layers of the specimens were separated after the test, they were only slightly peeled off. This separation of layers was caused by the difference in failure mode in the fiber direction of the veneer, not by the Poisson effect. Compared with the PW, the OSB did not show a clear clack line. Additionally, the surface layer of the OSB was peeled off more significantly than that of the PW. Therefore, based on a comparison between the PW and OSB, in-plane failure and out-of-plane failure were dominant in the PW and OSB, respectively.

To correlate these failure behaviors with the material property, the "in-to-out plane strength," which is defined by the tensile strength divided by the internal bond strength, was introduced. The in-to-out plane strengths of the PW and OSB were 14.6 and 34.6 respectively. A comparison of the in-to-out plane strength of panels shows that a panel with a higher in-to-out plane strength is dominated by the out-to-plane failure. The fracture mechanism is shown in Figure 7. These results suggests that the in-to-out plane strength is related to the failure behavior under the bearing pressure.

Number of specimens where STF occurred at D~G is shown in Table 2. About all of panels, STF more likely

	1	2	0	3	3	6	0	6	4

occurred at the position of D and F than of E and G respectively. It is considered to be because ESF occurred earlier than STF when edge distance was short. This Table also indicates that STF more likely occurred when *d* was 5.2mm than when 12mm. According to some previous studies about embedment of timber[9)], stress spreading range is absolute range: not depending on the pressure area. Configurating the length of edge distance based on the diameter in this test, stress spreading range was wider relatively with d = 5.2mm than d = 12mm. Assuming that STF occurred when strong stress reached to the edge of specimen, this difference of the range is considered to result in the difference of the number of specimen where STF occurred. STF also more likely occurred loading in weak axis than in strong axis. This result suggests that horizontal stress spread range of weak axial specification was wider than that of strong one. Compared in the two kinds of panels, STF occurred more likely in OSB.

2.2.2 Evaluation method of characteristic value

Stress was calculated by dividing the load by the projection area of the dowel, after which the stress–displacement curves were obtained. Based on these displacement curves, the maximum stress σ_{max} (MPa), yield stress σ_y (MPa), and ultimate displacement u (mm) were derived using the method presented next.

A simple illustration of the method is shown in Figure 8. u was defined as the displacement at 80% of the maximum stress of the entire stress–displacement curve. σ_y was derived via the 5%-offset method using a linear elastic line in the linear range (i.e., offset the length to equal to 5% of the dowel diameter). Additionally, based on the cases where STF occurred, STF was shown to be

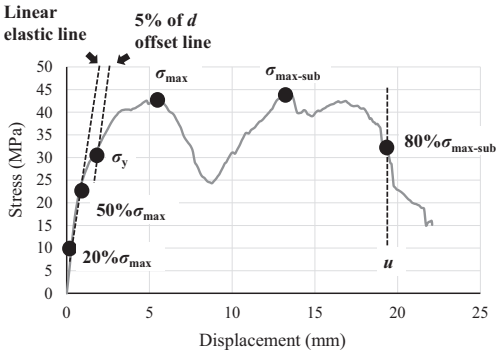

Figure 8: *Evaluation of characteristic values based on stress–displacement curve.*
Note: *The parameters of the specimen were as follows: panel type, PW-s; d, 5.2 mm; ph, 0; dowel position, A.*

a brittle failure, and the intersection between its curve and the offset line typically occurred after σ_{max}. In this case, σ_{max} was regarded as σ_y.

2.2.3 Comparison of ductility

The ultimate displacement is typically used to compare ductility. However, as the ultimate displacement measured in this study was significantly affected by the original end distance, it was not regarded as an appropriate indicator of ductility. Additionally, the original end distance was set based on d, and u is also affected by d. Hence, the remaining distance (*RD*) was introduced, which is derived by dividing the difference between u and the length of the original end distance by d. Figure 9 shows a comparison of the *RD* values. The shorter the *RD*, the higher is the ductility.

The trends observed in all the panel types were as follows: (1) The *RD* of A and B was similar, (2) the *RD* at D or F and their standard deviations were higher than those at any other dowel positions, and (3) the *RD* for d = 5.2 mm was typically higher than that for d = 12 mm.

First, the *RD* of A and B was similar, i.e., from 2 to 4. For the bearing of timber, if the ratio of the thickness to d is low and dowel bending is not observed, then brittle splitting will typically occur. For the bearing of wood-based panels, when the edge distance was sufficient, the failure mode was ductile, and the load did not decrease until the remaining end distance reached a certain value. This implies that the prevalent belief for timber is not valid for wood-based structural panels. This mechanism is independent of the original end distance.

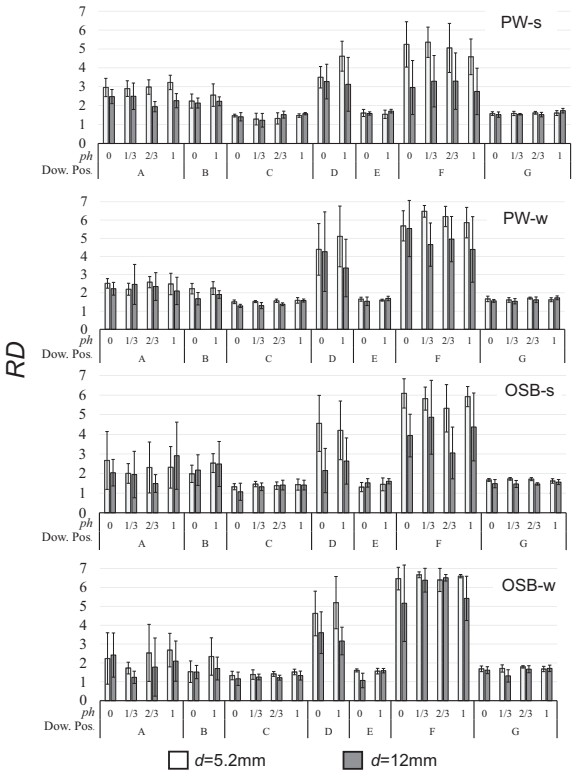

Figure 9: *Comparison of RD values.*
Note: *Dow. Pos. means dowel position. Error bars indicate standard deviation.*

https://doi.org/10.52202/069179-0036

Second, the values of *RD* at D or F and their standard deviations were higher than those at any other dowel positions. As described previously, the failure mode at dowel position D or F was STF in some cases and brittle. Consequently, the values of *RD* at D and F were high. In addition, a mixture of failures involving both ESF and STF occurred in the same specification, which resulted in a significant variation in the *RD*.

Third, the *RD* for d = 5.2 mm was higher than that for d = 12 mm. As described above, the spreading range of the horizontal stress was assumed to be larger when d = 5.2 mm in comparison with d = 12 mm. Therefore, the results at positions D–G, where STF is likely, can be theorized as in the previous section. Although ESF occurred at dowel positions A–C, the same justification can be used to explain these results, assuming the spreading range of the longitudinal relative stress was also larger when d = 5.2 mm. Therefore, this suggests that the relative stress spreading range was larger both horizontally and vertically when d = 5.2 mm in comparison with d = 12 mm.

A comparison of the *RD* values based on calculated "strong axial specification - weak axial specification" values for the PW and OSB are shown in Figure 10.

The values were positive at positions A–C and negative at positions D and F for both the PW and OSB. In the weak axial specification, STF occurred more frequently, and the *RD* was higher, as described above. Therefore, the values were negative at positions D and F. To account for the results at positions A–C, it is necessary to assume that the vertical stress spreading range is important for the *RD* when ESF occurs and that the vertical stress spreading range is larger in the strong axial specification. This makes it easier for stress to reach the top end and causes earlier fracture of the strong axial specification. These results suggest that the stress spreading range of the strong axial specification was larger vertically and smaller horizontally than that of the weak axial specification.

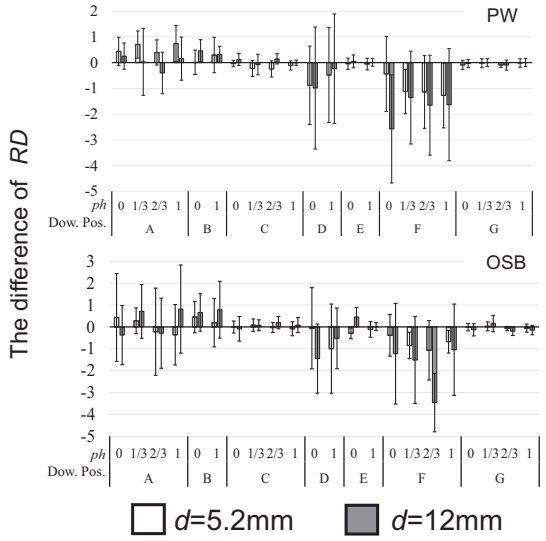

Figure 10: *Comparison of RD differences between strong and weak axial specifications.*
Note: *Values of "strong axial specification - weak axial specification" are presented.*
Error bars indicate standard deviation.

2.2.4 Standardized multiple regression analysis of characteristic values

To quantitatively verify how much each parameter had an influence on each characteristic value, SMRA was conducted.

The characteristic values with five explanatory variables are expressed in Eq. 1.

$$y = \sum_{i=1}^{5} a_i x_i + \epsilon\,, \tag{1}$$

where y is the objective variable, x_i is the explanatory variable, a_i is its partial regression coefficient, and ε is the error.

Five explanatory variables were set as follows: dowel diameter d (mm), ratio of the pilot hole *ph*, ratio of the end distance to the diameter *e*, variable *side2* that equals to 1 when the dowel position was D or E and 0 otherwise, and variable *side3* that equals to 1 when the dowel position was F or G and 0 otherwise. Additionally, σ_{max} and σ_y were set as the objective variables. Each variable was standardized to have a mean of 0 and standard deviation of 1 using Eq. 2 before analysis.

$$\bar{p} = \frac{p - \mu}{\sigma}\,, \tag{2}$$

where p is the original value, $\bar{p}$ is the standardized value, μ is the average value, and σ is the standard deviation.

Supposing that the variable with the upper line indicates they have been standardized, Eq. 1 can be rewritten as in Eq. 3.

$$\bar{y} = \sum_{i=1}^{5} a_i \bar{x_i} + \epsilon \tag{3}$$

The partial regression coefficients are representative of the influence degree of the parameter on the characteristic value. Therefore, this value can reveal the dominant influencing factor.

A comparison of the values of the partial regression coefficient is shown in Figure 11.

As shown in Figure 11, the overall results of σ_y and σ_{max} are roughly the same, but the degree of how the value is spread varies. Figure 11 indicates that *ph* had a stronger influence on σ_y than on σ_{max}. It also indicates that *e*, *side2*, and *side3* had a stronger influence on σ_{max} than on σ_y. These results are consistent where the stress redistribution increased the stress spreading range at σ_{max}. Based on this assumption, the nailed damaged area was not small enough to ignore at σ_y, the stress spreading range widened at σ_{max} and the damaged area narrowed relatively. Similarly, even when the end or edge distance was narrow, it had no effect on σ_y because the stress spreading range at σ_y was also small. However, when the stress spreading range widened to some extent at σ_{max}, the range reached the edge and affected the strength. Consequently, the coefficients for σ_y and σ_{max} would differ. However, this cannot be confirmed only by these results.

An analysis of the $a_{\bar{e}}$ of σ_{max} suggests that *e* exerted the strongest influence on the σ_{max} of the PW and a stronger

influence on the σ_{max} of the strong axial specifications than on their weak axial specifications. As described previously regarding the *RD*, the strong axial specification indicated a lower ductility than the weak axial specification when ESF occurred. This is assumedly attributable to the larger spread range of vertical stress in the strong axial specification. Based on this assumption, the σ_{max} of the strong specification will certainly be affected by *e*.

Based on a comparison between $a_{\overline{side2}}$ and $a_{\overline{side3}}$, the overall trends were similar and the absolute value of $a_{\overline{side3}}$ was larger than that of $a_{\overline{side2}}$. Additionally, the values of $a_{\overline{side2}}$and $a_{\overline{side3}}$ of σ_{max} were strongly negative for PW-w and OSB-w. In general, a large stress spreads horizontally when a compressive stress is applied in the direction perpendicular to the grain, and the spreading of this stress contributes to the strength [8]. Therefore, it is natural that the weak axial specification was highly influenced by the edge distance.

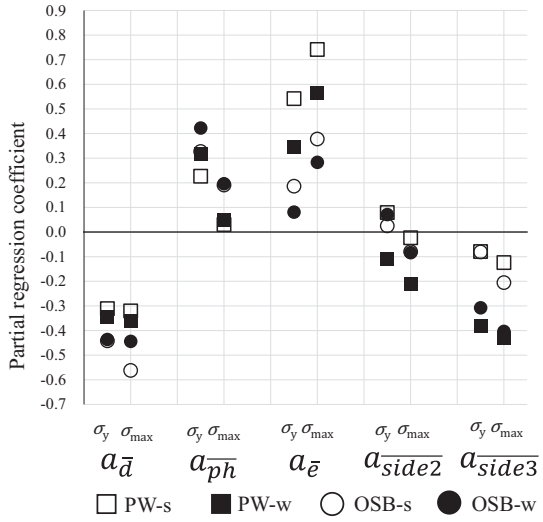

Figure 11: *Comparison of partial regression coefficients.*

3 STUDY BASED ON DETALED OBSEVATION

3.1 MATERIAL AND METHOD

In this section, the process of stress spread, and fracture was clarified by utilizing DIC and CT scanning. Additionally, the assumptions suggested in the previous section: (1) PW and OSB is deformed dominantly in-plane and out-of-plane respectively; (2) the relative stress spread range is decreased with the larger diameter of the dowel; (3) the stress spread range is widened by load step; and (4) the bearing stress is spread vertically and horizontally in strong and weak specification respectively, also verified in this section.

Parameter was *d* (5.2 and 12mm) and material (PW-s,w and OSB-s,w). *ph* was configurated as 1. Number of the specimen were two per a specification. The test setup was the same as in the previous section. Three test steps were set as shown in Figure 12 (1st step: 50% of the maximum load, 2nd step: maximum load, 3rd step: displacement equal to the diameter of the joint), and the force was applied and removed each time. DIC was conducted during load process and CT scanning was conducted after unloaded. In the 1st step, the average value of the maximum load in the previous section was used as the predicted value, and when the load reached 50% of this value, the test was stopped, and the specimen was unloaded. In the 2nd step, when the load dropped 0.01 kN, the specimen was considered to have reached a certain maximum load and was unloaded. The test speed was 0.5mm/min for *d*=5.2mm and 1mm/min for *d*=12mm in the first and second step. In the third step, the test speed was twice.

For DIC procedure, random black dots on a white surface was painted on the face of the specimen. The surface image was captured at frequency of 0.2 Hz in the loading process.

In the CT scanning, specimens were scanned at 200 kV/200 μA source output level, with no filters, scanning distance 962.5 mm to the specimen and 1400mm to the dictator, with 2000 angular projections (0.18 deg increments) and 0.75 second of exposure time per projection. The definition was 250 μ m/pixel.

3.2 RESULTS OF DIC TEST

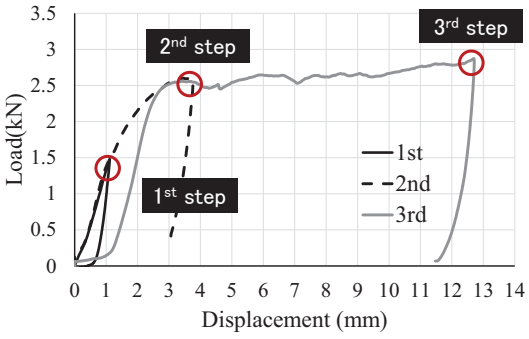

Figure 12: *Schematic of three steps.*

As shown in Figure 13, the *x*, *y* and shear strain distributions were obtained for five cross sections (load direction was regarded as *y* axis).

Figure 14 shows an example of the obtained strain distribution, which indicates that the strain is stronger in the central area than in other areas, and that some areas are not measured due to failure. We considered this area to be the local strain and fracture spread due to the bearing stress and measured the length of these areas by the following method. First, as shown in Figure 15, the mean μ and standard deviation σ of the

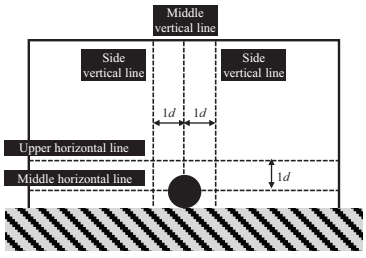

Figure 13: *Measurement line of DIC.*

https://doi.org/10.52202/069179-0036

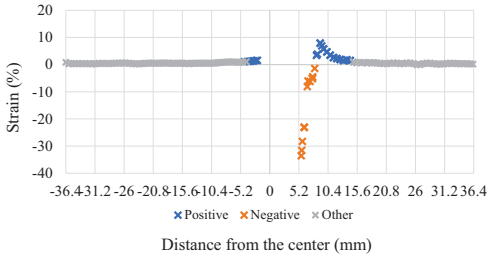

Figure 14: *Example of strain distribution.*
Note: *material; PW-w, cross section; Middle horizontal line, diameter; 5.2mm, step; 3rd, strain; y.*

strain in the range of 1~2 *d* from the left and right edges of the central horizontal section and the top of the central vertical section were calculated based on the strain. Then, we calculated the range of strain that was not measurable due to fracture over the entire cross-section: failure, the range of strain higher than $\mu+3\sigma$: positive, and the range of strain lower than $\mu-3\sigma$: negative. This process

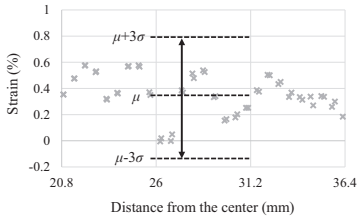

Figure 15: *Variation of the values of strain near the edge of specimen.*

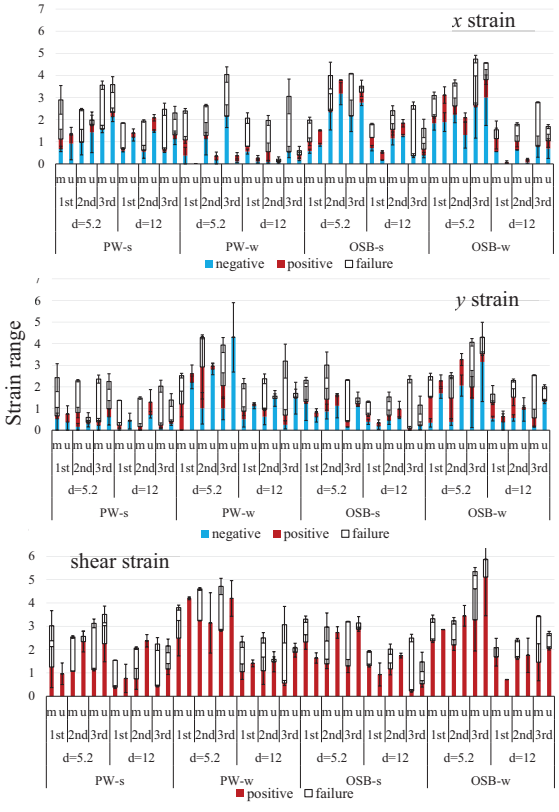

Figure 16: *Comparison of strain range of horizontal cross section.*
Note: *"1st", "2nd" and "3rd" indicate the test steps. "m" and "u" mean middle and upper horizontal cross section respectively.*

was conducted for each strain direction, specimen, and step. The value obtained was divided by *d*, and the standardized value was defined as "strain range".

Figure 16,17 shows comparison of strain ranges in the horizontal and vertical section respectively. The overall trend exhibited three distinct characteristics: I, the strain range was widened during each loading phase, particularly in the horizontal section; II, the relative strain range diminished with an increase in diameter; III, the strain range spread vertically and horizontally in the strong and weak axial specification respectively. The difference between strong and weak axial specification was more pronounced in PW. These results support the assumption referred in the previous section.

In PW-s, the range of vertical x-strain in the central and side sections exhibits positive and negative values, respectively. This outcome implies that the fiber was ruptured just above the dowel and concentrated on the lateral aspect of the dowel. This mechanism resulted in the compressive stress in the side section. The difference by *d* was smaller in PW-s than in any other panel type. The strain range was widened both horizontally and vertically during each loading phase.

The salient feature of the strain distribution in PW-w is that the y-strain spreads horizontally and extensively, akin to a stress distribution when timber is embedded laterally. The variation in *d* was substantial, which is likely attributed to the fact that the extent of spread is a fixed

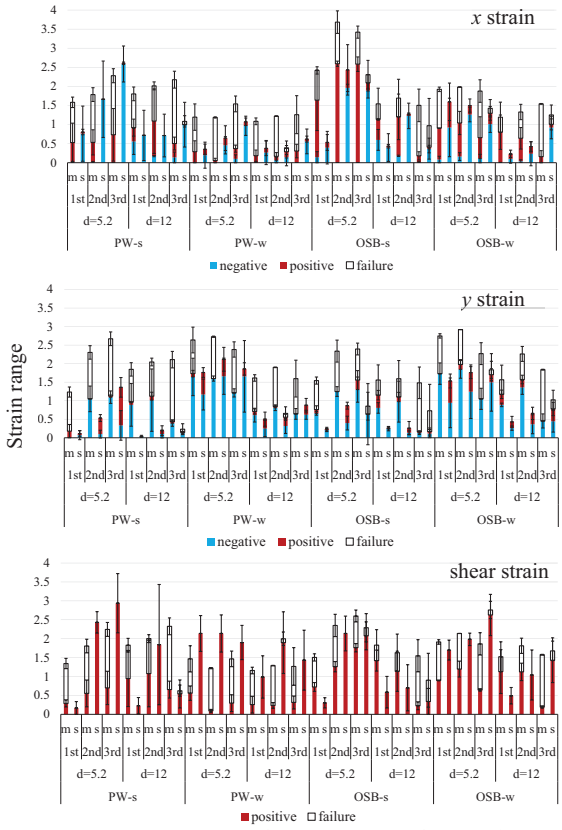

Figure 17: *Comparison of strain range of vertical cross section.*
Note: *"1st", "2nd" and "3rd" indicate the test steps. "m" and "s" mean middle and side vertical cross section respectively.*

range, regardless of the pressure area, and in alignment

with prior research[9]. Although the strain range was broadened horizontally during each loading phase, this was not the case for the vertical angle, suggesting that the embedding depth remained unchanged by the step.

The difference between strong and weak axial specification was pronounced more slightly in OSB than in PW. The variation in *d* was substantial. The strain range was broadened significantly only horizontally during each loading phase.

The shear strain in the horizontal section exhibited minimal expansion during each loading phase except horizontal section in OSB-s. Furthermore, the shear strain in the central vertical section was less pronounced than that in the peripheral section. As depicted in Figure 18, a graph of *y* strain and shear strain are superimposed in the upper horizontal section. The peak of shear strain was coincident with the base of the *y* strain peak. Thus, the range of shear strain can be considered to be situated at the periphery of the *y* strain range, and the length of this boundary did not expand, even as the range of *y* strain widened.

3.3 RESULTS OF CT SCANNING TEST

Internal cross-sectional images of five plywood layers and three OSB layers were acquired via CT scanning at the locations depicted in Figure 18. The brightness and contrast of each step were harmonized using the procedure illustrated in Figure 19, and differences in brightness were utilized to determine regions void or densified due to bearing pressure. The difference images were obtained for the "1st step-2nd step (plasticity difference (PD))" and "2nd step-3rd step (ultimate difference (UD))" for each specimen and each cross-section.

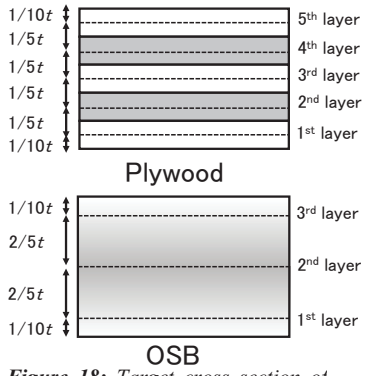

Figure 18: *Target cross section of analysis.*

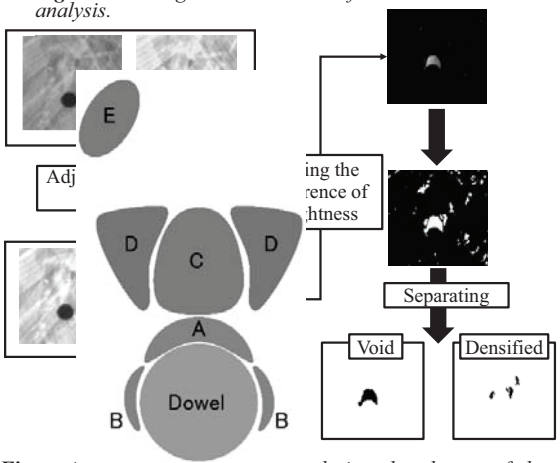

Figure 19: *Overall method of analysing the change of the density.* ***Figure 20:*** *Classification of void or densified area.*

For the derived difference images, the void and densified regions were categorized as A (immediately above to the dowel), B (left and right of the dowel), C (above the dowel), D (diagonally above the dowel), and E (otherwise), as depicted in Figure 20, to ascertain the location of the alteration for each specification, each layer, and each step. Based on this identification of fracture location, it was established whether the layer of varying specifications manifested identical forms of fracture or not. The concrete procedure is as follows.

Initially, an assessment was conducted to determine if the mode of failure varied contingent on the location of the target layer, either on the surface or inner layer. In this regard, the first and fifth layers of plywood, and the first and third layers of OSB were deemed as surface layers, while the third layer of plywood and the second layer of OSB were deemed as inner layers. The likelihood of density changes occurring under each condition was evaluated, and a comparison list was generated and presented in Table 3. Subsequently, a regression analysis was performed on this list, yielding a graph as depicted in Figure 21, with the R^2 value serving as an indicator of similarity in fracture form between surface and inner layers when other conditions were matched. This analysis was separately conducted for plywood and OSB, and for PD and UD, resulting in four distinct R^2 values. A similar method was utilized to establish whether the failure modes differed between strong-axis and weak-axis layers.

Table 4: *Comparison of R^2 values.*

Comparison	Material	Step	R^2 value
Inner vs Outer	PW	PD	0.85
		UD	0.66
	OSB	PD	0.66
		UD	0.38
Strong vs Weak	PW	PD	0.61
		UD	0.24
	OSB	PD	0.55
		UD	0.53

Table 3: *Schematic of list for comparison of failure behavior between outer and inner layer.*

Direction	Diamter (mm)	Void or densified	Probability of change in density at ...	Outer	Inner
			A	1	1
			B	0.5	0.5
		void	C	0.5	1
	5.2		D	0	0
			E	0	0
Strong		densified	A	1	1
		…	…		
		void	A		
		…			
	12	densified	…	…	…
		…			
Weak	5.2	void	A		
…	…	…	…		

The findings, presented in Table 4, demonstrate that for plywood, the impact of the layer's position on failure mode is negligible, whereas the variation in fiber direction accounts for the discrepancy in failure mode. Conversely, for OSB, the results indicate that the layer's position

https://doi.org/10.52202/069179-0036

significantly influenced the failure mode, particularly in the UD direction, and that the variance in fiber direction had no impact on the variation in failure mode. These results demonstrate the assumption referred in the previous section.

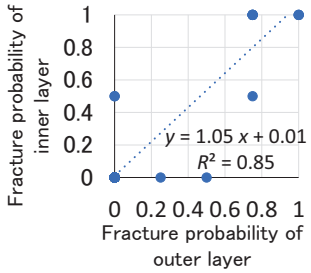

Figure 21: *Examples of regression analysis of fracture probability.*

Moreover, the orientation of the fibers in the odd-numbered veneer layers in PW-s and the even-numbered veneer layers in PW-w (and vice versa) are identical. Consequently, a common method was employed to ascertain if the disparity in fracture form was due to the disparity between the odd- and even-numbered layers. The R^2 value was 0.82 for PD and 0.80 for UD, demonstrating that the mode of plywood failure is predicated on the direction of the veneer fibers, independent of the layer's arrangement.

Table 5 illustrates the probability of density fluctuation occurring in each specification. The occurrence of densification at position B was commonplace in the case of strong axial veneers in plywood, which may be attributed to the convergence of fibers on both sides of the dowel brought about by fiber dissociation in the center. At location C in the UD, void and densification also occurred, likely as a result of the upward propagation of cracks during large deformation. The weak axial veneer experienced void and densification at locations C and D in the UD, whereby the veneer was altered by bearing stress and undergoes plasticization and fracture above and to the right and left of the dowel, with the deformation failing to recover even upon unloading. The surface layer of OSB displays a plethora of void areas (B, C, D and E), presumably resulting from surface delamination. Only the inner layer of OSB experienced densification, with void and densification occurring frequently at location C. The fracture location of the inner layer can be characterized as intermediate between a strong-axis veneer and a weak-axis veneer. These findings suggest that out-of-plane delamination is predominant in the surface layer, while in-plane compressive deformation is predominant in the inner layer.

The area of the difference image is divided by the area of the dowel and standardized for comparison in Figure 22. In PW, the weak axial veneer has a larger densified and void area than the strong axial veneer, and the difference in densification area is larger. This is because the covergence to the left and right due to fiber dessociation was an indirect deformation caused by a stress perpendicular to the direction of the applied force, while the embedment into the weak axial veneer is a direct deformation occurring parallel to the direction of the applied force. The densifi ed area decreased with increasing diameter, but the void area did not change significantly with diameter. As mentioned above, it can be concluded that OSB causes delamination in the surface layer and compressive deformation in the inner layer. In addition, the standardized void area of the surface layer shows differences depending on the diameter, although the standard deviation is significant. In other words, the absolute value of the delamination area does not seem to vary with diameter.

4 CONCLUSIONS

The comprehensive testing of wood-based panels was performed to assess their bearing capacity. A systematic examination was carried out to discern the correlation between failure mode and parameters. By incorporating the remained distance, the interdependence between ductility and parameters was validated. Standardized multiple regression analysis of the characteristic values was also executed, yielding an understanding of the influence of various conditions on the values. These results provide insights into the failure behavior and stress distribution, supporting certain hypotheses.

A detailed investigation was performed using DIC and CT scanning techniques to shed light on the stress distribution and fracture processes. Three load steps were configured and subjected to cyclic loading. Verification and comparison were carried out for each specification, layer, and step, providing a clearer understanding of the stress distribution and fracture processes. These results are

REINFORCEMENT OF TIMBER STRUCTURES VERSUS CLIMATE IMPACT

Bettina Franke[1], Steffen Franke[2], Marcus Schiere[3]

ABSTRACT: Wood is a hygroscopic material. The moisture content of wood changes due to ambient climate variations. The moisture content changes first on the surface and a moisture gradient develops over the cross section and results in moisture induced stresses (MIS). MIS occur in addition to normal stresses for the load-bearing resistance and can affect mechanical reinforcements. The paper shows results from experimental test series on the load, moisture, and deformation investigation of structural glulam members reinforced with internal mechanical fasteners. Stepwise climate scenarios were applied and considered climates experienced by the structural timber member before or after reinforcement. For the estimation of the swelling and shrinkage behaviour, effective hygro-expansion coefficients have been determined. The coefficients are significantly lower than previously assumed in the standards. This enables engineers to estimate more realistic wood deformations and the impact on reinforcements which is not neglectable and reduces damage in a wide range of applications. The research results promote the use of wood by ensuring quality, performance, and aesthetics in timber constructions.

KEYWORDS: Wood, reinforcement, self-tapping screws, moisture induced stress, hygro-expansion coefficients

1 INTRODUCTION

The performance of structural timber members can be enhanced by mechanical reinforcements e.g., in the form of bonded in rods, self-drilling fully threaded screws or threaded rods. Reinforcements of connections or timber members become necessary by restricted cross-sectional geometry or if e.g., curved, notched, or members with holes are used, as shown among others in [1], [2], [3], [4], [5], [6].

Wood as a hygroscopic capillary porous material adsorb or release water from the ambient air. Directly on the wood surface, an equilibrium moisture content develops, which depends on the relative humidity and temperature. The moisture transport over the cross-section takes place by diffusion and is very prolonged, [7]. Therefore, a moisture profile is formed over the cross-section which leads to moisture induced stresses (MIS) due to the non-uniform shrinkage and swelling of the wood cross section, [8]. In addition, the internal reinforcements not only improve the performance of timber structures but also change/restrict the free deformation behaviour of the cross-section which also leads to MIS. The two aspects, MIS and internal reinforcement, occur together in the life cycle of timber structures. The research done by Danzer et al. [9] shows that the load-carrying capacity of reinforced members with notches can even be reduced compared to unreinforced ones.

The objective is to provide answers to the load-bearing behaviour of reinforced timber constructions exposed to climate changes. The focus is on systematically defined experimental investigations on glulam beams of practical relevance with different reinforcement ratios. The research work focuses on findings on effective hygro-expansion coefficients for internal reinforced glulam members under drying and wetting climate exposure which can be used to estimate shrinkage and swelling deformations as well as additional stresses within the reinforcements.

2 STATE OF THE ART

2.1 CLIMATE IMPACT

Structural damage related to moisture was quantified by a study in which existing buildings in southern Germany were assessed. Moisture accounted for half of the observed structural damage: too wet, too dry, or varying moisture conditions [10]. The latter accounted for approximately one sixth of the damage in need of repair [11]. About 90% of the encountered damage was found in glued laminated timber. The damage not related to moisture content concerned wrong assumption of loads or errors in calculation of load-bearing capacities for instance.

Varying climatic stresses occur not only in exterior components but also in interior components in non-air-conditioned structures or through specific user profiles, [13], [14]. The analyses of monitoring data show that in heated not climatized structures (generally service class 1 according to EN 1995-1-1:2004 [15]), relative humidity in winter is lower than in summer. In buildings that are not heated but ventilated (generally service class 2 according to EN 1995-1-1:2004), the relative humidity is low in summer whereas it increases towards autumn/winter.

2.2 REINFORCEMENTS IN TIMBER STRUCTURES UNDER CLIMATE EXPOSURE

Reinforcements improve in general the load-bearing behaviour, but the full utilization level cannot be applied. The EN 1995-1-1:2004 [15] does not contain information on this reduced load carrying behaviour. Some national annexes or standards provide information for the calculation of the design value of the tensile force acting on the reinforcement, structural information is given on the distances between each other, from the edge of the notch or opening and on the insertion length for curved or pitched roof beams. Guidance on the calculation of the deformation behaviour or the consideration of additional moisture-induced stresses due to single or varying climate changes is not given in standards. It is known that the hygro-expansion coefficient is not fully effective due to viscoelastic behaviour, but only minor information is given, [16].

Research on mechanical internal reinforcements like bonded in rods, self-drilling fully threaded screws or threaded rod, was mainly done for the static short term load-bearing behaviour in constant climate, e.g. [17], [18]. There are first experiences available for reinforced beams under varying dynamic climate, [9], [6], [19], [20]. Sjödin [20] confirms an indeed reduced load-bearing capacity of steel-timber dowel joints loaded parallel to the grain under initial drying exposure. Wallner [19] only investigated processes during restricted shrinkage. There are no studies on restricted swelling, where tensile stresses in the screw can overlap with tensile stresses from external loads, and under varying climates. Likewise, the increasing influence of end-grain moisture transport was not considered. Trautz [6] measured the deformations of self-tapping screws as connectors and reinforcements on rigid frame corners in exterior climatic to evaluate the creep of the screws and the connections. The results for the specimens with a high degree of utilization also show a decrease of load-bearing capacity after an exterior exposure of 2 years.

The fact that damage can occur even in reinforced curved and pitched roof beams, support areas, notches and holes is well known, [21], [22]. Relaxations of 50% are realistic according to SIA 265/1, [16], [23] and would theoretically double the allowable moisture change. Dietsch [24] also states that a moisture reduction of 1% already cancels out the effect of the reinforcement measure. This was calculated for a curved beam and 50% relaxation.

3 MATERIAL AND METHOD

3.1 MATERIAL

Glulam produced from softwood is still one of the most important building materials in modern timber construction industry and most research focused on softwood members. Hence, GL24h from Spruce was used for the experimental test program. The glulam members were reinforced with 16 mm SFS WB-T threaded screws/rods.

Widths of glulam beams in modern timber engineering range between 160 mm and 240 mm, [13]. In discussions with practical engineers, the heights of glulam beams range from 600 mm to 2000 mm and rarely over 2000 mm. Therefore, the experimental test series comprises unreinforced and reinforced specimens with a standard beam width of 160 mm and heights of 600 mm and 1000 mm. The element lengths were either 160 mm or 320 mm, in line with work performed by Wallner [19]. The size of the elements and reinforcement ratio were chosen such that the reinforcement would have approximately the same stiffness as the glulam member, or twice the stiffness of the glulam member, cf. equation (6).

3.2 CLIMATE SCENARIOS

The ambient climate at structural members depends on the building occupation, their use, the meteorological conditions, local topography or environment, and altitude and varies throughout the year. The annual variations can easily be simplified using a sinus shape model, [14]. For further simplification, three stepwise climate changes A, B, and C were used for the experimental test programme considering sudden climate changes experienced by the wood before or after reinforcing (Figure 1). In each case the elements of the test programme were climatized in climate chambers. The start of the three step-climate changes is always related to the moisture content of 12 M% from the production phase.

- In climate scenario A, the climate change represents the reinforcement of the timber member during production directly going into service as in sports hall with a drying/desorption process.
- The climate scenario B also represents a reinforcement of the timber member during production but going into a construction period of 38 days with wetting/adsorption

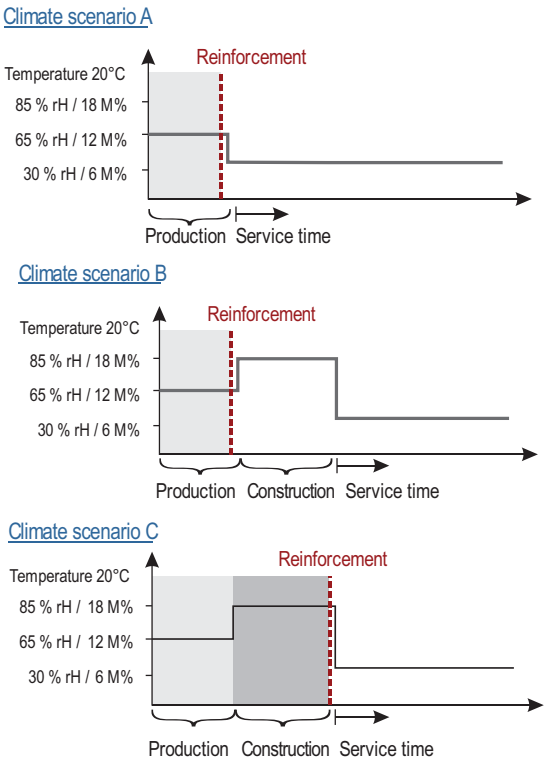

Figure 1: *Illustration of the three stepwise climate scenarios applied within the experimental test programme.*

https://doi.org/10.52202/069179-0037

process before starting service time with a drying/desorption process.

- In climate scenario C, the reinforcement is installed on-site at the end of the construction period of 38 days followed by service with a drying process. This results in a higher moisture load after reinforcing.

3.3 EXPERIMENTAL PROGRAMME AND CLIMATE CONDITIONING

The total of 28 test specimens was divided into the three defined climate scenarios A, B, C. Figure 2 shows an overview of the samples used, geometries, reinforcements, and climate loads. The end grains of most of the glulam beams were sealed to represent a continuous beam, only few end-grains were not sealed to represent reinforcements being located close to end grains, as at notches, holes or supports. The end grain sealing was done with aluminium tape.

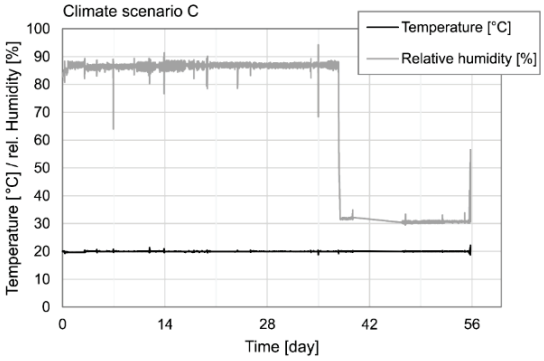

Figure 3: *Recorded climate data for climate scenario C, starting with 85% relative humidity and 20 °C to achieve a moisture content of 18 M%, followed with 30% relative humidity and 20 °C to achieve a moisture content of 6 M%*

To reach the moisture content steps of about 12, 18, and 6 M%, climates of 65, 85, and 30% relative humidity have been used respectively. The temperature was constant at 20 °C. Figure 3 shows representative the climate data for the drying process of climate scenario C. The measurement of climate was performed with calibrated Elprolog TH1 sensors and logged every 10 minutes.

4 MEASURING METHODS

4.1 MOISTURE CONTENT VARIATIONS/DISTRIBUTIONS

Moisture content variations within the glulam beams were measured using the electrical resistance method. Pairs of partially insulated GANN electrodes of 15 mm, 25 mm, and 40 mm lengths were inserted in predrilled holes at the corresponding measuring depths. The measurements of the electrical resistance were done and logged with the equipment of Scanntronik Mugrauer GmbH. Temperature sensors were installed too for temperature compensation within the conversion process from electrical resistance to the moisture content, [25]. The accuracy of this method lies between 1 M% to 2 M%, [25]. The moisture content at the surface was taken as equilibrium moisture content calculated from the surrounding climate using the Simpson equation, [26]. The measurement frequency was 1 hour.

Each measurement point was named according to the element number, the type of measurement, the location, and the length of the electrode:

- Px, specimen name/number
- HF, moisture content
- MI for middle (lengthwise) and SH for end grain
- 15, 25 or 40, measuring depth/length of electrode pair in millimetres

The name P3-HF-MI-15 represents the moisture content measurement, midsection at 15 mm depth of the test specimen P3.

Figure 2: *Overview of all experimental test series considering the climate scenarios and individual configuration*

https://doi.org/10.52202/069179-0037

4.2 DEFORMATION OF THE REINFORCEMENT

For the estimation of the deformation behaviour of the reinforcement, a measuring frame with gauge was used. The deformations of the reinforcement within a 600 mm high beam were estimated to be around 2 mm ($E_{t,90,m}$ = 300 N/mm^2 and α_{90} = 0.25%/M%) when reaching the tension strength perpendicular to the grain of $f_{t,90}$ = 0.5 N/mm^2 (EN 14080:2013). Therefore, a measuring frame/rig was constructed and equipped with a dial gauge of 10 mm measuring range and 0.01 mm measuring resolution, Figure 4. To reduce measurement uncertainties due to thermal expansion, a reference bar from the same material was measured together with the glulam beams and elongations were corrected. The errors lie within the measurement resolution of the gauge but remain small (order of 1/100th of a millimetre). Right after the start or the change of the climate, the deformations were measured more often than close to the end of the tests.

4.3 DEFORMATION OF THE GLULAM BEAM

For the deformation of the timber elements at the surface, a deformeter with measuring range of 100 mm and 200 mm was used. Before each measurement, the deformeter was calibrated using fixed reference bars.

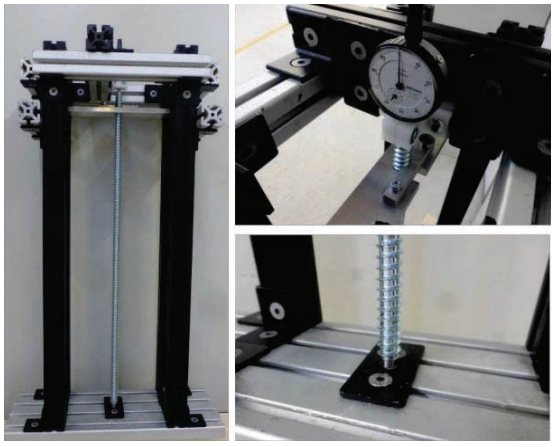

Figure 4: *Picture of the constructed frame (left) to measure 600 mm high beam with a gauge at the top (top right) and a nut (bottom right) to fit the screw into on the bottom*

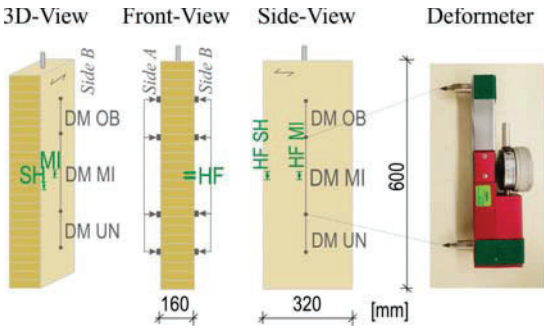

Figure 5: *Illustration of the positions and naming of the measurement of deformations on the wood surface of glulam beams as 3D-, front- and side view using the deformeter (right)*

Measurements were made on both sides of the beams and averaged, see Figure 5. Because an eccentricity in loading of 10% (width b and height h) lead to a measurement error of 60% if strains are measured on one side only. Averaging these two strains results in a representative strain.

$$\varepsilon_{\pm h/2} = \frac{F}{AE} \pm \frac{My}{IE} = \frac{F}{AE} \pm \frac{0.1hF0.5h}{IE}$$
$$\varepsilon_{\pm h/2} = \frac{F}{E}\left(\frac{1}{bh} \pm \frac{12h^2}{20h^3b}\right) = \frac{F}{Ebh}(1 \pm 0.6) \quad (1)$$

5 EXPERIMENTAL RESULTS

5.1 MOISTURE CONTENT MEASUREMENTS

The moisture content measurements are plotted in Figure 8. Since not all specimens could be equipped with moisture measurement sensors, the measured values are applied to all specimens of the same climate/group for further analyses.

The intended pre-climatization of the elements to a moisture content of 12 M% and 18 M% was not fully achieved for climate scenario A and C respectively.

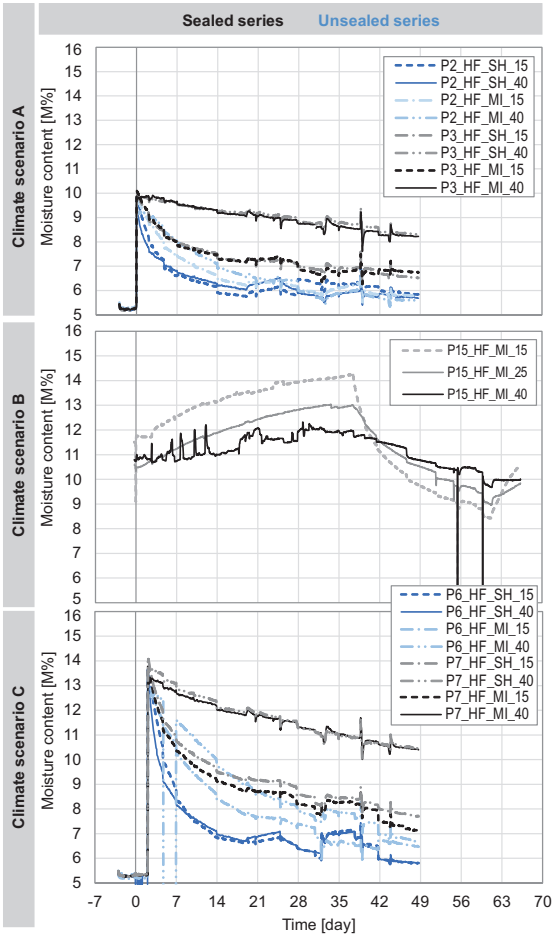

Figure 6: *Moisture content development of the three different climate scenarios, shown for the test specimen per series over the different depths observed*

https://doi.org/10.52202/069179-0037

Instead, moisture content levels of 10 M% and 14 M% were achieved because of too low relative humidity set up and conditioning time estimated. The climatization of the second series (P11 to P27) was adapted accordingly. To achieve the moisture content of 18 M%, the elements were stored in a climate chamber with a relative humidity of 85%. Instead of maintaining the temperature at 20 °C, like was done in the first series, a higher temperature of nearly 40 °C was maintained. In addition, the elements were artificially wetted by spraying water onto the end grains of the elements to accelerate the climatization. In the second series, the achieved moisture content at the start of the tests was around 13 M% and 18 M%.

The function of sealing can clearly be seen; the moisture transport in general is reduced. Once the end grain is not sealed like in P2 and P6, the moisture content on the cross section reduces more rapidly and equilibrium is reached after about 20 days. There is not only a moisture gradient along the width of the element but also along the length of the element. Whereas equilibrium is not reached for the sealed ones within 50 days (P3 and P7) and there is almost no difference between the measuring points in the centre (MI) and near the end grain surface (SH).

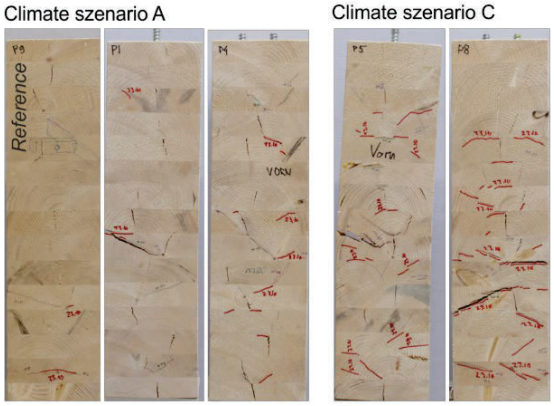

Figure 7: *Cracking pattern of the end grains for reference specimen P9 and specimens with double reinforcement stiffness P1, P4, P5, and P8 (l.t.r.)*

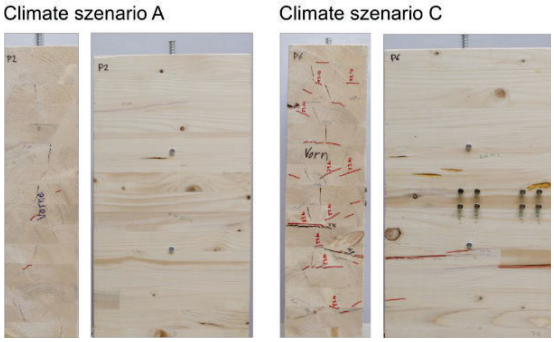

Figure 8: *Cracking pattern of the end grains for reference specimen P9 and specimens with double reinforcement stiffness P1, P4, P5, and P8 (l.t.r.)*

5.2 CRACK GROWTH BEHAVIOUR

Cracking was recorded for all specimens as e.g., shown in Figure 7 and Figure 8. For the higher moisture load of about $\Delta = 12$ M% (climate scenario C) more cracks developed at the end grain and even cracks on the side are visible. Almost no cracks are visible at the side for the lower moisture load with $\Delta = 6$ M% (climate scenario A). Specimen with single reinforcement show pronounced larger cracks on one side together with quite large bending deformations compared to the specimen with double reinforcements.

The relation between moisture content change and crack growth is illustrated in Figure 9. The cracked specimens show in average slightly smaller moisture content changes at time of failure compared to the uncracked specimens. P19 was perhaps prone to cracking, as a crack was visible already before the test starts.

5.3 DEFORMATION AND STRAIN

The measured deformations at the reinforcement and at the timber surface are shown as strains for each climate scenario and configuration in Figure 10. It can be seen that:

- Small moisture content changes (elements P1 to P4) have high deformation; medium moisture content changes (P5 to P8 and P11 to P14) lead to small deformation.
- An effect of the double reinforcement on 600 mm high elements is observed (P4/P2 ≈ 0.8 and P8/P6 ≈ 0.5)

6 EVALUATION OF THE EFFECTIVE HYGRO-EXPANSION COEFFICIENT

Based on the measured change of moisture content, the dependency of the strain of the reinforcement on moisture content change can be calculated too. This is like a hygro-expansion coefficient with the unit as %/M%. The effective hygro-expansion coefficient is calculated by Equation (5). This is based on a model for composite structures consisting of two different materials 1 and 2 with assuming equal strain in the materials, as shown in Figure 11 and expressed by following equations (2) to (6):

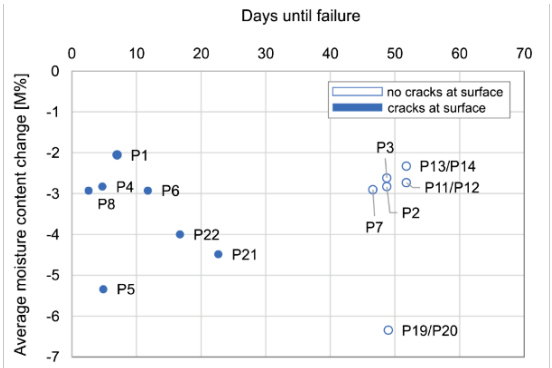

Figure 9: *Relation between days until failure and changed moisture content at time of failure*

https://doi.org/10.52202/069179-0037

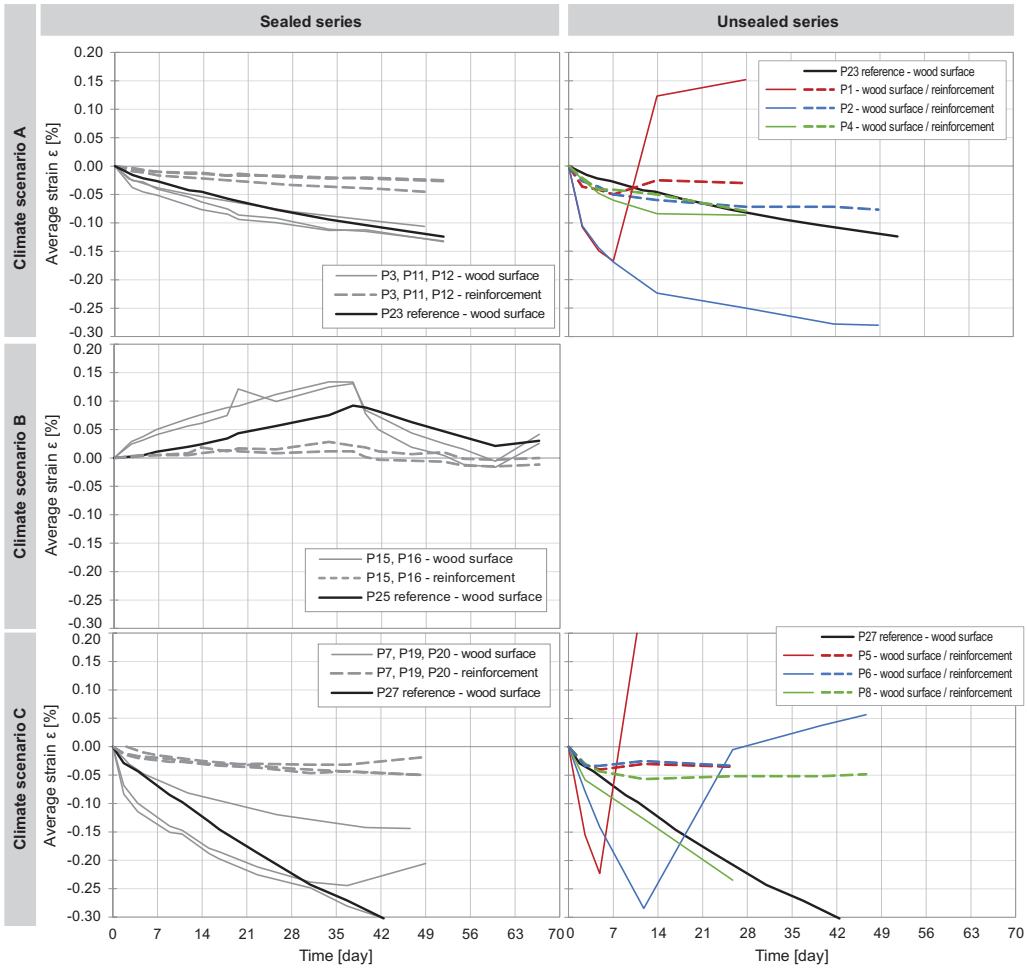

Figure 10: *Strain development in the reinforcement and on the surface separated for the sealed and unsealed specimens*

$$\Delta\varepsilon = \Delta\sigma / E + \alpha\Delta u \tag{2}$$

$$\Delta\varepsilon_0 = \left(F_e + \alpha_1 \Delta u_1 A_1 E_1\right) / \left(A_1 E_1 + A_2 E_2\right) \tag{3}$$

$$\begin{aligned} \Delta\sigma_1 &= \left(\left(F_e + \alpha_1 \Delta u_1 A_1 E_1\right) / \left(A_1 E_1 + A_2 E_2\right) - \alpha_1 \Delta u_1\right) E_1 \\ \Delta\sigma_2 &= \left(F_e + \alpha_1 \Delta u_1 A_1 E_1\right) / \left(A_1 E_1 + A_2 E_2\right) E_2 \end{aligned} \tag{4}$$

$$\begin{aligned} \Delta\sigma_1 &= \alpha_1 \Delta u_1 \left(\gamma - 1\right) E_1 \\ \Delta\sigma_2 &= \alpha_1 \Delta u_1 \gamma E_2 \end{aligned} \tag{5}$$

with γ as the ratio of stiffness between the timber cross section and the total cross-section, a value between 0 and 1:

$$\gamma = \frac{A_1 E_1}{A_1 E_1 + A_2 E_2} \tag{6}$$

The stress in the reinforcement is calculated from the strain corrected with the S-factor of 1.42 for 600 mm high beams considering the non-uniform strain distribution over the depth of the beam, cp. Figure 11. Furthermore, a correction on height of the specimen is also done to obtain the stresses in an infinitely high specimen. Therefore, investigation with different depths can directly be compared. The stresses in the reinforcement from the 600 mm high specimens are therefore corrected by a coefficient of 0.68. All strains and wood moisture content are taken from the last measurement before fracture was observed or at the end of the climatization.

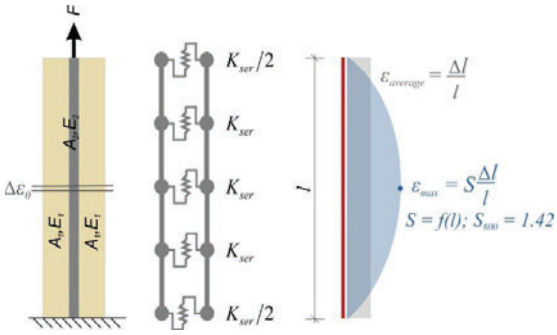

Figure 11: *A composite structure consisting of two different materials 1 and 2*

https://doi.org/10.52202/069179-0037

Figure 12 shows the calculated values as a function of time for the test specimens of climate scenario A. The hygro-expansion coefficient ends up between 0.05 and 0.10%/M% for this specimen series. Only specimen P1 shows much higher values just at the beginning of the climate change. This was also the time when fracture occurred.

The calculated effective hygro-expansion coefficients before failure are plotted in relation of the final moisture content changes the elements experienced just before the failure, see Figure 13. The value from specimen P1 can be excluded due to the early failure and the unsafe value. In average, an effective hygro-expansion coefficient of 0.055%/M% are calculated. No difference in the hygro-expansion coefficient between elements with or without end grain sealing or drying and wetting processes are observed. Generally, the expansion of the reinforcement is therefore about 1/5th of the hygro-expansion coefficient of wood perpendicular to the grain (0.24 %/M%, SIA 265).

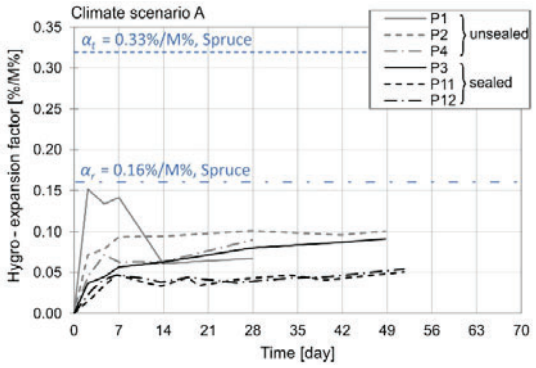

Figure 12: *Calculated hygro-expansion coefficients development for climate scenario A over time*

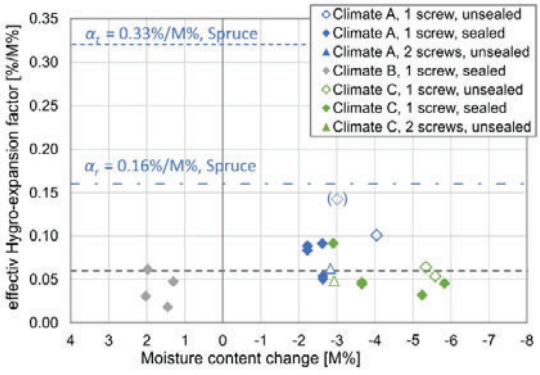

Figure 13: *Derivation of the effective hygro-expansion coefficient of the glulam cross-section according to the composite structure theory*

7 CONCLUSIONS

The calculated effective hygro-expansion coefficients for all specimens and climate scenarios presented show a quite constant reduced coefficient compared to the hygro-expansion coefficients for free swelling and shrinkage or even the half value for restricted shrinkage as specified in [16].

Using a simplified model, effective hygro-expansion coefficients could be calculated. In these calculations, theoretical design values for E-moduli (300 N/mm ^{2}) had to be used. An important conclusion is that whereas theoretical hygro-expansion values of wood perpendicular to the grain lie around 0.24%/M% (SIA 265, 2012), these might lie close to a fifth of this value in reality. This explains why larger moisture content values are possible without cracking and reflect reality more. To what extend this value is valid for other cross section ratios need to be proved.

Using a value of 0.055%/M% in combination with a correction for a height effect, allows estimation of realistic moisture induced strain changes of reinforced glulam cross-sections. The 0.055%/M% does not reflect the real hygro-expansion coefficient but is expected to be more of an 'effective' value that includes effects of mechano-sorptive relaxation and time-dependent creep too under the presence of reinforcements. To calculate the possible generated additional stress in a cross section due to moisture content changes, Equations (5) can be used where a hygro-expansion coefficient of 0.05%/M% is recommended.

ACKNOWLEDGEMENT

COMPONENT METHOD IN TIMBER CONNECTIONS: END-PLATE COMPRESSING TIMBER PARALLEL TO GRAIN COMPONENT STRENGTH

Arthur S. Rebouças[1], Jorge M. Branco[2], Paulo B. Lourenço[3], Hidelbrando J. F. Diógenes[4]

ABSTRACT: The component method considers the whole joint as a set of individual basic components, dividing them into zones of tension, compression, and shear. The strength of end-plate and timber parallel to grain in compression may influence total resistance and failure mode of the joint. The objective of this work is to characterize the strength of the component corresponding to a glulam beam under compression by an end-plate in bending within an application in moment-resisting timber connections. For this, an experimental campaign was conducted through compression tests on 25 specimens composed of steel T-stubs with five different flange thicknesses and glulam GL24h. The results were compared to reference compression tests using a rigid plate. A decrease in the component resistance was observed with the reduction in the flange thickness. The failure of the component was governed by the T-stub, due to flange yielding, while the timber did not show characteristic failure. Based on the Eurocode 3 equivalent plate concept, an approach with variable stress distribution was proposed, it proved to be coherent with the experimental behavior of the component and with a possible application in design since the analytical values maintain an acceptable safety margin in relation to the experimental ones.

KEYWORDS: Timber connections, Component method, Glulam beam in compression, End-plate in bending.

1 COMPONENT METHOD

One of the current design practices to predict the rotational behavior of steel joints adopted by EN 1993-1-8 [1] is based on the component method, an analytical method that considers the whole joint as a set of individual basic components, dividing them into zones of tension, compression and shear. It allows to obtain the design moment resistance, rotation capacity, initial and post-peak stiffness and built a moment-rotation curve using these data [2]. The application of component method provides a tri-linear moment-rotation curve to characterize a connection and requires the following steps:

I. Identification of the active/relevant components in the joint being considered;
II. Evaluation of the stiffness and/or resistance characteristics for each individual basic component (specific characteristics – initial stiffness, design resistance, … – or whole deformability curve);
III. Assembly of all the constituent components and evaluation of the stiffness and/or resistance characteristics of the whole joint (specific characteristics – initial stiffness, design resistance, … – or whole deformability curve).

The relevant components are the ones that transfer significant internal forces based on the joint behavior. Each of these basic components possesses its own strength and stiffness either in tension, compression or shear. The coexistence of several components within the same joint element can obviously lead to stress interactions that are likely to decrease the resistance of the individual basic components.

A large amount of research in the field of steel structures was conducted applying the component method to mechanical analysis of steel joints, since Zoetemeijer [3] and Jaspart [4] until more recent studies for cyclic loading [5] and other geometries [6]. From the recognition of the reliability and relevance of the component method to characterize steel joints, some research was conducted in several types of timber connections: historical [7], slotted-in steel plates [8], glued-in rods [9,10] and glued-in steel plates [11]. On the other hand, despite a considerable part of the timber joints using steel components, the effectiveness of the component method in the analysis of timber joints has not been fully assessed.

Therefore, the objective of this work is to characterize the strength of the component corresponding to a glulam beam under compression by an end-plate in bending within an application in moment-resisting timber connections.

2 GLULAM BEAM IN COMPRESSION AND END-PLATE IN BENDING

Tomasi et al. [12] and Andreolli et al. [9] modelled the glulam beam and the end-plate/steel profile flange in compression as equivalent T-stub in compression. In the connection studied by them (Figure 1), there is a direct contact between the end-plate and the glulam along the total joint depth. In this approach, the effective area of compression plays an important role, as it is directly related to the compressive resistance and stiffness of the component. In these studies, the compressive area was proposed according to EN 1993-1-8 [1], considering that the compression stress is uniformly distributed over a rectangular area measuring by an effective length ($l_{eff,c}$) and width ($b_{eff,c}$), as shown in Figure 2. These dimensions can be taken by the additional bearing width (c_t), which was also calculated based on the EN 1993-1-[1] with some adaptations (Equation 1). The glulam beam compression strength was determined by Equation 2.

$$c_t = t_{ep}\sqrt{\frac{f_y}{3 \cdot f_{c,0} \cdot \gamma_{M0}}} \quad (1)$$

$$F_{R,gb,c} = f_{c,0,d} \cdot b_{eff,c} \cdot l_{eff,c} \quad (2)$$

Where, t_{ep} [mm] is the thickness of end-plate, f_y [N/mm²] is the yield strength of steel, $f_{c,0}$ [N/mm²] is the compression strength parallel to grain of the glulam beam, and γ_{M0} [unitless] is the coefficient equal to 1.

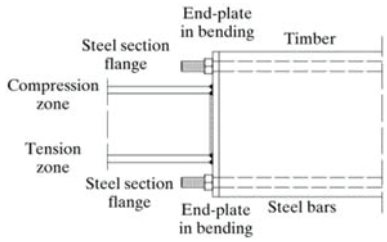

Figure 1. *Connection studied by Tomasi et al. [12] and Andreolli et al. [9].*

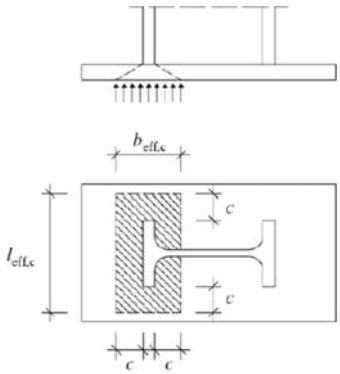

Figure 2. *Compressive area defined in Tomasi et al. [12] and Andreolli et al. [9].*

Yang et al. [10] and Tao et al. [11] applied the procedure proposed by [9] to calculate the resistance of glulam beam in compression parallel to the grain. In these studies, the timber beam is under compression by a steel plate which structural behavior can be modelled as an equivalent T-stub. In the connection studied by Yang et al. [10] (Figure 3), there is a contact area between the steel box and timber beam, where both are under compression. As the steel box width is equal to the glulam beam width, the effective compression area of glulam beam was defined as shown in Figure 4. The effective width was defined as equal to the glulam width (b_b) and the effective bearing length was taken as $0.5 \cdot h_{srt}$. However, no additional explanation was given on how to obtain these values. The glulam beam compression resistance was determined by Equation 3.

$$F_{R,gb,c} = f_{c,0} \cdot b_b \cdot 0.5 \cdot h_{srt} \quad (3)$$

Where b_b [mm] is the width of glulam beam and h_{srt} [mm] is the cross-sectional depth of the steel box.

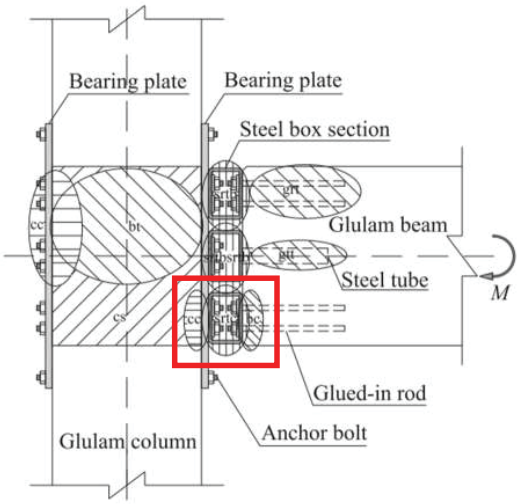

Figure 3. *Compression sub-region in the bottom of connection Adapted from [10].*

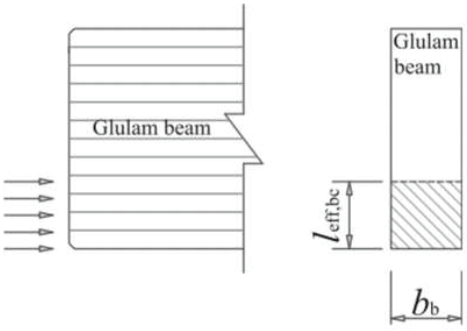

Figure 4. *Effective compression area of glulam beam. Adapted from [10].*

Nevertheless, the c_t and $F_{R,gb,c}$ mentioned above were determined from an adaptation of [1] for the component called "base plate and concrete block in compression". According to Steenhius et al. [13] this component is a base

https://doi.org/10.52202/069179-0038

plate, assumed to be flexible in bending and modelled as a T-stub in compression, supported by a concrete block in compression, with stresses concentrated around the footprint of the column section under the plate. Stockwell [14], Murray [15] and Steenhuis and Bijlaard [16] introduced the concept of replacing a flexible plate with a non-uniform stress distribution by an equivalent rigid plate with a uniform stress distribution, later added to Eurocode 3 (Figure 5).

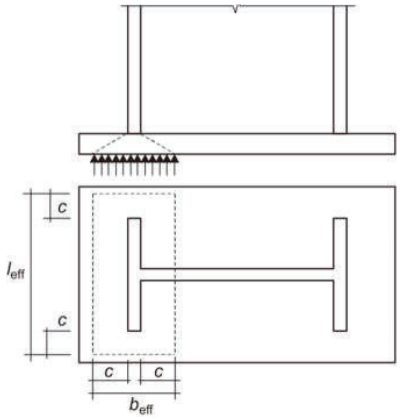

Figure 5. *Effective area of T-stub in compression [1]*

The resistance of the component is determined by two parameters: the bearing strength of the concrete and the dimensions of the equivalent rigid plate. The design compression resistance of the component $F_{C,Rd}$ and the maximum additional bearing width c is defined in the EN 1993-1-8 [1], section 6.2.5, as shown in Equations 4 and 5, respectively.

$$F_{C,Rd} = f_{jd} \cdot b_{eff} \cdot l_{eff} \quad (4)$$

$$c = t\sqrt{\frac{f_y}{3 \cdot f_{jd} \cdot \gamma_{M0}}} \quad (5)$$

Where b_{eff} [mm] is the effective width of the T-stub flange; l_{eff} [mm] is the effective length of the T-stub flange; t [mm] is the thickness of the T-stub flange; f_y [N/mm²] is the yield strength of the T-stub flange and f_{jd} [N/mm²] is the design bearing strength of the joint. It should be determined from Equation 6.

$$f_{jd} = \frac{\beta_j \cdot F_{Rdu}}{b_{eff} \cdot l_{eff}} \quad (6)$$

Where β_j [unitless] is the foundation joint material coefficient, which may be taken as 2/3 provided that the characteristic strength of the grout is not less than 0.2 times the characteristic strength of the concrete foundation and the thickness of the grout is not greater than 0.2 times the smallest width of the steel base plate. In cases where the thickness of the grout is more than 50 mm, the characteristic strength of the grout should be at least the same as that of the concrete foundation; F_{Rdu} [N/mm²] is the concentrated design resistance force given in EN 1992-1-1 (2014), here in Equation 7.

$$F_{Rdu} = A_{c0} \cdot f_{cd} \quad (7)$$

Where A_{c0} [mm²] is the loaded area, here equal to $b_{eff} \cdot l_{eff}$.

Therefore, it is possible to identify, by comparing the Equations 4, 5 and 7 with 1, 2 and 3 ones, that the formulation used by [9] and [12] is very close to the one used to concrete block in compression. For the resistance and the additional bearing width, it differs only by the strength of the material used.

It is believed that this approach needs some adaptations, since the deformation of a glulam beam under compression by a steel plate (equivalent T-stub) can be much pronounced than that seen in a concrete block. It also directly influences the computation of effective area in the equivalent rigid plate.

3 EXPERIMENTAL CAMPAIGN

An experimental campaign was conducted through compression tests on 25 specimens composed of steel T-stubs, with five different flange thicknesses (6, 8, 10, 15 and 20mm), connected to glued laminated timber specimens. The results were compared to reference compression tests using a rigid plate with thickness equal to 40mm, these specimens are regular plates, not T-stubs. Five tests were made for each group.

3.1 SPECIMENS

As timber elements, glulam made of spruce (*Picea abies*) from strength class GL24h, according to EN 14080:2013 [17], were used. As steel elements, T-stub specimens of steel S235, with yield strength equal to 235N/mm² and ultimate tensile strength of 360N/mm², according to the EN 1993-1-1:2010 [18] were applied. The timber specimens had the same dimensions for all test series, 120×240×240mm³. T-stubs geometry are similar (Figure 6), only the thickness varies, as presented in Table 1. The name of each series was defined as "T' plus its corresponding thickness and the reference one was called "REF". The front face of each specimen was painted to be adequate to DIC measurements, the detailed information about the whole configuration is presented in Figure 7. A summary of T-stub and timber specimens tested can be found in Table 1.

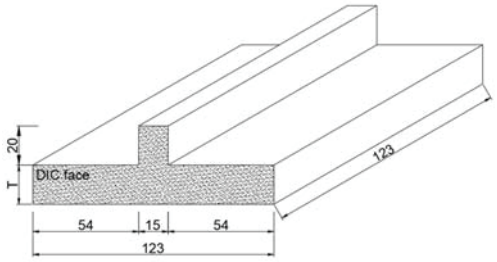

Figure 6. *T-stub specimens dimensions (mm)*

https://doi.org/10.52202/069179-0038

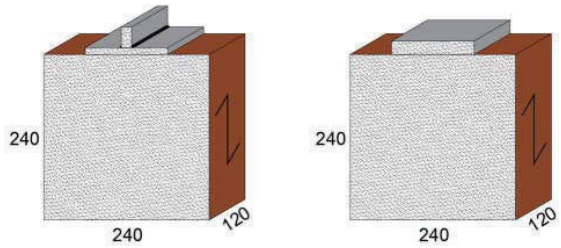

Figure 7. *Detailed geometry of the specimens, including T-stub and glulam, the DIC painted front face and positions of (a) T-stub specimens and (b) Reference specimens. Dimensions in mm.*

Table 1: *Summary of the steel and timber specimens tested, including the reference group (each series comprehends 5 specimens).*

Series	Steel specimens		Timber specimens	
	T-stub flange thickness [mm]	Plate thickness [mm]	Geometry [mm]	
			Cross section	Height
REF	-	40	120×240	240
T20	20	-	120×240	240
T15	15	-	120×240	240
T10	10	-	120×240	240
T8	8	-	120×240	240
T6	6	-	120×240	240

3.2 TEST METHOD

The compression tests of the specimens were carried out on a hydraulic jack with a load cell of 1500 kN under displacement control at a rate of 3 mm/min. The load was applied along the center part of T-stub. The tests were finished when the force reached 80% of the maximum force or when the central displacement reached 2,5% of the specimen total height. The vertical displacements were monitorized by three LVDTs positioned according to the Figure 8, as follows: the central one measured the total displacement of glulam specimen; the left and right ones measured the displacement from each T-stub edge to the glulam specimen. The 3D displacements, deformations, and local strains on the surface between the two materials were determined by the Digital Image Correlation (DIC). In the scope of this work, INSTRA 4D V4.4.7 x64 software was used along with two cameras (Master and Slave) of 2.0 megapixels positioned 100 cm between each other. The acquisition frequency to obtain the frames was 1 Hz.

Figure 7. *Positions of displacement transducers. The right and left ones were named based on the front face of the specimen (painted face).*

3.3 RESULTS

The average maximum experimental stress of the "REF" series was 33.35 MPa, 38.95% higher than the 24 MPa guaranteed by the manufacturer. For the other series, measuring the experimental stress applied by the T-stub flange on timber is complex, due to the lifting of the T-stub flange edges, there is a gradual reduction in the contact area between the two materials. Therefore, the resistance of the component can be better characterized in terms of force.

The Figure 9 shows the force-displacement curves, measured from the center transducer data for tests with average response in each thickness range. In the results of the series "REF" the force decreased gradually after maximum point, whereas for all other series, the force stayed on a plateau with a large increase in displacement. In general, a decrease in the maximum force was observed with the reduction in the thickness of the flange.

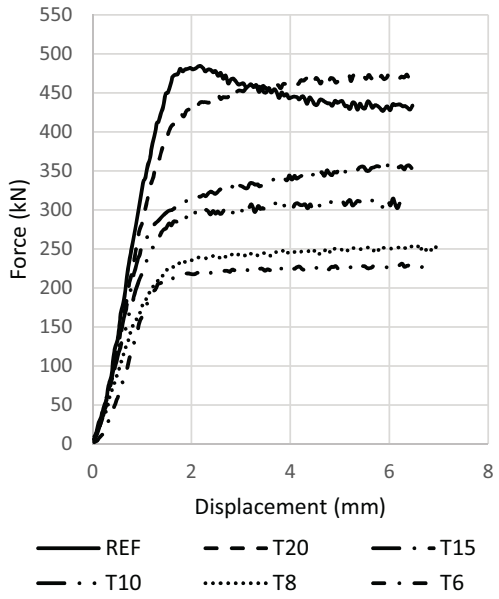

Figure 9: *Force-displacements curves for all different T-stub flange thicknesses.*

https://doi.org/10.52202/069179-0038

In all series, there was a greater displacement of the center of the T-stub flange in relation to the ends, from the beginning of the test. For example, this bending can be seen in the Figure 10, that shows the deformed shape of the T15 specimen when the maximum force was achieved.

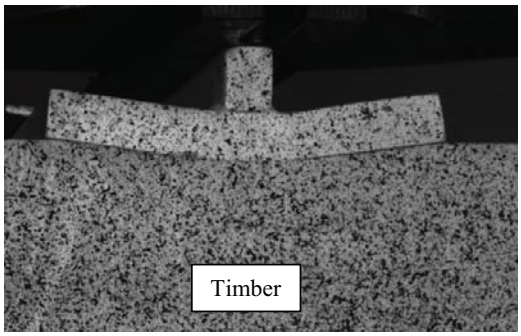

Figure 10: *Deformed shape of specimen T15-E4 at maximum force.*

The smaller the thickness of the flange, the greater was this difference in displacement between center and edges. For thicknesses of 10, 8 and 6 mm, a negative displacement was observed (the position of the end of the plate was smaller than its position at the beginning of the test), an example is shown in Figure 11.

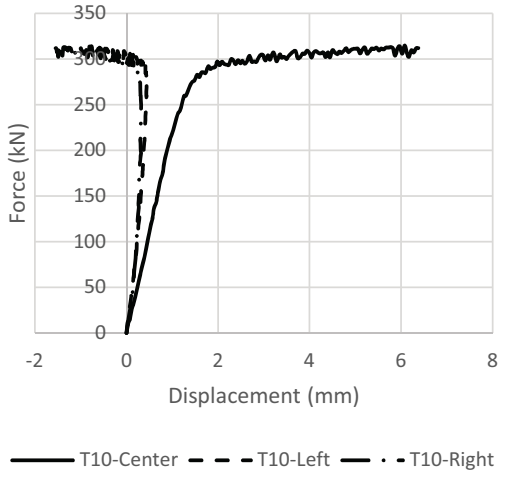

Figure 11: *Force-displacements curve for T10-E4.*

In all tests, the failure of the component was governed by the T-stub, due to the excessive displacement of its edges, without rupture (T-stub flange yielding), while the timber did not show characteristic failure (Figure 12). Except for "REF" series, which the timber presented local failure due to compression under the loading plate (Figure 13).

Figure 12: *Failure of specimen T6-E3 due to T-stub flange yielding.*

Thus, the component experimental behavior is based on identifying whether the stress applied by the T-stub to the timber is sufficient to reach the compressive strength parallel to the grain before reaching the plastic resistant moment of its flange. In all cases studied, although the elastic limit of timber has been clearly reached (see Figures 9 and 11), the compressive strength of the timber was not achieved, therefore, all T-stub flanges can be considered flexible.

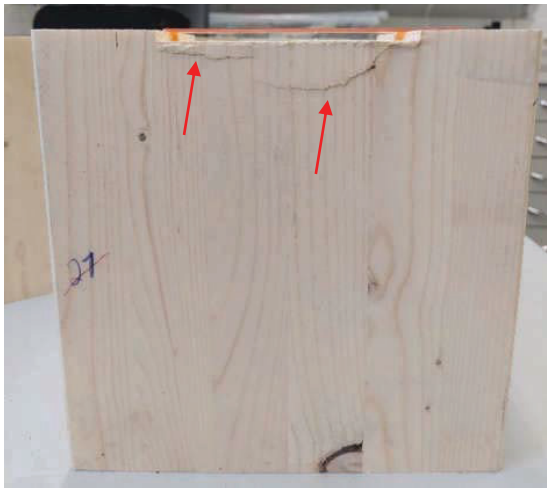

Figure 13: *Deformed shape of specimen T15-E4 at maximum force.*

The component strength based on the formulation proposed by Andreolli et al. [9] was assessed, considering the elastic moment resistance of the T-stub flange and the average maximum experimental stress of the "REF" series (33.35 MPa), as timber strength. It was identified,

from the DIC measurements, that the T-stub flanges are still below the steel yield strain limit for all tested series. The displacements in timber and steel when the force applied was equal to the component strength found by [9] proposition are shown in Figure 14. The strain values were obtained from the vertical displacement and the applied force.

4 COMPONENT RESISTANCE PROPOSALS

4.1 PLASTIC RESISTANCE OF STEEL

The plastic bending moment resistance of the base plate per unit length should be taken as presented in Equation 8.

$$M_{pl} = \frac{1}{4} t_{ep} \cdot f_y \qquad (8)$$

Each side of T-stub was modeled as a cantilever beam and a uniform stress distribution in the contact between the plate and the timber was considered (Figure 15). According to the equivalent plate theory, equaling the plastic bending moment resistance of the base plate to a bending moment on the plate, Equation 9 is obtained to determine the equivalent bearing width. The resistance of the component can be obtained from the equivalent area, but in this case using the plastic additional bearing width (c_{tp}).

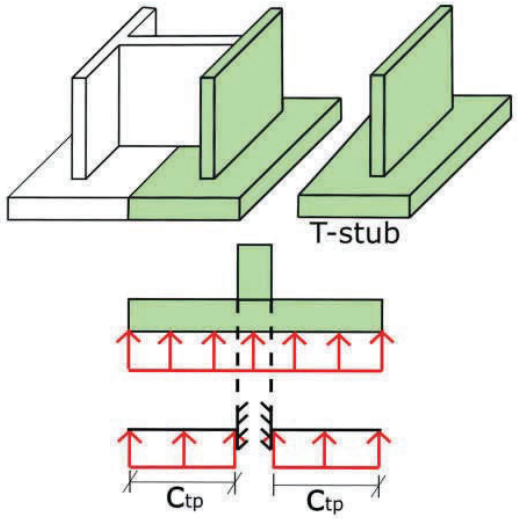

Figure 15. *Structural idealization of the component corresponding to the steel T-stub applying compression parallel to grain in timber member.*

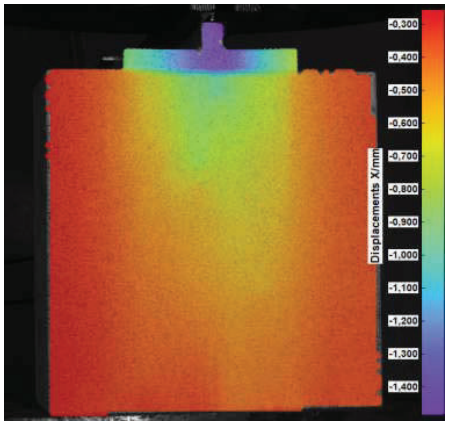
$$c_{tp} = t_{ep} \sqrt{\frac{f_y}{2 \cdot f_{c,0} \cdot \gamma_{M0}}} \qquad (9)$$

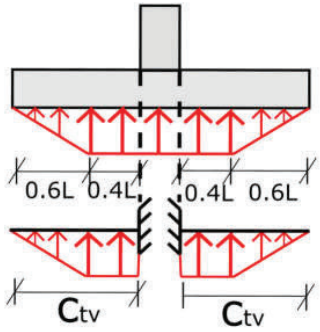
4.2 VARIABLE STRESS DISTRIBUTION

From the DIC measurements, it was observed that, as expected, there is a non-uniform distribution of displacements in the contact between the steel plate and the timber. As shown in Figure 16(a), the displacements around the central part of the T-stub are greater, reducing towards the edges. This was repeated in all test types and for all plate thicknesses, since the beginning of the compression application. Based on those observations, a new approach is proposed for determining the equivalent bearing width, considering a variable distribution of stresses in contact between both materials, as shown in Figure 16(b).

https://doi.org/10.52202/069179-0038



(a)



(b)

Figure 16. *(a) General displacements distribution from DIC tests. (b) Structural idealization for T-stub and timber in compression component with variable stress distribution.*

Considering this new stress distribution, the maximum moment acting on the T-stub becomes equal to $0.26 \cdot q \cdot L^2$ and, assuming the plate in elastic range, the Equation 10 can be formulated to calculate the c_{tv}. The component strength can be obtained from the equivalent area using variable distribution additional bearing width (c_{tv}).

$$c_{tv} = t_{ep}\sqrt{\frac{f_y}{1.56 \cdot f_{c,0} \cdot \gamma_{M0}}} \qquad (10)$$

5 RESULTS AND DISCUSSION

For simplicity in discussion of the results, the following nomenclatures were given for the propositions: Andreolli's one was called uniform distribution in elastic range (UD-ER), the plastic bending preposition was uniform distribution in plastic range (UD-PR) and the variable stress distribution was VD-ER. The analytical values of the component strength were calculated computing the $f_{c,0}$ equal to 24 MPa.

In Figure 17, it is possible to observe the curves of the relative displacements between the center and the edges of the T-stub flanges of two tests and in Table 2 the average strains for all the tests carried out. It appears that even considering the plastic limit of steel (UD-PR) or the variable stress distribution (VD-ER), the T-stub seems to be in a safe region from the design point of view, since the highest analytically determined strength is approximately 70% for specimen T20 and 55% for specimen T6 in relation to the experimental component strength.

As it is the T-stub that governs the structural behavior of the component, the strength reserve and ductility of steel can be exploited.

Figure 17: *Force-relative displacements curves for (a) T20 GT2 (b) T6 GT2.*

Table 2: *Summary of the steel and timber specimens tested, including the reference group.*

		UD-ER	UD-PR	VD-ER
T20	Force (kN)	251,32	298,10	331,81
	Relative Displac. (mm)	0,36	0,45	0,53
	Strain	0,0025%	0,0039%	0,0053%
T15	Force (kN)	199,29	234,37	259,66
	Relative Displac. (mm)	0,38	0,50	0,62
	Strain	0,0027%	0,0046%	0,0072%
T10	Force (kN)	147,26	170,65	187,51
	Relative Displac. (mm)	0,47	0,55	0,62
	Strain	0,0042%	0,0056%	0,0073%
T8	Force (kN)	126,45	145,16	158,65
	Relative Displac. (mm)	0,62	0,75	0,87
	Strain	0,0073%	0,0107%	0,0144%
T6	Force (kN)	105,60	119,67	129,78
	Relative Displac. (mm)	0,60	0,67	0,75
	Strain	0,0074%	0,0088%	0,0111%

The Figure 18 shows the maximum experimental component resistances and the theoretical values obtained by the three presented approaches: UD-ER, UD-PR and VD-ER. The proposals are coherent compared to the experimental tests. The bearing capacity of test specimens at T-stub failure is in the range from 1.36 (T20) to 1.88 (T6) times the capacity calculated according to variable distribution proposal, considering the average of experimental component strength. An improvement in the accuracy of the results was identified, since for UD-ER approach, the values were 1.80 (T20) and 2.31 (T6). In addition, the use of a variable distribution in elastic range (VD-ER), with greater displacements in the central region of the T-stub, is more consistent with the experimental behavior of the component.

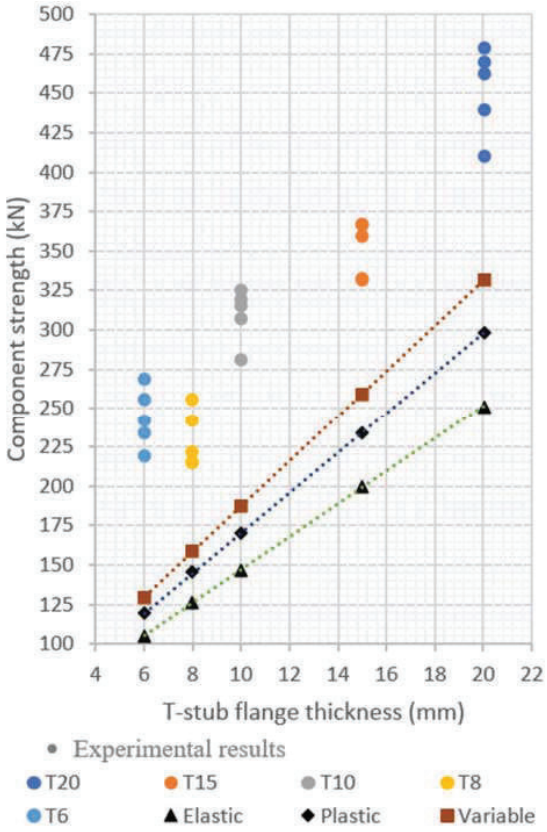

Figure 18: *Maximum component experimental resistances and theoretical values for the three different proposals.*

6 CONCLUSIONS

The structural behavior of the end-plate compressing timber parallel to grain component is governed by the yielding of the T-stub flange, for thicknesses usually used in design. In all compression tests, the timber did not show a clear and well-characterized failure, as occurred in the reference tests with a rigid plate.

As the stresses transmission is carried out by the contact between the two materials and according to the T-stub stiffness, the component strength is proportional to the thickness of the plate, that is, the greater the thickness of the plate, the greater the component strength.

From the beginning of each test, there is a difference in displacements between the central part and the edges of the T-stub flange, which indicates the occurrence of a non-uniform stress distribution between the T-stub flange and the timber. To analytically evaluate and predict the component strength, the concept of equivalent rigid plate was used, but in three different approaches.

The proposition of the equivalent plate with variable stress distribution proved to be coherent with the experimental behavior of the component and with a possible application in design, since the analytical values maintain an acceptable safety margin in relation to the experimental ones.

COMPARISON BETWEEN EXPERIMENTAL RESULTS AND DESIGN EQUATIONS OF ARTIFICIALLY DEGRADED SINGLE STEP JOINTS

Daniel F. Lima[1], Jorge M. Branco[2], Lina Nunes[3]

ABSTRACT: In the case of interventions in existing buildings, the assessment of timber elements and joints, such as the Single Step Joint, is a challenge for engineers, especially when timber presents signs of biological degradation. In this context, many roof structures are subject to unnecessary substitutions due to the lack of knowledge about the behaviour of these types of joints, and specially the consequences of eventual biological attacks. This study aims to evaluate the residual shear strength of Single Step Joints artificially degraded by wood boring insects from the Anobiidae family (e.g. *Anobium punctatum)*. To achieve the established objectives, destructive tests were carried out on undamaged (reference level) and artificially degraded Single Step Joint specimens, varying the level of degradation. The results were analysed in terms of degradation level and compared with the results obtained with design equations for this type of joint found in the literature. From the analysis of the results, it was possible to observe the tendency of reduction of the shear strength with the increase of the degradation level.

1 INTRODUCTION

Applying wood as a building material requires special attention, especially when it is used for structural functions. Despite its high complexity, when applied correctly with adequate protection and maintenance, wood is one of the most efficient building materials.

Like other natural organic materials, wood is subject to biological degradation, where the main agents are fungi and insects. Despite its recognized tradition and presence in the built heritage, knowledge about the biological degradation process of wooden structures, as well as its impacts on the service life of buildings, remains, to a certain extent, unknown.

Concerning degradation caused by insects, in countries with temperate climates, subterranean termites and woodboring beetles stand out, due to their ability to cause severe damage to structural elements with a consequent reduction in the service life of the structure [1]. On the other hand, anobiids (like the common furniture beetle or woodworm) represent a considerable challenge since the quantification of their impact on the mechanical strength of structural elements still raises many questions.

Typically, woodboring insects' infestation is assessed by the visual inspection of the element. In this case, the intensity of infestation is quantified by the density of apparent exit holes on the element surface. However, the diffuse attack of this insect makes the assessment of damage intensity more difficult [2]. In fact, despite being the most recurrent, this evaluation method presents too many uncertainties, since the number of internal galleries drilled by the insects is greater than the surface exit holes, which can lead to an underestimation of the level of degradation [3,4].

Regarding the reduction of the mechanical capacity caused by the anobiid infestation, in general, it is considered in the structural verification of old structural elements either by the reduction of the cross-section of the element (considering that the degraded zone does not present any strength) or assuming reduced mechanical properties for that element [5,6]. However, there is a clear lack of studies that can serve as a basis for engineers to adopt the appropriate reduction factors.

The lack of knowledge, combined with the difficulty in assessing the extent and severity of damage, is responsible for many unnecessary replacements of structures that could be subjected to curative treatments and/or reinforcements. In this context, timber roofs represent a great challenge, being common to find elements and joints degraded by insects and fungi due to their constant contact with the supporting masonry [7].

The present paper aims to discuss the impact of anobiids on the shear strength of Single Step Joints. Previously, Single Step Joint design equations were studied by [8] and will be used as reference to identify the need of introducing a safety factor for woodworm degraded elements.

2 Traditional Carpentry Joints

Carpentry connections are usually composed of notched joints and are traditionally used to connect the rafter and

[3] Lina Nunes, National Laboratory for Civil Engineering (LNEC), Portugal, linanunes@lnec.pt

https://doi.org/10.52202/069179-0039

the tie beam in timber trusses, where the stresses are transferred between the elements by axial compression and/or friction [9,10]. Over time, geometric variants of this type of connection have been developed, standing out the Single Step Joint and the Double Step Joint, being the former the most common due to their simplicity and easier manufacturing process.

Among Single Step Joints, exist three main families: the Geometrical Configuration Ideal Design (GCID), the Geometrical Configuration Perpendicular to the Rafter (GCPR), and the Geometrical Configuration Perpendicular to the Tie Beam (GCPTB) [11]. The difference between the three families relies on the inclination of the front notch (α) in relation to the rafter skew angle (β), where the GCID has α equivalent to β/2, the GCPR has α equivalent to β and the GCPTB has α=0º (figure 2.1).

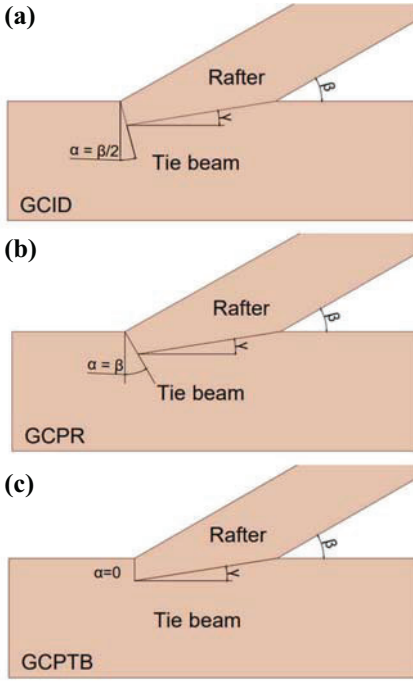

Figure 2.1: *Main SSJ geometrical variations. (a) Geometrical Configuration Ideal Design (GCID); (b) Geometrical Configuration Perpendicular to the Rafter (GCPR); (c) Geometrical Configuration Perpendicular to the Tie Beam (GCPTB)*

With the development of new precise technologies (for example CNC) and because it is considered the most efficient, the GCID is the recommended. However, due to the lack of accurate carpenter tools in the past, the other two configurations are commonly found in older constructions with low quality (in terms of carpenters' skills) [8].

Two possible failure modes are considered for the SSJ: shear parallel to the fibres at heel depth and crushing parallel to the fibres at the front notch [7]. However, Verbist et al. [8] questioned the consideration of crushing at the front notch as a failure mode for the SSJ, since the crushing will only cause the densification of the wood fibres and consequent deformations at the joint, being shear the final failure mode.

In recent decades, several studies have addressed the mechanical behaviour of Single Step Joint, for example, Verbist et al. [8], Branco et al. [7], Munafò et al. [12], Palma et al. [13], among others. Despite being traditional and commonly found in constructions, both in new and older constructions, the SSJ continue to present knowledge gaps to be explored.

3 Materials and methods

3.1 SSJ specimens

The Single Step Joints specimens with structural dimensions used on this study were made of scots pine (*Pinus sylvestris* L.), acquired in Northern Spain, followed the Geometrical Configuration Perpendicular to the Tie Beam (GCPTB), consequently, the front notch perpendicular to the tie beam grain (α=0°). Additionally, a skew angle between the tie beam and the rafter of 30° ($\beta = 30°$), a heel depth of 30mm ($h_V = 30mm$), a width of 100mm ($b = 100mm$), and a heel length of 100mm ($l_V = 100mm$) were adopted (figure 3.1). The geometry of the specimens was defined based on the results obtained by [8], with the aim to induce failure by shear at the heel depth.

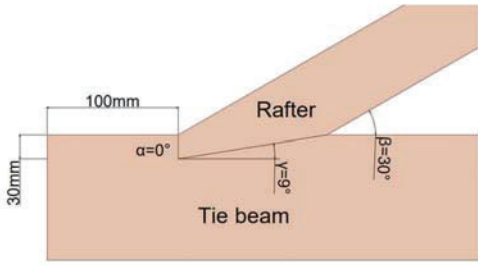

Figure 3.1: *Geometry adopted for the SSJ specimen*

Before carrying out the procedures of the experimental campaign, the specimens were stored in a climatic chamber at a constant temperature of 20 ± 1°C and a relative humidity of 60 ± 5% until mass stabilization (i.e., difference ≤ 0.1% between consecutive measurements, EN 13183 [14]]). Under these climatic conditions, the equilibrium moisture content of the wood should be approximately 12% [15]. Additionally, density ($\rho_{12\%}$) was determined following the procedures of NP 616 [16].

3.2 Visual grading

To ensure a control quality of the wood and to confirm the strength class in accordance with EN 338 [17], a visual grading of the specimens was carried out, based on a photographic survey followed by the application of the procedure described by UNE 56544 [18]. Therefore, all the defects and singularities referred to in the applied standard were duly identified and measured, namely: knots, resin pockets, fissures, wane, biological damage,

distortions, and width of the annual rings, among others. For visual inspections on structural elements with a rectangular cross-section width greater than 70mm, UNE 56544 [18] defines only one quality class named MEG (*Madera Estructural de Gruesa escuadría*). The quality class is correlated with the strength class (EN 338 [17]) using EN 1912 [19], which establishes that the scots pine classified as MEG quality, with origin in Spain, fits within strength class C22.

3.3 Shear test parallel to grain performed on small specimens

Additionally, the shear strength parallel to grain of the wood used in the SSJ tests was obtained out based on shear tests on small specimens. The test method was adopted according to the recommendations of the American standard ASTM D143 [20]. The test was performed on 50 by 50 by 63mm defect-free specimens to obtain failure in the 50 by 50mm section, as shown in figure 3.2.
The test was carried out with a load application controlled by the displacement of the actuator at a constant rate of 0.6 mm/min until failure.

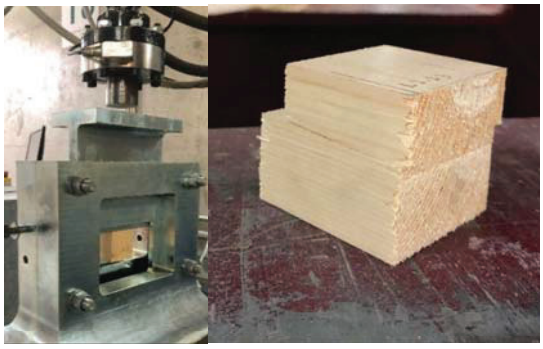

Figure 3.2: *Shear tests parallel to the grain performed on small specimens*

The shear strength was calculated using the Equation (1).

$$f_{v,SP} = \frac{N}{A_v} \quad (1)$$

Where $f_{v,SP}$ is the shear strength (MPa), N is the maximum load recorded by the load cell (N), and A_v is the shear-resistant area (mm^2) measured for each specimen after the test.
In total, 88 specimens were tested, and the value of the 5th percentile was adopted as the characteristic shear strength. All specimens used in those tests were stored in a climatic chamber at a constant temperature of 20 ± 1°C and a relative humidity of 60 ± 5% until mass stabilization and density ($\rho_{12\%}$) was determined following the procedures of NP 616 [16].

3.4 Simulation of the degradation

The degradation by anobiids was simulated by manual drilling in the direction parallel to the grain on the tie beam-end element [21]. The dimensions of the perforated galleries were approximately 2 mm in diameter and 100 mm in length, since the furniture beetle normally makes circular galleries of 1 to 3 mm in diameter [15], and the length of the tie beam-end is 100 mm.
Three different levels of degradation were adopted (DL-I, DL-II, and DL-III) varying the density of perforated galleries (1.67 holes/cm², 3.33 holes/cm², and 4.00 holes/cm²), seeking to achieve realistic degradation levels.

3.5 SSJ Tie beam-end shear test

The destructive test consists of applying an increasing normal load (N_{rafter}) on the rafter, controlled by the actuator displacement with a constant rate of 0.01 mm/s (figure 3.3). The normal load (N_{rafter}) results in compressive stresses on the surfaces of the SSJ (compression parallel to the grain on the Front Notch and perpendicular to the grain on the Bottom Notch) and shear stresses on the tie beam-end.
The expected failure mode of the specimen is the shear failure at the tie beam-end, induced by the low skew angle (β=30°) and reduced ratio between the heel depth and the shear length (lv/tv≤6) (section 3.1) [8].

Figure 3.3: *SSJ Tie beam-end shear test*

Forty specimens were tested: 4 undamaged specimens (i.e., reference) and 12 specimens for each of the three levels of degradation (section 3.4).

3.6 Design rafter load-bearing capacity ($N_{rafter,Rd}$)

In this study, Equation (2) [8] will be used to verify the design rafter load-bearing capacity ($N_{rafter,Rd}$).

https://doi.org/10.52202/069179-0039

$$N_{rafter,Rd} \leq k_{v,red} \cdot f_{v,k} \frac{k_{mod}}{\gamma_M} \cdot \frac{b \cdot k_{cr} \cdot l_{v,eff}}{cos\beta} \quad (2)$$

Where, $k_{v,red}$ is the reduction factor considering the non-uniform shear stress distribution, $f_{v,k}$ is the characteristic shear resistance, k_{mod} is the modification factor considering duration of load and moisture content, γ_M is the partial factor for wood properties, b is the width, k_{cr} is reducer factor considering the eeccentricity between the joint and the support of the tie beam, $l_{v,eff}$ is the effective shear length, and β is the skew angle between the rafter and tie beam.

4 RESULTS AND DISCUSSION

4.1 Visual grading

From the visual grading, it was possible to identify a series of natural defects inherent to the sawn wood. The most frequent defects were knots and drying fissures. However, all specimens submitted to the tests comply with the verifications established in UNE 56544 [18] and fall within the MEG quality class. Thus, applying the correlation from EN 1912 [19], the timber tested in this study was classified as C22. Moreover, EN 338 [17] establishes that the characteristic shear resistance of softwood classified as C22 is 3.8 MPa.

4.2 Shear test parallel to grain performed on small specimens

The results of the shear tests on small specimens and quantification of density, are presented in table 4.1.
The shear strength values varied between 5.42 MPa and 8.01 MPa, with an average of 6.59 MPa and a coefficient of variation of 8.88%. The characteristic shear strength parallel to the grain obtained on these tests is 5.66 MPa (5th percentile).
Regarding the density of the specimens, the values vary between 405.0 kg/m^3 and 566.3 kg/m^3, with an average of 501.6 kg/m^3. The EN 384 [22] standard considers the value of the 5th percentile of the sample as the characteristic density of wood (ρ_k). In the case of the present study, 419.9 kg/m^3.

***Table 4.1**: Shear tests parallel to the grain and density results for the 88 tested specimens*

	Shear strength ($f_{v,SP}$)	**Density ($\rho_{12\%}$)**
Max. Value	8.01 MPa	566.3 kg/m^3
Min. Value	5.42 MPa	405.0 kg/m^3
Average	6.59 MPa	501.6 kg/m^3
Stand. dev.	0.58 MPa	38.6 kg/m^3
C.V.	8.88%	7.69%
5th percentile	5.66 MPa	419.9 kg/m^3

4.3 Design rafter load-bearing capacity ($N_{rafter,Rd}$)

In this study, two different theoretical SSJ shear strength will be considered. The first, is considering the characteristic shear resistance as the value obtained through the visual grading, while the second considers the shear test on small specimens' 5th percentile value. Thus, the two characteristics shear strength adopted to apply on Equation (2) are 3.8 MPa and 5.42 MPa, respectively.
Regarding the other inputs for Equation (2), table 4.2 presents the values adopted and the references used to adopt it.

***Table 4.2:** Input values and references adopted for Equation (2)*

	Value	**References**
$k_{v,red}$	0.96	[8,23]
k_{mod}	0.9	[24]
γ_M	1.3	[24]
k_{cr}	1	[8]
$l_{v,eff}$	$\min(l_v; 8h_v) = 100mm$	Section 3.1,
b	100mm	Section 3.1
β	30°	Section 3.1

Therefore, the two values for the design rafter load-bearing capacity ($N_{rafter,Rd}$) obtained are 27.7 kN (for $f_{v,k}$=3.8 MPa) and 39.5 kN (for $f_{v,k}$=5.42 MPa).

4.4 SSJ Tie beam-end shear test

Table 4.3 presents the results obtained in the SSJ tie beam-end shear tests and the quantification of density.

***Table 4.3:** Summary of the results obtained from the quantification of the density and the SSJ tie beam-end shear tests*

Group		REF	DL-I	DL-II	DL-III
Nº		4	12	12	12
$\boldsymbol{\rho_{12}}$ [kg/m³]	$\bar{X}$	529	514	511	493
	σ	26	50	41	52
	C.V.	4.9%	9.8%	7.9%	10.6%
$\boldsymbol{N_{rafter,SSJ}}$ [kN]	$\bar{X}$	43.4	45.3	39.6	38.6
	σ	2.3	8.2	3.4	5.2
	C.V.	5.2%	18.2%	8.7%	13.5%

$\bar{\boldsymbol{X}}$ – Average; $\boldsymbol{\sigma}$ – Standard Deviation; C.V. – Coefficient of variation; $\boldsymbol{\rho_{12}}$ – Density corrected to a 12% moisture content; $\boldsymbol{N_{rafter,SSJ}}$ – Experimental rafter load-bearing capacity

As expected, all 40 specimens presented shear failure without crushing parallel to the grain at the front notch or perpendicular to the grain at the bottom notch (figure 4.1).

Figure 4.1: *Characteristic shear failure on the tie beam-end observed in the 40 SSJ specimens tested.*

Regarding the rafter load-bearing capacity, firstly, it was verified that the distribution of the results fit the normal distribution through the Shapiro-Wilk test (p-value = 0.14).

As previously mentioned, drilling densities equivalent to 1.66 holes/cm², 3.33 holes/cm², and 4.00 holes/cm² were adopted, corresponding to groups DL-I, DL-II, and DL-III, respectively. Figure 4.2 shows the bar chart that graphically represents the shear strength mean values and the respective standard deviations of the degradation groups.

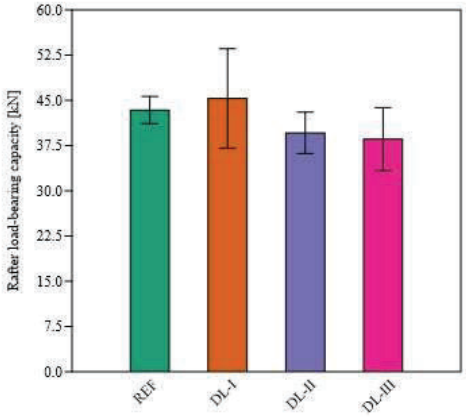

Figure 4.2: *Bar chart of the results of the tie beam-end shear tests*

Through the analysis of table 4.3 and figure 4.2, it is possible to observe that the group with the lowest level of degradation (DL-I) presented superior results (+4%, on average) compared to the reference group (REF). Therefore, it is possible to conclude that, at this level, the degradation was not enough to cause significant damage to the specimen and, in this group, other properties such as density and wood natural variability, were more determinant in the shear strength parallel to the grain. On the other hand, the higher two levels of degradation showed lower tests results than the reference group (-10% and -11%, on average), demonstrating the influence of the drilled galleries.

4.5 Comparison between experimental results and design equations

Table 4.3 presents the comparison between the theoretical rafter load-bearing capacity, calculated from Equation (2), and the average results of the SSJ tie beam-end shear tests. The comparison is made in terms of the relative variation $\Delta_{rel,rafter}$ (%). In table 4.4, $N_{rafter,Rd1}$ represents the design rafter load-bearing capacity considering the results of the visual grading, while $N_{rafter,Rd2}$ considers the results of the shear test on small specimens.

Table 4.4: *Experimental results divided by drilling density, design equation results, and relative variation between the experimental and theoretical results.*

	N_{rafter} [kN]	$\Delta_{rel,rafter1}$	$\Delta_{rel,rafter2}$
$N_{rafter,Rd1}$	27.7	-	-
$N_{rafter,Rd2}$	39.5	-	-
$N_{rafter,SSJ,REF}$	43.4	56.6%	9.8%
$N_{rafter,SSJ,DL-I}$	45.3	63.6%	14.7%
$N_{rafter,SSJ,DL-II}$	39.6	43.0%	0.2%
$N_{rafter,SSJ,DL-III}$	38.6	39.2%	-2.4%

From table 4.4, it is possible to observe the reliability of the design equation when considering the shear test on small specimens performed on this study ($\Delta_{rel,rafter2}$ between 14.7% and -2.4%), while the C22 grading shows theoretical results much lower than the experimental results ($\Delta_{rel,rafter}$ between 63.6% and 39.2%).
The results are exposed in figure 4.3 in a scatter plot, where the blue line represents the $N_{rafter,Rd1}$ and the red line $N_{rafter,Rd2}$.

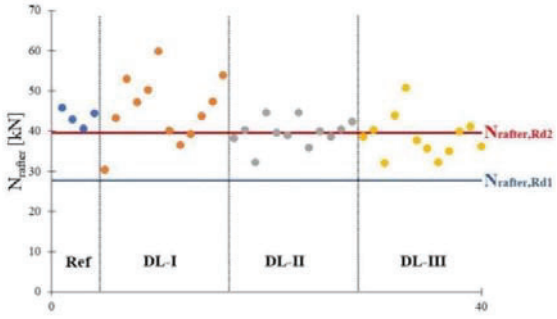

Figure 4.3: *Tests results separated by level of degradation and comparison with design values.*

Analysing the graph exposed in figure 4.3, it is possible to infer that, when considering the strength class C22 proposed by EN 1912 ($N_{rafter,Rd1}$), all 40 specimens presented higher values, discarding the need to consider a reduction factor due to degradation by anobiids. On the other hand, when considering the value of the characteristic resistance obtained by shear test on small specimens ($N_{rafter,Rd2}$), it is possible to notice that all the reference specimens (without degradation) presented

https://doi.org/10.52202/069179-0039

values slightly higher than those obtained by applying the equation (2) and that the number of tests with values below the $N_{rafter,Rd2}$ line increase with increasing of the level of degradation (3 tests for the DL-I, 5 for the DL-II and 7 for the DL-III level).

Therefore, based on the analysis of table 4.4 and figure 4.5, it can be concluded that although the shear test on small specimens more accurately represents the value of the wood's characteristic shear strength ($f_{v,k}$), it indicates the need to assign a reduction factor due to biological degradation to Equation (2) for the correct determination of the design rafter load-bearing capacity of SSJ degraded by anobiids.

5 CONCLUSIONS

From the results of the experimental campaign and the application of the design equation, it is possible to infer that, when considering the strength grading C22 for scots pine, the degradation achieved in this study is not enough to reduce the load-carrying capacity to the point that element replacement is required, confirming the theory that many replacements are unnecessary [3]. On the other hand, shear test on small specimens presented a more precise characteristic shear strength, and, in this case, it is clear the tendency of reducing the shear strength with the increase of the level of degradation and the necessity to impose a reduction factor to the design equation due to biological degradation. Thus, for future developments, it is intended to establish a correlation between the level of degradation by anobiids and the residual shear strength of SSJ, with the aim to propose values for that reduction factor.

STUDY ON THE RELATIONSHIP BETWEEN INTERLAYER DEFORMATION ANGLE AND TORN WALLPAPER OF WOODEN HOUSES

Sora Sunakozawa[1], Kiyotaka Terui[2], Hideyuki Nasu[3]

ABSTRACT: The purpose of this study is to clarify the elongation rate of wallpaper required to prevent wallpaper from breaking in wooden houses due to medium earthquakes. For this purpose, it is necessary to clarify the relationship between the elongation rate of wallpaper and the interlaminar deformation angle at which the wallpaper breaks. However, there is no defined method to measure the elongation rate of wallpaper. Therefore, this study first aimed to establish a method to measure the elongation rate of wallpaper and conducted three types of tensile tests. In addition, a shear test was conducted to reproduce the original tearing of the wallpaper, and the results were compared with those of the tensile test to verify which tensile test results are valid as a measurement method.

KEYWORDS: Wooden Houses, Interlayer deformation angle, Wallpaper, Plasterboard

1 INTRODUCTION

There is a problem of wallpaper tearing in houses due to earthquakes and other events. This is because horizontal forces acting on the house cause interlaminar deformation, which rotates the plasterboard, the base of the interior, and causes misalignments and openings between adjacent boards. According to the Japanese Building Standard Law, the angle of interstory deformation generated by a moderate earthquake should be kept within 1/120 rad. if no part of the house is damaged due to deformation of structural members. The interlaminar deformation angle at this point is generally called the damage limit. According to this definition, it can be interpreted that the house can be used continuously without repair if it is within the damage limit. However, previous studies have shown that wallpaper breaks even at interlaminar deformation angles smaller than the damage limit. Therefore, the objective of this study was to estimate the target elongation rate of wallpaper necessary to prevent the wallpaper from tearing within the damage limit.

2 SUMMARY OF RESEARCH

To estimate the target value, the relationship between the elongation rate of wallpaper and the interlaminar deformation angle at which breakage occurs is investigated. Since there is no established method for measuring the elongation rate of wallpaper, tensile tests of wallpaper were conducted to establish a measurement method. However, since the tensile test alone does not reproduce the original wallpaper breakage, a shear test of the wallpaper was conducted and compared with the results of the tensile test to confirm the correlation.

3 STANDARD TENSILE TESTS

3.1 SPECIMEN SPECIFICATIONS

The test specimens were made by cutting wallpaper into strips 15 mm wide and 280 mm long (Fig.1,2). The gripping position was set at 50 mm from both ends, and the center 180 mm was set as the elongation allowance. Six types of vinyl wallpaper, which are frequently used in Japan, were used for the test specimens. Six types of vinyl wallpaper with different surface shapes, foam amounts, and elasticity were used (Table 1). The first letter of the test specimen name is derived from the surface shape, and the second letter from a word indicating the characteristics of each specimen. A total of 36 specimens, six of each specification, were used.

Table 1 List of specimen specifications

Specimen name	Surface form	Thickness [mm]	Feature
SN	Stone	0.42	Normal vinyl cloth
SF	Stone	0.60	Foamed to increase thickness
SF’	Stone	0.55	Foamed to increase thickness
SS	Stone	0.58	Stretch performance
FF	Fabric	0.60	Foamed to increase thickness
FL	Fabric	0.72	Used for a long time

3.2 SUMMARY OF EXPERIMENTS

Tensile tests were conducted to measure the elongation rate of wallpaper. For the test, tensile force was applied to the specimen using a 1 kN universal testing machine at the Nippon Institute of Technology (Fig. 3). The test was applied at a rate of 20 mm/min until the wallpaper broke. Rupture was determined when the load dropped from the maximum load to half of the maximum load. Elongation was determined by dividing the displacement at break by the elongation threshold and expressed as a percentage.
If the wallpaper broke due to the tightening force when the testing machine gripped the specimen, the correct elongation rate of the wallpaper could not be measured. Therefore, if the specimen broke within 10 mm from the gripping position, the result was considered invalid (Fig. 4, 5).

Figure 3. *Testing machine*

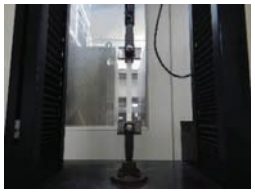

Figure 4. *Specimen installed*

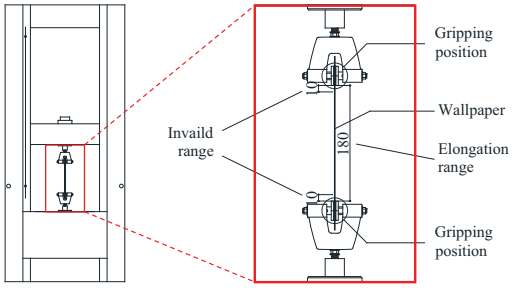

Figure 5. *Specimen installation state and invaild range*

3.3 EXPERIMENTAL RESULT

The test results from the standard tensile test are shown in Table 2 and Fig. 6. Slight differences in elongation rate and maximum proof stress were observed among the wallpaper types. The highest elongation value was obtained with SF, which has a stony surface and a large amount of foam, while SS, which has a stretch performance, showed the third highest elongation value. Fracture behavior was similar for all specifications, with the wallpaper breaking instantaneously at maximum load. One reason for the lack of difference was the shape of the vinyl wallpaper. Vinyl wallpaper is manufactured by coating vinyl chloride resin onto backing paper. Although the backing paper has higher resistance than the vinyl resin, it is not elastic and is therefore prone to rupture. When the backing paper breaks, the vinyl resin also breaks, and it is thought that it was difficult to obtain a difference in results.
However, when vinyl wallpaper is applied, a large amount of water is used to dilute the glue, which may reduce the resistance of the backing paper. Therefore, in the next test, the resistance of the backing paper will be reduced by adding moisture to the wallpaper, and the elongation rate will be measured with the effect reduced.

Table 2 *Standard tensile tests results*

Specimen name	Elongation rate [%]	Pmax [N]
SN (Stone Normal)	1.58	49.82
SF (Stone Foamed)	2.22	66.04
SF' (Stone Foamed)	1.86	70.05
SS (Stone Stretch)	1.89	71.07
FF (Fabric Foamed)	1.60	50.69
FL (Fabric Long)	2.11	62.91

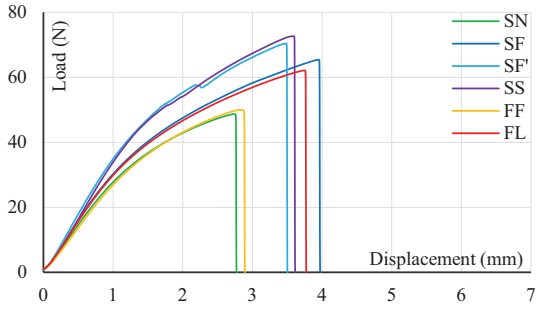

Figure 6. *Std. tensile tests graph*

4 WET TENSILE TESTS

4.1 SPECIMEN SPECIFICATIONS

The shape of the specimen was the same as in the standard tensile test. The same six types of vinyl wallpaper were used as in the standard tensile test. The test specimens were six of each specification, for a total of 36 specimens. The condition of the specimens was also changed to reduce the influence of the backing paper. In order to reproduce the decrease in resistance due to moisture in the glue when applying vinyl wallpaper, the specimens were impregnated with water for 5 minutes, and the excess water droplets were wiped off using tissue paper (Fig. 7,8).

Fig. 7 *Impregnating wallpaper*

Fig. 8 *Wiping off excess moisture*

4.2 SUMMARY OF EXPERIMENTS

In order to measure the elongation rate of wallpaper with the influence of the backing paper reduced, tensile tests were conducted with the specimens wet. For the test,

https://doi.org/10.52202/069179-0040

tensile force was applied to the specimens using a 1 kN universal testing machine at the Nippon Institute of Technology. After impregnating the specimen for 5 minutes before applying the force, water droplets on the surface were wiped off and the force was applied immediately. The test was applied at a rate of 20 mm/min until the wallpaper ruptured. Rupture was determined when the load dropped from the maximum load to half of the maximum load. Elongation was calculated by dividing the displacement at break by the elongation threshold and expressed as a percentage.
If the wallpaper broke due to the clamping force when the testing machine gripped the specimen, the correct elongation rate of the wallpaper could not be measured. Therefore, if the specimen broke within 10 mm from the gripping position, the result was considered invalid.

4.3 EXPERIMENTAL RESULT

The test results of the wet tensile test are shown in Table 3 and Fig. 9. As a result of the moisture content in the wallpaper, there were large differences in the maximum proof stress and elongation rate. In addition, the wallpapers exhibited two types of fracture behavior: integrally fractured and plastically deformed. The one-body break type (Fig. 10) is a rupture behavior in which the vinyl resin and the backing paper rupture at the same time, and was observed in SF, SF', FF, and FL, which have large amounts of foam. The plastic deformation type (Fig. 11) is a failure behavior in which the vinyl resin and backing peel off at the maximum proof stress (Fig. 12), and only the backing breaks, causing plastic deformation of the vinyl, and was observed in standard SN and SS with stretch performance. The stretch performance of SS was particularly clear, showing an elongation rate of 8.06 %, more than 60 % higher than the elongation rate of other specifications, which was around 5 %.
We believe that the wet tensile test was able to measure the performance of the vinyl resin itself by wetting the wallpaper and reducing the effect of the backing paper. However, the wallpaper is actually wet only when it is installed, and the glue is considered to have already dried when the earthquake occurs. Therefore, in the next tensile test, we decided to reproduce the wallpaper after it had dried and apply force.

Table 3 *Wet tensile tests results*

Specimen name	Elongation rate [%]	Pmax [N]
SN (Stone Normal)	5.43	16.04
SF (Stone Foamed)	5.24	32.32

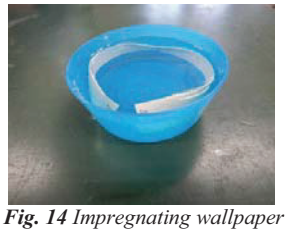
5 DRY TENSILE TESTS

5.1 SPECIMEN SPECIFICATIONS

The shape of the test specimen was the same as in the standard and wet tensile tests. In this test, three types of vinyl wallpaper (SN, SF, and SS) were tested for verification purposes. A total of 18 specimens were tested, six for each.
After impregnating the specimens under the same conditions as in the wet tensile test, the specimens were allowed to dry for three days (Fig. 14, 15). This reproduced the condition of the wallpaper after drying at the time of the earthquake.



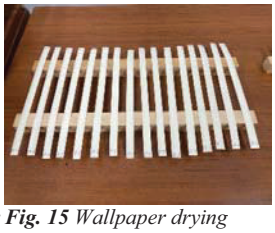


Fig. 14 *Impregnating wallpaper* ***Fig. 15*** *Wallpaper drying*

5.2 SUMMARY OF EXPERIMENTS

In order to reproduce the condition after the glue dried and measure the elongation rate of the wallpaper, a tensile test was performed by wetting the specimen and then drying it. For the test, tensile force was applied to the specimens using a 1kN universal testing machine at the Nippon Institute of Technology. After impregnating the specimens for 5 minutes, the force was applied to the specimens that had dried for 3 days. The test was applied at a rate of 20 mm/min until the wallpaper ruptured.

Rupture was determined when the load dropped from the maximum load to half of the maximum load. Elongation was calculated by dividing the displacement at break by the elongation threshold and expressed as a percentage. If the wallpaper broke due to the tightening force when the testing machine gripped the specimen, the correct elongation rate of the wallpaper could not be measured. Therefore, if the specimen broke within 10 mm from the gripping position, the result was considered invalid.

5.3 EXPERIMENTAL RESULT

The test results of the dry tensile test are shown in Table 4 and Fig. 16. Reproducing the results after the glue dried, the difference in elongation rate caused by the different types of wallpaper was minimal. The highest elongation value was observed for SF, which has the highest amount of foam, followed by SS, which has the highest stretch performance, and standard SN, which had the lowest elongation. The reason for the lack of difference could be due to the effect of the backing paper, as in the standard tensile test. We believe that the moisture absorbed during the impregnation process was dried, and the backing paper's resistance was restored.

Table 4 *Dry tensile tests results*

Specimen name	Elongation rate [%]	Pmax [N]
SN (Stone Normal)	1.66	48.95
SF (Stone Foamed)	2.51	71.37
SS (Stone Stretch)	2.29	71.40

	Wet	5.23	15.23
FL (Long)	Standard	2.11	62.91
	Wet	4.83	14.89

6.1 STANDARD-WET COMPARISON

A graph comparing standard tensile testing to wet tensile testing is shown in Fig. 17. Wetted wallpaper reduced Pmax by more than half for all specifications, but increased elongation by more than twice. In addition, all exhibited similar fracture behavior in the standard tensile test due to the influence of the backing paper, but differences in fracture behavior were observed when the backing paper was wetted and its bearing capacity was reduced. Based on the above, it can be considered that the standard tensile test almost always measures the performance of the backing paper, while the wet tensile test can measure the performance of the vinyl resin.

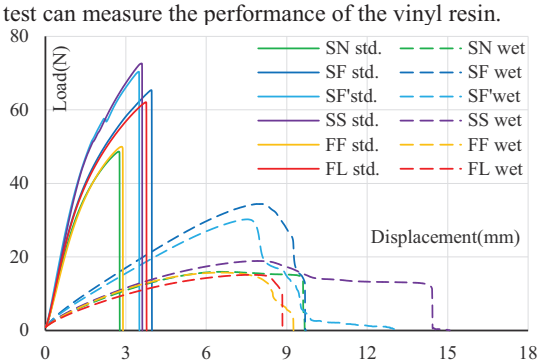

Figure 17. *Std.-Wet tensile tests comparison graph*

6.2 STANDARD-DRY COMPARISON

A graph comparing standard tensile testing to dry tensile testing is shown in Fig. 18. Compared to the standard wallpaper, the wallpaper that was dried after being moistened showed comparable values for both maximum proof stress and elongation. This is thought to be due to the fact that the backing paper, although once moistened, dried and returned to its original strength. Therefore, it was found that the dried tensile test showed equivalent test results to the standard tensile test.

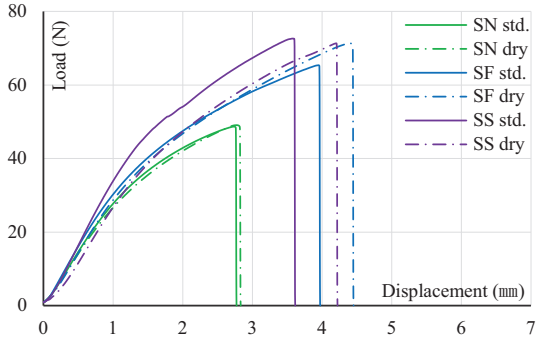

Fig. 18 *Std.-Dry tensile tests comparison graph*

6.3 TENSILE TEST CONCLUSIONS

We have conducted three tensile tests so far, and it is clear that vinyl wallpaper has a higher resistance than backing

https://doi.org/10.52202/069179-0040

paper, and that no difference can be seen due to the influence of the backing paper when tested in its original state. It is also clear that the effect of the backing paper can be reduced by adding moisture, and the difference in performance of the vinyl resin can be confirmed.
However, the actual cause of wallpaper breakage is the displacement or opening of the plasterboard, not pure tensile fracture. Therefore, we decided to conduct shear tests on wallpaper that reproduced the displacement of the plasterboard to confirm the displacement that causes rupture. The results of the shear test were compared with the results of the respective tensile tests to verify which elongation rate in the tensile test was a reasonable value for evaluating the rupture.

7 SHEAR TESTS

7.1 SPECIMEN SPECIFICATIONS

Since it is difficult to apply shear force to a single piece of wallpaper, we decided to reproduce the original house interior. 3 sheets of plasterboard (70 x 200 mm at both ends and 140 x 230 mm in the center) were lined up and the wallpaper was attached (Fig. 19). The gluing was done in such a way as to straddle all the plasterboards. A curing period of one week was allowed for the glue to dry.
Wooden frames (Fig. 20) were also made to hold the specimens in place. Only the plasterboards at both ends were fastened to the frame with screws; the center board was not fastened (Fig. 21). The frames were secured using a testing machine and bolts.
The wallpapers used were four types of wallpaper with stone surface geometry.

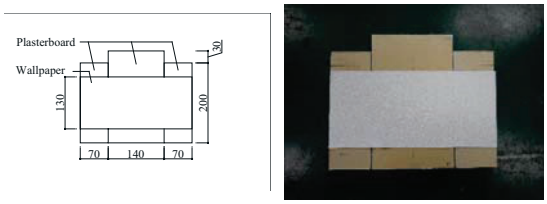

Figure 19. *Wallpaper placement of specimen*

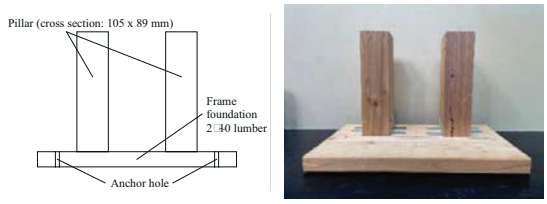

Figure 20. *Frame for specimen fixation*

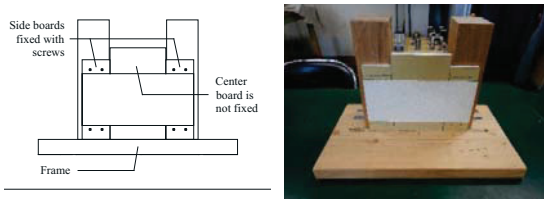

Figure 21. *Specimen fixed to the frame*

7.2 SUMMARY OF EXPERIMENTS

A wallpaper shear test is performed to measure the relative displacement between plasterboards when wallpaper breaks. A 50 kN universal testing machine from the Nippon Institute of Technology was used for the test. After the frame to which the specimen was fastened was fixed to the testing machine, the plasterboard in the center, which was not fastened, was grabbed by the upper jig of the testing machine (Fig. 22, 23), and the displacement of the boards was reproduced by raising only the center board. The force was applied at a rate of 2 mm/min until the wallpaper completely ruptured. Since it was difficult to determine rupture by the decrease in bearing capacity, damage was checked every 0.5 mm of displacement, and rupture was determined when more than half of the wallpaper was ruptured at the top of the joints.

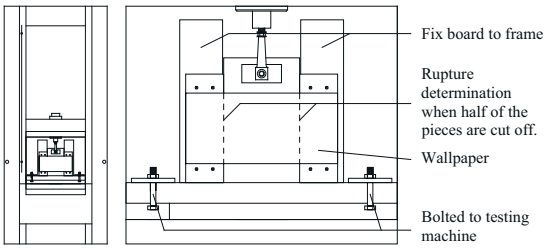

Figure 22. *Specimen installation state and invaild range*

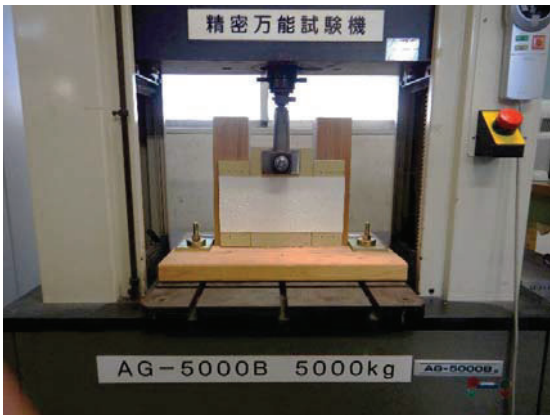

Figure 23. *Specimen installation state*

7.3 EXPERIMENTAL RESULT

The results of the shear test are shown in Table 6. The standard wallpaper, SN, and the wallpapers with high foam content, SF and SF', broke when the displacement was around 3.4 mm. On the other hand, SS, which has a stretch function, failed at a displacement of 4.5 mm at rupture compared to the other specifications (Fig.24). From the above results, it is considered that the stretch function is effective against shear failure.
Assuming that the plasterboard rotates at the same angle as the interlaminar deformation angle, the interlaminar deformation angle can be estimated from the board-to-board misalignment. 4.5mm corresponds to approximately 1/200 rad. However, this is only the case when there is no resistance to rotation of the faceplate, and is not an accurate estimate. It is necessary to actually test

https://doi.org/10.52202/069179-0040

the gypsum board bearing walls and measure the relative displacement between boards and the interlaminar deformation angle, and then re-evaluate the results. In addition, the chamfered edges of the gypsum board and the putty used to fill them were not reproduced in this study, so actual reproduction is also necessary.

Table 6 *Shear tests results*

Specimen name	Board displacement at break [mm]	Estimated interlayer deformation angle at break [rad.]
SN (Normal)	3.18	1/286
SF (Foamed)	3.67	1/247
SF' (Foamed)	3.34	1/272
SF (Foamed)	4.51	1/201

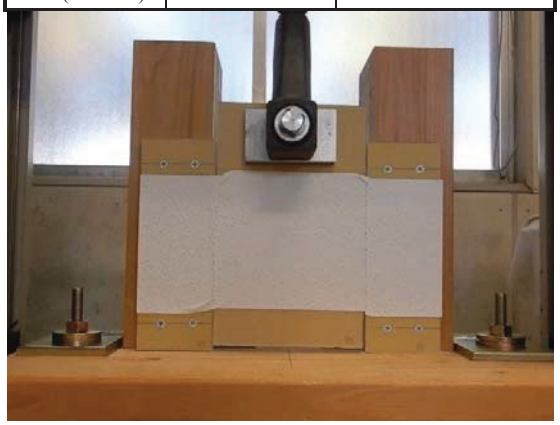

Figure 24. *Wallpaper at break judgment (SS)*

8 COMPARISON

The relationship between the increase in elongation in the standard tensile test and the rupture displacement in the shear test is shown in Fig. 25, and the relationship between the increase in elongation in the wet tensile test and the rupture displacement in the shear test is shown in Fig. 26. The trend of increasing elongation in the standard tensile test appears to be generally consistent with the trend of increasing rupture displacement in the shear test. However, the SS rupture displacement with stretching performance in the shear test is large and deviates from the trend. The trend of the rupture displacement in the shear test was generally consistent with the trend of the elongation ratio in the wet tensile test. In particular, the values of SS in both tests were very high compared to the other three specifications, which were similar. Therefore, it can be seen that there is a strong relationship between the rupture displacement in the shear test and the elongation rate in the wet tensile test.

Figure 25. *Tensile(std.)-shear tests result comparison*

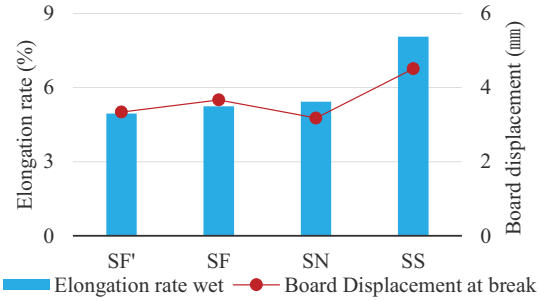

Figure 26. *Tensile(wet)-shear tests result comparison*

9 CONCLUSIONS

By moistening the wallpaper, the influence of the backing paper was reduced, and the elongation rate could be measured while the performance of the vinyl resin itself was brought out. The fact that the elongation rate in the wet tensile test is strongly related to the breaking displacement in the shear test indicates that there is a relationship between the interlaminar deformation angle at which the wallpaper breaks and the results of the wet tensile test. In the future, we plan to conduct static force tests on full-scale walls actually covered with wallpaper to measure the interlaminar deformation angle at which the wallpaper breaks, and to clarify the relationship with the results of partial tests.

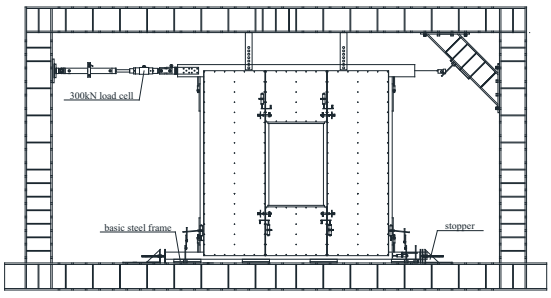

Figure 27. *Plan for in-plane shear static force test*

ACKNOWLEDGEMENT

The test specimens used in this study were provided by POLUS R&D Center of Life-Style Co., Ltd. I would like to thank all those involved.

GLUED-LAMINATED TIMBER UNDER EXTREME COLD TEMPERATURES SUBJECTED TO IMPACT LOADING

Nicole Wight[1], Christian Viau[2], Patrick Heffernan[3]

ABSTRACT: With the increasing turbulence in the global security environment, comes the requirement for an increasing presence in the Canadian Arctic to respond to regional challenges and provide security. Such presence requires temporary and permanent installations, which must inherently carry with it some considerations for extreme load events, such as blast and impacts. In tandem with this is the expanding need to build more environmentally sustainable buildings, for which wood has been identified in recent years. However, questions remain on how wood responds to blast and impact loads when exposed to cold temperatures, typical of the arctic region. To respond to this gap in research, an experimental program was carried out to investigate the flexural behaviour of glued-laminated timber (glulam) subjected to impact loading under ambient and winter arctic temperatures. Dynamic testing was conducted using a drop weight impact hammer. For strain rates between 1.13 to 1.38 s^{-1}, an average dynamic increase factor of 1.23 on the maximum resistance at ambient temperatures was observed. The cold temperature beams were seen to experience a 13% increase in strength beyond their normal temperature counterparts under dynamic effects. Increases in stiffness due to cold temperature were also observed under static and dynamic loading.

KEYWORDS: Impact, Glulam, Arctic, Strain Rate, Cold Temperature, Dynamic Increase Factor

1 INTRODUCTION

In recent decades, there has been an upward trend in infrastructure and buildings being exposed to blast and impact loading, as well as an increased use of wood as a construction material for mid- and high-rise timber and timber-hybrid structures. However, despite wood being mentioned in blast design standards [1, 2], current provisions are lacking in quantity and extent, due to them being based on limited early research on light-frame wood shelters [3]. The exposure of structural materials to high strain rates typically leads to increases in strength and, in some cases, stiffness, generally quantified using a dynamic increase factor (DIF). Shock tube testing, which simulates the effects of far-field blast explosions, has been used to determine DIF values for various wood elements under normal temperature, most notably glued-laminated timber (glulam) and cross-laminated timber (CLT), where DIFs of 1.14 and 1.28, respectively, have been reported [4, 5]. Other studies investigating the behaviour of light-frame wood systems [6-9] and timber connections under high strain-rates [10-12] have also been conducted.

Various countries, including Canada and allies, have a vested interest in asserting sovereignty in their Northern regions, and the need to have an active and visible presence in these cold environments has become incredibly prevalent with the current global security environment [13]. Canadian Forces Station (CFS) Alert, located 817 km from the geographic North Pole, represents not only the most northerly permanently inhabited place in Canada, but also in the world, where during the winter months the average daily temperature is -40 °C [14]. As such, materials capable of withstanding these temperatures without adverse effects on their mechanical properties and durability are critical to expanding infrastructure in Northern Regions of Canada. Already, large infrastructure constructed with engineered wood products are being developed for use in colder regions of Canada. For example, the Macaisagi Bridge in northern Quebec, Canada, built in 2011 out of CLT and glulam with a 1,790 kN capacity, spans 68 m and experiences temperatures as low as -45 °C [15]. Understanding how extreme cold temperatures affect a material's mechanical properties is required to provide users with safe, durable, and effective designs. Despite its application in cold weather regions, little research has been conducted on the performance of glulam under arctic conditions, none of which examined static or dynamic bending strength [15-17].

Beirnes et al. investigated the impact resistance of thin ultra-high performance fibre reinforced concrete (UHPFRC) panels under extreme cold temperatures. An increase in the static strength and an increase in the panel residual strength under impact loading of the cold panels compared to their ambient temperature counterparts was observed [18]. No additional studies investigating the effects of cold temperature on the impact or blast resistance of structures could be found.

Canada's Blast Design Standard, CSA S850, currently provides a DIF value for glulam of 1.4 under flexural loading [1], a value which has been reported to be nonconservative by recent studies on glulam [4, 19]. In addition, current blast design standards do not account for the cold weather behaviour of materials under blast loading [1, 2]. To address this gap in research, the below experimental program investigated the effect of extreme cold temperature on the mechanical strength properties of glulam under both quasi-static and high-strain rates for the purpose of expanding glulam's use in structures under extreme cold temperatures.

2 EXPERIMENTAL PROGRAM

2.1 DESCRIPTION OF TEST SPECIMENS

A total of fifteen 137 mm x 178 mm x 1650 mm NordicLam+ 24F-ES grade glulam beams were tested under quasi-static and dynamic loading, at both ambient and extreme cold temperatures, to document high strain-rate effects and their behaviour under impact loading conditions. As previous research has indicated that finger joints may affect the failure of beams under high strain rates, beams of multilaminate widths were chosen to minimise this effect [4]. For all specimens presented in this paper, the prefix "S" refers to a specimen that was tested quasi-statically, while the prefix "D" refers to a specimen that was tested dynamically. Similarly, this was followed by the letter "A" or "C", indicating that the specimen was tested at ambient temperature or cold temperature, respectively.

2.2 TEMPERATURE MONITORING

All cold specimens were placed into a cold temperature freezer at -70 °C for a minimum of seven days prior to testing. All beams were equipped with a Type T thermocouple adhered to their side approximately 8 cm from the centreline in order to record the beam's surface temperature. In order to assess internal temperatures of the specimens, a test beam was placed in the cold temperature freezer with thermocouples installed at depths of 63 mm, 42 mm, 21 mm, and on the surface. The readings obtained from the test beam were then used to develop a relationship between the surface and internal temperatures. Using this information to develop a correlative relationship, the time to required for the beams to reach an internal temperature of -70 °C and the beams' internal temperatures at the time of testing could be determined.

2.3 STATIC TESTING

Quasi-static four point bending flexural tests were conducted on seven of the fifteen specimens to serve as a baseline with which to compare the dynamic results. The quasi-static test setup can be seen in Figure 1. These tests, adapted from ASTM D198 [20], resulted in the quasi-static flexural strength values that were normalised to a standardized 1-minute load duration, as outlined in Section 3.2. A linear variable differential transformer (LVDT) connected at the beam's midspan recorded the beam's displacement, while two strain gauges positioned on the tension side of the beam and two on the compression side of the beam at midspan measured the specimens' strain deformations. A load cell within the hydraulic head measured the applied force, and applied a load at a displacement-controlled rate of 1 mm/min. This resulted in an average time to failure of 15.2 mins for the small normal temperature beams and 13.4 mins for the cold temperature beams. Simply supported boundary conditions were provided using the same rollers and load transfer bar used for the dynamic tests. A clear span of 1,479 mm was used throughout testing, with the load being applied at the beam third points. This allowed for an area of constant moment and zero shear force in the central third of the beam. To avoid crushing, 150 mm long plates at the load-application points and beam ends were used.

Figure 1: *Static test setup*

2.4 DYNAMIC TESTING

Dynamic testing was conducted using the newly established drop weight impact testing facility at the Royal Military College of Canada (Kingston, ON Canada), capable of imparting up to 23 kJ of energy onto small- to full-scale structural elements. The impact hammer consists of a weighted box that travels along six-meter-tall rails using six pillow block ball bearings to guide the box. All ambient temperature dynamic beams were subject to an 1800 mm drop with a weight of 141.7 kg and all cold temperature beams were subject to a 2000 mm drop with a weight of 141.7 kg. The dynamic test set-up can be seen in Figure 2. A data acquisition system capable of recording up to 500 kHz was used. An electromagnet was used to raise the box to the required

https://doi.org/10.52202/069179-0041

drop height, which was determined using a linear encoder attached to the drop weight. The linear encoder also permitted for the box kinematics at impact to be determined.

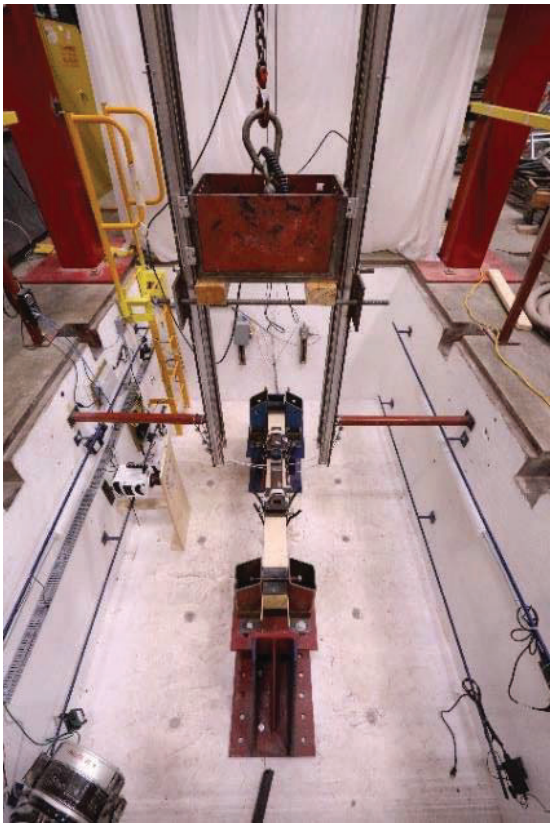

Figure 2: *Dynamic test setup*

Support rollers identical to those in the static test setup were utilized, facilitating the comparison between both sets of tests. Lateral supports were provided at the beam ends to minimize the likelihood of lateral beam instability during response. Additionally, brace plates were placed on top of the beam at each end to prevent upward motion of the beam after initial impact. A load transfer beam was used to distribute the impact load across the central third of the beam in order to create an area of constant moment and zero shear force. The beams were instrumented with piezoelectric force sensors under each support and under the load application points in order to determine the support reactions and the applied load. The beam's displacement-time history was recorded using both a laser and a string potentiometer, while two strain gauges positioned on the tension side of the beam and two on the compression side of the beam at midspan measured the specimens' strains. Three high speed cameras, capturing images at 10,000 fps, 1,000 fps and 500 fps, were used to record the beam's behaviour and potential failure locations.

3 EXPERIMENTAL RESULTS

3.1 TEMPERATURE MONITORING

Specimen SC3 was prepared in the manner outlined in Section 2.2. Upon conditioning, SC3 was removed from the freezer and the change in internal temperature was monitored over time. The output of this test allowed for the temperature time curves to be used to relate the internal temperatures to those of the various tests. The average rate of warming in the beam across the four thermocouple depths was 0.72 °C/min. The surface thermocouple temperatures recorded during the tests were also compared to the values obtained by the test beam and good agreement was observed. As a result, the average internal temperature for all static beams was -46.8 °C at the midpoint of testing and -43.5 °C at failure. Due to the short duration of testing, the average internal temperature for all dynamic beams was -47.1 °C at failure. In all cases, these temperatures are within the range of temperatures experienced in the Arctic.

3.2 STATIC TESTING RESULTS

Failure was established to be the point during testing where the specimen experienced a sudden drop in load and could no longer support additional load. The stiffness was taken as the slope of the resistance displacement curve from 40% to 90% of the beam's ultimate capacity. The failure load for each beam was normalized to a 100% strength value corresponding to a testing time of 1 minute in order to normalise all static results using Equation (1) [21].

$$SL = 100.0 - 3.5Log_{10}T_r \quad (1)$$

where SL = stress level factor in the beam and T_r = time to failure in minutes.

The results from the normal and cold temperature static tests are summarized in Table 1, including the static maximum resistance ($R_{s,max}$), stiffness (K), strain rate ($\dot{\epsilon}$), the time-to-failure and whether the beam failed in flexure, shear, or combined flexure and shear.

The average peak resistance for the normalized static normal temperature tests was 185.6 kN with a coefficient of variation (COV) of 0.12. From the results, it can be observed that some of the beams failed in flexure, while others failed in shear. Before testing, the beams' capacities were checked for governing failure mode, and the shear failure capacity of the beams was determined to not govern the design of the specimens. When only the beams that failed purely in bending were considered, the peak resistance was 166.3 kN with a COV of 0.02. The average stiffness for the normalized static normal temperature tests was 11,900 kN/m with a COV of 0.02. As would be expected, when only the bending failures are considered, the stiffness does not change dramatically, with the average stiffness being 11,670 kN/m with a COV of 0.01. The average surface temperature of the normal temperature beams was 19.7 °C during testing.

https://doi.org/10.52202/069179-0041

Table 1: *Static test results*

Sample	$R_{s,max}$	K	$\dot{\varepsilon}$ (x10^{-6})	Time to Failure	Failure Mode
	kN	kN/m	s^{-1}	mins	
Normal Temperature Beams					
SN1	163.4	11,490	5.48	13.3	Flexure
SN2	190.0	12,250	4.74	13.6	Shear
SN3	169.3	11,840	4.98	14.6	Flexure
SN4	219.6	12,020	5.08	19.3	Shear
Avg	185.6	11,900	5.07	15.2	
Std Dev	22.0	275	2.64	2.4	
COV	0.12	0.02	0.05	0.16	
Cold Temperature Beams					
SC1	182.9	13,760	6.44	13.0	Flexure
SC2	189.8	13,800	4.95	13.4	Shear
SC3	155.0	13,950	4.99	10.9	Flexure
Avg	175.9	13,840	5.46	12.4	
Std Dev	15.1	79	0.70	1.1	
COV	0.09	0.01	0.13	0.09	

The average peak resistance for all normalized static cold temperature tests was 175.9 kN with a COV of 0.09. When only the beams that failed purely in bending were considered, the peak resistance was 168.9 kN with a COV of 0.08. The average stiffness for all normalized static cold temperature tests was 13,840 kN/m with a COV of 0.01. As would be expected, when only the bending failures are considered, the stiffness does not change dramatically, with the average stiffness being 13,850 kN/m with a COV of 0.01. The average internal temperature of the cold temperature beams at failure was -43.5 °C and the average surface temperature at failure was -39.9 °C.

3.3 DYNAMIC TESTING

Dynamic failure of the beam specimens was determined to occur at the peak resistance, consistently followed by a sudden drop in resistance. Unlike static loading, the dynamic resistance of a beam cannot be obtained by the simple summation of the reactions as this will not give an accurate reflection of the beam's response. This is due to the dynamic resistance being dependant not only on the dynamic reactions, but also the boundary conditions, whether the element response is elastic or inelastic, and the applied load [22]. The dynamic resistance was obtained using Equations (2) and (3), where the latter was used in order to account for the distributed mass of the beam and the point loads of the load transfer beam. Further information on the derivation of these expressions can be found in [22, 23].

$$R(t) = \frac{6}{L}[V(t) \times x_{eq} + 0.5 \times \left(\frac{L}{3} - x_{eq}\right) \times F(t)] \qquad (2)$$

$$x_{eq} = \frac{0.102\bar{m} \times L^2 + 0.290m_c \times L}{0.319\bar{m} \times L + 0.870m_c} \qquad (3)$$

where $R(t)$ = beam dynamic resistance, $V(t)$ = dynamic reaction, $F(t)$ = applied force, L = beam clear span, x_{eq} = distance from the support to the point of application of the equivalent inertia force, $\bar{m}$ = the distributed mass of the beam and m_c = half of the mass of the load transfer beam lumped at the load application points.

Similar to the static tests, the initial beam stiffness was taken as the slope of the resistance displacement curve from 40% to 90% of the beam's ultimate capacity. The results from the dynamic tests for normal and cold temperature beams can be seen in Table 2, including the dynamic maximum resistance ($R_{d,max}$), stiffness (K), strain rate ($\dot{\epsilon}$), duration of load and whether the beam failed in flexure, or shear.

Table 2: *Dynamic test results*

Sample	$R_{d,max}$	K	$\dot{\varepsilon}$	Durat-ion of Load	Failure Mode
	kN	kN/m	s^{-1}	ms	
Normal Temperature Beams					
DN1	210.7	12,890	1.36	9.5	Flexure
DN2	207.7	16,140	1.13	10.0	Flexure
DN3	190.3	14,340	1.38	9.6	Flexure
DN4	208.9	15,410	1.33	9.4	Flexure
Avg	204.4	14,700	1.30	9.6	
Std Dev	8.2	1,220	0.10	0.2	
COV	0.04	0.08	0.08	0.02	
Cold Temperature Beams					
DC1	226.8	16,500	1.25	8.9	Shear
DC2	226.0	17,640	1.28	9.1	Flexure
DC3	229.2	16,700	1.14	10.0	Flexure
DC4	239.4	17,360	1.31	10.3	Flexure
Avg	230.3	17,050	1.25	9.6	
Std Dev	5.4	465	0.06	0.6	
COV	0.02	0.03	0.05	0.06	

For strain rates between 1.13 to 1.38 s^{-1}, the average dynamic peak resistance for the normal temperature beams was 204.4 kN with a COV of 0.04. The average stiffness for the normal temperature beams was 14,700 kN/m with a COV of 0.08.

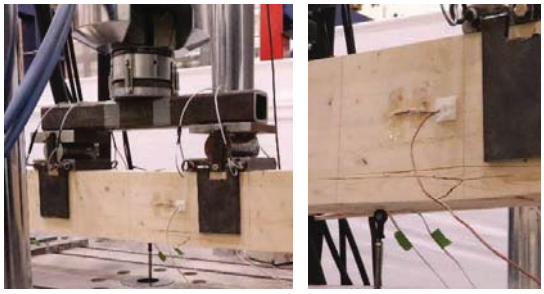
All but one dynamic cold temperature beam failed in flexure, with specimen DC1 failing in shear. For strain rates between 1.14 to 1.31 s^{-1}, the average dynamic failure resistance for the cold temperature beams was 230.3 kN with a COV of 0.02. The average stiffness for the cold temperature beams was 17,050 kN/m with a COV of 0.03. If only the flexural failures are considered, the average dynamic failure resistance for the cold temperature beams was 231.5 kN with a coefficient of variation (COV) of 0.02. The average stiffness for the cold temperature beams was 17,236 kN/m with a COV of 0.02. As can be seen from these values, the beam that failed in shear, had very

similar failure values to the other beams and as such the results do not differ greatly when this beam's data is omitted.

3.4 FAILURE MODES

All specimens behaved in a linear elastic manner and failed in a brittle manner via tensile failure initiated at a knot or natural defect. Some specimens failed in shear or combined flexural and shear. One potential cause is the presence, or lack, of defects in the central third of the beam, where the bending moment is constant and at its maximum. In all cases of flexural failure, this was identified as having been initiated at a knot or natural defect in the beam. However, in all specimens that failed in shear, no visible natural defects, or knots on the tensile outer edge of the beams within the central third could be identified. This caused a shift in governing failure mode to a shear dominated failure mode, rather than flexural as initiated on the bottom tension-side fibres. While specimens without defects were not specifically chosen for this study, the beams were limited in size due to the geometrical constraints of the cold temperature freezer, whereas beams used in construction would likely be significantly greater in size, largely guaranteeing that defects would always be present.

Static normal temperature specimens consistently had more prominent crack dimensions than their cold temperature counterparts. Images of a representative failure of a specimen under static loading is shown in Figure 3. The failure in both the normal temperature and cold temperature beams, occurred at a knot or natural defect, and both exhibited a similar crack pattern.



***(a)** Global view* ***(b)** Close-up view*

***Figure 3:** Failure of static normal temperature specimen SN3*

Figure 4 and Figure 5 show still images taken from one of the high-speed cameras of specimens DN4 and DC4, respectively, immediately following failure. It can be seen that the crack pattern in the normal temperature beam is more apparent that the crack pattern in the cold temperature beam. Both dynamic specimens, when viewing the beams after testing, had similar crack propagation patterns to the statically tested specimens.

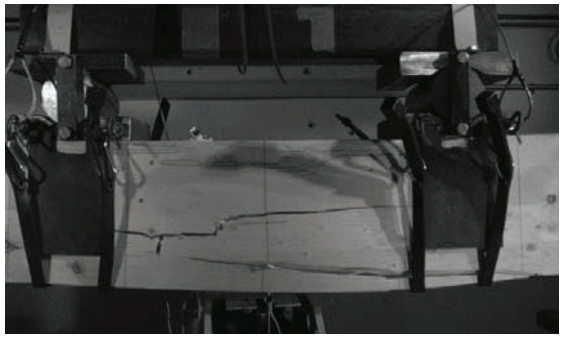


***Figure 4:** Failure of dynamic normal temperature specimen DN4*

***Figure 5:** Failure of dynamic cold temperature specimen DC4*

4 HIGH STRAIN RATE AND COLD EFFECTS

For the analysis presented below, inferences regarding the experimental test results must be limited to specimens with identical failure modes. It is for this reason that all specimens which failed in shear were not considered when determining the DIF for the resistance and stiffness. Representative resistance curves from the static and dynamic testing can be seen in Figure 6. In each resistance curve, the point at which failure occurred, based on the maximum resistance, is denoted with an 'x'. Here the trends in the data can be visually observed.

No increase in strength between the normal and cold temperature static tests is observed; however, it can be seen that the cold temperature specimens seem to experience an increase in stiffness.

The dynamic resistance curves can be seen to have more fluctuation, likely caused by dynamics of the system, or more specifically the vibrations that occur within a dynamic system, which is to be expected under impact loading. Earlier it was mentioned that 40-90% of the resistance curves were used in order to calculate the stiffness of the beams. The reasoning behind this is apparent when the curves are viewed. All dynamically tested beams exhibited a higher initial stiffness as the system settled, which was not representative of the remainder of the resistance curve. There is then a relatively constant second slope which was taken to be the beams actual response to the impact loading up until near failure. When looking at the dynamic resistance curves, it

https://doi.org/10.52202/069179-0041

can be seen that the dynamic specimens exhibited higher capacity and stiffness than their static counterparts, indicating the increase in strength and stiffness experienced by the glulam at high strain rates.

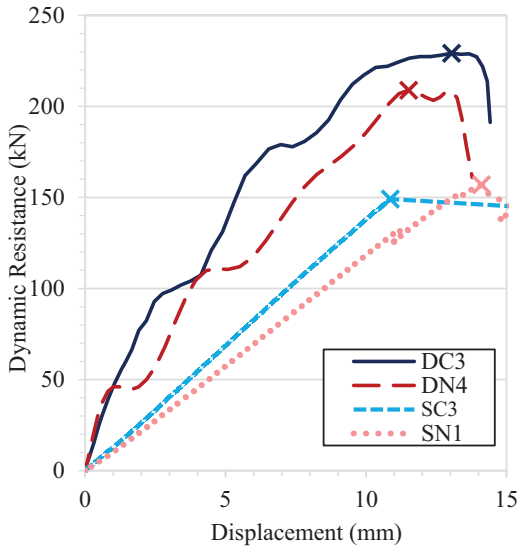

Figure 6: *Representative resistance curves*

The use of identical spans, boundary conditions, and loading conditions allowed for a direct comparison between the static and dynamic test results for the purpose of quantifying high strain-rate effects on the glulam specimens. The DIF on the peak resistance was calculated using Equation (4).

$$DIF = \frac{R_{d,max}}{R_{s,nor}} \quad (4)$$

where $R_{d,max}$ = maximum dynamic resistance and $R_{s,nor}$ = maximum static resistance normalized to a 100% strength value corresponding to a testing time of 1 minute based on Karacabeyli and Barrett [21].

The dynamic testing results, for strain rates in the range of 1.13 to 1.38 s^{-1}, revealed an increase in strength for both the ambient and cold temperature beams. For the normal temperature specimens, an average DIF of 1.23 on the normal temperature beam's peak resistance was determined when compared to the average static peak resistance. Looking at the current Canadian Blast Design Standard [1], a value of 1.4 is given, which is much higher than the value determined under normal temperature testing. For the cold temperature specimens, an average DIF of 1.37 was determined when compared to the average static cold temperature peak resistance. It is clear that high strain-rate effects are present within the cold specimens, and the preliminary results indicate that a higher DIF is attributable to cold temperature effects. A further number of tests are required to fully substantiate these effects. There is currently no stipulation for the performance of structures under cold temperatures in the current Canadian Blast Design Standard [1]. The observed DIFs can be visually seen in Figure 7, which summarises the obtained dynamic increase factors.

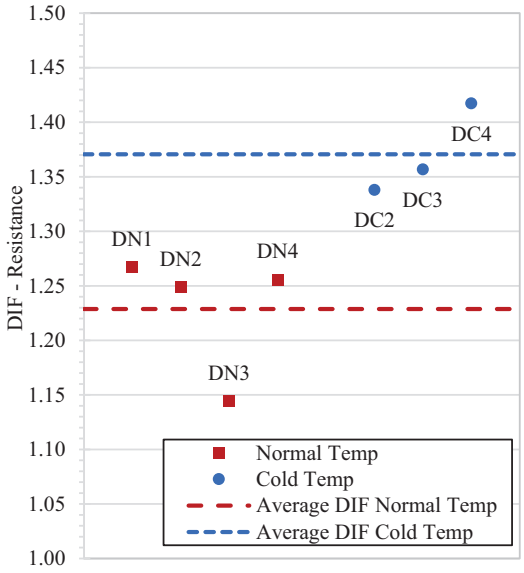

Figure 7: *Summary of observed DIFs*

Statistical analysis was done on each of these observations. It was found that the normal temperature beams dynamic to static resistance values were supported by statistical analysis using a T-Test with a 95% confidence interval. However, when looking at the cold temperature data the confidence interval that the results were statistically significant was only supported by a confidence interval of 85%. This was due to the smaller sample size, due to the omission of the specimens having failed in shear in the analysis. As such, it is recommended that further testing be done regarding the effects of cold under impact loading to further reinforce the observation that cold temperature beams under high strain rates exhibit an apparent increase in resistance when compared to their static cold temperature counterparts.

An increase in stiffness was observed when comparing the dynamic tests to their normal temperature counterparts. An average DIF on the modulus of elasticity of 1.26 and 1.24 on the beam's stiffness was determined for the normal and cold temperature specimens, respectively, when compared to their respective static tests. These observations were supported by statistical analyses by using a T-Test, with a confidence interval of 95%.

Cold temperature effects are summarized in Table 3 where cold temperature effects on the mechanical properties of glulam under static and dynamic loading were quantified.

In all cases, the normal and cold temperature values were juxtaposed against one another by comparing the static-to-static tests and dynamic-to-dynamic tests. These observations were supported by statistical analyses via T-Tests, with a confidence interval of 95%. Specifically, no cold temperature effects could be identified for the static resistance. Considering the dynamic tests, the cold temperature beams experience a 13% increase in strength compared to their normal temperature counterparts.

https://doi.org/10.52202/069179-0041

Table 3: *Effect of cold on strength and stiffness*

Comparison	Avg. Normal Temp. Value	Avg. Cold Temp. Value	Cold Factor
Static normal to cold temperature resistance (kN)	166.3	168.9	1.02
Static normal to cold temperature stiffness (kN/m)	11,670	13,850	1.19
Dynamic normal to cold temperature resistance (kN)	204.4	231.5	1.13
Dynamic normal to cold temperature stiffness (kN/m)	14,700	17,240	1.17

Previous research on clear wood found an 18% increase in bending strength at 4% moisture content on clear wood at -50 °C compared to 20 °C [24]. However, this testing was not on glulam but involved clear wood, which is void of defects and finger joints. As outlined in the above test results, the presence of defects highly influences the failure load of specimens. As such, the effects of cold temperature on the overall lignin matrix in the wood may be insignificant when compared to the effects of defects. No studies on the flexural behaviour of glulam under similar temperatures could be found.

One possible cause of this discrepancy between static and dynamic strengths amongst the cold temperature specimen is the effect of ice between the wood fibres. The ice content in the specimens from the inherent moisture content of the wood may alleviate and delay the initial growth of microcracks, resulting in a higher strength under short duration loading. When looking at the static tests, since the loading occurs under a much longer duration, microcrack growth is able to develop and not affect the beam strength over the significantly longer load duration. Additionally, the tested beams had a relatively low moisture content (on average 8.9%), which would have reduced the ice content, thereby reducing the effect that the water molecules would have on the behaviour of the glulam specimens.

In terms of initial stiffness, an apparent increase in stiffness observed in the cold temperature specimens under both static and dynamic testing when compared to their normal temperature counterparts could be observed. This observation is corroborated by previous studies, which studied different forms and types of wood at lower temperatures [16, 24-26]. This is likely due to the freezing of the water content within the beams and potentially the stiffening of the adhesive used. When looking at the static tests there was a 19% increase in stiffness observed. When looking at the dynamic tests, there was a 17% increase in stiffness observed. Both values are very close to one another, indicating a uniform increase in stiffness due to cold, regardless of the type of loading.

From a design perspective, cold temperature effects appear to improve the dynamic performance of glulam at cold temperatures. As such, if the structure is expected to remain at cold temperature for the duration of it's use and occupancy, then these potential strength increases could be considered. However, if the structure is expected to experience a wider range of temperatures, then cold temperature effects can conservatively be omitted for design purposes.

5 CONCLUSIONS

For a dynamic strain-rate range of 1.13 to 1.38 s^{-1}, a DIF of 1.23 on the maximum resistance at ambient temperatures was observed. An increase in strength of 13% in the cold temperature beams under dynamic loading was observed. The cold did not appear to influence the static resistance of the beams. Dynamic effects caused an increase in the stiffness, resulting in an average DIF on the stiffness of 1.25 for both the normal and cold temperatures beams. The cold resulted in an average stiffness increase of 18% under both static and dynamic conditions.

Further studies need to be completed to conclusively determine the effects of cold temperatures on glulam's stiffness under high strain-rate effects. Additional samples are required to confirm the results presented above. Additionally, tests at a wide variety of temperatures and cyclic temperatures should be considered. Lastly, considering specimens of other dimensions could improve the dataset and reliability of the effects reported in this study.

EXPERIMENTAL AND NUMERICAL ANALYSIS OF CLT FLOOR SUBASSEMBLIES UNDER CATENARY ACTION

Alicja C. Przystup[1], Thomas Tannert[2], Yong Lu[3], Thomas Reynolds[4]

ABSTRACT: Behaviour under combined axial tension and out-of-plane bending, typically observed in catenary action after loss of a support, was investigated on Cross Laminated Timber (CLT) floors. Uni-axial tension tests as well as combined tension and bending tests on CLT component and floor subassembly levels with screw butt joints and varying boundary conditions were performed. Bending moment capacity was shown to decrease with increasing of horizontal tension on the connection. Combined loading failure envelope was developed to observe a correlation between the test results of different scale, showing the potential of using component tests as predictors of the behaviour of more complex subassemblies.

KEYWORDS: Robustness, disproportionate collapse, progressive collapse, catenary action, combined loading

1 INTRODUCTION

1.1 Background

Robustness of large-scale mass timber buildings has become an important design consideration with their rise in scale and popularity [1]. The current tallest timber building is over 86m in height [2], and timber is increasingly widespread in multi-storey buildings. Ensuring that localised accidental damage will not result in disproportionate and progressive collapse is a vital design step that could save lives [3]. Eurocode robustness [4] design guidance is material independent. Since this objective-based approach is based on research conducted before mass timber was a commonly used construction material, research is required to provide design parameters and to ensure that the Eurocode framework can be reliably applied to mass timber. This need for more research and new comprehensive design guidance has been recognised by researchers and industry alike [5,6].

1.2 Catenary action in mass timber

One of the primary load resistance mechanisms after the loss of a load-bearing member is catenary action, which allows for redistribution of load in the structure [7] as visualised in Figure 1. It is also the main load redistribution mechanism allowed for in Eurocode 1 [4], which provides formulas for horizontal and vertical tie forces required for catenary to form. Under catenary action, the floors are subjected to combined bending and tension and therefore understanding of the effect of such combined loading on mass timber connections is instrumental for effective modelling and performance-based design. To date some early experimental work has been performed at a substructure level [8,9], but empirical data is lacking on the behaviour of variety of connections and types of engineered wood products used in practice.

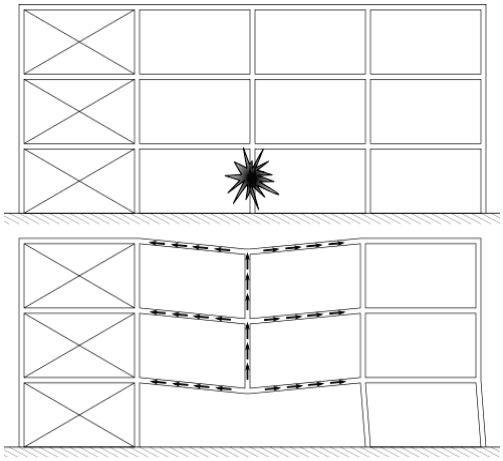

Figure 1: *Catenary action after compressive element loss*

1.3 Objective

The goal of the project presented in this paper was to apply a combined axial load and bending test method on substructures and components of mass timber floor systems that produces data to model the redistribution of forces in various substructure configurations. This correlation observed between the different scales of test results show that there is possibility for the component tests to be good predictors of the behaviour of the more complex subassemblies.

2 MATERIALS AND METHODS

2.1 Combined loading

The experiments were designed to investigate the influence of the applied tensile force on rotational stiffness, ultimate strength, and maximum angle of rotation of the floor panel-to-panel connection. A test method adequate for this purpose is one that can be replicated for multiple types of connections; therefore, it ought to be easily repeatable and cost effective. Since full-span set-ups might not be necessary to isolate the connection behaviour, a component test was proposed alongside full-span floor tests to investigate influence of specimen size. The free body diagram shown in Figure 2 allowed for conversion of the pushdown force P, applied tension at supports T, and displacement u data into moment M (Equation 1) and rotation θ. This allowed for direct comparison of the connection behaviour independently of scale.

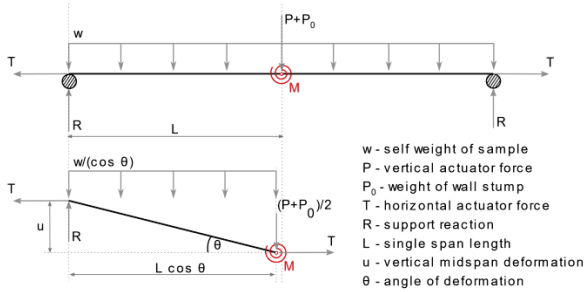

Figure 2 *Free body diagram of the tests*

$$M = \frac{P \cdot L\cos\theta}{2} + \frac{P_0 \cdot L\cos\theta}{2} + \frac{\omega \cdot L^2 \cos\theta}{2} - T \cdot u \qquad (1)$$

This calculated bending moment resistance of the connection in case of a butt joint will come from the moment couple forming between the compressive force forming at the top face and tension in the screws (Figure 3), which can be calculated as per Equation 2.

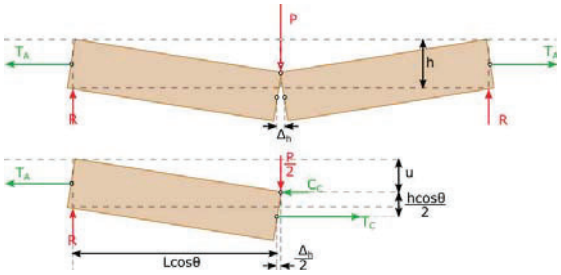

Figure 3: *Free body diagram showing the resultant connection forces dependant on component geometry*

$$T_c = P \cdot \frac{L}{h} + T_A \cdot \left(1 - \frac{2u}{h}\right) \qquad (2)$$

2.2 Materials

The CLT panels used were 5-ply 100 mm thick Binderholz BBS 125 of 20-20-20-20-20 mm layer thickness and 10% moisture content. SWG fully threaded self-tapping screws (STS) ϕ8 mm x 140 mm installed at 45° angle were used to make a butt connection, as shown in Figure 4. The full-scale test specimens had a width d = 600 mm and either 4 or 6 screws with spacings of a = 130 mm, b = 260 mm and c = 110 mm; the tension as well as component specimens had the width of d = 400 mm and spacings a = 110 mm, b = 100 mm and c = 90 mm.

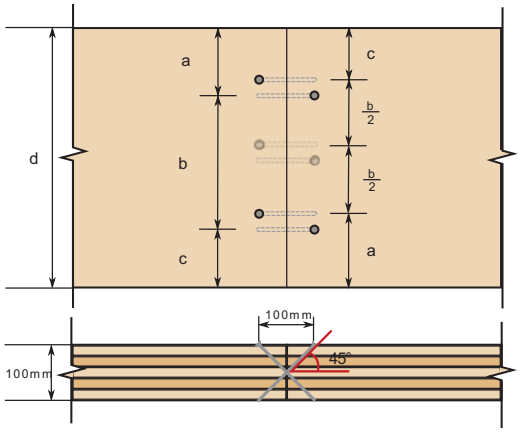

Figure 4: *Butt-joint connection design*

2.3 Axial tension tests

The horizontal force and stiffness of the connection is instrumental in dictating the force-displacement behaviour, the ultimate strength and deformation of the catenary substructure. It is therefore necessary to measure the mechanical behaviour of the connection under pure axial loading. To eliminate any bending effects of gravity loading, an upright configuration was chosen (Figure 5). The samples were attached with 6 tight-fit 15 mm diameter steel dowels on each side to minimise the slack in the system. Displacement was measured by two potentiometers installed on either side of the connection. The connections design was the same as in the component tests and therefore tension test results were also used as the equivalent of the combined test loads under maximum utilisation of tension (100% T).

Figure 5 *Axial tension test experimental setup*

https://doi.org/10.52202/069179-0042

2.4 Component tests

The component tests (Figure 6) were performed on the same test set-up as the full-span tests (Figure 7), but with the wall supports moved inwards to create the desired shorter span. The aim of the component tests was to gather information on the influence of tension level on the moment rotation behaviour and ultimate limit state values; therefore, the test series were designed in even increments of tension utilisation from 0%-75% (Table 2). These utilisation ratios were based on the average ultimate strength obtained from the axial tension tests. Together with the axial tension tests this allows for investigating of the changes in mechanical bending properties depending on the tensile utilisation ratio.

Figure 6: *Component test experimental setup*

Table 1: *Connection utilisation ratios in component tests*

Series	Tension utilisation	Tension (kN)	#STS
C1-B-0	0%	0.00	4
C1-B-25	25%	7.96	4
C1-B-50	50%	15.91	4
C1-B-75	75%	23.87	4

2.5 Full-span tests

The full-span pushdown tests were performed in 3-point bending on two butt-jointed panels with an effective length (midspan to support) of 3000 mm, see Figure 6. Four vertical string pots on either side were placed at 1 m increments and two additional string pots at the underside of the connection to monitor the joint opening.

The first full-span floor specimens were tested in a simply supported arrangement. This was used to verify whether moment rotation behaviour of the connection remained the same in such larger subassemblies as the component tests. Later specimens were tested using a variety of wall details and support conditions.

The problem with comparing tests of different spans while section size and connection design remain unchanged is the increase in relevance of the compressive arching, as it is directly proportional to the section depth to span ratio. To mitigate that issue, the tension was applied utilising chains rather than fixing the support to another member or directly to the strong wall, while the sample rested above steel rollers. That way, there was no horizontal compressive reaction possible aside from friction from the rollers which can be assumed to be negligible. Therefore, in this setup compressive arching was largely eliminated. The load was applied by two actuators, one vertically at midspan for pushdown and one installed horizontally on one end of the assembly for axial load application.

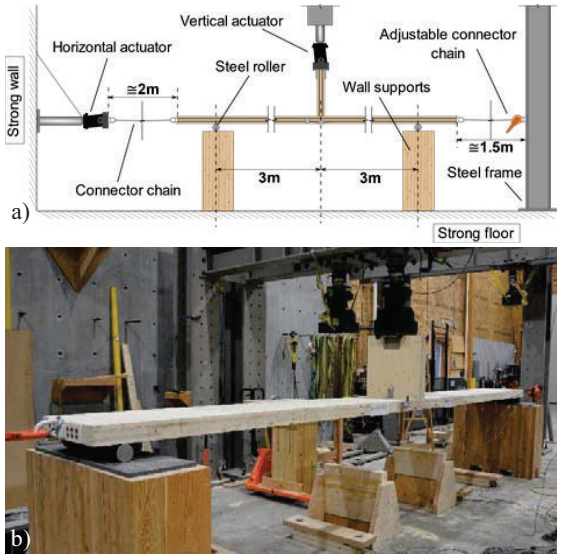

Figure 7 *Full-span test setup: a) schematic, b) photo*

Five variables were changed across the test series, summarised in Table 2. The first is the point of load application through the wall stump which either done by placing the wall loosely on top (*loose)* or attaching the load with one pair of Simpson ABR105 CLT angle bracket angle brackets installed on both sides close to the centre (*anchored)*. The second parameter was the support condition which was either simple *pin* or simulated double continuous span behaviour through restraining the overhang (*restrained)*. The tests had either 6, 4 or no screws (*#STS*). The series with no screws relied solely on the angle brackets (S5-N-P-L-15) and was performed as a control of the remainder of the tests using that connection alongside the butt joint.

Table 2: *Test series overview in full-span tests*

Series	Load	Support	T (kN)	STS
S1-B-P-L-15	Loose	Pin	15	6

3 RESULTS AND DISCUSSION

3.1 Axial tension tests

The axial tension test results are shown in Figure 8. An initial high-stiffness elastic region is followed by a peak and a softening branch. The mean value of the maximum force is 31.8 kN from the four tests. After around 6 mm displacement, the load reached a plateau, in most cases, at approximately 15 kN, until failure.

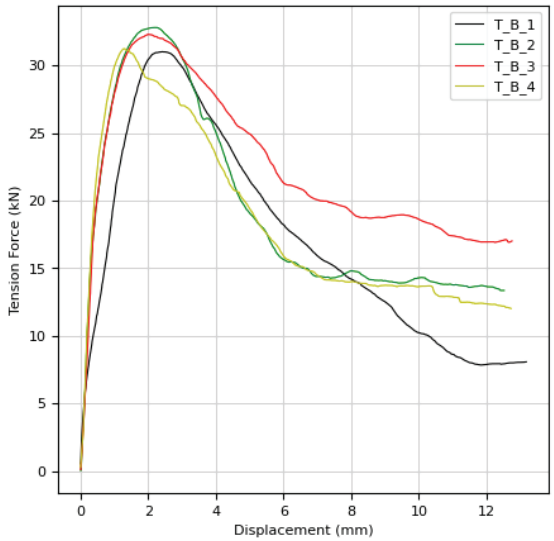

Figure 8: *Axial force displacement curves*

The initial stiffness k_0, maximum tension force T_{max}, and its corresponding deformation U_{Tmax} as well as the deformation at 50% load drop-off U_{T50} are summarised in Table 3. The latter is presented to investigate the extreme deformation behaviour which was relatively plastic. The long plateau of plastic behaviour after the initial drop-off past peak value could potentially allow for sufficient deformation to decrease tensile demand. However, the rapid loss of stiffness would lead to accelerations in the system and further release of kinetic energy. This would likely negate the initial benefits from this type of deformation and still result in connection failure.

Table 3 *Axial force test results summary*

Specimen	k_0 (kN/mm)	T_{max} (kN)	U_{Tmax} (mm)	U_{T50} (mm)

mean	8.998	31.83	4.46	12.09
CoV	4%	2%	9%	34%

3.2 Component tests

The maximum force, displacement, moment and rotation of the component-level tests are summarized in Table 4. In Figure 9, the force displacement behaviour of one specimen from each series is plotted to illustrate the main variabilities. The maximum vertical force resistance as well as maximum rotation initially increase between series C1-B-0 and C1-B-25, with one of the latter samples not failing fully after reaching the maximum actuator stroke (Figure 11a). This demonstrates activation of the catenary action. The benefit of the tensile force to the overall strength in comparison to the bending only series is also clearly visible in the C1-B-50, however with a relatively lower deformation capacity from C-B-25. The last test series with 75% tension utilisation ratio had vertical force resistance comparable to the bending only samples, but with a much higher variability.

Table 4: *Component test results summary*

Series	P_{max} (kN)	U_{max} (mm)	M_{max} (kNmm)	θ_{max} (rad)	Fracture (y/n)
C1-B-0	4.10	55.2	1668	0.028	y
	4.10	62.3	1668	0.026	y
	4.03	95.2	1640	0.028	y
	3.58	249.6	1461	0.026	y
C1-B-25	10.90	476.0	1779	0.442	n
	5.91	241.4	1336	0.035	y
	3.71	133.7	1349	0.036	y

	5.41	270.7	960	0.074	y

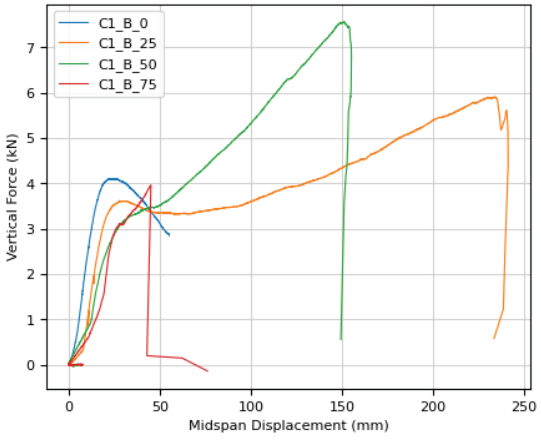

Figure 9: *Component test force displacement curves*

The maximum moment capacity of the connection, which can be observed as the peak values in Figure 10, drops proportionally to the level of tension applied to the connection. It can also be observed that the specimens loaded to the middle range of force between 25-50% performed best both in maximum deformation and

maximum force. However, all the tests reached their maximum moment at the same rotation of approximately 0.04 rad. Any further increase in vertical force resistance for the C1-B-25 and C1-B-50 samples occur directly from catenary action activation, which is only possible through the post-failure plastic plateau.

Failure of the screws in the component tests was observed in two different modes. Screws failed in withdrawal, with some having punched through the material from the headed side of the screw (Figure 11b). In either scenario material in the traverse layers of the panels was pulled due to the tension perpendicular to the grain. Some of that failure was shown to split all the way to the edge of the sample, indicating that a higher edge spacing and therefore more material to distribute the localised stresses could have a positive impact on the overall strength of that connection.

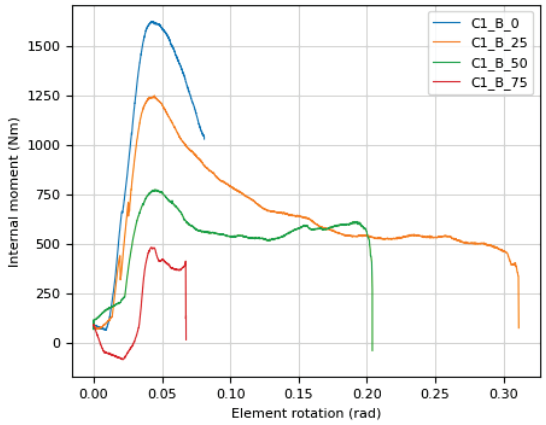

Figure 10: *Component test moment rotation curves*

Figure 11: *Butt joint component tested to maximum stroke (a) and to failure (b)*

3.3 Full span tests

Maximum force, displacement, moment, and rotation values recorded for each test are summarized in Table 5. One of the challenges of full-span testing was the relatively low vertical stroke to span ratio, which led to some of the samples not failing throughout the duration of the test (greyed out fields), meaning that their maximum values will likely be larger than the tabulated data shown.

Table 5: *Full span test results summary*

The shape of the load displacement curve is strongly influenced by the way in which the axial tension is applied, which confirms that the catenary action is the primary load resistance mechanism. For instance, in the test series where tension was increasing along with pushdown through fixed horizontal displacement (S4 and S6), the support stiffness of the system increased

https://doi.org/10.52202/069179-0042

throughout the test (Figure 12). The maximum tension values at supports for these test series are shown in **Error! Not a valid bookmark self-reference.**. The presence of angle brackets connecting the wall stub to the floor panels did not have a great influence on the maximum tension capacity; however, it did allow for a greater deformation which positively affects the overall force capacity presented in Figure 12.

Table 6: *Maximum tension in the fixed horizontal displacement tests*

	T_{max}	U_{Tmax}

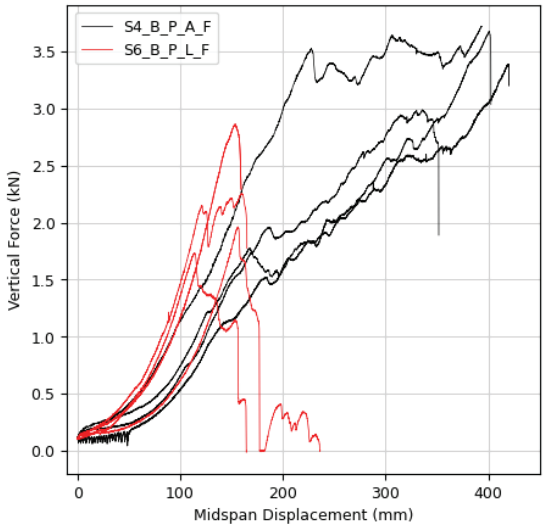

Figure 12: *Fixed displacement tests force displacement curves*

The effect of the additional brackets in samples S3-B-P-A in the load hold is less apparent, showing almost exactly the same behaviour as their S1 counterparts under the same 15 kN loading, see Figure 13. This is because due to the load control nature of the loading even a small drop-off in tensile force will lead to the actuator rapidly increasing the rate of displacement and therefore causing immediate failure. The caveat of such tests is if the connection does in fact have some remaining strength after that initial peak, but reduced stiffness, this will allow for greater deformation and therefore decreased tension demand, allowing to potentially achieve load equilibrium once again. However, the majority of timber connections being relatively brittle do not in fact have a large enough residual strength to be able to accommodate the resulting kinetic effect. Moreover, with the large variability of timber, especially in the region close to failure, it would not be safe to rely on this behaviour past the peak strength as a robustness design feature.

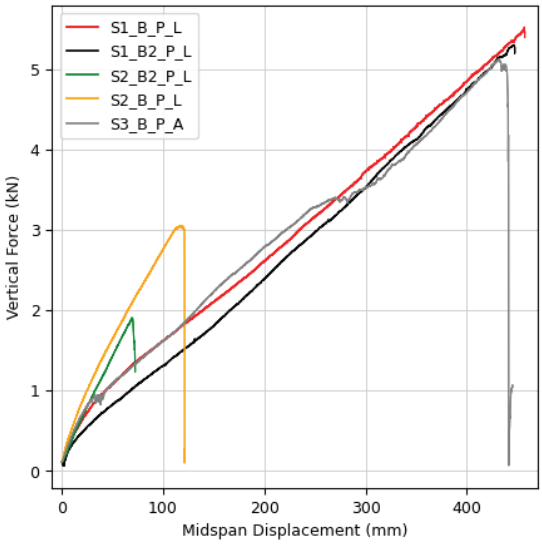

Figure 13: *Selected axial load hold tests force displacement curves*

Results of the test series which were tested over roller supports and in the horizontal tension load hold are presented in Figure 14. The stiffness of the system is again largely governed here by the tension and therefore the test series S2_B and S2_B2 which are under 30 kN horizontal load hold are visibly stiffer in comparison to the S1_B, S1_B2 and S3_B which were loaded with 15 kN. Notably, the number of screws (S1_B and S2_B with 6 screws total and S1_B2 and S2_B2 with 4 screws total) nor the presence of the wall bracket connection did not visibly affect the stiffness. Both the wall brackets and the extra pair of screw did have a positive effect on the ultimate load and moment capacity and maximum deformation/rotation as seen in Table 5.

The samples that have been tested to full failure, just as in the component tests, were observed to have failed in screw withdrawal, see Figure 14a. Most of them did not however have the layer split travel to the edge of the sample, which could be due to the extra 20 mm edge spacing. Connections in both full-scale and component tests were designed well within the minimum spacing, therefore when designing for large deformations, the guidance made for connections for the elastic limit might not apply in the same way.

Samples with the continuous span have produced the highest vertical force resistance of 14-18 kN, with more than 3x higher resistance than the catenary action. The failure mode of these samples was initially rolling shear in the traverse layers and eventually tensile splitting of the uppermost layer (Figure 14b). The test was stopped after this first load drop off due to the panel failure and before the ultimate failure of the connection due to safety concerns. The maximum moment exhibited by the

connection was on average lower than but approaching the values in series S1-B2 of the equivalent connection properties and magnitude of tension applied. This explains lack of connection failure but also implies that it was imminent, and the overall force capacity of the system was unlikely to rise back up above the initial peak.

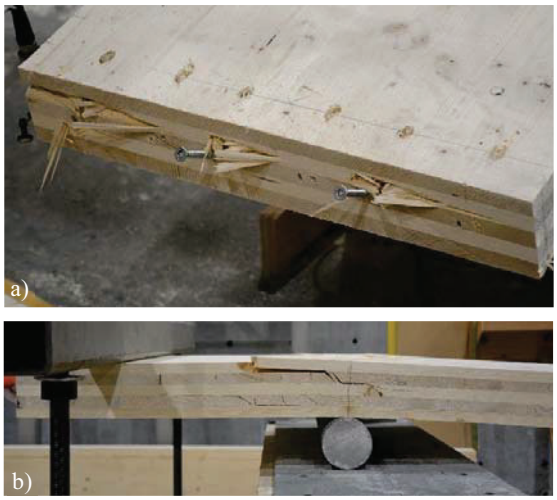

Figure 14: *Failure of the connection in test series S1 (a) and over the support in test series S6 (b)*

3.4 Combined analysis

Internal connection tension forces in selected component tests derived from equilibrium of forces as per Eq.2 are shown in Figure 15. In essence the tension present in the connection is a combination of the moment couple present from the opening of the joint and the tension resultant from catenary forces.

Although this was similarly visible in the component tests, several differences can be observed between tension displacement behaviour when comparing to the uniaxially loaded specimen illustrated in Figure 9. This was due to the slight changes in the failure modes, as the bent screws redistributed internal loads differently based on the angle of deformation. The ultimate strength however remained consistent across all samples, which means that despite different bi-axial load combinations this can be the reliable parameter for failure checks.

Results of the pin-support tests under constant tension have been summarised as a failure envelope for combined tension and bending in Figure 16. Each datapoint represents the maximum moment experienced by the sample and the corresponding tension utilisation value based on the axial load tests. An extreme value distribution analysis was performed on the results from 4 specimen in each of the component test series and linear regression lines were fitted through the corresponding median values and the upper and lower bounds of the 95% confidence interval.

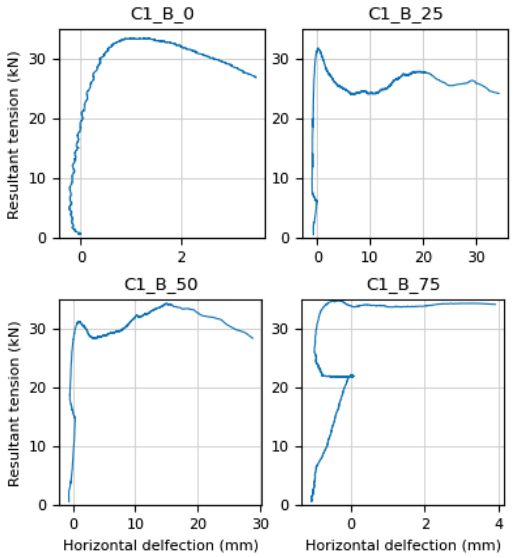

Figure 15: *Internal tension forces in component test results*

The moment capacity of both component and full span tests drops proportionally to the increased tensile utilisation. Horizontal withdrawal of the screw is the governing failure mode and both increased system tension as well as bending of the connection increase the tension resultant at the screw, therefore this relationship is numerically justified. As shown in Figure 15, the total of those two resultants reaching tensile capacity of the connection is the cause of connection failure.

The values of the full-span tests when compared to the component test data fit does fall on the higher side of the data distribution. This could be due to a multitude of factors such as data errors and the active changes in the effective span due to the horizontal travel distance of steel rollers, small changes in screw spacing and proportionally large variability of timber properties. However, they do still largely follow the same trend and are a deemed a good predictor of the large-scale behaviours.

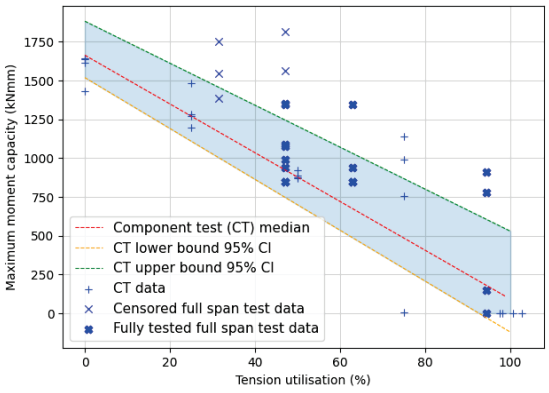

Figure 16: *Combined loading failure envelope*

https://doi.org/10.52202/069179-0042

4 CONCLUSIONS

The presented tests provide much-needed insight into the possibilities of smaller scale experiments as a base for empirical-based robustness analysis of mass timber floor systems. This correlation observed between the different scales of test results show that there is possibility for the component tests to be good predictors of the behaviour of the more complex subassemblies.

The analysis has shown that the tension increase in the system has both beneficial and compromising effects on the total force capacity on the system – the tension allows for the load redistribution to form, consequently lessening the bending capacity demand on the system, but at the same time decreases the bending capacity itself. In the tested samples the region where these two were balanced was between 25-50% of tension utilisation. However, the maximum moment capacity is consistently being reached at minimal deformations and the subsequent catenary activation occurs on a sample effectively past its failure load. Moreover, the variability of results increases drastically at the higher end of the utilisation scale meaning that relying on that behaviour is not advised.

The paper presents testing that can form the basis of future performance-based design frameworks. Still, a significant amount of research is needed to develop comprehensive, functional design guidance. Aiming for standardisation of test, modelling and design methods is essential for continuous growth of the industry and use of timber as modern construction material for years to come.

ACKNOWLEDGEMENTS

The authors acknowledge the financial support received by the Royal Society of Edinburgh Lessels Travel Scholarship. The experimental work was funded by the government of Canada through a Canada Research Chair. The support by the UNBC technicians Michael Billups, James Andal, and Ryan Stern is greatly appreciated.

UNREINFORCED AND STEEL-REINFORCED COLUMNS MADE OF EUROPEAN BEECH GLUED-LAMINATED TIMBER

Katharina Sroka [1], Pedro Palma [2], René Steiger [3], Thomas Ehrhart [4], Andrea Frangi [5], Thomas Strahm [6], Ernst Gehri [7]

ABSTRACT: With the aim of promoting the use of glued-laminated timber (GLT) made from European beech (*Fagus sylvatica* L.), experimental and numerical studies were conducted on high-strength columns for residential, office, and industrial applications. The experimental research comprised compression tests on stocky and slender unreinforced and steel-reinforced beech GLT columns of strength classes GL40h, GL48h, and GL55h. A finite element model was developed to perform parametric studies on geometrical and mechanical properties and to evaluate the load-carrying capacity across different slenderness ratios. The investigations revealed that the columns can be designed using the *effective length method*, however with adapted critical relative slenderness $\lambda_{rel,0}$ and straightness factor β_c. Corner steel reinforcement of grades ST900/1100 and ST950/1050 leads to a marked increase in the load-carrying capacity of stocky as well as slender GLT columns.

KEYWORDS: hardwood, GLT, column, buckling, compressive strength, steel-timber hybrid member

1 INTRODUCTION

Growing interest in timber high-rise buildings is creating demand for high-strength timber columns. In high-rise or industrial buildings, the required cross-sections of timber columns can become excessively large, critically limiting the available floor space or even the structural feasibility, and obstructing window views. Compared to softwood, European beech (*Fagus sylvatica* L.) glued-laminated timber (GLT) offers a high compressive strength parallel to the grain. Beech wood is widely available in Central European forests, but it is barely used for structural purposes [1] and beech GLT is not integrated in the European standards.

With the aim of using beech GLT for high-strength columns in residential, office, and industrial applications, the company *neue Holzbau AG* developed hybrid beech GLT columns reinforced with steel bars. The steel reinforcement substantially improves the load-carrying capacity and helps to overcome the buckling issues that limit the utilisation of the higher compressive strength, often making slender columns uneconomical. The steel reinforcement offers additional advantages by enabling an increased ductility of the columns, stiff connections to other elements, a ductile failure mode governed by the connections, reduced differential settlements to concrete elements in hybrid structures, and better resistance to impact loading. The glued-in steel bars can also be used to increase structural robustness by allowing floor-to-column and column-to-column connections to carry tensile forces and hold the floor below in case a column fails [2]. A similar strategy was implemented using glued-in steel rods as vertical ties in the HoHo building in Vienna [3].

Full-scale experiments and numerical simulations were conducted to investigate the axial load-carrying capacity of unreinforced and steel-reinforced columns with different slenderness ratios. Key factors influencing the load-carrying capacity were identified from parametric studies. A design model that can be easily adopted in engineering practice was developed.

The objective was to enhance the understanding of the buckling behaviour of these high-strength columns and to demonstrate their application potential.

2 EXPERIMENTS

2.1 MATERIALS

2.1.1 Hardwood GLT

Swiss-grown European beech boards were used for the production of the GLT columns. The boards were strength graded into tensile strength classes T33 (for GL40h), T42 (for GL48h), and T50 (for GL55h), applying the strength grading rules described by Ehrhart et al. [4]. The laminations were bonded using a 1-comp. PU adhesive and a primer [5]. The lamination thickness was 25 mm and the wood moisture content was $\omega = 8 \pm 2\%$ representing the climatic conditions of indoor use.

2.1.2 Reinforcement

The steel reinforcement bars placed either in the centre or in the four corners of the cross-section (Figure 1) were profiled Swiss-GEWI bars of grade ST900/1100 for diameters below 29 mm, and of grade ST950/1050 for diameters greater than 29 mm. The steel grades were chosen from products available on the market. To avoid preliminary yielding of the reinforcement, the yield strength of steel was chosen based on Formula (1).

$$\frac{f_y}{E_s} > \frac{f_{c,0,05}}{E_{c,0,05}} \therefore f_y > \frac{62.5 \cdot 210\,000}{15\,400} \approx 850 \text{ MPa} \qquad (1)$$

where f_y = yield strength of steel, E_s = modulus of elasticity of steel, $f_{c,0,05}$ = 5th percentile value of the compressive strength parallel to the grain for GL48h made of beech, and $E_{c,0,05}$ = 5th percentile value of the compressive modulus of elasticity parallel to the grain for GL48h made of beech. 5th percentile values for GL48h columns with a square cross-section and side length of 200 mm were reported by Ehrhart et al. [6, 7].

To insert the steel reinforcement, the GLT specimens were cut lengthwise at the designated position of each steel bar. Lengthwise notches for the steel bars were milled into the GLT pieces which were then block glued under pressure, using a 1-comp. PU adhesive with primer. Finally, the steel bars were inserted into the notches which were filled using an epoxy adhesive.

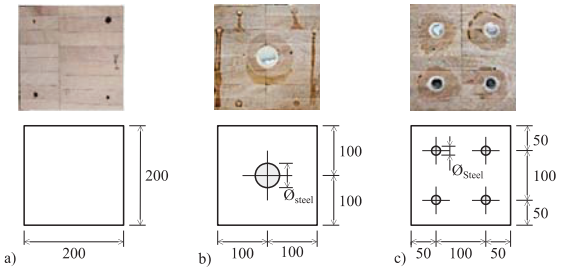

***Figure 1**: Unreinforced (a) and reinforced cross-sections using one central rebar (b) or four corner rebars (c).*

2.2 COMPRESSION TESTS ON STOCKY COLUMNS

2.2.1 Test configurations

Compression tests on 1200 mm long stocky columns were carried out to evaluate the axial compressive strength of unreinforced and steel-reinforced European beech GLT (Table 1). Due to the support conditions prescribed by EN 408 [8] (loading heads locked against rotation during the test), the effective length was $L_{eff} \approx 0.6\ L$ [9]. The tests on unreinforced beech GLT columns were performed by Ehrhart et al. [6, 7]. For the steel-reinforced columns, different arrangements (diameter $Ø_{steel}$ and number of bars n_{rebars}) and degrees (ρ) of steel reinforcement were investigated to optimise the axial load-carrying and deformation capacities, while considering the increase in production effort.

***Table 1:** Compression test specimens (square side length a = 200 mm, L_{eff} = 720 mm).*

Strength class [-]	$Ø_{steel}$ [mm]	n_{rebars} [#]	ρ [%]	$n_{specimens}$ [#]
GL40h	-	-	-	7
GL48h	-	-	-	7
GL55h	-	-	-	7
GL55h	30	1	1.77	3
	40	1	3.14	3
	15	4	1.77	3
	20	4	3.14	3

2.2.2 Test results

During the compression tests on the stocky columns, no horizontal displacement was observed before failure. Crushing of the fibres initially occurred close to local imperfections (i.e. knots, finger joints, deviations in the direction of wood fibres) and finally progressed over the whole cross-section, followed by splitting. Sample force-displacement curves of individual specimens are shown in Figure 2.

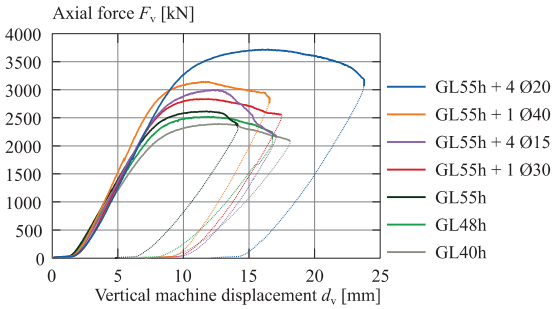

***Figure 2**: Sample axial force-displacement curves obtained for individual specimens in the compression tests on stocky columns.*

The steel reinforcement bars increased the compressive strength and the modulus of elasticity parallel to the grain of the beech GLT columns (Table 2). The corner reinforcement with 20 mm diameter (ρ = 3.14%) led to a particularly pronounced increase in the axial load-carrying capacity of around 40% compared to the unreinforced specimens. An equal amount of central reinforcement only led to a 20% increase, likely due to a less favourable distribution of the applied axial load into the cross-section.

In the tests on unreinforced columns, very similar mean values of compressive strength parallel to the grain $f_{c,0,mean}$ were obtained for all tested strength classes, with an increase of only 3% from GL48h to GL55h (Table 2). The stocky steel-reinforced specimens (Section 2.2) were of

https://doi.org/10.52202/069179-0043

strength class GL55h, whereas the slender steel-reinforced columns (Section 2.3) were of strength class GL48h. The results of both test series can be analysed together given the very small difference in compressive strength between GL48h and GL55h, which indicates that the strength class (GL48h or GL55h) has little influence on the axial load-carrying capacity in compression.

Table 2: *Mean experimental axial load-carrying capacity $R_{c,0,mean}$, compressive strength $f_{c,0,mean}$, and modulus of elasticity $E_{c,0,mean}$ parallel to the grain.*

Strength class [-]	$n_{specimens}$ [#]	$R_{c,0,mean}$ [kN]	$f_{c,0,mean}$ [MPa]	$E_{c,0,mean}$ [GPa]
GL40h	7	2393	60.4	15.1
GL48h	7	2526	63.8	16.0
GL55h	7	2607	65.8	17.0

GL55h + 4 Ø15	3	2985	74.6	19.0
GL55h + 4 Ø20	3	3585	89.6	23.3

2.3 BUCKLING TESTS ON SLENDER COLUMNS

2.3.1 Test configurations

Slender columns of strength class GL48h and with effective lengths of 2400 mm and 3600 mm were subjected to buckling tests. These effective lengths were chosen to represent the typical heights of columns in high-rise and industrial buildings. The planned initial eccentricity was $e_0 = L_{eff}/500$ but deviations occurred due to manufacturing inaccuracies. The tested configurations are listed in Table 3, the test setup is depicted in Figure 3. The tests on unreinforced beech GLT columns were performed by Ehrhart et al [6, 7].

Table 3: *Buckling test specimens (a = 200 mm, GL48h).*

L_{eff} [mm]	$Ø_{steel}$ [mm]	n_{rebars} [#]	$n_{specimens}$ [#]	$L_{eff}/e_{0,mean}$ [-]
2400	-	-	5	382
3600	-	-	5	590
2400	40	1	3	436
3600	40	1	3	554

3600	20	4	3	618

2.3.2 Test results

The buckling tests on slender columns focused on the reinforcement layouts with higher reinforcement ratio (1× Ø40, 4× Ø20), since these demonstrated the maximum gain in mechanical properties during the compression tests on stocky columns.

The test results are presented in Figure 4, sample load-displacement curves are shown in Figure 8. For GL48h, the central reinforcement of 40 mm diameter led to a 20% gain in the axial load-carrying capacity in columns of low to medium effective length (≤2400 mm) and to a 10% gain for long columns (3600 mm). The corner reinforcement with four rebars of 20 mm diameter and an edge distance of 50 mm led to a 40% increase in the load-carrying capacity across the investigated buckling lengths because it increases the bending stiffness of the columns.

3 NUMERICAL SIMULATIONS

3.1 FINITE ELEMENT MODEL

A framework to model unreinforced and steel-reinforced GLT columns under compressive axial loads was developed using OpenSeesPy [10], which is a Python [11] library for the OpenSees finite element framework [12]. The model considered geometric and material nonlinearity. The initial deformed shape of the discretised column followed a sinusoidal curve with user-defined initial mid-span eccentricity. Boundary conditions were defined as depicted in Figure 5. An external vertical compression force (or displacement, as chosen by the user) was applied at the upper node.

The cross-section of the column elements was modelled as a fibre section using different patches for the timber laminations and the steel reinforcement (Figure 6). The fibres in these patches were associated with the uniaxial stress-strain relationship of the corresponding material. A bilinear material without hardening was adopted for the steel fibres, while the timber fibres were assigned the nonlinear material model for European beech defined by Glos [13].

Beech GLT material properties were based on the mean experimental results for unreinforced GL48h columns

https://doi.org/10.52202/069179-0043

with a section size of 200 mm ($f_{c,0,mean}$ = 63.8 MPa; $E_{c,0,mean}$ = 16.0 GPa). The quasi-static structural analyses were performed under load control, since the aim of the simulations was to determine the load-carrying capacity of the columns.

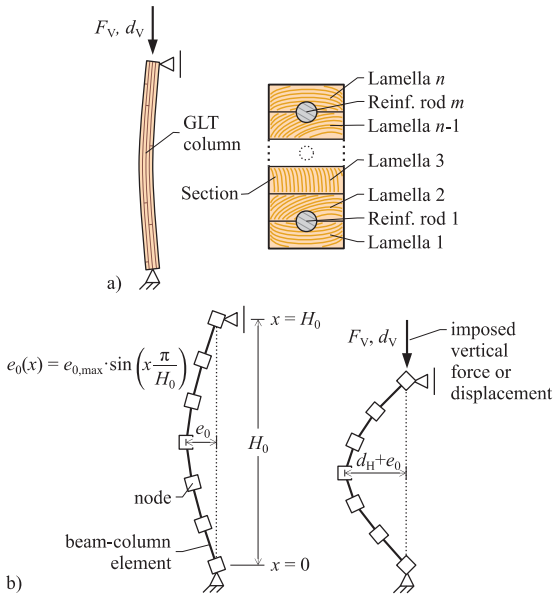

***Figure 5**: Numerical model of the GLT column: a) idealisation of the column and cross-section; b) FE model, including initial deformed shape.*

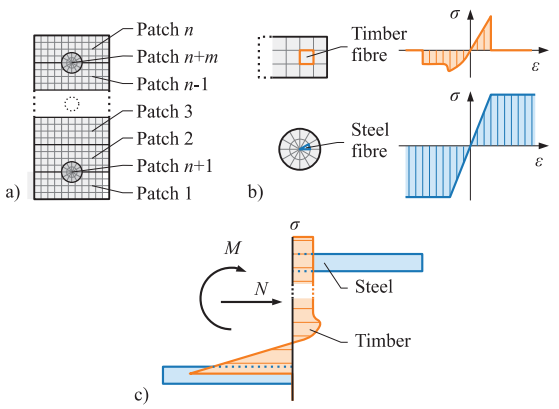

***Figure 6**: Modelling of the cross-sectional behaviour: a) fibre patches; b) uniaxial material models for timber and steel; c) stresses and internal forces in the cross-section.*

3.2 MODEL VALIDATION

The model was validated using the experimental results. A comparison between simulated and experimental load-carrying capacities is presented in Figure 7, showing a very good agreement. A small deviation occurred for the unreinforced specimens with effective length of 3600 mm. In contrast to the experimental results, the simulated load-carrying capacity of the unreinforced column was higher than that of the centrally reinforced column at high slenderness (see the orange and green data points in Figure 7 with load-carrying capacities between 1000 and 1500 kN). Since the buckling curves of unreinforced and centrally reinforced GLT columns converge for high slenderness, the impact of this deviation is negligible.

The load-displacement curves obtained from the simulations also agree well with the experimental results, as shown in Figure 8 for three exemplary specimens with effective length of 2400 mm. Since the simulations were carried out under load control, the post-peak behaviour is not captured by the numerical results.

The validation shows that the model was able to simulate the buckling behaviour of the columns and estimate the mean load-carrying capacity with adequate accuracy.

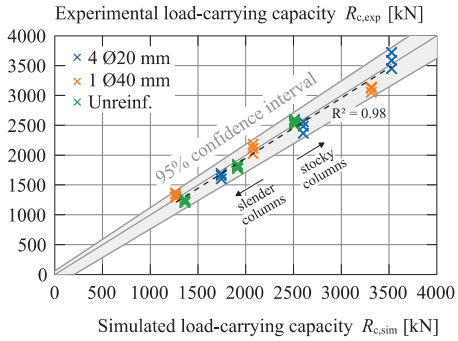

***Figure 7**: Validation of the numerical results: comparison with the experimental mean axial load-carrying capacity for each reference configuration (GL48h unreinforced, GL48h with 1× Ø40, GL48h with 4× Ø20).*

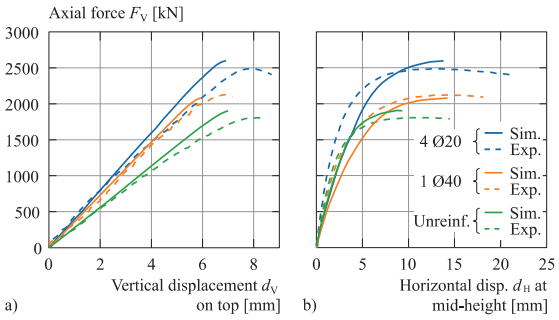

***Figure 8**: Comparison of simulated and experimental load-displacement curves for GL48h columns with L_{eff} = 2400 mm: a) vertical displacement at the top of the column; b) horizontal displacement at mid-height of the column.*

3.3 PARAMETRIC STUDIES

The objective of the numerical framework was to gain further insights into the buckling behaviour of the composite columns. First, buckling curves were generated by simulating columns of varying effective lengths around the experimental range (Figure 9). Second, parametric studies were conducted on the most important parameters identified in the experimental campaign: i) initial eccentricity ($e_0 = L_{eff}/300$, $L_{eff}/500$, and $L_{eff}/1000$); ii) diameter of the central and corner steel bars (1× Ø30, 1× Ø40, 4× Ø15, 4× Ø20, 4× Ø25); iii) size of the cross-section (a = 200, 250, and 300 mm); iv) timber strength class (GL40h, GL48h, and GL55h). Benchmarking values were $e_0 = L_{eff}/500$, a = 200 mm, and GL48h.

https://doi.org/10.52202/069179-0043

Maximum reductions in the load-carrying capacity of 13 to 17% were observed when increasing the initial eccentricity from L_{eff}/1000 to L_{eff}/300 (Figure 10). Decreasing the diameter of the central steel rod from 40 to 30 mm led to reductions of 15% for stocky columns and of less than 5% for slender columns (Figure 11). The load-carrying capacity for all investigated slenderness ratios reduced by more than 20% when changing the diameter of the four corner steel bars from 25 to 15 mm (Figure 12). The size of the cross-section has a pronounced impact on the load-carrying capacity for column lengths relevant for structural applications (Figure 13). The edge distance of 50 mm was kept constant when varying the section size of corner-reinforced columns. Figure 14 confirms that the influence of the GLT strength class is very limited.

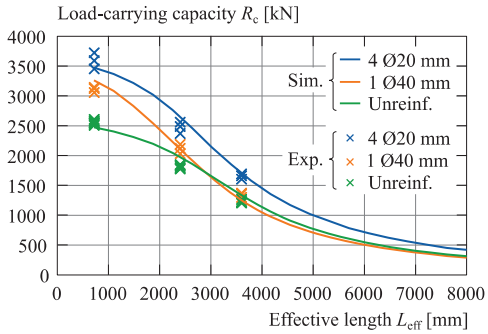

***Figure 9**: Simulated buckling curves for the three reference configurations, compared with the experimental results.*

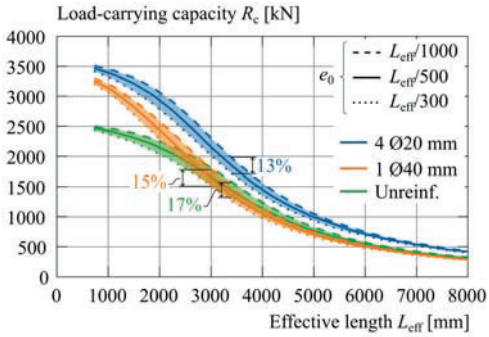

***Figure 10**: Parametric study on the impact of the initial eccentricity e_0 on the load-carrying capacity of the column.*

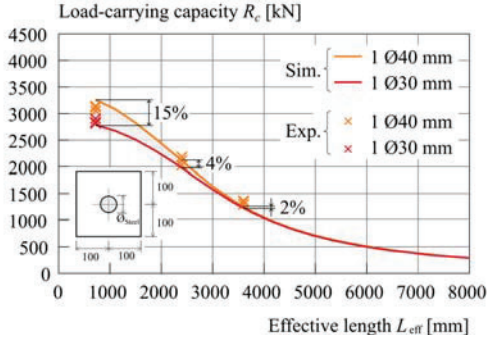

***Figure 11**: Parametric study on columns with different diameter of a single central reinforcement bar.*

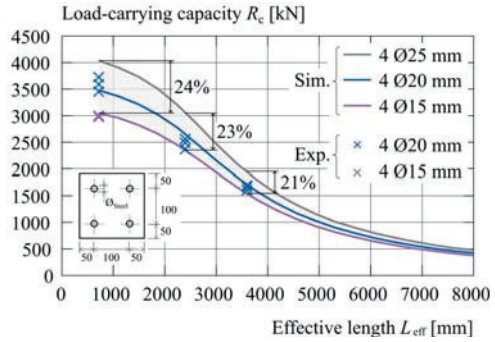

***Figure 12**: Parametric study on columns with different diameters of the four corner reinforcement bars.*

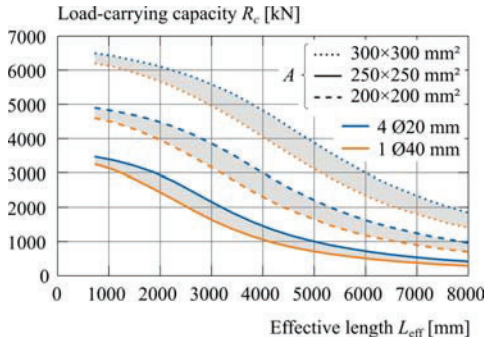

***Figure 13**: Parametric study on the impact of the cross-section size on the axial load-carrying capacity of the column.*

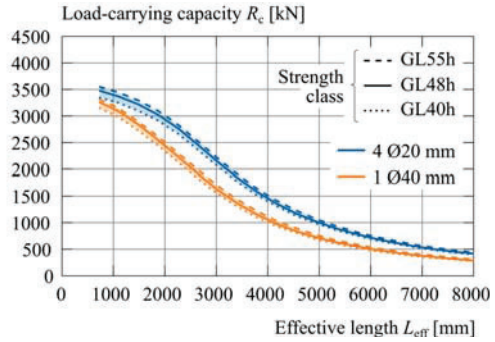

***Figure 14**: Parametric study on the impact of the GLT strength class.*

All parametric studies were carried out for effective lengths of up to 8000 mm to approximately match the range of slenderness ratios covered by buckling curves in current design standards, even though such long columns are not relevant in typical structural applications. Simulated results for these lengths were not verified by experiments and should thus be regarded with caution.

4 DESIGN MODEL

4.1 UNREINFORCED COLUMNS

The design rules in EN 1995-1-1:2004 (Eurocode 5) [14] for verifying the stability of columns subjected to axial compression are based on the *effective length method*, see Formulae (2)-(5).

https://doi.org/10.52202/069179-0043

$$R_{c,0} = k_c \cdot f_{c,0} \cdot A \tag{2}$$

$$k_c = \frac{1}{k + \sqrt{k^2 - \lambda_{rel}^2}} \tag{3}$$

$$\lambda_{rel} = \frac{L_{eff}}{\pi \sqrt{\frac{I}{A}}} \sqrt{\frac{f_{c,0,k}}{E_{0,05}}} \tag{4}$$

$$k = 0.5 \left(1 + \beta_c \left(\lambda_{rel} - \lambda_{rel,0}\right) + \lambda_{rel}^2\right) \tag{5}$$

where k_c = buckling factor, A = cross-sectional area, λ_{rel} = relative slenderness ratio, I = second moment of area, $f_{c,0,k}$ = characteristic value of the compressive strength parallel to the grain, $E_{0,05}$ = 5th percentile value of the modulus of elasticity parallel to the grain, β_c = straightness factor or imperfection coefficient, and $\lambda_{rel,0}$ = critical relative slenderness ratio. Both β_c and $\lambda_{rel,0}$ are material-dependent. The straightness factor β_c describes the steepness of the buckling curve while the critical relative slenderness $\lambda_{rel,0}$ defines the threshold relative slenderness above which buckling should be taken into account.

The experiments on unreinforced slender columns [6, 7], accompanied by the numerical investigations showed that the design parameters $\lambda_{rel,0} = 0.30$ and $\beta_c = 0.10$ currently specified for softwood GLT in Eurocode 5 [14] lead to an overestimation of the axial load-carrying capacity of up to 18% (L_{eff} = 2400 mm) in the case of unreinforced beech GLT columns. This deviation arises because the ratio between the compressive strength and modulus of elasticity parallel to the grain is higher for beech (1/250) [15, 16] than for softwood (1/370 to 1/420) GLT [17].

Ehrhart et al. [7] found a low scatter in compressive strength and modulus of elasticity parallel to the grain, based on tests on stocky columns according to EN 408 [8]. Values on a similar level were also reported by Westermayr et al. [16].

The calibration of buckling curves was conducted on the mean level of the material properties, including only results from test specimens of strength class GL48h. Mean values $f_{c,0,mean}$ = 60.6 MPa and $E_{c,0,mean}$ = 15.7 GPa were used, based on a more comprehensive set of test specimens with varying cross-section sizes [7]. The critical relative slenderness $\lambda_{rel,0}$ was determined based on the effective length of the stocky specimens. The straightness factor β_c was calibrated to the experimental data. A critical relative slenderness ratio of $\lambda_{rel,0} = 0.25$ and a straightness factor of $\beta_c = 0.25$ are proposed to ensure that the *effective length method* can be applied to verify the stability of beech GLT columns of strength classes GL40h, GL48h, and GL55h [7].

Figure 15 shows the load-carrying capacity as a function of the effective length according to the current and proposed buckling curves, along with the experimental and numerical results for unreinforced beech GLT of strength class GL48h.

4.2 STEEL-REINFORCED COLUMNS

At the same reinforcement ratio, corner reinforcement was shown to be much more effective in improving the mechanical properties of GLT columns than a single central rebar. Despite the more complex manufacturing process, four steel bars placed in the corners of the section are preferable for an economic design in demanding applications. A design approach was thus developed only for the corner reinforcement with four rebars of 20 mm diameter and 50 mm edge distance.

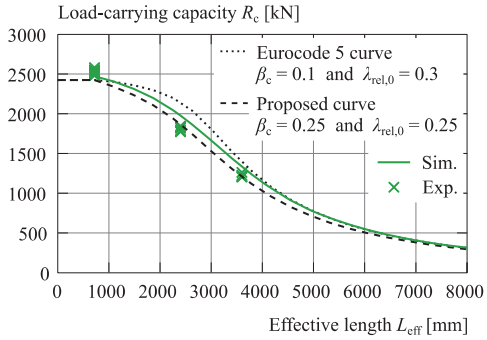

***Figure 15**: Comparison of current Eurocode 5 and proposed buckling curves for unreinforced European beech GLT columns of strength class GL48h, along with the experimental and numerical results [7].*

The *effective length method* cannot be applied directly to composite sections because the load is distributed across the materials in proportion to their stiffness. An equivalent unreinforced GLT section can be determined using Formulae (6)-(8). The method is valid for rigid (i.e. glued) composite sections and assumes direct load transfer to the cross-section at the supports without any load redistribution within the section. The steel has a reinforcing function and should not yield before the timber fails.

$$n = \frac{E_s}{E_{c,0,mean}} \tag{6}$$

$$A_c = A_{GLT} + (n - 1) \cdot A_s \tag{7}$$

$$I_c = I_{GLT} + (n - 1) \cdot I_s \tag{8}$$

where n = scaling factor to account for stiffness variation, A_c = cross-sectional area of an equivalent timber section, A_{GLT} = gross cross-sectional area of the timber (including the holes for the steel bars), A_s = cross-sectional area of the steel, I_c = second moment of area of an equivalent timber section, I_{GLT} = gross second moment of area of the timber (including the holes for the steel bars), and I_s = second moment of area of the steel cross-section.

The *effective length method* (Formulae (2)-(5)) can be adapted for composite sections as given in Formulae (9)-(10). As for unreinforced beech GLT, the buckling curve was calibrated based on the mean experimental results for GL48h, i.e. $f_{c,0,mean}$ = 60.6 MPa and $E_{c,0,mean}$ = 15.7 GPa [7].

$$\lambda_{rel} = \frac{L_{eff}}{\pi \sqrt{\frac{I_c}{A_c}}} \sqrt{\frac{f_{c,0,mean}}{E_{c,0,mean}}} \tag{9}$$

$$R_{c,0} = k_c \cdot f_{c,0,mean} \cdot A_c \tag{10}$$

https://doi.org/10.52202/069179-0043

A design based on the parameters currently specified by Eurocode 5 leads to an overestimation of the experimental buckling resistance by up to 20% (L_{eff} = 2400 mm) in the case of the corner-reinforced beech GLT columns, as shown in Figure 16. The same figure shows the buckling curve fitted for corner-reinforced European beech of strength class GL48h with four ST900/1100 rebars of 20 mm diameter and 50 mm edge distance. A least squares fitting to the experimental data points resulted in a straightness factor $\beta_c = 0.255$ and a critical relative slenderness ratio $\lambda_{rel,0} = 0.261$. Since the deviation from the buckling curve proposed for unreinforced European beech GLT is small, the same curve ($\beta_c = 0.25$ and $\lambda_{rel,0} = 0.25$) is proposed for corner-reinforced beech GLT. The resulting curve of the proposed buckling factor k_c is given in Figure 17.

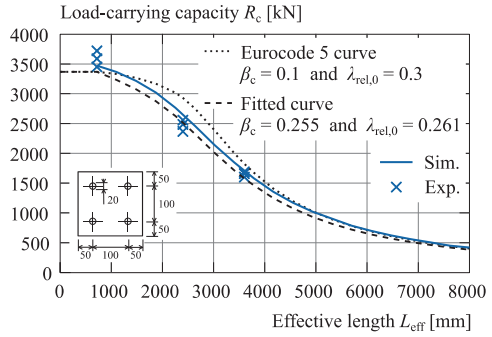

***Figure 16**: Comparison of current Eurocode 5 and fitted buckling curves for corner-reinforced beech GLT columns of strength class GL48h, along with the experimental and numerical results.*

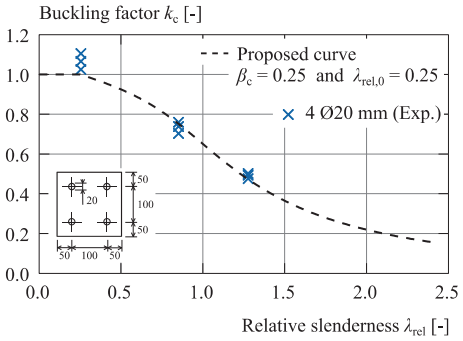

***Figure 17**: Proposed buckling curve for corner-reinforced beech GLT columns of 200×200 mm² and strength class GL48h with four ST900/1100 rebars of 20 mm diameter and 50 mm edge distance, along with the experimental results.*

5 CONCLUSIONS

The full-scale experiments on unreinforced and steel-reinforced European beech GLT columns revealed their immense potential for application in highly demanding residential, office, and industrial projects.

Material properties of European beech GLT were identified from the experiments on unreinforced columns. Different layouts of steel reinforcement were investigated in compression and buckling tests. A finite-element model was developed and shown to reliably predict the buckling behaviour of these high-strength columns and parametric studies were performed to investigate the main factors influencing their load-carrying capacity. The ultimate failure load was found to be mainly dependent on the column slenderness, the arrangement and diameter of the steel bars, the section size, and the initial deformed shape (eccentricity e_0). The strength class (GL40h, GL48h, or GL55h) was found to have very little impact.

The steel reinforcement using profiled Swiss-GEWI bars of grades ST900/1100 and ST950/1050 led to an increase of both the compressive strength and the modulus of elasticity parallel to the grain of European beech GLT. A central ST950/1050 rebar of 40 mm diameter was found to increase the load-carrying capacity of beech GLT columns by 20% for low ($\lambda_{rel} < 0.5$) to medium ($\lambda_{rel} \approx 1.0$) slenderness and by 10% for slender columns ($\lambda_{rel} \approx 1.5$).

At the same reinforcement ratio, corner reinforcement (four bars of 20 mm diameter, 50 mm edge distance, and grade ST900/1100) offers a much more pronounced gain of about 40% in the load-carrying capacity across all slenderness ratios relevant in structural applications. This is because the eccentric arrangement contributes to the bending stiffness of the column. Though requiring more manufacturing steps, corner reinforcement thus enables highly demanding structures such as high-rise buildings to be built using timber columns while avoiding excessively large cross-section sizes that reduce available floor space and obstruct window views. Sufficient timber cover must be provided for all steel bars to ensure fire safety and prevent buckling of the steel bars.

Current Eurocode 5 [14] design parameters were found to overestimate the load-carrying capacity of both unreinforced and reinforced beech GLT columns. Based on the experimental and numerical results, the *effective length method* as applied by Eurocode 5 was adapted for beech GLT. Proposed design parameters are $\lambda_{rel,0} = 0.25$ and $\beta_c = 0.25$ for both unreinforced and corner-reinforced European beech GLT columns. The buckling curve for corner-reinforced beech GLT was developed for square cross-sections of 200 mm width and strength class GL48h, reinforced with four ST900/1100 bars of 20 mm diameter, which were placed in the corners of the section with an edge distance of 50 mm.

Further experimental investigations and numerical simulations with probabilistic material modelling should be carried out to verify the presented findings while taking into account the variability of the mechanical properties. Research into the manufacturing process of corner-reinforced GLT could reduce its complexity and increase the economic viability of reinforced GLT columns, which offer a huge potential regarding moment resisting and tension connections, thereby enabling a reduction of the effective length and the use of columns to transfer tensile forces in alternative loads paths following element-removal scenarios.

ACKNOWLEDGEMENT

The investigations on the unreinforced specimens were supported by the *Swiss Federal Office for the Environment FOEN* within the framework of the *Aktionsplan Holz*, Project no. REF-1011-04200.

MECHANICAL BEHAVIOUR OF COLUMN BASES FOR CLT ROCKING FRAMES

Akira Masuda[1], Chisato Inutsuka[2], Kazuhiro Matsuda[3]

ABSTRACT: Although Cross Laminated Timber (CLT) mid-to-high-scale buildings have been realised worldwide, the technology for controlling damage in these buildings, which could minimise damage and facilitate continued use of buildings after a significant earthquake, is still in the developmental stage. In this study, a static horizontal loading experiment was conducted on CLT wall columns with origin return characteristics by introducing prestress, and the mechanical behaviour of the CLT wall columns was investigated. We determined the difference in the origin return characteristics and damage of wall columns when the prestress introduced to the wall columns and the diameter of the PC bar were varied. We also propose a method to evaluate the relationship between the bending moment and rotation angle of the column base. The evaluation method applies calculations that are commonly used for joints in large wooden buildings. In this case, it was necessary to evaluate the uplift of the column base in advance, and we created a spring model to evaluate the uplift. Although this evaluation method has some limitations, it is believed that the experimental results can be accurately replicated.

KEYWORDS: CLT, Rocking Wall-Column, Prestress, Embedding Stiffness, Anchorage Plate

1 INTRODUCTION

1.1 BACKGROUND

Due to the social imperative of sustainable and healthy forestry development and environmental CO_2 reduction, there is increasing demand for mid-to-high-rise wooden buildings, leading to the proliferation of Cross Laminated Timber (CLT). In general, CLT buildings use CLT panels as walls and floors (e.g. in Japan, CLT panel buildings [1]). However, because the restoring force characteristics exhibit slip behaviour [2, 3], it may be difficult to maintain the function after a large earthquake. Thus, developing damage control technology for CLT buildings to minimise damage and enable continued use after large earthquakes is crucial.

Matsuda et al. [4] conducted an experiment on a passively controlled CLT structure, utilising both a rocking wall column and a damper, resulting in a structure with reduced residual deformation and high energy absorption performance. While the behaviour of the frame was analysed, the behaviour of the wall column was not comprehensively identified.

Pei et al. [5], Sarti et al. [6], and Iqbal et al. [7] conducted research on damage control structures for mid-to high-scale wooden buildings. Pei et al. introduced prestressing by placing PC bar at the centre of the CLT wall column. This wall column was deformed by uplift while rotating the column base. Because the slip is reduced by prestress, the wall column is a structural system with high-origin return characteristics.

Isoda et al. [8] examined the implementation of Japanese specifications by referring to CLT rocking columns overseas. Harada et al. [9], Komoriya et al. [10], and Tanaka et al. [11] proposed CLT shear walls with a PC bar inserted at each edge of the wall column. In addition, Nagashima et al. [12] conducted an experiment on a laminated wood wall column in which prestress was introduced with a PC bar and proposed an evaluation method with high reproducibility in the elastic region.

1.2 PURPOSE AND STRUCTURE

In this study, a static horizontal loading experiment was conducted on CLT wall columns with origin return characteristics by introducing prestress to investigate the mechanical behaviour of the CLT wall column. We proposed a method for evaluating the relationship between the bending moment and rotation angle of the column base.

Figure 1 shows an image of the mid-to high-scale wooden buildings proposed in this study. By introducing a passively controlled CLT structure into a part of a general CLT building, such as a CLT panel building [1], we realise a mid-to-high-scale wooden building with excellent performance maintenance after an earthquake. The PC bar, which introduces prestress, is anchored to the column capital and the column base of the passively controlled frame with an anchorage plate. Steel dowels were used as the shear resistance for the column base. By creating steel dowel details that do not resist pulling

https://doi.org/10.52202/069179-0044

out, that details actively causes rotation and rocking of the column base. Steel dowels were installed at the column-beam joint, and a tensile bolt was installed at the centre of the beam to actively cause rotational deformation at the column-beam joint of the passively controlled frame. However, a damper is installed in the passively controlled CLT frame because the prestressed wall column alone does not have sufficient seismic energy-absorbing performance. In addition, because the effect of creep cannot be neglected when the stress level increases, we assume that the detail of the passively controlled frame minimises the burden of long-term axial force on the wall columns. Section 2 describes the outline and results of the static experiment. Chapter 3 proposes an evaluation procedure for the relationship between the bending moment and the rotation angle of the column base.

2 STATIC EXPERIMENT WITH CLT ROCKING WALL COLUMNS

2.1 EXPERIMENT OUTLINE

Figure 2 shows the shapes of the specimens. The five specimens were RW0, RW30, RW50, RW30φS, and RW30φL, and CLT rocking wall columns with a width of 1,000 mm and a height of 2,970 mm. The CLT was composed of five layers and six plies of cedar (the thickness of one lamina was 25 mm), the strength grade was S60, and the cross-sectional dimensions were 150 mm × 1000 mm. A 30 mm × 30 mm through-hole was made at the centre of the cross-section of the CLT to insert the PC bar. A groove of 15 mm × 30 mm was made in the centre of three layers and three plies of CLT, and the through-hole was made by secondarily adhering the two CLTs with the grooves facing each other. The PC bar was anchored by the anchorage plate provided on the column capital and jig for fixing. The anchorage plate on the column was a 500 mm × 150 mm × 32 mm SS400 steel plate with a φ30 mm hole in the centre. The anchorage plate of the fixing jig was made of SS400 with a thickness of 60 mm, which is sufficiently stronger than that of the column capital. Two φ50 steel dowels were provided on the column base as shear resistance.

Table 1 lists the prestress applied to each specimen and the diameter of the PC-bar used for each specimen. The introduced prestresses were 0%, 30%, and 50% of the long-term allowable compressive strength, corresponding to the numbers in the names of the specimens. The long-term allowable compressive strength is the standard strength [1] multiplied by 1.1/3, and the cross-sectional area. The PC bars used were B2-type (manufactured by Neturen), with diameters of φ17, φ23, and φ32. ϕS in the name of the specimen corresponds to φ17, φL to φ32, and no dose to φ23.

Figure 3 shows the setup of the experimental specimen. The steel dowels and anchorage plate of the foundation were firmly fixed to the fixing jig using bolts. After the two points of the column capital were constrained out of the plane with the pantograph, a 200kN oil jack was connected at a height of 2,400 mm from the column base, and positive and negative alternating loads were applied. The positive force direction is shown on the right in Figure 3. As for the loading schedule, positive and negative deformations up to 1/450, 1/300, 1/200(1), 1/150, 1/100(1), 1/200(2), 1/75, 1/50, 1/100(2), 1/ 30 and 1/20 rad were repeated three times, and then pulled off in the positive direction. In addition, because the anchorage plate was significantly deformed just before 1/20 rad, RW-30φL was pulled without applying 1/20 rad.

Figure 4 shows the measurement items. The absolute horizontal displacement of the column capital was measured using a wire displacement meter (DP-500G, manufactured by Tokyo Sokki), and the absolute

horizontal displacement of the column base was measured using a contact-type displacement meter (CDP25, Tokyo Sokki). The storey deformation angle θ was obtained by dividing the displacement difference between the column capital and column base by the height of the loaded point. The load was measured using a 200kN load cell attached to the oil jack. Displacement gauges $u_{c\,1}$ and $u_{c\,2}$ were installed on the column base, and the rotation θ_{cb}, uplift u_{cb}, embedded width $x_{n\,cb}$, and bending moment M_{cb} were calculated using Eqs. (1 ~ 4). These equations assume that the embedded triangle and the axial force of the PC bar are balanced. The tensile force acting on the PC bar was measured using a 1000 kN load cell.

2.2 RESULT OF THE EXPERIMENT

Figure 5 shows the relationship between the bending moment of the column base M_{cb} and rotation angle of the column base θ_c. All specimens showed an origin return history and had a high initial stiffness until the bending moment required to release the initial tension was applied. Subsequently, the stiffness decreases as the deformation increases. In (a) RW0, (b) RW30, and (c) RW50, the edge of the column base was damaged, as shown in Figure 6. No CLT damage was observed in (d)RW30φS. (e) RW30φL caused severe damage to the column capital.

(a) RW0 showed no decrease in stress at θ= 1/100 rad (2), indicating that θ= 1/100 rad (1) and θ= 1/100 rad (2) have almost the same history. Therefore, the rocking wall column can be expected to maintain its performance after a severe earthquake. RW0 behaved almost linearly up to 1/50 rad, after which the original return characteristics gradually disappeared.

(b) RW30 showed no decrease in stress at θ= 1/100 rad (2), indicating that θ= 1/100 rad (1) and θ= 1/100 rad (2) had almost the same history. In addition, before θ = 1/30 rad, no significant decrease in yield strength was observed. After experiencing 1/20 rad, the initial stiffness part was lost, and after experiencing maximum deformation, the original return characteristics were also lost. The bending moment required to release the initial tension decreased owing to the decrease in the initial tension of the PC-bar, as shown in Section 2.3.

Considering the initial stiffness in the order of RW-0, RW-30, and RW-50, it can be confirmed that the stiffness increased. In addition, RW50 showed almost the same history at θ= 1/200 rad (2) and θ= 1/200 rad (1), but θ= 1/100 rad (2) is slightly lower than θ= 1/100 rad (1). As

the initial tension increased, the initial stiffness increased; however, the CLT was damaged more quickly than RW30. (d) RW30φS of θ=1/100rad(2) is slightly lower than θ=1/100rad(1). After experiencing 1/30 rad, the initial stiffness part was lost, and after experiencing the maximum deformation, the origin return characteristic was also lost.

Observing the order of RW-30φS, RW-30, and RW-30φL, the range in which the initial stiffness is lost decreases. (e) RW-30φL showed no decrease in stress at θ = 1/100 rad(2), indicating that θ = 1/100 rad(1) and θ = 1/100 rad(2) had almost the same history. In addition, before θ = 1/30 rad, no significant decrease in stress was observed, and after experiencing maximum deformation, the original return characteristic was lost.

Figure 7 shows the relationship between the PC-bar tension T_{cb} and uplift of the base column u_{cb}.

RW0 exhibited linear hysteresis, except for the last pull-off, and the maximum yield strength was 389 kN.

RW30 exhibited a maximum yield strength of 419 kN. The hysteresis was linear up to θ=1/50 rad, and the initial stiffness was slightly lower than that of RW0. Subsequently, a decrease in the initial tension was observed when u_{cb} = 0. This decrease in tension is slight at θ = 1/100 rad.(2) and became significant at θ = 1/30 rad.

RW50 had a maximum yield strength of 410 kN. The hysteresis was linear up to θ=1/75 rad, and the initial stiffness was slightly lower than that of RW30. Subsequently, a decrease in the initial tension was observed when u_{cb} = 0.

RW30φS had a maximum yield strength of 230 kN. The hysteresis was linear up to θ=1/150 rad, and the initial stiffness was slightly lower than that of RW30. Subsequently, a decrease in the initial tension was observed when u_{cb} = 0.

RW30φL had a maximum yield strength of 601 kN. The hysteresis was linear up to θ=1/50 rad, and the initial stiffness was slightly higher than that of RW30. Subsequently, a decrease in the initial tension was observed when u_{cb} = 0. Figure 8 shows the anchorage plate of the RW30φL. Just before 1/20 rad, the anchorage plate began to embed into the column capital of CLT while undergoing a large bending deformation, as shown in Figure 8.

Figure 9 shows the changes in the ratio θ_{cb}/θ of the column base rotation angle θ_{cb} and the story deformation angle θ. The vertical axis is θ_{cb}/θ and the horizontal axis is θ. (a) RW0, RW 30, and RW 50 with different prestresses and (b) RW30φS, RW30, and RW30φL with different PC-bar diameters.

RW0 always exhibited a value close to 100%. Because no prestress is introduced in RW0, it is thought that the column base joint behaves closer to a pin joint. The ratio of RW30 was lower at a small deformation than that of RW0 and gradually increased as the deformation increased. Because RW30 has a prestress introduced, it is considered that the ratio of bending deformation and shear deformation of CLT increased, and the behaviour became closer to that of a rigid joint. The ratio of RW50 was lower at a small deformation than that of RW30 and gradually increased as the deformation increased. Because RW50 introduced more prestress than RW30, it is thought that the rate of bending deformation and shear deformation of the CLT increased further. Figure 9(b) shows that there was no significant difference between RW30φS, RW30, and RW30φL.

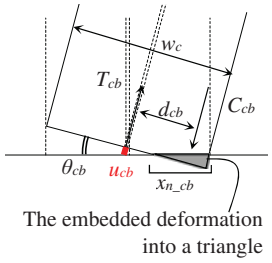
3 THEORETICAL EVALUATION METHOD

Figure 10 shows an image of the rotation angle of the column base of the CLT wall column, and Eq. (5) and (6) are the evaluation representing the evaluation methods proposed in [13]. The CLT has a very high in-plane stiffness, and the performance of the column base is directly linked to the performance of the entire CLT wall column. Various parameters, such as M_{cb}, θ_{cb}, and x_{n_cb} must be obtained to evaluate the deformation and stress of the column base. Their parameters are obtained by solving the simultaneous equations of the two equations, the equation of compressive force C_{cb}, Eq. (5), and the equations of compatibility for the embedded triangular, Eq. (6). Their simultaneous equations are solved for θ_{cb} and x_{n_cb} based on the following two points: (i) It is assumed that T_{cb}, tension, and C_{cb}, the compressive force of the embedded triangle, are balanced, (ii) k_g is the slope of the envelope of the CLT-embedded experiment described in Section 3.1. In this case, u_{cb} must be requested in advance.

A mechanical model of u_{cb} is shown in Figure 11. The mechanical model was a spring model with a series combination of K_t: axial stiffness of the PC bar, K_p: embedded stiffness of the anchorage plate, and K_w: compressive stiffness of the CLT middle zone. Here, K_t was created as a skeleton curve with reference to the mill sheet value of the PC-bar. K_p is the envelope of the embedding anchorage plate experiment described in section 3.2. K_w is the envelope of the CLT partial compression experiment described in section 3.3. The skeletal curve of K_t is shown in Table 2 with reference to the mill sheet.



$$T_{cb} = C_{cb} = \frac{1}{2} k_g \theta_{cb} x_{n_cb}^2 b \quad (5)$$

$$x_{n_cb} = w_c / 2 - u_{cb} / \theta_{cb} \quad (6)$$

C_{cb} : Compressive force

3.1 THE EMBEDDED CLT EXPERIMENT

Figure 12 shows the specimens of the CLT-embedded experiment, which were created by cutting out the less damaged parts of the specimens in the static horizontal loading experiment. The number of specimens is 4. The force position was at the edge of the specimens, and a steel plate (19 × 100 × 260 mm) was used to load vertically downwards. The measurement parameters were the load T_g and absolute vertical displacement δ_g of the steel plate. Figure 13 shows the relationship between the stress σ_g and embedding displacement δ_g. The σ_g–δ_g relations of the four specimens were averaged, and the embedded stiffness was a straight line approximated by the least-squares method between 10% and 40% of the maximum stress. The yield stress was considered as the average value of the highest stress point.

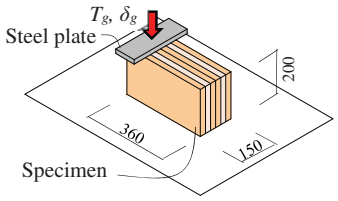

***Figure 12**: The CLT embedded experiment*

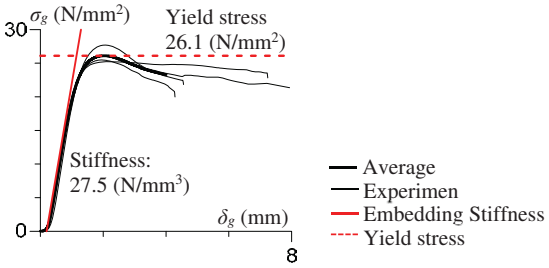

***Figure 13**: The relationships between σ_g and δ_g*

3.2 THE EMBEDDING ANCHORAGE PLATE EXPERIMENT

Figure 14 shows the setup of the embedded anchorage plate. The specimens were created by cutting out the less damaged parts from the wall column specimens. The number of specimens is 3. The anchorage plate was loaded by pulling the PC bar with the centre-hole jack. The measurement items are the tension of the PC-bar, T_p, and the embedding displacement of the anchorage plate, x_p. Figure 15 shows the relationship between T_p and x_p. Note that x_w is the deformation up to 28 mm from the top surface of the CLT.

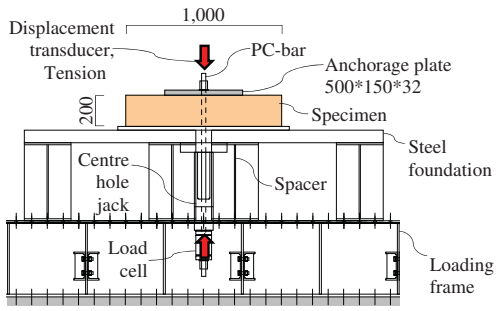

***Figure 14**: The experiment of the embedding anchorage plate*

https://doi.org/10.52202/069179-0044

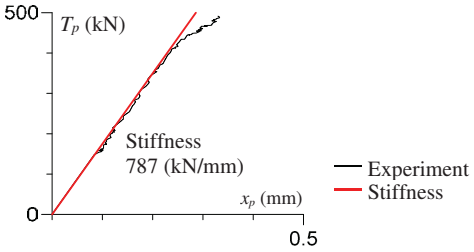

***Figure 15**: The relationships between T_p and x_p*

3.3 THE CLT PARTIAL COMPRESSION EXPERIMENT

Figure 16 shows the setup of the CLT partial compression experiment. The CLT used was different from that used in the static horizontal loading experiment. To understand the difference in the material properties from the CLT of the static horizontal loading experiment, a separate CLT material experiment was conducted. The number of specimens used was one. Assuming a rocked wall column, a load was applied to the centre of the column capital and the edge of the column base. The specimen was loaded with a 500kN oil jack and was placed so that the three points were on the same straight line: (i) the centre of the jack, (ii) the centre of the load-applying surface on the column capital, and (iii) the centre of the load-applying surface on the column base (hereafter referred to as "the load line"). Fifty-ton pins were installed on the column capital and base of the CLT wall column. The 50-ton pin on the column base side was fixed to the loading frame and that on the column capital side was connected to the oil jack. The right end of the oil jack was fixed to the loading frame, and the lower left end of the oil jack was connected to a linear rail that moved only in the direction of the load line. The measurement items were T_w, the load of the jack, and, x_w, the compressive deformation of the CLT on the load line. Note that x_w does not include deformations within 28 mm above and below the CLT. Figure 17 shows the relationship between T_w and x_w.

3.4 METHOD OUTLINE

T_0 evaluate the column base, it is necessary to calculate u_{cb} in advance. The mechanical model of u_{cb} is a spring model with a series combination of K_t, K_p, and K_w. The tension T_{cb} applied to the spring model is the sum of T_0, the initial tension, and dT, the tension change amount after the introduction of the initial tension, as shown in Eq. (7). dT was varied at 0.1 kN increments. The u_{cb} is the sum of dx_t, dx_p, and dx_w; each deformation change amount of the element after the introduction of T_0 as shown in Eq. (8). dx_t, dx_p, and dx_w are the differences between x_t, x_p, x_w, each deformation of the element at T_{cb} and x_{t0}, x_{p0}, x_{w0}, each deformation of the element when T_0 is introduced, as shown in Eqs. (9–11). x_t: The deformation of the PC bar at T_{cb} was calculated using Eq. (12), and x_{t0}, the deformation of the PC-bar when T_0 was introduced and calculated using Eq. (13). x_p, the embedding deformation of the anchorage plate was used as the result of the embedding anchorage plate experiments obtained in Section 3.2. x_w, compression deformation of the CLT middle zone was used as the result of the wall column

partial compression experiment described in Section 3.3. K_t, the stiffness of the PC bar is the axial stiffness, as shown in Eq. (14).

Figure 18 shows the stress distribution of the column base. For evaluating the column base, two simultaneous equations were solved, and the state of the compressive force was applied according to the degree of deformation. There are five stress distributions of the compressive force: (a) initial point, (b) anchor process, (c) limit anchor point, (d) elastic process, and (e) yield process. (a) The initial point is the state before horizontal deformation when the initial tension T_0 is applied. (b) The anchor process is a state in which the entire cross-section of the column base is in contact with the foundation, although horizontal deformation has occurred. (c) The limit anchor point is the state in which the entire cross-section is in contact, and the edge of the column base has no stress. (d) The elastic process is a state in which the stress distribution is triangular while the column base is uplifted. (e) The yield process is the state in which part of the stress distribution reaches the yield stress when the column base is uplifted.

In (a) Initial point, because horizontal deformation does not occur, there is no need to solve simultaneous equations for θ_{cb} and x_{n_cb}. So that, dT=0 and T_{cb}=T_0 from Eq. (7) and u_{cb}= − x_{g0} from Eq. (8).

Next, (b) anchor process must be evaluated, but this is not performed because it is very difficult to formulate. Therefore, because the deformation is small, (b) the anchor process is assumed to be in the elastic range and a skeletal curve is created by connecting (a) the initial point and (c) the limit anchor point with a straight line.

Next, (c) limit anchor point is presented. As the embedded width x_{n_cb}=w_c, the compressive force equation is given by Eq. (15), and the deformation compatibility equation is expressed by Eq. (16). These two equations were solved.

In (d), elastic process, the solutions of θ_{cb} and x_{n_cb} were obtained from the simultaneous equations of the compressive force C_{cb} (Eq. (17)) and compatibility equation (Eq. (18)).

In (e) yield process, Eq. (19) was used instead of Eq. (17). σ_{gy}, yield stress, and k_g, embedded stiffness, were used as the average yield stress and slope of the envelope obtained in the CLT-embedded experiment in Section 3.1. M_{cb} was calculated using Eq. (20).

The story deformation angle θ of the wall column is the sum of θ_{cb}: the column base rotation angle, θ_b, the storey deformation angle contribution of bending deformation, and θ_s, the storey deformation angle contribution of shear deformation, as shown in Eq. (22). Next, we demonstrate the effect of the stiffness involved in the series u_{cb} spring model on θ_{cb}. Figure 19 shows the deformation of the column base with a focus on θ_{cb}. As shown in Eq. (25), θ_{cb} can be calculated from u_{cb} and x_{ge}. x_{ge} means embedding deformation at the edge of the column base. u_{cb} is the sum of dx_t, dx_p, and dx_w with x_{g0} removed, as in Eq. (8). By rearranging Eq. (8), (22), and (25), Eq. (27) can be obtained. Therefore, θ_{cb} can be expressed as dx_t, dx_p, dx_w, and dx_g. Note that x_{ge} is the product of the rotation angle θ_{cb} and embedded width x_{n_cb} as shown in Eq. (26), and dx_g is the value obtained by subtracting x_{g0} from x_{we}, as shown in Eq. (28).

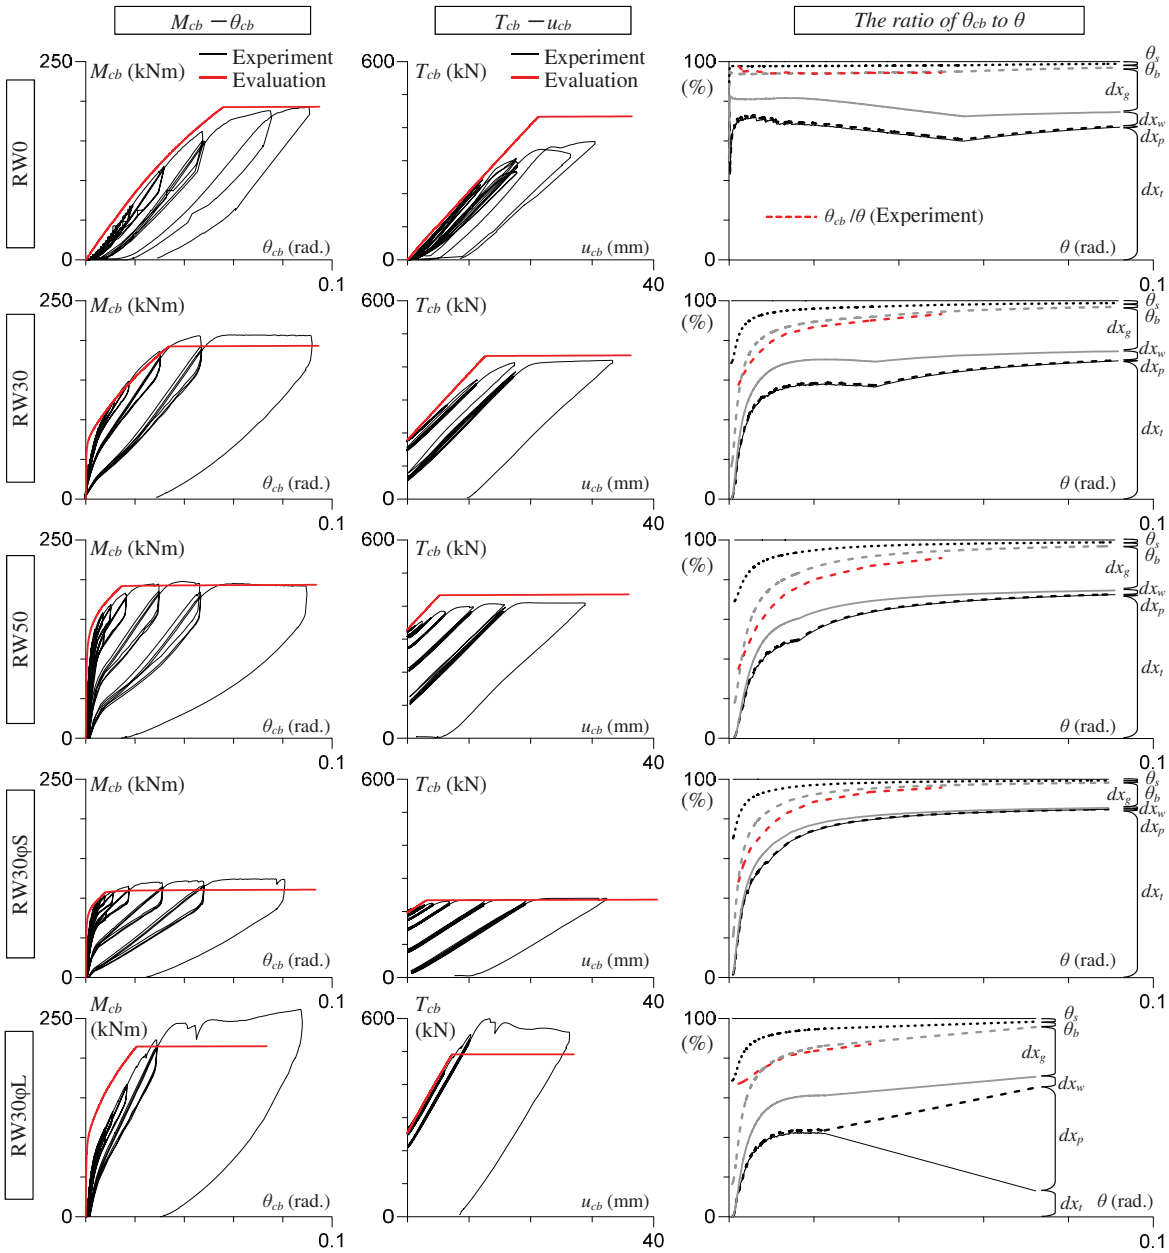

***Figure 20**: Compare the experiment and evaluation*

3.5 COMPARISON BETWEEN THE EXPERIMENT AND EVALUATION

Figure 20 compares the experimental and evaluation values. In the T_{cb}-u_{cb} relationship, the stiffness of RW30 and RW50 is slightly higher than the experimental value, but the evaluated value roughly reproduce the stiffness of the five experimental values. The yield points of RW0, 30, and 50 do not match, but the cause has not been elucidated. For RW30φL, in the experiments conducted to create the spring model in Chapters 3.2 and 3.3, the environment and equipment for applying a load of 500 kN or more could not be prepared. Therefore, deformation after reaching 500kN was not used as a reference.

In the M_{cb}-θ_{cb} relationship, the initial stiffness of RW30 and RW30φL were highly evaluated, but the other specimens reproduced the envelope of the experimental values well. Because T_g-δ_g relationship has a gentle slope when the stress is small, as shown in Figure 13, the experimental values of RW30 and RW30φL show lower initial stiffness than the evaluation values. Because the evaluation value does not reflect the part with low stiffness in the spring model, the evaluation value overestimated the initial stiffness. This aspect needs a more detailed examination in the future.

In θ_{cb}/θ, the horizontal axis is θ and the vertical axis is on the right side of Eq. (27). The distance between the lines corresponds to the proportion of the deformation that occupies θ. The dashed red line represents the experimental value of θ_{cb}/θ, which is compared with the sum of the ratios dx_t, dx_p, dx_w, and dx_g. In other words, the

https://doi.org/10.52202/069179-0044

dashed red line is compared with the dashed gray line. At RW0, dx_t was dominant for θ. Because the experimental (the dashed red line) and evaluation values of θ_{cb}/θ (the dashed gray line) are almost the same, the evaluation value can reproduce the deformation sharing of the rocking wall column without the initial tension. For RW30 and RW50, the effect of dx_t was small at small deformations, and dx_g, θ_b, θ_s were more dominant than RW0. The dashed gray line is the line of close shape to the experimental values of θ_{cb}/θ. RW30φS was influenced more by dx_t than RW30, i.e., the dashed gray line is a curve close to the experimental value of θ_{cb}/θ. In RW30φL, the deformation of the anchorage plate dx_p is dominant. Notably, the deformation of 500 kN or more cannot be used as a reference in relation to T_{cb}-u_{cb}, but the yield load of the PC-bar is approximately 800 kN, and the yield load of the CLT is considered to be even higher. Therefore, yielding at the anchorage plate was considered deterministic. In the experiment (Fig. 8), we confirmed a large deformation of the anchorage plate.

4 CONCLUSIONS

In this study, a static horizontal loading experiment was conducted on CLT wall columns with an origin return characteristic, by introducing prestress, and the mechanical behaviour of the CLT wall columns was investigated. We also proposed a method to evaluate the relationship between the bending moment and rotation angle of the column base. These are summarised as follows:

[Static horizontal loading experiment with CLT rocking-wall columns]

・ We determined the difference in the origin return characteristics and damage of wall columns when the prestress introduced to wall columns and the diameter of the PC steel bar was changed.

[Theoretical evaluation method]

・The proposed evaluation method was characterised by a detailed classification of the stress distribution of the column base and a detailed model of the uplift of the column base.

・Although the evaluation value has issues such as overestimating the initial slope of the M_{cb}–θ_{cb} relationship, the experimental value of some experimental specimens can be roughly reproduced.

ACKNOWLEDGEMENT

This research was supported by the 2016-2019 Grant-in-Aid for Scientific Research, Young Scientists (A): "Development of damping technology and proposal of damping design method for wooden high-scale buildings" (Project number: 16H06107, Research representative: Kazuhiro Matsuda). We would also like to thank Mr. Tomohiro Morimoto of Meiken Kogyo Co., Ltd., for his advice. In the experiment, I received the cooperation of Mr. Chisato Inutsuka, Mr. Keiichiro Goto, Mr. Masaki Sugimori and Mr. Yuta Hisada, former students at Meijo University. Here, we express our gratitude to you.

INVESTIGATION OF CROSS LAMINATED TIMBER'S LONG-TERM PERFORMANCE (CREEP)

Aaron DeSantis[1], Michael Stoner[2], Weichiang Pang[3]

ABSTRACT: Cross laminated timber (CLT) and its use as a structural wood product is relatively new compared to other engineered wood products. While current design standards for CLT subjected to long term deflection or creep provide a value for the time dependent deformation factor (creep factor), direct validation of such a value has not been conducted. The 2018 version of the National Design Specification (NDS) recommends a creep factor of 2.0 be used for CLT. Eurocode recommends a value equivalent to 1.8 for normal moisture and temperature conditions. To provide a point of comparison to the design values suggested in US standards, full scale long-term deflection testing of CLT panels is being conducted under a variety of load levels. The increasing deflections over time give an indication of the creep factor. This paper describes the short-term destructive tests and the first 3 months of progress of the long-term tests. Preliminary results indicate creep factors approaching values glue-laminated timber and solid sawn lumber in the NDS after the first 3 months.

KEYWORDS: Cross laminated timber, CLT, Creep, deflection, wood design

1 INTRODUCTION

With increased use of CLT as a construction material in larger buildings, including midrise and high-rise buildings, the work to fully understand CLT grows in importance. Larger structures, especially commercial use cases require larger spans for gather spaces. This includes meeting rooms, open concept office spaces, recreational spaces and auditoriums. Creep in CLT is of concern for these designs due to wood's low stiffness relative to other building materials such as concrete and steel. As seen in fundamental mechanics lower stiffnesses result in greater deflections for the same spans and strengths. Wood structures, utilizing CLT or not, are therefore more likely to be controlled by deflection limit states rather than strength design.

Current understanding of CLT's performance under creep is lacking. The American Wood Council (AWC) currently group CLT with other panelised products in the 2018 edition of the National Design Specification (NDS) for wood construction [1]. Current provisions from the AWC prescribe equation 1 for calculating long term deflection.

$$\Delta_T = K_{cr}\Delta_{LT} + \Delta_{ST} \quad (1)$$

Where Δ_T is the total deflection of the member, K_{cr} is the time dependent deformation factor also known as the creep factor, Δ_{LT} is the immediate deflection due to the long-term component of the design load, and Δ_{ST} is the deflection due to short term or normal component of design load. [1]. These deflections are calculated using the modified effective bending stiffness shown in equation 2.

$$(EI)'_{eff} = (EI)_{eff} C_M C_t \quad (2)$$

Where $(EI)'_{eff}$ is the adjusted effective bending stiffness, $(EI)_{eff}$ is the effective bending stiffness, C_M is the wet service factor, and C_t is the temperature factor.[1]. The NDS specifies a creep factor of 1.5 to most wood products and lumber in dry service conditions and 2.0 in wet service conditions. CLT is assigned a 2.0 creep factor for both wet and dry service conditions like plywood. Service conditions are based upon expected moisture contents in the structural member. Internal moisture contents above 19% are considered in a wet service condition except for laminar products like CLT and CLT where exceeding 16% is considered wet service. The assignment of the creep factor and the categorization of CLT was made on the recommendation of a study done on European CLT for adoption in Eurocode[4].

Eurocode deals with creep similarly to the NDS though uses a single modification factor, k_{def}, for both the reduction in young's modulus and the magnification of instantaneous deflections where the NDS utilise three different terms, C_M, C_t, and K_{cr}. The modification factor in Eurocode differs by product and service class. The service classes are labelled numerically one to three and are based on escalating moisture content within the material, denotated by averaged ambient temperature and the average relative humidity of the air [4]. Additional discussion on the service classes notes that softwoods in each service class typically stay under certain moisture contents. For service class one softwood moisture content stays below 12%, softwoods in service class two remain below 20% moisture content, and service class three exists for conditions where softwoods are above 20%

[1] Aaron DeSantis, Clemson University, USA, agdesan@g.clemson.edu

[3]Weichiang Pang, Clemson University, USA, wpang@clemson.edu

https://doi.org/10.52202/069179-0045

moisture content [4]. This system is analogous to the NDS's wet and dry service conditions. Service class one to dry service and service class two and three to wet service. Both deflection magnifications and reductions in member stiffness differ based upon the expected environmental conditions under Eurocode 5. CLT is not explicitly included in the later version as a product though associated standards assign the same values as Type EN 636-2 Plywood for all service classes [5]. For service classes one and two k_{def} is 0.8 and 1.0 respectively. CLT does not have a creep deformation factor for service class three. When these terms are applied, they produce an 80% and 100% magnification in deflections due to long term loads. The NDS only provide one magnification level for long term loads on CLT, a 100% magnification.

The investigation of creep factors for CLT is necessary to provide experimental evidence to support the creep factors suggested in the NDS or propose changes if necessary. To evaluate the long-term performance of CLT panels a series of tests have been conducted. Short term testing to establish the strength and stiffness characteristics of the CLT specimens followed by a long-term creep test. The experimental test setup and current results will be presented and discussed.

2 EXPERIMENTAL TESTING

2.1 SHORT TERM TEST

Two specimens out of the available CLT panels were randomly selected for short term testing. The specimens used throughout the experiment were 5-ply CLT panels with a cross-sectional area of 14.5 cm x 30.5 cm and 5.5 m in length (6.75 in x 12 in x 18 ft). Each panel is a V3 CLT panel per PRG 320 [3] and was tested using four-point loading as shown in Figure 1.

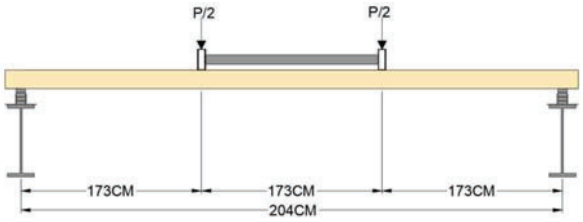

Figure 1: *Loading configuration for short-term testing.*

Four-point loading used for this experiment aligns with previous work for ease of comparison. [4] The load is transferred to the specimen through steel hollow structural sections 7.62 cm (3 in) wide and 20.32 cm (8 in) tall. The specimen rests on top of wood blocks placed on top of steel W-sections as supports spaced at 204 cm (17 ft) center-to-center. Specimens showed no visible signs of crushing at the bearing locations after short term tests.

Specimen subjected to the short-term loading produced moment failure, pictured in figure 2, by fiber rupture in the tension side of the panel. The resulting load displacement graphs are shown in Figure 3.

Figure 2: *Moment failure of specimen in destructive test*

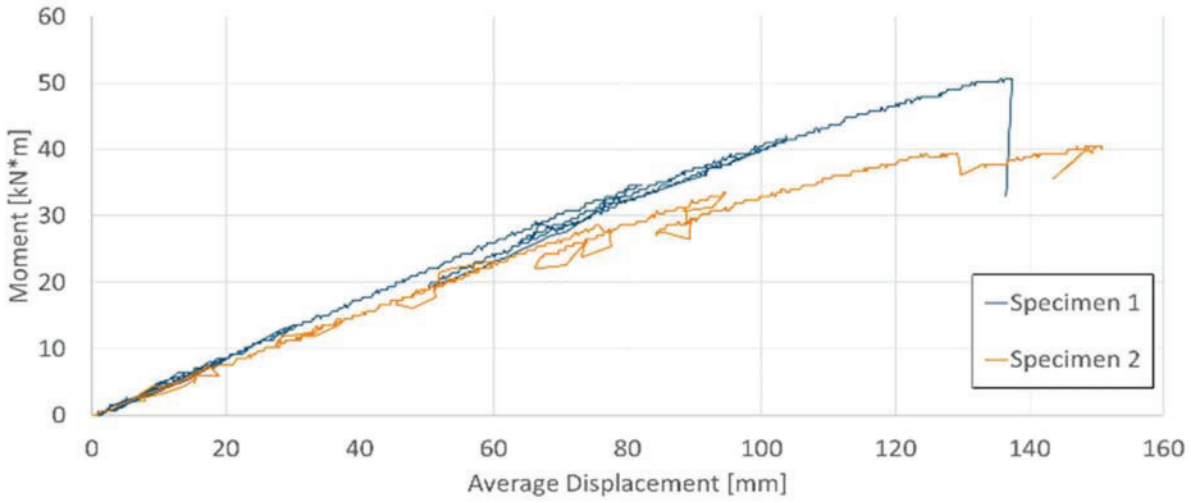

Figure 3: *Short-term test Load-Displacement curves*

https://doi.org/10.52202/069179-0045

The average experimental moment capacity of the CLT specimens was calculated from the following relationship:

$$M = \frac{P}{2}a \quad (3)$$

Where M is the moment capacity, a is the distance from center of bearing to the center of load application (173 cm, 68 in.), and P is the total load applied to the specimen. The load P is split and by a spreader beam and applied evenly according to Figure 1. The moment capacity for each specimen is reported in Table 2 along with the associated peak load and deflection at the peak load. Peak load is reported as total force applied to the specimen. Table 2 also reports the average moment capacity based on the two experimental tests shown in the last row of the table.

Table 2: *Destructive test results and specimen characteristics*

Specimen Number	Peak Load [kN]	Deflection at peak load[mm]	Peak Applied Moment [kN*m]
1	58.7	135.6	50.8
2	46.8	147.1	40.5
Average	52.8	141.5	45.6

2.2 LONG TERM TEST

The primary goal of long-term testing was to measure the creep in a series of CLT specimens. Loading towers were used to maximize the space which was available. Figure 4 shows a representation of the loading towers.

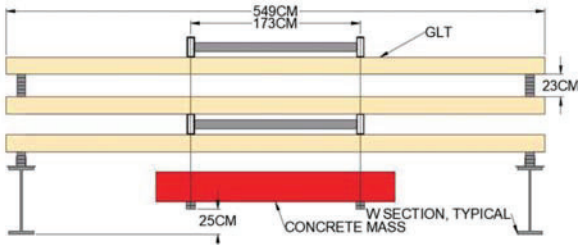

Figure 4: *Schematic view of loading tower for the long-term testing*

Deflection characteristics of the specimen as found during the short-term tests were used to inform the design of the towers such as clearances between specimens within the load towers and the required height of the pedestals to allow sufficient space for the hanging mass. Each tower consists of two CLT panels and a flat-wise glulam beam acting as a transfer member. The load is transferred from the hanging concrete mass below the bottom specimen to the glue laminated timber(GLT) beam using steel threaded rod The GLM beam bends in positive bending and transfers the load to the CLT specimen below at the bearing locations on each end of the beam. The next CLT specimen in the load path will be in negative bending under this load. In total three loading towers have been constructed testing six CLT panels and three GLT beams. Using loading towers introduces variation in the loading due to the accumulation of load due to specimens and equipment self-weights. This additional load was accounted for in all calculations based on an assumed specific gravity for Southern Pine of 0.55, the self-weight of the CLT members were calculated to be 1.57 kN (354 lb). Similarly, the self-weight of the GLT members were calculated to be 1.88 kN (422 lb). LRFD and ASD moment capacities were calculated in accordance with Table 10.3.1 of the 2018 NDS for wood construction. [1] The resulting moment capacities and self-weights of the specimens were used to find the most appropriate load levels to use for the long-term test. The load levels used for the creep test are shown in Table 3. The load levels are reported as a percentage of the average peak moment reported in Table 2 and includes the mass above the specimens and self-weight.

Table 3: *load level information*

Load [kN]	Applied Moment [kN*m]	% Ultimate
P	M	---
8.7	15.1	17
10.6	18.4	20
11.6	20.0	22
13.5	23.3	26
14.7	25.4	28
16.6	28.7	32

The load levels used for this experiment ensure the CLT specimens remained within the linear elastic region ensuring no change in stiffness throughout the creep test. Because the load displacement curves in Figure 1 show no obvious yield point, the 40% rule was used to determine the elastic region of the beam. With this method young's modulus is determined using the load-displacement data associated with 0% to 40% of the failure load. Appendix X2.5-6 of ASTM D198 permits the use of this method when visual inspection of the data is insufficient to identify the yield point.

The creep factors will be back calculated by rearranging equation (1) from the NDS shown as equation (4):

$$K_{cr} = \frac{\Delta_T - \Delta_{ST}}{\Delta_{LT}} \quad (4)$$

Where Δ_T =total deflection, Δ_{LT} =instantaneous deflection due to long-term loadings, Δ_{ST} =instantaneous deflection due to short-term loadings, and k_{cr} = creep factor. For this test there is no short-term loading as all load is applied for the duration of the experiment, therefore equation 4 simplifies to the ratio of total deflection to instantaneous deflection as shown in Equation 5:

$$k_{cr} = \frac{\Delta_T}{\Delta_{LT}} \quad (5)$$

https://doi.org/10.52202/069179-0045

The application of the load for the six CLT specimens and three GLT specimen in three separate stacks was applied on December 20, 2022. The stacks are shown in Figure 5.

Figure 5: *Loading setup of long-term deflection testing.*

3 PRELIMINARY LONG-TERM DEFLECTION RESULTS

The following discussion presents the first 12 weeks of experimental data for the long-term testing. Midspan deflections of each of the six CLT panels and three GLT beams have been collected every minute. Figure 6 reports the daily average deflections for three specimens loaded between two different towers. Daily averages are reported for clarity. Deflection characteristics for the various specimens agree with expected behaviour. Lower load levels produce smaller displacements. Discontinuities in the data are missing data caused by battery and power outages. The instantaneous deflection due to long term loadings were recorded within 3 min of initial loading as per the recommendation of ASTM D6815 [6]. Equation 4 was applied to subsequent readings using this initial deflection to produce the plot in Figure 7.

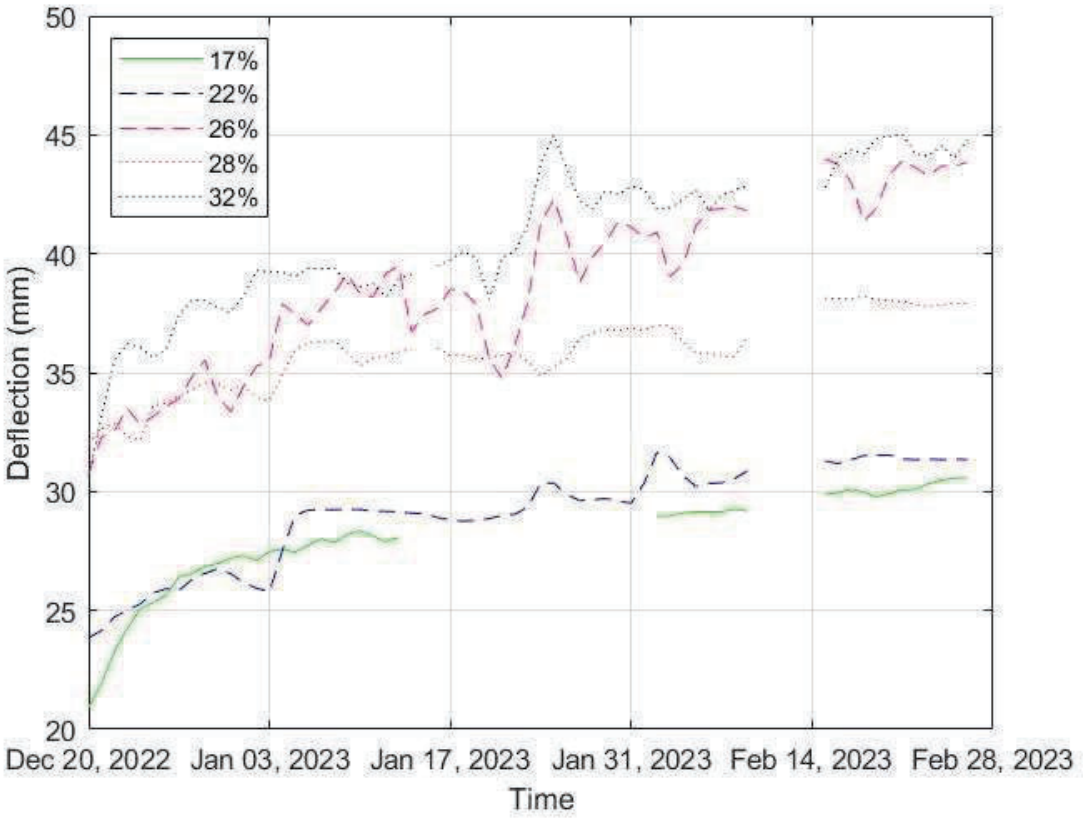

Figure 6: *Daily average deflection time history for all CLT specimen*

https://doi.org/10.52202/069179-0045

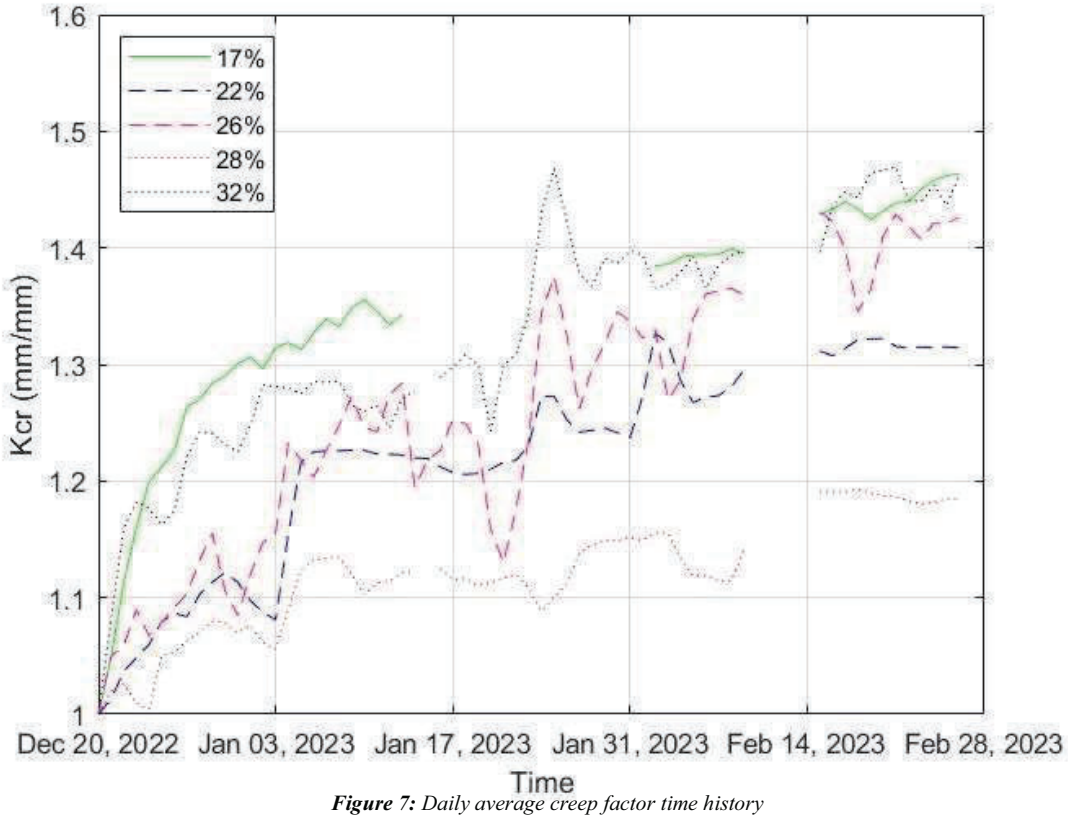

Figure 7: *Daily average creep factor time history*

Figure 6 displays the creep time history for the various specimens at different load levels. Creep factors slowly increase over time as the specimens continue to experience increases in strain. Specimens show a consistent overall creep behaviour, though day-to-day increase in deformation for each specimen differ. The rate of deformation is decreasing over time which is consistent with expected behaviour and previous tests [2]. After three months the CLT specimens experienced 18% to 46% increases in deflection resulting in k_{cr} factors ranging between 1.18 to 1.46. Subjects experienced significant increases in deformation over the first 10 days of the test. The rate of creep then declined significantly and continue to level as the testing period expands. The rate of creep is expected to decline to a level that is considered negligible after 24 months.

4 CONCLUSIONS

An experimental setup was designed to test the long-term deformation (creep) behavior of cross-laminated timber (CLT) to determine the applicability of current design provisions in both the National Design Specification (NDS) and Eurocode. Recommendations for normal temperature and moisture service for NDS recommends amplifying long-term deformations by a factor of 1.5, while Eurocode recommends a factor equivalent to 1.8 for similar conditions. Current time dependent deformation (creep) factors are below the 1.5 recommendation for GLT and solid lumber and below the service class one recommendation under Eurocode, though tests are still ongoing. Past tests indicate that creep continues past the first three months and more time is necessary to obtain an accurate creep factor [2]. Future results will indicate whether the current value prescribed by the NDS is appropriate for CLT or if a lower creep value is appropriate for dry service conditions. Creep factors will continue to be collected and once sufficient data is gathered these values will be evaluated with the currently prescribed values within the NDS.

LOW-TEMPERATURE BONDING OF TIMBER STRUCTURES

Morten Voß*, Tobias Evers* & Till Vallée*

ABSTRACT: Any bonding operation requires a tight control of environmental conditions (most importantly temperature and moisture) to ensure the desired mechanical performance during service life. To overcome these restrictions, the study shows how inductively heated Curie particles can be used to cure wood adhesives (epoxy and polyurethane) under low temperature conditions (+5 and –10 °C). The investigations were carried out using standardised specimens (dogbone / wooden lap shear joints) as well as large Glued-in Rods (GiR). The process is very well suited for the epoxy adhesive, which showed a mechanical performance equal to that of the references. In contrast, the technique is not applicable to polyurethane adhesives bonded on wooden adherends due to moisture diffusion, which interferes with the polymerisation – a problem, which might be solved by using a different particle type with lower Curie temperature, T_c.

KEYWORDS: Low-temperature curing, onsite bonding, induction heating, Curie particles

1 INTRODUCTION

A severe disadvantage of adhesively bonded joints compared to mechanical joining techniques represents the fact that the polymerisation progress is significantly influenced by ambient conditions, most importantly temperature and moisture [1,2]. As a result, practitioners have to costly adapt their production processes to the requirements of the respective adhesive in order to ensure durability and performance of the connections during service life. Furthermore, the bonding-related constraints exclude the use of adhesives for many applications from the start (e.g. onsite bonding in timber engineering).

Up to now, low-temperature curing of polymers is not a well-defined field of research, whereby generally two application approaches may be distinguished: Firstly, the bond may both be produced and cured at low temperatures, secondly, only adhesive application and joining is carried out at low temperatures while the polymerisation is accelerated in the following, e.g. by introducing thermal energy. Both approaches have yet been little studied, with investigations of Moussa et al.[3,4] and Ratsch et al.[5] being available. While Moussa et al. focused on changes in polymer characteristics due to low-temperature curing of a structural adhesive, Ratsch et al. concentrated on providing thermal energy by heating threaded steel bars in a Glued-in Rod (GiR) connection over an external electromagnetic field (EMF).

In order to overcome the temperature-related constraints, the authors investigated if inductively heated Curie particles (CP) can principally be used to cure structural wood adhesives under adverse temperature conditions (+5 and –10 °C). The particles are added to the adhesives and may be heated up to their material-specific Curie temperature, T_c, but not beyond. Thus, a curing process is designed, which automatically reduces the risk of overheating while the heat can be used to enable curing starting from low temperatures.

2 MATERIALS & METHODS

2.1 ADHESIVES

The investigations covered two thermosetting two-component adhesives (epoxy and polyurethane), which are frequently used for different structural applications throughout the German construction sector. In detail, the adhesives Fischer EM390S (abbreviated as Fi390, Fischerwerke GmbH & Co. KG, Germany) and Loctite Purbond CR421 (LP421, Henkel AG & Co. KGaA, Germany) have been selected. Their most important material properties have been listed in Table 1.

Table 1: *Material properties of the adhesives Fi390 and LP421 taken from technical data sheet (TDS) or * that have been measured, ** calculated based upon Arrhenius law* [6]*, tensile strengths measured with v = 1 mm/min and specimens type 1A according to DIN EN ISO 527[7]*

Property	Adhesive	
	Fi390	LP421
Adhesive type	2K-EPX	2K-PUR
Density, ρ [g/cm^3]	1.50	1.35
Pot life at +23 °C [min]	14-30	10
Curing time at +23 °C [h]	18	|240
Curing time at –10 °C [h]	160**	1920**
Young's modulus, E [MPa]	5230*	2760*
Tensile strength, σ_u [MPa]	40.0*	28.6*
Elongation at break, ε_u [%]	1.2*	1.6*
T_g for curing at +23°C [°C]	73.4*	81.3*

2.2 CURIE PARTICLES

Softmagnetic manganese-zinc (MnZn) ferrite particles (Ø0.5–25 µm, cf. Figure 1) with a T_c of 110 °C served as susceptors. The T_c was chosen so to match the heating requirements of the considered adhesives (permissible

**Fraunhofer Institute for Manufacturing Technology and Advanced Materials IFAM, Bremen, Germany*

https://doi.org/10.52202/069179-0046

heating rate / maximum curing temperature), which were determined by preliminary experiments. Moreover, the ceramic particles were selected, since they are corrosion resistant and have a comparatively low coercivity, which ultimately favours heat generation by hysteresis losses. In-depth information about the CP and their characteristics can be found in [8].

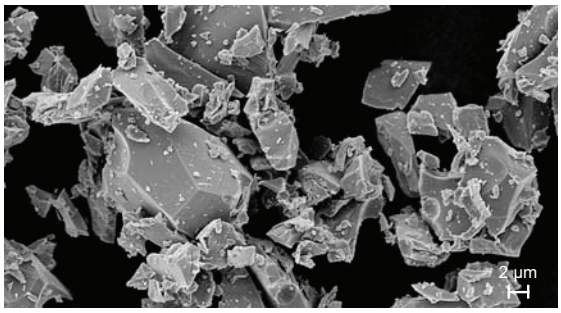

Figure 1: *SEM image of flake-shaped CP (Hengdian Group DMEGC Magnetics Co., Ltd., China)*

2.3 MIXING

All adhesive-CP mixes were prepared under vacuum conditions (100 mbar) using a Speedmixer of type DAC 800.2 VAC-P (Hauschild GmbH & Co. KG, Germany). Mixing was carried out for 60 s at 1.000 rev/min. To maintain comparability, a CP content of 33.3 w/w-% (~8–9 vol-%) was chosen for all produced specimens.

2.4 SPECIMEN TYPES

2.4.1 Dogbone

To analyse the impact of low-temperature curing on tensile properties, dogbone (DB) specimens acc. to DIN EN 527[7] type 1BA were produced, with the adhesive-CP mixes being applied into silicon moulds using a syringe.

2.4.2 Lap shear specimens

In order to characterise the performance of the low-temperature cured adhesives on a small joint scale, single lap shear specimens (SLS, 100 x 25 x 6 mm) acc. to DIN EN 1465[9] were produced using spruce adherends (*picea abies*) with a moisture content of 8.9 ± 0.6 %. The joints overlapped by 12.5 mm. For SLS series bonded with LP421, wood adherends were dried in an oven.

2.4.3 Glued-in Rods

Finally, the experiments were up-scaled to a large joint geometry, so-called Glued-in Rods (GiR). The connection consists of a spruce block (120 x 120 x 300 mm), equipped with bore holes so to embed a reinforcement bar made of glass-fibre reinforced polymer (G-FRP, Ø16 mm). Way more details regarding GiR production and the materials involved can be found in e.g. [10] and will not be repeatedly presented herein.

2.5 LOW-TEMPERATURE EXPERIMENTS

2.5.1 Pre-conditioning at low temperatures

Prior induction heating, all specimens for which low-temperature curing was targeted (cf. Table 2), were pre-conditioned within climate chambers at a temperature of –30 °C (cf. Figure 2). This was done to ensure adhesive temperatures of +5 and –10 °C at the start of inductive heating by letting the specimens re-warm under laboratory RT conditions until the starting temperatures were reached. Depending on the joint geometry, total duration for pre-conditioning differed to ensure that all parts of the joints were cooled to the target temperature.

Figure 2: *Pre-conditioning of wooden SLS joints equipped with thermocouple within climate chamber at –30 °C, adhesive-CP mix applied but not yet cured*

For DB and SLS specimens, the adherends and silicon moulds pre-cooled. Afterwards, adhesive-CP application was done within the climate chambers, which immediately cooled down the mixes and reduced polymerisation progress to a minimum. When the respective DB specimen or SLS series was cooled, they were transported to the induction device (~1 min). Finally, thermocouples were attached to the measurement electronics and the induction device was switched on when thermocouple temperature reached +5 or –10 °C.

2.5.2 Experimental setup & inductive heating

For all low-temperature inductive heating operations, the induction device TrueHeat HF 5010 (Trumpf Hüttinger GmbH & Co. KG, Germany) was used. As an example, Figure 3 shows the inductive heating of a set of five spruce SLS joints (thermocouple attached to middle specimen).

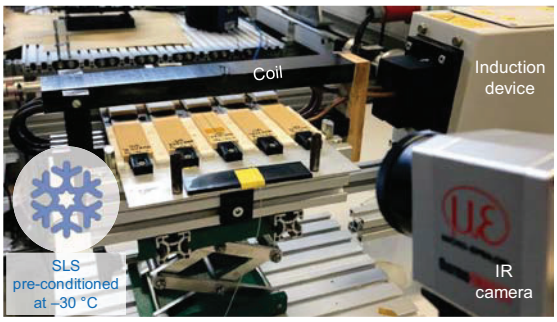

Figure 3: *Experimental setup for inductive heating using five SLS joints (herein bonded with LP421) as an example, P = 2.9 kW, I = 15.8 A, U = 384 V, f = 134 kHz*

All specimen were placed centrally within the induction coils (cf. Figure 3) and cured for 10 min with the EMF in

order to maintain comparability between the specimen types investigated. However, for some low-temperature GiR series, induction time had to be increased to 12.5 min in order to reach high temperatures and thus ensure full cure.

2.6 MECHANICAL TESTING

All specimen types were destructively tested using Zwick||Roell universal testing machines (UTM's). Testing was performed at a speed of 2 mm/min under RT conditions (23 ± 2 °C, 50 ± 10 °C). Testing times were dependent upon the cooling rates of the specimens, with SLS and DB specimens tested ~0.5 h and GiR ~2 h after inductive heating ended. To get an impression of the mechanical tests, Figure 4 shows the setups used for GiR and DB specimens.

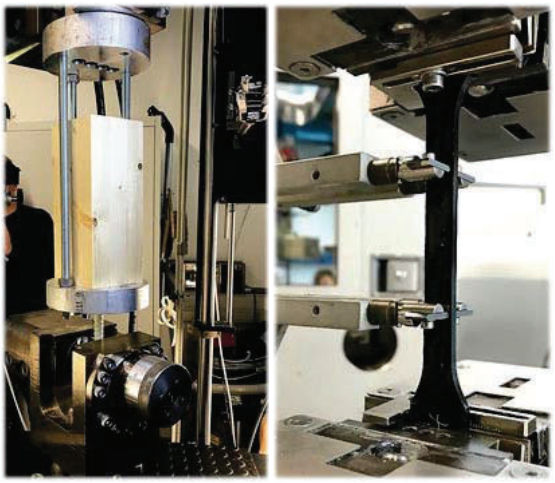

Figure 4: *Setups for mechanical testing of low-temperature cured GiR (left) and DB specimens (right), testing performed at RT*

2.7 EXPERIMENTAL PROGRAM

For a better overview, the complete experimental program has been summarised in Table 2. The experiments included references (unfilled and CP-filled) as well as inductively cured specimens starting from +23, +5 as well as –10 °C for both considered adhesives. The testing times can be found in section 2.6.

Table 2: *Experimental program produced for each Fi390 (2K-EPX) as well as LP421 (2K-PUR), CC = Cold cured at RT, IND = Inductively cured*

Type	Series				
	CC_ Ref	CC_ CP	IND_ +23	IND_ +5	IND_ -10
DB	-	-	5	5	5
SLS	5	5	5	5	5
GiR	5	5	4	4	4

3 RESULTS

3.1 HEATING BEHAVIOUR

In a first step, the heating behaviour for SLS and GiR joints bonded with Fi390 have been visualised in Figure 5. It can be seen that, depending upon specimen geometry, curing temperatures develop fundamentally different. Thus, for the way smaller SLS joints, curing temperatures of roughly 100–110 °C after ~4 min of continuous induction heating can be measured. In contrast, the bigger GiR do not reach the same temperature range although total induction time was 2.5 min longer (12.5 min) as for the SLS specimens (10 min). Consequently, the SLS temperature curve shows a clear flattening around T_c (110 °C), while mean GiR temperatures are still ~90 °C.

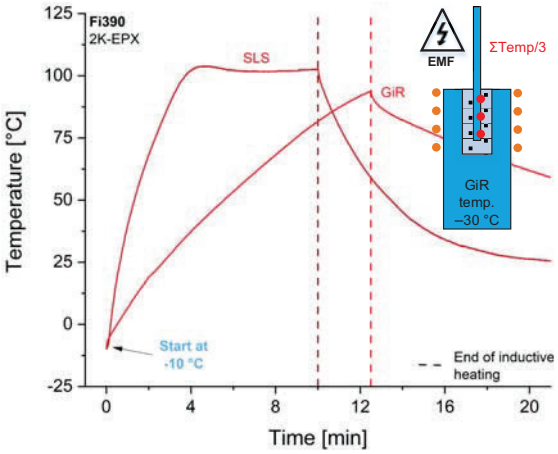

Figure 5: *Curing temperatures during inductive heating of joints bonded with Fi390 recorded with thermocouples embedded within the adhesive-CP mixes*

3.2 MECHANICAL PERFORMANCE

3.2.1 Dogbone

The mechanical results for the inductively cured DB specimens are shown in Figure 6.

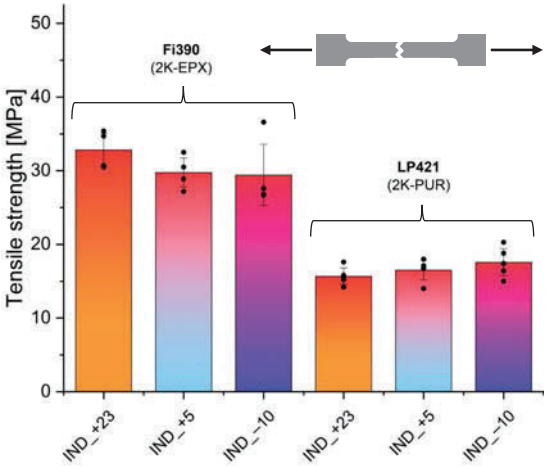

Figure 6: *Mechanical results for tensile strengths measured with DB specimens type 1BA for the two considered adhesives, v = 2 mm/min, tested at RT, Zwick\|Roell UTM 50 kN*

The data reveals that the starting temperature of the induction process has no influence on measurable tensile strengths, which holds true for both considered polymers. At this point, the authors want to point out that a direct comparison with tensile strengths listed in Table 1 is not given since specimens geometry and testing conditions differed.

https://doi.org/10.52202/069179-0046

3.2.2 Lap shear specimens

In the next step, lap shear strengths have been visualised in Figure 7. It can be seen that generally all series result in a tear-off of the wooden fibres, with lap shear strengths of 7–9 MPa being reached. In addition, fracture patterns within the respective series are identical. These observations are valid for both the 2K-EPX as well as the 2K-PUR adhesive.

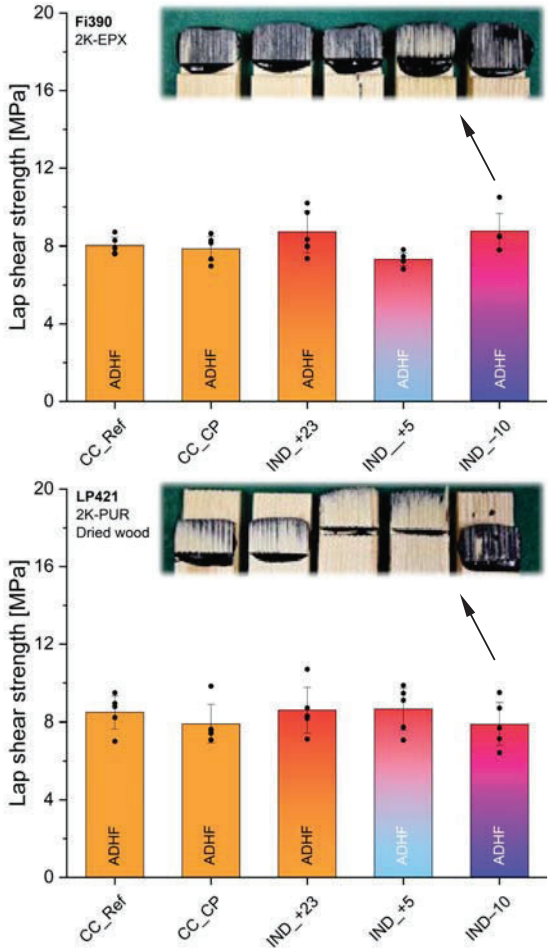

Figure 7: *Mechanical results for spruce SLS joints bonded with the two considered adhesives, v = 2 mm/min, tested at RT, Zwick|Roell UTM 20 kN; ADHF = Adherend failure; adherends for polyurethane dried in oven (moisture content of 0 %, measured immediately prior adhesive-CP application)*

3.2.3 Glued-in Rods

Finally, the mechanical results of the GiR-related mechanical tests have been illustrated in Figure 8. For the first adhesive under investigation, Fi390, all series – independently of the curing conditions considered – resulted in a pull-out of a wooden plug, indicating that the wooden adherends were the weakest part of the connections – a result, which corresponds to the findings on lap shear scale.

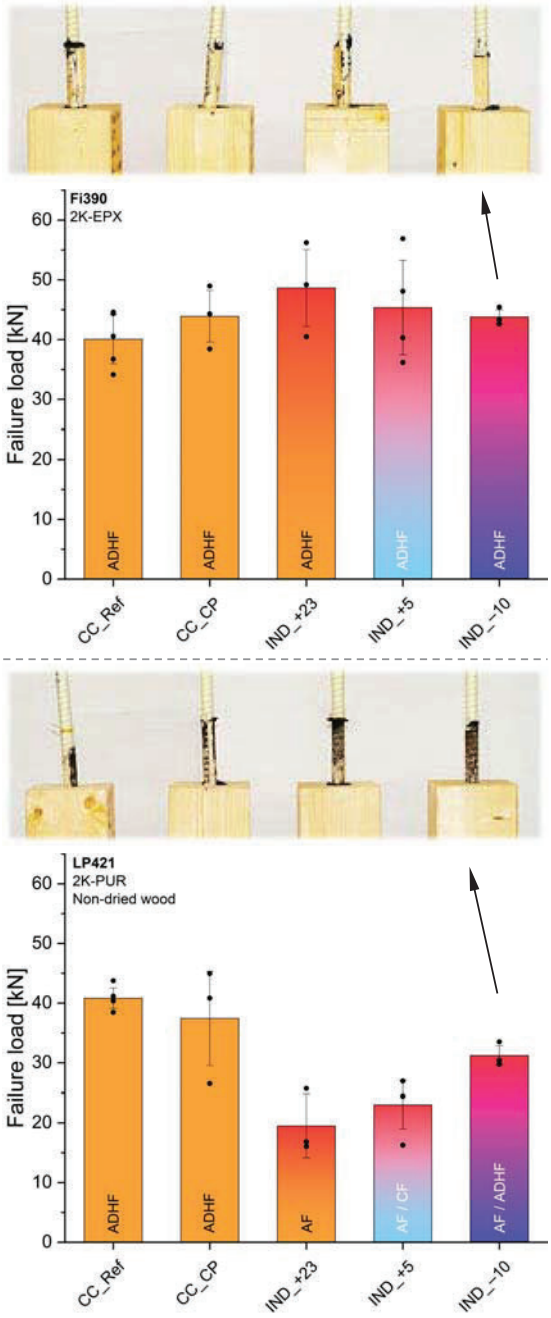

Figure 8: *Mechanical results for GiR joints bonded with the two considered adhesives, v = 1 mm/min, tested at RT, Zwick|Roell UTM 100 kN; ADHF = Adherend failure, all adherends non-dried with moisture content of 8.7 ± 0.9 %*

In contrast, GiR bonded with the 2K-PUR show another behaviour. Thus, for those series that were cured without the use of thermal energy, mechanical tests resulted in a failure of the wooden adherends (wood tear-out). However, when heat is introduced over the particles, failure loads decrease by ~60 % (inductive heating starting from +23 °C), ~50 % (+5 °C) as well as ~25 % (–10 °C), indicating that mechanical performance increases the lower the starting temperature of the joints is chosen. Aforementioned behaviour is accompanied by changes in

fracture patterns from adhesion failure on side of the wood (+23 °C) to mixed adherend / adhesion failure (–10 °C).

4 DISCUSSION

4.1 HEATING BEHAVIOUR

With regard to the curing temperatures (cf. Figure 5), the results revealed a strong influence of joint geometry on the heating behaviour. Compared to the small SLS joints, the way bigger GiR (120 x 120 x 300 mm) needed significantly more time (~10 min) to be heated to the necessary temperature range (> 80 °C) to cure the joints in a decent amount of time. These observations can be traced back to the fact that the comparatively long adhesive layer of the GiR (100 mm) promotes heat dissipation from the adhesive towards the remaining parts of the joints, resulting in lower heating rates in the following. In contrast, the way smaller SLS joints require less heat due to the smaller ratio between adhesive layer thickness and area available for heat transfer. Furthermore, a significantly lower mass of material has to be heated.

A further aspect to be considered is the heat that is released by the exothermic polymerisation, which can be expected to be different depending on the kinetics of the respective polymer. It is already known that this effect may lead to strong inhomogeneity's in heating depending upon joint geometry and adhesive layer thickness[11]. It can thus be concluded that any practical application will require a numerical simulation model, which covers heating-related effects and enables identification of best boundary conditions for optimal and most homogeneous heating. The aforementioned relations have already been presented and discussed in many publications of the authors and will thus not be repeatedly described herein [8,12].

4.2 MECHANICAL PERFORMANCE

4.2.1 Bulk level – Dogbone specimens

The tensile tests on the level of inductively cured DB specimens with different curing conditions resulted in indistinguishable results for both adhesives when the starting temperature of the induction process was varied between +23, +5 as well as –10 °C. These promising results suggest that the general build-up of cohesion is neither hindered nor prevented by the presence of the particles, the inductive heating process as well as the low starting temperatures of the polymerisation. However, from previous investigations it is already known that the mere presence of the much stiffer particles may lead to stress concentrations and earlier failure when unfilled reference and CP-filled DB specimens cured at RT are compared. These negative impacts are, however, counterbalanced when thermal energy is introduced over the susceptors – a process that brings tensile strengths back to the level of the unfilled references [13].

4.2.2 Compound level – Lap shear and Glued-in Rods

The mechanical tests on both the level of SLS as well as GiR joints resulted in promising findings, whereby all EPX-bonded specimens showed a clear adherend failure of the wooden substrates. It can thus be concluded that the general capability of the adhesive to build up significant adhesive strength is not hindered by both the curing process as well as the cold adherend temperatures. The process is thus very well suited for the 2K-EPX adhesive Fi390.

With regard to the LP421-bonded joints (2K-PUR), results behaved differently. In detail, the GiR cured at elevated temperatures showed significantly lower failure loads as well as mixed failure modes (adhesion / cohesion failure). The reason for the deterioration in mechanical performance can be found in the moisture contrained within the wood adherends, which diffuses from the adherends towards the adhesive layer when temperature is applied. In the following, the authors assume that the isocyanate groups of the polyurethane react with the released moisture, leading to both lowered cohesive as well as adhesive strength on side of the wood in the following. These assumptions are supported by the results on lap shear scale (cf. Figure 7-bottom) for which dried adherends were used and thus clear substrate failure could be achieved. In addition, the authors suppose that mechanical performance for low-temperature cured GiR is better due to slower heat development, i.e. slower moisture diffusion (cf. Figure 5, curve for GiR). However, since targeted drying of wooden structures may not represent a realistic solution with regard to practical application, these circumstances might exclude the use of polyurethane adhesives for the technique when temperatures. As a workaround, particles with a lower T_c might offer a way out of the wood-polyurethane-related problems discussed and thus enable their safe CP-curing.

In summary it has been shown that curing of adhesively bonded wooden structures starting in temperature ranges currently not intended by building authorities can be achieved by application of induction heating. Since onsite polymerisation under adverse temperature conditions like those presented would last weeks or not occur at all, the findings might pave the way for additional application fields for bonded timber connections in the future.

5 CONCLUSION

The study focuses on low-temperature curing of structural wood-adhesives (epoxy and polyurethane) using Curie particles (CP), which are added to the polymers and can be heated by an electromagnetic field (EMF) up to T_c but not beyond. For that, experimental investigations were carried out considering three different starting temperatures for the polymerisation (+23, +5 and –10 °C). In a first step, standardised specimen types (dogbone and single lap shear) were produced, after which the investigations were scaled up to the level of large wooden) Glued-in Rods (GiR). The following important findings were made:

- The heating behaviour of low-temperature cured wooden joints using inductively heated particles represents complex due to multifarious conditions such as joint geometry, the materials involved, joint starting temperature,

https://doi.org/10.52202/069179-0046

polymerisation enthalpy as well as the particle type determining the temperature distribution throughout the joint. For better process control, a numerical model would thus be necessary to identify optimal heating conditions and thus avoid cumbersome preliminary experiments.

- The mechanical results showed that tensile strength is identical for different starting temperatures of the induction process (+23, +5, -10 °C). The development of significant cohesive strength takes place, which was observed for both adhesives. In addition, it is known that two counteracting effects have to be considered: Firstly, deterioration of mechanical performance by the mere presence of the particles embedded within the polymers, secondly, counterbalance of negative impact by heat introduction to or above the level of the references[13].
- On the level of small (SLS) and large joints (GiR), a substrate failure could be attained for all EPX-bonded joints, suggesting that the technique is very reliable for EPX adhesives. For the 2K-PUR adhesive, a restriction has to be formulated: When wooden adherends are used and heat is introduced over the particles, moisture diffuses from the wooden adherends and interferes in the cross-linking reaction of the polyurethane. In the following, both adhesive as well as cohesive strength is deteriorated. In order to solve this problem, the authors assume that a lower T_c of the particles will lead to better mechanical results. On the level of SLS joints, polyurethane-bonded dried wood adherends showed a fracture behaviour indistinguishable to those of the references.
- Above all it can be summarised that low-temperature curing of wood structures has been made possible with the presented technique. In detail, the two considered structural adhesives would need weeks to cure at a temperature of –10 °C, which has been reduced to an induction time of ~10 min – a time window, which can be further reduced by e.g. inclusion of the cooling phase for curing or adapting the CP.

ACKNOWLEDGEMENT

The authors sincerely thank Dr. Joachim Schätzel of the Fischerwerke GmbH & Co. KG and Mr. Gordian Stapf from the Henkel AG & co. KGaA for providing the adhesives.

World Conference on Timber Engineering Oslo 2023

Rapid bonding of timber structures

Morten Voß*, Jona Haupt* & Till Vallée*

**Fraunhofer Institute for Manufacturing Technology and Advanced Materials, IFAM, Bremen, Germany*

ABSTRACT: Adhesively bonded timber-based elements are often manufactured with two-component (2K) adhesives (mostly epoxies and polyurethanes), which usually need many days until full cure, i.e. mechanical performance, has developed. The study shows how wooden components can be bonded in significantly less time by using inductively heated Curie particles (CP), which are added to the polymers and heated by an electromagnetic field (EMF) up to the particle's Curie temperature, T_c, but not beyond. The investigations were carried out using small single lap shear (SLS) as well as medium- and large-sized Glued-in Rods (GiR), all of which produced with spruce adherends. Furthermore, two frequently used 2K adhesives were analysed (epoxy and polyurethane). It could be shown that curing times can be reduced from 1/10 days down to 10 min of inductive heating by application of the technique.

KEYWORDS: Accelerated curing, wood adhesives, induction heating, Curie susceptors

1 INTRODUCTION

Depending on the respective application scenario, polymerisation can be a very slow process. Especially in many structural applications, the usually applied high-strength thermosets – mostly two-component (2K) epoxies (EPX) and polyurethanes (PUR) – require a lot of time (up to many days) until full cure has been achieved and the connections can be stressed or moved for further processing. The reason of these circumstances can be traced back to the comparatively long pot life, which is regarded as a prerequisite to be able to apply the adhesives onto the substrates in time.

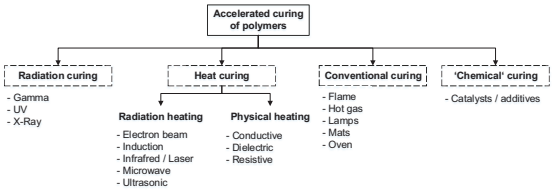

Figure 1: *Methods for accelerated curing of adhesives (no claim to completeness)*

Due to these (and many more) application-related limitations, many techniques for accelerated curing emerged, which can be achieved by different means (cf. Figure 1). The methods range from UV-curing [1], over electron beam[2] or microwave curing [3], to more conventional methods such as ovens. Many of them use heat that is introduced into the adhesive to increase monomer mobility and thus speed up the curing progress.

Probably one of the fastest ways for heat generation represents the use of electromagnetic induction[4] when metallic materials are subjected to an external electromagnetic field (EMF). In context of adhesive bonding technology, induction-based heating can be either used for direct heating of metallic adherends[5] or (when the joint consists of materials that are non-sensitive to EMF) for the heating of susceptors materials (e.g. fibres[6], particles[7], meshes[8] etc.) that are added to the polymers to be cured. In the following, the adhesives are cured 'from the inside'.

In this study, a special type of susceptors, Curie particles (CP), were investigated, which make use of the material-specific Curie temperature, T_c, to control the heating process (no more heat development above T_c) and thus prevent overheating – aspects, which many publications in the field do not consider[9,10]. It was thus targeted to create a self-regulating accelerated curing process, which eliminates the need to store timber-based elements for many days until they can be used.

2 Materials & methods

2.1 Adhesives

The investigations covered two thermosetting 2K adhesives (epoxy and polyurethane), which are frequently used in the German construction sector for wooden applications.

Table 1: *Material properties of the adhesives Fi390 and LP4821 taken from technical data sheet (TDS) or * that have been measured*

Property	Adhesive	
	Fi390	LP821
Adhesive type	2K-EPX	2K-PUR
Density, ρ [g/cm^3]	1.50	1.32
Pot life at +23 °C [min]	14-30	30
Curing time at +23 °C [h]	18	240
Young's modulus, E [MPa]	5230*	1.000
Tensile strength, σ_u [MPa]	40.0*	45.0
Elongation at break, ε_u [%]	1.2*	5.0
T_g for curing at +23°C [°C]	73.4*	71.5*

https://doi.org/10.52202/069179-0047

In detail, Fischer EM390S (abbreviated as Fi390, Fischerwerke GmbH & Co. KG, Germany) and Loctite Purbond CR821 (LP821, Henkel AG & Co. KGaA, Germany) were chosen. Most relevant material properties are listed in Table 1.

2.2 Curie particles

Since no EMF-sensitive materials were involved in all three joint types (cf. section 2.4), particulate Curie susceptors were added to the polymers to be able to heat the adhesives inductively. The particles had a Curie temperature, T_c, of 110 °C, which was selected based upon permissible heating requirements of the polymers. An in-depth characterisation of the CP type has e.g. been presented in [11], which is why it will not be repeatedly described in the present publication.

2.3 Mixing

All adhesive-CP mixes were prepared using a Speedmixer of type DAC 800.2 VAC-P (Hauschild GmbH & Co. KG, Germany). To ensure most homogeneous particle distributions, mixing was carried out under vacuum (100 mbar) using identical parameters for all adhesive-CP mixes prepared (v = 1.000 rev/min, t_{mix} = 60 s). Two different particle contents were used: 33.3 w/-% (~11–13 vol-%) as well as 7.5 w/w-% (2–3 vol-%). Corresponding results have been marked in the result section.

2.4 Specimen types

2.4.1 Lap shear joints

To analyse the performance of the inductively cured adhesives on a small joint scale, single lap shear (SLS) specimens acc. to DIN EN 1465[12] were produced using spruce (*picea abies*) adherends with dimensions 100 x 25 x 6 mm. Their overlap length was 12.5 mm and adhesive layer thickness was selected to be 0.3 mm. The moisture content of the adherends was measured for five adherends at five locations each and amounted to 9.8 ± 0.8 %.

2.4.2 Glued-in Rods

Besides the small SLS joints, experiments were up-scaled in the following to the level of medium- and large-scaled GiR connections, which represent a frequently used timber engineering application[13,14]. The latter consisted of blocks of spruce (*picea abies*, moisture content 8.1 ± 0.3 %) as well as rebars made of glass-fibre reinforced polymer (G-FRP), which were bonded into the wooden blocks. The pultruded rebars are marketed under the name Schöck ComBar® (Schöck Bauteile GmbH, Germany) and have a high resistance against corrosion. The joint geometry of the medium-scaled GiR can be seen in Figure 2.

The complete production approach of the GiR has been described in detail in e.g. [15], which is why detailed information regarding their manufacture will not be repeatedly presented in the present paper. However, the applied steps for induction heating are described in section 2.5.2 of the manuscript.

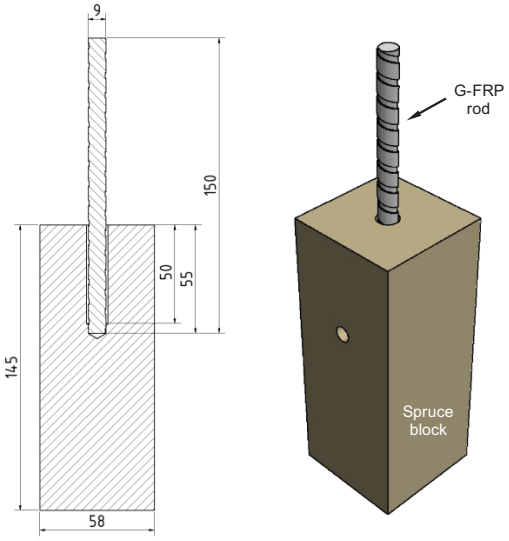

Figure 2: *Geometry of medium-sized wooden Glued-in Rods (GiR) used as an exemplary application for the inductive heating experiments, dimensions for large-scale GiR correspond to a doubling of all dimensions shown, all dimensions in mm*

2.5 Inductive heating

2.5.1 Experimental setup

For all inductive heating operations, the commercially available induction device TrueHeat 5010 (Trumpf Hüttinger GmbH & Co. KG, Germany) was utilised to cure the wooden joints. Depending on coil geometry and mounted capacitors, the system operates in a frequency range of ~50–500 kHz. Essential induction parameters have been summarised in Table 2. For validative purposes, curing temperatures were monitored with thermocouples embedded within the adhesive layers. Figure 3 shows the experimental setup for a medium-sized GiR as an example.

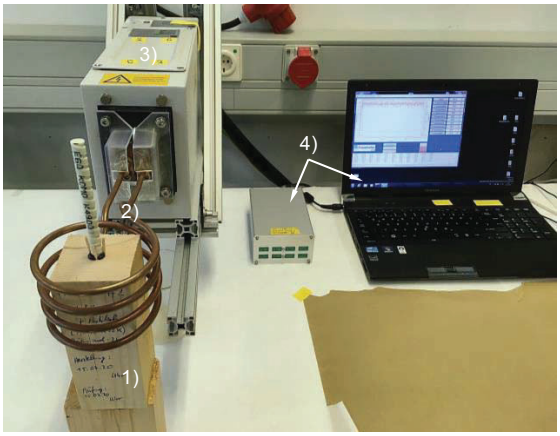

Figure 3: *Experimental setup used for inductive heating with 1) medium-sized GiR (exemplary joint, herein bonded with LP821), 2) induction coil, 3) induction device and 4) measurement electronics / software for thermocouple data evaluation*

https://doi.org/10.52202/069179-0047

Table 2: *Induction parameters for the different joint geometries*

Joint type	P [kW]	I [A]	U [V]	f [kHz]
SLS	4.8	26.3	640	134
GiR_M	4.7	35	650	177
GiR_L	3.8	29.4	795	120

2.5.2 Heating procedure

After mixing was complete, the adhesive-CP mixes were decanted into syringes or 1K disposable cartridges to be able to apply them onto the substrates – a process that has been visualised in Figure 4. All G-FRP rods were degreased with isopropanol 99.9 % and the wood blocks were freed of bore durst using compressed air- If temperature sensors were involved, these were fixed on the substrates using temperature resistant adhesive tape prior adhesive-CP application was performed. To minimise the possibility for air entrapments within the adhesive layer, all GiR joints were filled from bottom to top using a feedhole, which was drilled in the wooden blocks and ended flush with the hole that was used to centre the rods vertically.

Figure 4: *Application of the adhesive-CP mixes to the substrates using syringe for SLS joints (left) as well as 1K disposable cartridge for large-scale GiR (right), application for medium-sized GiR corresponds to right scenario but with syringe*

After adhesive-CP application was complete, the joints were placed within the induction coil (cf. Figure 3), so to ensure that all parts of the adhesive layer were tightly enclosed by the coil. Independently of the different joint geometries, the preparation never exceeded a time window of 7.5 min, which was well within pot life (cf. Table 1).

2.6 Mechanical testing

In order to check the capability of the technique for accelerated curing, the joints were destructively tested at different times after inductive heating ended. However, to exclude any influence of the elevated temperatures on the mechanical results, testing could earliest be performed when the connections had cooled down to RT, which took ~15 min for SLS specimens as well as ~1.5 h, for the GiR. Furthermore, additional time for preparation of the testing devices (~15–30 min) was needed. In detail, testing times of 2, 24, 240 as well as 720 h were investigated, with the GiR setups being illustrated in Figure 5.

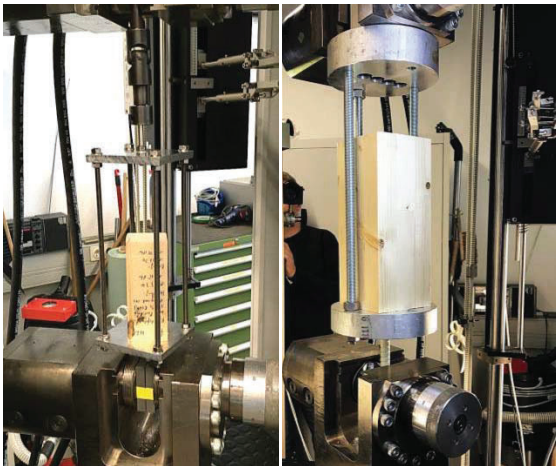

Figure 5: *Configurations for mechanical testing of medium- (left) and large-sized GiR (right), v = 2 mm/min, Zwick\|Roell UTM 100 kN, all tests performed at RT*

2.7 Experimental program

The investigations covered different test series, which have been summarised in Table 3. Besides the inductively cured joints (labelled as IND), reference sets with and without the addition of CP were produced. The latter were 'cold cured' (CC) at RT (23 ± 2 °C, 50 ± 10 % RH) following the protocols that were provided by the adhesive manufacturers. In addition, the expressions GiR_M and GiR_L stand for medium- as well as large-scaled GiR series, respectively.

Table 3: *Experimental program produced for each Fi390 (2K-EPX) as well as LP821 (2K-PUR), CC = Cold cured at RT, IND = Inductively cured, 2h = mechanical testing performed two hours after induction device was switched off*

Type	**Series**					
	CC_ Ref	CC_ CP	IND_ 2h	IND_ 24h	IND_ 240h	IND_ 720h
SLS	5	5	5	5/3	5	5
GiR_M	3	3	3	3	3	-
GiR:L	5	3	3	3	3	-

3 RESULTS

3.1 HEATING BEHAVIOUR

The first step of the evaluation of the results circumvented the analysis of the heating behaviour of the inductively cured joints, as shown in Figure 6. It can be seen that the two adhesives behave fundamentally different during the heating phases of 10 min. Thus, all joints bonded with Fi390 reach the T_c of the particles (110 °C) after different times, whereby ~3 min (SLS), ~5–6 min (GiR_M), as well as 10 min (GiR_L) are needed depending on the respective joint geometry.

In contrast, joints bonded with the 2K-PUR reach slower heating rates, with temperatures recorded for the SLS

https://doi.org/10.52202/069179-0047

joints showing a clear flattening at a curing temperature of approximately 70 °C. Furthermore, both GiR sizes reach temperatures of ~100–110 °C at the end of the inductive heating phase (t = 10 min).

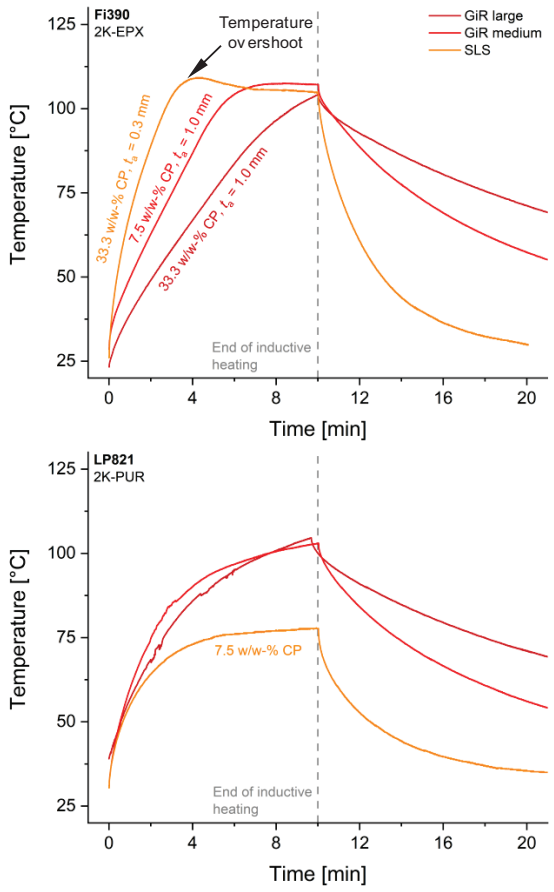

Figure 6: *Heating behaviour recorded with thermocouples embedded within the adhesive-CP mixes for the different joint geometries bonded with the two investigated adhesives, temperatures for medium- and large-sized GiR correspond to arithmetic mean out of three temperature sensors along the rod axis (top, middle, bottom)*

A particularity of the temperature data visualised in Figure 6 can be seen for SLS joints bonded with Fi390 between an induction time of 3–6 min. In this time window, the data reveals a slight temperature overshoot to ~120 °C after which the curve flattens again towards the Curie temperature of 110 °C.

Finally, it can be observed that cooling progresses largely different for the three specimen types, whereby SLS joints – independently of the adhesive – reach RT ~15–20 min after the induction device has been switched off. In contrast, medium- (~30–40 min) and large-sized GiR (~90 min) require significantly more time for cooling.

3.2 MECHANICAL PERFORMANCE

3.2.1 Lap shear specimens

The results for the mechanical SLS tests have been summarised in Figure 7, with the produced series for each adhesive being illustrated as a bar chart. The data shows that both adhesives behave fundamentally different in terms of their lap shear characteristics, i.e. attained lap shear strengths and fracture patterns. In detail, all SLS series produced with Fi390 resulted in a failure of the wooden adherends, indicated by the torn off wood fibres that can be seen in the exemplary failure modes in Figure 7-top. Furthermore, lap shear strengths across all series ranged between ~6–10 MPa independently of the curing conditions considered.

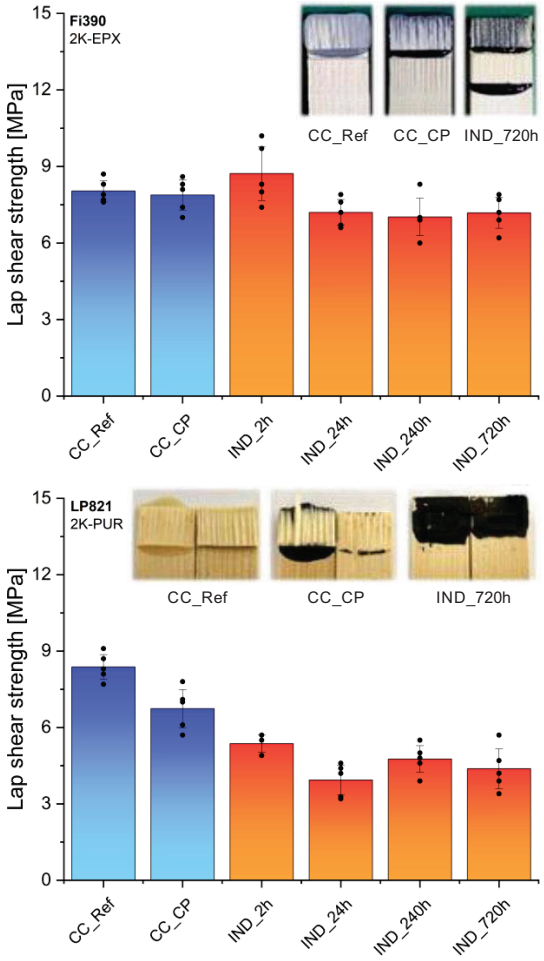

Figure 7: *Mechanical results for wooden SLS joints bonded with the two investigated adhesives, v = 2 mm/min, Zwick|Roell UTM 20 kN, all tests performed at RT*

When the results of the second adhesive (LP821) are compared to those of Fi390, clear differences can be observed. In detail, both series that were cured at RT (with and without added CP) resulted in substrate failure. However, when heat is introduced over the CP, lap shear strengths are lowered to ~3–5 MPa, which is accompanied

by a change in fracture patterns from substrate to cohesive failure (cf. Figure 7-bottom, rightmost pattern). This observation holds true for all inductively cured series of LP821, which were tested at different times (2–720 h) after inductive heating ended.

3.2.2 Glued-in Rods

In the next step, mechanical results for medium- and large-sized GiR were analysed and plotted in the form of bar charts in Figure 8 and Figure 9. Above all, the mechanical tests on GiR level confirmed the findings made on the standardised lap shear scale. Thus, for the 2K-EPX (Fi390) all produced series attained a failure of the wooden adherends, with wood plugs being pulled out of the blocks. Excluding outliners for the medium GiR, shear strengths mainly lie in the range of ~12–19 MPa, whereas large-scale GiR showed failure loads between ~30–55 kN (~4.8–8.8 MPa).

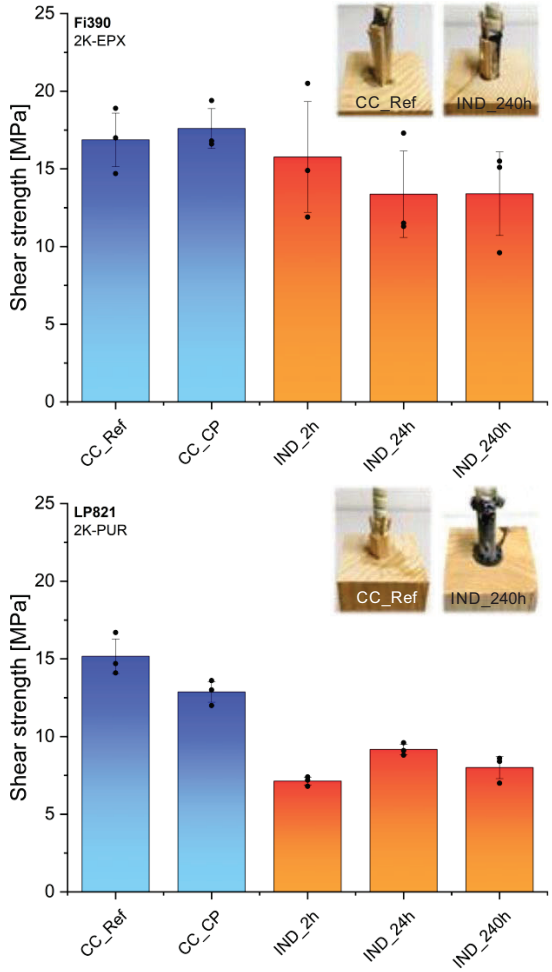

Figure 8: *Mechanical results for medium-sized GiR bonded with the two investigated adhesives; v = 2 mm/min, Zwick|Roell UTM 100 kN, all tests performed at RT*

Focusing on the LP821-related GiR results, the very same trend as on SLS scale became visible, with all CP-cured series cured at elevated temperatures showing a mixed cohesive / adhesive failure (wood side) – a result that is not changed by subsequent conditioning at RT. Furthermore, the mere addition of the susceptors did not impact the fracture behaviour on GiR level, proved by the RT-cured series with added CP.

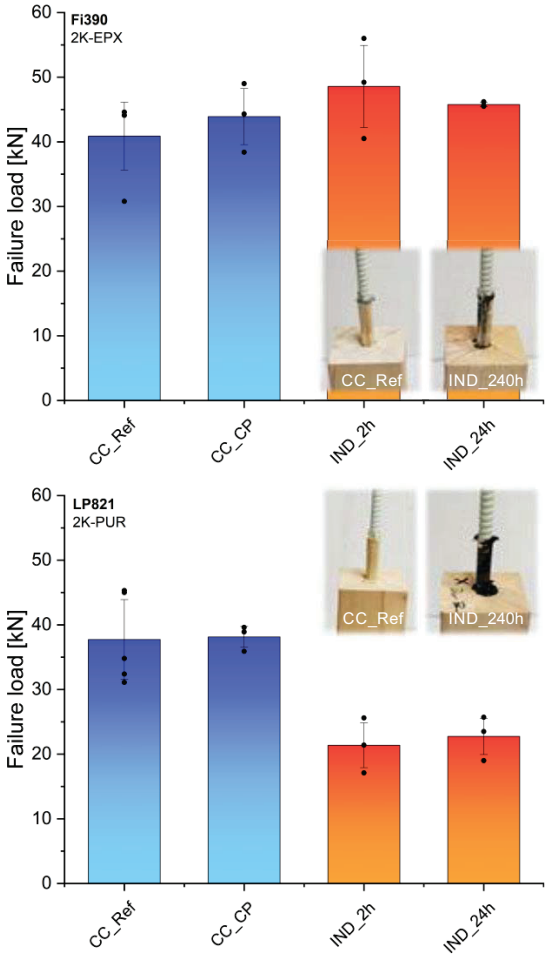

Figure 9: *Mechanical results for large-sized GiR bonded with the two investigated adhesives; v = 2 mm/min, Zwick|Roell UTM 100 kN, all tests performed at RT*

DISCUSSION

3.1 HEATING BEHAVIOUR

In general, the investigations regarding the heating of the different joint geometries revealed slower heating rates for LP821 compared to Fi390 across the specimen types studied. Since all remaining experimental conditions (CP content, coils, induction time, substrates etc.) were kept identical, the authors strongly assume that the curing kinetics, i.e. polymerisation enthalpy and rate of its release, contributed to the temperature distribution throughout the joints. It is already known that the 2K-EPX (Fi390) has faster kinetics and contains more enthalpy [16], which is why the connections can be heated way faster to the relevant temperature ranges. Especially at the beginning of the induction processes, the self-accelerating character of the cross-linking reaction plays a decisive

https://doi.org/10.52202/069179-0047

role, since a lot of enthalpy is released in a relatively narrow time window – a conclusion, which is supported by the enthalpy-related temperature overshoot recorded for Fi390-bonded SLS joints after 3–6 min of inductive heating (cf. Figure 6-top, orange curve).

Besides these adhesive-related differences in heatability, the presented temperature data additionally reveals that the joint type, i.e. the geometry and materials involved, represent a decisive influencing factor for the development of curing temperatures. This becomes particularly clear when the results for Fi390-bonded large-scale GiR and SLS joints (both produced with 33.3w/w-% of CP) are compared (cf. Figure 6-top, dark red and orange curves). Thus for the GiR, a way slower heating can be seen than for the small SLS joints, although adhesive layer thickness, i.e. enthalpy and potential for self-acceleration, is higher. It can thus be surmised that large joints are more difficult to heat but not necessarily excluded for the technique.

From these relations, it becomes clear that an efficient production planning would require a numerical model in which heating-related conditions are mapped to predict the temperature development. Without a simulation model, enthalpy- and geometry-related impacts on the heating can only be determined based upon cumbersome preliminary experiments.

Excluding the slight temperature overshoot for Fi390-bonded SLS joints, it could also be shown that self-regulating heating was successful achieved. However, practitioners have to consider that enthalpy-related overheating can occur if joint and induction conditions favour fast heating – aspects that have to be considered if a numerical model is set up. Parts of such a model have already been presented by the authors [11,17].

3.2 MECHANICAL PERFORMANCE

The extensive experimental campaign revealed a uniform behaviour on the three joint types (SLS, medium and large GiR). For Fi390, all series attained a failure of the wooden substrates – a very promising result. The authors conclude that neither the adhesives capability to build up cohesive as well as adhesive strength is significantly deteriorated by application of the process. However, it is known that both cohesive [18] as well as adhesive strength [19] might be influenced / altered by both the presence of the CP as well as the inductive heating.

In contrast to the EPX adhesive, joints bonded with LP821 systematically showed a mixed failure (adhesive / cohesive) when heat is introduced over the CP. The authors know that this effect does not originate from the nature of the polyurethane adhesive considered, but rather from the moist substrates that were used. In detail, the moisture diffuses out of the wooden adherends when heat is applied and interferes in the polymerisation of the adhesive, i.e. the isocyanate groups react under the formation of CO_2 (indicated by the bubbles that can be seen in the associated fracture patterns). In the following, adhesion / cohesion build-up is significantly deteriorated. It can be expected that the process is also applicable to the 2K-PUR when substrates are changed or the wood is dried before curing.

4 CONCLUSION

The study deals with the accelerated curing of adhesively bonded wooden joints for structural timber applications. For that, so-called Curie particles (CP) were added to two adhesives (2K-EPX and 2K-PUR), which are frequently used throughout the German construction industry. The particles can be heated by an electromagnetic field until their Curie temperature, T_c, is reached, above which the heating is capped by the nature of the particles. Based on these relations a self-regulating curing process is created, which eliminates the need for cumbersome temperature control and enables practitioners to bond under adverse conditions in significantly less time. For the experimental investigations, an up-scaling approach was chosen, with three different specimens types being investigated: standardised single lap shear (SLS) joints as well as medium- and large-scaled Glued-in Rod (GiR) connections – all of which produced with spruce adherends. In addition, the joints were tested at different times after the inductive heating to validate their mechanical performance immediately after and with increasing time after induction curing was complete. After evaluation of all data, the following impotant findings were made:

- The heating behaviour of CP-cured joints is largely determined by component geometry and the adhesive considered, in particular its curing kinetics and polymerisation enthalpy release, which contributes to the curing temperatures. Above all, larger joints are more difficult to heat, especially when long adhesive layers are heated, which offer a larger area for heat dissipation with the remaining parts of the joints.
- With regard to the mechanical performance of the adhesives, the 2K-EPX showed a fracture behaviour indistinguishable to the reference sets, which holds true for all specimen types considered. In contrast, the 2K-PUR showed strengths reductions of ~30–50 % across all joints when heat is applied over the added CP. This was attributed to moisture diffusion from the wooden substrates towards the adhesive layer, which interferes with the cross-linking reaction of the polyurethane. However, this problem might be solved by future investigations by e.g. using a CP type with a lower T_c. In addition, it is already known that the technique works when the adherends are dried prior the induction curing.
- Above all, the findings have to be assessed as very positive, since curing times of both considered adhesives could be reduced from 1 (Fi390) or 10 days (LP821) to an induction time of only 10 min. For future studies, it should be

targeted to include temperatures during the cooling phase or adapt the CP regarding their size and shape to further reduce times needed to cure the joints.

ACKNOWLEDGEMENT

The authors sincerely thank Dr. Joachim Schätzel of the Fischerwerke GmbH & Co. KG and Mr. Gordian Stapf from the Henkel AG & co. KGaA for providing the adhesives.

EXPERIMENTAL RESEARCH ON POINT-SUPPORTED CLT PANELS: PHASE 1: ROLLING SHEAR STRENGTH

Md Shahnewaz[1], Carla Dickof[2], Houman Ganjali[3], Christian Slotboom[4], Mandy Tam[5], Robert Jackson[6], Marjan Popovski[7], Thomas Tannert[8]

ABSTRACT: Rolling shear strength is one of the key design parameters for point-supported cross-laminated timber (CLT) flat-slab system where the panels are directly supported by columns without any beams. The specified rolling shear strength of CLT in the current Canadian design standard could be conservative estimates considering the variability in wood species, stress grade, thickness of lamellas, layups and grain orientations. To address these gaps in knowledge for the North American market, a Post + Plank research project is being undertaken by Fast+Epp structural engineers in collaborations with the University of Northern British Columbia. In the first phase of the project, presented herein, CLT rolling shear strength under in-plane shear loading was evaluated. A total of 330 specimens (11 series with 30 replicate each, sized 100 mm (width) × 300 mm (length) were tested. The parameters varied were thickness: 3-ply of 89 mm and 105 mm, and 5-ply of 139 mm and 175mm with multiple species and fabricators, and both visual and machine stress graded CLT. The mode of failure was crack development along the growth ring. The results show that the mean rolling shear strength of various Canadian CLT species was between 0.94 MPa to 1.8 MPa. Although thin layers exhibited relatively higher rolling shear strength, these differences were found not to be statistically significant.

KEYWORDS: Point-supported Floors, Cross-laminated Timber, Rolling Shear Strength, Punching Shear Failure.

1 INTRODUCTION

1.1 BACKGROUND

Cross-laminated timber (CLT) has become popular construction material for mid- to high-rise buildings because of its benefits to sustainability, fast installation, design flexibility and overall good acoustic, thermal, fire and seismic performances. Point-supported CLT is a flat-slab building system, where CLT panels are supported directly on columns without drop beams, as designed in the 18 storey Tall Wood House in Vancouver (Figure 1) [1]. This configuration is appealing due to its ease of construction, ease of mechanical and electrical distribution, and reduction of the floor assembly depth. However, the transfer of force at the column faces leads to high shear stress near supports [2].

The strength of CLT in shear is governed by the rolling shear strength in the lamella perpendicular to the direction of loading. In this context, rolling shear refers to stresses causing tension perpendicular to the wood grain in layer perpendicular to the loading, creating a tendency for lamella to roll over each other [3].

Rolling shear strength values adopted in Canadian and American wood design standards [4,5] are much lower than longitudinal shear, and will often govern the capacity of point-supported panels. However, recent studies on [3,6,] suggested that the short-term rolling shear values specified by different standards are overly conservative.

1.2 ROLLING SHEAR STRENGTH IN CLT

Wood is an anisotropic material with three major axes: longitudinal, tangential, and radial relative to the log. Rolling shear occurs in the tangential-radial plane perpendicular to grain direction; failure occurs when the longitudinal fibers roll over each other. Rolling shear strength (f_s) is lower than longitudinal shear strength parallel to grain (f_v), and often "taken as approximately one-third" [3]. The specified CLT rolling shear strengths in Canadian Standard for Engineering Design in Wood [4] range from 0.43 to 0.63 MPa, the allowable stress design values in American Design Standard [5] is between 0.24 to 0.41 MPa depending on the base-material stress grade. For both edge-glued and non-edge-glued CLT made of laminations with a minimum width-to-depth ratio of 4, the recommended rolling shear strength in Europe is 1.4 MPa [7]. If the minimum width-to-depth ratio requirement is not met, then a value of 0.7 MPa is recommended instead.

Rolling shear properties of CLT do not currently have universally standardized test configurations and methods, primarily short span bending tests and in-plane shear tests are conducted. In-plane shear test apply load to a specimen at a 14° angle on the outer lamellas, similar to EN408 [8]. Four-point bending tests for CLT allow to indirectly determine the rolling shear strength. Kumar et al. [9] reported that the in-plane shear test resulted 10-20% higher strength compared to rolling shear estimated from bending tests. EN 16351 [7] adopts both methods and ANSI PRG 320 [10] refers to short span bending tests.

Amongst the several factors that influence the rolling shear properties of CLT: wood species, density of wood, annual ring orientation, the lamella aspect ratio (width to thickness of lamella), knots, and edge gluing or edge gaps, species appears to have the largest impact [9]. Previous studies completed on European species reported the mean rolling shear strength to range from 1.5 MPa to 2.8 MPa for softwoods and up to 5.6 MPa for hardwoods [5]. The mean rolling shear strength observed in North American species ranged from 1.3 MPa to 2.3 MPa [11-13]. The mean rolling shear strength observed for various Australian/New Zealand wood species ranged between 2.0 MPa to 3.6 MPa [3].

Further research found that the shear strength of CLT is increased near column supports [14, 15]. This increase is largely due to two effects: i) the lamella confinement of adjacent layers; and ii) additional confinement against rolling from compression forces. In North America, there have been few tests to confirm these findings, nor has the increase in rolling shear capacity due to confinement s been evaluated for a variety of support conditions. At time of writing, only one research program has completed full-scale panel test [2].

1.3 RESEARCH PROGRAM OVERVIEW

To address these gaps in knowledge for the North American market, a Post + Plank research project is being conducted by Fast+Epp structural engineers in collaborations with the University of Northern British Columbia. This research program will expand industry knowledge on point-supported CLT floors by experimentally testing a wide range of variables critical for point supported CLT construction.

The Post+Plank project will investigate the structural performance of North American CLT panels in point-supported construction through a series of numerical analyses and experimental testing. The experimental testing program will consist of four phases. Phase 1 of testing will use small CLT billets to test short-term rolling shear strength and stiffness of a variety of species, layups, and grades. The results to date from this phase will be reported in-depth in this paper.

In phase 2, the CLT rolling shear strength under 4-point bending loading will be determined for both short-term and long-term duration of load. In phase 3, the punching-shear strength will be evaluated under variation of following parameters: a) support condition (columns at the panel centre, edge, and corner; b) CLT lamella species and grade; c) column support geometry; and d) level of screw reinforcement. Panels sized 1.7×1.8 m, 1.5×1.8 m, and 1.5×1.5 m will be used. Six repetitions per test series for a total of 180 specimens will be tested. Phase 4 will be completed on full-scale floor systems to validate the strength predictions from phases 1 and 3. Six two-span continuous panels will be tested with varying parameters including panel width and presence of penetrations.

2 PHASE 1: SHORT-TERM ROLLING SHEAR STRENGTH

2.1 MATERIALS

In Table 1, and overview of all test series including wood species, stress grade, test layer orientation, and thickness is provided. Tests are completed for E and V rated CLT samples for different species, including Black Spruce and SPF. Each species and grade is tested in both major and minor layer orientations for 3-ply of 89 mm and 105 mm thicknesses and 5-ply of 175mm and 139mm thicknesses CLT panels to evaluate the impact of lamella aspect ratio. The numbers in bold and underlined show the layup, orientation, and thickness of the tested layers.

Table 1: *Test series overview*

Series	Stress Grade	Layup	Species	Tested layer
S1	E1	35/**19**/35	Spruce	Minor
S2	E1	35/**35**/35	Spruce	Minor
S3	E1	35/35/**35**/35/35	Spruce	Major
S4	V2	35/**19**/35	SPF	Minor
S5	V2	35/**35**/35	SPF	Minor
S6	E1	35/35/**35**/35/35	SPF	Major
S9	V2	35/17/**35**/17/35	SPF	Major
S10	V2	35/17/35/**17**/35	SPF	Minor
S11	V2	35/**19**/35	SPF	Minor
S12	V2	35/**35**/35	SPF	Minor
S13	E1	35/35/**35**/35/35	SPF	Major

https://doi.org/10.52202/069179-0048

2.2 METHODS

The specimens were prepared and tested at the University of Northern British Columbia Wood Innovation and Research Laboratory in Prince George. All specimens were conditioned at 20 °C and 65% relative humidity prior to testing. The nominal length and width of each specimen was 300 mm and 100 mm, respectively. The thickness of the lamella of interest varied depending on the layup of the specimen; test specimens of different width are presented in Figure 2. The exact dimensions of the lamellas within the shear plane were measured for each specimen by means of a calliper prior to testing.

Small-scale in-plane shear tests following EN 408 [8] were conducted with the modification where the specimen is inclined against the vertical axis by 14° [16], as shown in Figure 3. The tests were performed using a universal test machine with a calibrated 100kN load cell, at a loading rate of 1 mm/min.

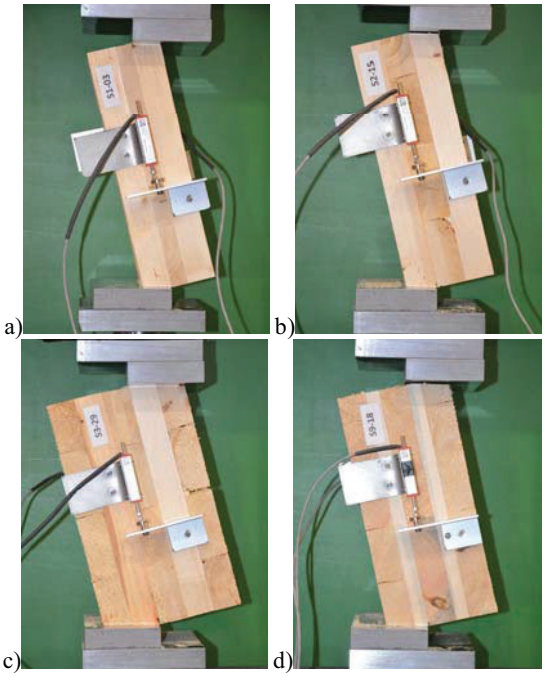

Figure 2: *Test specimen of different width: a) 89mm; b) 105mm; c) 175mm; d) 139mm*

Each specimen was loaded to failure and the rolling shear strength (τ) and shear modulus (G) were calculated by Equation (1) and Equation (2), respectively:

$$\tau = \frac{P_{max}\, cos\alpha}{L\, w} \quad (1)$$

$$G = \frac{t_c}{L\, w}\frac{P}{\Delta}\, cos\alpha \quad (2)$$

Where, P_{max} is the peak load, L and w are the length and the width of the specimen, t_c is the thickness of cross layer, P/Δ is the slope of the linear range of the load deformation curve between 10% and 40%, and ∝ is the angle between the shear plane and the force (14°).

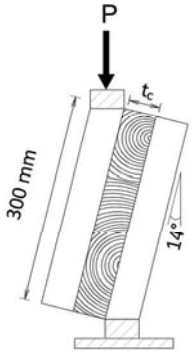

Figure 3: *Modified planar-shear test*

To calculate the average rolling shear modulus of each test series, two linear variable differential transformers (LVDTs) were used to measure the relative displacement between CLT layers adjacent to the loaded layer, on both front and back faces on 15 randomly selected specimens from each series. Load vs. the relative displacement curves of the specimens from S10 are shown in Figure 4. Most specimens exhibited quasi-linear behaviour until failure and sustained some load after peak and failure.

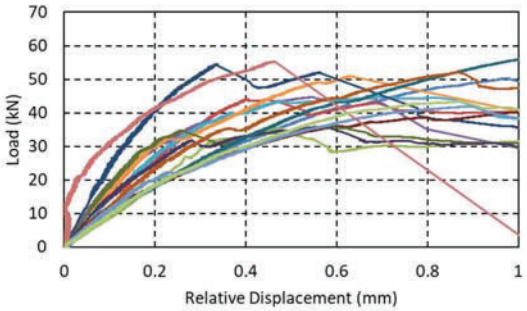

Figure 4: *Load vs. the relative displacement curves of S10.*

Since CSA 086 [4] gives the same value for rolling shear strength of 0.5 MPa for both strength grades, all 13 series were grouped together and the corresponding characteristic rolling shear strength is calculated. Nonparametric percent point estimate (NPE) and parametric tolerance limit (PTL) approaches described in EN 789 [17] were evaluated to calculate the 5th percentile rolling shear strength values. The NPE approach requires fewer assumptions and is deemed more conservative, while the PTL assumptions may lead to inaccurate results, thus NPE is adopted in the rest of this report.

EN 16351 [7] provides rolling shear strength values of CLT panels based on their lamination width-to-depth ratio. Therefore, all specimens with a tested layer thickness of 35 mm were considered as one group called "Thick" and the specimens having tested layer thicknesses of 19 mm and 17 mm were considered as a second group called "Thin". Outliers are excluded from each individual group of specimens. To further groups based on the stress grade of the specimens, E1 and V2, are also created and named accordingly.

https://doi.org/10.52202/069179-0048

2.3 ROLLING SHEAR STRENGTH RESULTS

The results from the in-plane rolling shear tests of all series are summarized in Table 2. The average of the rolling shear strength varied from 0.94 MPa to 1.81 MPa with a coefficient of variation (COV) between 14% to 37%. The average shear moduli range from 84 MPa to 157 MPa with a COV between 11% to 35%. When compared to those obtained in previous research, the measured mean value from this study is in a good agreement with those of the previous studies on the same softwood species.

The characteristic rolling shear strength values of each series are also presented in Table 2. It should be noted that these values need to be adjusted for normal duration of load, i.e., they should be divided by 1.15, if they are to be compared with the specified values in CSA O86 [4].

Table 2: *Summary of test results*

Series	Rolling shear strength			Rolling shear modulus	
	Mean [Mpa]	COV [%]	$\tau_{0.05}$ (NPE), [MPa]	Mean [Mpa]	COV [%]
S1	1.55	18	1.02	157	21
S2	0.94	19	0.60	87	22
S3	1.06	21	0.73	135	32
S4	1.81	23	1.27	104	23
S5	1.72	22	1.23	126	20
S6	1.51	14	1.23	150	11
S9	0.96	24	0.61	140	34
S10	1.54	20	1.10	85	35
S11	1.69	37	0.70	87	21
S12	1.10	20	0.67	102	34
S13	1.48	20	1.08	138	20

Previous findings suggest that the width to thickness ratio of the CLT lamellas influences its rolling shear strength where thinner boards with a higher width to thickness ratio have a greater rolling shear strength were confirmed. For instance, the thinner series, S1 (19 mm) has a greater average rolling shear strength value than the series having thicker test layer from this provider, S2 (35 mm). Similar finding can be observed by comparing values of the series from the panels provided by the same manufacturer.

The cumulative distribution of the rolling shear strength of all E1 and V2 series and the two other combined groups (Thin and Thick) are shown in Figures 5-8. The characteristic rolling shear strength value of E1 and V2 series combined groups are 0.73 MPa and 0.79 MPa, while the characteristic rolling shear strength value of Thin and Thick combined groups are 0.85 MPa and 0.72 MPa respectively.

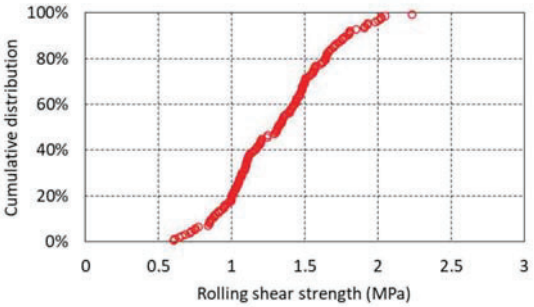

Figure 5: *Cumulative distribution for rolling shear strength of all E1 panel series.*

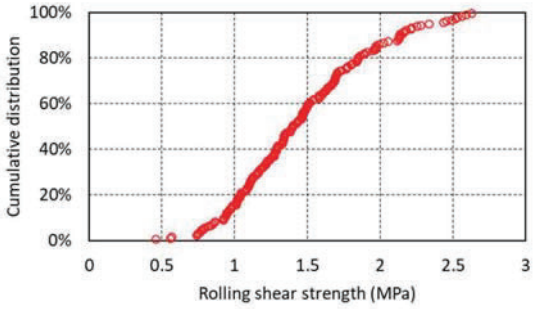

Figure 6: *Cumulative distribution for rolling shear strength of all V2 panel series.*

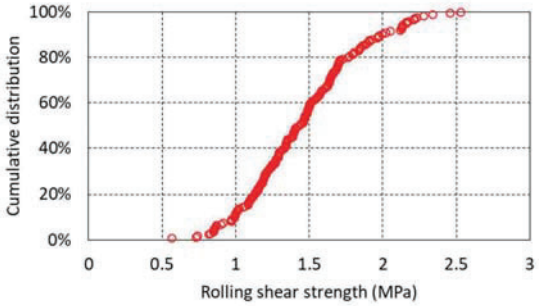

Figure 7: *Cumulative distribution for rolling shear strength of all "Thin" width-to-depth ratio.*

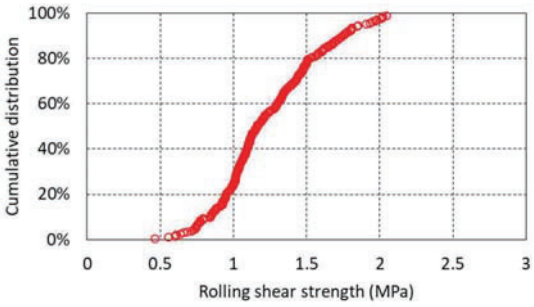

Figure 8: *Cumulative distribution for rolling shear strength of all "Thick" width-to-depth ratio*

https://doi.org/10.52202/069179-0048

For an in-depth investigation of the measured values, one-way ANOVA test [18] was performed with a significance level of 95% and a cut-off *p*-value of 0.05. The obtained *p*-value <0.001 showed that there were statistically significant differences between the test series. Therefore, a Tukey's multiple comparison test was conducted, see Table 4. It can be observed that despite the difference in their average rolling shear strength values, not all *"Thin"* series are different from *"Thick"* series. For instance, it cannot be claimed that S1 is different from S5, S6, and S13. Similarly, it also cannot be claimed that all *"Thick"* are not different from each other; as shown in Table 4, there is a significant difference between S2 and S5.

Table 4: *Tukey's multiple comparison test results.*

Series	Grouping[1]	Grade	Thickness
S1	ca	E1	Thin
S2	b	E1	Thick
S3	b	E1	Thick
S4	c	V2	Thin
S5	ca	V2	Thick
S6	a	E1	Thick
S9	b	V2	Thick
S10	a	V2	Thin
S11	ca	V2	Thin
S12	b	V2	Thick
S13	a	E1	Thick

[1] There is no significant difference at the 0.05 level between groups having at least one letter in common.

2.4 FAILURE MODES

The typical rolling shear failure mechanisms are illustrated in Figure 9. In the most common failure mechanism, cracks formed and propagated along the growth ring and led to a separation. In most tests, the crack(s) stopped at the bonding surface of loading plates and test layer, which resulted in the ultimate fracture. This was occasionally interrupted by steps along the wood ray. The presence of a pith in a specimen also led to the rolling shear failure, where a crack suddenly formed around the pith and then propagated along either the growth ring or a wood ray direction. Same scenario might happen when the wood ray which is a weak zone in a wood section is present. As shown in Figure 9, cracks were caused by tension perpendicular to grain stresses and propagated along the wood ray. During the tests, each or any combination of the above-mentioned mechanisms may have been the reason for initiation of failure, but as the load increased a combination of all three failure mechanisms was likely to be observed.

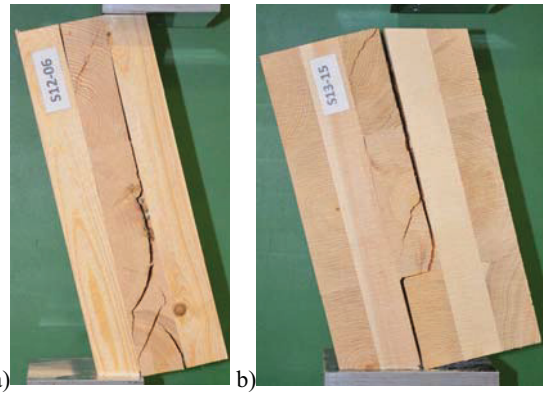

Figure 9: *Typical rolling shear failure of (a) 3-ply, (b) 5-ply*

3 CONCLUSIONS

The Post+Plank program will assess the punching shear capacity of CLT flat slab systems through a large of experimental program. Results for the first phase of testing is overviewed in this paper, showing the base rolling shear strength for North American manufacturers of CLT. The following observations were made:

1. The predominant mode of failure was due to the development and extension of cracks along the growth ring, eventually resulting in separation. Additionally, the presence of a pith in the specimen results in rolling shear failure, wherein a crack abruptly initiates around the pith and extends either along the growth ring or along a wood ray direction.
2. The average of the measured rolling shear strength varied from 0.94 MPa to 1.81 MPa and the average shear moduli ranged from 84 MPa to 157 MPa.
3. The CLT series with a thinner layer exhibited higher average rolling shear strength than the thicker ones, corroborating earlier research that established a positive correlation between width-to-thickness ratio (lamella aspect ratio) and rolling shear strength; however, ANOVA showed these differences not to be consistently statistically significant.
4. The characteristic rolling shear strength values of the combined groups of E1 and V2 series after adjustment for normal duration loading were 0.63 MPa and 0.69 MPa, respectively. These values are 26% and 37% higher than what is specified in the CSA O86 standard [4].

The ongoing structural testing program at Fast + Epp and the University of Northern British Columbia will provide design inputs for point supported CLT.

PRELIMINARY TEST RESULTS ON THE IN-PLANE STRENGTHENING OF TIMBER FLOORS WITH THE DOUBLE PLANKING TECHNIQUE

Giovanni Metelli[1], Alessandra Marini[1], Stefania Cominelli[1], Francesca Feroldi[1], Anna Maria Basso Bert[2], Ezio Giuriani[1]

ABSTRACT: The seismic retrofit of existing masonry buildings often needs global interventions to guarantee the box-structural behaviour to inhibit the onset of local mechanisms. However, the so called box structural system requires a correct organization of the diaphragm, as well as its adequate connection to the masonry walls. The use of a new crosswise single layer of wooden planks is here proposed for the in-plane strengthening of existing timber floors. According to this solution, the new layer made with wooden planks has an inclination of 45° with respect to the existing ones that are arranged orthogonally to the wooden beams. The wall-to-floor connection is made of studs fixed to perimeter chord, which is in turn nailed to the wooden planks. The aim of this work is to highlight the role of the type and arrangement of the connections between the wooden planks and the steel plate on the shear behaviour of the diaphragm, as well as on the transmission of the actions from the perimeter chords to the diaphragm inner web-panel by means of an analytical model. The test results on in-plane cyclic shear behaviour of the diaphragm shows a linear trend of shear stresses along the plates, contrary to the usual design practice that assumes a uniform distribution.

KEYWORDS: diaphragm, seismic upgrade, double-planks, nailed connections, in plane shear behaviour

1 INTRODUCTION

The high seismic vulnerability of historical masonry buildings is mainly due to onset of local collapse mechanisms, which involve the detachment of the perimeter walls perpendicular to the inertial actions [1]. In the worst-case scenario, the detachment is followed by the rigid out-of-plane overturning of the masonry blocks or of the whole wall, thus causing also the floors' collapse. Widely used techniques for the retrofitting of masonry buildings rely on the adoption of roof and floor diaphragms. When efficiently connected to the perimeter walls, the diaphragm can collect the inertial forces of the floor and of the wall loaded out-of-plane and transfer them to the shear resistant walls, thus preventing the onset of local mechanism and guaranteeing a box-like behaviour of the whole building [2-5].

Traditional techniques for the construction of a rigid diaphragm entail the use of reinforced concrete slabs. Such a solution was also recommended by past national codes: for example, before the enacting of the Italian building Code (D.M. 2008 [6]), earlier Italian codes recommended replacing the existing timber floor with a new heavy concrete slab, with the exception of historical and monumental buildings for which the conservation of the existing materials was a mandatory requirement for the preservation of the cultural heritage.

Recent Italian earthquakes (2016, 2017) showed the ineffectiveness of the concrete slabs to provide the box-behaviour of stone-masonry buildings, since the walls were not able to withstand significant seismic actions generated mainly by the high mass of this type of diaphragm.

Several techniques were proposed in the past for the construction of in-plane floor diaphragm. Initially, the same techniques proposed for the flexural strengthening of existing wooden floors, fully compliant with the conservation principles of heritage buildings, were further engineered as to also activate a diaphragm action. They rely on the replacement of the non-structural existing screed placed between the wooden planks and the floor, with a structural overlay, stud-connected to the wooden joists, thus generating a composite cross section. The collaborating structural overlay may consist of ordinary [7-8], or natural hydraulic lime mortar [9]. Alternatively, the extrados retrofit may be obtained with a very thin steel plate [10], or of Fiber Reinforced Polymers (FRP) [11]. Recently, efficient dry composite sections were also proposed by using single or double-crossed timber planks [12] or Cross Laminated Timber panels (CLT) [13-16], connected to the existing joists by steel dowels or screws. More recently, specific solutions for wooden floor diaphragms were proposed. The in-plane behaviour under shear loading of strengthened wooden floors was experimentally and numerically investigated by considering: i) composite materials [13, 17-19] ii) single and double diagonal wooden boards, having different thicknesses and orientation of the planks, for varying the connection type and the arrangement between the adjacent boards [13, 17-19]; iii) CLT panels [14, 16]. Other experimental studies investigated retrofitted wooden diaphragms with a different test set-up allowing the development of both the in-plane flexural and shear deformation of diaphragms like in a real building. Several stiffened configurations were considered: i) a single layer of plywood panels or flooring boards connected with

[2] Anna Maria Basso Bert, Soprintendenza Archeologia Belle Arti e Paesaggio per le province di Bergamo e Brescia , Italy,

https://doi.org/10.52202/069179-0049

stapled metal sheets [5, 20]; ii) a single overlay of nailed plywood panels [21, 22]; iii) a second diagonal layer of wooden planks, nailed on the existing planks; iv) diagonal bracing consisting of screwed steel plates or epoxy-resin glued FRP strips; v) multi-layers of plywood panels glued on the existing floor; vi) traditional thin reinforced concrete slab connected by means of steel stud to timber joists [23, 24]; vii) a steel truss fixed to the joists' intrados [21].

The experimental results showed that the several proposed configurations can efficiently enhance the in-plane capacity and stiffness of the strengthened timber floor. Furthermore, the experimental results may be considered as an effective benchmark for the validation of numerical and analytical models aiming at shedding light on the capability of flexible diaphragms to affect the global response of the whole buildings, by controlling the out-plane detachment of masonry walls and by contributing to dissipate energy during a seismic event [16; 25].

Among all the cited techniques for the retrofitting of the existing timber floors, it is worth acknowledging that the application of an extrados double crossed planks or timber panels (either plywood or CLT panels) has been widely accepted in the field of architectural restoration as less invasive, with a high degree of reversibility and without the risk of moisture and water percolation. Furthermore, these dry wood-based techniques are very light and the seismic retrofitting of the whole building can benefit from reduced seismic actions with respect to the use of the concrete overlay.

The effectiveness of the retrofit interventions, based on the adoption of either floor or roof diaphragms, is governed by the correct detailing of the connections between the diaphragm and the perimeter walls transferring both the out-of-plane inertial forces of the walls to the floor diaphragm, and the seismic floor actions to the seismic resistant walls. Specific technological, experimental and analytical studies can be found in literature focusing on the local behaviour of steel studs connecting the perimeter diaphragm chords to the masonry walls [26, 27]. This technique has been widely accepted and adopted in the construction practice for the retrofit of many historical monuments since it minimally invasive as opposed, for example, to dovetail joints, and it improves reversibility of intervention.

The literature survey shows that, despite many experimental results on the in-plane strengthening of existing wooden floors, there is a lack of scientific studies focusing on the correct detailing of the connections between the floor diaphragm web panel and the perimeter chords, commonly realized by steel plates. Such a detailing is critical since it governs the distribution of the shear forces/stresses along the diaphragm edges during a seismic event. This paper focuses on the fundamental role of these connections and it aims at presenting design criteria and rules for a correct design of the boundary elements in a wooden diaphragm with double planks.

2 AIMS OF THE RESEARCH

The present research deals with light-dry-wooden diaphragms with double crossed floorboards because this technology complies with the conservation principles of historical buildings, such as compatibility with existing materials, high-reversibility and low-invasiveness. Furthermore, the use of overlaying double planks allows the floor to be breathable while wood panels, like plywood, laminated veneer lumber (LVL) and CLT, can entail vapour barrier due to the presence of adhesive layers which may produce water condensation, thus favouring the degradation of the existing materials.

In the case of the double crossed planks technique, the diaphragm is obtained with the application of new planks overlaying the existing floorboards. the new layer of planks can be placed either perpendicularly (α=90°) or with an inclination of α=±45° to the existing ones. It should be pointed out that the two solutions differ in the capability of transferring the shear actions within the diaphragm. While in the former configuration the resisting shear flow depends both on the width of the overlaid planks and on the number of nails placed at the intersection of the planks, in the latter configuration the resisting shear flow mainly depends on the number of nails placed along the diaphragm boundaries [28]. Furthermore, it can be easily proved that the arrangement with perpendicular planks requires a total amount of nails ten times greater than the configuration with diagonal planks since each intersection between the overlaying timber boards needs at least four nails.

For these reasons, the research work was restricted to the case with diagonal planks only, for which nail connections can be limited, in principle, along the contour to guarantee equilibrium. The connection between the floor diaphragm and the perimeter walls is provided by the diaphragm perimeter chords, usually made with steel profiles (either L-shaped or rectangular section, Fig. 1). The chords are nailed to the double wooden boards and jointed to the seismic-resistant masonry wall by means of shear dowels and to the walls perpendicular to the earthquake direction by means of steel ties which transfer the inertial actions to the diaphragm.

The present work aims at investigating the transfer phenomenon of the shear actions from the boundary steel chords to the diaphragm web panel made of overlaid double planks. Experimental and theoretical studies are presented that focus on the role and the arrangement of the connections on the transmission of actions from the perimetral chords to the inner web of the diaphragm.

As a result, specific design detailing of the boundary connection, with the adoption of additional nails, is proposed to guarantee the effectiveness of the diaphragm. In the first part of the paper, the behaviour of the connections between the overlaying double crossed planks and the perimeter steel chords is analytically studied, whilst in the second part the experimental results of a full-scale test on the proposed wooden diaphragm are presented.

3 DESIGN OF THE CONNECTION

3.1 EFFECT OF SHEAR FLOW DISTRIBUTION ON THE ACTIONS IN THE CONNECTIONS

A rectangular floor diaphragm is considered (Fig. 2). At a given storey, the seismic actions (f_0) produce a uniform distribution of shear flow q= V / L_y, being V the force transferred to the seismic-resistant walls and L_y the diaphragm depth. The shear flow (q) transferred from the perimeter steel chord to the diaphragm web panel depends on the orientation of the timber joists, which can either be perpendicular (case 1 in Fig. 3), or parallel to the diaphragm edge (case 2 in Fig. 3), respectively. In the diagonal configuration, the horizontal and vertical translational equilibriums of a floor length equal to the joist spacing (Δx) allow for the evaluation of the axial action (F_y) in the joist and in the diagonal wooden plank (f_{wd}), as follows:

$$q\,\Delta x = f_{wd}\,\Delta x\,cos^2\alpha \quad F_y = f_{wd}\,\Delta x\,cos\alpha\,sin\alpha \qquad (1)$$

where α is the inclination of the diagonal planks. If α = 45°, the actions in the joists and in the diagonal planks are given by:

$$f_{wd} = 2\,q \qquad F_y = q\,\Delta x \qquad (2)$$

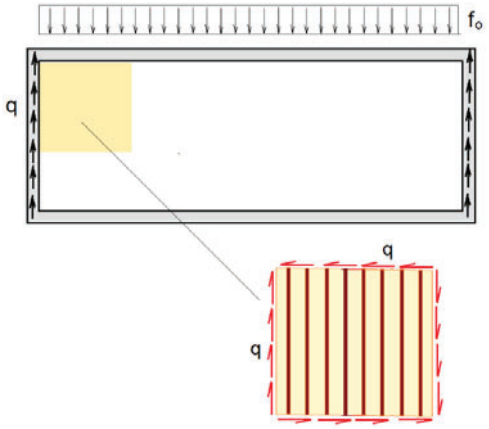

Figure 2: *Shear flow distribution in the diaphragm*

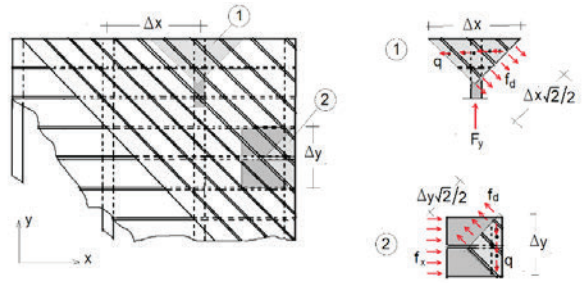

Figure 3*: equilibrium of timber planks along the diaphragm edge*

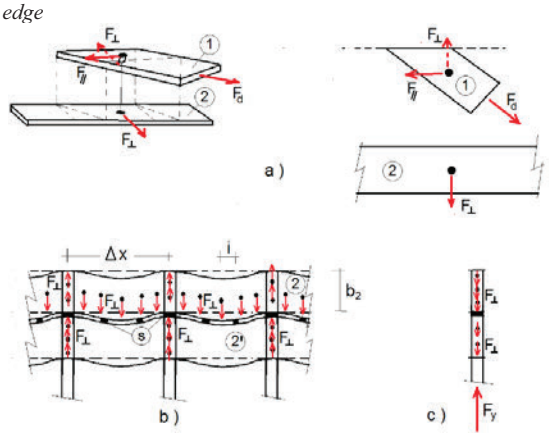

Figure 4: *Portion of the diaphragm with the joist perpendicular to the edge: actions in the nailed connection (a) in the lower existing plank (b) and in the joist (c)*

Furthermore, the shear flow along the diaphragm edge is transferred from the perimeter steel chord to the diaphragm's web panel made of the double-crossed planks through local forces acting in each nailed connection perpendicularly ($F_\perp$) or parallel ($F_{//}$) to the edge (Fig. 4a), as given by the following equation once it is assumed that the steel chord is nailed over the double-crossed planks with a given nail spacing (i) and with plank orientation of α=45°:

$$F_\perp = F_{//} = q\,i \qquad (3)$$

As shown in Figure 4b, the plank parallel and close to the edge is loaded by the bending action induced by the transverse forces $F_\perp$of the nailed connections. Thus, the bending moment (M_2) in the perimeter planks is given by:

$$M_2 = \beta(F_\perp/i)\Delta x^2 \qquad (4)$$

where $\beta = \frac{1}{10} \div \frac{1}{12}$ if the outer plank is modelled as a continuous beam supported by timber joists. As a result, the reaction in the inner supports can be approximately assumed as equal to (Fig. 4c):

$$R = \frac{F_\perp}{i}\Delta x = F_y \qquad (5)$$

It should be noted that each joist has to be connected to the outer plank (labelled as 2 in Fig. 4) by the same number of nails ($n_{nails} = \Delta x/i$) placed along the edge length (Δx). Since in most cases all these nails cannot be placed within a single outer plank (b_2), it is necessary to

https://doi.org/10.52202/069179-0049

include also the inner planks in the connection. In the case of clearance between the existing floor boards, specific wooden or steel wedges have to place between them in order to engage the bending stiffness of the inner plank. Thus, the bending stress of the outer planks having the same width (b_2) (2 and 2' in Figure 4) is:

$$\sigma_2 = \sigma_{2'} = M_2(2t_2 b_2^2/6) \quad (6)$$

The number of nails to connect the steel chord to the double-crossed diaphragm within the joists spacing is:

$$n_{nails} = q\Delta x / V_{Rd,n} \quad (7)$$

where $V_{Rd,n}$ is the shear design strength of each nailed connection. The same number of nails connects the outer planks (2 and 2' in Fig. 4) to each joist.

Along the edge parallel to the joist (case 2 in Fig. 3), the connection does not produce any bending in the perimeter joist since the two layers of planks guarantee the translational equilibrium of the perimeter chord length (Δy). In other words, referring to Fig. 3, the horizontal component of the axial action in the diagonal planks is balanced by the action in the floorboards perpendicular to the joists, while the vertical component by the shear flow along the steel chord length (Δy).

Thus, the translational equilibrium of a diaphragm portion (2 in Fig. 3) along the two directions allows the evaluation of the forces per unit length in the double-planks, as shown by the following equations:

$$q\Delta y = f_{wd}\,\Delta y\, cos\alpha\, sen\alpha \qquad f_x \Delta y = f_{wd}\,\Delta y\, cos^2\alpha \quad (8)$$

By assuming an inclination of the diagonal planks α=45°, the actions in the planks are:

$$f_{wd} = 2q; \qquad f_x = q \quad (9)$$

3.2 STRENGTH AND STIFFNESS OF THE NAILED CONNECTIONS

The bearing capacity of the nailed connections between the steel chord and the double-crossed planks depends on the steel grade of the nail, the nail diameter, and on the local bearing strength of wood (mainly affected by the density of the timber element), and by the angle of the action with respect to the wooden fibers. The nail needs a minimum embedded length of 50÷60 mm in order to connect the three overlaying elements (the existing plank, the new plank and the steel plate). It should be noted that considering the connection between the steel chord and the diagonal plank, the point load acts with an inclination of 45° with respect to the diagonal plank grain direction , while at the interface between the two timber boards the angle to the grain of the point load is equal to 45° in the upper diagonal plank and 90° or 0° in the lower existing plank for the portions 1 and 2, respectively (Fig. 4).

Preliminary tests [28] were carried out according to EN 383 [30] to evaluate the bearing strength and the stiffness of spruce timber for nails with a diameter (ϕ) of 4 mm, commonly used to fix the planks in existing floors. Some test results are presented in Figure 5.

The test results show that the bearing strength (f_{hw}) of spruce wood for ϕ=4 mm nails depends on the load angle with respect to the timber grain, differently from the equations of the main international Codes [31], for which the bearing strength is a function of the wood density and of the nail diameter only. The bearing strength (f_{hw}) is equal to 50, 42 and 37 MPa for an angle to the grain β of 0°, 45° and 90°, respectively, measured for a relative displacement of 4 mm. Furthermore, the local compressive stresses were substantially elastic up to a nail relative displacement of about 1 mm, as it is shown in Figure 5, where the bearing strength is plotted as a function of the nail-to-timber relative displacement. The average initial slope of the curves (Fig. 5) is the elastic stiffness of foundation soil which varied between $k_{w,0}$ = 80 N/mm^3 and $k_{w,90}$= 30 N/mm^3, depending on the action to wooden grain angle.

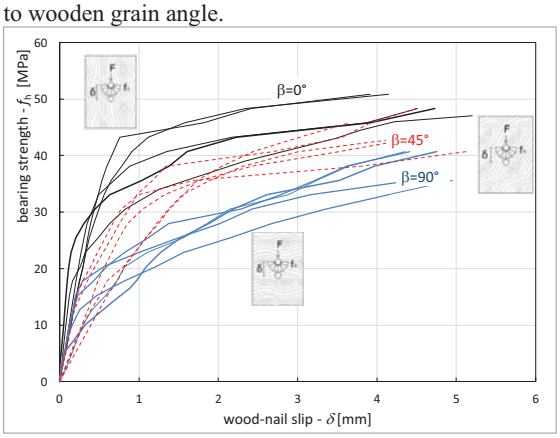

***Figure 5**: Experimental results on the local compressive behaviour of spruce timber (f_{hw}) with 4 mm nails for an action parallel (β=0°), with angle of 45° (b) and perpendicular to the grain (β=90°) (MC=12% during the tests).*

***Table 1**: Bearing strength ($f_{hw,\beta}$) and stiffness $k_{w,\beta}$ of spruce planks for varying direction (β) of the action with respect to wood fibers*

β =0°		β =45°		β =90°	
$f_{hw,0}$ (N/mm^2)	$k_{w,0}$ (N/mm^3)	$f_{hw,45}$ (N/mm^2)	$k_{w,45}$ (N/mm^3)	$f_{hw,90}$ (N/mm^2)	$k_{w,90}$ (N/mm^3)
50	80	40	50	37	30

it is possible to determine the shear stiffness of the nailed connections on the basis of the classical approach of the beam on elastic foundation [9]. Thus, the stiffness of the steel chord - to diagonal plank connection is expressed by the following equation:

$$K_{cp} = 2E_s J \left(\frac{k_{w45}\phi}{4E_s J}\right)^{3/4} \quad (10)$$

while the stiffness of the connection between the existing and the new overlaying diagonal plank in the portion 1 and 2 of the diaphragm are given by the following equations, respectively:

https://doi.org/10.52202/069179-0049

$$K_{pp,1} = 2E_s J \left[\frac{1}{\left(\sqrt[4]{\frac{k_{w45}\phi}{4E_s J}} \right)^3} + \frac{1}{\left(\sqrt[4]{\frac{k_{w90}\phi}{4E_s J}} \right)^3} \right]^{-1} \quad (11)$$

$$K_{pp,2} = 2E_s J \left[\frac{1}{\left(\sqrt[4]{\frac{k_{w45}\phi}{4E_s J}} \right)^3} + \frac{1}{\left(\sqrt[4]{\frac{k_{w0}\phi}{4E_s J}} \right)^3} \right]^{-1} \quad (12)$$

where E_s is the steel modulus of elasticity and J the moment of inertia of the nail cross-section.

For relative displacements greater than 2 mm, the wood local compressive behavior approaches the plastic phase, up to the bearing strength. By assuming a homogeneous isotropic behaviour of the timber and that the bearing strength of the nailed connection does not depend on the ratio between the nail diameter and sapwood thickness, the bearing capacity of the nailed connections can be evaluated by considering the collapse mechanism with two plastic hinges in the nail shank having a fixed end in the steel plate [8]. The strength in the connection depends on the wooden bearing strength in the direction of the applied load, on the yield strength of steel and the nail diameter. The resistance of the steel chord-to-diagonal plank nailed connection is given by the following equation [8]:

$$V_{Rn} = f_h \, \phi \, L_w \quad (14)$$

$$L_w = L'_w - t/2 \quad (15)$$

$$L'_w = L \left\{ -1 + \sqrt{2 + \frac{2}{3}\frac{f_y}{f_{hw,45}} \left(\frac{\phi}{L}\right)^2 + \frac{1}{2}\left(\frac{t}{L}\right)^2} \right\} \quad (16)$$

where t and t_p are the thickness of steel plate and wooden plank, respectively, L_w is the effective length of the nail, f_y the nail yield strength, and $f_{hw,45}$ is the timber bearing strength for an inclination of the shear force of β=45° with respect to grains.

The shear strength of the existing-to-new diagonal timber plank connection depends on the timber bearing strength of the two overlaying planks, which are loaded with a different inclination of the shear action with respect to their grains [31]. The following equations express the shear strength of the existing-to-new plank nailed connection in the portion 1 (with the steel chord perpendicular to the timber joist, Fig. 3) and in the portion 2 of the diaphragm (with the steel chord parallel to the timber joist, Fig. 3), respectively:

$$V_{R,u} = f_{h,90}\Phi^2 \sqrt{\frac{2}{3}\frac{f_y}{f_{hw,90}}\left(1 + \frac{f_{h,90}}{f_{hw,45}}\right)} \frac{1}{1+\frac{f_{hw,90}}{f_{hw,45}}} \quad (17)$$

$$V_{Rn} = f_{h,0}\Phi^2 \sqrt{\frac{2}{3}\frac{f_y}{f_{hw,0}}\left(1 + \frac{f_{h,0}}{f_{hw,45}}\right)} \frac{1}{1+\frac{f_{hw,0}}{f_{h,45}}} \quad (18)$$

In Table 2, the connections stiffness and strength are listed considering a ϕ=4 mm nails, a steel yield strength of 1000 MPa, a thickness of the planks and of the steel chord equal to 22 mm and 3 mm, respectively, along with the bearing strength and the stiffness of the spruce found experimentally (Table 1).

***Table 2**. Stiffness K and strength V_{Rn} of the nailed connections (ϕ=4 mm; t=3 mm; t_p=22 mm)*

Type of connection	K [N/mm]	V_{Rn} [kN]

4 TEST ON DOUBLE-PLANKING DIAPHRAGM

4.1 GEOMETRICAL AND MECHANICAL PROPERTIES OF THE SPECIMEN

A portion of a double planking diaphragm was tested at the University of Brescia with the aim to investigate its in-plane cyclic behaviour under a shear action. A square specimen having a side of 2.0 m was designed on the basis of the seismic actions in a reference two-storeys masonry building with timber floors [28] (Fig. 6). A design shear action V_{Ed}= 30kN was considered in the floor diaphragm during the seismic event. By assuming a design shear resistance $V_{rn,d}$=1.5 kN of the nailed connection, a minimum of 13 nails/m are needed to connect the perimeter steel chord to the wooden diaphragm.

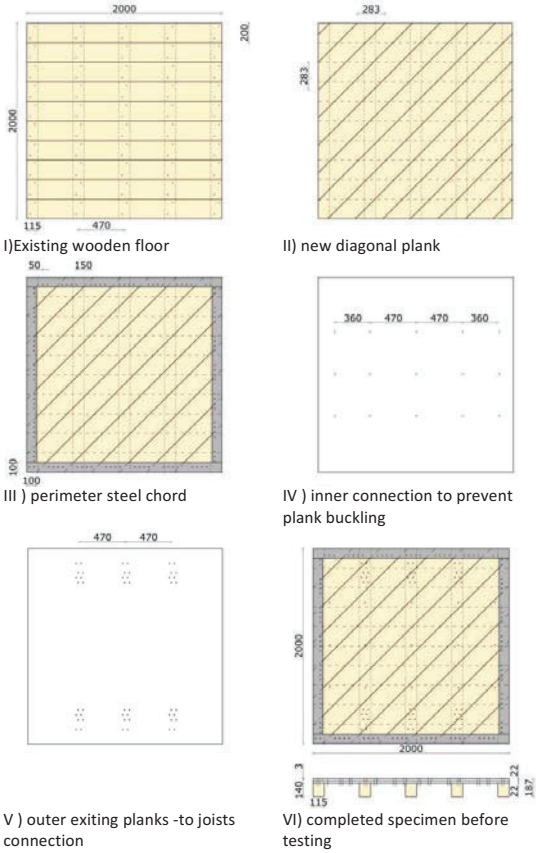

***Figure 6**: Scheme of the assembly stages of the tested specimen*

The specimen consists of spruce joists having a section of 130x110 mm^2 and a spacing of 0.50 m, over which

perpendicular timber planks (190x22 mm^2), resembling the existing floorboards, are connected by means of two 4 mm nails at each joist-to-beam joint. Overlaying diagonal planks are arranged with an inclination of α=45° with respect to the horizontal ones (Fig. 6). Along the perimeter, 3x100 mm steel plates are connected to the double-crossing planks by means of groups of four 4 mm nails (L=70mm) hammered into calibrated holes, corresponding to 13 nails/m. Each group of nails has a spacing of 150 mm; they are inserted into calibrate holes along a single row with a distance of 25 mm to the inner edge of the steel chord (Fig. 6). To avoid the bucking of the diagonal planks, inner screws (d4x70 mm) are set in correspondence of each lower joist. A group of eight nails connects each joist end to the outer horizontal plank to balance the component of the diagonal plank force acting perpendicular to diaphragm edge (Fig. 6). It should be noted that these connections activate the flexural behaviour of the outer existing planks, as already discussed in the previous section.

4.2 TEST SET UP

The testing bench consists of a rigid reaction frame within which the diaphragm specimen is placed. The sample is placed inside the testing bench so that the joists are horizontal (Figure 7). The test was carried out by imposing cyclic displacements of increasing amplitude to the upper chord of the diaphragm using a hydraulic jack fixed to the reaction frame. A steel collector welded to the upper chord of the diaphragm allowed the applied horizontal forces to be distributed as a shear flow along the specimen side. The bottom steel chord of the diaphragm was welded to the supporting beam of the bench.

To measure the specimen deformations and displacements, Linear Variable Differential Transformers (LVDTs) and potentiometers were installed as shown in Figure 7. The horizontal displacement of the diaphragm is measured by a Linear Variable Differential Transformers (LVDTs) while the force acting on the specimen is measured by a load cell placed between the reaction frame and the collector. The deformations of the diagonal planks were measured by potentiometric transducers equipped with extensions, and arranged on the main diagonals of the specimen, one parallel and the other orthogonal to the axis of the plank (diagonal "a" and “b” in Fig. 7). Finally, several potentiometric transducers were placed along two orthogonal sides of the panel, for a continuous acquisition of relative slip between the perimeter steel chord and the diagonal planks. In particular, along two sides of the specimen, three pairs of transducers were arranged to record the relative in plane displacements (slip δ) between the perimeter steel chord and the diagonal planks (detail in Figure 7).

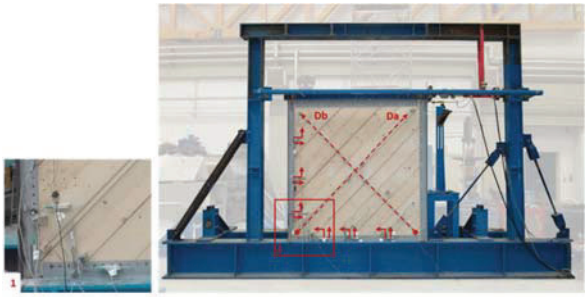

***Figure 7**: Details of the test set up.*

4.3 EXPERIMENTAL RESULTS

Eleven symmetrical cycles of increasing amplitude were applied to the top of the specimen up to a 0.5% drift (corresponding to a lateral displacement η of 10 mm) when a significant damage in the nailed perimeter connections between the steel chord and the diagonal planks was observed. The test started with two cycles with 0.25 mm and 0.5 mm top displacement, respectively, followed by five cycles having an increment of 0.5 mm up to 3.0 mm amplitude. Finally, the last four cycles had an amplitude increment of 2.0 mm.

In Figure 8 the cyclic behaviour of the tested diaphragm is shown in term of shear force (V) versus applied drift (d_r). A symmetrical response of the diaphragm was observed, with an anelastic behaviour beyond a drift of 0.025%, corresponding to a lateral displacement of 0.5 mm and a shear action of 5 kN. The elastic stiffness measured for a drift of 0.025% was K_d=12 kN/mm.

For an applied load equal to the design shear action in the diaphragm of the reference building (V_d=30 kN), a top displacement of 4.55 mm was measured, corresponding to a drift of 0.23%. The secant shear stiffness of the wooden diaphragm is therefore equal to K_d=6.6 kN/mm. The behavior was mainly stable up to the design shear action V_d=30 kN, whilst the failure of the connections at the specimen corners was observed for V=1.5V_d. Then, the test was interrupted to avoid damage in the steel chords.

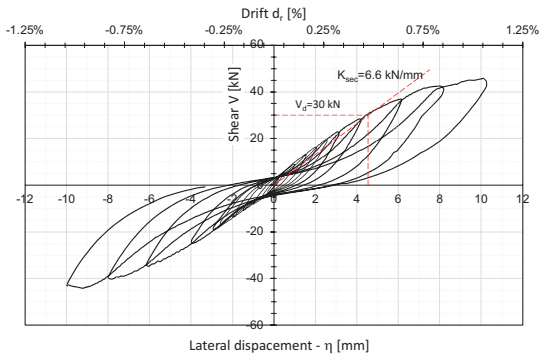

***Figure 8**: Test results: horizontal shear load (V) vs. drift (d_r)*

The measured relative slips between the outer steel chord and the inner web of the diaphragm are shown in Figure 9. It should be noted that the slip parallel to the perimeter

https://doi.org/10.52202/069179-0049

chord (black curves) increases with the applied load, but it gradually reduces along the chord proceeding from the left end (H1), where the longest diagonal plank is located, towards the right corner (H3), where the planks are shorter. A similar trend was measured for the relative slip perpendicular to the perimeter chord (red curves in Figure 9), which shows the maximum value in correspondence to the device (V1) placed on the left longest diagonal plank. Similar values of the relative slips between the outer steel chord and the diaphragm web panel were measured along the vertical left side of the specimen [32]. Based on the experimental results, it can be stated that shear flow between the web and the outer chords of the diaphragm is not uniform, as usually assumed in the current design practice, but it has a linear trend with the maximum value at the corner, where the longest diagonal plank is placed, as shown in Figure 10.

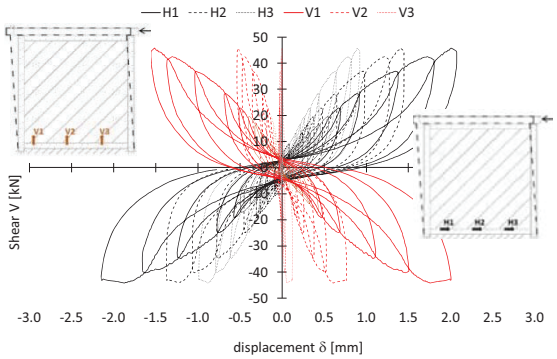

***Figure 9**: Test results: horizontal shear load (V) vs. slip (δ) between the perimeter steel chord and the inner wooden web*

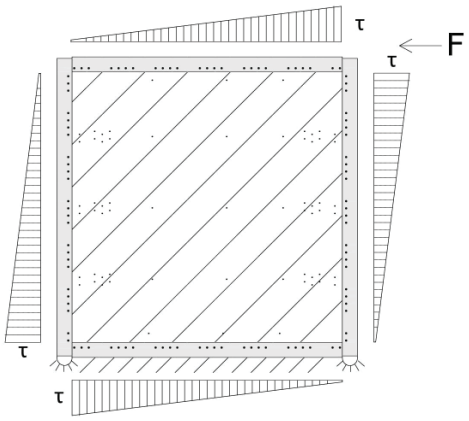

***Figure 10**: Scheme of the distribution of the shear flow along the edges of the diaphragm web.*

5 CONCLUSION

In the seismic retrofit of existing masonry buildings, the global, box-like structural behavior may be guaranteed through the correct organization of the floor diaphragms and their connections to the masonry walls.

Aim of this research is to study the in-plane shear response of wooden diaphragm made with the double planking technique. The proposed technique is characterized by the use of new diagonal planks overlaying the existing planks (which are laid perpendicular to the floor joist). The in-plane shear resisting mechanism of the floor diaphragm is guaranteed by the nailed connections between the perimeter steel chords and the double-crossed overlaying planks. This double planking technique is easy to apply and allows for a significant reduction of the number of nailed connections with the respect to the traditional double crossed timber planks with orthogonal timber boards.

The research focuses on the role and the arrangement of the connections on the transmission of actions from the perimetral chords to the inner web of the diaphragm. An analytical model is proposed to assess the stiffness and the strength of these connections.

The experimental results of a quasi-static cyclic test on a portion of the diaphragm subjected to in-plane shear action show a stable behaviour of the diaphragm up to a load 1.35 times higher than the design shear action. Furthermore, the test results highlight a linear trend of the shear stresses along the perimeter steel chords, contrary to the usual design practice that assumes a uniform distribution.

The shear flow distribution along the edges of the diaphragm is mainly governed by the stiffness of the perimeter nails connections, which is much lower than the axial stiffness of the diaphragm core planks. As a result, the shear flow along the edges of the diaphragm web tends to concentrate where the panel undergoes larger deformation, that is in correspondence of longer planks of the diaphragm core.

ACKNOWLEDGMENTS

The study presented in the paper was partly carried out within the research activities carried out in the frame of the 2022–2023 ReLUIS Project—WP5 funded by the Italian Department of Civil Protection. Note that the opinions and conclusions presented by the authors do not necessarily reflect those of the funding entity. The assistance of Eng. A. Molinari and Eng. M. Rizzi during the experimental campaign is gratefully acknowledged.

A NEW APPROACH TO DETERMINE AND EVALUATE THE POISSON´S RATIO OF WOOD

Klara Winter[1], Roland Maderebner[2], Philipp Dietsch[3]

ABSTRACT: Modern timber engineering requires increasing application of the finite element method (FEM). In such analyses, the elastic constants including the Poisson´s ratios are required. The latter have mostly been neglected so far, since these vary to a great degree in related literature. Hence, an experimental method based on compression tests was developed and benchmarked on numerous preliminary tests in order to determine the Poisson´s ratios on spruce wood (Picea Abies). For the first time, the extended measurement uncertainty was taken into account. On the basis of these values, a comparison with values from literature was conducted. Several observations indicate that, in addition to the wood properties, the load application as well as the test setup have a significant influence on the Poisson´s ratios. In summary, all obtained values lie in the medium range of the literature values. Consequently, the developed test method for determining the Poisson´s ratios is considered to be suitable. In addition, an expanded Poisson's ratio was determined taking into account the measurement uncertainty in order to obtain a symmetrical compliance matrix.

KEYWORDS: Wood, Spruce (Picea Abies), Poisson´s Ratios, FEM, Elastic behaviour, Measurement uncertainty

1 INTRODUCTION

For numerical calculation of increasingly complex timber structures and three-dimensional timber connections using the finite element method (FEM), the Poisson´s ratios are required. When loading a body in its axial direction this measure indicates the ratio between lateral (ε_l) and axial strain (ε_a). The ratios published so far, vary greatly in their order of magnitude. Therefore, the Poisson´s ratios are often neglected in numerical calculations. Moreover, numerous studies leave uncertainty, which and why a certain test method was applied.

In the context of this work, an own test procedure was developed to clarify, what influences the Poisson´s ratios and what causes the great deviation in the published values. Within this process, the most suitable out of three available measurement techniques was selected. Depending on the measurement technique and the test procedure the extended measurement uncertainty was calculated as well. Thus, a range, in which the true mean value of the determined Poisson´s ratio lies can be stated with a confidence of approx. 95 %. Moreover, computer tomography (CT) measurements were conducted to verify the linear elastic range.

Although there are several different wood species, this study only refers to spruce wood, as this, together with fir, makes up the largest share of construction timber in Central Europe.

Preliminary literature on determining the Poisson's ratios predominantly applied tensile tests (e.g. [1]-7]). For the sake of simplicity and as is stated in [7] and [8] the load type was assumed to have no direct influence on the Poisson's ratio. Only compression tests were performed within this work.

2 MATERIALS AND METHODS

2.1 WOODEN SPECIMENS

All measurements on wood were performed on spruce wood (Picea). The source of the wood was near Iseltal in Austria. The specimens were conditioned in a climate chamber at a temperature of (20 ± 1)°C and a relative humidity of (65 ± 3) % according to [9] and [10]. A total, of three different specimen groups (L, R and T) were prepared in order to perform the preliminary tests and main tests for all six Poisson´s ratios. To achieve the most accurate results, the fibre orientation should be as parallel to the specimen axes as possible. Therefore, the maximum specimen length was examined on the available wood, without having to accept a strong deviation of the fibre orientations. This resulted in specimen dimensions of l x h x b = 100 x 30 x 30 mm³ (Figure 1).

The specimen surfaces were sanded to straighten protruding fibres and saw edges. A total of a 150 specimens per specimen group were manufactured. In this way, it was ensured that enough test specimens were

available for the preliminary tests and the 20 specimens for each Poisson´s ratio for the main tests.

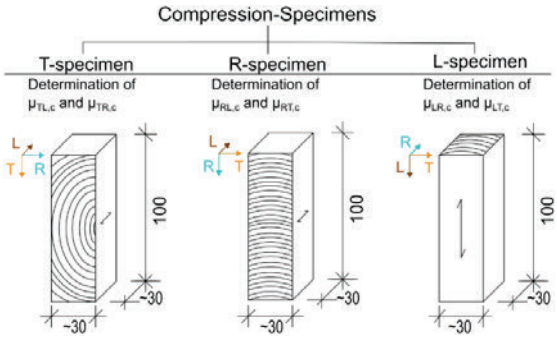

Figure 1: *Different specimen groups including dimensions in [mm]*

The test specimens had further to be pre-drilled on two opposite sides to realize the measurements using DD1 displacement and strain transducers (Figure 2).

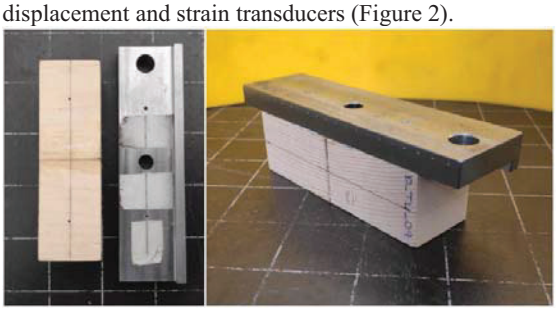

Figure 2: *Metal drilling template on a wooden specimen; left: top view, right: side view*

2.2 ALUMINIUM SPECIMEN

In addition to the wooden test specimens, an aluminium specimen was prepared. This was used as part of the preliminary tests to select the measurement. It was made of the material *EN AW-2007-T4* and its dimensions were l x h x b = 100 x 30 x 30 mm³.
Like the wooden specimens, the aluminium specimen also had to be pre-drilled for the measurements using the strain gauged based DD1 displacement and strain transducers.

2.3 MEASUREMENT TECHNIQUE

The measurement technique was chosen based on comparative measurements preliminary to the main tests. In this regard, the most suitable out of three available measurement techniques including strain gauges, strain gauged based DD1 displacement and strain transducers and videoextensometry was to be selected. The repeatability was investigated by means of the aluminium specimen under compression. Aluminium was chosen as it was expected to not change its properties within the elastic range. The specimen was loaded eight times with each measurement technique. In between the individual loadings the aluminium specimen was removed and inserted into the testing machine again in order to simulate the subsequent test sequence on the wooden specimens as equal as possible. All measurement techniques led to nearly the same average Poisson´s ratio of μ_{alu} = 0,356 but showed significantly different scattering (Figure 3).

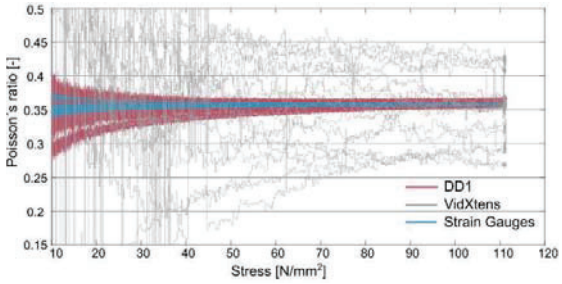

Figure 3: *Comparison of the measurement signals obtained with the three measurement techniques on the aluminium specimen*

The DD1 displacement and strain transducers showed a comparably good repeatability with a standard deviation of 5,33·10^{-3} and a CoV of 1,49 %. As these also required considerably less time for specimen preparation, this technique was chosen for all further measurements. In case of the measurements determining μ_{RL} and μ_{TL} a combination of both DD1 displacement transducers and strain gauges was applied. Reason for this are the significantly smaller lateral strains in grain direction that cause higher signal noise.

2.4 TEST SETUP USING DD1 DISPLACEMENT AND STRAIN TRANSDUCERS

A *Shimadzu Autograph* with an *EDC 580* control unit from *DOLI Elektronik GmbH* was used for all measurements. A spherical cap and a steel cube on top of the wooden specimen ensured uniform load application within all tests (Figure 4).

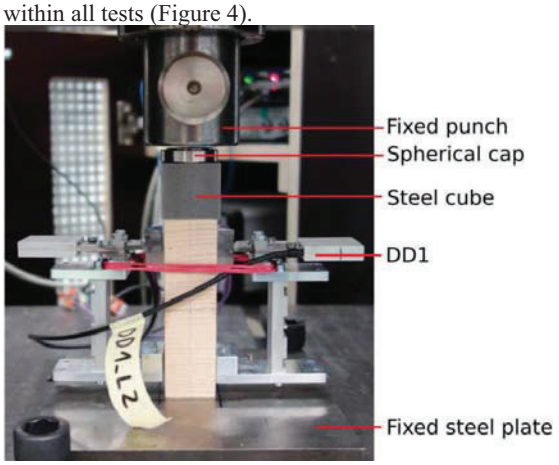

Figure 4: *Load application and strain measurement using DD1 displacement and strain transducers*

The lateral displacement in R- and T-direction could only be recorded using one DD1 displacement and strain transducer. In order to measure the axial displacement two DD1 were attached to opposite sides of the specimen (Figure 5). Thus, possible bending effects could be eliminated. The axial DD1 displacement transducers were attached to the specimen using small nails. Further, two

https://doi.org/10.52202/069179-0050

metal prisms were attached to the upper part of the specimen on opposite sides using small nails as well. The probe tips of the displacement transducers for the axial measurement were in contact with these. The distance between the nails and thus the initial length l was set to 60 mm.

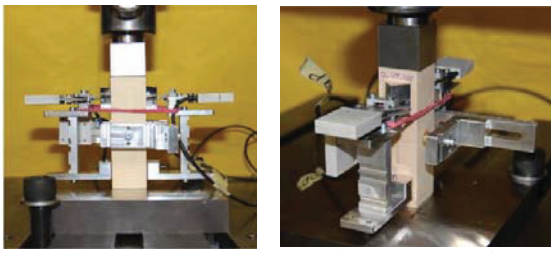

Figure 5: *Test setup with DD1 displacement and strain transducers on wooden specimen; left: Front view; right: Oblique view*

Figure 6 shows the test setup for measuring μ_{RL} and μ_{TL}. For given reasons, two strain gauges were adhered on opposite sides of the specimen in order to measure the lateral displacement in grain direction.

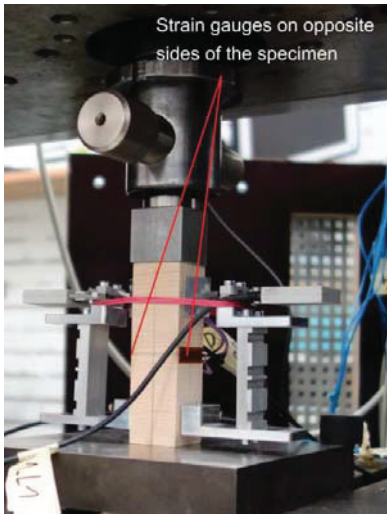

Figure 6: *Measurement configuration used for determining μ_{RL} and μ_{TL}*

2.4.1 Test procedure

All specimens were tested within one hour after removal from the climate chamber, as prescribed in [11]. Preceding the measurement, the specimens were prepared in the measurement room and the duration of the test itself was about 20 minutes. All tests were load-controlled, so that the theoretical compressive strength $F_{c,max}$ would be reached in approx. 90 seconds [9]. Thus, the influence of creep deformations on the Poisson´s ratio are eliminated. The load was applied in such a way that the test specimens were only loaded in their linear-elastic range. Hence, the upper load limit within the preliminary tests was set to 30 % of the compressive strength ($f_{c,90,k}$ resp. $f_{c,0,k}$) given in [12] for spruce wood of class C24. The maximum load applied within the main tests is derived from the CT verification tests described in Section 3.1.3. All measurements were load controlled and started at a load level of 20 N.

Within the determination of the Young´s modulus on concrete, this is loaded in several cycles. Thus, an initial and a stabilized Young´s modulus is defined [13]. Following this procedure, measurements consisting of numerous loading and unloading cycles were performed.

2.4.2 Three-dimensional Hooke´s law for orthotropic materials

The three-dimensional Hooke´s law is based on the assumption that stress σ_{ij} and strain ε_{kl} are linearly related. To describe the three-dimensional elastic behaviour of orthotropic materials 12 compliance coefficients S are necessary [14].

Furthermore, it is valid for orthotropic materials that shear stresses that act in the main direction do not generate normal strains. Normal stresses do not generate shear strains either. Moreover, shear strains are only generated by shear stresses in the same plane. [15] Several compliance parameters of orthotropic materials are therefore zero and the three-dimensional Hooke´s law can be given in the following compliance form:

$$\begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \gamma_{23} \\ \gamma_{13} \\ \gamma_{12} \end{pmatrix} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & & & \\ S_{12} & S_{22} & S_{23} & & & \\ S_{13} & S_{23} & S_{33} & & & \\ & & & S_{44} & & \\ & & & & S_{55} & \\ & & & & & S_{66} \end{bmatrix} \cdot \begin{pmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \tau_{23} \\ \tau_{13} \\ \tau_{12} \end{pmatrix} \quad (1)$$

where ε = strains [-], γ = shear strains [-], σ = normal stresses [N/mm²], τ = shear stresses [N/mm²], S_{ii} for i = 1,2,3: Strain numbers [mm²/N], S_{ii} for i = 4,5,6: Shear strain numbers [mm²/N], S_{ij} for i,j = 1,2,3: Poisson´s ratios; $i \neq j$ [mm²/N].

Further, the compliance parameters can be replaced by the engineering parameters Young´s modulus E, Shear modulus G and Poisson´s ratio μ. The indices can be replaced with the common labels L, R and T. Hooke´s law then takes the form of Equation (2):

$$\begin{pmatrix} \varepsilon_{LL} \\ \varepsilon_{RR} \\ \varepsilon_{TT} \\ \gamma_{RT} \\ \gamma_{LT} \\ \gamma_{LR} \end{pmatrix} = \begin{bmatrix} \frac{1}{E_L} & -\frac{\mu_{RL}}{E_R} & -\frac{\mu_{TL}}{E_T} & & & \\ -\frac{\mu_{LR}}{E_L} & \frac{1}{E_R} & -\frac{\mu_{TR}}{E_T} & & & \\ -\frac{\mu_{LT}}{E_L} & -\frac{\mu_{RT}}{E_R} & \frac{1}{E_T} & & & \\ & & & \frac{1}{G_{RT}} & & \\ & & & & \frac{1}{G_{LT}} & \\ & & & & & \frac{1}{G_{LR}} \end{bmatrix} \cdot \begin{pmatrix} \sigma_{LL} \\ \sigma_{RR} \\ \sigma_{TT} \\ \tau_{RT} \\ \tau_{LT} \\ \tau_{LR} \end{pmatrix} \quad (2)$$

It is only applicable if the stresses and deformations are referred to the main axes [16]. If the main axes of the wood deviate from the reference system coordinate transformations as described e.g. in [14] and [17] must be applied.

https://doi.org/10.52202/069179-0050

The compliance matrix itself is symmetric. Due to this symmetry condition, only nine of the 12 parameters are independent of each other. It applies:

$$\frac{\mu_{LR}}{E_L} = \frac{\mu_{RL}}{E_R} \tag{3}$$

$$\frac{\mu_{LT}}{E_L} = \frac{\mu_{TL}}{E_T} \tag{4}$$

$$\frac{\mu_{RT}}{E_R} = \frac{\mu_{TR}}{E_T} \tag{5}$$

Further requirements for the compliance matrix are given in [16] and [2].

2.4.3 Calculation of the Poisson´s ratio

The Poisson´s ratio describes the lateral contraction/elongation (ε_l) of a body as it elongates or contracts normal to the force (ε_a) (Equation (6)). Thus, it is also called passive deformation. The Poisson´s ratio is always negative since compression is defined as negative tension.

$$\mu_{al} = -\frac{\varepsilon_l}{\varepsilon_a} \tag{6}$$

2.4.4 Calculation of the Young´s modulus

The Young´s moduli $E_{i,ij}$ were examined on the basis of the tenth loading and unloading cycle between 20 % and 55 % of the estimated upper load limit $F_{c,max,est}$ using Equation (7):

$$E_{i,ij} = \frac{(\sigma_{i,55} - \sigma_{i,20}) \cdot 60mm}{\Delta l_{i,55} - \Delta l_{i,20}} \tag{7}$$

where *i,j* = Anatomical directions resp. load directions, each can attain independently L,R or T [-], $\sigma_{i,20}$, $\sigma_{i,55}$ = stress at 20 % resp. 55 % of $F_{c,max,est}$ when loaded in i-direction [N/mm²] , $\Delta l_{i,20}$, $\Delta l_{i,55}$ = Axial displacement in i-direction at 20 % resp. 55 % of $F_{c,max,est}$.

2.4.5 Data processing

Within the scope of this work, the Poisson's ratios and Young´s moduli were determined on the basis of several loading and unloading paths. However, due to the dissipated energy during specimen deformation, the paths individually would lead to varying results. This effect is called hysteresis [18]. Hence, these were averaged. Figure 7 shows this effect by means of a randomly selected loading and unloading path of a measurement on the aluminium specimen. This specimen was loaded and unloaded once in the stress range between 60 to 105 N/mm². The red path, which is then used for further evaluation represents the average of the loading and the unloading path.

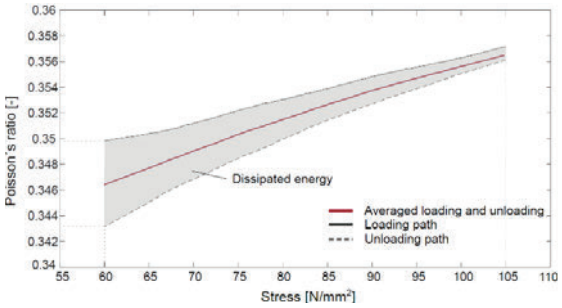

Figure 7: *Hysteresis effect on the basis of a loading and unloading path of the aluminium specimen measured with the DD1 displacement and strain transducers*

Those measurements that still exhibited signal noise after averaging were further denoised, using the *Savitsky-Golay* filter.

2.4.6 Determination of the measurement uncertainty

When specifying a physical variable, it is important to include the measurement uncertainty *u*(x), as all measurement results include errors. The calculation of the measurement uncertainty is described here in detail on the basis of the Poisson's ratio. However, the measurement uncertainty for the Young´s modulus was calculated according to the same systematic.

A physical variable can be given with $\bar{x} \pm s_m$ (absolute specification) or $\bar{x} \pm \frac{s_m}{\bar{x}}$ (relative specification), where s_m is the measurement uncertainty or the standard error.

However, the average Poisson´s ratio does not result from a direct averaged measurement but from a function of several, as is shown in Equation (8). Therefore, the Poisson´s ratio depends on the average lateral displacement Δb, the average axial displacement Δl and both original average lengths l and b ($\mu_{lb} = f(\Delta b; \Delta l; b; l)$).

$$\mu_{lb} = -\frac{\Delta b/b}{\Delta l/l} = -\frac{\Delta b \cdot l}{\Delta l \cdot b} \tag{8}$$

Hence, the uncertainty of the Poisson´s ratio requires the calculation of a combined uncertainty using the *Gaussian error propagation law*. Therefore, all individual variables need to be normally distributed [19]. Using the *Shapiro-Wilk-test* this was checked within this work. However, each individual variable given in Equation (8) is in turn also influenced by several factors. In case of the specimen width *b* for example, the inaccuracy of the calliper and the staff (the lab assistants who measure and prepare the specimens) already influence the variable. Hence, a combined standard error must already be determined for each individual variable included in Equation (8).

The general *Gaussian error propagation law* is given with:

$$u(X) = \sqrt{\left(\frac{\delta X}{\delta y_i} \cdot u(y_i)\right)^2 + \cdots + \left(\frac{\delta X}{\delta y_k} \cdot u(y_k)\right)^2} \tag{9}$$

https://doi.org/10.52202/069179-0050

To determine the combined standard uncertainty of the Poisson´s ratio, this equation takes the following form when formulating the partial derivatives:

$$u(\mu) = \sqrt{\left(-\frac{l \cdot \Delta b}{\Delta l \cdot b^2} \cdot u(b)\right)^2 + \left(\frac{l}{\Delta l \cdot b} \cdot u(\Delta b)\right)^2 + \left(\frac{\Delta b}{\Delta l \cdot b} \cdot u(l)\right)^2 + \left(-\frac{l \cdot \Delta b}{b \cdot \Delta l^2} \cdot u(\Delta l)\right)^2} \quad (10)$$

The extended measurement uncertainty is calculated by multiplying the measurement uncertainty from Equation (10) by the coverage factor 1,96, which is often round up to 2,0.

$$U(\mu) = u(\mu) \cdot 2 \quad (11)$$

By indicating the respective extended measurement uncertainty of each test series a range of values is given. With a certainty of 95 % the true average Poisson´s ratio lies within this range.

3 RESULTS AND DISCUSSION

3.1 PRELIMINARY TESTS

3.1.1 Hygric behaviour of wood as an influence on the Poisson´s ratio

First tests consisted of 15 loading and unloading cycles. However, no convergence of the averaged Poisson´s ratios was noticeable. The hygric behaviour of wood was considered to be the reason for this since the specimens were measured in another climate after being conditioned at 20°C and 65% r.h. . In order to verify this, comparative tests were performed.

Therefore, six μ_{RT}-specimens were stored in two different climates. Three in the climatic chamber and three in the room, where the testing machine was located. The temperature in this measurement room was around 21°C with a relative humidity of approx. 40 %.

In total three comparative tests were performed. Each measurement included two specimens, one that was conditioned in the climatic chamber (CC-specimen) and one that was conditioned in the measurement room (MR-specimen).

All three comparative tests showed very similar results. Figure 8 exemplarily shows one of the resulting graphs.

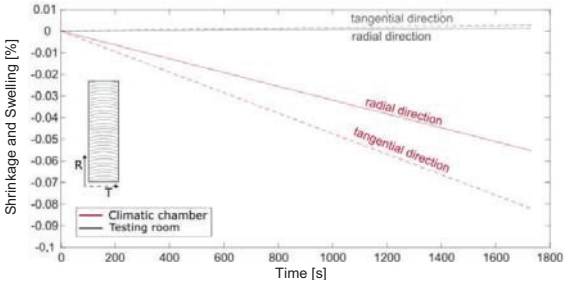

Figure 8: *Shrinkage and swelling deformations in [%] on the basis of comparative measurements*

The specimens conditioned in the climatic chamber show a significantly greater shrinkage in contrast to the specimens conditioned in the measurement room. On the basis of these comparative tests, it is apparent that the change in the ambient climate has a considerable impact measured within one hour after removal from the climatic chamber, as demanded in [11].

Since it was not possible to move the testing machine to the climatic chamber within the scope of this work, all specimens were conditioned in the measurement room.

Figure 9 shows the averaged paths of 15 loading and unloading cycles of two μ_{RT}-specimens conditioned in the measurement room and of one specimen conditioned in the climate chamber. This clearly shows that testing the specimens in the same climate in which these where conditioned leads to a significantly lower dispersion. Hence, the shrinkage and swelling effects on the Poisson´s ratios could be eliminated to a certain degree. Further, it is evident that the Poisson´s ratios of the specimens conditioned and tested in the measurement room are more or less constant over the respective stress range and therefore already show a somewhat linear elastic behaviour. Moreover, a stronger convergence of the cycle paths from the tenth cycle onwards was noticeable for all specimen orientations.

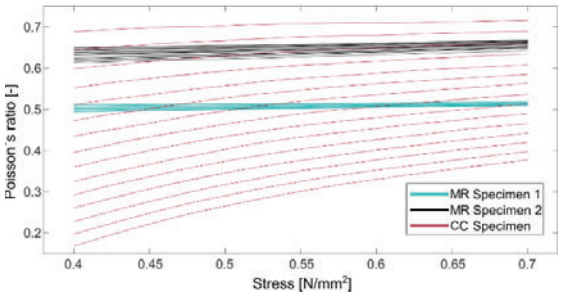

Figure 9: *μ_{RT}-measurements in relation to the stress on the basis of two specimens preconditioned in the measurement room*

3.1.2 Impact of creep deformations on the Poisson's ratio

Subsequently it was to be checked if creep deformations had an influence on the test procedure. For this reason, times of constant load of 20 seconds between loading and unloading were included. These were anticipated to lead to a faster convergence of the paths. Therefore, three specimens already tested without times of constant load were tested again including times of constant load within 15 cycles. In addition, three, yet untested specimens were tested including times of constant load. Figure 10 shows the resulting averaged paths for each specimen over the applied stress range.

The specimens measured for the second time including times of constant load show significantly smaller Poisson´s ratios than before. This is not inevitably due to creeping but could also be the result of compaction of the specimen during the previous measurements. However, this would also indicate that the linear elastic range had already been exceeded.

https://doi.org/10.52202/069179-0050

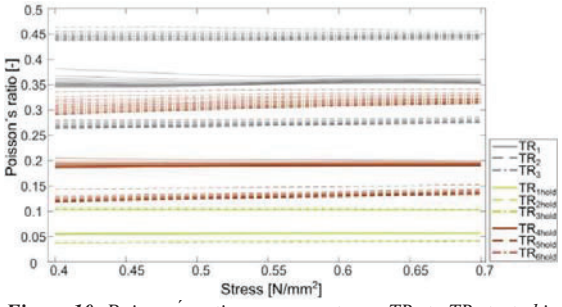

Figure 10: *Poisson´s ratios μ_{TR} over stress; TR_1 to TR_3 tested in 15 load cycles without times of constant load; $TR_{1,hold}$ to $TR_{3,hold}$ tested with times of constant load; $TR_{4,hold}$ to $TR_{6,hold}$ not previously loaded specimens tested with times of constant load*

Considering the specimens that were not previously loaded ($TR_{4,hold}$ to $TR_{6,hold}$) the Poisson´s ratios are approximately 30 % lower ($\mu_{mean,4\text{-}6,hold} = 0{,}213$) compared to the specimens tested without constant loads ($\mu_{mean,1\text{-}3} = 0{,}358$). The latter Poisson's ratios measured without times of constant load fit better with the Poisson's ratios measured on spruce wood in previous literature (e.g. [3],[4]).

In conclusion, including times of constant load appears to have an influence on the Poisson´s ratios. However, only few tests were carried out here including times of constant load. Similar tests in earlier literature are neither found for compression nor tensile loads. Therefore, the observed results would need to be verified in future studies using a significantly higher number of test specimens. Within this work, times of constant load are omitted.

3.1.3 Verification of the linear elastic range

A difficulty often mentioned in previous literature, regarding the Poisson´s ratios, was the occurring asymmetry. Therefore, the assumed linear elastic range was checked prior to the main tests. In order to determine if micro cracks with a width of 10-20 µm occur in the assumed linear elastic range, the specimens were scanned before and after loading in a CT-scanner. Due to dimension restrictions only the middle part (30 x 30 x 30mm³) of the specimens was examined. Figure 11 explains the schematic procedure of the CT-measurements. In order to estimate $F_{c,max}$ two "twin" specimens for each specimen group were taken from the same wooden log at adjacent locations and conditioned in the climate chamber. One of the twins was then loaded till failure. The other twin was used to detect occurring micro cracks following the procedure shown in Figure 11. In total, due to availability reasons of the CT-scanner, only three specimens were tested.

The comparison of individual sections of the generated 3D model, exemplarily shown in Figure 12, showed no noticeable changes at the micro level after loading the specimens up to 60 % of $F_{c,max}$ in all three anatomical directions.

In addition, due to availability reasons, only one specimen per load direction was examined. Concluding, the results obtained suggest that the linear elastic range is not exceeded up to 60 % of $F_{c,max}$. However, this needs to be verified on the basis of further measurements including a larger number of specimens and if possible, scanning a bigger part of the specimens.

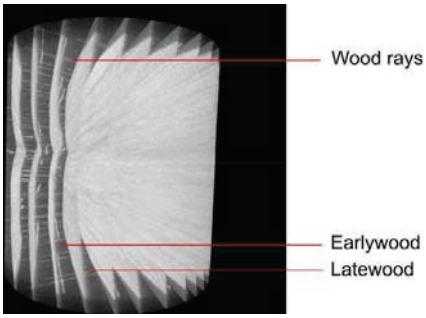

Figure 12: *Exemplary CT-image of the 3D model of the specimen loaded in the tangential direction*

3.1.4 Preliminary tests – Conclusion

The preliminary tests resulted in the following conclusions that were applied within the test procedure of the main tests.

- Conditioning of the specimens in the measurement room as the hygroscopicity of wood makes it impossible to measure the Poisson´s ratios
- The linear elastic range is verified for all three anatomical directions up to 60 % of $F_{c,max,est.}$
- The Poisson´s ratio of each test specimen is evaluated in the range between 20 % and 55 % of the respective applied load

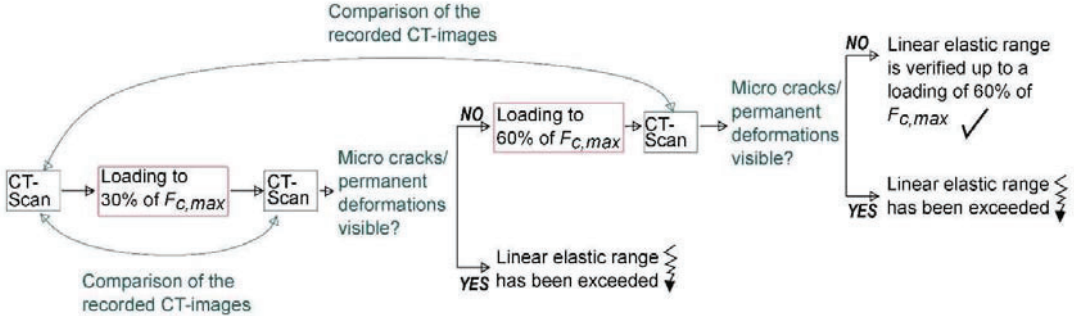

Figure 11: *Schematic procedure of the CT-measurements and the verification of the linear elastic range of spruce wood*

https://doi.org/10.52202/069179-0050

3.2 MAIN TESTS

After the test method and handling of samples was defined in several preliminary tests, the main tests were carried out to determine all Poisson's ratios by means of compression tests on spruce wood. The results are shown on the basis of boxplots in Figure 13 and are directly compared to the Poisson´s ratios found in literature (square markers, Figure 13). The different colours indicate the respective load types (red: tensile test, blue: compression test and green: bending test) that were applied in literature in order to measure the Poisson´s ratios. Table 1 summarizes all Poisson´s ratios and Youngs moduli including the measurement uncertainty and the associated average density and wood moisture contents of the respective test series.

Examining the boxplots in Figure 13 it is evident that almost all Poisson´s ratios determined in Tripolt [7] and Kumpenza et al. [6] are higher than the ratios determined within this work. Both applied tensile tests and used optical measurement techniques (electronic speckle pattern interferometry (ESPI) and a combination of laser- and videoextensometry). For these measurement techniques, Kumpenza et al. [6] specifies the following measurement resolutions: ESPI 0,03 µm, video-extensometry 0,2 µm and laserextensometry 0,11 µm. The Poisson´s ratios in both studies were determined on specimens with a higher wood moisture content (12 %) than present in this work (~7,4 %, Table 1). Further literature values, determined under the same conditions, though, do not show increased values (see NC [4] in Figure 13). As a consequence, neither the wood moisture content nor the load type appear to be responsible for the increased values. In fact, several indications lead to the assumption that the increased values in Kumpenza et al. [6] and Tripolt [7] resulted from strain measurements during the initial loading of the test specimens. Presumably this has to do with the residual stresses still present during the first loading [4].

This was also evident during the preliminary tests realized in the work presented here.

In case of the μ_{LT} values the Poisson´s ratios given in Tripolt [7] lie within the inter-quartile range. Presumably, this is due to creep respectively shrinkage effects during capturing the images when using ESPI. That is why Kumpenza et al. did not give any values for μ_{LT} [6]. Furthermore, Tripolt mentions difficulties using ESPI on flat sawn where early and late wood alternate and thus, cause inhomogeneous stress conditions [7].

Furthermore, the values determined in Kumpenza et al. [6], using a combination of laser- and videoextensometry, are all higher than the ratios determined within this work. As the strains were only recorded on one side of the specimen using this technique possible bending effects

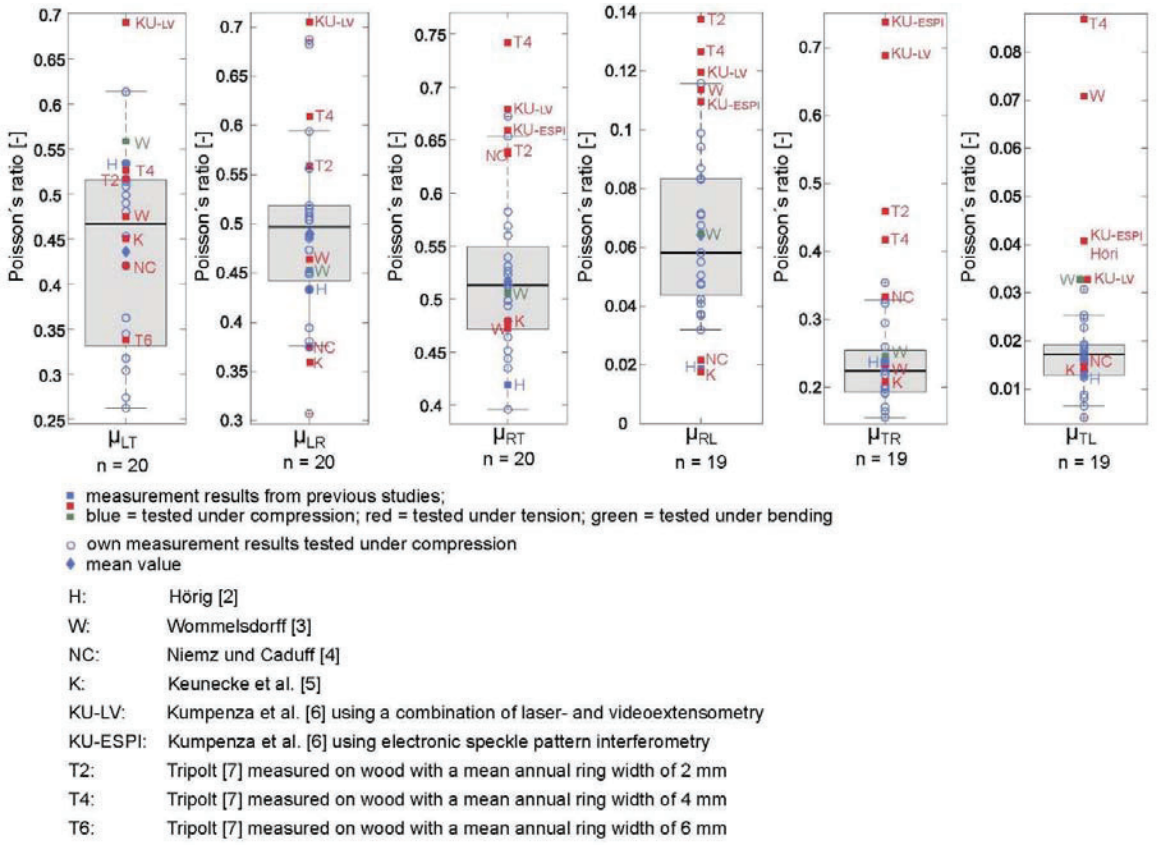

Figure 13: *Boxplot of the Poisson´s ratios of all test series on the basis of n specimens including the Poisson´s ratios determined in previous studies; red: tension tests, blue: compression tests, green: bending tests*

were neglected potentially influencing the resulting Poisson´s ratios.
A quite good agreement of the values determined within in this work is seen regarding the Poisson´s ratios determined in Hörig [2], Wommelsdorff [3], Niemz und Caduff [4] and Keunecke et al. [5]. Here, the test procedure also consisted of several load cycles. Almost all values lie within the inter-quartile range. Only for the RL-series the Poisson´s ratios given in [2], [4] and [5] are below this range. It should be mentioned that the Poisson´s ratio given in Keunecke et al. [5] is a calculated value and not an outcome of a measurement. However, as already mentioned, the measurement of the lateral strain in longitudinal direction is generally problematic due to the higher stiffness in grain direction. Nevertheless, the Poisson´s ratio determined within this work shows a significantly lower deviation (CoV = 38 %) than stated in other studies (e.g.: CoV = 62 % [4], CoV = 59 % [6]). Moreover, the observed wood moisture contents of around 10 to 12 % given in these references are also higher than present in this work. Since the wood moisture content in radial direction has a greater influence, this might be the reason for the higher deviation of the values. Considering the values for μ_{TL} such a deviation cannot be observed which is probably due to the already higher outside temperatures at that time and thus a higher moisture content of around 9,5 % of the specimens. Since the measurement uncertainty has not been a part in previous research further conclusions are difficult to draw.

Table 1: *Determined Poisson´s ratios and Young´s moduli including the measurement uncertainty and associated Density, Moisture content and Annual ring width of all test series*

Poisson´s ratio		[-]
	μ_{RT}	0,517 ± 0,085
	μ_{TR}	0,233 ± 0,044
	μ_{TL}	0,016 ± 0,005
	μ_{LT}	0,436 ± 0,085
	μ_{RL}	0,064 ± 0,017
	μ_{LR}	0,492 ± 0,123
Young´s moduli		[N/mm²]
	E_L	12068 ± 1460
	E_R	966 ± 103
	E_T	302 ± 42
Density		[kg/m³]
	ρ_L	430
	ρ_R	428
	ρ_T	378
Moisture content		[%]
	$u_{L,mean}$	7,4
	$u_{R,mean}$	7,4
	$u_{T,mean}$	9,4
Approx. annual ring width		[mm]
	arw	2

Also noteworthy is the resulting Poisson´s ratio μ_{RT}, that is above 0,5 (Table 1). As a matter of fact, this would indicate that a body under a hydrostatic pressure increases its volume [16]. However, this compressibility condition is only valid for isotropic materials. Wood is an anisotropic material with different Young´s moduli in the three main directions (L,R and T). Therefore, and since Poisson's ratios above 0,5 have also been found in earlier studies, the Poisson's ratio determined for the RT-series is feasible.
The Young´s moduli result in the following ratio $E_T : E_R : E_L$ of 1 : 3,20 : 39,96. For comparison Niemz and Caduff [4] state a ratio of 1 : 2,43 : 25,4, Tripolt [7] a ratio of 1 : 1,57 : 27,6, Kumpenza et al. [6] a ratio of 1: 3,69 : 52,08 and the determined Young´s moduli in Keunecke et al. [5] correspond to a ratio of 1 : 1,57 : 32,24. Overall the determined orders of magnitude are therefore in agreement with the literature. The still persistent differences in the ratio of $E_R : E_T$ can be traced back to the varying annual ring widths [4].
The largest deviation from the literature values is evident regarding the Young´s modulus E_T. This test series also shows a significantly lower density value and the highest moisture content. A possible reason for the lower density might be the small sample geometry combined with the annual ring width [4]. Since the Young´s modulus decreases with lower density [20], this might be the reason for the deviation. The lower moisture content of 9,4% compared to the literature values (~12%) should cause a higher Young´s modulus. Compared to the influence of the density, however, this seems to have less impact on the Young´s modulus.

3.2.1 Symmetry condition

When summarizing all obtained values and inserting these into the compliance matrix, the matrix should fulfil the symmetry condition.

$$\begin{bmatrix} \frac{1}{E_L} & -\frac{\mu_{RL}}{E_R} & -\frac{\mu_{TL}}{E_T} \\ -\frac{\mu_{LR}}{E_L} & \frac{1}{E_R} & -\frac{\mu_{TR}}{E_T} \\ -\frac{\mu_{LT}}{E_L} & -\frac{\mu_{RT}}{E_R} & \frac{1}{E_T} \end{bmatrix} = \begin{bmatrix} \frac{1}{12068} & -\frac{0,064}{966} & -\frac{0,016}{302} \\ -\frac{0,492}{12068} & \frac{1}{966} & -\frac{0,233}{302} \\ -\frac{0,436}{12068} & -\frac{0,517}{966} & \frac{1}{302} \end{bmatrix} = \begin{bmatrix} 8,29 & -6,63 & -5,3 \\ -4,08 & 103,52 & -77,15 \\ -3,61 & -53,52 & 331,13 \end{bmatrix} \cdot 10^{-5} \quad (12)$$

It is seen, that at first glance, based on the presented compliance matrix in Equation (12) the symmetry condition is not identified as fulfilled. This is why the determined measurement uncertainties are additionally considered in the following. Thereby, the symmetry conditions are examined individually.
First symmetry condition:

$$\frac{\mu_{LR}}{E_L} = \frac{\mu_{RL}}{E_R}$$
$$\frac{0,492 \pm 0,123}{12068 \pm 1460} = \frac{0,064 \pm 0,017}{966 \pm 103} \quad (13)$$
$$[2,73;\ 5,88] \cdot 10^{-5} = [4,40;\ 9,39] \cdot 10^{-5}$$

with: [min; max]. This results in an overlapping area of $5,8 \cdot 10^{-5} - 4,4 \cdot 10^{-5} = 1,4 \cdot 10^{-5}$. Therefore, the symmetry condition can theoretically be fulfilled if both values lie within this range. Since the true average

https://doi.org/10.52202/069179-0050

Poisson´s ratio and the true Young´s modulus lie in the respective range with a 95 %-confidence, both values lie in the overlap range with a confidence of approx. 12 %.
Following this example, the second symmetry condition (Equation (14)) is theoretically met on a confidence level of approx. 20 % and the third symmetry condition (Equation (15)) is met on a confidence level of approx. 13 %.

$$\frac{\mu_{LT}}{E_L} = \frac{\mu_{TL}}{E_T} \tag{14}$$

$$\frac{\mu_{RT}}{E_R} = \frac{\mu_{TR}}{E_T} \tag{15}$$

In general, it can therefore be assumed that the compliance matrix determined here corresponds to the symmetry requirement. This supports the developed testing method and the applied measurement technique.
The matrix given in Equation (12) can then take the following symmetrical form and may be applied in the context of FEM.

$$\begin{bmatrix} 8{,}29 \cdot 10^{-5} & -5{,}14 \cdot 10^{-5} & -4{,}11 \cdot 10^{-5} \\ -5{,}14 \cdot 10^{-5} & 1{,}04 \cdot 10^{-3} & -6{,}24 \cdot 10^{-4} \\ -4{,}11 \cdot 10^{-5} & -6{,}24 \cdot 10^{-4} & 3{,}31 \cdot 10^{-3} \end{bmatrix} \tag{16}$$

4 CONCLUSION AND OUTLOOK

This paper takes the extended measurement uncertainty into account. As a result, the six determined average Poisson´s ratios can be stated with a 95 %-confidence. The results obtained seem to be consistent, since the average values lie in the middle range of the results stated in literature. This also includes the Young´s moduli and the density values.
However, it was seen that measurements based on the first loading, lead to significantly higher Poisson´s ratios due to residual stresses. Within future studies it is therefore particularly important to provide more precise information on the test and load procedure. In this context, it is of interest whether measurements using ESPI or a combination of laser- and videoextensometry result in similar Poisson´s ratios as found within this work, when determining the Poisson´s ratio based on the 10th load cycle.
Besides the load procedure, it also appears that the one- or two-sided measurements of the strains on a specimen influence the results. On the one hand this can be concluded from the values determined using laser- and videoextensometry in [6]. There, the strains were determined on only one side of the specimen and are above the determined average in all test series. On the other hand, a measurement on a μ_{TL}-specimen in this work caused an extremely high Poisson´s ratio. This is why this measurement was eliminated within the evaluation here. Reason for this increased Poisson´s ratio was most likely the fact that one of the strain gauges was defective. Thus, the lateral strain was only recorded on one side of the specimen here as well.
Additionally, it should be pointed out, that measuring μ_{TL} and μ_{LT} by means of optical measurement techniques is rather impractical. Difficulties due to different proportions of early- and latewood on the measuring surface were mentioned for example in [7]. Considering that these values, given in Tripolt [7] deviate significantly from the values determined here, this can be confirmed on the basis of this paper.
What could not be confirmed within the present thesis is the stress dependence of individual Poisson´s ratios found in [3]. Prerequisite for an accurately constant Poisson's ratio and thus a stress independent Poisson´s ratio is the accurately linear progression of the axial and lateral strain. On a random basis a linear regression was carried out on these strains over the stress. In each case, the strains run linearly, however, not perfectly. The resulting smallest deviations lead to a deviation of the Poisson's ratio over the stress. As a consequence the partial stress dependence is more an artefact of the measurement fluctuations or measurement uncertainty than an actual stress dependence. This should be verified in detail in future studies, as the above finding is only based on a small sample number. In case it turns out that measurement fluctuations and the measurement uncertainty are not the reason for the partly recognisable stress dependence, the assumption of a rhombic-crystalline behaviour of wood would have to be rejected, as was already mentioned by Wommelsdorff [3].
The present results of the preliminary tests further confirm that in the event of future studies investigating the influence of wood moisture on the Poisson's ratios, special care needs to be taken to perform the measurements in the same climate in which the specimens are conditioned. Otherwise, shrinkage and swelling influences have already a considerable influence on the Poisson´s ratios within a short time periode.
Significant correlations were only evident in a few cases. Moreover, these often differ from the correlations found in [7]. In addition, the Poisson's ratios are not only dependent on the density and the Young's modulus, but also on the microfibril angle and the cell shape angle [21]. These parameters were not recorded within the scope of this paper. Future studies should therefore examine correlations using a larger number of specimens and taking into account more wood properties such as the microfibril angle, the cell shape angle, etc..
Furthermore, creep also seems to have an influence on the measurement results of the Poisson's ratio, as is apparent from the preliminary tests. In this context, it seems reasonable to determine Poisson's ratios including the creep influence in future studies. These could be of particular importance for components subjected to long-term stress.
In summary, the determination of extended Poisson´s ratios of spruce wood has been achieved by integrating the measurement uncertainty. From an engineering perspective subsequent research should validate the Poisson´s ratios determined on clear wood specimens. For this purpose, a combination of finite element method (FEM) calculations in conjunction with associated

measurements on component-sized specimens suggests itself.

ACKNOWLEDGEMENT

This paper is based on my Master's thesis [22] which I was able to write in cooperation between the Technical University of Munich and the University of Innsbruck, supervised by my Co-Authors. Additionally, I would like to thank Dr.-Ing. Patrik Aondio for his support throughout the thesis. Furthermore, I want to acknowledge the entire TVFA team of the University of Innsbruck, without whom I would not have been able to conduct all the measurements. At this point additional thanks go to the Unit of Material Technology at the University of Innsbruck, that enabled the CT-measurements.

THEORETICAL AND EXPERIMENTAL INVESTIGATION ON PREDICTING LONGITUDINAL AND TANGENTIAL ELASTIC CONSTANTS AND RATIOS OF WOOD

Shaghayegh Kurzinski[1], Paul L. Crovella[2]

ABSTRACT: Among all the elastic constants of wood that are required for the engineering design of wood structures, only the modulus of elasticity in the longitudinal (L) direction (E_0 or E_L) is readily available or can be readily measured for the majority of species. Longitudinal and tangential moduli of elasticity and shear moduli are required to predict the structural performance of any composite timber product such as mass timber products. This study selected a low-density local softwood; eastern white pine, and a high-density local hardwood; black locust, to investigate their longitudinal and tangential elastic properties. The eastern white pine and black locust defect-free specimens were prepared and tested under centre-point bending loading (ASTM D198-2015 [1]) alternately on true longitudinal and tangential surfaces. Also, linear regressions with respect to the longitudinal modulus of elasticity were performed on the tangential elastic modulus, and the longitudinal-radial and tangential-radial shear moduli of the softwood and hardwood species with available mechanical properties ratios published in the USDA Wood Handbook [2]. These elastic constants and their ratios from the experiment have been compared to the predicted values and ratios from the regressions using the published values of the species in the USDA Wood Handbook. This provides data on the accuracy of assumed elastic ratios in published references for elastic and shear moduli.

KEYWORDS: Shear modulus, Modulus of elasticity, Centre-point bending test, Elastic ratios of wood, Elastic constants of wood.

1 INTRODUCTION

The arrangement and geometry of wood cells in the tree define three local symmetric axes in the material which are referred to as longitudinal (L, parallel to the grain direction and tangent to the growth rings), tangential (T, perpendicular to the grain) and radial (R, perpendicular to the grain direction and normal to the growth rings) [3]. These three axes determine the mechanical properties of wood by nine elastic constants and related compliances typically used in the engineering design of wood structures. Characterization of these constants in classical mechanics is done in reference to orthogonal axes. However, it should be noted that wood is not a truly orthotropic material because of growth ring curvature. Plain-sawn timber boards are generally used as typical layers of composite engineered timber products when the majority of the surface perpendicular to the major load direction is the tangential surface rather than the radial surface. Therefore, as shown in **Figure 1** the longitudinal and tangential elastic moduli (E_L and E_T) can be referred to as elastic moduli parallel to the grain (E_0) and perpendicular to the grain (E_{90}) respectively. Similarly, the longitudinal-radial and tangential-radial shear moduli can also be referred to as shear moduli parallel to the grain (G_0) and perpendicular to the grain (G_{90}) respectively.

The modulus of elasticity in the longitudinal (L) direction (E_0 or E_L) is readily available or can easily be measured for the majority of wood species. The other elastic constants, such as elastic moduli in the radial (R) and tangential (T) directions, the three Poisson's ratios, and the three shear moduli associated with the three major orthotropic planes, have not been thoroughly examined for most species due to the difficulty of making appropriate experimental measurements.

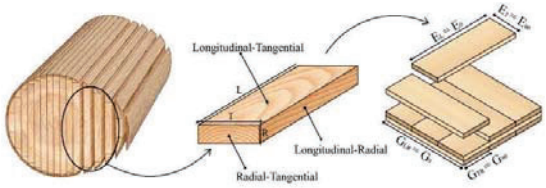

Figure 1: *Plain-sawn Cut Board Details and Usage in a Cross-laminated Timber Panel, multi-layered mass timber product [4]*

To make up for the lack of engineering data on a large number of species, there have been a few methods proposed to predict the elastic constants and their correlations in different species. Adamopoulos [5] studied the difference between the shear modulus in two orientations of longitudinal-radial (G_{LR}) and longitudinal-tangential (G_{LT}), in juvenile and mature black locust wood. They performed centre-point bending tests on 66 small clear specimens and measured the shear modulus in each load direction. Their study showed that the shear moduli in longitudinal-radial and longitudinal-tangential for black locust samples were not significantly different.

[1] Shaghayegh Kurzinski, Ph.D., shaykurzinski@gmail.com
[2] Paul L. Crovella, Ph.D., Assistant Professor, Construction Management, SUNY ESF, Syracuse, NY. USA. plcrovella@esf.edu

https://doi.org/10.52202/069179-0051

The shear moduli values in juvenile wood, however, were slightly lower than the values in mature wood. Divos et al. [6] used three different methods: static bending tests, torsional vibration, and the variation of span method to determine the shear modulus of construction-size timber. They found that between these methods, the static bending test and torsional techniques provided a more precise prediction of the shear constant in different directions.

In research done by Sliker [7], longitudinal-tangential and longitudinal-radial shear moduli of a variety of softwood and hardwood species were determined by two methods: the two-plate shear test and the off-axis tensile test at a 20° angle of load to the grain. In the longitudinal-tangential plane, the shear modulus (G_{LT}), calculated from the off-axis tensile test ranged from 0.87 to 1.25 times the shear modulus (G_{LT}), from the plate test. In the longitudinal-radial plane, the shear modulus (G_{LR}), from the off-axis tensile test ranged from 0.98 to 1.26 times the shear moduli G_{LR}, from the plate test. For the tested species, the linear regressions done for Poisson's ratios in correlation with shear and elastic moduli did not show any significant relationships for either of Poisson's ratios ν_{lr} or ν_{tr} as functions of density, E_L, or E_T.

Yoshihara et al. [8] examined the applicability of Timoshenko's theory and proposed an empirical equation to derive the shear modulus. To validate this empirical approach, three softwoods and three hardwoods were tested. First, the Young's and longitudinal-radial shear moduli were measured by free-free flexural vibration tests. Then three-point static bending tests were undertaken, varying the depth/span ratios. Additionally, the bending tests were simulated by the finite element method (FEM). The longitudinal-radial shear moduli obtained by these methods were then compared. They concluded a new prediction method for determining the longitudinal-radial shear modulus by modifying Timoshenko's theory.

The longitudinal modulus of elasticity to shear modulus ratios of different lumber species is not constant. It varies between 5 and 24 depending on the softwood and hardwood species and the grain direction (L, T, and R). There are published references that assume a typical ratio for longitudinal-radial and tangential-radial shear and tangential elastic moduli regarding the longitudinal elastic modulus (E_L/E_T, E_L/G_{LR}, E_L/G_{TR}). For instance, the North American and European Cross-laminated Timber (CLT) standards; ANSI/APA PRG 320-2019 [9] and EN 16351-2021 [10] assume these ratios to be: E_0/E_{90}=30:1, E_0/G_0=16:1, and E_0/G_{90}=160:1 for softwood species. The timber standards for Australia/New Zealand AS1720-2010 [10] and the Brazilian Timber standard [12] assume the ratio of E_0/G_0 to be around 15:1 for softwoods [13].

This study has selected one local low-density softwood and one local high-density hardwood species to investigate the shear and elastic moduli in two grain directions, longitudinal and tangential. Also, using linear regressions, the study evaluates the elastic ratios of E_0/E_{90}, E_0/G_0, E_0/G_{90} for softwoods and hardwoods with available elastic ratios in the USDA Wood Handbook [2]. The values and ratios of the elastic constants from the experimental testing have been compared to those from the regressions. This study can provide insight into predicting elastic ratios for species with no available published or tested elastic constant values.

2 MATERIALS AND METHODOLOGY

2.1 SPECIMEN PREPARATION AND DIMENSIONS

A total of 20 small black locust specimens and 20 eastern white pine specimens, 19-mm thick and 19-mm wide, with different lengths over a range from 89-mm to 280-mm (as shown in **Table 1**) were cut (respectively) from two defect-free, ungraded, rough-sawn black locust boards obtained from a local sawmill in Newfield, NY and one defect-free NeLMA [14] finish grade board purchased from a local lumber supplier near Syracuse, NY. The specimens' cross-section and lengths have been prepared according to the standard's requirement [1] for the centre-point bending test explained in **Section 2.2**. The boards were surfaced and planed to the desired thickness before the cutting process. The final cut specimens were straight-grained and free from any visible defects. The specimens were conditioned in an environmental chamber set at 20°C and 65% relative humidity until a constant weight was achieved. The final measured moisture content of the boards was approximately in the range of 12±1%. The specimens were prepared to be tested in two different directions relative to the wood grain orientation.

The centre-point bending test has been used to determine the apparent modulus of elasticity by measuring the uniform strain state at the centre of the specimens which is a combination of shear and bending deflection. The relative contribution of bending and shear deflections to the total deflection vary with span-to-depth ratio of the specimen. The measured apparent modulus of elasticity can help determining the shear-free modulus of elasticity by excluding the shear deflection to provide a true bending stiffness.

Table 1 shows the matrix of samples of each species divided into two groups tested under centre-point bending tests in the longitudinal and tangential directions for measuring the apparent modulus of elasticity (E_{app}) in both longitudinal and tangential directions and (respectively) the shear-free longitudinal elastic modulus (E_L) with longitudinal-radial shear moduli (G_{LR}) and shear-free tangential elastic modulus (E_T) with the tangential-radial shear modulus (G_{TR}). **Figure 2** shows the final specimens with different span lengths.

https://doi.org/10.52202/069179-0051

Table 1: *Specimens and Testing Details*

Species	Sample (Test Direction)	Sample Size	Span to Depth (l/d)
Eastern White Pine	Longitudinal-Radial Specimen	10	14:1, 11.3:1, 10.6:1 10:1, 9.3:1, 8.6:1, 8:1, 7.3:1, 6.6:1, 6:1
	Tangential-Radial Specimen	10	10:1, 9.3:1, 8.6:1, 8.3:1, 8:1, 7.6:1, 7.3:1, 7:1, 6.6:1
Black Locust	Longitudinal-Radial Specimen	10	14.8:1, 14.1:1, 13.5:1, 12.8:1, 12.1:1, 9.1:1, 8.4:1, 7.7:1, 7:1, 6:1
	Tangential-Radial Specimen	10	7.6:1, 7.3:1, 7.1:1, 7:1, 6.6:1, 6.5:1, 6.3:1, 6:1, 5.6:1, 5.3:1

Figure 2: *Specimen Samples with Different Span Lengths Prepared for Centre-point Bending Test (Eastern White Pine: Left, Black Locust: Right)*

2.2 CENTRE-POINT BENDING TEST

A non-destructive centre-point bending test as described in ASTM D198-2015 [1] (section 7.3.2.2) was performed on the specimens to provide the shear modulus and modulus of elasticity. The standard requires at least four different span lengths and the same depth such that the span-to-depth ratio (l/d) is between 20:1 and 5:1 ($0.0025 < (d/l)^2 < 0.035$). Using this method, the apparent modulus of elasticity and the shear modulus were predicted. The centre-point bending test was performed using a tabletop Shimadzu Precision Universal Tester 10KN AGX model machine set to a loading rate of 0.889 mm per minute. The test was performed until the proportional limit in the elastic range was reached and before the total failure of the specimen. The data was recorded with Trapezium X Software and a video extensometer. **Figures 3** and **4**, respectively, show illustrative and actual details of the test configuration and the loading direction in each group with respect to the wood grain orientation.

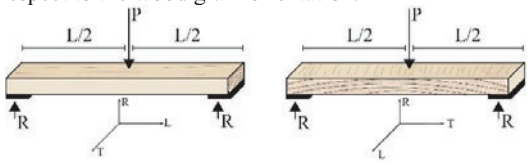

Figure 3: *Center-point Bending Test Details with Respect to Specimens' Grain Orientation*

Figure 4: *Actual Center-point Bending Tests to Determine Shear and Elastic Moduli*

According to ASTM D198-2015 [1] to calculate the shear modulus, first, the value for the apparent modulus of elasticity should be acquired using **Equation 1**:

$$E_{app} = \frac{PL^3}{4bd^3\Delta} \quad (1)$$

where E_{app} is the apparent elastic modulus at a specific span-to-depth ratio and grain orientation, P is the load at the proportional limit, b is the width of the specimen, d is the depth of the specimen and Δ is the deflection that occurs up to the proportional limit.

After determining the values for apparent elastic modulus for different span lengths, their inverses were plotted versus the span-to-depth ratios. The slope of this linear curve is a factor in predicting the shear modulus according to **Equation 2**,

$$G = \frac{6}{5K_1} \quad (2)$$

where G is the shear modulus with respect to the loading direction on the specific grain orientation, and K_1 is the slope of the inverses of apparent elastic moduli versus the span-to-depth ratio (**Error! Reference source not found. 5**).

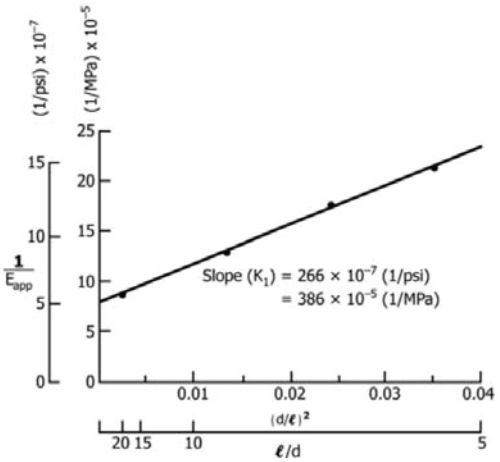

Figure 5: *Shear Modulus Determination based on the Apparent Elastic Modulus and Span-to-Depth Ratio [13]*

After the shear modulus is found for each group of specimens, the shear-free modulus of elasticity can be calculated using **Equation 3**.

$$E_{sf} = \frac{PL^3}{4bd^3\Delta\left(1-\frac{3PL}{10bd\Delta G}\right)} \quad (3)$$

where E_{sf} is the shear-free modulus of elasticity, P is the load at the proportional limit, b is the width of the

specimen, h is the depth of the specimen and Δ is the deflection that occurs up to the proportional limit, and G is the shear modulus with respect to the loading direction on the specific grain orientation.

2.3 THEORETICAL INVESTIGATION OF SHEAR AND ELASTIC MODULI CORRELATION

One of the most easily measured physical properties of wood is the Young's modulus or modulus of elasticity (MoE) in the longitudinal direction (E_0 or E_L). This quantity is available for the majority of the wood species in technical publications, or it can also be obtained on a piece-by-piece basis from non-destructive testing. The USDA Wood Handbook [2] provides ratios for shear moduli in different grain directions (RT, LT, LR) and elastic moduli in tangential and radial directions with respect to the elastic modulus in the longitudinal direction for a few hardwood and softwood species. To predict tangential elastic modulus and longitudinal-radial and tangential-radial shear moduli of eastern white pine and black locust, the Handbook's softwood and hardwood species with available elastic ratios were selected (include the number). The shear moduli in longitudinal-radial and tangential-radial and elastic modulus in tangential directions were calculated for these softwoods and hardwoods using the available elastic ratios. Linear regressions for each elastic constant from the selected species were performed using Microsoft Excel [15] to provide a predicted ratio with respect to the longitudinal elastic modulus. Since the available reference [2] shows a true linear relation of Y=AX, for each elastic constant regarding the longitudinal elastic modulus, an intercept-free linear model was selected for predicting the elastic ratios. These ratios were used to theoretically estimate values for shear moduli in longitudinal-radial and tangential-radial directions (G_{LR} and G_{TR}) and tangential elastic modulus (E_T) for eastern white pine and black locust with respect to their published longitudinal elastic modulus (E_L).

3 RESULTS AND DISCUSSION

3.1 MEASURED ELASTIC CONSTANTS AND RATIOS BY CENTER-POINT BENDING TESTS

The curves showing the correlations between $1/E_{app}$ and span-to-depth ratios (l/d) obtained from the centre-point bending tests for longitudinal-radial and tangential-radial specimens are presented in **Figures 6** and **7**, for eastern white pine, and **Figures 8** and **9** for black locust. The shear moduli values have been calculated from these curves using **Equation 2**. The final values of shear moduli (G_{LR} and G_{TR}) and the measured apparent and shear-free elastic moduli in each loading direction (E_L and E_T) are presented in **Table 2**.

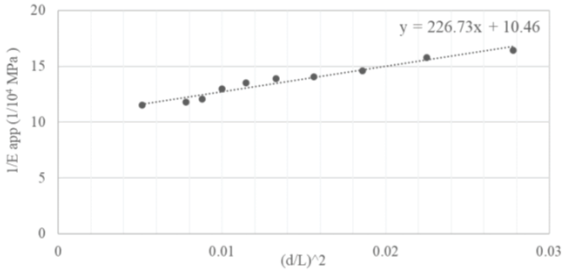

Figure 6: *Apparent Elastic Modulus vs. Span-to-Depth Ratio Curves of Eastern White Pine Specimens in Longitudinal-Radial Direction*

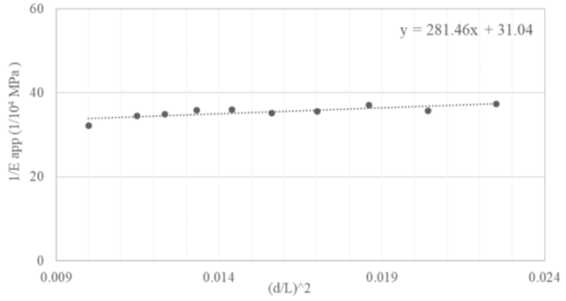

Figure 7: *Apparent Elastic Modulus and Span-to-Depth Ratio Curves of Eastern White Pine Specimens in Tangential-Radial Direction*

Table 2: *Final Measured Values of Apparent Elastic Modulus of Small Specimens Under Centre-point Bending Test*

Species	Properties	Longitudinal	Tangential
Eastern White Pine	Apparent Modulus of Elasticity (MPa)	E_{app} = 7,418	E_{app} = 283
Black Locust	Apparent Modulus of Elasticity (MPa)	E_{app}= 14,993	E_{app}= 1,013

3.2 THEORETICAL PREDICTED ELASTIC CONSTANTS AND RATIOS FROM THE ELASTIC REGRESSIONS

The published longitudinal modulus of elasticity (E_L) values of eastern white pine and black locust have been found from the USDA Wood Handbook [1] to be respectively 8,555 MPa and 14,134 MPa. To theoretically predict the values of longitudinal-radial and tangential-radial shear and tangential elastic moduli of these two species, the estimated elastic ratios from the regressions on the USDA Wood Handbook's [2] softwoods and hardwoods were used. These linear regressions of tangential elastic modulus and shear moduli with respect to longitudinal elastic modulus are presented in **Table 3**. The final theoretical elastic ratios and values of eastern white pine and black locust with respect to the predicted elastic ratios from the regressions are shown and compared to the measured ratios and values, respectively in **Table 4** and **Table 5**.

Table 3: *Linear Regression Components of Tangential Elastic and Shear Moduli of USDA Wood Handbook Softwood and Hardwood Species with Respect to their Longitudinal Modulus Species*

Species	Regression	R^2 Value	Regression Model
Softwood	E_L - E_T	0.9157	Y=0.0547X
	E_L - G_{LR}	0.8631	Y=0.073X
	E_L - G_{TR}	0.7426	Y=0.0057X
Hardwood	E_L - E_T	0.9386	Y=0.061X
	E_L - G_{LR}	0.9403	Y=0.0921X
	E_L - G_{TR}	0.941	Y=0.0194X

Table4: *Predicted and measured Shear and Elastic Moduli Values with Respect to Longitudinal Elastic Modulus (EL) from Regressions on the USDA Wood Handbook Species*

Species	Properties	Longitudinal	Tangential
Eastern White Pine	Predicted Modulus of Elasticity (MPa)	E_L = 8,550	E_T = 468
	Predicted Shear Modulus (MPa)	G_{LR} = 624	G_{TR} = 49
	Measured Modulus of Elasticity (MPa)	E_L = 9,569	E_T = 322
	Measured Shear Modulus (MPa)	G_{LR} = 529	G_{TR} = 43
Black Locust	Predicted Modulus of Elasticity (MPa)	E_L= 14,134	E_T= 862
	Predicted Shear Modulus (MPa)	G_{LR} = 1,302	G_{TR} = 274
	Measured Modulus of Elasticity (MPa)	E_L = 17,925	E_T = 1,294
	Measured Shear Modulus (MPa)	G_{LR} = 1,215	G_{TR} = 133

Table 4: *Measured and Predicted Ratios of Shear and Elastic Moduli (LR: Longitudinal-Radial, TR: Tangential-Radial)*

Species	Ratio	Measured	Predicted
Eastern White Pine	E_L/E_T	29.6	18.3
	E_L/G_{LR}	18.0	13.7
	G_{LR}/G_{TR}	12.4	12.8
Black Locust	E_L/E_T	13.8	16.4
	E_L/G_{LR}	14.8	10.85
	G_{LR}/G_{TR}	9.1	4.7

According to the experimental and theoretical results, the longitudinal shear-free elastic moduli for eastern white pine and black locust from the centre-point bending tests are respectively 11% and 26% higher than the published longitudinal elastic modulus in the USDA Wood Handbook [2]. The predicted shear-free tangential elastic modulus from regressions is approximately 45% higher and 33% lower than the measured tangential elastic modulus for eastern white pine and black locust respectively. The predicted longitudinal-radial shear modulus is 15% and 6% higher than the measured longitudinal-radial shear modulus for eastern white pine and black locust respectively. Also, the predicted tangential-radial shear modulus is 14% and 106% higher than the measured tangential-radial shear modulus for

https://doi.org/10.52202/069179-0051

eastern white pine and black locust respectively. Between the elastic ratios from measured constants, the ratio of eastern white pine longitudinal-radial shear modulus to tangential-radial shear modulus is almost the same (3% difference percentage) as the one predicted from regressions. However, the same ratio (G_{LR} /G_{TR}) for black locust is almost half of what is found based on the measured constants from the centre-point bending tests. Also, the elastic ratio of predicted longitudinal to the tangential modulus of elasticity for eastern white pine is approximately 30% of the measured one while the other predicted elastic ratios from the regressions have a percentage prediction error between 10% and 20% of the measured ratios from the tests.

4 CONCLUSIONS

This research investigated the values and ratios of shear and elastic moduli of black locust and eastern white pine experimentally and empirically. The results showed that longitudinal and tangential shear moduli and tangential elastic modulus can be predicted using longitudinal elastic modulus. The measured elastic ratios of longitudinal to the tangential modulus of elasticity (E_L/E_T) for eastern white pine from the tests were in agreement with the suggested ratios of modulus of elasticity parallel to the grain to the modulus of elasticity perpendicular to the grain (E_0/E_{90}) for softwoods in North American Cross-laminated Timber standard, ANSI/APA PRG 320 [9] to be 30:1. The measured longitudinal elastic modulus to the longitudinal-radial shear modulus ratio (E_L/G_{LR}=18:1) of the eastern white pine was approximately 17% higher than the suggested elastic ratio of shear modulus parallel to the grain to the modulus of elasticity parallel to the grain (E_0/G_0=16:1) for softwoods in ANSI/APA PRG 320 [9]. Therefore, it can be concluded that ANSI/APA PRG 320 [6] provides a conservative prediction of softwoods' elastic ratios compared to the regressions from the USDA Wood Handbook [2] elastic values.

The regression between hardwoods' tangential-radial shear modulus to the longitudinal modulus of elasticity showed a non-conservative agreement with the measured value. The reason for this difference may be the small sample size for the regression. The USDA Wood Handbook [2] provides the tangential-radial shear modulus (G_{TR}) for only six hardwood species. Except for the predicted longitudinal-radial shear modulus of black locust to its published longitudinal modulus of elasticity, the other predicted elastic ratios for this species with respect to the hardwoods' regressions, have predicted a ratio with a percentage prediction error approximately between 10% and 20% of the measured ratios from the tests.

This study provided methods for predicting the shear and elastic moduli in different grain directions of the species without available published elastic constants values. To predict the final stiffness value of any composite or mass timber product (e.g. CLT), the shear and elastic values of the species used in the layers are required. There are several non-standard species that might benefit the timber industry due to density, resource availability, locality, etc. but are not being used for the fabrication since there is no available published value for their elastic constants. Therefore, predicting the elastic constants of different wood species with unknown elastic values can help in using them as individual layers in several mass timber products such as Cross-laminated Timber panels. Further research is recommended to experimentally investigate the elastic values of other softwoods and in particular hardwoods to validate the predicted elastic ratios from the regressions provided in this study.

PYTHON-BASED PLATE MODEL TO SIMULATE THE EFFECT OF KNOTTY AREAS ON SAWN TIMBER.

Jorge Uribe Cisternas[1], Diego Valdivieso Cascante[2]

ABSTRACT: This paper introduces a computational python-based model of a timber plate of Pinus Radiata D. Don specie grown in Chile. The effect of knotty areas is considered for the simulation of stiffness and resistance in a simply supported plate subjected to out-of-plane bending assessing the failure with the Von Mises normalized and Tsai-Wu criteria. The computational model is implemented based on the Reissner-Mindlin plate theory, considering a rectangular orthotropic model to simulate the behavior of wood. When the knotty area ratio (KAR) reaches its maximal value, 1, stiffness and resistance decrease by 19% and 56%, respectively. Through the Monte-Carlo method, 500 wooden plates are simulated by randomly distributing the lengths of internodes and whorls, which shows a difference of 14% in vertical displacement. It is concluded that the open-source numerical model was able to capture the effect of the knotty areas on the bending behavior of timber elements. The next step involves the calibration of the input parameters of the numerical model from the test results.

KEYWORDS: Plate, KAR, Whorl, Internode, Finite Elements Models, Pinus Radiata

1 INTRODUCTION

Wood has been used repeatedly in Chile for small constructions. Nowadays, the need to carry out sustainable constructions based on renewable materials and with that cause a low impact on the environment makes wood head the list of most required materials in the future.

For the same reason, the Chilean construction industry has evaluated the alternative of building wooden constructions to eventually replace concrete and steel constructions. However, compared to concrete and steel, there is still a lack of knowledge about the behavior of wood products made from Pinus radiata grown in Chile and the effect of their natural defects (i.e., knotty area and its distribution on the tree length) on their mechanical properties [1].

This article aims to contribute to the development of an open-source plate model based on Python that allows quantifying the effects of knotty areas on the bending behavior of wood elements through the finite element method.

2 COMPUTATIONAL MODEL

2.1 GENERAL

A plate is defined as a flat solid whose thickness is much smaller than its other dimensions (length and width). In this paper, a finite element model for plate bending is presented based on the Reissner-Mindlin plate theory for small elastic strains, which includes the transverse shear effect [2,15] (see Figure 1).

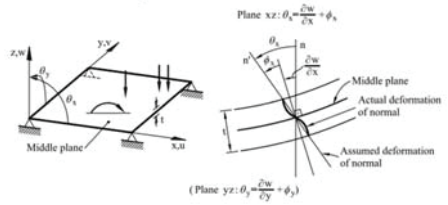

Figure 1: *Reissner-Mindlin plate theory. Sign convention for the displacements and the rotations of the normal. Taken from [9].*

2.2 FORMULATION

2.2.1 Force Formulation

According to [5], the strong formulation of the boundary problem of plate theory is:

$$
(S)\quad \left\{ \begin{array}{l} \textit{Considering } F, C_\alpha, M_\alpha, Q, W \textit{ and } \Theta_\alpha, \textit{find } w \textit{ and } \theta_\alpha \textit{ such that:} \\ \left.\begin{array}{rl} m_{\alpha\beta,\beta} - q_\alpha + C_\alpha &= 0 \\ q_{\alpha,\alpha} + F &= 0 \\ m_{\alpha\beta} &= -c_{\alpha\beta\gamma\delta} k_{\gamma\delta} \\ q_\alpha &= c_{\alpha\beta}\gamma_\beta \\ k_{\alpha\beta} &= \theta_{(\alpha,\beta)} \\ \gamma_\alpha &= -\theta_\alpha + w_{,\alpha} \end{array}\right\} \forall x \in A \\ \left.\begin{array}{rl} \theta_\alpha &= \Theta_\alpha \\ w &= W \\ m_{\alpha n} = m_{\alpha\beta} n_\beta &= \mathrm{M}_\alpha \end{array}\right\} \begin{array}{l} \forall x \in \Gamma_{\theta\alpha} \\ \forall x \in \Gamma_w \\ \forall x \in \Gamma_M \end{array} \end{array} \right.
$$

https://doi.org/10.52202/069179-0052

$$q_n = q_\alpha n_\alpha = Q \qquad \} \forall x \in \Gamma_Q$$

Where, F= applied transverse force per unit area, C_α= applied moment couple per unit area, M_α= prescribed moments at the boundary, Q= prescribed shear force at the boundary, W= prescribed displacement at the border. Also $m_{\alpha\beta}$ is the moment tensor, q_α is the shear force vector $k_{\alpha\beta}$ is the curvature tensor and γ_α is the shear strain vector. The $\Gamma'_{(.)S}$ represents the different parts of the boundary.

2.2.2 Finite Element Formulation

We start the weak formulation by defining the spaces:

$$\mathcal{S} = \{w, \theta_1, \theta_2 \in H^1(\Omega, \mathbb{R}) | w = W \ \forall \in \Gamma_w, \theta_\alpha = \Theta_\alpha \ \forall x \in \Gamma_{\theta\alpha}\}$$

$$\mathcal{V}_{\theta\alpha} = \{\delta\theta_\alpha \in H^1(\Omega, \mathbb{R}) | \delta\theta_\alpha = 0, \ \forall x \in \Gamma_{\theta\alpha}\}$$

$$\mathcal{V}_w = \{\delta w \in H^1(\Omega, \mathbb{R}) | \delta w = 0, \ \forall x \in \Gamma_w\}$$

Where $\mathcal{S}$ is the solution space, $\mathcal{V}_{\theta\alpha}$ and $\mathcal{V}_w$ are the test spaces, H^1 is the Sobolev space, W and Ω_α are the prescribed displacements and rotations (essential or Dirichlet conditions), and $\Gamma_{\theta\alpha}$ and Γ_w are the Dirichlet boundaries.

The variational formulation is obtained by multiplying the equations of the strong formulation by the functions test and integrated by parts in the domain $w = A$. Defining $\delta\gamma_\alpha = \delta\theta_\alpha + \delta_{w,\alpha}$ we have:

$$(W)\begin{cases} Considering\ F, C_\alpha, M_\alpha, Q, W\ and\ \Theta_\alpha, find\ w\ and \\ \theta_\alpha \in \mathcal{V}\ such\ that, \forall \delta_w \in \mathcal{V}\ and\ \delta\theta_\alpha \in \mathcal{V}_{\theta\alpha} \\ \int_A \left(-\delta\theta_{(\alpha,\beta)} m_{\alpha,\beta} + q_\alpha \delta\gamma_\alpha\right) = \int_A (\delta_w F - \delta\theta_\alpha C_\alpha) - \\ \int_{\Gamma_M} \delta\theta_\alpha M_\alpha + \int_{\Gamma_Q} \delta_w Q \qquad \forall x \in A \end{cases}$$

Where M_α and Q are the prescribed moments and shear forces (natural or Neumann boundary conditions) Γ_M and Γ_Q are the Neumann frontiers.

From the variational formulation and discretizing the **Ω** domain, the finite element formulation is determined:

$$(L^{FEM})\begin{cases} Considering\ \mathbf{K} \in \mathbb{R}^{NxN}\ and\ \mathbf{F} \in \mathbb{R}^M, \\ find\ \mathbf{d}\ such\ that: \\ \mathbf{K}\,\mathbf{d} = \mathbf{F} \end{cases}$$

Where **d** is the nodal displacement value $\mathbf{d} = \begin{bmatrix} w \\ \theta_1 \\ \theta_2 \end{bmatrix}$

Where:

$$K_{ij} = \iint_A B_i^T \widehat{D} B_j \, dA \ ;$$

$$F = \iint_A N^T p_j - \int_{\Gamma_M} N^T \overline{M} + \int_{\Gamma_Q} N^T \overline{Q}$$

$$p_j = [f_z \quad m_x \quad m_y]^T$$

$\widehat{D}$ is the generalized constitutive matrix.

The stiffness matrix of each element can be divided into bending (k_b) and transverse shear (k_s). The global equilibrium equation is written as

$$(K_b + K_s)d = F \qquad (1)$$

$$K_{ij}^{(e)} = \iint_{A^{(e)}} \begin{bmatrix} B_{bi}^T & B_{si}^T \end{bmatrix}^T \widehat{D} \begin{bmatrix} B_{bj} \\ B_{sj} \end{bmatrix} dA = K_{b_{ij}}^{(e)} + K_{s_{ij}}^{(e)} \qquad (2)$$

Where:

$$B_{bi} = \begin{bmatrix} 0 & N_{i,x} & 0 \\ 0 & 0 & N_{i,y} \\ 0 & N_{i,y} & N_{i,x} \end{bmatrix}; \quad B_{si} = \begin{bmatrix} N_{i,x} & -N_i & 0 \\ N_{i,y} & 0 & -N_i \end{bmatrix}$$

The vector of forces remains:

$$F^{(e)} = \iint_{A^{(e)}} N^{(e)T} p_j - \int_{\Gamma_M^{(e)}} N^{(e)T} \overline{M} + \int_{\Gamma_{Q^{(e)}}} N^{(e)T} \overline{Q}^{(e)} \qquad (3)$$

Where:

$$N_i = \begin{bmatrix} N_i & 0 & 0 \\ 0 & N_i & 0 \\ 0 & 0 & N_i \end{bmatrix}$$

2.3 TYPE OF ELEMENTS CONSIDERED

In order to verify the accuracy of the model, four different elements were implemented: Q4, QS8, QL9, and QH9 based on [9]. The shape functions referring to these elements are presented below:

- Four-node element – Q4

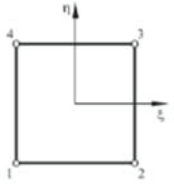

Figure 2: *Bilinear element (Q4).[9]*

$$N_i = \frac{1}{4}(1 + \xi\xi_i)(1 + \eta\eta_i), i = 1,2,3,4 \qquad (4)$$

- Eight-nodes element – QS8

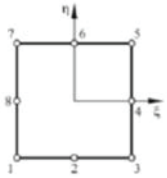

Figure 3: *Serendipity Quadratic element (QS8).[9]*

$$N_i = \frac{1}{4}(1+\xi\xi_i)(1+\eta\eta_i)(\xi\xi_i+\eta\eta_i-1), i = 1,2,3,4$$
$$N_i = \frac{1}{2}(1+\eta\eta_i)(1-\xi^2), i = 5,7 \quad (5)$$
$$N_i = \frac{1}{2}(1+\xi\xi_i)(1-\eta^2), i = 6,8$$

- Nine-nodes element – QL9

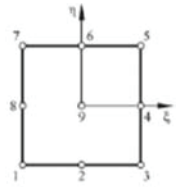

Figure 4: *Lagrangian Biquadratic element (QL9).[9]*

$$N_i = \frac{1}{4}(\xi^2+\xi\xi_i)(\eta^2+\eta\eta_i), i = 1,3,5,7$$
$$N_i = \frac{1}{2}\eta_i^2(\eta^2+\eta\eta_i)(1-\xi^2)+\frac{1}{2}\xi_i^2(\xi^2+\xi\xi_i)(1-\eta^2)$$
$$, i = 2,4,6,8$$
$$N_i = (1-\xi^2)(1-\eta^2), i = 9 \quad (6)$$

- Nine-nodes hierarchical – QH9

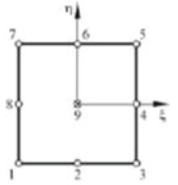

Figure 5: *Hierarchical element (QH9).[9]*

$$\theta_x = \sum_{i=1}^{8} N_i\,\theta_{x_i} \;;\; \theta_y = \sum_{i=1}^{8} N_i\,\theta_{y_i}$$
$$w = \left(\sum_{i=1}^{8} N_i w_i\right) + \overline{N_9} w_9 \quad (7)$$

where N_i are the standard shape functions for the QS8 element and $\overline{N_9} = (1-\xi^2)(1-\eta^2)$. The hierarchical variable w_9 is the difference between the nodal deflections obtained with QS8 and QL9 elements. [9]

2.4 DETERMINATION OF THE BEST ELEMENT TO BE USED

The performance and meshing of the implemented plates with different elements were compared against the analytical solutions from the author S. Timoshenko [12], through the results of the vertical displacement in the center of the plate.

In Figure 6, it shows that the four elements give a result like to Timoshenko formulation due to the low percentage error (i.e., less than 5%) in vertical displacement, however, the QH9 element shows the best accuracy (i.e., 0.002%) due to the addition of a "spring" that eliminates spurious mechanisms [9]. The next steps of this investigation were carried out with the QH9 element.

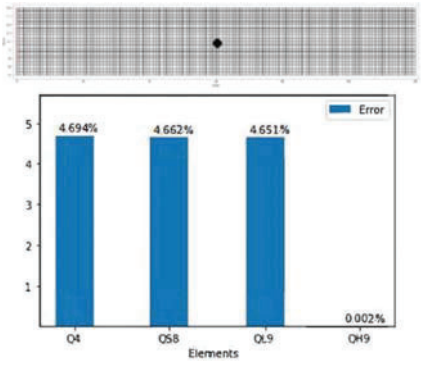

Figure 6: *(up) Evaluation in the center of the discretized plate, (down) Graph of the percentage error of each element.*

3 EVALUATION OF NATURAL DEFECTS ON WOOD PLATES

In each computational model, the displacement and deformation fields were calculated. Subsequently, to evaluate the behavior of the plate, the knotty areas were used, taking as a reference the properties of the Blass study [3], in addition, the properties and distribution of the knotty areas in Radiata Pine specie were replicated. The Knotty Area Ratio (KAR) is varied increasing from 0.1 to 1 to evaluate the impact on the displacement and stress in three control points along the simulated plate (P1, P2, and P3 illustrated in Figure 8). The coordinates of each point are located at (Lx/4, Ly/2), (Lx/2, Ly/2), (3Lx/4, Ly/2) respectively. To evaluate the stress interaction in the plate, the Von Misses Normalized [14] and Tsai-Wu [13] failure criteria were used.

In order to evaluate the effect of knotty area distribution, five hundred wood plates with a fixed KAR but with a different distribution of knotty areas, varying the whorl of internodes and whorls were assessed. The center point of the plate is chosen as the control point and the vertical displacement of the 500 wooden plates is plotted.

3.1 EFFECT OF THE KNOTTY AREA

In order to quantify the accuracy of the model, a virtual test of a representative 120 cm x 20 cm x 6.5cm wood plate made of Radiata Pine grown in Chile was simulated (see Figure 7). A rectangular orthotropic law was considered for the wood constitutive, considering the

https://doi.org/10.52202/069179-0052

mechanical properties from [4]. The model was considered as simply supported and uniformly loaded with 4 [N/cm^2] over the entire surface. The geometry of the element was discretized into 1 cm x 1 cm elements. To include the effect of the knotty area in the model, discrete length stripes were considered whose properties were calculated by means of a linear regression equation determined experimentally in reference [3] based on the knotty area ratio (KAR) (see eq. 8 and 9). The dimensions of the knotty areas (whorl and internode length, see Figure 8) were determined from a study on Radiata Pine grown in Chile (see Table 1) [8].

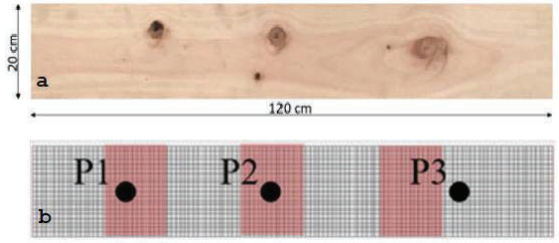

Figure 7: *(a) Representative timber element, (b) Discretization of the wooden plate with the knotty area.*

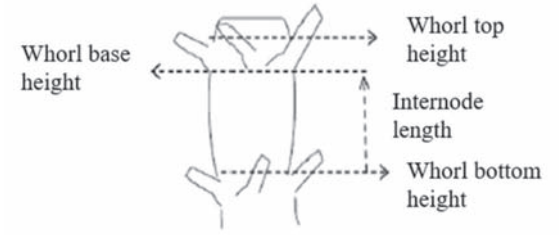

Figure 8: *Base height and top of a whorl. Taken from [8]*

Table 1: *Branch range of the Radiata Pine tree in regions VII and IX of Chile. Take from [8].*

Variable	Range
Internode length [cm]	30 - 110
Whorl length [cm]	20 - 40

$$\ln(\mathrm{E_L}) = 7.90 + 3.81 * 10^{-3} * \rho_0 - 0.369 * KAR$$

With r = 0.773 and S_R = 0.165 (8)

$$\ln(f_\mathrm{L}) = -9.09 + 1.36 * ln(\mathrm{E_L}) - 0.978 * KAR$$

With r = 0.839 and S_R = 0.274 (9)

Where the modulus of elasticity (E_L), resistant tension in flexion (f_L) are in N/mm^2, anhydrous density (ρ_0) in kg/m^3 and the KAR is dimensionless.

3.2 EFFECT OF THE WHORL AND INTERNODE LENGTH

In order to understand the behavior of the timber elements with knotty areas of different lengths of internodes and whorls, a fixed KAR of 66% (KAR = 0.66) was considered to simulate 500 cases with different knotty area dimensions (i.e., whorl and internode length variation) through the Monte-Carlo method.

3.3 FAILURE CRITERIA

3.3.1 VON MISES NORMALIZED

In the reference [14] the authors develop a simplified method for the evaluation of the failure by the resistant tension in flexion (f_L).

$$\frac{\sigma_{vm}}{f_L} = \frac{\sqrt{\sigma_{xx}^2 - \sigma_{xx}\sigma_{yy} + \sigma_{yy}^2 + 3\tau_{xy}^2}}{f_L} \leq 1 \quad (10)$$

Where: σ_{xx}, σ_{yy}, τ_{xy}, are the uniaxial and shearing stress components in the respective directions and sections of an isotropic model and f_L is given by equation 8.

3.3.2 TSAI-WU

For a planar orthotropic model, the failure criteria is given by:

$$F_1\sigma_L + F_2(\sigma_R + \sigma_T) + F_{11}\sigma_L^2 + F_{22}(\sigma_R^2 + \sigma_T^2 + 2\tau_{RT}^2) + F_{66}(\tau_{LR}^2 + \tau_{LT}^2) + 2F_{12}(\sigma_L\sigma_R + \sigma_L\sigma_T) + 2F_{23}(\tau_{RT}^2 - \sigma_R\sigma_T) \leq 1 \quad (11)$$

Where: σ_L, σ_R, σ_T, τ_{LR}, τ_{RT}, τ_{LT} are the uniaxial and shearing stress components in the respective directions and sections of an orthotropic model. F_1, F_2, F_{11}, F_{22}, F_{66} and F_{23} are coefficients obtained from uniaxial stresses (i.e., in tension f_t and compression f_c) and shear stress f_v parallel or perpendicular to the grain (i.e., denoted as 0 or 90 for parallel or perpendicular, respectively), through the reference [7]. F_{12} is a coefficient that represents, the biaxial resistance (parallel and perpendicular).

$$F_1 = \frac{1}{f_{t0}} - \frac{1}{f_{c0}};\ F_2 = \frac{1}{f_{t90}} - \frac{1}{f_{c90}}$$

$$F_{11} = \frac{1}{f_{t0}f_{c0}};\quad F_{22} = \frac{1}{f_{t90}f_{c90}}$$

$$F_{66} = \frac{1}{(0.72f_{v0})^2};\quad F_{23} = \frac{1}{2}\left(\frac{1}{f_{v90}^2} - \frac{1}{f_{t90}f_{c90}}\right)$$

For the factor F_{12} the reference [6] proposes the following:

$$F_{12} = \frac{1}{2}\left(\frac{1}{f_{t0}f_{c90}} + \frac{1}{f_{c0}f_{t90}} - \frac{1}{f_{v0}^2}\right)$$

Experimental data from reference [10] in Radiata Pine is taken into consideration for defining the uniaxial and

shear stress input necessary for calculating the coefficients, F_i. The characteristics will be considered in a dry condition (humidity < 19%).

4 RESULTS

The results of the computational plate model based on QH9 elements are illustrated in Figures 9 to 11, where the displacements and stresses variation as a function of the knotty area ratio (KAR), whorl length, and internode length are evaluated.

4.1 DISPLACEMENT AND DEFORMATION FIELD

The displacements and stresses of the plate are shown in Figure 9 considering a plate without a knotty zone and another with a KAR of 66%. Figure 9.a shows that the vertical displacement at the edge of the plate increases by 12% because of the knotty area effect. Figure 10 shows visually how the KAR influences the stress distribution.

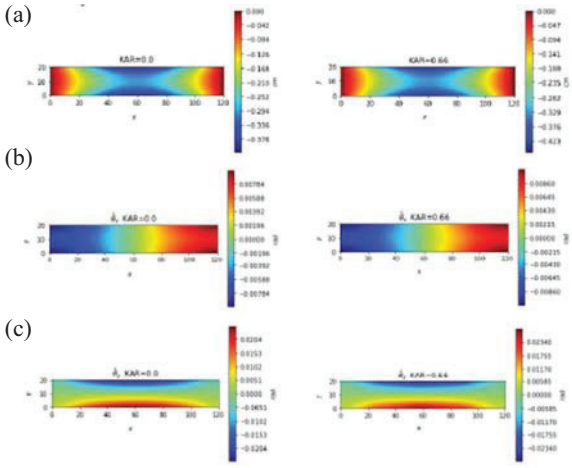

Figure 9: *(left) KAR=0.0, (right) KAR=0.66. (a) Vertical displacement, (b) rotation about X-direction and (c) rotation about Y-direction*

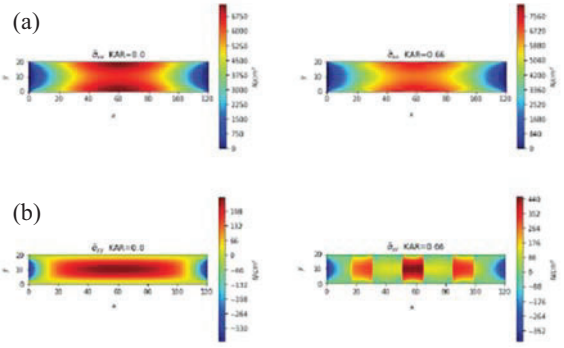

Figure 10: *(left) KAR=0.0, (right) KAR=0.66. Stress field in (a) X and (b) Y direction, respectively*

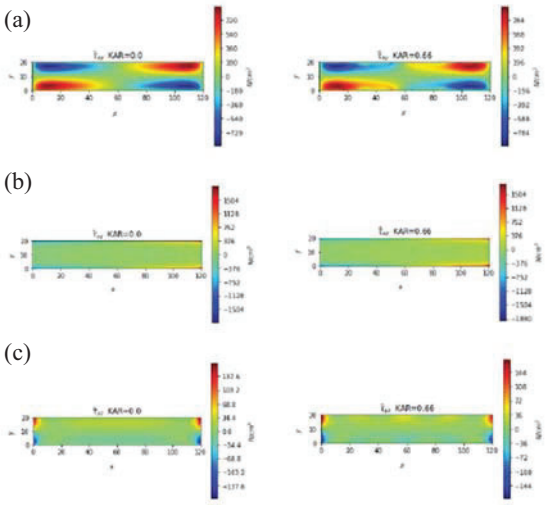

Figure 11: *(left) KAR=0.0, (right) KAR=0.66. Shear stress field (a) XY, (b) XZ and (c) YZ.*

4.2 FAILURE CRITERIA

Two failure criteria were selected to analyze the stress state in the evaluated wood plate. By using the Tsai-Wu criterion, the area where the failure is expected to occur can be identified due to the integration of all the stresses that interact in the plate and the consideration of real Radiata Pine wood coefficients F_i. On the other hand, the Von Mises Normalized criterion does not consider stresses interaction since it is designed for isotropic materials.

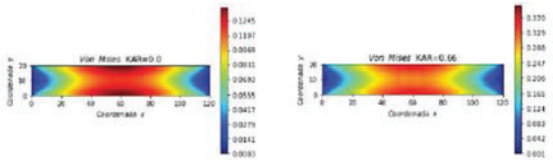

Figure 12: *Failure criterion Von Mises Normalized with (left) KAR=0.0 and (right) KAR=0.66.*

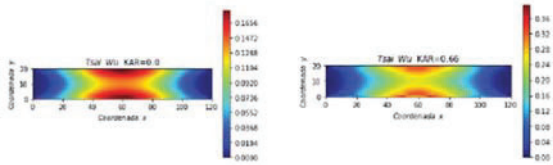

Figure 13: *Failure criterion Tsai Wu with (left) KAR=0.0 and (right) KAR=0.66.*

4.3 EFFECT OF THE KNOTTY AREA

Considering out-of-plane displacement results (see Figure 14), it is observed that as the KAR increases, the vertical displacement increases proportionally, generating an increase of up to 19% in the out-of-plane displacement, being the point P2 with the highest displacement increments, the rotation θ_x increases by 14% at points P1 and P3.

https://doi.org/10.52202/069179-0052

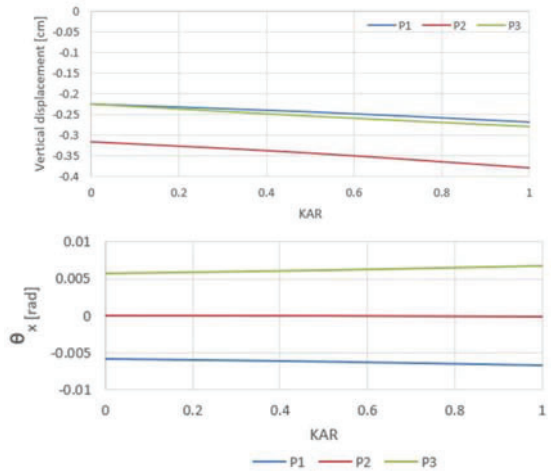

Figure 14: *Effect of the KAR in (top) vertical displacement and (bottom) rotation about X.*

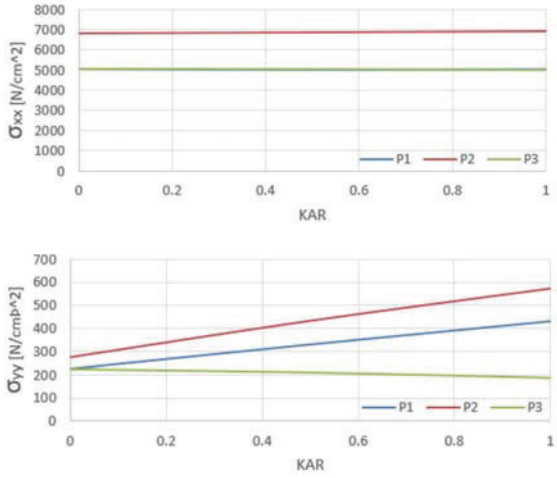

Figure 15: *Effect of the KAR in (top) stress xx and (bottom) stress yy.*

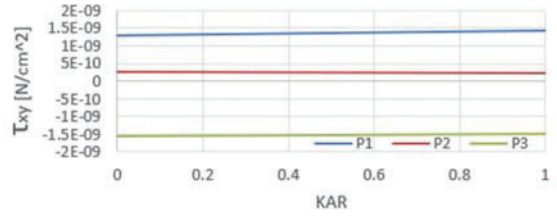

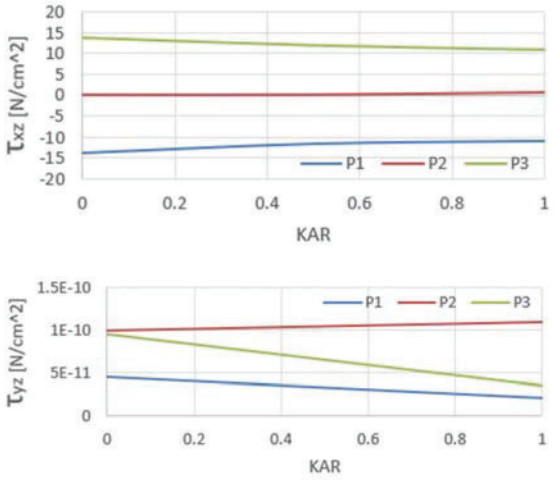

Figure 16: *Effect of the KAR in (top) Taú xy, (middle) Taú xz and (bottom) Taú yz.*

Figure 15 shows that as the KAR increases, the stresses yy (σ_{yy}) increase proportionally, causing a high stress concentration at the points with knotty areas.

Figure 17 shows that for KAR values less than 0.5, the Tsai-Wu criterion is the most conservative in predicting failure whereas for KAR values greater than 0.5 the Von Mises Normalized criterion is the most conservative for failure prediction. The Tsai-Wu criterion utilization factor shows an increment of up to 56% as the KAR increases, while the Von Mises Normalized criterion produces an increment of up to 78%.

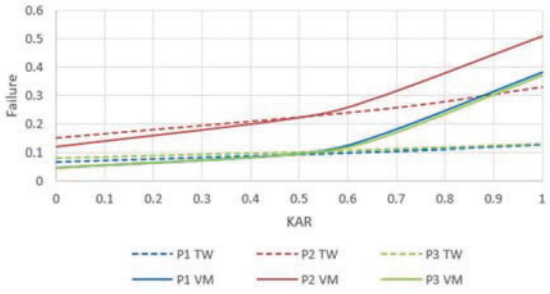

Figure 17: *Effect of the KAR in failure criteria utilization factor.*

4.4 EFFECT OF THE WHORL AND INTERNODE LENGTH

Figure 18 illustrates the evolution of the vertical displacement (*D*) for the 500 simulated cases measured in point P2, considering a KAR=0.66 and varying the lengths of internodes and whorls. Moreover, there is a minimum of one knotty area along the length. From the simulation results, equation 12 is proposed by using the least squares method.

https://doi.org/10.52202/069179-0052

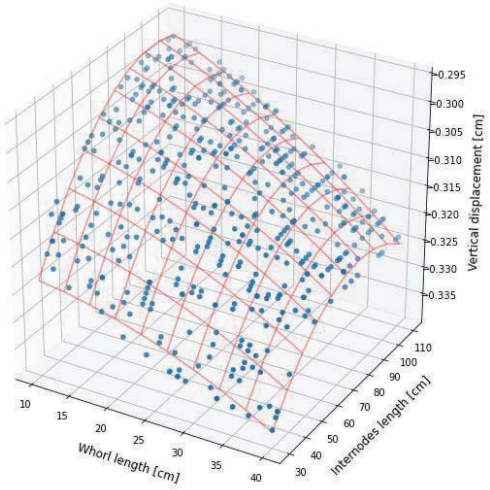

Figure 18: *Vertical displacement at node P2 of the 500 simulated wooden plates with KAR=0.66.*

$$D = 1.879 \cdot 10^{-4} \cdot W + 1.178 \cdot 10^{-3} \cdot I - 1.034 \cdot 10^{-5} \cdot W^2 - 5.256 \cdot 10^{-6} \cdot W \cdot I - 5.803 \cdot 10^{-6} \cdot I^2 \quad (12)$$

Where D= vertical displacement [cm], W= whorl length [cm] and I= internode length [cm].

Figures 19 and 20 show an increment of up to 14% in the vertical displacement depending on internode length or whorl length.

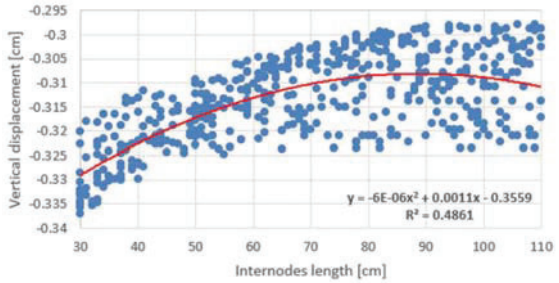

Figure 19: *Vertical displacement v/s internodes length.*

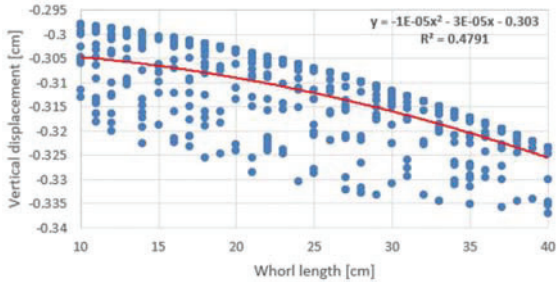

Figure 20: *Vertical displacement v/s whorl length.*

The contour plot shows that the longer the internode length and the shorter the whorl length, the smaller the vertical displacement. On the other hand, between shorter internodes length and greater whorl lengths, the vertical displacement is greater. In the first case, since the length of the internode is so large, it only reaches to one knotty zone along the plate length while the shorter the internode is, there are more knotty zones along the plate. Due to the dimensions of the plates, it only reaches a maximum of three knotty areas.

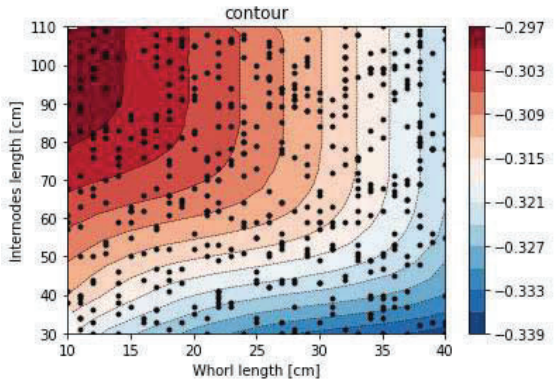

Figure 21: *Internodes length v/s whorl length effect on the vertical displacement at node P2.*

5 CONCLUSIONS

The Python-based model was able to capture the effect of the knotty areas in the response of wood plates subjected to out-of-plane bending. When the KAR reaches its maximum value, the stiffness and strength of the plate decrease by 19% and 56%, respectively. The previous statement can be supported by the failure criteria which takes its maximum values in the wood adjacent to the knotty areas in the center of the plate. Talking about the effect of different lengths of internodes and whorls, the shorter the length of the internode and the longer the whorl, the greater the vertical displacement of the plate, reaching an increment of up to 14%. It is concluded that the open-source numerical model was able to capture the effect of the knotty areas on the bending behavior of timber elements. The next step involves the calibration of the input parameters of the numerical model from the test results.

SIMULATION OF WOOD FRACTURE MECHANICS USING THE PHASE FIELD METHOD FOR FRACTURE

Sebastian Pech[1], Markus Lukacevic[2], Josef Füssl[3]

ABSTRACT: Fracture mechanics simulations play a crucial role in predicting the failure of materials in various engineering applications. However, modeling fracture in inhomogeneous materials with complex microstructures is challenging. This work applies a non-brittle hybrid multi-phase field model to simulate wood failure. The approach is based on a stress-based split for orthotropic materials and includes multiple phase field variables, incorporating preferable fracture planes. The proposed model is initially applied to two examples, single-edge notched plates with varying fiber inclines and a wooden board with a single knot and spatially varying fiber directions. Both examples show that the model covers the effect of the wood microstructure on macroscopic crack propagation. Subsequently, the model is validated on experimental studies from the literature. We show that by choosing the input parameters, the tensile strength and the fracture energy release rate, in a reasonable range for wood, the model agrees well with the results of the experimental studies. Those findings open the application of the model to more complex situations like wooden boards with multiple knots and show that the used input parameters are not model-specific numerically tuned parameters but rather material-specific quantities.

KEYWORDS: Fracture, phase field method, wood

1 INTRODUCTION

Wood is consequently gaining importance in fields of civil engineering, where mainly steel and concrete constructions have dominated until now. This uprise is primarily due to new developments of high-performance wood-based products, the rediscovery of the excellent performance of wood as a building material and ecological benefits.

Understanding the complex mechanical nature of wood is critical to opening its application in new fields and optimizing its usage.

The microstructure of wood strongly influences its mechanical properties. Crack growth starts on the microscopic scale from defects in the cell wall material. After the localization of a macroscopic crack, a fracture process zone forms [31]. Subsequently, toughening effects like fiber bridging [11,35] set in. Microcracks and toughening effects result in a cohesive material behavior. The microstructure also strongly influences the macroscopic crack orientation. Wood fibers, which were produced at the same time, lie on so-called growth surfaces. Such growth surfaces give structure to the material. With a weak interface between the fibers, cracks tend to follow the direction of least resistance along the fiber [31]. Together with a spatially strongly varying fiber orientation, macroscopic crack topologies become very complex. In summary, for simulating wood fracture, a numerical method is required capable of accounting for an orthotropic constitutive behavior, cohesive fracture, preferable fracture planes, and complex three-dimensional cracks.

At the Institute for Mechanics of Materials and Structures (IMWS), we followed two quite promising methods in recent years: Finite element-based limit analysis [19] and the extended finite element method (XFEM) [21,24]. Both approaches show a good but not yet satisfying performance. Particularly the latter approach suffers geometrical limitations which do not allow for modeling the complex crack paths found in wood fracture.

A method well suited for crack paths of arbitrary complexity is the phase field method for fracture [4,5,12,23]. It is based on Griffith's theory of brittle fracture [13], formulated by a variational approach, minimizing the total energy of the system. An auxiliary field $d \in [0,1]$ models cracks, including a smooth transition between the intact ($d = 0$) and the cracked ($d = 1$) solid.

The original phase field method cannot account for wood fracture phenomena. In particular, the formulation does not include orthotropic materials, cohesive behavior, and favorable fracture planes. In recent years, several publications addressed these issues. In [3], an additional phase field was added to the original formulation. This allows for distinguishing different failure modes like matrix or fiber failure in composite materials. In [8,15,34], the so-called structural tensor was introduced, which accounts for favorable fracture planes by scaling the spatial gradient of the phase field. Failure in composite materials was considered by multiple researchers; actively

https://doi.org/10.52202/069179-0053

pursued approaches are comprehensively summarized in [6,40]. Research regarding the use of the phase field method for wood was performed in [7] on the microscopic scale, in [33] on the macroscopic scale by incorporation of a representative crack element theory and in [27,28] by a hybrid macroscopic multi-phase field model based on the unified phase field theory. This work focuses on a discussion of the model developed in the latter works.

2 FUNDAMENTALS AND METHODS

Figure 1 shows the approximation of a sharp crack Γ with multiple diffuse representations $\Gamma_i(d_i)$ on a body Ω with the boundary $\partial\Omega$. The model from [27], a hybrid multi-phase field model for orthotropic materials with favorable fracture planes, is based on the unified phase field theory [39]. This adds a cohesive zones model to the formulation to account for effects like micro-cracking and fiber-bridging [31]. As the fracture behavior of wood is highly direction-depended, multiple phase fields [3] are used for cracks perpendicular to the longitudinal, radial and tangential direction.

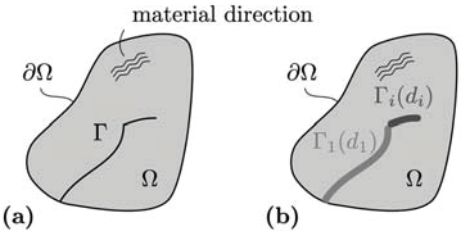

Figure 1: *Sharp and diffuse crack representation*

Excluding body forces and surface tractions, the regularized form of the total energy Π of the system, defined on the domain Ω, reads:

$$\Pi(\mathbf{u},\mathbf{d}) = \int_\Omega \left[\, \psi^+(\boldsymbol{u},\boldsymbol{d}) + \psi^-(\boldsymbol{u})\right] dV + \sum_{i\in\{L,R,T\}} G_{c,i} \int_\Omega \gamma_i(d_i)\, dV, \tag{1}$$

where i denotes the i-th phase field, $\boldsymbol{u}$ the displacement field, $\boldsymbol{d}$ the phase field of dimension 3 and $G_{c,i}$ the critical energy release rate. The strain energy terms $\psi^+(\boldsymbol{u},\boldsymbol{d})$ and $\psi^-(\boldsymbol{u})$ denote the degraded energy and undegraded energy, respectively. The crack geometry is approximated by the volume integral over the crack surface density function $\gamma_i(d_i)$. In the unified phase field theory, $\gamma_i(d_i)$, extended to include the structural tensor, is defined as

$$\gamma_i(d_i) = \frac{1}{c_{0,i}}\left(\frac{1}{l_i}\alpha_i(d_i) + l_i \nabla d_i \boldsymbol{A_i} \nabla d_i\right), \tag{2}$$

with $c_{0,i} = 4\int_0^1 \sqrt{\alpha_i(\beta)}d\beta$, $\alpha_i(d_i) = 2\,d_i - d_i^2$ as the local part of the dissipated fracture energy, and $\boldsymbol{A}_i = \boldsymbol{I} + \beta_i\,(\boldsymbol{I} - \boldsymbol{a}_i \otimes \boldsymbol{a}_i)$ as the structural tensor, where $\boldsymbol{a}_i$ is the material direction and β_i is the scaling factor of the structural tensor for phase field i.

Crack propagation is driven by an energetic force $\psi^+(\boldsymbol{u})$, which also dictates the constitutive behavior through the degraded strain energy $\psi^+(\boldsymbol{u},\boldsymbol{d})$. The phase field model described in [27] uses a stress-based split [32] to decompose the strain energy density into two parts: one that drives cracks and one that is inactive. The crack driving strain energy density is defined based on fracture mechanics failure modes I, II, and III for a crack perpendicular to $\boldsymbol{a}_i$. This includes the assumption that cracks mainly propagate following the principal material directions, which is motivated by the commonly observed "zig-zag" failure pattern of wood shown in Figure 2.

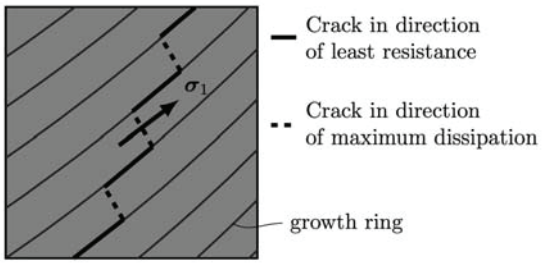

Figure 2: *Typical crack pattern of wood [31]*

The crack driving stress $\boldsymbol{\sigma}^+$ can be determined by projecting the undamaged stress tensor $\boldsymbol{\sigma}$ onto a fictitious crack surface with the crack normal vector $\boldsymbol{a}_i$ [16,27,32]. Subsequently, the mode I, II and III stresses are identified, allowing computation of $\psi_i^+(\boldsymbol{u})$. The crack orientation i that results in the largest energy release, indicated by the largest $\psi_i^+(\boldsymbol{u})$, defines the driving failure mechanism. As a result, Equation (1) is modified by replacing the original strain energy terms by

$$\begin{aligned}\psi_i^+(\boldsymbol{u},\boldsymbol{d}) &= \omega_i(d_i)\,\psi_i^+(\boldsymbol{u}) \text{ and}\\ \psi_i^-(\boldsymbol{u},\boldsymbol{d}) &= \psi_i(\boldsymbol{u}) - \psi_i^+(\boldsymbol{u}).\end{aligned} \tag{3}$$

Cohesive behavior is introduced by tuning the coefficients in the degradation function $\omega_i(d_i)$ and the crack surface density function $\gamma_i(d_i)$ on a one-dimensional bar problem with a single crack and a linear softening law [39].
The resulting energy minimization problem is solved with a staggered algorithm [4,22]. In addition, a hybrid approach [1] is used for degradation. This improves the solver's performance by making the deformation problem linear and, as shown in [27] and further outlined in Section 3.1, is required for adequately modeling the "zig-zag" crack pattern of wood. To prevent the interpenetration of crack faces, the hybrid approach is coupled with a smooth traction-free crack boundary condition [16]. Irreversibility of the phase field is enforced globally by an active-set reduced-space method [41]. An adaptive load increment scheme is adopted for further performance improvement which uses a trial point checker and a step size controller [14], restricting the increment size close to sudden changes in the dissipated energy and maintaining large increments during the linear elastic loading phase. The trial point checker performs an additional, however, very small load step, after a converged solution for the problem was found, and rejects

https://doi.org/10.52202/069179-0053

the converged state if the small additional step resulted in a change in the sign of the strain energy's slope. The step size controller works independently of the trial pointer checker an assures that after a failed load increment, the increment's size is reduced only as much as necessary to meet the convergence criterion.
The entire code is implemented in Julia [2]. For automatically deriving the element stiffness matrices and residual vectors from the energy formulation, the ForwardDiff-Package [30] is used. Pardiso 6.0 [10,18,36] is employed as the sparse linear solver.

3 RESULTS

3.1 VERIFICATION OF THE PHASE FIELD MODEL FOR WOOD

Initially, the described phase field model was verified on single-edge notched plates with varying fiber inclines and a more advanced example of a single knot in a wooden board with spatially varying principal material directions [27].
Figure 3 shows the edge notched plate under tensile loading by prescribing the vertical displacement at the upper edge. The fiber incline rises from 0 to 90 degrees. Initially, the crack path follows the weak interface between the growth rings. In a transition zone, the commonly found "zig-zag" pattern is recovered, and ultimately, the specimen fails with a crack perpendicular to the fiber direction.

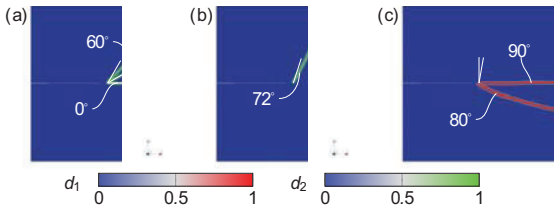

Figure 3: *Transition of failure modes from parallel to perpendicular to the fiber.*

Accurate reproduction of the "zig-zag" pattern in Figure 3 (b) requires applying the hybrid approach. This is related to the stress-based decomposition of the strain energy density described in Section 2. For forming the d_1 crack in Figure 3 (b), an energy state is required with substantial mode I, II and III stresses for the fictitious crack face defined by the normal vector in the longitudinal direction. Figure 4 shows a comparison of the longitudinal stress (i.e., the mode I stress for the d_1 crack) right before the failure of the specimen. Equation (3) is directly used to derive the constitutive relation in the variationally consistent approach. Therefore, the longitudinal stress is not degraded and, thus, peaks at the initial notch, reducing the crack driving energy at the diffuse crack tip for crack d_1. In comparison, in the case of the hybrid approach, everything except compressive mode I stresses is degraded. Therefore, the stress peaks at the diffuse crack tip, thus, allowing propagation of a $d_1$crack.

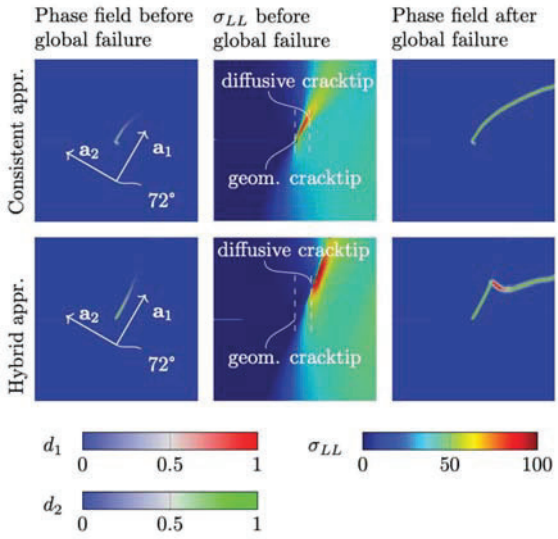

Figure 4: *Comparison of the hybrid and the consistent approach before the specimen's complete failure.*

Subsequently, the phase field model was tested on a more elaborate example. Figure 5 shows a wooden board with a single knot. The board is loaded at the bottom left edge, such that the initial crack is under tensile loading. The spatial fiber course is computed in each integration point using the model from [20]. As expected, the crack follows the fiber direction along the weak interface and shifts downwards in the vicinity of the knot until the whole specimen is cracked.

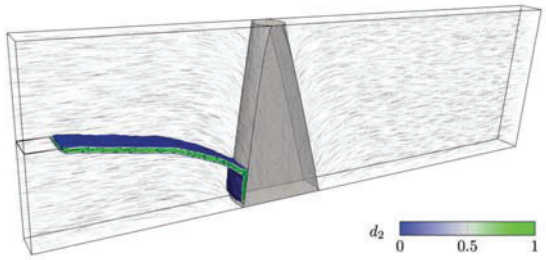

Figure 5: *Phase field crack in a wooden board with a single knot and spatially varying fiber courses.*

The results show that the hybrid multi-phase field model for wood can reproduce commonly found crack patterns of wood. Thus, it can account for the macroscopic structural effects influenced by the wood microstructure. Next, the model was validated on experimental setups in [28].

3.2 VALIDATION OF THE PHASE FIELD MODEL FOR WOOD

Three different types of tests were considered: A single edge-notched beam (SENB) [9,11], a double cantilever beam (DCB) [25] and an end-notched beam (ENB) [29]. Both the SENB and the DCB setups test for mode I

https://doi.org/10.52202/069179-0053

fracture properties; the ENB setup tests for mode II fracture properties.

In Equation (2), the structural tensor $\boldsymbol{A}_i$ is introduced in the formulation of the crack surface density function. The related scale factor β_i is an unknown quantity for wood and defines the intensity of the penalty constraint for invalid crack propagation directions. Due to the configuration of the SENB and the DCB test, β_i does not affect the crack orientation. However, the ENB test is strongly influenced by this quantity. Figure 6 shows the effect of increasing the scale factor for the primary driving failure mode in this test from 0 (isotropic formulation) to 90. This simulation allowed finding a lower bound of the structural tensors scale factor for wood. A value of 70 adequately reproduces the horizontal crack observed in the experiments in [29] and reduces the influence on the maximum load.

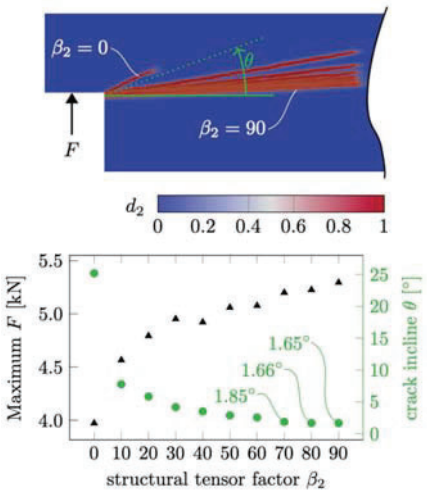

Figure 6: *Influence of the structural tensor's scale factor on the crack orientation and the ultimate load in the ENB test.*

Next, the SENB tests were simulated using the structural tensor scale factor value found for the ENB tests. Figure 7 shows the results for the tests in [9]. Using a multi-phase field model, it was possible to reproduce the experimental data very well with just a single model configuration (tensile strength and fracture energy release rate for L, R and T). Remarkably, the substantial difference in the ultimate load for a crack in the RL-plane and a crack in the TL-plane, also shown in [21], could be captured very well. Figure 8 shows the ultimate crack phase field for the SENB test in the RL-plane.

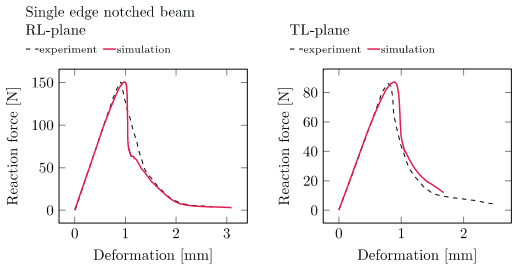

Figure 7: *Simulation and experimental graph of two SENB tests [9] with differently oriented failure planes (crack in RL-plane or TL-plane)*

Figure 8: *Fully cracked SENB specimen for the setup from [9] in the RL-plane*

Subsequently, the model was tested on the DCB tests from [25]. Figure 9 shows a large scatter of the experimental data already in the linear elastic range. This was accounted for in the model by performing simulations for different scale factors of the elastic stiffness from 0.6 to 1.0. Keeping the tensile strength and the fracture energy release constant allowed the reproduction of the experimental data very well. To reduce the computational effort, only the region right after the initial notch was finely discretized. The crack in Figure 10 was sufficient to reproduce a substantial part of the experimental data in Figure 9.

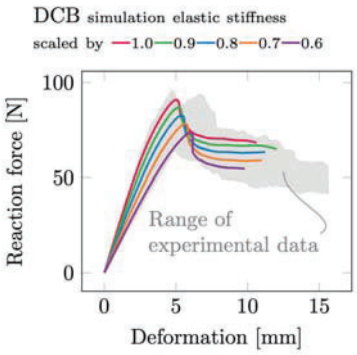

Figure 9: *Simulation and experimental results of a DCB test [25].*

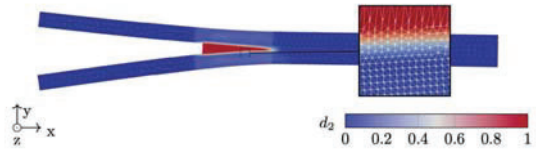

Figure 10: *Cracked DCB specimen*

Finally, the model was validated on the ENB test, which was already used to tune the scale factor of the structural tensor. In addition to a model with a tuned parameter configuration for this specific test, the material parameter found for the SENB tests of [9] were also used in the ENB model. The simulation and experimental results are shown in Figure 11. For both parameter sets, the response was within the experimental results.

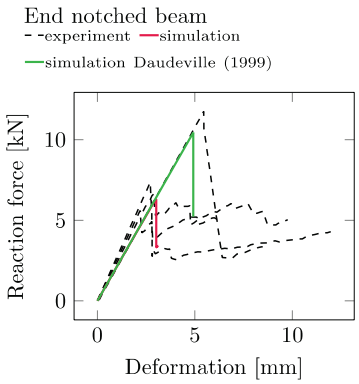

Figure 11: *Simulation and experimental results of the ENB test [29] for tuned model parameters and parameters from the SENB test from [9]*

The validation results in [28] show that the model is very well capable of reproducing experimental results, with the defining material properties, the tensile strength and the fracture energy release rate, well in a range known for wood. Furthermore, a lower bound for the structural tensor's scale factor was found, allowing the reproduction of the horizontal crack in the ENB test.

The phase field model presents a significant advantage over other models commonly used for simulating such experimental studies. Unlike in those models, the crack paths are not predefined. Instead, the model considers the local crack-driving energies and non-local effects induced by the microstructure of wood to form cracks. This approach makes the phase field model more adaptable and suitable for complex situations where the crack path is unknown in advance.

4 CONCLUSION AND SUMMARY

The present work describes implementing, validating, and verifying a phase field model for orthotropic non-brittle fracture of materials with favorable fracture planes and multiple, different failure mechanisms. The model is solved using a generally applicable staggered algorithm with globally enforced irreversibility constraints and an efficient load-stepping scheme. Using this model, it is possible to reproduce commonly found crack patterns of wood and the results of experimental tests. The model's input parameters, the tensile strength, and the fracture energy release rate are for all investigated tests within the range known for wood. Furthermore, values tuned to one experimental setup could be transferred to another setup with a different geometry. This suggests that the input parameters are material-specific rather than model-specific numerical parameters.

Compared to other three-dimensional finite element fracture mechanics simulation frameworks, the main advantage of the phase field method is that cracks of arbitrary complexity can be modeled. This is a fundamental requirement when simulating more complex wooden specimens like knot groups with spatially strongly varying fiber orientations. This work constitutes an important step towards the simulation of such complex models, which allow improved prediction of the load-bearing capacity of wooden boards. Based on an exact simulation using geometrical reconstructions of wooden boards with knots [17], homogenization procedures allow deriving metamodels similar to those in [21]. Such a simplified model allows the application to larger-scale structures or tasks, e.g., for the failure prediction of GTL beams [37], size-effect studies in GLT beams [38] or optimization of GLT beams [26].

NUMERICAL SIMULATION OF MOISTURE-INDUCED CRACKING IN INDOOR CLIMATE

Florian Brandstätter[1], Maximilian Autengruber[2], Markus Lukacevic[3], Josef Füssl[4]

ABSTRACT: Wood has the property to absorb and desorb moisture due to its hygroscopicity resulting in dimensional changes. Due to constrained non-uniform direction-depending expansion caused by moisture changes and gradients, respectively, stresses are induced, which may lead to crack initiation and propagation, reducing the load-bearing capacity of timber structures. However, little is known about the correlation between moisture changes or gradients and crack depths, and no quantitative prediction exists of crack depths caused by moisture gradients. Thus, based on numerical simulations, the cracking process for different initial moisture contents (MC) and various relative humidity (RH) reductions is investigated for two solid timber and one glued laminated timber cross-section. As a result, correlations between moisture gradients and maximum crack depths are derived, thus enabling the estimation of crack depths. The investigation revealed that cross-section size significantly influences the relation. In addition, more significant moisture gradients occur in larger cross-sections, resulting in earlier crack initiation compared to smaller ones, and crack development in larger cross-sections tends to last longer.

KEYWORDS: Extended finite element method, Multisurface failure criterion, Crack depth, Indoor climate, Wood

1 INTRODUCTION

Wood is a building material that is significantly affected by moisture. About 50% of the damages in timber constructions subjected to indoor climate conditions are caused by high and low moisture content (MC) as well as MC changes, with about half of the damage being cracks [1]. As wood is a hygroscopic material, the cell walls of wood absorb and desorb moisture from the surrounding climate, resulting in volume changes, which are additionally influenced by temperature. The strains caused by variations in MC and temperature induce stresses, as the non-uniform direction-dependent expansion is constrained. Increasing the stress level can lead to crack initiation and propagation if the strength of wood is exceeded, reducing the load-bearing capacity of timber structures. In addition, MC and temperature also influence material properties, such as strength and stiffness, which vary with the directions characteristic of wood (longitudinal, radial, and tangential). The effect of MC on material properties is limited by the so-called fiber saturation point (FSP) [2], which is the maximum amount of bound water in wooden cells. If further moisture is absorbed, it is present as free water in the lumen in addition to water vapor.

The most intense MC changes for indoor applications occur during the first winter after construction and from the beginning of erection until commissioning [1]. From December to February, the RH indoors can decrease to an average of 30 % [3-6] for two to four weeks resulting in an equilibrium MC of 8.2 % in case of pure desorption. Under uncommon conditions [7], even average RH levels of 25 % (7.2 % MC) over 30 days and 20 % RH (6.2 % MC) over 22.5 days occur. As the initial MC of wooden timber elements after production is usually between 10 % and 12 % [8], and DIN EN 14081-1:2019 allows measurement errors of ±3 % [9], during the first winter, immense moisture differences likely occur, inducing significant stresses, which may result in crack formation. However, it is unknown how deep moisture-induced cracks may propagate, and no quantitative relationship exists between crack depth and MC gradients caused by moisture changes.

Based on numerical simulations, this work aims to find a correlation between crack depth and moisture gradients and quantitatively estimate the crack depth in indoor climate conditions. Therefore, a moisture transport model based on the multi-Fickian theory [10-15] and a model for fracture in wood using the extended finite element method (XFEM) for the simulation of crack development are defined in Section 2. In addition, to find a relation for two solid timber (ST) and one glued laminated timber (GLT) cross-sections, numerous drying scenarios, which are characterized by different initial MCs and different drying loads, are simulated. When the simulation is initialized, the temperature is kept constant, but the initial RH is

decreased in a single step, which causes the moisture field to change and induce stresses. A multisurface failure criterion [16-19] is used to evaluate whether the induced stresses lead to crack formation. Section 3 illustrates the drying scenarios' results, and the relation between moisture gradient and crack depth is analyzed. In Section 4, the conclusion and outlook are shown.

2 MATERIALS AND METHODS

For the investigation of the relation and the prediction of the crack depth, two simulations per drying scenario are performed. In the first, moisture fields are determined based on the multi-Fickian theory. In the subsequent XFEM simulation, the moisture fields are used as a loading for the stress simulation based on linear-elastic material behavior (viscoelasticity, mechano-sorption, and plastification are not considered). For each increment in each integration point, stresses are calculated, and cracks initiate or propagate if they exceed the wood's strength. The latter is defined by a multisurface failure criterion presented in [16-19].

The commercial finite element software Abaqus (from Dassault Systèmes, Vélizy-Villacoublay, France) was used for the simulations. Quadratic brick elements with linear interpolation functions (C3D8) were used to discretize the cross-sections, and the equations were solved using the modified Newton method. The material is defined as cylindrical-orthotropic in each integration point to enable the consideration of different pith locations of the cross-sections.

2.1 MATHEMATICAL MODEL FOR MOISTURE TRANSPORT IN WOOD

The moisture transport model of [10-15] was used based on the multi-Fickian theory. It describes the transport of water vapor c_v in the lumen, as well as the transport of the bound water c_b in the cells, where the sorption rate $\dot{c}_{bv}$ is used to couple both processes, considering a hysteresis effect. As the MC in the simulations never exceeds the FSP, it is assumed that no free water occurs. To determine the change of the bound water, water vapor and energy, the following three differential equations are used:

Conservation of bound water concentration:

$$\frac{\partial c_b}{\partial t} = \frac{\partial}{\partial x} D_b \frac{\partial c_b}{\partial x} + \dot{c}_{bv} \tag{1}$$

Conservation of water vapor concentration:

$$\frac{\partial c_v}{\partial t} f_{lum} = \frac{\partial}{\partial x} D_v \frac{\partial c_v}{\partial x} f_{lum} - \dot{c}_{bv} \tag{2}$$

Conservation of energy:

$$\begin{aligned} \frac{\partial (ph)}{\partial t} = {} & \frac{\partial}{\partial x} K \frac{\partial T}{\partial x} + \frac{\partial}{\partial x} D_b \frac{\partial c_b}{\partial x} \overline{h}_b + \frac{\partial}{\partial x} D_{bT} \frac{\partial T}{\partial x} \overline{h}_b \\ & + \frac{\partial}{\partial x} D_v \frac{\partial c_v}{\partial x} h_v f_{lum} \\ & + \dot{c}_{bv} (h_v - h_b) \end{aligned} \tag{3}$$

On the left-hand side of Equations (1) to (3) the change rate of the concentrations c_b and c_v as well as of the energy (ph) are defined. The transport tensors of bound water D_b and water vapor D_v describe the diffusion processes, while K accounts for the thermal conduction. While c_b is related to the whole volume of the representative volume element (RVE), c_v is only referred to the volume proportion of the lumen f_{lum}. Whereas $\overline{h}_b$ and h_b define the average and specific enthalpy of bound water, respectively, h_v describes the enthalpy of water vapor.

The constitutive equations for the model are obtained from Autengruber et al. [20]. To implement equations (1) to (3) in Abaqus, the user element subroutine UEL was used.

[13] investigated the interaction between water vapor and bound water, using the sorption rate for description. An isothermal hysteresis was assumed for the simulations, as the temperature was kept constant.

For the initial conditions, it is assumed that the initial bound water concentration $c_{b,ini}$ and the initial water vapor concentration $c_{v,ini}$ are in equilibrium. $c_{b,ini}$ derives from the initial temperature T_{ini} and $c_{v,ini}$, which depends on the initial RH level.

The surrounding climate influences the moisture transport at the wood surfaces, where the effects are considered with Neuman boundary conditions. The given fluxes of water vapor Φ_v and energy Φ_T across the boundary are described by the following equations:

$$\Phi_v = k_{c_v}(c_v - c_{v,0}) f_{lum} \tag{4}$$

$$\Phi_T = k_T(\mathrm{T} - T_0) + k_{c_v}(c_v - c_{v,0}) f_{lum} h_v \tag{5}$$

with

$$k_{c_v} = \frac{Sh}{L} D_{air} \tag{6}$$

k_{c_v} is a film boundary coefficient that considers air flow and convection depending on air speed and surface roughness. Sh is 1 and L is 0.035 m [10] and $D_{air}$is the diffusion coefficient for water vapor in air. k_T defines the heat transfer coefficient and $T_0$is the temperature of distant air, where T is kept constant at 293.15 K.

2.2 MODEL FOR FRACTURE IN WOOD

After the moisture simulation, an XFEM simulation is performed to determine stresses caused by constrained shrinkage deformations, where the moisture fields are used as loading. For the XFEM simulations, moisture-dependent stiffness properties are presented, and the multisurface failure criterion from [16-19], defining the strength of wood, is introduced. The user element subroutine UDMINI was used to implement the criterion in Abaqus. In addition the enrichment regions for all cross-sections are defined and a certain distance is introduced, which is to be referred to as crack depth.

The moisture-dependant material properties of wood are based on the micromechanics material model of [21] with a clear wood dry density of 420 kg m^{-3} for Norway spruce (Picea abies). Based on this, elasticity tensor components for MC levels between 3 % and 30 % were determined and implemented in *Abaqus* (see [22] for details).

For the strength of wood, a multisurface failure criterion from [18], which considers the structure of wood at the

https://doi.org/10.52202/069179-0054

level of annual rings (late- and earlywood), is used. Based on multiple load combinations, the criterion was formulated, leading to eight Tsai-Wu surfaces [23] for the definition of failure:

$$f_i^{cw}(\sigma) = a_{LL,i}\sigma_{LL} + a_{RR,i}\sigma_{RR} + a_{TT,i}\sigma_{TT} + b_{LLLL,i}\sigma_{LL}^2 + b_{RRRR,i}\sigma_{RR}^2 + b_{TTTT,i}\sigma_{TT}^2 + 2b_{RRTT,i}\sigma_{RR}\sigma_{TT} + 4b_{LRLR,i}\tau_{LR}^2 + 4b_{RTRT,i}\tau_{RT}^2 + 4b_{TLTL,i}\tau_{TL}^2 \leq 1 \quad (7)$$

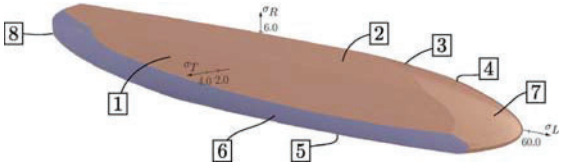

Figure 1: *Surfaces of the failure criterion, illustrated in the* $\boldsymbol{\sigma_{LL} - \sigma_{RR} - \sigma_{TT}}$ *stress space from [18].*

Only the surfaces describing brittle failure (surfaces 1,2,3, and 7) are considered in this work. If the induced stresses exceed the limits of the criterion, the corresponding failure surface defines the orientation of the crack initiation or propagation. The strength limits vary depending on the material orientation (longitudinal 56 MPa, radial 5 MPa, and tangential 2 MPa).

In *Abaqus*, so-called enrichment regions have to be defined to enable cracking. Unless multiple elements violate the failure criterion within the same time increment, only one crack can initiate per region. The enrichment configuration of the cross-sections is based on [22]. While for the GLT cross-section each lamella is divided into two equal-sized regions, one on top of the other, a cross-section configuration of eight rows and three columns is used for the ST cross-sections.

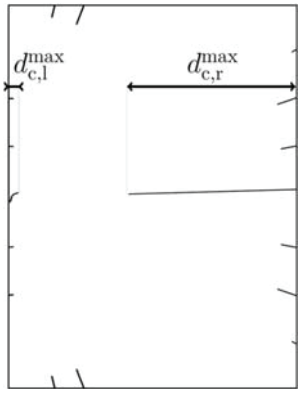

Figure 2: *Exemplary crack pattern of the cross-section ST 6 x 8. The deepest cracks on both the left and right edges are defined as* $\boldsymbol{d_{c,l}^{max}}$ *and* $\boldsymbol{d_{c,r}^{max}}$*, respectively.*

In the XFEM simulations, the crack pattern development is expected to vary depending on cross-section size, initial MC, and drying load. As the deepest cracks affect the safety of structures most, the maximum crack depth is analyzed to describe the evolution of the crack pattern, where the crack depth d_c is defined as the perpendicular distance from the surface to the crack tip. Since cracks on both edges are expected, the maximum crack depths on the left ($d_{c,l}^{max}$) and right ($d_{c,r}^{max}$) edges are determined and subsequently summed, defined as the maximum total crack depth d_c^{max} (see Figure 2).

2.3 DRYING SCENARIOS

Initially, the MC, which results from the surrounding RH, is uniform across the cross-section. When the simulation is initialized, the RH is reduced in a single step to a certain level, which is kept constant for 30 days, leading to moisture field changes. The RH level is reduced so that the expected equilibrium MC is decreased by a Δu_{equ} of 1 % up to 15 % (see Table), considering the desorption isotherm. Due to the non-linear shape of the isotherm, different initial MC levels (10.0 %, 11.9 %, 15.3 %, and 22.0 %) are investigated, which correspond to the RH levels 40.0 %, 50.0 %, 65.0 %, and 85.0 %, respectively. The initial values are based on RH, as this is easier to measure than Δu_{equ} in wood components. The initial RH values derive from the limits of the service classes in EC 5 [24].

Table 1: *Overview of the single-step relative humidity (RH) reductions at the boundary, resulting in differences in equilibrium moisture content* $\boldsymbol{\Delta u_{equ}}$ *of 1 % up to 15 % from four initial RH levels (40 %, 50 %, 65 %, and 85 %) determined with the desorption isotherm.*

Δu_{equ}	initial RH [%] (initial MC [%])			
	40 (10.0)	50 (11.9)	65 (15.3)	85 (22.0)

2.4 GEOMETRIES

For the simulations, two solid timber (ST) and one glued laminated timber (GLT) cross-section are studied in this work. The cross-sections are ST 6 x 8, ST 14 x 28, and GLT 20 x 40 (width x height in centimeters), commonly used for timber structures (see Figure 3). The pith location of the ST cross-sections is in the middle of the left edge,

as the deepest cracks are expected for this configuration, as shown by [22]. The lamella height of the GLT cross-section is 4 cm, the pith is located in the middle of the bottom, and the lamellas' orientation is based on common production standards [9]. It is assumed that the glue lines are made of melamine, which only minimally affects moisture transport since the diffusion characteristics of melamine and solid timber are similar [25].

To model plain-strain conditions, only one element with a depth of 1 mm in the longitudinal direction is defined. An overview of the other dimensions of the mesh is presented in Table 2. A hinged support in the center point and a roller support in the middle of the cross-section's right edge are defined for the geometric boundary conditions. Plain-strain conditions are assumed, and therefore, no deformations out-of-plane are allowed. In addition, no initial eigenstresses from, e.g., production processes, are assumed.

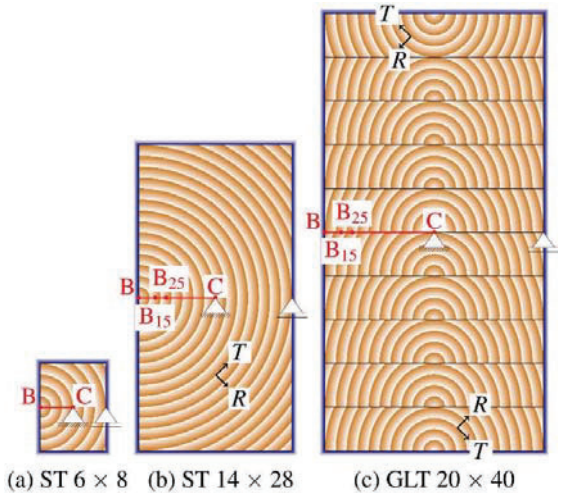

Figure 3: *Illustration of the used cross-sections, including the annual rings, pith locations, the definition of the local coordinate systems, and finite element node reference points: B, B_{15}, B_{25}, and C, where B_{15} and B_{25} are 15 mm and 25 mm, respectively, distant to the boundary. B_{15} and B_{25} are required for the moisture gradient definition in Section 3.2 [26].*

Table 2: *Mesh configurations of the cross-sections*

Elements	ST		GLT
	6 x 8	14 x 28	20 x40
Number	60 x 80	60 x 84	60 x 80
Width [mm]	1	2-4	2-5
Height [mm]	1	2-5	5

3 RESULTS

In the following, the crack initiation and propagation process is presented as well as the development of d_c^{max} for all initial MCs and Δu_{equ} are analyzed. The relationship between moisture gradients and crack depth is investigated based on the development results.

First, the crack initiation and propagation process are described in more detail using Figure 4, where the initial RH was reduced from 65 % to 20.2 % (final state) for the GLT 20 x 40 (see Figure 4 a). This results in a Δu_{equ} of 9 %. When the moisture simulation is initialized, the uniform moisture field adapts to the single-step reduction of the RH, leading to a non-uniform moisture distribution (see Figure 4 b). In the subsequent XFEM simulation, the stresses induced by the moisture field are determined per increment. At the same time, in each integration point, the multisurface failure criterion is evaluated, and if its limits are exceeded, cracks initiate (see Figure 4 c) or propagate (see Figure 4 d and e). Cracking is finished as soon as the criterion is not fulfilled anymore (see Figure 4 f).

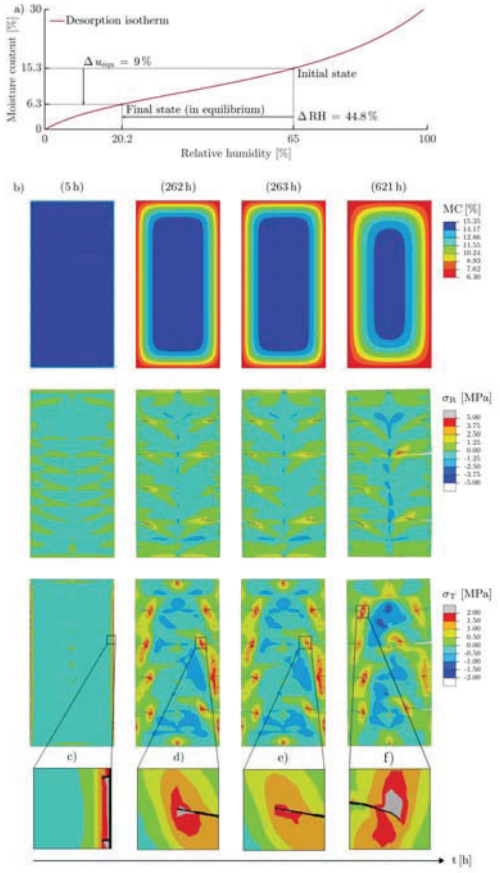

Figure 4: *Cracking process description: (a) Reducing the relative humidity causes moisture field adaptions (b). Stresses, such as $\boldsymbol{\sigma_R}$ and $\boldsymbol{\sigma_T}$, cause (c) initiation and (d-e) propagation of cracks, if the multisurface failure criterion is violated. As soon as the moisture-induced stresses no longer exceed the limits of the criterion, the cracking process is completed [26].*

3.1 CRACK DEPTH DEVELOPMENT

Before the crack depth development investigation, the crack formation at the end of the simulations for all cross-sections is presented, exemplified for an MC reduction from 15.3 % to 2.3 % (Δu_{equ} = 13 %) to show a characteristic crack pattern. For the ST cross-sections, multiple cracks on the top, bottom, and right edge occur,

https://doi.org/10.52202/069179-0054

whereas, on the left edge, only a few cracks can be seen due to the pith's location. However, it is noticeable that for the ST 6 x 8, the deepest crack is located at the middle height, while for the ST 14 x 28, the deepest one is at three quarters of the height. In the case of Δu_{equ} below 12 %, for the ST 14 x 28, the deepest crack also occurs in the middle of the cross-section. Furthermore, additional simulations confirmed that deep vertical cracks can be observed for the ST 14 x 28, which is related to the height-to-width ratio. The GLT 20 x 40 shows a different cracking behavior compared to the ST cross-sections. As the piths are located at the bottom of the lamellas, cracks occur on both the left and right edges. It can be seen that there are lamellas with one deeper and one shorter crack, as well as lamellas with three tiny cracks occur.

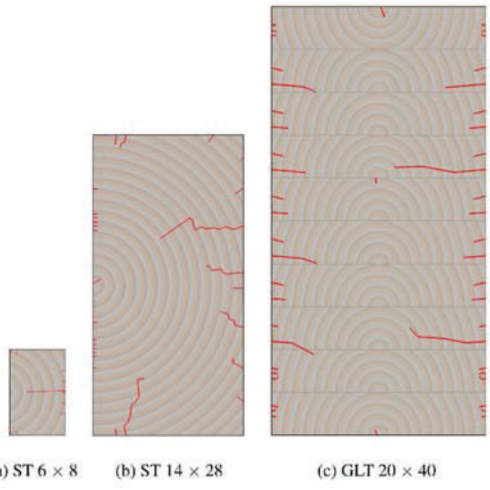

***Figure 5**: Overview of the crack pattern for all cross-sections at the end of the simulation (t = 30 d), exemplified for a reduction of the initial MC from 15.3 % to 2.3 %. In addition, the pith location and the annual rings are illustrated. [26].*

In the following, the development of d_c^{max} is analyzed. Therefore, for all cross-sections, the evolution of d_c^{max} for different MCs and various Δu_{equ} over the complete simulation time is illustrated in Figure 6. For each drying scenario, $d_{c,l}^{max}$ and $d_{c,r}^{max}$ were documented at 0.25 d, 0.5 d, 1 d, 2 d, 3 d, 5 d, 10 d, 15 d, 20 d, 25 d, and 30 d, and subsequently, d_c^{max} was determined. [27] presented that $d_{c,l}^{max}$ and $d_{c,r}^{max}$ of 15 mm to 30 mm are in an acceptable range for timber structures to be considered safe, but the shape of the GLT girder, as well as the type of load, should be matched to the expected crack depth in the design of timber structures. Therefore, for the GLT cross-section in Figure 6, a d_c^{max} of 2 x 15 cm is marked. As the load-bearing capacity of ST cross-sections is also affected by cracking, a depth of 15 mm is highlighted because the pith location results in an asymmetric crack formation.

Figure 6 shows the development of d_c^{max} for all cross-sections under all drying scenarios given in Table 2, where d_c^{max} is given both in mm and in percent (cracked width). For all cross-sections, it can be seen that with increasing cross-section size, cracking stops later under the same conditions. For the ST 6 x 8, cracking ends between 1 d and 3 d, while for the GLT 20 x 40, crack propagation comes to a halt between 5 d and 30 d (in a few cases, the theoretical crack formation can even last longer than 30 d). This is related to the reduction of the MC in the cross-section's center. As soon as the RH is reduced, the MC decreases from both edges toward the center at the same rate. When the center is reached, the MC reduction is accelerated by the contribution of the opposite side. If the boundary condition is applied to only one side, the MC reduction rate would not be increased, as shown in [28]. Therefore, for smaller cross-sections, cracking stops earlier compared to larger cross-sections. In addition, it is noticeable that for the GLT 20 x 40 and the ST 14 x 28, cracking occurs from a Δu_{equ} of 3 %, whereas for the ST 6 x 8, a Δu_{equ} of 4 % is required for cracks to initiate. Only in the case of an initial MC of 22.0 %, a Δu_{equ} of 4 % leads to the first cracks for the ST 14 x 28. Since the moisture distribution is similar during the first hours and the MC in the center is minimally reduced, it can be concluded that cross-section size influences the drying load required to cause crack initiation due to larger moisture-induced stresses. The remaining effects on crack depth development caused by variation in Δu_{equ} are described in detail in [26].

3.2 RELATION OF CRACK DEPTH AND MOISTURE GRADIENT

Since a quantitative prediction of d_c^{max} seems possible for installations where equilibrium MC is given initially, the relation between crack depth and moisture gradient is studied. Dietsch et al. [1] revealed that about 50 % of the damages in timber structures are related to low and high MC and MC changes, resulting in moisture gradients. In [1], they were evaluated between 15 mm and 25 mm from the surface [28]. In this work, a similar approach was chosen: the moisture gradient is defined as the difference in MC between the two points P_1 and P_2, divided by their distance $(\Delta u/\Delta x)_{P_1P_2}$. [22] showed that the deepest moisture-induced cracks occurred when the difference in MC between the surface and the center was at maximum. It follows that the positions where the moisture gradient is evaluated also have to be considered. Therefore, the positions B, B_{15}, B_{25}, and C located on the path between B and C are investigated (see Figure 3), where B_{15} and B_{25} are 15 mm and 25 mm distant to the surface, respectively. For B_{15} and B_{25}, the nodes closest to them define the points for the moisture gradient, as at exactly 15 mm and 25 mm from the surface, there do not have to be finite element nodes (for details see [26]). The following three $(\Delta u/\Delta x)_{P_1P_2}$ configurations are examined: the moisture gradient between B and C $(\Delta u/\Delta x)_{BC}$, between B_{15} and B_{25} $(\Delta u/\Delta x)_{B_{15}B_{25}}$ and between B_{15}^{B} and B_{15}^{c} $(\Delta u/\Delta x)_{B_{15}^{B}B_{25}^{C}}$.

https://doi.org/10.52202/069179-0054

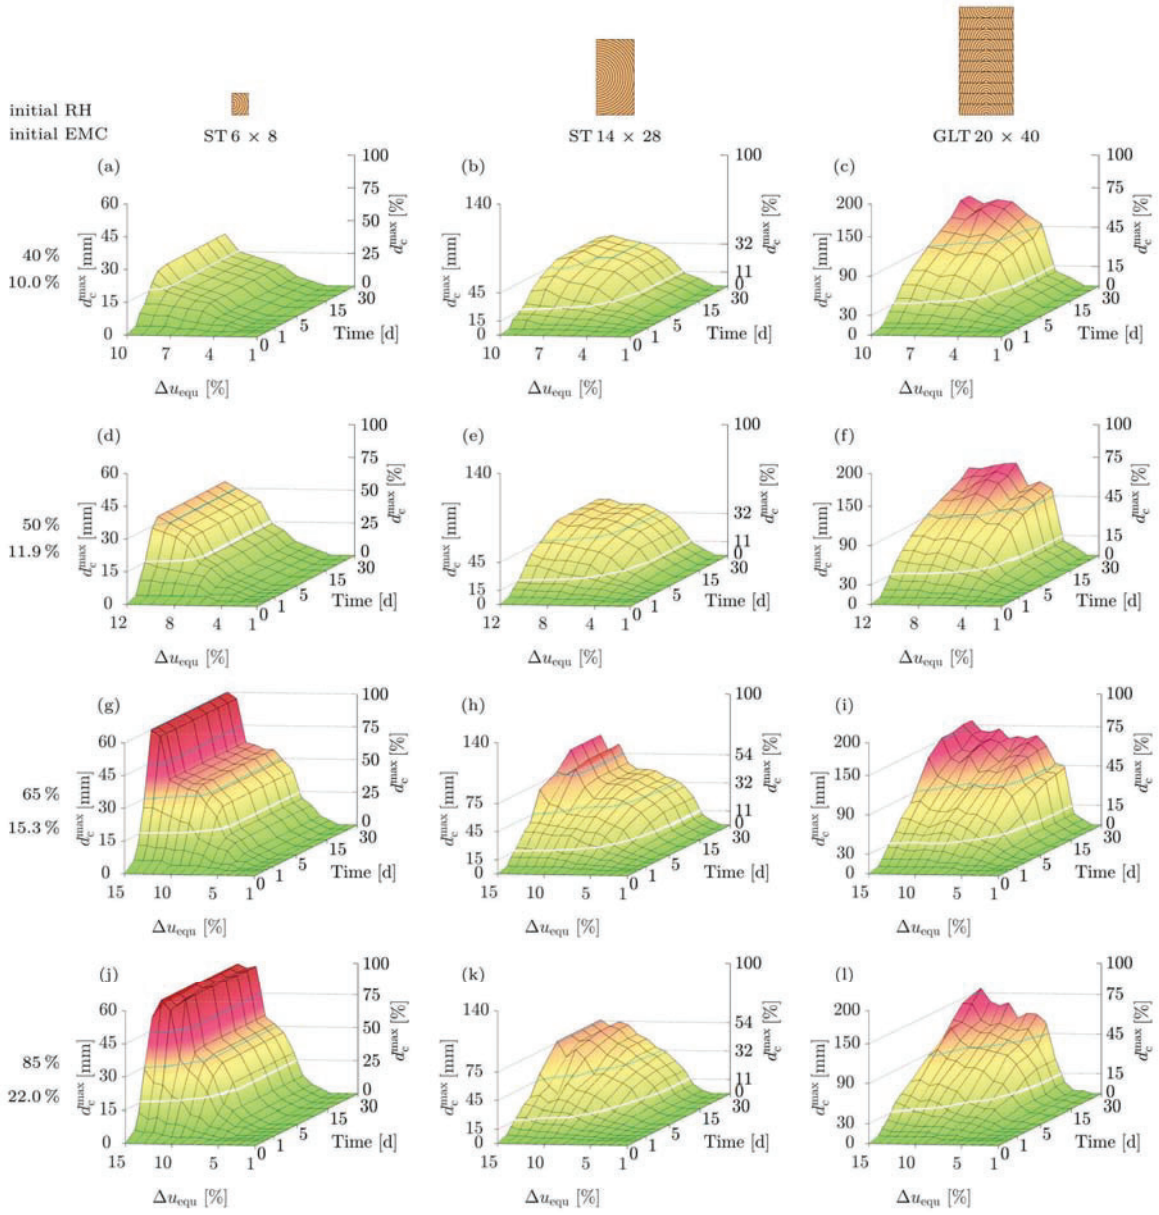

***Figure 6**: Development of the maximum total crack depth $\boldsymbol{d_c^{max}}$ (absolute and in percent of the width) for all cross-sections with initial moisture contents of 10.0 % (a, b and c), 11.9 % (d, e, and f), 15.3 % (g, h and i) and 22.0 % (j, k and l) when the equilibrium moisture content $\boldsymbol{\Delta u_{equ}}$ is reduced from 1 % up to 10 %, 12 % and 15 %, respectively, over 30 days. The white lines mark the limits (ST:15 mm; GLT: 30 mm), above witch the shape of the GLT girder as well as the type of load should be matched to the expected crack depth in the design of timber structures [27]. The blue dotted lines improve the perceptibility of $\boldsymbol{d_c^{max}}$ [26].*

In case of $(\Delta u/\,\Delta x)_{B_{15}^{B}B_{25}^{C}}$, the nodes closest to B15 are used for the definition of the moisture gradient, where one is closer to B (B_{15}^{B}) and the other closer to C (B_{15}^{C}). As the diffusion coefficients in radial and tangential directions are assumed equal, and the mesh is symmetrically along the vertical middle axis, B can be located on the left or on the right edge without affecting $(\Delta u/\Delta x)_{P_1P_2}$.

In the following, the approach to describe the relation between d_c^{max} and, exemplary, $(\Delta u/\Delta x)_{BC}$ is shown, with the result illustrated in Figure 7. For the ST 6 x 8, the developments of d_c^{max} and $(\Delta u/\Delta x)_{BC}$ are displayed with an initial MC of 15.3 % and for a Δu_{equ} of 5 %, 7 %, and 9 % (see Figure 7a). Observing Figure 7a reveals that for each point in time, a d_c^{max} can be connected to a $(\Delta u/\Delta x)_{BC}$, but as the deepest cracks are essential for the design of timber structures, the maximum d_c^{max} is related to the largest $(\Delta u/\Delta x)_{BC}$. More details about the relation and developments of Δu_{equ} and $(\Delta u/\Delta x)_{BC}$ are presented in detail in [26].

https://doi.org/10.52202/069179-0054

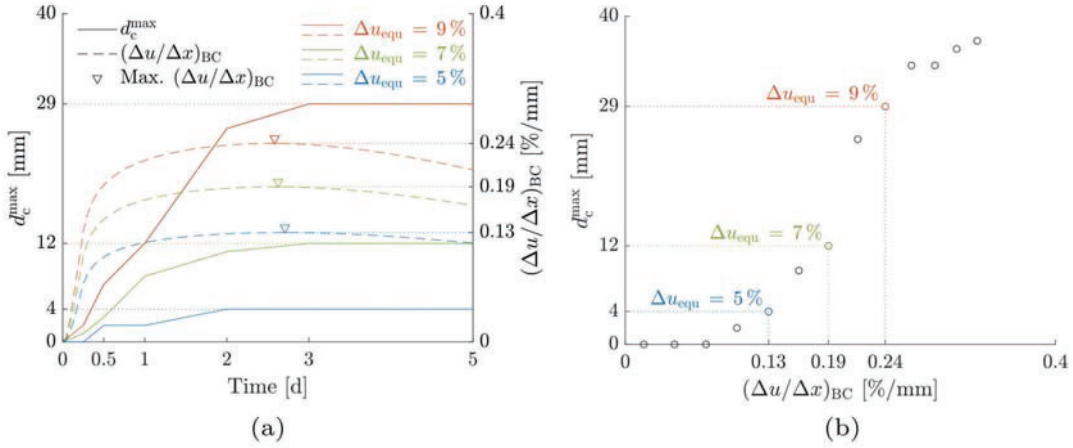

***Figure** 7: Relation between the moisture gradient $(\Delta u/\Delta x)_{BC}$ between the two points B and C (B: boundary; C: centre; see* Figure 3*) and the maximum total crack depth (d_c^{max}) for the ST 6 x 8with an exemplary initial moisture content of 15.3 % In (a), the developments of d_c^{max} and $(\Delta u/\Delta x)_{BC}$. for three different reductions of the equilibrium moisture content Δu_{equ} (*5 %, 7 % and 9 %*) are displayed. In (b), the maxima of d_c^{max} and $(\Delta u/\Delta x)_{BC}$. For Δu_{equ} reductions from 1 % up to 13 % are shown, illustrating the relation between d_c^{max} and $(\Delta u/\Delta x)_{BC}$ [26].*

In Figure 7 b), the maxima of d_c^{max} and $(\Delta u/\Delta x)_{BC}$. For Δu_{equ} reductions from 1 % up to 13 % are shown, excluding 14 % and 15 %, as they are assumed outliers. Observing the data, an exponential increase can be seen, followed by a leveling off of the trend. This behavior can be described with the so-called Gompertz function, which is defined as:

$$d_c^{max}((\Delta u/\Delta x)_{P_1P_2}) = g^{max} e^{-g^l e^{-g^g (\Delta u/\Delta x)_{P_1P_2}}} \quad (8)$$

with d_c^{max} as the maximum total crack depth in mm, the moisture gradient between two points, P1 and P2, $(\Delta u/\Delta x)_{P_1P_2}$ in [%/mm] as well as the function parameters g^{max}, $g^{l,}$ and g^g. g^{max} defines the asymptote and, therefore, the maximum d_c^{max}, g^l sets the displacement along the ordinate axis, and g^g describes the inflection point's growth rate.

Next, the influence of the moisture gradient configuration on the relation is investigated (see Figure *8*). For all cross-sections, the relation between d_c^{max} and $(\Delta u/\Delta x)_{BC}$, $(\Delta u/\Delta x)_{B_{15}B_{25}}$, and $(\Delta u/\Delta x)_{B_{15}^B B_{25}^C}$ with an initial MC of 15.3 % is illustrated, where for each configuration, the best fitting Gompertz function and the corresponding coefficient of determination are shown. As the coefficients of determination are all above 0.97 and the curves fit the data, it follows that such functions can be used to relate the moisture gradients to d_c^{max}, depending on the size of the cross-section. The differences between the configurations are minimal, and therefore, for further investigations, $(\Delta u/\Delta x)_{BC}$ is recommended, due to better possible prediction of the MC at the boundary and the center for larger cross-sections, as presented by [29]. More details about the influence of the moisture gradient configurations on the relation are presented in [26]. In addition, in [26], the effect of varying initial MC on the relation is investigated, and the influence of reducing the RH linearly over time on crack depth development is studied. Furthermore, a simplified crack depth determination for indoor climate conditions is presented.

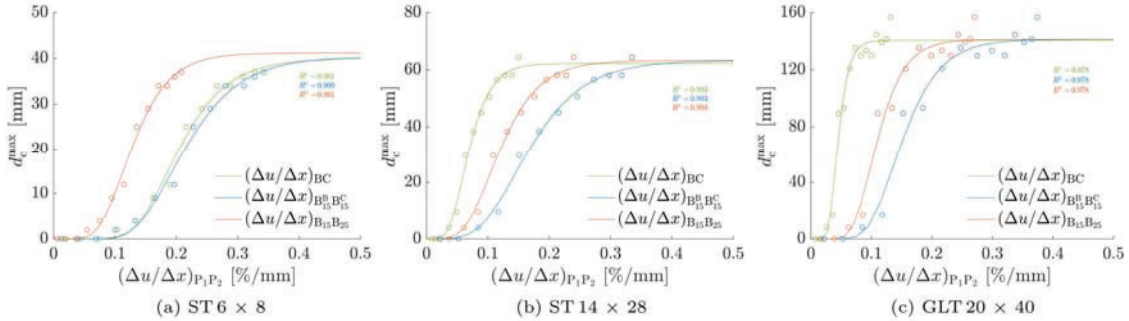

***Figure** 8: Development of the maximum total crack depth d_c^{max} depending on the moisture gradient configuration between two points P_1 and P_2 $(\Delta u/\Delta x)_{P_1P_2}$ to analyse the effect of the positions P_1 and P_2 (B, B_{15}, $B_{25,}$ and C) on the relation with an initial MC of 15.3 % for all cross-sections. The positions are on the path between boundary B and center C (see* Figure 3*). The data illustrated as circles represent the maxima of d_c^{max} related to the maxima of the corresponding $(\Delta u/\Delta x)_{P_1P_2}$ (see Figure 7) [26].*

4 CONCLUSIONS AND OUTLOOK

To quantitatively estimate crack depths in indoor climate conditions and to find a relation between crack depth and moisture gradient, in this work, the crack depth development of two solid timber and one glued laminated timber cross-section for different immediate RH reductions and initial MCs was analyzed numerically. Based on the simulation results, a relation between the maximum total crack depth d_c^{max}, which is the sum of the deepest cracks on the right and left side, and the moisture gradient was established. Thus, the prediction of d_c^{max} in indoor climate conditions for installations, where after production, timber members are protected from environmental influences to have a uniform initial moisture field at the beginning of the operation, seems possible. A multi-Fickian moisture transport model [10-15] was used to simulate the moisture distribution developments within the cross-sections. Those were then used as a loading for the subsequent XFEM simulations, where moisture-induced stresses were determined considering linear-elastic material behavior. For these fracture simulations, a multisurface failure criterion [18] for describing failure behavior and a multiscale material model [21] to determine the moisture-dependant stiffness tensor were used. The main findings are summarised as follows:

- Moisture gradients were correlated to d_c^{max}, where the relation depends on cross-section size.
- In larger cross-sections, larger moisture gradients occurred, which is why cracks initiate earlier compared to smaller cross-sections.
- For larger cross-sections, crack propagation lasted longer than for smaller cross-sections.

For future work, the cracking behavior of different cross-sections or wood products could be analyzed. E.g., [30] used these models to investigate the moisture transport in a timber-concrete composite plate after cast-in-place concrete application, indicating potential moisture-induced cracking behavior due to low surrounding RH.

EXPERIMENTAL DETERMINATION OF R CURVES FOR EUROPEAN SPRUCE USING DCB TESTS

Marija Todorović[1], Marko Pavlović[2], Ivan Glišović[3], Mathieu Koetsier[4]

ABSTRACT: This paper presents an experimental procedure for obtaining the fracture resistance (R curve) of solid wood specimens made of spruce. Double Cantilever Beam (DCB) tests were performed in order to determine energy release rate vs crack length in Mode I wood fracture (crack opening). Ten wood specimens were loaded using the Universal Testing Machine and force-displacement curves were recorded. The most important parameter - crack length was monitored as the crack propagates using Digital Image Correlation (DIC) method. In order to obtain accurate R curve results, procedure which includes calculating cumulative released energy was employed. The cohesive energy G_f was determined based on the R curves. These results can further be analysed in order to obtain cohesive law for Mode I fracture of wood.

KEYWORDS: Mode I fracture, wood, DCB, DIC, R curve

1 INTRODUCTION

Sustainability, renewability and circularity have become great concerns for today's society. Since the construction industry represents one of the biggest sectorial emitters of greenhouse gases causing anthropogenic climate change, application of sustainable and/or natural materials for buildings is advisable as a significant mitigation measure. Aside from its aesthetic appeal, wood represents an eco-friendly material with a significant potential for civil engineering. In order for wood to be implemented correctly for structural purposes, its mechanical behaviour has to be defined for different stress states that can appear in the design process.

Often, timber beam's height needs to be reduced at the supports (notched) so as to satisfy different structural and architectural requirements. Notches represent potentially weak spots in timber structural elements, as stress concentration occurs at the notch corner, decreasing the overall load-carrying capacity. In order to determine possibilities for strengthening and adequate design procedures, comprehensive research has been performed on end-notched timber beams [1]. The research results have proved that a dominant failure mechanism of unreinforced end-notched beams is Mode I fracture - crack opening (Figure 1) caused by excessive tensile stress perpendicular to grain of timber with unstable crack propagation. The unreinforced end-notched have experienced a considerably reduced load-carrying capacity compared to the expected load-carrying capacity of the beams without notches. In order to accurately describe the behaviour of end-notched timber beams, it is necessary to determine Mode I fracture parameters. Therefore, cohesive law for Mode I fracture of wood is necessary for adequate analysis of stress state around the notch area.

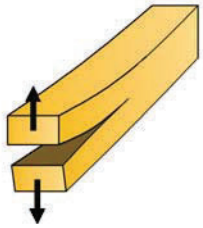

Figure 1: *Mode I fracture – crack opening*

Cohesive law for Mode I fracture can be determined based on the analysis of damage process zone which develops in wood in the case of propagating cracks. Development of the damage process zone causes toughness to change as the crack propagates, which is characteristic of many materials including wood. Process zone development in wood is a direct consequence of fibre-bridging effect (unbroken fibres connect the crack surfaces and slow down the crack growth).

Crack propagation experiments in materials which develop fibre bridging across the crack start with a machined notch that has no process zone [2]. As the load is applied fibre-bridging zone develops with two crack tips. One crack tip is the actual crack tip and one is at the edge of the fibre-bridging zone defined as the notch root, with the distance between them representing the process zone length (Figure 2). At the initial point of fracture, the crack tip moves while the notch root remains stationery

and toughness is low. As the process zone develops, since unbroken wood fibres that connect crack surfaces can carry load, toughness tends to raise with crack growth. Once the connecting fibres break, the process zone length stabilizes (steady-state crack propagation). Onward, the process zone propagates together with the developing crack, and the toughness becomes constant. The fracture resistance curve (R curve) is a representation of Mode I fracture toughness of the material in relation to crack propagation. In order to correctly describe the fracture process of any material, including wood, an accurate definition of the R curve is necessary. In accordance with the explained process zone mechanism, the R curve starts at a minimum initial value (corresponding to the low toughness) and then rises with the development of fibre-bridging zone. Once steady-state crack propagation is reached, the R curve becomes constant (corresponding to the constant toughness). The plateau of R-curve represents the cohesive energy - G_f.

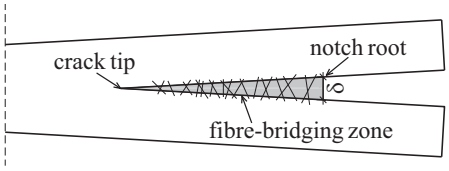

Figure 2: *Crack tip region with fibre-bridging zone*

In order to determine Mode I fracture properties of wood, different methods have been used so far by the researchers. Testing procedures included: three-point bending test [3,4], single-edge-notch specimen [5], wedge-splitting test [6-8], tapered double cantilever beam test [9,10], and double cantilever beam test [11-13]. The single-edge-notch specimen and wedge-splitting test represent standard geometries for determination of fracture energy for wooden products employed in timber engineering. On the other hand, the double cantilever beam test and tapered double cantilever beam test geometries are mostly used in different scientific research activities [14].

In this paper an experimental procedure for determining the fracture resistance curve of wood is explained. Double cantilever beam (DCB) tests were performed in order to determine Mode I fracture (crack opening) properties of spruce wood. As wood represents an orthotropic material, the fracture behaviour of wood is orientation-specific. Hence, six different material fracture planes can be defined - LR, LT, RL, RT, TL, TR (Figure 3), where the first letter indicates the direction perpendicular to the crack plane, and the second letter indicates the direction of crack propagation. The letters L, R and T represent longitudinal, radial and tangential direction of the fibres, respectively. In accordance with the large-scale experiments performed on the end-notched beams crack propagation is considered in the radial-longitudinal direction - RL direction. In order to overcome the main obstacle occurring with the DCB tests, which is crack length measurement, Digital Image Correlation (DIC) method was applied for recording the crack opening and propagation. Jamaaoui et al. [15] demonstrated that DIC method can be successfully used to estimate the crack length and the mechanical state at the crack tip. R curves were obtained from the slope of cumulative energy - crack length curve. The cohesive energy G_f was determined from the R curves. Based on these results, cohesive law for Mode I fracture can be defined.

2 MATERIALS AND METHODS

2.1 TEST SET-UP

Altogether ten specimens made from European spruce (Picea Abies) were tested as DCB to the point of failure at the TU Delft, Faculty of Civil Engineering and Geosciences, Department of Engineering Structures. The specimens were made from spruce timber classified in the strength class C22 according to the standard EN 338 [16]. The specimens were made out of the same wood as were the large-scale end-notched beams tested previously, so that the results could be used in further numerical analysis of Mode I fracture.

DCB test set-up and specimen geometry are presented in Figure 4. The specimens' cross section dimensions were 20 x 30 mm and length was 300 mm. They were denoted as S1-S10. The initial 100 mm long crack was formed using a saw with 1 mm thickness. Steel pins with a diameter of 3 mm were used for joining the specimens to the loading fixture.

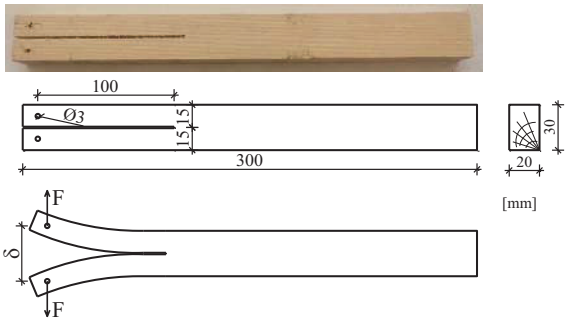

Figure 4: *DCB test set-up and specimen geometry*

https://doi.org/10.52202/069179-0055

Universal testing machine UTM-25 was employed for the experimental testing (Figure 5). Load was applied monotonically with a displacement-controlled rate of 5 mm/min. Load and displacement were recorded using the loading cell with a frequency of 2 Hz. All tests were performed under ambient conditions (at a temperature of about T = 20º C and a relative humidity of about RH = 65%). Using a digital hygrometer moisture content was measured in all the specimens and it had values in a range of 11.0% to 11.9%.

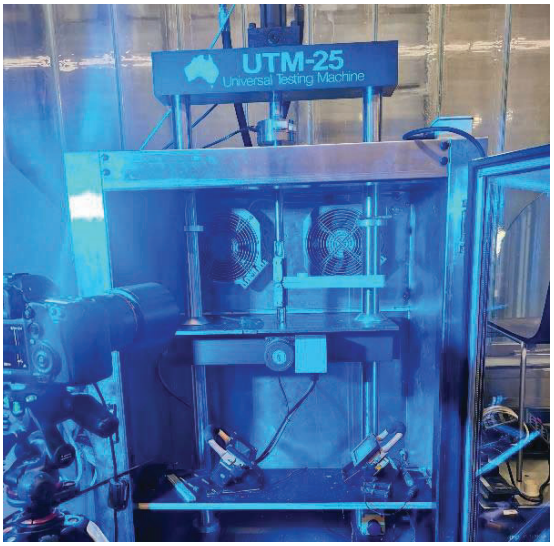

Figure 5: *Experimental set-up*

DIC method was employed for crack length measurement, as well as the measurement of crack opening during the testing. The main problem of this experiment is accurate crack length reading which is necessary for the correct definition of R curves. To overcome this problem, images recorded with a camera were analysed with GOM correlate software. By defining two curves on the upper and lower crack surfaces which are easily visible during the analysis, and measuring the separation between these curves allowed for the accurate crack length reading at each loading step.

2.2 PROCEDURE FOR ENERGY RELEASE RATE

The force-displacement curves recorded during the experimental research were used to obtain R curves (energy release rate vs crack length) based on the procedure explained in the paper by Wilson et al. [17]. This approach can be applied only to fracture mechanics tests with elastic materials (such as European spruce). In elastic materials, the fracture energy is released only due to the development of the damage process zone and the crack growth in the crack plane. For these materials no energy is released due to the non-linear (plastic or damage) behaviour of the materials surrounding the crack plane. Procedure consists of calculating the cumulative energy released up to the certain value of the loading point displacement δ (presented as shaded area in Figure 6). In order to determine cumulative energy, unloading from this point would be required. As Wilson et al. [17] argue in their paper, the fibre-bridging zone would interfere with the unloading and the curve would not return to the origin. Furthermore, authors explain that energy from such crack plane interference during unloading is not a part of the energy released during monotonic crack propagation, and it should not be a part of the cumulative released energy. Therefore, the proposed method assumes that the unloading would return to the origin displacement - δ_0. As suggested, cumulative released energy can be calculated as in accordance with the following expression:

$$U(\delta) = \int_{\delta_0}^{\delta} F(x)dx - \frac{1}{2}F(\delta)(\delta - \delta_0) \quad (1)$$

where U = cumulative energy, δ = displacement, δ_0 = origin displacement and F = force.
Afterwards, cumulative energy is cross-plot in the function of the corresponding crack length (Figure 6). Crack lengths were read from the DIC images for the corresponding force and displacement during the experimental testing. Finally, the R curves represent the slope of cumulative energy - crack length curve, calculated as follows:

$$R = \frac{1}{b}\frac{dU(a)}{da} \quad (2)$$

where R = energy release rate, b = specimen width and a = crack length.

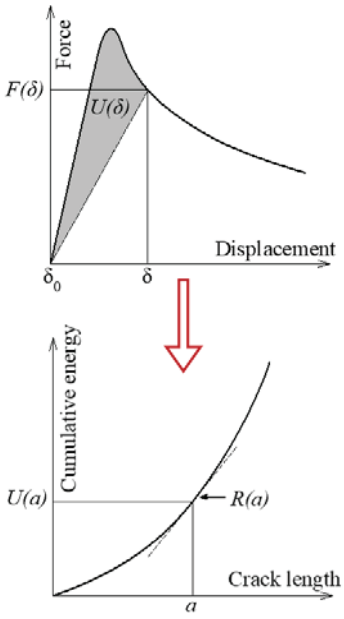

Figure 6: *Procedure for determining R curves based on cumulative released energy [15]*

https://doi.org/10.52202/069179-0055

3 RESULTS AND DISCUSSION

All tested specimens experienced the expected Mode I fracture - crack opening, caused by excessive tensile stress perpendicular to the grain of wood. Typical failure mechanism of tested specimens is presented in Figure 7. Force - displacement curves of all ten tested specimens are presented in Figure 8. As it can be seen from the curves, behaviour of the specimens was entirely linear until ultimate load corresponding to the initial crack opening was reached, with a sudden drop in load at this point. Afterwards, crack propagation and its growth led to a complete separation of the specimens in two parts, with generally clear and straight surfaces between two separated parts. Crack paths followed fibre directions, with minor exceptions in the case of existing defects in wood.

Figure 7: *Typical Mode I failure mechanism of tested specimens*

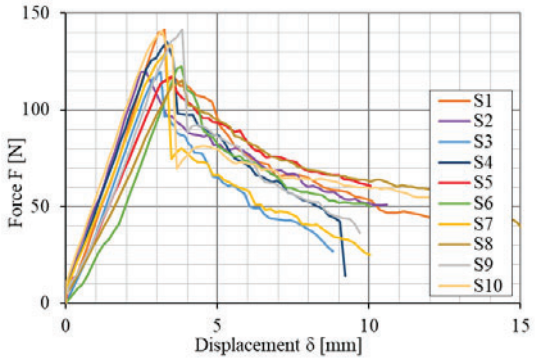

Figure 8: *Force-displacement curves*

After implementing the previously described procedure for energy release rate, cumulative energy vs crack length was calculated from the Equation (1) and presented in Figure 9. Based on these curves, using the Equation (2), R curves of tested specimens were calculated and presented in Figure 10. The recorded data of force - displacement was comprehensive enough to be easily integrated. For each step of loading, corresponding crack length was read from the DIC images analysed with GOM correlate software. Differentiation of the cumulative energy vs crack length curves was performed by fitting them with adequate third-degree polynomial curves. Afterwards, these polynomial curves easily numerically differentiated in order to obtain respective R curves for each specimen.

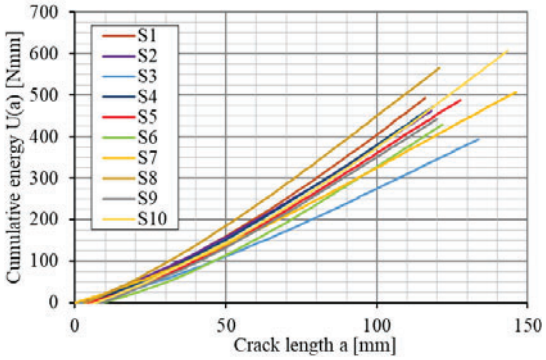

Figure 9: *Cumulative energy-crack length curves and (b) R-curves*

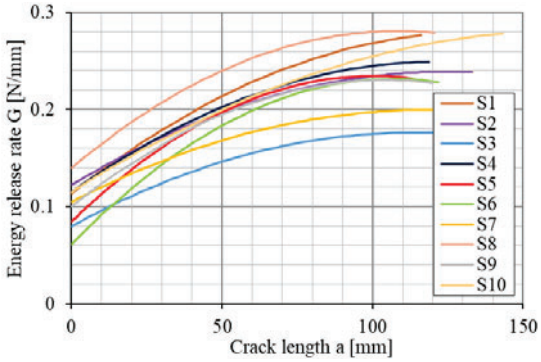

Figure 10: *R-curves*

The cohesive energy or critical value of energy release rate at propagation - G_f corresponds to the plateau value of the R curve [14]. This parameter values are estimated once the toughness stabilized after fibre-bridging process completed and R curves appear to be reaching the steady state. The experimental results for cohesive energy of tested spruce specimens are given in table 1. Cohesive energy values vary between 0.18 - 0.28 N/mm, with the mean value of 0.24 N/mm, and coefficient of variation of 13.7%.

Table 1: *The cohesive energy values*

Specimen	G_f (N/mm)
S1	0.275
S2	0.239
S3	0.181
S4	0.248
S5	0.235
S6	0.231
S7	0.200
S8	0.281
S9	0.230
S10	0.278
Average	0.236
Standard deviation	0.032
Coef. of variation (%)	13.7

https://doi.org/10.52202/069179-0055

The obtained cohesive energy values are comparable to the values obtained in other studies performed in order to determine fracture properties of Norway spruce. Authors Coureau et al. [14] cite cohesive energy values in the range of 0.25 - 0.31 N/mm depending on the test performed (where the value of 0.25 N/mm corresponds to the results of the DCB test). Ostapska and Malo [7] obtained mean cohesive energy value of 0.25 N/mm from the wedge splitting test. Since the results are similar to the ones obtained in this research, it can be said that the proposed procedure for determining R curves in this paper can be considered to be successful in evaluation of the cohesive energy of European spruce.

Crack opening displacement at the initial crack tip was also read from the DIC recorded images uploaded in the GOM correlate software. Crack opening displacement was determined by choosing two points at the initial crack tip, positioned at the future crack surfaces, and measuring their distance in each step as the crack opens and propagates. This parameter was necessary for further analysis in order to obtain the cohesive law for the specimens. Energy release rate plotted against crack opening displacement at the initial crack tip once it is differentiated gives the cohesive law of tested wood specimens [18]:

$$\sigma(\delta^*) = \frac{dG(\delta^*)}{d\delta^*} \tag{3}$$

where σ = nominal stress, δ* = crack opening displacement at the initial crack tip, G = energy release rate. The cohesive law for tested European spruce specimens is given in Figure 11. This was performed using the Equation (3) for an average value of the obtained R curves.

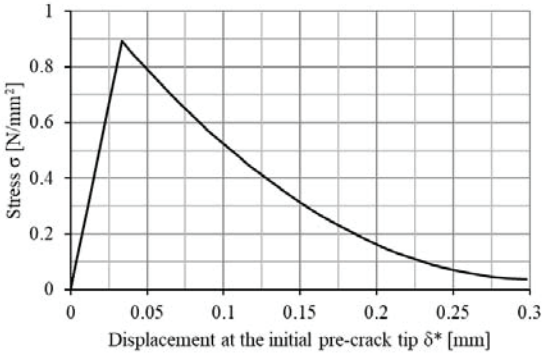

Figure 11: *Cohesive law of tested specimens*

Maximum value of nominal stress equals 0.9 N/mm^2 from the cohesive law curve and it corresponds to the value obtained by Oudjene et al. [19] also from DCB tests. Authors of the mentioned paper also successfully modelled the progressive cracking of the notch details of spruce timber beams using the parameters obtained from the DCB tests.

4 CONCLUSIONS

The condition of steady state crack propagation is required to estimate relevant fracture properties of wood. Adequate test procedure and recording are necessary in order to obtain accurate behaviour of wood in Mode I fracture (crack opening). Comprehending fracture in timber allows to determine the expected behaviour of timber structural elements in terms of load-carrying capacity, ductility and damage tolerance.

An efficient test and analysis procedure to obtain the Mode I fracture energy based on the double cantilever beam (DCB) tests is proposed in this paper. The force-displacement curves recorded during the experimental research were used to obtain fracture resistance curves (R curves). Based on the obtained results, the cohesive energy corresponding to the plateau value of the R curve was determined to be 0.24 N/mm for specimens made of European spruce. Furthermore, R curves were analysed in order to determine cohesive law of wood. The described method has been proven to be successful in determination of Mode I fracture properties of wood.

Cohesive law can be further implemented in the numerical analysis of large-scale timber elements like notched beams and beams with holes. The numerical modelling, as well as the experimental research, can help in better understanding of crack initiation and crack growth phenomenon in timber structures.

THE INFLUENCE OF WOOD COATINGS ON THE MOISTURE BUFFERING CAPACITY OF CLT AND THE INDOOR ENVIRONMENT

Ulrich Hundhausen[1], Robbe Heyvaerts[2], Samee Ullah[3], Dimitrios Kraniotis[4]

ABSTRACT: The objective of the study was to determine the influence of wood coatings for CLT on the moisture buffering capacity and the indoor environment regarding relative humidity and heating demand. Based on the results of a previous screening of a wide range of coatings, three commercial products were chosen: a flooring oil, an alkyd-based interior wall stain and a fire-retardant stain that were considered to provide both, i) high water vapor permeability to maintain wood's hygroscopicity, and ii) adequate protection of CLT under storage, transport, installation and service. A climate chamber test revealed a good moisture buffer capacity of untreated CLT and a limited one of CLT cladded with gypsum. CLT's glue lines in the frontal plane were not found to affect moisture dynamics. The flooring oil and the wall stain reduced the practical moisture buffer value by 39% and 10%, respectively, as compared to the uncoated CLT. CLT coated with the fire-retardant stain had an even higher practical moisture buffer value than uncoated wood, which is explained by the stain's pronounced hygroscopicity. In all elements tested in a heat flux experiment, the theoretical U-values were higher than the experimentally obtained and simulated values. Hygrothermal energy simulations using a room of 50 m^2 as 'reference model' showed that wood's moisture buffer capacity is beneficial for the indoor environment, by means of passive regulation of RH and lower energy demand for humidification and dehumidification.

KEYWORDS: fire retardant, heating demand, indoor environment, moisture buffering, U-value, wood coating

1 INTRODUCTION

Hygroscopic materials change their moisture content (MC) dependent on the ambient climate. As climate conditions permanently vary in real-use conditions and the inertia of sorption, a hygrothermal equilibrium with its surrounding environment is hardly attained [1]. This material property to absorb and desorb moisture and thereby to moderate the indoor variations in relative humidity, RH, is referred to as moisture buffer capacity, MBC [2,3]. The MBC may be utilized to improve indoor climate [e.g. 4] and save energy [e.g. 5,6,7]. Regarding wood, the MBC has been determined in many studies on a wide range of products including solid wood [e.g. 8], plywood [e.g. 9], paneling [e.g. 10], wood-based insulated panels [e.g. 11] and furniture [e.g. 12]. The challenge of fully utilizing wood's MBC is that wood products are usually coated for improving their aesthetics and technical properties; these coatings may significantly reduce the MBC [13,14,15].

The objective of the present study was to determine the influence of coatings for cross laminated timber (CLT) made of Norway spruce (*Picea abies*) on the MBC and the indoor environment regarding RH and the building's energy demand. As producers of CLT claim a need for surface treatments that are industrially applicable, the premise was to find mechanically resistant coatings that protect CLT under storage, transport, installation and service but at the same time maintain wood's hygroscopicity.

2 MATERIALS AND METHODS

The methodological apporach of the study is shown is shown in Figure 1.

In an initial screening, a literature and market study as well as pre-tests on the water vapor permeability, moisture buffer capacity, scratch resistance and blocking were carried out on clearwood specimens to identify potentially suitable coatings for industrial CLT production. Based on those results (not shown in this paper), three commercial coatings were chosen for further

investigations on CLT: a flooring and furniture hardwax oil (RMC Oil Plus C, Rubio Monocoat, Dal, Norway), a waterborne alkyd interior wall stain (Lady Pure Nature, Jotun, Sandefjord, Norway) and a fire-retardant (FR) stain (NT Deco, Nordtreat, Vantaa, Finland). The latter is a certified Euroclass B-s1, d0 treatment for CLT. The coatings were applied according to the producers' specifications on five CLT-elements and one solid wood element with a dimension of 100 x 100 x 60 cm^3 (width x height x thickness). The commercial CLT-elements (KLH Massivholz GmbH, Teufenbach-Katsch, Austria) were composed of five-layers made of Norway spruce (*Picea abies*) glued with an polyurethane adhesive. Uncoated CLT and CLT cladded with gypsum of 12.5 mm thickness served as references. In addition, an uncoated solid wood element was included to study a possible influence of the glue lines in the frontal plane of CLT (Table 1).

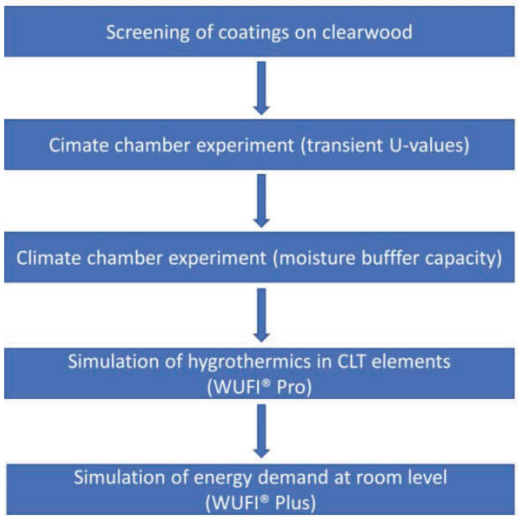

Figure 1. *Methodology of the study*

Table 1. *CLT-elements used in the climate chamber experiment and hygrothermal model. FR = fire retardant*

Element	Coating	Application rate, wet [g/m^2]

2. CLT+gypsum	/	
3. CLT	Hardwax oil	23
4. CLT	Alkyd stain	79
5. CLT	FR-stain	350
6. Solid wood	/	

The elements were installed in a two-room climate chamber that simulated a steady outdoor climate of -2°C/50% and a fluctuating room climate of 23°C/75% and 23°C/33% for 8 h and 16 h, respectively (Figure 2). The interior conditions followed the climate regime described in the NORDTEST protocol to determine the practical moisture buffer value, $MBV_{practical}$ [2]. Before testing, five of the six faces of each element were sealed with vapor barrier tape (FLEX Tape Dampsperre, Isola AS, Porsgrunn, Norway). The unsealed face was exposed to the interior climate. Both air temperature and RH were logged (TH501, Celsicom AB, Varberg, Sweden) in each zone. In addition, the MC in the CLT-elements was logged with electrical resistance moisture meters (MC501, Celsicom AB). In total, five sensors were used, one in each lamella of the elements. The climate chamber experiment provided measurements of the heat flux using plate sensors (TRSYS 02, Hukseflux Thermal Sensors, Delft, The Netherlands), as shown in Figure 3.

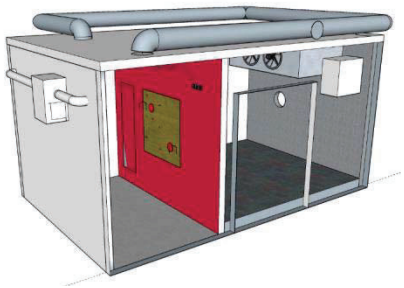

Figure 2*. The two-rooms climate chamber used for measuring the heat flux through the 1 m2 large elements.*

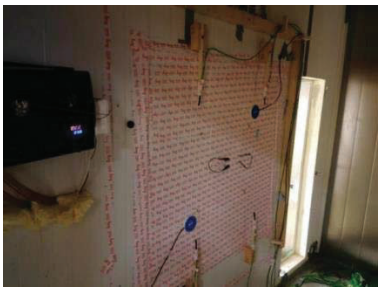
(a)



(b)

Figure 3*. The face of the uncoated CLT-element. The red and blue plates are the heat flux sensors, on the interior (a) and exterior (b) surface of the wall.*

https://doi.org/10.52202/069179-0056

The measurements were then used to calculate the thermal trasmittance, i.e. U-values, during the experiments. After the heat flux experiment, specimens were cut from each CLT-element for measuring the wood density and the MC according to the oven-dry method (Figure 4). In addition to the specimens used for density and MC measurements, five specimens were cut from each CLT-element, which were used for determining gravimetrically the $MBV_{practical}$ according to the NORDTEST protocol [2].

The experimental results from the climate chamber test were compared with modelled sorption dynamics and simulated transient U-values in each of the CLT-elements, employing the HAM (heat, air and moisture transport) software WUFI® Pro [16]. The values of T, RH, density and MC measured during the experiment were used as input data. In addition, the S_d-values of the coatings were used for modelling that had been determined in a dry-cup test according to EN ISO 12572:2016 during the screening phase of the study. Eventually, the experimentally obtained U-values (U_{exp}-values) as well as the simulated U-values (U_{sim}-values) in WUFI® Pro were compared with the theoretical (steady state) U-values calculated according to ISO 6946:2017 (U_{th}-values).

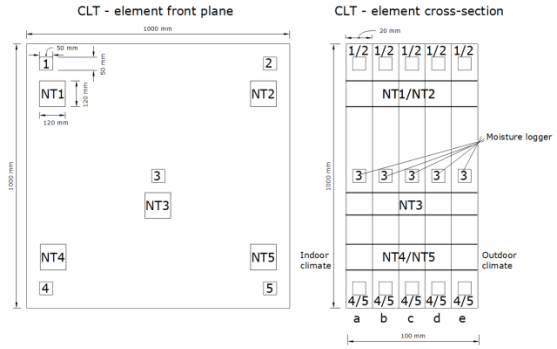


Figure 4. *After the end of the climate chamber test, 25 specimens (five per CLT-lamella) were cut from each CLT-element to measure the density and MC (1 to 5). In addition, five specimens were extracted for determining the $MBV_{practical}$ according to the NORDTEST method (NT1 to NT5).*

To model the moisture dynamics at room level, the hygrothermal energy simulation tool WUFI® Plus [17] was employed. A reference, a room with an area of 5 m x 10 m was used (Figure 5), which is part of a residential building; therefore, the relevant specifications regarding the indoor environment and HVAC systems were followed as described in SN-NSPEK 3031:2020 [18]. The following scenarios were considered:

Two building systems: i) with CLT/solid timber wall systems both as exterior (Figure 6) and interior walls (Figure 7) and ii) a conventional stud wall system as exterior wall (Figure 8 A) and concrete as internal wall (Figure 8 B). All external walls are insulated and the U-value is 0.18 W/m^{2}K. An overview of the scenarios is shown in Table 2.

For the cases with CLT/solid timber wall systems as external and internal walls, the six different cases that had been tested in the climate chamber and validated using the WUFI® Pro 1D were used.

The sixth case consists of a conventional insulated stud wall, with exterior wooden cladding and interior cladding in gypsum board, and a concrete internal wall with only plaster as finishing in both surfaces.

Two different functions in the HVAC system were considered: i) with humidification and dehumidification and ii) without humidification and dehumidification.

Two different functions in the HVAC system were considered: i) with moisture recovery and ii) without moisture recovery. Today, the vast majority of the HVAC systems include only heat recovery but not moisture recovery, which might be important when combined with hygroscopic materials.

Two different levels of mechanical ventilation rate were considered: i) a rate according to the Norwegian Standard SN-NSPEK 3031:2020 for the apartments and ii) a rate reduced by 50% compared to (i).

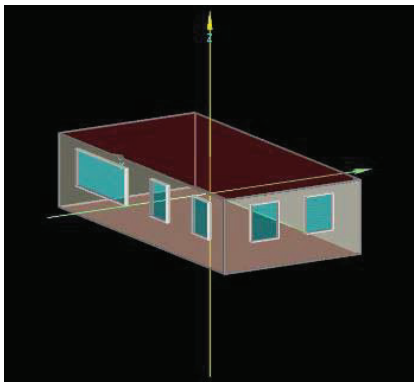

Figure 5. *3D view of the room model used in the hygrothermal energy simulations in WUFI® Plus. The two facades with windows are external walls while the other two are internal walls. The long façade (10 m) and the short façade (5 m) are oriented towards the south and east, respectively.*

#6	Insulated stud wall, with wood panel as exterior cladding and gypsum board as interior cladding	Non-insulated concrete wall, with mortar on both surfaces

3 RESULTS AND DISCUSSION

3.1 MOISTURE BUFFER CAPACITY AND TRANSIENT U-VALUES

Table 3 shows the $MBV_{practical}$, the S_d-values of the three coatings as well as the U_{th}-values, U_{sim}-values and U_{exp}-values. The $MBV_{practical}$ of 1.06 classifies the MBC of uncoated CLT as "good" and of CLT cladded with gypsum as "limited" [2]. $MBV_{practical}$ of untreated Norway spruce found in the literature range from 0.91 [13] to 1.36 [2,8]. The hardwax flooring oil and the alkyd-based interior wall stain decreased the $MBV_{practical}$ by 39% and 10%, respectively, as compared to the uncoated CLT. A reduction by 10% is rather low compared to those reported in other studies on wood coatings [14,15]. Lozhechnikova et al. [13] found for example that a two-layer coating of linseed oil and a spray laquer reduced the $MBV_{practical}$ by approximately 20% and 70%, respectively. CLT coated with the FR-stain had an even higher $MBV_{practical}$ than uncoated wood, which is explained by the stain's pronounced hygroscopicity due to the FR-actives in the formulation. This hypothesis is supported by the observation of small water droplets on the specimen surface (Figure 9 A) and discoloration most likely due to salt crystalization (Figure 9 B), which occured during the moist RH step in both climate chamber tests (Figure 1).

Overall, the $MBV_{practical}$ of the three coated CLT differ more than the SD-values of the coatings suggest (Table 2). A relationship between the MBV and the S_d-values is not found.

Table 3. *The$MBV_{practical}$, the S_d-value of the coatings as well as the theoretical (U_{th}), simulated (U_{sim}) and experimental (U_{exp}) U-values of the six wall elements tested in the climate chamber.*

Element	MBV [g/m² %RH]	S_d [m]	U-value [w/(m²K)]		
			U_{th}	U_{sim}	U_{exp}
1. CLT	1.06		0.93	0.87	0.79
2. CLT+gypsum	0.28		0.89	0.84	0.78
3. CLT+HW linseed oil	0.65	0.01	0.93	0.88	0.80
4. CLT+alkyd-stain	0.95	0.01	0.92	0.87	0.76
5. CLT+FR-stain	1.61	0.59	0.93	0.88	0.75
6. Solid wood	0.98		1.00	0.91	0.92

For all six elements, the U_{th}-values, calculated according to ISO 6946:2017, are higher than the U_{sim}-values and U_{exp}-values (Table 3). Our results confirm the hypothesis that the moisture adsorption and absorption in wood increases the thermal resistance of the element due to the latent heat of sorption, i.e. the heat released due to phase change of water vapor to bounded water in wood. The findings are in agreement with previous studies that have shown the temperature in wood increased with moisture uptake, increasing in this way

https://doi.org/10.52202/069179-0056

the thermal resistance of the element [6,7,19].

(A) (B)

Figure 9. *Water droplets occurred on the CLT-element treated with the FR-stain during the absorption step (A). The discoloration of the surface (B) appeared in the beginning of the absorption step but quickly disappeared again.*

An influence of the three coatings on the U-values does not become apparent (Table 3). This is expected for the U_{th}-values because the thermal resistance of thin materials, with primarly moisture resistive function, like coatings is considered as neglectible and the calculation method does not account for sorption effects. However, we neither observe a significant influence of the coatings on the U_{sim}-values nor the U_{exp}-values although the $MBV_{practical}$ show that the coatings do influence the sorption properties of wood. This suggests that there is no practical difference by means of thermal performance of wood due to moisture uptake between the untreated and treated wood if the latter is coated with highly water vapor permeable coatings.

3.2 MOISTURE DYNAMICS AT ROOM LEVEL

3.2.1 Buffering of RH indoors

Figures 10, 11 and 11 show the minimum and maximum RH indoors in the simulated room when the HVAC system does not include humidification/dehumidification. In Figure 10, the mechanical ventilation is set according to SN-NSPEK 3031:2020, i.e. it is constant at 90 m3/h. In this case, the maximum RH indoors is lowest in case #1 (59.4%) and #5 (59.1%), which is the uncoated CLT-element and the uncoated solid timber element, respectively (Table 2). In comparison, the maximum RH is highest in case #2 (63.2%) and #6 (63.6%), which is the CLT-element cladded with a gypsum board and the stud wall with the gypsum board as interior cladding. The picture is contrary for the minimum RH: the highest values show case #1 (4.9) and #5 (5.0) whereas the lowest values were found for case #2 (3.8%) and #6 (3.4%). The maximum RH is by 4.5% lower and the minimum RH by 1.5% higher in case #5 (most beneficial) than in case #6 (least beneficial). In other words, the wall design with uncoated wood and without gypsum revealed the lowest difference between maximum and minum RH. This behavior is beneficial in terms of passive control of the indoor environment.

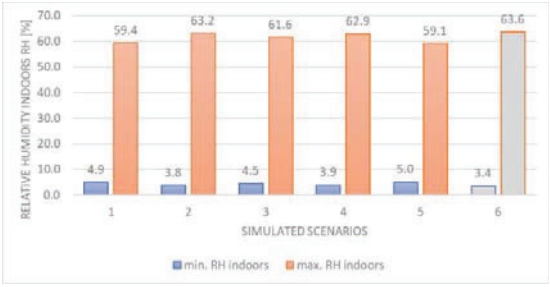

Figure 10. *Simulated minimum and maximum RH indoors in the simulated room without humidification/dehumidification. The mechanical ventilation is set according to SN-NSPEK 3031:2020 and there is no moisture recovery in the HVAC system.*

The moisture buffering effect becomes clearer when moisture recovery is included in the HVAC system (Figure 11). The maximum RH is by 9.4% lower and the minimum RH by 4.6% higher in case #5 (most beneficial) than in case #6 (least beneficial).

A general observation about this set of simulations, i.e. with moisture recovery in the HVAC system (Figure 11), is that the minimum RH is significantly higher than that of the previous set of simulations where moisture recovery was not included in the HVAC system (Figure 10). This means that regardless the type of interior surface, it will be beneficial for the indoor environment if moisture is also recovered, along with heat, in the mechanical ventilation. This seems to be of particular need in spaces/rooms with relatively limited moisture production.

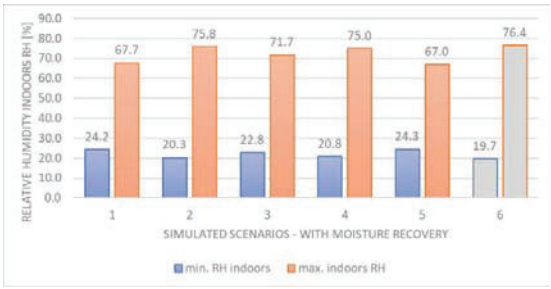

Figure 11. *Simulated minimum and maximum RH_i in the model room without humification/dehumification when moisture recovery is included in the HVAC system.*

Finally, Figure 12 shows the results from the last set of simulations, where the flow rate in the mechanical ventilation was reduced by 50% compared to standard requirements (Figure 10). The reduction resulted in an elevation of both, the maximum and the minimum RH. However, the relationship between the six cases regarding the RH maxima and minima is the same as for the HVAC-systems shown in Figure 10 and Figure 11.

https://doi.org/10.52202/069179-0056

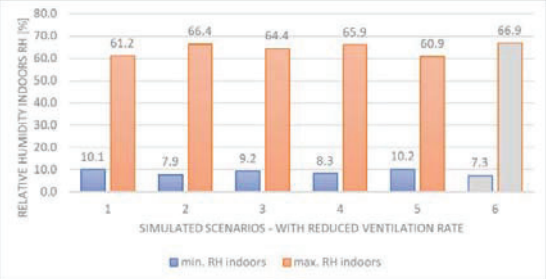

Figure 12. *Simulated minimum and maximum RH indoors in the simulated room without humidification/dehumidification when the mechanical ventilation is reduced by 50% compared to the requirements specified in SN-NSPEK 3031:2020.*

Independent from the type of HVAC-system, the coatings reduce the moisture buffering effect of wood (case #3 and #4, Figure 10, 11 and 12). This applies especially to the FR-stain. Considering the MBV-values (Table 3), the CLT-element coated with the FR-stain (case # 4) should have buffered the RH in the model room best. However, the WUFI® Plus simulations take into account the S_d-values and not the MBV. Against this background, the comparitively high S_d-value of the FR-stain (0.59 m) has a negative impact in the simulations although the MBV of 1.61 W/(m²K) suggests the opposite.

3.2.2 Required energy for humidification and dehumidification

Figure 13, 14 and 15 show the energy used for humidification and dehumidification to maintain the RH indoors within 25% and 60%. Overall, the required energy decreases the better the MBC of the wall system is. However, the impact of the MBC strongly depends on the type of HVAC system.

Figure 13 shows the results of the set of simulations where the mechanical ventilation was set according to SN-NSPEK 3031:2020, i.e. constant to 90 m³/h without moisture recovery in the HVAC system. Case #5 (uncoated solid timber) requires 477.3 kWh for humidification while case #6 (stud wall with gypsum board as interior cladding) requires 502.2 kWh for humidification and 0.3 kWh for dehumidification. Case #1 (uncoated CLT) shows a similar performance like case #5 and case #2 (CLT cladded with gypsum) shows a similar performance like case #6.

The range of 25 to 60% for indoor RH corresponds to the Indoor Environmental Quality class 2, which is the target range for new buildings. Both, Figure 10 and 12 and consequently Figure 13 reveal a large difference between the need for humidification and dehumidification, which shows that the minimum RH is a challenge in modern residential buildings.

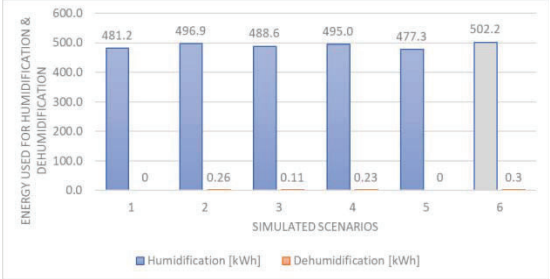

Figure 13. *Energy used for humidification and dehumidification to maintain the RH indoors within 25% and 60% when mechanical ventilation is set according to SN-NSPEK 3031:2020 and there is no moisture recovery in the HVAC system.*

The inclusion of moisture recovery in the HVAC system reduces significantly the need for humidification (Figure 14). In particular, for case #5 (exposed and uncoated solid timber) there is negligible humidification need (0.1 kWh) while for case #6 (stud wall with gypsum board as interior cladding) the humidification need is 4.6 kWh. Case #5 shows also the lowest need for dehumidification (8.2 kWh), which reflects the contribution of this building component to the passive regulation of the RH indoors. In contrast, case #6 shows the highest need for dehumidification (26.9 kWh). As in the other cases, case #1 is similar to case #5, and case #2 is similar to case #6.

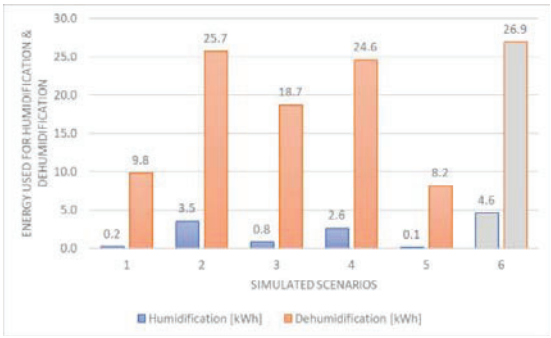

Figure 14. Energy used for humidification and dehumidification when moisture recovery is included in the HVAC system.

Figure 15 shows the results when the flow rate of the mechanical ventilation system is reduced by 50% compared to the standard rate (the indoor air quality (IAQ) was yet exceptional). The results in this set of simulations are similar to the ones of the previous sets.

https://doi.org/10.52202/069179-0056

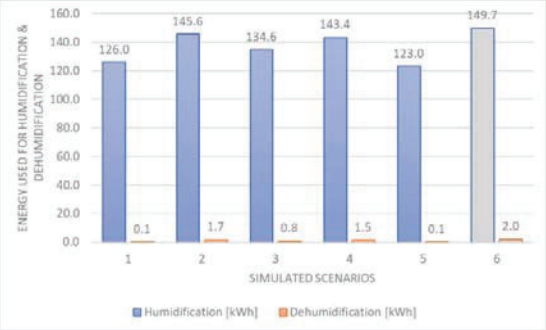

Figure 15. *Energy used for humidification and dehumidification to maintain the RH indoors within 25% and 60% when the mechanical ventilation is reduced by 50% compared to the requirements in SN-NSPEK 3031:2020.*

4 CONCLUSIONS

The study confirms the hypothesis that wood's MBC is beneficial for the indoor environment, by means of RH and energy demand for humidification and dehumidification, as well as for the thermal conductivity of CLT. In other words, there is need to take into consideration the humidity level to calculate a realistic U-value.

Gypsum was found to decrease the MBC of CLT from "good" to "limited" ($MBV_{practical}$ of 0.28). Highly-permeable coatings reduce CLT's $MBV_{practical}$ only slightly. From the practical point of view, a replacement of gypsum is difficult to realize in applications with strict requirements to fire safety. To a certain extent, this might be possible by using an FR-stain, which even increased the $MBV_{practical}$ of untreated CLT from $MBV_{practical}$ 1.06 to 1.61. However, it is to consider that an FR-treatment as its best may improve the reaction-to-fire performance of wood from Euroclass D to B.

Finally, the study on the FR-stain reveals a weakness in the methodology of quantifying the MBC and simulating its impact on the indoor environment and, consequently, on energy requirements related to the HVAC system. The $MBV_{practical}$ of a coating may be high due its hygroscopicity although its water vapor permeability is low.

EVALUATION OF MODELS OF FIBRE ORIENTATION IN SAWN TIMBER USING SYNCHRONISED COMPUTED TOMOGRAPHY AND OPTICAL SCANNING DATA

Johannes A. J. Huber[1], Osama Abdeljaber[2], Johan Oja[3], Anders Olsson[4]

ABSTRACT: Optical scanning and X-ray computed tomography (CT) scanning of sawn timber provide a large number of data points, on which data-driven numerical models can be based for simulations. These models require information about the deviations of the fibre orientations in the vicinity of knots. Optical scanning can be used to measure the in-plane fibre orientation on wood surfaces. In CT scans of sawn timber, the fibre orientation around knots can be estimated using a new fibre reconstruction algorithm based on the density gradient. The goal of this paper is to compare and synchronise optical and CT scanning data of sawn timber and then use the combined data set to evaluate fibre orientations derived from both representations. The material comprised sawn timber of Norway spruce, in which alignment holes were drilled. The timber was scanned in an industrial CT scanner and subsequently in an industrial optical scanner where scanning was repeated after successive planing of the sawn timber surface. The results show that a projective mapping in combination with a spline interpolation are required for synchronisation, and that the in-plane fibre orientations calculated from the density gradients are qualitatively similar to the orientations derived from the optical data.

KEYWORDS: Knots, Tracheid effect, CT scanning, Strength grading, Image analysis, Gradient structure tensor

1 INTRODUCTION

Strength-graded sawn timber constitutes the base of most solid timber-based structures or engineered wood products used in these structures. Knowledge about the mechanical properties of the used timber is therefore imperative for design. For individual pieces of sawn timber, the exact values of these properties are, however, unknown and for strength specifically, they are inherently unknowable without destructive tests.

In machine strength grading, *indicating properties* (IPs) of sawn timber are used in regression models to predict the *grade-determining properties* density, stiffness and strength. For timber graded into C classes, stiffness and strength relate respectively to the bending modulus of elasticity (MoE) and the bending modulus of rupture (MoR), according to the European standard EN 408 [1]. Sawn timber is graded into a few strength classes at sawmills, where the properties of each class are governed by the characteristic values of strength and density, respectively, and by the characteristic mean value of the MoE. IPs can be derived from various measurements using different technologies [2], but usually large variations in the mechanical properties of individual pieces of sawn timber remain, with coefficients of variation often exceeding 20%.

Comparatively high prediction accuracy can be achieved by IPs based on measuring the in-plane fibre orientation on sawn timber surfaces by laser scanning utilising the tracheid effect [3]. This technology accounts for both the presence of knots and the resulting fibre deviations around knots on the board surface. Nevertheless, the plethora of data points needs to be condensed to one or a few scalar parameters for IP-based predictions in regression models.

Recently, some sawmills have also adapted X-ray computed tomography (CT), currently used for sorting logs and to optimise log positioning regarding yield before sawing [4]. The supplied density data in the log volume lends itself for an automated detection of the location of the pith and knots by image analysis [5]. The

abundant 3D data gathered is however currently not used for prior-to-sawing strength evaluations.

Knots, and the deviations of the fibre orientation caused by them, strongly affect the stiffness and strength of sawn timber. The complex patterns of fibre orientations around knots have been investigated using laser scanning in successively planed sections of sawn timber [6], and in greater detail by using micro-CT scanning [7].

Gathering high-resolution data of sawn timber facilitates the use of numerical models, e.g. 3D finite element (FE) models, for predicting the properties of individual boards. These models require information about wood features like the pith location, the size and shape of knots, and the fibre orientations. Apart from measuring the in-plane fibre orientation, optical surface data can be used to find knots and determine the location of the pith [8]. Surface data has been used previously for FE models, e.g. to predict the bending stiffness profile in [9], where the location of the pith was estimated by fitting concentric circles to growth rings, the knots were idealised as cones and the fibre deviations were calculated on the basis of a mathematical model [10].

In a recent study [11], CT data also has been used to create FE models of the exact shape of sawn timber, whereby image analysis methods were used to locate the pith, detect knots, and furthermore reconstruct the 3D fibre orientations around knots in a new way, which accounts for irregular shapes of knots. To refine the methodology in [11], verifications are required for the fibre orientations and the size of the regions around knots in which the fibres are disturbed. In the future, CT-based modelling could also be used for logs, to predict the mechanical properties of individual virtual boards in logs already before sawing.

Data-driven models which incorporate the rich data of measurements on individual logs or individual pieces of sawn timber can yield accurate predictions and can facilitate the production of timber with bespoke mechanical properties instead of being binned into predefined strength classes with high variability. Tracking individual pieces and their properties also opens the possibility of planning their structural use in a construction already at the sawmill, as part of a purpose-based grading process.

The objective of this study is therefore to compare and synchronise the high-resolution data obtained from optical scanning and CT scanning, respectively, of sawn timber. More specifically, the goal is to use the combined data set to evaluate fibre orientations around knots derived from both data sets.

2 MATERIAL & METHODS

2.1 MATERIAL PREPARATION

Norway spruce (*picea abies*) sawn timber from Sweden with dimensions 45 × 145 × 3600 mm^3 was prepared by drilling positioning holes at equally spaced positions, see Figure 1. Starting at a lengthwise distance of 50 mm from each edge, and subsequently spaced 700 mm from the first position, three holes at each wide face and two holes on each short face were drilled. The outer holes on the wide faces and the holes on the short faces were spaced 15 mm from the edges of the sawn timber. The third hole on the wide face was centred between the edge holes. At 1450 mm from each edge, only a single hole in the middle of the wide faces was drilled.

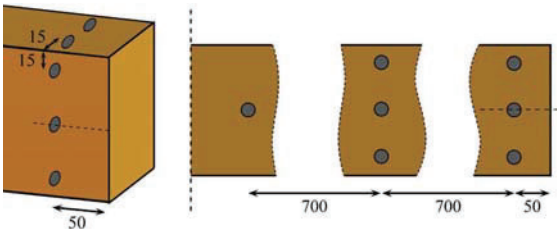

***Figure 1**: Arrangement of the positioning holes*

2.2 DATA ACQUISITION

CT images were acquired of the timber using an industrial CT scanner (Microtec Mito) adapted for research purposes at the facilities of Luleå University of Technology in Skellefteå, Sweden. The sawn timber was wrapped in plastic to contain its moisture content and simply supported at its ends and standing upright, which minimised the bending deflection under its own weight while the scanner moved along the timber, see Figure 2. The reconstructed 3D image stack had a voxel (3D pixel) size of 0.3 × 0.3 × 0.3 mm^3. Each voxel carried a 16-bit grayscale value which represented density in kg/m^3 at the corresponding location.

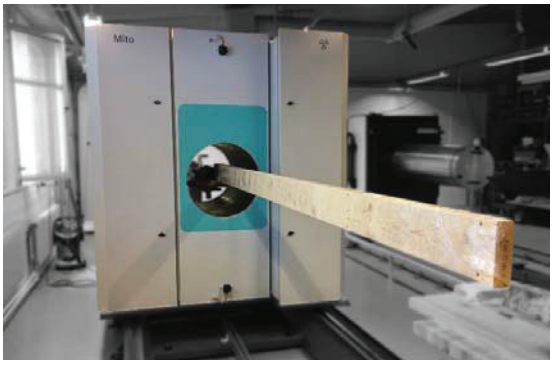

***Figure 2**: CT scanner moving along the sawn timber*

After transport and removal of the plastic wrapping, the sawn timber was scanned using the industrial optical wood scanner Microtec WoodEye (WE) at the facilities of Linnaeus University in Växjö, Sweden. The scanner recorded RGB images of all faces at a pixel size of 0.8 × 0.07 mm^2 (lengthwise × crosswise) and it recorded the in-plane fibre directions using laser tracheid scans at a resolution of 1 × 4.4 mm^2 (lengthwise × crosswise).

To receive a distribution of the in-plane direction in the volume of the boards, the timber was planed successively by a depth of 1 mm at each wide face**,** and after each planing operation, the optical scanning process was repeated, see Figure 3. Nine slices were planed off on each wide face, i.e. 18mm were removed in total.

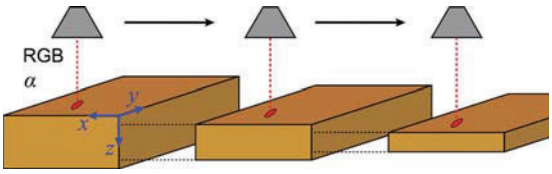

***Figure 3**: Progressively planing and optical scanning*

2.3 CT IMAGE PROCESSING

The CT images represented an equally spaced rectangular grid of density values $\rho(x, y, z)$ in 3D space. The processing of the CT data was primarily performed using code in Julia [12]. For segmenting timber from air, a binary image $B(x, y, z)$ was created by thresholding ρ and filling internal holes.

Since the timber was twisted around its long axis, a misalignment existed between the sawn timber surfaces and the axes of the CT image. To be able to compare flat surfaces in the WE data to corresponding surfaces in the CT images, the latter first needed to be "untwisted". The twist was corrected by rotating and aligning each cross-sectional CT slice to the image axes, see Figure 4. This required estimating the twist angle θ_i of each CT cross-section along a board as well as the translation in both directions (Δx_i and Δz_i) from a fixed reference point. To do so, in each CT cross-section in B the shift in both directions Δx_i and Δz_i from the centroid of the resulting region to the reference point as well as the angle θ_i that the principal axis of the region makes with the horizontal image axis were calculated. These values indicate how much each cross-section should be translated and rotated to straighten the board. The estimates of these values were affected by noise in the CT images, which was partly due to the plastic wrapping around the timber and reconstruction artefacts present in the images. A moving mean filter was therefore applied to denoise the variations of Δx_i, Δz_i, and θ_i before correcting the twist of the board.

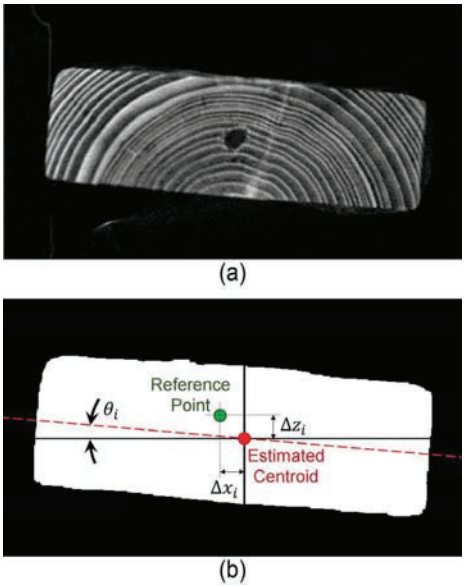

***Figure 4**: Correction of twist in boards; twisted cross-sectional CT image (a), and estimated parameters for untwisting (b)*

To estimate the fibre orientation (*l*-direction) in the untwisted CT image, an adapted version of the method presented in [11] was applied, which is based on finding the smallest gradient in the density field [13]. In a first step, the partial derivatives of the density were calculated by Equation (1).

$$\rho_x = \frac{\partial \rho}{\partial \mathrm{x}} \approx w_{\sigma 1} * (w_{\Delta x} * \rho) \tag{1}$$

where $w_{\Delta x}$ is a convolutional kernel for finite differences [14], $w_{\sigma 1}$ is a Gaussian kernel with a standard deviation of 1 voxel and ρ from here on represents the density of the untwisted CT image. The partial derivatives were equivalently calculated for y and z. In a second step, the *gradient structure tensor* (GST) was constructed, see Equation (2).

$$\mathrm{GST}\big(\rho(x,y,z)\big) = w_{\sigma 2} * \begin{pmatrix} \rho_x^2 & \rho_x\rho_y & \rho_x\rho_z \\ & \rho_y^2 & \rho_y\rho_z \\ \mathrm{sym} & & \rho_z^2 \end{pmatrix} \tag{2}$$

where $w_{\sigma 1}$ is a Gaussian convolutional kernel with standard deviation 3 voxels. In the last step, the eigenvalues and eigenvectors of $\mathrm{GST}(\rho)$ were extracted for each voxel and the eigenvector corresponding to the lowest eigenvalue was taken as the estimated *l*-direction. The result was a vector field $\boldsymbol{l}_{\mathrm{CT}}$ over the entire CT image.

A bounding boxing around the untwisted binary image was calculated to locate the initial surfaces of the sawn timber before planing. The calculation was performed by requiring that the outer slices of the bounding box contained a sufficiently large contiguous area of the untwisted binary image. From the outer slices, consecutive slices corresponding to the planing depths were extracted from the wide faces. For each slice, both the density values and the vector field of the estimated *l*-direction were extracted and exported for the subsequent synchronisation.

2.4 WOODEYE DATA PROCESSING

The WE data consisted of RGB intensity values and the in-plane fibre orientation angle α, which was defined as the shortest angle between the longitudinal scan direction (y) and the measured major axis of the ellipse formed by the laser point due to the tracheid effect. The data processing and the subsequent synchronisation was performed using code in MATLAB [15].

The data corresponded only to the scanned board surfaces and thus made a bounding box search unnecessary. Both the RGB and orientation data were available at points on non-uniform grids. To prepare the synchronisation, all WE data was therefore resampled by bicubic interpolation to the uniform grid of the corresponding slices from the untwisted CT image.

2.5 SYNCHRONISATION

Since some distortions existed in the WE data, e.g. due to the fact that the speed of the conveyor belt placed before the scanner was not perfectly aligned to the operational speed of the scanner, a mapping function needed to be

https://doi.org/10.52202/069179-0057

calculated to synchronise the WE data to the CT images. The synchronisation was based on the resampled WE RGB images of each face and the corresponding grayscale 2D slices obtained from the untwisted CT image.

The predrilled positioning holes served as an easily detectable reference in both representations and their centres were labelled manually in a user dialog in MATLAB by fitting circles, see Figure 4. The circle centres served as an input for calculating the mapping between the WE images to the CT faces. A projective 2D transformation matrix was estimated for performing the first part of the mapping, see Equation (3).

$$\begin{pmatrix} x' \\ y' \\ 1 \end{pmatrix} = \begin{pmatrix} r_1 & r_2 & t_1 \\ r_3 & r_4 & t_2 \\ p_1 & p_2 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ 1 \end{pmatrix} \quad (3)$$

where x and y are the original coordinates of the wide face in the WE image, $x'$and y' are the coordinates after the projective transformation, and r_1 to r_4, t_1 and t_2, and p_1 and p_2 are the shear-rotational, translational, and projective coefficients of the transformation, respectively.

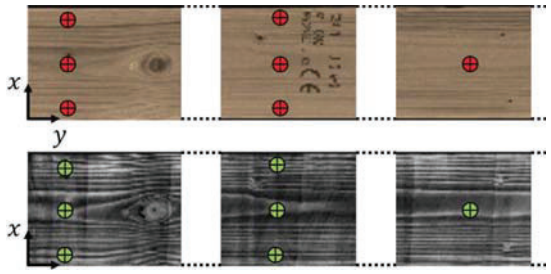

Figure 5: *Circle fitting in WE (top) and CT faces (bottom)*

Since a slight misalignment remained in the y-direction (lengthwise), cubic spline interpolation was used to map the y-coordinates of the transformed WE image (y') to a new set of y-coordinates (y'') that better match the CT image. The coefficients of the spline interpolation were calculated given the y-coordinates of the centres of the holes in the CT image along with the corresponding coordinates in the WE image after the projective transformation. The final transformation was composed of first applying the projective transformation and subsequently the spline interpolation.

The synchronisation needed to be performed separately for each surface of the sawn timber, and for each planing depth. Each calculated final transformation was applied to the corresponding WE data, i.e. both RGB and in-plane fibre orientation.

2.6 COMPARISON

The transformed WE data was compared to the untwisted CT image. The RGB images were converted to grayscale to visually compare it to the grayscale CT images. From the vector field $\boldsymbol{I}_{\mathrm{CT}}$, only the in-plane components were kept and compared to a vector field $\boldsymbol{I}_{\mathrm{WE}}$ which was derived from the WE orientations. Additionally, the absolute value of the in-plane angle $\mathrm{abs}(\alpha)$ of both representations was calculated and qualitatively compared in colour-coded plots.

3 RESULTS AND DISCUSSION

Below, the results of the synchronisation of a single piece of sawn timber are presented, for selected planing depths and primarily for the surface facing to the pith. The results differed little for the surfaces facing away from the pith.

3.1 SYNCHRONISATION MAPPING

Figure 6 shows the relative development of those parameters of the projective transformation matrix which were most different from zero, for increasing planing depth. The parameters associated with the perspective mapping differ before and after planing. The explanation for this is probably that when the holes were drilled with a handheld tool, the drill was not oriented perfectly perpendicular to the board face. Additionally, a human error factor was involved when manually locating the hole centres in the images.

Figure 7 shows the correction in y-direction from the spline interpolation after the projective transformation, for increasing planing depth. The characteristic of the correction is consistent for all planing depths, with decreasing amplitude at increasing planing depth, and with the profile being horizontally mirrored at mid-length of the board. The consistency of this transformation points to a systematic component in the distortion in the data.

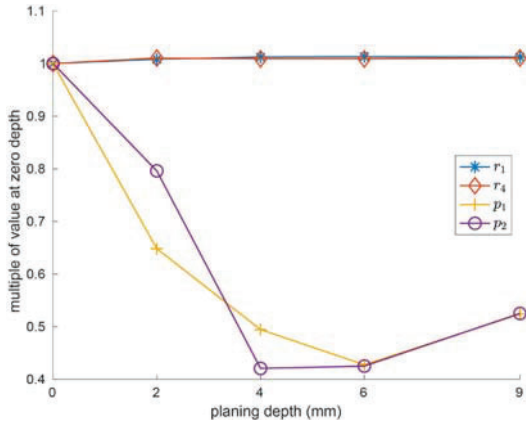

Figure 6*: Parameters of the projective transformation matrix as multiples of their respective values before planing*

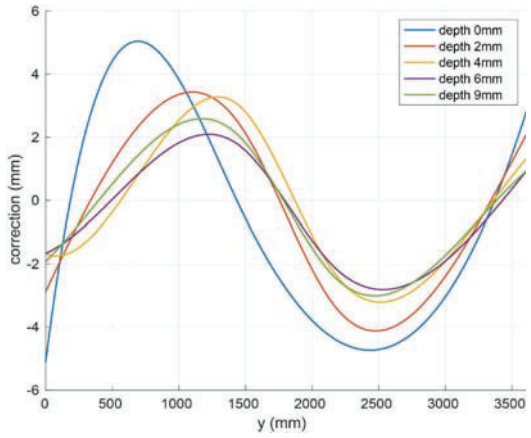

Figure 7*: Spline interpolation correction over the board length*

Figure 8 illustrates the alignment between WE and CT images for the surface of the board before planing, before and after the transformations at the positioning holes of one half of the board. After the projective transformation, a positioning error remained mostly at the holes towards the middle of the board. The error was decreased after the additional spline transformation.

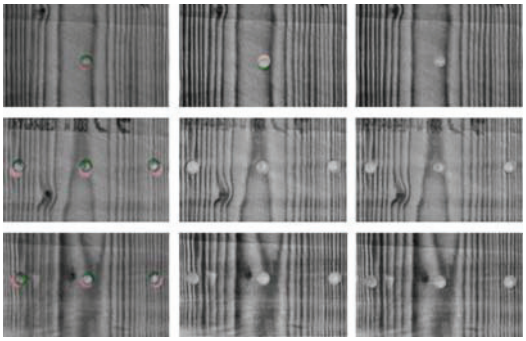

***Figure 8**: Hole alignment before transformation (left column), after projective transformation (middle), and after additional spline transformation (right), differences in red/green*

3.2 IN-PLANE FIBRE ORIENTATION

For a qualitative assessment, three regions along the board containing knots are reported, which comprised lengths of 160 mm in the proximity of the first, second and third row of positioning holes from one end of the board. Those regions will henceforth be referred to as region 1, 2 and 3.

Figures 9, 10 and 11 show the in-plane components of $\boldsymbol{l}_{WE}$ and $\boldsymbol{l}_{CT}$ plotted respectively on the transformed WE RGB image and the untwisted CT slice before planing of the surface facing the pith, and the corresponding angle, for regions 1, 2 and 3, respectively. Figures 12, 13 and 14 show the equivalent plots for a planing depth of 9 mm.

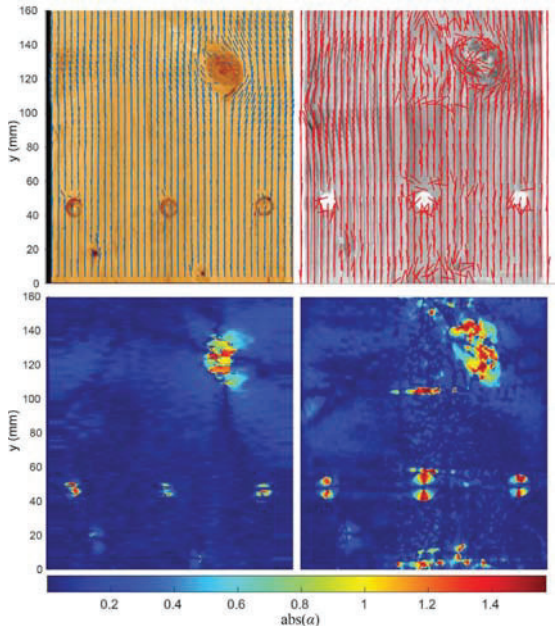

***Figure 9**: WE (left) and CT (right) in-plane vector fields (top) and orientation angle (bottom) for region 1 before planing*

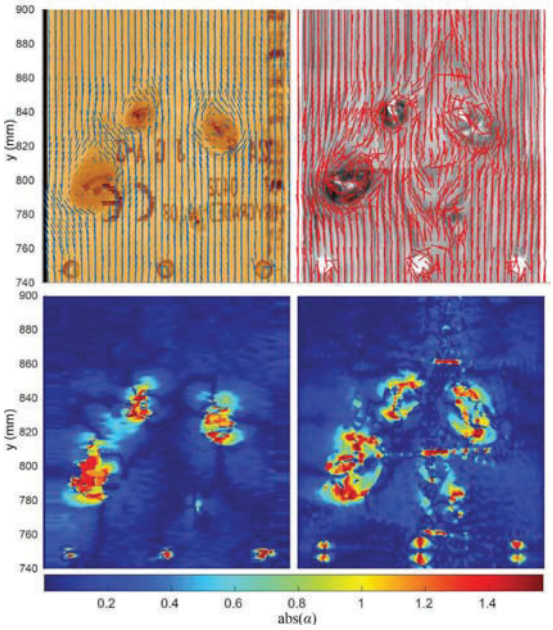

***Figure 10**: WE (left) and CT (right) in-plane vector fields (top) and orientation angle (bottom) for region 2 before planing*

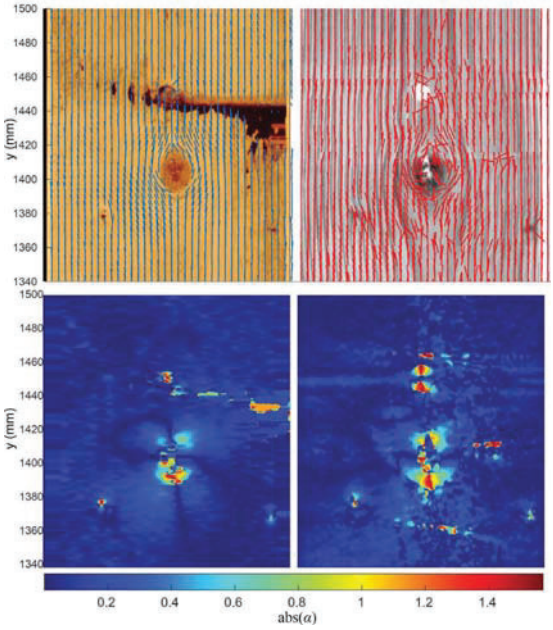

***Figure 11**: WE (left) and CT (right) in-plane vector fields (top) and orientation angle (bottom) for region 3 before planing*

Both, $\boldsymbol{l}_{WE}$ and $\boldsymbol{l}_{CT}$ reproduced a disturbed flow around the knots and a relatively laminar flow in regions without knots. Less variation existed in $\boldsymbol{l}_{WE}$ and the edges of the positioning holes were more clearly visible in $\boldsymbol{l}_{CT}$, due to the large density gradient between wood and air and the smaller pixel size in the CT image. However, $\boldsymbol{l}_{CT}$ was more sensitive to noise than $\boldsymbol{l}_{WE}$, in particular for the surface before planing, where the large density gradient between wood and air in the CT image affected the calculation of the GST. This effect is visible for regions 1 and 2 (Figures 9 and 10), where $\boldsymbol{l}_{CT}$ seems to follow the

https://doi.org/10.52202/069179-0057

apparent grain at the surface before planing, but it is less pronounced for the corresponding planed surfaces (Figures 12 and 13). Additionally, the plastic wrapping disturbed the calculation of $\boldsymbol{l}_{CT}$ in some regions where it was tightly packed. This is most clearly visible in Figure 10, where straight streaks across the surface in the CT image correspond to noise in α along equivalent streaks at the same locations. The field $\boldsymbol{l}_{CT}$ was generally more sensitive than $\boldsymbol{l}_{WE}$ to smaller knots and defects, due to its smaller original pixel size, resulting e.g. in deviations also around pitch pockets, see Figure 12.

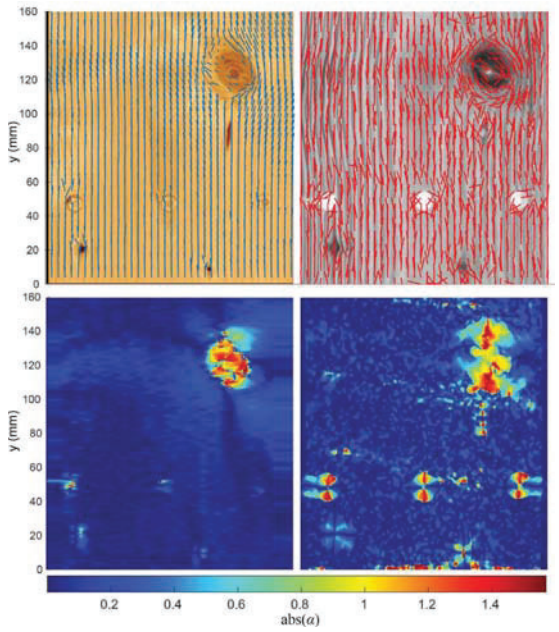

***Figure 12**: WE (left) and CT (right) in-plane vector fields (top) and orientation angle (bottom) for region 1 at a depth of 9 mm*

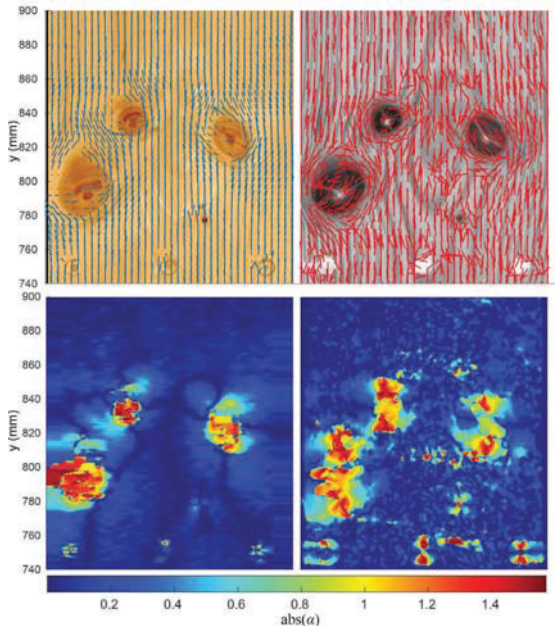

***Figure 13**: WE (left) and CT (right) in-plane vector fields (top) and orientation angle (bottom) for region 2 at a depth of 9 mm*

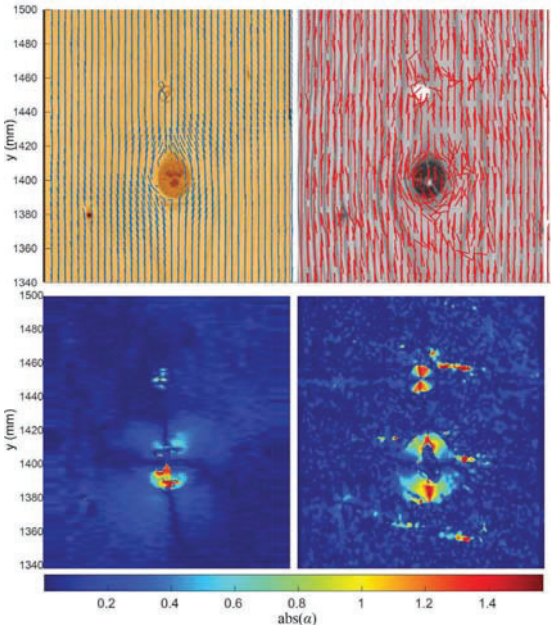

***Figure 14**: WE (left) and CT (right) in-plane vector fields (top) and orientation angle (bottom) for region 3 at a depth of 9 mm*

Figure 15 additionally shows the equivalent plot for region 2 before planing, but for the opposite side, i.e. the surface facing away from the pith. This surface included wane, which consequently affected the derived fibre orientations. For the CT image, vectors in the regions of wane can be removed easily by thresholding on density values. The field $\boldsymbol{l}_{CT}$ is notably affected by the apparent surface grain due to the surface effect described earlier.

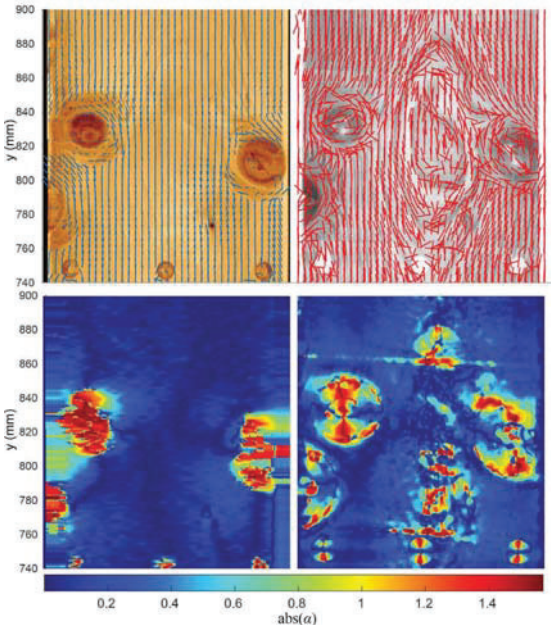

***Figure 15**: WE (left) and CT (right) in-plane vector fields (top) and orientation angle (bottom) for the surface facing away from the pith in region 2 before planing*

The field $\boldsymbol{l}_{CT}$ was strongly affected by the gradient out of plane in the shown image slices, e.g. inside knots where the *l*-direction followed the knot orientation, see Figure 16. For $\boldsymbol{l}_{WE}$, the out-of-plane component also followed the knot direction, but the in-plane component became generally less reliable due to small differences between the major and minor axes of the laser ellipse.

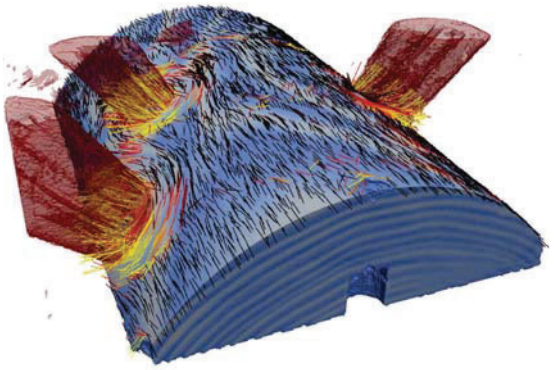

***Figure 16**: The field $\boldsymbol{l}_{CT}$ on a cylindrical cut around the pith in region 2 including segmented knot volumes*

4 CONCLUSION

In this study, optical scanning data of sawn timber was synchronised to corresponding CT images and the combined data set was used to compare and evaluate the fibre orientations derived from laser tracheid scanning and an image analysis-based method based on the density gradient structure. The results show that:

- a projective transformation in combination with a cubic spline interpolation for correction of the lengthwise position can synchronise the optical scanning data to a corresponding surface in the CT image,
- the in-plane fibre orientations calculated from the CT image gradients are qualitatively similar to the orientations derived from the optical data,
- the in-plane orientations from the CT image are more sensitive to noise and small defects, and they are less reliable on the original surface of the sawn timber.

The density gradient-based estimation of the fibre orientation should be further refined to reduce its sensitivity to noise. Further investigations are required on a larger number of samples to quantify the accuracy of this method, both in the vicinity of knots and in clearwood. To improve the accuracy of the synchronisation in future investigations, the location of the centres of the positioning holes should be automated, e.g. by ellipse fitting after an edge detection in the images, to minimise the effects of human error.

MODELLING THE EFFECT OF THREE-DIMENSIONAL GRAIN ANGLE ON THE TENSION STRENGTH OF BIRCH WOOD

Steven Collins[1], Joonas Jaaranen[2], Gerhard Fink[3]

ABSTRACT: In the present paper, the effect of three-dimensional grain direction on the tension strength of small-scale birch wood specimens is investigated. The grain angles are measured on all four surfaces of the specimens using laser light scattering technique, and afterwards, the specimens are destructively tested in tension. A numerical model is developed to predict the tensile strengths. The model is a combination of a linear elastic finite element model, with local orthotropic material orientations defined based on the measured grain orientations, and stress-based phenomenological failure criteria, with stress averaging. Strength predictions from the numerical model are compared to the experimental results, and, additionally, material strength properties are calibrated by minimizing the difference between the predictions and experimental results. A simple analytic model is further investigated and evaluated against the numerical model. Results indicate that the numerical model can predict the tensile strength of the specimens based on the measured grain angles. Stress averaging improved strength predictions by reducing localized stress peaks. Calibrated strength properties further improved the predictions and are compared with the literature. With only grain angle information, however, the numerical model does not significantly improve predictions, relative to the simple analytical model.

1 INTRODUCTION

Wood is a highly orthotropic material with much higher stiffness and strength in the longitudinal direction, compared to the transverse direction. As such, the strength of wood is dependent on fibre orientation (i.e., the grain angle), relative to the loading direction. The inclusion of grain orientation in material models may therefore improve the prediction of strength. For example, in [1], a three-dimensional (3D) material model was developed to consider the effect of knot related grain deviations on the bending strength of Scots pine. The results were validated experimentally, and the effect of knot type and knot combinations were considered in the simulation of various structural timber pieces. In another study [2], the 3D fibre direction was modelled, based on the surface grain direction obtained from laser scanning. The results indicate accurate simulations of local effects for timber boards of Norway spruce.

In previous experimental investigations on birch timber boards [3, 4], tension tests were conducted, and the tension failures often involved clear wood with grain deviations. However, methods for modelling the birch species (a diffuse porous hardwood), which consider grain orientation are lacking. Therefore, the purpose of this study was to develop and evaluate a numerical model for the prediction of tensile strength in birch small-scale clear wood specimens with known grain orientations.

2 EXPERIMENTAL INVESTIGATIONS

Data from small-scale tests specimens of silver birch wood from southern Finland was considered in this study. A total of 119 specimens were investigated. The specimens were sawn from the ends of timber boards with a wide range of grain angles [5]. The specimens are (dog-bone) shaped with a reduced gauge region of 200 mm in length (Figure 1). The radial and tangential directions of the wood are inconsistently oriented in the specimens and as such, a square cross section (w x t = 15 x 15 mm^2) was used in the reduced gauge region. The dimensions of the clamping region were l x w x t = 110 x 45 x 25 mm^3 with a 60 mm transition radius between the clamp and gauge regions. The specimens were conditioned in a climate chamber at 20ºC and 65% RH, according to international standard, ISO 13061-6 [6].

The grain angle was measured on the specimens by means of laser light scattering technique (for softwoods, termed the tracheid effect). Five laser points, spaced at 35 mm intervals, were shone on the surface, in the gauge region of the specimen, and digital images captured the elliptical reflection patterns. Figure 1a shows the laser light reflection patterns and the corresponding measurement locations. All four sides of the specimen were laser imaged. Local fibre direction is determined according to the major axis of an ellipse fit to the reflection patterns, see e.g., [7].

Boundary conditions are shown at the fixed and loaded (μ_x) ends. Element mesh size increased for illustrative purposes.*

Tension tests are subsequently conducted on the specimens using a universal testing device and the tension strength is determined according to the international standard, ISO 13061-6 [6]. The clamped area during testing was 80 x 45 mm^2. After testing, the failure mode of the specimens is analysed and documented [8].

Density was measured from a section of the gauge region after testing and the influence of density on the tension strength of this sample was investigated in a previous study [5]. Wherein, it was found that density had no unambiguous relationship with the tension strength. Therefore, density is not considered in the development of the numerical model.

3 NUMERICAL MODEL

The prediction model combines stress analysis by linear elastic finite element (FE) model with subsequent post-processing. In post processing, strength-based failure criteria with stress averaging were used to estimate the failure loads of the specimens.

3.1 STRESS ANALYSIS

The stress analyses were performed in Abaqus (Dassault Systèmes, Vélizy-Villacoublay, France) with a model of the axially loaded wood specimens, as illustrated in Figure 1c. The geometry follows nominal geometry of the actual specimens, and the model was meshed using eight-node brick elements with eight integration points (C3D8).

The mesh size was selected to have 15 x 10 elements over the specimen cross-section (note: in the figure, larger elements are used for illustration purposes). The material model was orthotropic, linear elastic, with constant properties over the whole specimen. The elastic properties were based on values for birch clear wood in [9] and are summarized in Table 1.

The grain orientations are accounted for by adjusting the local material orientations for each element. The local coordinate system is defined such that the 1-axis aligns with grain orientation and the transverse plane aligns with 23-plane.

The local orientations were determined from two grain angles, β_y and β_z (angles about the global y- and z-axes, respectively). For each element's centre point, local orientations were calculated by bilinear interpolation between the nearest measured in-plane grain angles, on opposite faces of the specimen. This is illustrated in Figure 1b. For example, the grain orientation β_z at arbitrary point (x,y,z) is obtained by interpolating between the four nearest measured grain angles $\beta_{z,i,j}$, with respect to x- and z-coordinates, while the value is constant in the y-direction. The same applies for β_y and the local grain orientation at the point is determined accordingly. Wood regions outside the limits of grain angle measurements, i.e., regions outside the gauge region, were modelled with constant grain direction according to nearest measured values.

https://doi.org/10.52202/069179-0058

Boundary conditions were applied to imitate gripping and loading in the universal testing machine. In the lower end of the specimen, all nodes on the wide faces of the gripping area are fixed in all directions. In the gripping area of the upper end of the specimen, displacement load u_x was applied in x-direction and the other directions were fixed.

For post-processing, the nodal coordinates, nodal stresses, and applied axial load F (sum nodal force in x-direction on loaded faces) were exported from each simulation. The stresses were in local coordinate systems of each node such that they can be directly used in the failure criteria. For the stresses, typical engineering notation convention is used, where σ_i are the axial stresses and τ_{ij} are the shear stresses. The indices refer to local material orientations. When referring to all the stress components at a certain point, a bold symbol $\boldsymbol{\sigma}$ is used to denote a stress vector.

Table 1: *Elastic properties in the FE model*

Property	
MOE par. to the grain E_1 [GPa]	16.3
MOE perp. to the grain $E_2 = E_3$ [GPa]	0.86
Longitudinal shear modulus $G_{12} = G_{13}$ [GPa]	1.05
Rolling shear modulus G_{23} [GPa]	0.19
Poisson's ratio $\nu_{12} = \nu_{13}$	0.46
Poisson's ratio ν_{23}	0.58

3.2 FAILURE CRITERIA

Local stresses, output from the FE model, were input into Matlab (Mathworks, Natick, Massachusetts, USA), where post-processing was performed for the prediction of tensile strength. The tensile strength was defined by most critically stressed point in the gauge region. Since there was data only for the grain orientation (longitudinal axis), but not for rotation angle of the tangential and radial axes of wood, only rotationally invariant transverse isotropic failure criteria were investigated here. Applicable criteria include Hashin criteria [10] and Tsai-Wu criterion [11]. They were originally created for composite materials but have also been widely utilised for wood. Transverse isotropic rotational invariance about 1-axis can be ensured by expressing the stress state in failure criteria in terms of following invariants [10]

$$I_1 = \sigma_1,\ I_2 = \sigma_2 + \sigma_3,\ I_3 = \tau_{23}^2 - \sigma_2\sigma_3,\quad I_4 = \tau_{12}^2 + \tau_{13}^2 \tag{1}$$

The failure criteria were based on the uniaxial strengths, namely, tensile strength parallel to the grain $f_{t,0}$, compressive strength parallel to the grain $f_{c,0}$, tensile strength perpendicular to the grain $f_{t,90}$, compressive strength perpendicular to the grain $f_{c,90}$, longitudinal shear strength f_v and rolling shear strength f_r.

The Hashin failure criterion [10] consist of four separate criteria, two for tensile modes and two for compressive modes. In this study, only the tensile failure modes were considered. The first mode (Equation 2) is "fibre tension" mode, which corresponds to failure parallel to the grain. The second mode (Equation 3) is "matrix tension" mode, which corresponds to failure perpendicular to the grain. In the equations, $\langle\ \rangle$ are Macaulay brackets denoting that $\langle x\rangle = x$ if $x > 0$, and $\langle x\rangle = 0$ otherwise.

$$\left(\frac{\langle\sigma_1\rangle}{f_{t,0}}\right)^2 + \frac{\tau_{12}^2 + \tau_{23}^2}{f_v^2} = 1 \tag{2}$$

$$\left(\frac{\langle\sigma_2 + \sigma_3\rangle}{f_{t,90}}\right)^2 + \frac{\tau_{23}^2 - \sigma_2\sigma_3}{f_r^2} + \frac{\tau_{12}^2 + \tau_{23}^2}{f_v^2} = 1 \tag{3}$$

Tsai-Wu [11] failure criterion consists of a single ellipsoidal failure surface in the stress space. Its transverse isotropic form is

$$\begin{aligned} &F_1\sigma_1 + F_2(\sigma_2 + \sigma_3) \\ &+F_{11}\sigma_1^2 + 2F_{12}\sigma_1(\sigma_2 + \sigma_3) + F_{22}(\sigma_2 + \sigma_3)^2 \\ &+F_{44}(\tau_{23}^2 - \sigma_2\sigma_3) + F_{55}(\tau_{12}^2 + \tau_{23}^2) = 1 \end{aligned} \tag{4}$$

in which F_i and F_{ij} are the strength parameters. They are defined in terms of uniaxial strengths as

$$\begin{aligned} F_1 = \frac{1}{f_{t,0}} - \frac{1}{f_{c,0}}, F_2 = \frac{1}{f_{t,90}} - \frac{1}{f_{c,90}}, \\ F_{11} = \frac{1}{f_{t,0}f_{c,0}}, F_{22} = \frac{1}{f_{t,90}f_{c,90}}, \\ F_{44} = \frac{1}{f_r^2}, F_{55} = \frac{1}{f_v^2} \end{aligned} \tag{5}$$

Parameter F_{12} (in Equation 4) is an off-axis strength parameter that, according to Tsai and Wu [11], should be determined based on off-axis tests. There exist also various approaches to estimate it from the other strength properties in the literature. However, in the present study, the criterion was simplified by setting $F_{12} = 0$.

3.3 STRESS AVERAGING

Purely stress-based strength predictions, without modelling related hardening or softening behaviour, assume a perfectly brittle material behaviour. However, stress-based criteria have been utilised also for quasi-brittle materials by stress averaging method [12, 13], which was also investigated in this study. Here, the averaging length was not derived from fracture mechanics since unambiguous fracture properties were not available, and the existing method for estimating the averaging length has been derived only for plane stress cases.

In the averaging approach adopted, the local stresses $\boldsymbol{\sigma}$ were replaced with average stresses $\overline{\boldsymbol{\sigma}}$ in the failure criteria (Equations 2-4). In this study, the same averaging is applied to all stress components. Averaged stresses at node k are computed by

$$\overline{\boldsymbol{\sigma}}_k = \frac{\sum_{p=1}^{N} w_{kp}\boldsymbol{\sigma}_p}{\sum_{p=1}^{N} w_{kp}} \tag{5}$$

where w_{kp} and $\boldsymbol{\sigma}_p$ are the weight and the stresses at point p. The weights are calculated with a Gaussian smoothing function, based on Euclidian distances d_{kp} between points k and p, as

$$w_{kp} = \exp\left(-\frac{d_{kp}^2}{l_c^2}\right) \quad (6)$$

where l_c is a length scale parameter. The length scale parameter is a distance after which the local stresses have relatively small contribution to the averaged stresses. The relation between the weight function and l_c is shown in Figure 2.

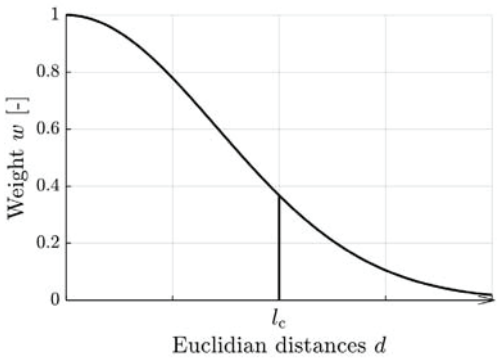

Figure 2: *Stress averaging weight factor w, as a function of Euclidian distance d to the surrounding FE nodes.*

3.4 ULTIMATE LOAD PREDICTION

Prediction of ultimate load was based on utilization ratio in the failure criteria and load F from the FE model. The utilization for point k was defined by the failure function in Equation (7), where $\overline{\boldsymbol{\sigma}}_{\boldsymbol{k}}$ is the averaged stress state at point k. Assuming proportional stresses, the ratio between failure stresses and applied stresses, g_k, was obtained by solving Equation (8). Furthermore, assuming linear elasticity, the ratio between ultimate load and applied load is equal to minimum g_k, and thus, the predicted failure load F_u can be estimated by Equation (9). Coordinates of the point with min(g_k) also give the estimated failure location.

$$f_k = f(\overline{\boldsymbol{\sigma}}_{\boldsymbol{k}}) \quad (7)$$

$$f_k(g_k \overline{\boldsymbol{\sigma}}_{\boldsymbol{k}}) = 1 \quad (8)$$

$$F_u = \min_{k=1\ldots N}(g_k)\, F \quad (9)$$

4 RESULTS

4.1 EXPERIMENTAL DATA

The failure modes were visually inspected and classified according to the five classes shown in Figure 3. A wide range of tension strength values, and grain angles are observed from the experimental investigations. Figure 4 shows the relationship between tension strength and the maximum 3D grain angle measured on the specimens. The grain angle has a clear influence on the strength. In most cases, the failure occurred within the gauge region of the specimens, however, specimens with splintering and longitudinal shear type failures (circle symbols) often had fractures that extend outside the gauge region and into the clamping zone. These specimens have greater scatter and present challenges for strength predictions.

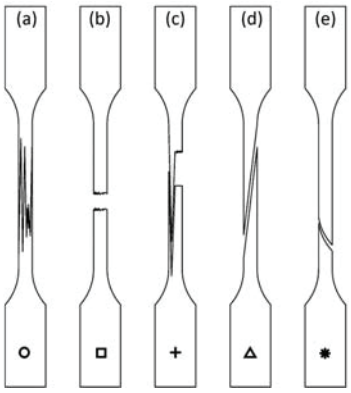

Figure 3. *Typical experimental failure modes used for classification: splintering/longitudinal shear (a), tension (b), combined tension & shear (c), sloping shear (d), and local (curved) grain deviation (e).*

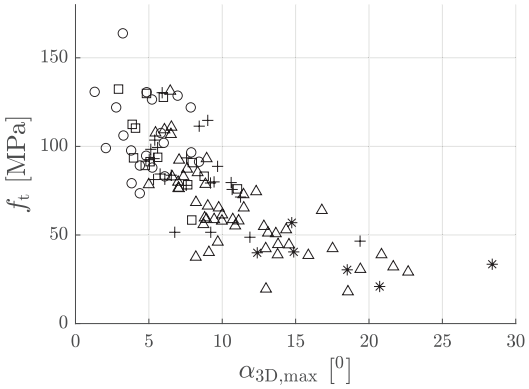

Figure 4: *Comparison between tension strength and measured maximum 3D grain angle.*

4.2 NUMERICAL MODEL

Figure 5 shows comparisons between the tensile strengths from the experimental tests and the predicted strengths according to the numerical models. The results are illustrated for the Hashin and Tsai-Wu failure criteria.

In all cases, stress averaging is applied, whereby the stress values obtained from FE analysis are effectively smoothed, i.e., the peak values are reduced, and the predicted strength values generally increase. Without stress averaging, the predicted strengths, using the initial strength values from literature (Table 2), are significantly underestimated, particularly for specimens of higher strengths. A range of l_c values (from 5 to 15 mm) were investigated and l_c = 5 mm was selected as it improves the initial results, i.e., the fit between predicted and experimental strengths. Nonetheless, l_c values up to 10 mm provide similar improvements. According to literature [14], averaging lengths from 4 mm to 20 mm are typical.

https://doi.org/10.52202/069179-0058

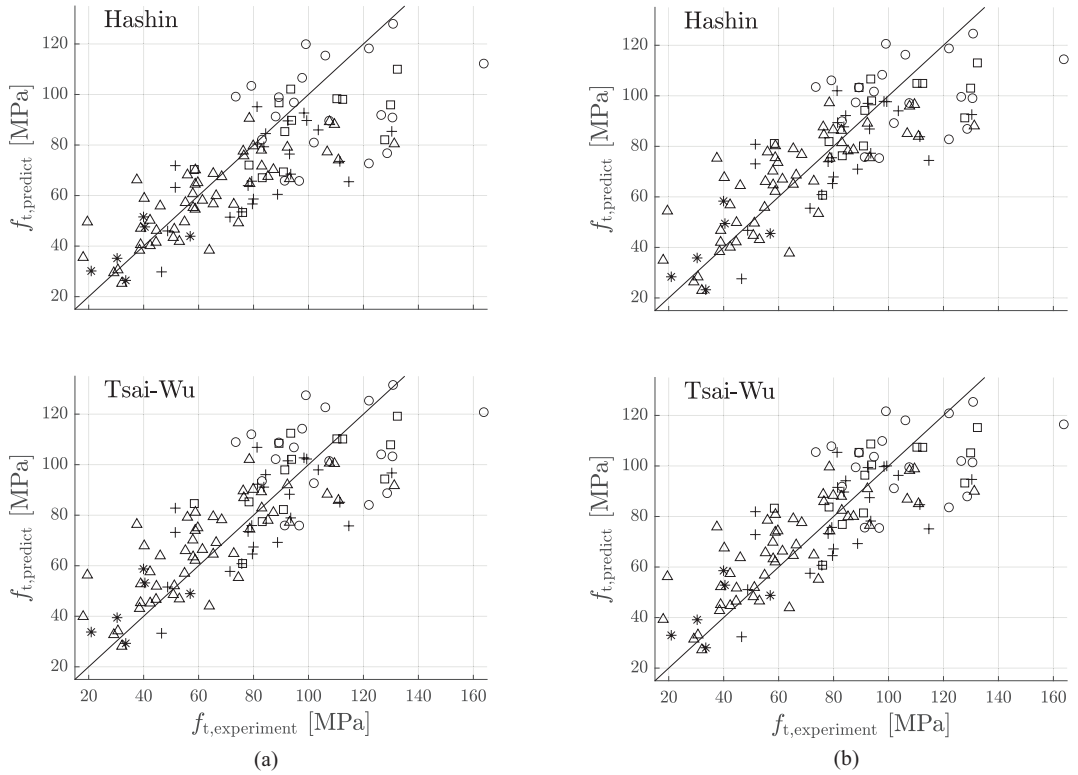

Figure 5. *Comparison between predicted and experimental strength for the Hashin and Tsai-Wu failure criteria when applying (a) strength values from literature, (b) calibrated strength values (calibrated to the whole sample). Stress averaging with l_c = 5 mm is applied in all cases.*

Table 2: *Initial and calibrated strength parameters. References for the initial parameters are shown next the values.*

	Initial	Hashin		Tsai-Wu		Hankinson	
	(uncalibrated)	Whole sample	Gauge	Whole sample	Gauge	Whole sample	Gauge
$f_{t,0}$ [MPa]	137 [15]	130	150	130	140	127	143
$f_{c,0}$ [MPa]	53 [16]	-	-	56	55	-	-
$f_{t,90}$ [MPa]	7.0 [15]	4.4	7.3	6.0	6.6	6.17	8.61
$f_{c,90}$ [MPa]	6.5 [16]	-	-	6.2	6.6	-	-
f_v [MPa]	12 [15]	15	13	13	12	-	-
f_r [MPa]	3.5 [17]	3.3	*	4.2	3.8	-	-
n	-	-	-	-	-	1.79	1.50

*Unstable parameter

Figure 5a illustrates the comparison when the strength properties from literature are considered. It is observed that the Hashin criterion underestimates specimens with higher strengths, yet the Tsai-Wu criterion has a minor bias towards overestimation of strength for the lower strengths and some underestimation for the highest strengths. Since the literature values (of which are generally lacking for silver birch) are from different source materials (excluding the compression strengths, they are determined from the same sample material), the literature values applied may not be ideal for the present sample.

An additional feature captured in the numerical model is the stress concentrations that develop around the curved tapering region of the dog-bone shaped specimen. This leads to predicted failures occurring more frequently in the ends of the gauge region, compared to the inner regions, and this behaviour is also exhibited experimentally.

Investigations into strength properties that are calibrated to the experimental results are conducted. Calibrated strength values are determined by simultaneously optimizing all uniaxial strength properties included in the failure criteria, by minimizing the sum of the squared residuals between

https://doi.org/10.52202/069179-0058

the predicted and experimental strengths. Stress averaging with l_c = 5 mm is maintained. Calibration is performed on both the whole sample and only on specimens that have failed within the gauge region (gauge specimens). Specimens with splintering or longitudinal shear type failure are predominantly those which have failures extending outside the gauge region. Effects from the test setup for specimens with failures extending into clamped region is not captured in the model and may have higher strengths, compared to the model predictions.

The strength properties after calibration are given in Table 2 and Figure 5b illustrates the comparison between experimental and predicted results, according to the calibrated strength properties for the whole sample. The calibrated strengths generally agree with the values from literature, although some considerable differences are obtained. The tension strengths (parallel and perpendicular to grain) calibrated to the whole sample are notably lower than the literature values, especially for Hashin. Calibrations with the gauge specimens and Tsai-Wu criteria largely concur with the literature values. For Hashin, calibrations with the gauge specimens provide similar values to literature except the tension strength parallel to the grain is, in this case, rather high.

Overall, the error when applying calibrated predictions (whether the whole sample or the gauge specimens are considered) is only slightly lower compared to the error when applying literature values, with mean absolute errors around 14 MPa and 15 MPa, respectively. The main difference when calibrating with only the gauge specimens compared to calibrating using the whole sample, is, as expected, larger scatter of the splintering/longitudinal shear type failure but a better estimate of the lower strength specimens, mainly the specimens with sloping shear type failures.

According to the failure criteria, the strength properties with the largest influence on the utilization ratio include tension strength parallel and perpendicular to the grain and the longitudinal shear strength. The model is relatively insensitive to the rolling shear strength values, and as such, the calibrated values may be extreme. The rolling shear was an unstable strength parameter when calibrating to the gauge specimens with Hashin criteria, and for predictions, the literature value was used in this case. It is also mentioned that the compression strength properties in Tsai-Wu may not be representative of the actual compression strengths since they are calibrated in absence of compression experimental data.

4.3 STRENGTH PREDICTION USING THE ANALYTICAL MODEL

To evaluate the numerical model's performance against a well-established analytical model, the generalized Hankinson's formula is considered. It defines off-axis tensile strength $f_{t,\alpha}$ as

$$f_{t,\alpha} = \frac{f_{t,0} f_{t,90}}{f_{t,0} \sin^n \alpha + f_{t,90} \cos^n \alpha} \tag{11}$$

where α is the angle between the load and the grain orientation, and n is a generalization parameter that is optimized by fitting the equation to the sample data, Generalization parameters within the range of 1.5 to 2.0 are typically regarded as suitable for predicting the (off-axis) tensile strength of wood [18].

The maximum 3D grain angle measured on the specimens are used in the formula. The strength properties and generalization parameter are calibrated to the data considering the whole sample and the gauge specimens. The calibrated parameters are given in Table 2. Figure 6 provides a comparison between the experimental and the predicted strengths, according to Hankinson's formula with strength properties calibrated to the whole data set.

The strength predictions of the analytical model are rather similar, in terms of error, when compared to the numerical model developed in this study. Indeed, compared to the analytical model, no significant improvement in the strength predictions was realized with the numerical model. An explanation to the similar results is given by analysis of the predicted failure locations. The location of failure is predicted for each specimen according to the most critical node. The critical node was frequently at the location of maximum 3D grain angle, which (due to the used interpolation method) is near the laser point measurements. In fact, the correlation coefficient between maximum 3D grain angle location and predicted failure location (for both failure criteria) was around 0.9. As such, both the numerical model and analytical model provide strength predictions largely based on the maximum measured 3D grain angle.

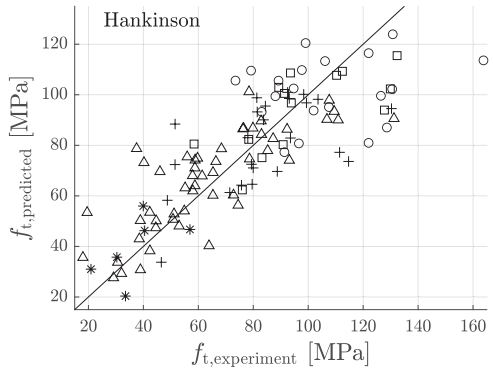

Figure 6: *Comparison between predicted and experimental strength for the Hankinson analytical model with strength properties and exponential parameter n calibrated to the whole sample.*

5 CONCLUSION AND OUTLOOK

In the present paper, a numerical model is developed for the prediction of tension strength of small-scale birch wood specimens with measured grain angles. The strength was predicted according to local stresses obtained from

https://doi.org/10.52202/069179-0058

the finite element model and two failure criteria, Hashin and Tsai-Wu, with a stress averaging approach. The model is compared to the experimental results and a simple analytical model. Results indicate:

- The maximum grain angle is a good indicator of strength. The predicted failure location of the model occurred around the location of the maximum measured 3D grain angles.
- The performance of the numerical model was limited by the information available of the test specimens. With grain angle being the driving indicator for strength, the maximum grain angle within the gauge region was the dominant factor in the strength predictions.

Potential future developments to the presented numerical model include the following:

- Associate the material properties (strength and stiffness) with various growth features identified on each specimen, such as growth ring width, distance to pith, or eigenfrequency. Use correlations between the growth features and the mechanical properties to estimate the material properties applied to the model and corresponding predictions.
- Include information about the location of the pith in the analysis. This way the material can be modelled with cylindrical orthotropy, i.e., tangential, and radial orientations can be defined, and orthotropic failure criteria can be used with related orthotropic strength properties.
- Increase the number of grain angle measurements (laser points) and measure also diving angles to better represent the grain flow of the specimen and the maximum grain angle.
- Consider the actual fracture process in the simulations. This can be implemented via damage or fracture mechanics-based formulations such as smeared crack models (local or non-local damage) or discrete crack models, e.g., cohesive cracks with extended finite element method.

EFFECTS OF THE CROSS-LINKING OF THE CELLULOSIC FIBRILLAR NETWORK ON THE EFFECTIVE MACROSCOPIC BEHAVIOUR OF WOOD

Nhat-Tung Phan[1], François Auslender[1], Joseph Gril[1,2], Rostand Moutou Pitti1[1,3]

ABSTRACT: This study aims at analysing the influence of the fibrils oscillations and interconnexions on the macroscopic behaviour of wood. For that, a multi-scale model of softwood has been developed, with two options for the cell-wall level: a reference with no oscillations (0S) and oscillations and interconnexions in two directions (2S). The cell-wall and tissue effective behaviours are determined by using numerical homogenization for periodic media, while the succession of earlywood and latewood is dealt with analytically. It is observed that the influence of the fibrils oscillations is significant for some macroscopic moduli, such as the effective shear moduli $\widetilde{G}_{LT}$ and $\widetilde{G}_{LR}$, while it isn't for other moduli at the macroscopic level. Furthermore, although the effect of the interconnexions is quite strong for some components of the elastic behaviour at the cell wall level, it would lose its significance at the macroscopic level, especially for low-density wood. This tendency can be explained by the interaction of layers from two neighbouring cells that compensate for the absence of interaction between fibrils in the 0S model. The effect becomes stronger in the case of a softened matrix.

KEYWORDS: macroscopic behaviour, hierarchical models, numerical homogenization, fibrils oscillations.

1 INTRODUCTION

Wood is one of the longest-standing and most universal materials used by humans. In response to environmental changes, population growth, and increasing standard of living, the global demand for lignocellulose material has accelerated [1]. The advantages of this material are mainly its availability and its excellent mechanical performance relative to the density, explained by its structural organization [2].

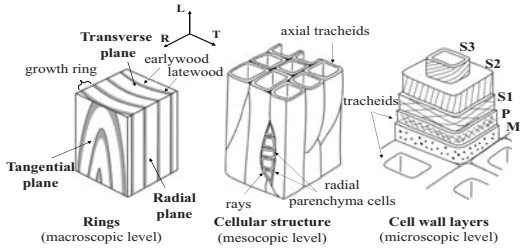

Figure 1: *Hierarchical structure and anisotropy of a softwood*

However, the study of wood has revealed a large variability of mechanical properties and various scales of heterogeneity. Thus, a better understanding of structure-property relationships is required to improve our capacity to design wood-derived products. Since wood is considered as a natural composite material with a complex multiscale organization, its behaviour is a consequence of both the deformation mechanisms of its constituents and their spatial distribution at different scales. In this study, having in mind the case of a softwood, we will then describe wood at three main levels (see Figure 1): the macroscopic level - scale of the grown-rings, the mesoscopic level - scale of the tissues, and the microscopic level - scale of the cell walls.

This paper aims to investigate the influence of a more realistic cell wall morphology on the macroscopic behaviour of wood by considering curved and interconnected fibrils, rather than considering them parallel as classically in the literature [3, 4, 5]. To this end, we develop a multiscale model incorporating three different scales of wood microstructure as described above, ranging from cell walls to annual grown-rings, from which both numerical and analytical homogenization methods will be used to determine their effective behaviour by defining a periodic elementary cell at each scale considered.

2 METHODOLOGY

2.1 MULTI-SCALE MODEL

2.1.1 An anisotropic material at all scales: from the secondary wall to the growth-ring

The illustration of the hierarchical structure of the wood at different scales in Figure 1 highlights the preferred

directions at each level. In this research, we make use of three orthonormal frames with in each case the first direction corresponding to the one with the most resistance and rigidity. They are represented in Figure 2 for the three considered levels. The three reference frames are: (L, R, T) for the growth-rings level, (1', 2', 3') for the tissues level and (1, 2, 3) for the cell walls level.

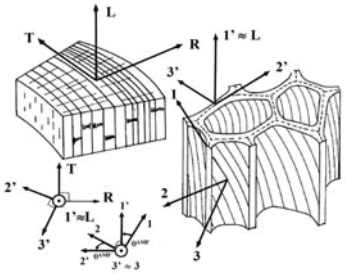

Figure 2: *Macroscopic, mesoscopic and microscopic orientations [6].*

2.1.2 Description of the wood microstructure at the 3 relevant scales

a) Wood cell wall microstructure

In the literature, the macrofibrils have classically been assumed to be straight and parallel to each other (Figure 3a). However, some experimental characterizations [7, 8] suggest that this is not the case and that the macrofibrils are curved and connected to each other [9]. These suggestions are similar to the models of an oscillating cellulose network originally proposed by Boyd [10], and later used by Gril [6].

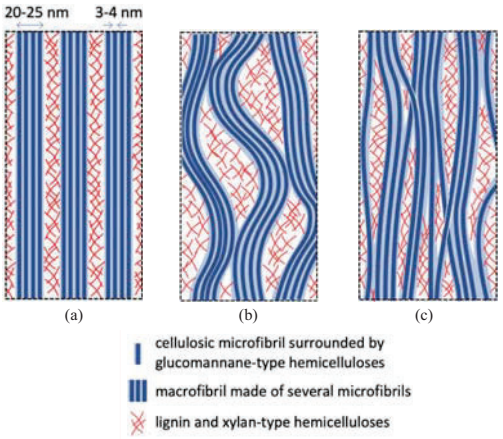

Figure 3: *Interpretation of the interconnexions between macrofibrils:* ***(a)*** *classical representation with straight and parallel microfibrils;* ***(b)*** *Oscillations and lateral contacts between macrofibrils through hydrogen bonding;* ***(c)*** *connexions resulting from the random transfer of oscillating microfibrils between neighbouring macrofibrils [11].*

Furthermore, this oscillating structure may be the reason for the puzzling orientation interpreted from tomography [12]. As to the nature of the links between macrofibrils, it can be speculated that macrofibrils oscillate by slight deviations from their main direction, and occasionally get into contact through hydrogen bonding with neighbouring macrofibrils (Figure 3b). An alternative explanation is that some of the microfibrils composing a macrofibril could occasionally shift to the neighbouring one, resulting in stronger connections (Figure 3c). In any case, it seems reasonable to assume the existence of a network of macrofibrils laterally connected, separated by lignified matrix incrustations with more or less lenticular shapes, and both interpretations would be compatible with the subsequent modelling approach. For the sake of simplification, the macrofibrils will be simply be called fibrils in what follows.

From the schematic description of the secondary walls proposed by Boyd [10], we assume that the fibrils oscillate around a principal direction, that we name direction 1, corresponding to the one defined by the MFA (Figure 4a). Taking the case of perfectly aligned fibrils as a reference (Figure 4b), we will examine the effect of oscillated fibrils (Figure 4c). In this study, we will describe oscillations for which the fibrils can oscillate within both planes (1, 2) and (1, 3).

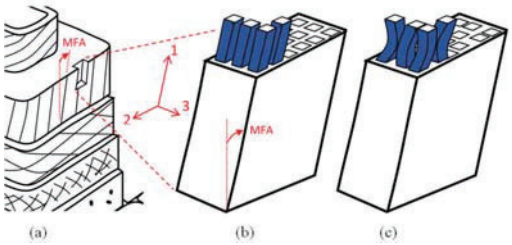

Figure 4: *Representation of the material constituting the secondary cell wall:* ***(a)*** *position and orientation of a portion of the cell wall,* ***(b)*** *classical representation with straight and parallel fibrils and* ***(c)*** *improved description with oscillated and connected fibrils [11].*

In order to analyse the influence of oscillated and connected fibrils on the effective behaviour of the cell wall, two periodic elementary cells that correspond to the 0S and 2S models, respectively, are meshed (Figure 5). The cell wall material is assumed to be the periodic repetition of each of the represented elementary cells.

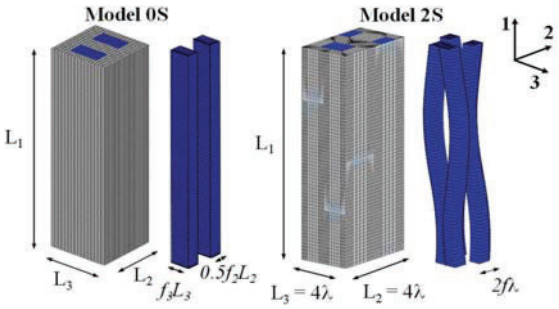

Figure 5: *two different morphological models to describe the periodic elementary cell (Cast3M)*

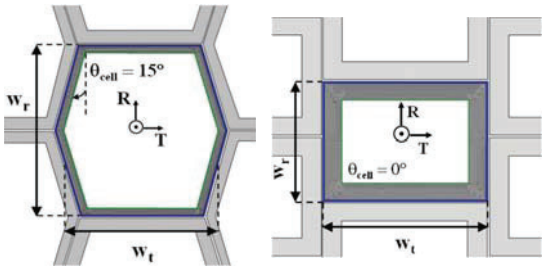
b) Cellular tissue microstructure

The tissue microstructure of wood is modelled on the basis of anatomical and morphological descriptions of the structure of wood at the tissue level, considering tissues composed only of longitudinal tracheids. We will thus neglect the parenchyma rays which are a minor component of softwood. The studied microstructure being

supposed to be periodic, we will consider a periodic unit cell to represent it and calculate its effective behaviour. Moreover, this elementary cell will be constructed by integrating additional assumptions, frequently used in the literature [13, 14, 15]:

- Invariance of the tissue structure in the longitudinal direction L, i.e. longitudinal irregularities at the points where the tracheids meet end to end are ignored;
- Invariance of the local density in the longitudinal direction.

Based on typical morphological parameters of softwoods at the tissue scale [16], earlywood (EW) and latewood (LW) are described as tissues consisting of a periodic arrangement of tissue microstructures of EW (Figure 6a) and LW (Figure 6b), respectively. Furthermore, each wall of the tissue microstructure consists of 3 layers (S1, S2, and S3), incorporating the primary wall and the middle lamella in the S1 layer.



(a) Model EW (a) Model LW

Figure 6: *Geometric description of the two microstructures of EW and LW in the RT plane.*

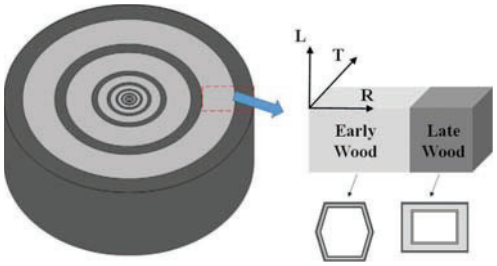


Figure 7: *Schematically idealized model for the annual ring*

c) Growth-ring microstructure

At the macroscopic scale, wood is described as a periodic arrangement of orthotropic homogeneous layers of EW and LW, without taking into account the curvature of the rings (see Figure 7). Although in reality the transition between EW and LW is gradual, the choice of a ring consisting of two layers has been made in order to achieve an equivalent effect in terms of contribution to transverse anisotropy.

2.2 CALCULATION OF THE EFFECTIVE BEHAVIOUR

On the one hand, we determine the effective elastic behaviour at both the cell wall and tissue scales by using a numerical homogenization procedure for its periodic microstructures in the first two steps of the developed multiscale model. On the other hand, the macroscopic elastic properties of the wood corresponding to the succession model of EW and LW are determined analytically and correspond to the last step of the multiscale model. Furthermore, the interaction of the material parameters between the different levels of the multiscale model are also taken into account**.**

2.2.1 Local problem

For determining the effective elastic properties of the different periodic microstructures, we make use of a deformation approach and apply to each periodic unit cell periodic boundary conditions of the type $\underline{u}(\underline{x}) = \underline{\underline{\varepsilon}}\,\underline{x} + \underline{u'}(\underline{x})$ where $\underline{\underline{\varepsilon}}$ is the imposed macroscopic strain and $\underline{u'}(\underline{x})$ a periodic displacement field [17]. The local problem to be solved reads as follows:

$$\left\{\begin{array}{l} \left.\begin{array}{l} \underline{div}\left(\underline{\underline{\sigma}}(\underline{x})\right) = 0 \\ \underline{\underline{\sigma}}(\underline{x}) = \underline{\underline{\underline{\underline{C}}}}(\underline{x}) : \underline{\underline{\varepsilon}}(\underline{x}) \\ \underline{\underline{\varepsilon}}(\underline{x}) = \frac{1}{2}\left(\frac{\partial \underline{u}(\underline{x})}{\partial(\underline{x})} + \frac{\partial \underline{u}(\underline{x})^T}{\partial(\underline{x})}\right) \end{array}\right\} \forall x \in \Omega \\ u(\underline{x}) = \underline{\underline{\varepsilon}}\,\underline{x} + u'(\underline{x}), \text{ with periodic } u', \forall x \in \partial\Omega \end{array}\right. \quad (1)$$

where Ω stands for the RVE, i.e. the periodic unit cell, and $\partial\Omega$ the cell boundary. The fourth-order tensor $\underline{\underline{\underline{\underline{C}}}}(\underline{x})$ is given by:

$$\underline{\underline{\underline{\underline{C}}}}(\underline{x}) = \sum_{r=M,F} \underline{\underline{\underline{\underline{C}}}}^r . \chi^r(\underline{x}) = \underline{\underline{\underline{\underline{C}}}}^M . \chi^M(\underline{x}) + \underline{\underline{\underline{\underline{C}}}}^F . \chi^F(\underline{x})$$

where $\chi^r(\underline{x})$ is the characteristic function of the phase *r,* equal to 1 if $\underline{x}$ belongs to the phase *r* and zero otherwise. The tensors $\underline{\underline{\underline{\underline{C}}}}^r$ are the tensors of the elastic moduli of the phases r.

2.2.2 Numerical homogenization

To calculate the effective behaviour of a periodic elementary cell corresponding to the cell wall (Figure 5) and tissue (Figure 6) microstructures, we make use of a deformation approach and apply periodic boundary conditions (PBC).

By applying 6 different elementary loadings to the periodic unit cell and solving by means of the FE method the local problem, we obtain for each elementary loading the local stress field, thus allowing us to determine the macroscopic stress which is classically defined by:

$$\overline{\underline{\underline{\sigma}}} = \langle \underline{\underline{\sigma}} \rangle = \frac{1}{|\mathrm{VER}|} \int_{\mathrm{VER}} \underline{\underline{\sigma}}(\underline{x}) d\underline{x} \quad (2)$$

The tensor of the effective elastic moduli $\tilde{\mathrm{C}}$ of the cell wall is then obtained by the following relation

$$\overline{\underline{\underline{\sigma}}} = \underline{\underline{\underline{\underline{\tilde{C}}}}} : \overline{\underline{\underline{\varepsilon}}} \quad (3)$$

which, by using Voigt notations, can be rewritten as

$$\begin{pmatrix} \bar{\sigma}_1 \\ \bar{\sigma}_2 \\ \bar{\sigma}_3 \\ \bar{\sigma}_4 \\ \bar{\sigma}_5 \\ \bar{\sigma}_6 \end{pmatrix} = \begin{pmatrix} \tilde{C}_{11} & \tilde{C}_{12} & \tilde{C}_{13} & \tilde{C}_{14} & \tilde{C}_{15} & \tilde{C}_{16} \\ \tilde{C}_{21} & \tilde{C}_{22} & \tilde{C}_{23} & \tilde{C}_{24} & \tilde{C}_{25} & \tilde{C}_{26} \\ \tilde{C}_{31} & \tilde{C}_{32} & \tilde{C}_{33} & \tilde{C}_{34} & \tilde{C}_{35} & \tilde{C}_{36} \\ \tilde{C}_{41} & \tilde{C}_{42} & \tilde{C}_{43} & \tilde{C}_{44} & \tilde{C}_{45} & \tilde{C}_{46} \\ \tilde{C}_{51} & \tilde{C}_{52} & \tilde{C}_{53} & \tilde{C}_{54} & \tilde{C}_{55} & \tilde{C}_{56} \\ \tilde{C}_{61} & \tilde{C}_{62} & \tilde{C}_{63} & \tilde{C}_{64} & \tilde{C}_{65} & \tilde{C}_{66} \end{pmatrix} \begin{pmatrix} \bar{\varepsilon}_1 \\ \bar{\varepsilon}_2 \\ \bar{\varepsilon}_3 \\ \bar{\varepsilon}_4 \\ \bar{\varepsilon}_5 \\ \bar{\varepsilon}_6 \end{pmatrix} \quad (4)$$

https://doi.org/10.52202/069179-0060

where $\overline{\sigma}_i = \overline{\sigma}_{ii}$, $\overline{\varepsilon}_i = \overline{\varepsilon}_{ii}$ for i = 1 to 3 and $\overline{\sigma}_4 = \overline{\sigma}_{23}$; $\overline{\sigma}_5 = \overline{\sigma}_{13}$; $\overline{\sigma}_6 = \overline{\sigma}_{12}$ and $\overline{\varepsilon}_4 = 2\overline{\varepsilon}_{23}$; $\overline{\varepsilon}_5 = 2\overline{\varepsilon}_{13}$; $\overline{\varepsilon}_6 = 2\overline{\varepsilon}_{12}$.

For instance, if we apply an elementary loading of the form $\underline{\underline{\varepsilon}} = \underline{e}_1 \otimes \underline{e}_1$, the first column of the second-order tensor $\underline{\underline{\widetilde{C}}}$ is given by:

$\widetilde{C}_{11} = \overline{\sigma}_1 = \langle\sigma_{11}\rangle$; $\widetilde{C}_{21} = \overline{\sigma}_2 = \langle\sigma_{22}\rangle$; $\widetilde{C}_{31} = \overline{\sigma}_3 = \langle\sigma_{33}\rangle$; $\widetilde{C}_{41} = \overline{\sigma}_4 = \langle\sigma_{23}\rangle$; $\widetilde{C}_{51} = \overline{\sigma}_5 = \langle\sigma_{13}\rangle$; $\widetilde{C}_{61} = \overline{\sigma}_6 = \langle\sigma_{12}\rangle$.

Accordingly, the application of 6 independent elementary loadings provide the whole effective tensor $\underline{\underline{\widetilde{C}}}$ of elastic moduli.

Moreover, by symmetry arguments related to the geometry of the elementary cell and the phase behaviour, it is shown that the effective behaviour of both the cell wall and tissue is necessarily orthotropic.

2.2.3 Analytical homogenization

The macroscopic behaviour of wood in the (L, R, T) directions is calculated by using an analytical solution for a bi-laminate consisting of the periodic repetition of two orthotropic elastic layers of earlywood and latewood (see Figure 7).

3 RESULTS AND DISCUSSION

In this work, we make use of the above-mentioned multiscale approach was used in this research to study the relationships between wood microstructure and its elastic properties. More specifically, this work aims to analyse through parametric studies the influence of oscillated and interconnected fibrils within the cell wall on the elastic effective properties of wood at three different scales.

3.1 THE CELL WALL LEVEL

The parametric studies are performed for both microstructure models (0S) and (2S) of the cell wall by varying different geometrical parameters such as the shape ratio $r_\varphi = L_1/L_2$, the fibril volume fraction c, the ratio of lamellar matrix on lenticular matrix $r_\lambda = V_{\text{lamellar matrix}}/V_{\text{lenticular matrix}}$ and material parameter (phase contrast: ratio E_L^F/E^M where E_L^F is the longitudinal Young's modulus of the fibrils and E^M is the Young's modulus of the matrix). Three effects associated with the fibrils oscillations are highlighted: those induced by the orientation of the fibrils, by the contact between the fibrils, and finally by the heterogeneous spatial distribution of the matrix between the oscillating fibrils (see Figure 8).

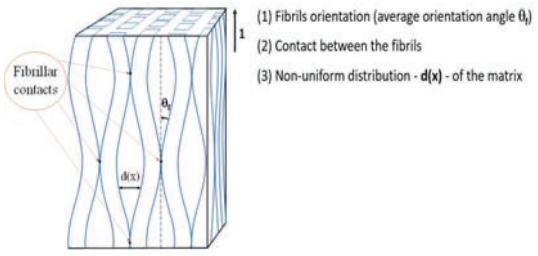

Figure 8: *Illustration of the 3 effects induced by the undulations of the fibrils.*

Furthermore, it is observed that the 2S model have a significant impact on the effective coefficients $\widetilde{C}_{12}$, $\widetilde{C}_{66}$ and $\widetilde{C}_{13}$, $\widetilde{C}_{55}$ which are significantly influenced by the fibril oscillations in the (1, 2) plane and (1, 3) plane, respectively. Besides, the 2S model is able to take into account the influence of oscillated fibrils in the (2, 3) plane by the observations associated with the effective coefficients et $\widetilde{C}_{23}$, $\widetilde{C}_{44}$, respectively.

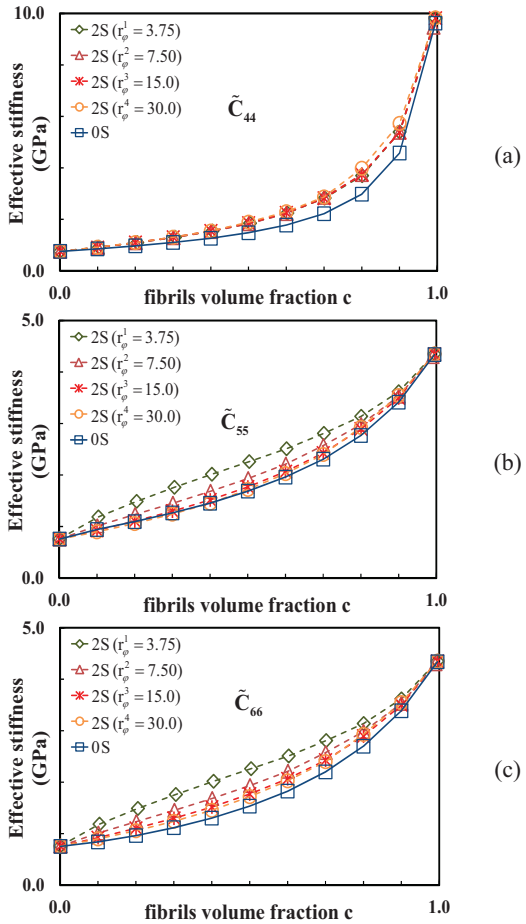

Figure 9*: Variations of the effective moduli $\widetilde{C}_{ij}$ as functions of the volume fraction (r_λ = 1)*

3.2 THE TISSUE LEVEL

Following the observations carried out at the cell wall level, we have shown at the tissue scale that the influence of the oscillated and interconnected fibrils increases with the relative density of the tissue. However, although the effects induced by the fibril oscillations are quite strong for some components of elastic behaviour at the cell wall scale, it loses its importance at the tissue level, especially for low density wood. This trend can be explained by the antisymmetric sloping of microfibrils in adjacent cell walls. Thus, for denser wood where the interaction between adjacent cell walls is less dominant, the effect of fibril oscillations remains significant. To highlight these results, we present in Figure 10 the evolutions of the 3

effective shear moduli $\widetilde{G}_{ij}$ as a function of relative density (wood density divided by cell-wall density) for the latewood case.

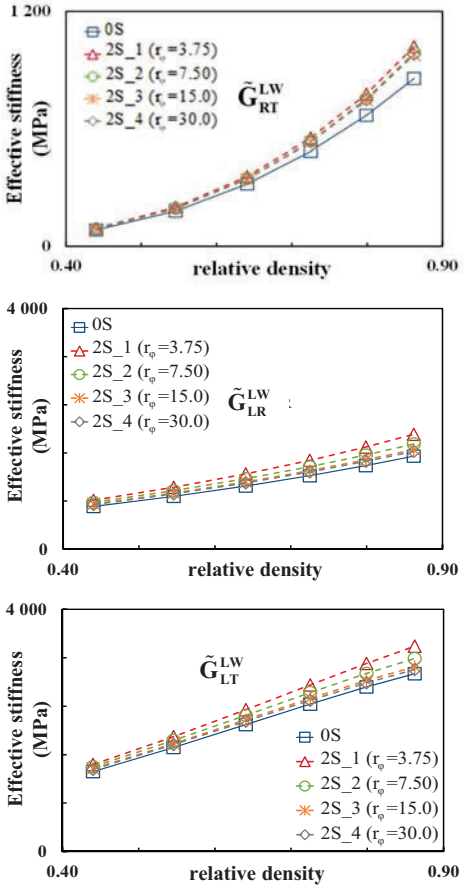

Figure 10: *Evolution of the effective $\widetilde{C}_{ij}$ components as a function of relative density for the LW model with the different data associated with the 0S and 2S models*

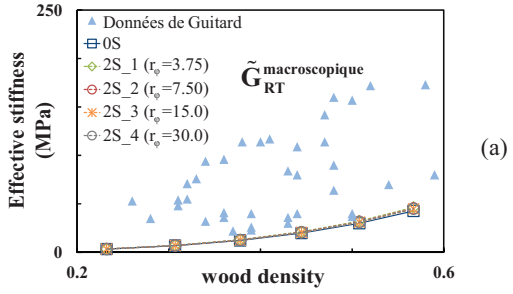
3.3 THE GROWN-RING LEVEL

Based on Figure 11, the study of the influence of fibril oscillations on the macroscopic behaviour of wood via the presented multiscale model shows that the results obtained are similar to those observed at the grown-ring level. In addition, we also present for comparison purposes the experimental data of Guitard [18] for softwood.



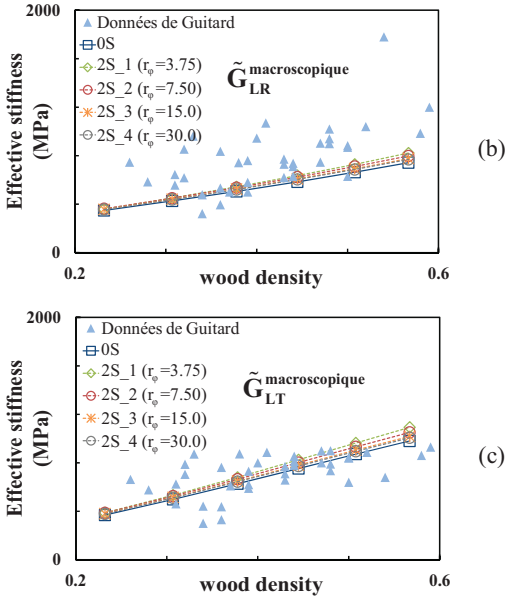


Figure 11: *Evolution of the effective moduli $\widetilde{C}_{ij}$ as a function of wood density for the two microstructures 0S and 2S*

4 CONCLUSION AND PERSPECTIVES

Using the presented multiscale model, we showed that the influence of the oscillated and interconnected fibrils is significant for some macroscopic moduli, such as effective shear moduli, while it is not significant for other moduli at the macroscopic level (grown-ring scale). Furthermore, the proposed multiscale model provides macroscopic elastic properties and their evolutions as a function of wood density which are close to those observed experimentally for softwoods, with the exception of the modulus $\widetilde{G}_{RT}$ which is strongly underestimated. Lastly, although the effect of fibril crosslinks is quite strong for some components of the elastic behaviour at the cell wall level, it loses its importance at the macroscopic level, especially for low-density wood.

In order to study the influence of fibril oscillations not only on the effective elastic properties of wood at the three scales considered, an extension of the presented procedure to the case of linear hygro-elastic behaviour, has been developed within the multiscale model. It is based on FE calculations associated with the linear thermo-elasticity model, has been developed within the multi-scale model. This procedure allows to take into account the deformations induced in the absence of mechanical loading by an increase (respectively a decrease) of the water content which leads to a swelling (respectively a shrinking) of the wood.

A MULTI-PHASE HYGRO-THERMAL MODEL FOR WOODEN BRIDGE COMPONENTS EXPOSED TO SOLAR RADIATION

Stefania Fortino[1], Petr Hradil[2], Timo Avikainen[3], Keijo Koski[4], Ludovic Fülöp[5]

ABSTRACT: This study demonstrates the modelling assisted long-term monitoring of wooden bridge components with surfaces exposed to solar radiation. An improved multi-phase finite element model is developed to predict the distribution of moisture content, relative humidity and temperature in wood. Hygro-thermal measurements are collected from the monitoring system of the stress-laminated Tapiola Bridge in Finland. The monitoring uses integrated sensors which provide both the relative humidity and the temperature in given locations of the deck, which are compared to the numerical results. The modelling assisted monitoring can help to reduce the maintenance costs of timber bridges, as well as the cost of instrumentation, and to increase the safety.

KEYWORDS: Wooden bridges, Wood moisture, Solar radiation, Monitoring, Multi-phase models, Finite Element Method

1 INTRODUCTION

Wooden bridges are economical, show an excellent environmental performance and can have a long service life. However, their durability under harsh climates represents one of the main problems for designers and owners. This is due to the material biodegradation caused by moisture content (*MC*) accumulated in wood for long periods, in combination with certain temperatures [1]. Although evidence exists that structural wood can retain its strength through many centuries, the variations of moisture content can strongly influence the structural integrity, the serviceability, and the loading capacity of timber bridges [2].

In this context, the monitoring of moisture content in wood is necessary for both the durability of the material and the performance of the whole structure. In the last decade, several studies have shown that numerical modelling can assist the sensor-based monitoring to get detailed information on the hygro-thermal response of wooden bridge components (see [3] and the related references).

In previous works [2,3], a multi-phase model with separated water phases was found efficient to study the moisture transport in uncoated and coated stress-laminated timber decks below the fibre saturation point (FSP) under outdoor environmental conditions characterized by continuous variations of temperature (T) and relative humidity (RH).

This paper presents a multi-phase hygro-thermal model able to simulate the effects of the external climate, including the solar radiation, on the sun exposed surfaces of timber bridge decks. As a case-study, the hygro-thermal analysis of the stress-laminated timber deck of Tapiola Bridge in Finland [2] is carried out by using the finite element method (FEM).

2 MULTI-PHASE MODEL FOR MOISTURE TRANSPORT IN WOOD

Below the FSP, the phenomena governing the moisture transport in wood are the diffusion of water vapour in the pores, the sorption of bound water and the diffusion of bound water in the cell walls [4]. Above the FSP, there are capillary pressure and gravity for the free water in the pores, sorption between the free water and the bound water phases, evaporation or condensation between the free water and the vapour water phases [5]. In the differential equations describing the above phenomena, the water phases are separated and the coupling between them is defined through conversion rates.

Compared to the previous works by some of the authors, in the present paper the influence of the solar radiation during time is considered by modifying the hygro-thermal boundary conditions for the temperature.

2.1 Governing equations

By using a matrix and vector notation, and considering as variables of the problem the bound water concentration c_b, the water vapour concentration c_v and the temperature T in the wood material, the related governing equations are defined as

[1] Stefania Fortino, VTT Technical Research Centre of Finland Ltd, Finland, stefania.fortino@vtt.fi
[2] Petr Hradil, VTT Technical Research Centre of Finland Ltd, Finland, petr.hradil@vtt.fi
[3] Timo Avikainen, VTT Technical Research Centre of Finland Ltd, Finland, timo.avikainen@vtt.fi
[4] Keijo Koski, VTT Technical Research Centre of Finland Ltd, Finland, keijo.koski@vtt.fi
[5] Ludovic Fülöp, VTT Technical Research Centre of Finland Ltd, Finland, ludovic.fulop@vtt.fi

https://doi.org/10.52202/069179-0061

$$\frac{\partial c_b}{\partial t} = -\nabla \cdot \mathbf{J}_b + \dot{c}_{bv} \quad (1)$$

$$\frac{\partial c_v}{\partial t} = -\nabla \cdot \mathbf{J}_v - \dot{c}_{bv} \quad (2)$$

$$c_w \varrho \frac{\partial T}{\partial t} = -\nabla \cdot \mathbf{J}_T - \nabla \cdot \mathbf{J}_b h_b - \nabla \cdot \mathbf{J}_v h_v + \dot{c}_{bv} h_{bv} \quad (3)$$

In the above equations, $\mathbf{J}_b$ and $\mathbf{J}_v$ represent the fluxes of bound water and water vapour defined as

$$\mathbf{J}_b = -\mathbf{D}_b \nabla c_b;\ \mathbf{J}_v = -\mathbf{D}_v \nabla c_v \quad (4)$$

where ∇ is the nabla operator, $\mathbf{D}_b$ and $\mathbf{D}_v$ are the diffusion matrices for bound water and water vapour phases and the thermal flux $\mathbf{J}_T$ is defined as

$$\mathbf{J}_T = -\mathbf{K} \nabla T \quad (5)$$

where $\mathbf{K}$ is the thermal conductivity matrix. Coupled hygro-thermal terms in fluxes of Equation (4) are not included since their effects were found negligible in the presence of Northern weather conditions [6].
In Equations (1-3) $\dot{c}_{bv}$ represents the conversion rate between the bound water and the water vapour phases. In Equation (3), h_b and h_v are the specific enthalpies and $h_{bv} = h_b - h_v$ the specific transition enthalpy from bound water to water vapour.
The bound water concentration is defined as $c_b = \varrho_0 MC$ where MC is the moisture content and ϱ_0 the dry wood density. The water vapour concentration c_v is a function of the partial vapour pressure p_v through the ideal gas law $c_v = \varphi\, p_v M_{H2O}/RT$ where R is the gas constant and M_{H2O} the molecular mass of water. The vapour pressure is expressed as a function of the relative humidity RH:

$$p_v = RH \cdot p_{vs} \quad (6)$$

where p_{vs} is the saturated vapour pressure given by the semi-empirical Kirchhoff expression [4].
The equation describing the conversion rate between bound water and water vapour is defined as

$$\dot{c}_{bv} = H_c(\varrho_0 MC_{bl} - c_b) \quad (7)$$

where H_c is the moisture dependent reaction rate and MC_{bl} represent the temperature dependent sorption isotherms based on the Anderson-McCarthy model:

$$MC_{bl,\alpha} = -\frac{1}{f_{2\alpha}} \ln\left(\frac{\ln\left(\frac{1}{RH}\right)}{f_{1\alpha}}\right),\ \alpha \in \{a, d\} \quad (8)$$

where a and d refer to adsorption and desorption and $f_{i\alpha} = \sum_{j=0}^{n} b_{ij\alpha} T^j,\ i \in \{1,2\}$.

All material properties of the model equations presented above, as well as the parameters of the Anderson-McCarthy model can be found in [3].

2.2 Hygro-thermal boundary conditions in the presence of solar radiation

The boundary conditions for bound water and water vapour concentrations are defined as:

$$\mathbf{n} \cdot \mathbf{J}_b = \mathbf{0};\quad \mathbf{n} \cdot \mathbf{J}_v = k_v^w c_v' - k_v^a c_v^a \quad (9)$$

where the first equation holds on all the external surfaces considering that the bound water cannot pass them and it is restricted in the cell walls. Therefore the model includes only exchanges of vapour and heat with the ambient air. In the second equation, defined on the surfaces exposed to RH and T, $\mathbf{n}$ represents the outward normal direction to the surface, $c_v' = c_v/\varphi$ is the concentration of water vapour divided by the wood porosity φ, c_v^a is the water vapour concentration of the air, k_v^w and k_v^a represent the surface permeances related to wood temperature and air temperature, respectively.
In the presence of a paint, the permeances of the coated wood referred to wood temperature and air temperature are defined as in [3]:

$$k_v^w = \frac{1}{\frac{1}{k_w} + \frac{1}{k_p}} \frac{RT}{M_{H2O}},\qquad k_v^a = \frac{1}{\frac{1}{k_w} + \frac{1}{k_p}} \frac{RT^a}{M_{H2O}} \quad (10)$$

where k_w is the permeance of uncoated wood and $k_p$the one of the paint.
The boundary condition for the temperature is defined as

$$\mathbf{n} \cdot \mathbf{J}_T = k_T(T - T^a) - q_{r,net} \quad (11)$$

where k_T is the thermal emission coefficient, T^a the temperature of the air, and $q_{r,net}$ represents the so-called net radiance at the wood surface [7]:

$$q_{r,net} = \alpha G + \varepsilon L - \varepsilon \sigma T^4 \quad (12)$$

where α is the solar absorptivity, G the incident solar radiation, ε the longwave emissivity of the surface, L the longwave incident radiation, and σ the Stefan-Boltzmann constant.
The values of dimensionless parameters α and ε depend on the wood material and the type of coating. In [7], the values of α for Korean wood species are around 0.3-0.5 and the values of ε around 0.4-0.7. According to [8], the solar absorptivity increases from a minimum of 0.25 for white paints to a maximum of 0.97 for black paints.
Following [8], the equation that relates the incident angle I on a surface with the solar altitude h, the surface solar azimuth A_{SS} and the orientation of the surface E (i.e. the angle of the surface from the horizontal), is the following:

$$Cos(I) = \cos(h)\cos(A_{SS})\sin(E) + \sin(h)\cos(E) \quad (13)$$

where the solar altitude is a function of the declination angle [9]. Therefore the incident radiation of Equation (12) is multiplied by the $Cos(I)$.

2.2.1 Implementation in Abaqus FEM code

The multi-phase model is implemented in the user subroutine UEL of Abaqus finite element code to describe the three differential equations of the material model and their boundary conditions [3]. At every time increment, the subroutine reads the weather data from the database of measured temperatures, air relative humidities, and solar radiation data. The shape functions for 8-nodes isoparametric brick elements are used to build a finite element with three variables per node (bound water concentration, water vapour concentration and temperature). The time integration is carried out using the fully implicit Euler scheme and the nonlinear system is solved using the Newton method at each time step. The subroutine allows to implement the FEM contributions to the residual vector and to the Jacobian iteration matrix.

3 ANALYSIS OF THE TAPIOLA BRIDGE DECK

The hygro-thermal data in wood are collected from the on-going monitoring of the stress-laminated timber deck of Tapiola Bridge built in the Spring of 2019 in the city of Espoo, Finland (Figure 1).

The Tapiola Bridge is composed of three spans and two of these are stress-laminated timber decks compressed by steel bars in the transverse direction. The bridge deck is composed of 46 timber beams in the width direction. The laminations are 0.215 m wide, and the deck thicknesses are 0.765 m for the 13.45 m span and 1.035 m for the 22.13 m span. The timber decks are 9.89 m wide and are protected with Valtti colour, an oil-based wood stain produced by Tikkurila corporation [10].

Five integrated humidity-temperature sensors, two force sensors and two displacement sensors were installed to monitor the bridge (Figures 3-5). The monitoring unit cabinet is equipped with two thermocouples for tracking its inside and outside temperature. The reader can refer to publication [2] for more details on the bridge structure and the monitoring system.

The parameters used for the boundary conditions of the case-study, are listed in Table 1. For the coated wood, the used parameters consider also the presence of a shading rail on the deck surface.

3.1 Description of the FEM model

The hygro-thermal model proposed in this work is based on the multi-phase moisture transport theory described in Section 2 with the aim to predict the distribution of *MC*, *RH*, and temperature in wood.

Table 1: *Boundary conditions parameters in the presence of solar radiation*

parameter	value	units
k_w	5.0E-9	kg/ m^2 s Pa
k_p	4.0E-9	kg/ m^2 s Pa
k_T	20	W m^{-2} K^{-1}
α (coated wood)	0.35	-
ε (coated wood)	0.5	-
α (asphalt)	0.7	-
ε (asphalt)	1.0	-
Stefan-Boltzmann constant	5.67×10^{-8}	W/m^2 K^4

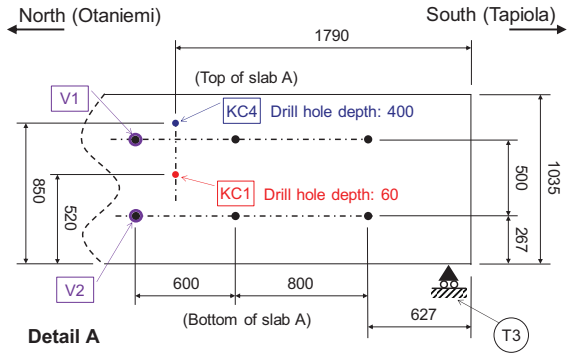

Figure 4: *Sensor locations in the side of the south-west corner of Slab A in the vicinity of support T3*

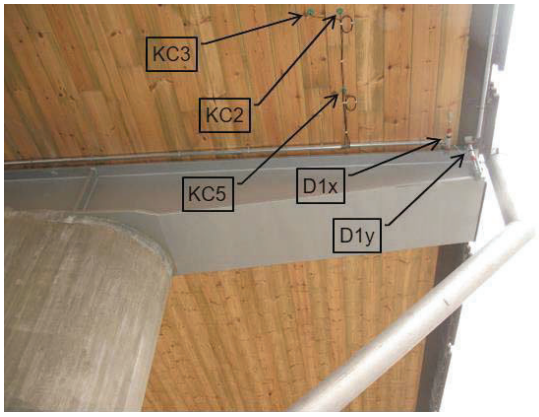

Figure 5: *Photo of the sensor locations on the bottom of the deck. KC2, KC3 and KC5: humidity and temperature sensors, D1x (slab longitudinal displacement) and D1y (slab vertical displacement)*

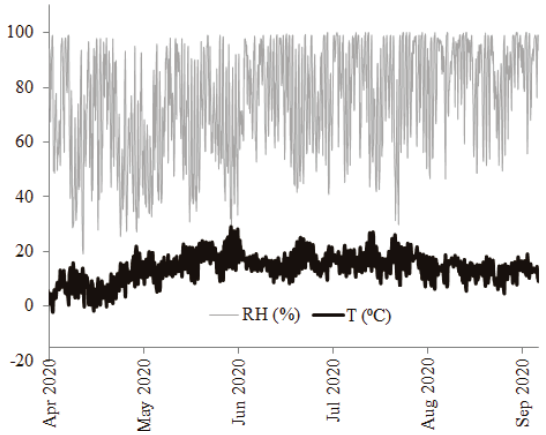

Figure 6: *Hourly relative humidity (RH) and temperature (T) of the air*

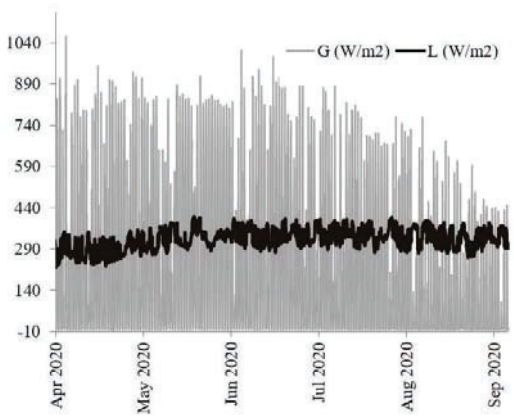

Figure 7: *Hourly incident solar radiation (G) and longwave incident radiation (L) on the exposed surface*

To investigate the hygro-thermal response of the timber deck during the sunny months, characterized by higher temperatures, a six month numerical analysis is carried out from the beginning of April 2020 to the end of September 2020. The hourly air temperature and *RH* are shown in Figure 6, while Figure 7 presents the hourly incident solar radiation and longwave incident radiation.
According to the approach proposed in [2], the modelling of the deck for the case-study investigated in this paper is based on the following scheme and assumptions:

- The deck model is schematized as a representative three-dimensional slice having a width of 215 mm (width of the lamination), height 1035 mm (thickness of the deck) and a thickness of 5 mm.
- Since the top surface is protected from moisture by the asphalt layer, it is considered to be exposed only to a thermal flux.
- The asphalt layer is not modelled as material, but higher values of solar absorptivity and longwave emissivity are applied on the top surface of the modelled slice (see Table 1).
- Compared to the model for internal lamination presented in [2], both fluxes of temperature and relative humidity act on the bottom surface as well as on the lateral surface of the lamination exposed to the air. The solar radiation acts on the lateral surface (Figures 3,4).
- The effect of the glue between laminations is not considered.

The used mesh size of the finite element model for the Abaqus analysis is set between 5 and 10 mm.
The solar radiation on the surfaces exposed to the sun affects the whole hygro-thermal response of the analyzed volume of wood because of the temperature increase on the surface. As observed in [8], the temperature of a vertical surface increases faster than for a horizontal surface because the vertical one receives more solar radiation in the early morning. When the sun rises, the incident angle on the vertical surface decreases while the incident angle on a horizontal surface increases. Therefore

https://doi.org/10.52202/069179-0061

the temperature of a horizontal surface can reach higher values than a vertical surface. The lateral surface of Tapiola Bridge's deck with sensor KC1 is north-west oriented and receives solar radiation during the afternoon.

3.2 RESULTS AND DISCUSSION

Figures 8 and 9 present the temperatures and the vapor pressures in the wood predicted by the model in the middle height of lamination at a distance of 60 mm from the lateral surface exposed to the afternoon solar radiation. The comparison with the measured temperatures and the vapor pressures in KC1 sensor are in good agreement. This also means that the parameters listed in Table 1 are suitable for the model used in the present case-study. The reported vapor pressure is based on the measured relative humidity. The numerical moisture content in the same location and the *MC* on the surface exposed to the sun are drawn in Figure 10. Table 2 summarizes the maximum and minimum numerical values of moisture contents in the sensor location affected by solar radiation (KC1) and on the sensor location at 60 mm from the bottom of the deck (KC2) previously investigated in [2]. It can be observed that the moisture contents are lower in the presence of solar radiation, and the differences are around 5%. On the exposed surface at the middle height of lamination, the predicted moisture contents in the studied period (Figure 10) are very similar to the ones founded at the bottom surface in a previous study [2]. It should be noticed that the lateral surface of the deck is also exposed to the variable relative humidity and this effect is coupled with the increase of temperature due to the solar radiation.

For future work, it is suggested to simulate cases of untreated wood and wood protected by different coatings to better evaluate the performance of the proposed model. Locations closer to the external surfaces should also be monitored by humidity-temperature sensors for accurate validation of the numerical model. In addition, different climates should be tested, especially in Southern Europe environments.

Developments of coupled hygro-thermal models for timber decks allow the accurate evaluation of moisture contents which is important for the prediction of moisture induced stresses (MIS) by using a sequential mechanical analysis [11]. The MIS can cause surface cracking, cupping deformations and losses of the pre-stress force in steel bars [1]. The accurate prediction of temperature increase due to solar radiation is also important for the investigation of wood decay and resistance of wood in connection with dose models [12].

Table 2: *Maximum and minimum predicted MCs in sensor locations from April 2002 to September 2020*

location	max *MC* (%)	min *MC* (%)
KC1	15.9	15
KC2	16.7	15.8

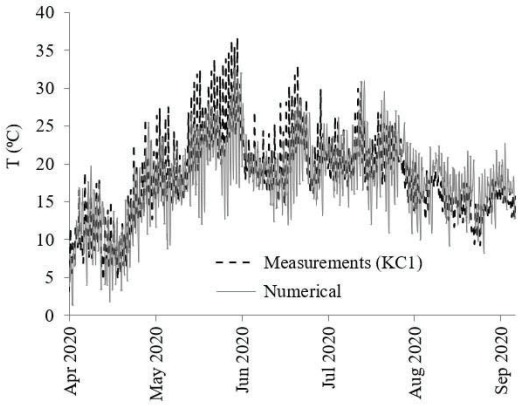

Figure 8: *Measured and predicted temperatures in KC1 sensor location*

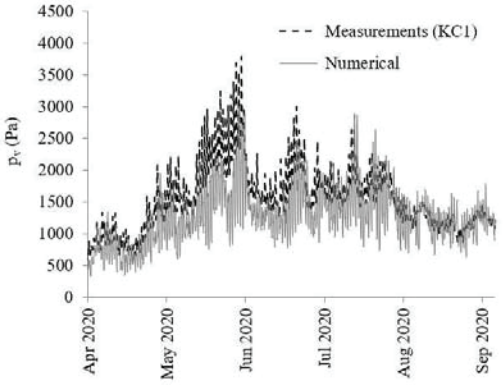

Figure 9: *Measured and predicted vapor pressures in KC1 sensor location*

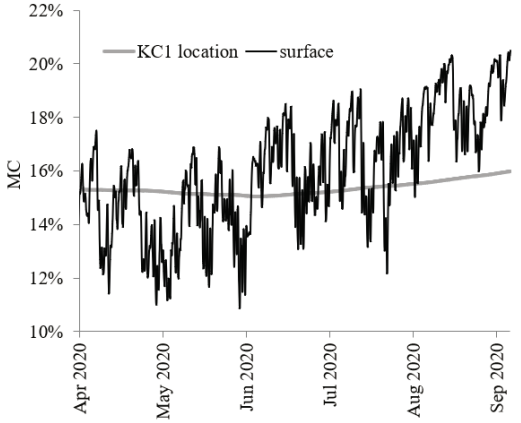

Figure 10: *Predicted moisture contents in KC1 sensor location and on the surface exposed to sun*

https://doi.org/10.52202/069179-0061

In future work, a more general model able to simulate the effects of external climates in wood also in the presence of rain, should consider the free water in lumens above the fibre saturation point [5].
Improved hygro-thermal models, along with sequential mechanical analyses, can reduce the whole costs of timber bridge monitoring and maintenance and increase their safety. The integration of numerical models with sensor-based instrumentation, will indeed reduce the number of needed sensors. In addition, predictions of moisture contents, moisture gradients and the possible crack risk due to the related surface MIS, provide important suggestions for optimal maintenance and eventual repair of the protective system. For instance, it would be practical to check the conditions of paints in certain seasons of the year, as the beginning of summer, characterized by drying in wood.

4 CONCLUSIONS

This paper proposed a multi-phase model for moisture transport able to simulate the hygro-thermal behaviour of a coated wooden bridge deck also considering the effects of solar radiation. The deck is schematized as a three-dimensional slice with the hygro-thermal fluxes on the exposed surfaces and therefore the related FEM analysis is efficient. The results of the model are in good agreement with the monitored data.
To the knowledge of the authors, the effect of solar radiation has not been deeply investigated within multi-phase models with separated water phases previously. Therefore, the proposed model contributes to the scientific advances of this field of research. However, further work is needed to properly validate the model for untreated wood materials and different coatings.
The improved model, used to assist the monitoring, can help to reduce the maintenance costs of timber bridges, as well as the cost of instrumentation, and to increase the safety of these structures.

ACKNOWLEDGEMENT

A part of this research was funded by project “Delivering Fingertip Knowledge to Enable Service Life Performance Specification of Wood - Click Design”, under ERA-NET action ForestValue co-found by the European Union’s Horizon 2020 research and innovation programme, grant agreement No 773324, and the Finnish Ministry of the Environment. The authors wish to thank the Finnish Transport Infrastructure Agency (Väylävirasto) and the City of Espoo for supporting the monitoring of Tapiola Bridge. This research was also funded by project “Image-based Modelling of Water Transport In Wood including material biodegradation – WaterInWood”, Academy of Finland, decision number 349194.

NUMERICAL HOMOGENISATION OF MECHANICAL PROPERTIES OF PINUS PINASTER (AIT.) LAMELLAE CONSTITUTING GLUED LAMINATED TIMBER

Romain Chevalier[1], Bruno Vuillod[2], Mathilde Zani[3], Marco Montemurro[4], Régis Pommier[5], Anita Catapano[6]

ABSTRACT:

Pinus pinaster (Ait.) is a softwood species considerably employed in the current wood industry in the Southwest of France. In a context of new environmental constraints, describing and predicting the behaviour of this local species becomes a matter of high priority. Nonetheless, the vast majority of industrial and research works still use classical softwood properties to determine various engineered Pinus pinaster (Ait.) products characteristics such as glued laminated and cross laminated timber.

This work proposes to employ general numerical homogenisation techniques used in the field of composite materials to obtain mechanical properties of Pinus pinaster (Ait.) as well as wood products such as glued laminated timber (Glulam). The proposed approach consists in decomposing and modelling glued laminated timber in four working scales: scale of glulam products, lamellae of several typologies composing such wood products (macroscopic scale), wood volumes considered analogous to laminar composites (mesoscopic scale) and composed of a few growth rings (microscopic scale) of initial and final wood. The homogenisation technique, adopted to compute properties from the microscopic to the macroscopic scale, is combined with approximation methods reposing on non-uniform rational basis spline entities to compute the mechanical properties of lamellae constituting glulam.

1 INTRODUCTION

Wood is a natural material whose importance has risen exponentially over the last few years. Indeed, this renewable material perfectly fits several "Sustainable Development Goals" set by the United Nations and is highly recommended by the IPCC's "Global Warming of 1.5°C" report [1] as a solution to reduce carbon footprints in building and civil-engineering. In the South West of France, the current wood industry (including the company Gascogne Bois (GB)) is particularly related to Pinus pinaster (Ait.), a softwood species indigenous of the South West of Europe, because of its vast presence across the whole area (between 75% to 84% of total forest area in two French departments [2]).

Glued laminated timber (glulam) is a wood product manufactured by gluing and finger-jointing multiple wood lamellae allowing flexibility in size and shape. Furthermore, wood distortions issued from thermo-hygric variations can be considerably reduced in glulam by assembling a disparity of lamellae properties [3]. This advantage is noticeably reduced when using Pinus pinaster (Ait.) timber. Several studies [4,5] tried to estimate the shape stability of multiple configurations of softwoods glulam. However, the vast majority of studies are focused on others softwood species or use classical softwood properties taken from [6]. Moreover, the variability of wood properties are also neglected.

Hence, the main purpose of this work is to propose a multi-scale mechanical model of lamellae constituting glulam able to take into account the physical properties and related variability of Pinus pinaster (Ait.).

The paper is organiser as follows : modelling of physical and mechanical properties of the two phases of initial and final wood constituting growth rings is presented in Section 2. Section 3 is dedicated to the description of the numerical homogenisation procedure of the mechanical properties of elementary volumes of Pinus pinaster (Ait.). The results of the numerical study is presented in Section 4. Approximation methods are then used to compute the properties of multiple typologies of lamellae in Section 5. Finally, conclusions and perspectives are dispensed in Section 6.

2 PINUS PINASTER (AIT.) STRUCTURE AND PROPERTIES

2.1 MULTI-SCALE DEFINITION

Wood is a highly heterogeneous and anisotropic natural composite whose structure can be defined at three working scales:

- Growth ring composed by the accumulation of wood cells (90% of longitudinal tracheids) at the microscopic scale.
- Elementary volume emerging from the alternation of a few initial wood (IW) and final wood (FW) growth rings at the mesoscopic scale considered as lamellar composite.
- Wood lamellae formed by the combination of elementary volumes of multiple growth ring patterns at the macroscopic scale.

2.2 MODELLING OF PINUS PINASTER (AIT.) LOG

A local orthotropic coordinate system is used to describe wood properties defined by three preferred directions according to Figure 1: longitudinal direction L, radial direction R corresponding to the diametrical growth direction, and tangential direction T to the annual growth rings. Three planes can be identified in this system: the transverse plane RT, the radial longitudinal plane LR and the tangential longitudinal plane LT.

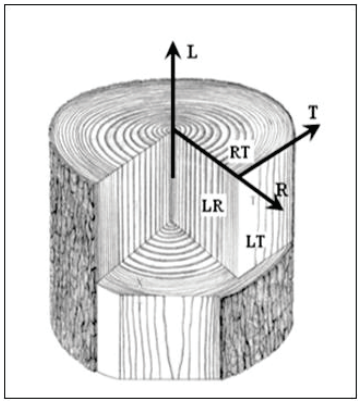

Figure 1: *Local reference system [7]*

The proposed model takes into consideration the difference between initial and final wood and the difference between juvenile and adult wood for growth rings from pith to bark.

Tree trunks are considered straight, with concentric growth rings, centred pith, and a circular shape of the transversal section (plane RT) across the whole L direction. Heartwood formation (no real influence on mechanical properties [8]), presence of knots, and reaction wood are neglected. Grain angle is considered null.

As for the physical properties, ring widths RW, mean relative density d, mean FW relative density FWd, and final wood proportion FWp (proportion of FW in a ring) are regarded at each ring number i. Globally, their variation is considered as function of the distance from the

https://doi.org/10.52202/069179-0062

pith R. Their dependency to the height H is neglected. Variability of such properties is considered at every growth ring. Properties are considered constant in the adult wood, which begins at the 15th ring (juvenile-adult wood limit at 12 years old [9] in the case of Pinus pinaster (Ait.)).

The physical properties relative to ring number i for our Pinus pinaster (Ait.) model are presented in Table 1. They are qualitatively extracted from several references [9,10,11]. The RW properties are adapted to match the data of GB company. Regarding FWp, d, and FWd, their evolution is considered linear with ring number in the juvenile wood and constant in the adult wood.

Table 1: *Physical properties for the Pinus pinaster (Ait) model.*

Ring N° i	RW [mm]	FWp [%]	d	FWd
1	2.5	8	0.43	0.56
2	9.4	10	0.439	0.57
3	10.0	12	0.447	0.58
4	10.2	14	0.456	0.59
5	10.1	16	0.464	0.60
6	9.9	18	0.473	0.61
7	9.0	20	0.481	0.62
8	7.8	22	0.490	0.63
9	6.5	24	0.499	0.64
10	5.3	26	0.507	0.65
11	4.3	28	0.516	0.66
12	3.4	30	0.524	0.67
13	2.8	32	0.533	0.68
14	2.3	34	0.541	0.69
15	2	36	0.55	0.70

In analogy to [12] in the case of a natural material, wood properties defined in this study are governed by uncertainty and their variability is described by a normal distribution at each ring number i (except the first three rings considered constant because of the lack of information in the scientific literature). For a generic property q_i, Equation (1) describes the normal probability density function $\psi(q_i)$ with $\lambda(q_i)$ and $\xi(q_i)$, respectively, the mean value and the standard deviation of the distribution of the property q_i:

$$\psi(q_i) = \frac{1}{\xi(q_i)\sqrt{2\pi}} exp\left(-\frac{\left(q_i - \lambda(q_i)\right)^2}{2\xi(q_i)^2}\right). \quad (1)$$

The mean value $\lambda(q_i)$, standard deviation $\xi(q_i)$, and coefficient of variation $C_v(q_i)$ [%] can be expressed as follows :

$$\lambda(q_i) = \frac{1}{N_v}\sum_{j=1}^{N_v} q_{i,j}\ ,$$
$$\xi(q_i) = \sqrt{\lambda\left(\left(q_i - \lambda(q_i)\right)^2\right)}, \quad (2)$$
$$C_v(q_i) = 100\frac{\xi(q_i)}{\lambda(q_i)}\ ,$$

where $q_{i,j}$ is the jth value of q_i occurring for N_v values :

Regarding the RW and the FWp, the coefficient of variation at each ring number is considered equal to 20% as to be in the same order of magnitude as the references in the scientific literature [11,13]. In the case of d and FWd, a hypothesis is made to consider the wood mass produced by a ring as constant. Hence, a modification of RW and FWp induce a variation of the densities values d and FWd.

The number of ring is defined by the age of the trees considered. In the Landes of Gascogne, 92% of the local forest is private property. Hence, traceability of stands processed by GB company is not ensured and tree ages are unknown.

Nonetheless, GB company possesses dendrological data on the mean and standard deviation of log diameter evaluated on 149727 logs. The measurements were performed for logs of 2.5m extracted between 0m-8m. (Note: GB standard deviation results are overvalued because referenced as 120 stacks of 2500 tree). Few information exists on the trees treated by GB including a minimal age of 40 years old and the possibility to reach 60 years old.

Our model has to take into consideration the heterogeneity of tree ages resulting in a varying number of rings relative to match the GB data. To this end, a hypothesis is introduced : in the following of this paper a half normal distribution with a mean age of 40 and a standard deviation of 7.5 admitting that age cannot be less than 40 years (99% of the ages are included between 40 and 62 years old) is considered. The mean diameter and standard deviation for the GB sample and for the numerical model, performed on a sample of 500 simulations, are presented in Table 2.

Table 2: *Mean diameter and standard deviation for wood logs taken from GB data and the parametric model.*

	GB sample	Parametric Model
Mean diameter [mm]	313.1	314.2
Standard deviation [mm]	19.15	20.34

2.3 ELASTIC PROPERTIES OF INITIAL AND FINAL WOODS AT THE MICROSCPIC SCALE

IW and FW elastic behaviour can be modelled at the microscopic scale through Hooke's law whose compliance matrix for wood is uniquely defined via 9 independent elastic constants: three Young's moduli E_m (m = L,R,T), three shear moduli G_{mn} (m,n = L,R,T and $m \neq n$), and three Poisson's ratios υ_{mn} (m,n = L,R,T and $m \neq n$):

https://doi.org/10.52202/069179-0062

$$\begin{Bmatrix} \varepsilon_L \\ \varepsilon_R \\ \varepsilon_T \\ \gamma_{LR} \\ \gamma_{TL} \\ \gamma_{RT} \end{Bmatrix} = \begin{bmatrix} \frac{1}{E_L} & -\frac{\upsilon_{RL}}{E_R} & -\frac{\upsilon_{TL}}{E_T} & 0 & 0 & 0 \\ -\frac{\upsilon_{LR}}{E_L} & \frac{1}{E_R} & -\frac{\upsilon_{TR}}{E_T} & 0 & 0 & 0 \\ -\frac{\upsilon_{LT}}{E_L} & -\frac{\upsilon_{RT}}{E_R} & \frac{1}{E_T} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G_{LR}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G_{TL}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{RT}} \end{bmatrix} \begin{Bmatrix} \sigma_L \\ \sigma_R \\ \sigma_T \\ \tau_{LR} \\ \tau_{TL} \\ \tau_{RT} \end{Bmatrix} \quad (3)$$

where ε_m and σ_m are the normal strain and stress, respectively, along m-th axis, whilst γ_{mn} and τ_{mn} are the shear strain and stress, respectively, in the mn plane.

In the scientific literature, wood elastic properties can be expressed as a linear function of the relative density [14]. In [6], the authors proposed a linear model to compute softwoods elastic properties based on experimental results on a large variety of softwood species which is frequently used in most studies. Nonetheless, this model is fairly accurate for lower relative densities; it looses in precision in the case of high density softwood such as Pinus pinaster (Ait.), whereas the model proposed in this paper takes into consideration a FW phase of high relative density.
In this study, we propose to employ data relative to Pinus pinaster (Ait.) mechanical properties taken from the scientific literature [15,16,17,18,19] to establish elastic laws accurately describing the behaviour of IW and FW relative to this softwood species while taking into consideration the dependency to density. To this end, we also admit a linear relationship of the Young's and shear moduli with relative density similarly to the one presented in [6]. Regarding the Poisson's ratios, there is not enough information in the case of Pinus pinaster (Ait.) and their values are considered constant.

2.3.1 Young's moduli

In the case of the trend of the longitudinal Young's modulus with the relative density, eight values were provided in [15], which are reported in Table 3.

Table 3: *Mean longitudinal Young's modulus and density obtained through flexural tests in [15]*

d	0.46	0.60	0.635	0.64	0.65	0.693	0.705	0.715
E_L [GPa]	13.2	15.7	16.11	16.6	16.435	16.794	17.775	17.1

A linear relationship between the mean longitudinal modulus E_L [MPa] and mean relative density d is found and is described in Equation 4 with a coefficient of determination of ${R_d}^2 = 0.9581$.

$$E_L = 5875 + 16209\, d\,. \quad (4)$$

Three references, [16,17,18], estimated Young's moduli but omitting the relative density of the specimens. By considering a similar behaviour in traction and compression from wood samples, the linear relationship Equation (4) allows to estimate the density of the samples from the above studies. The densities estimations and the elastic properties are displayed in Table 4.

Table 4: *Mean Young's moduli and with estimated relative densities from [16,17,18].*

	E_L	E_R	E_T	d
Cariou [16]	11369	/	703	0.3390
Pereira et al. [17]	15100	1910	1010	0.5690
Lahna [18]	16140	2086	/	0.6439

Thus, it is now possible to propose linear relationship with associated density d_k associated to the phase k =IW,FW for the three Young's moduli that are presented in Equation (5):

$$\begin{aligned} E_{L_k} &= 16209\, d_k + 5874.7, \\ E_{R_k} &= 2972.2\, d_k + 238.70, \\ E_{T_k} &= 1334.8\, d_k + 250.51, \end{aligned} \quad (5)$$

with E_{L_k}, E_{R_k}, and E_{T_k} the Young's moduli associated to the phase k = IW,FW.

2.3.2 Shear moduli

[19] characterised the shear moduli of Pinus pinaster (Ait.) by carrying out two shear test methods (Iosipescu and off-axis). Equation (6) presents the models proposed to link shear moduli in [MPa] with infra-density (IF) [20]. They are considered applicable on the densities examined in our study.

$$\begin{aligned} G_{RT_k} &= 495\, IF_k, \\ G_{TL_k} &= 2072\, IF_k, \\ G_{LR_k} &= 2402\, IF_k, \end{aligned} \quad (6)$$

where $IF_k = \frac{d_k}{1.12+0.159\, d_k}$, G_{RT_k}, G_{TL_k}, and G_{LR_k}, respectively, with k = IW,FW.

2.3.3 Poisson's ratios

In [16], the author characterised the elastic properties of Pinus pinaster (Ait.) thanks to experimental tests. Table 5 presents the Poisson's ratio obtained in [16]. As there is too few information in the literature about the variation of Poisson's ratios as a function of the relative density, the ratios υ_{RT_k}, υ_{TL_k}, and υ_{RL_k}, are considered constant for the two phases k = IW,FW.

Table 5: *Pinus pinaster (Ait.) Poisson's ratio, [16] with k=IW,FW.*

υ_{RT_k}	υ_{TL_k}	υ_{RL_k}
0.58	0.03	0.04

2.3.4 Validity of the model

It is necessary to check the conformity of the model with respect to the true wood behaviour. In [6,16], the authors expressed the plausibility for several ratios between elastic properties to be quasi-constant such as E_{L_k}/E_{T_k}, E_{L_k}/E_{R_k}, G_{LR_k}/G_{RT_k}, and G_{TL_k}/G_{LR_k}. In this study, a ratio is considered quasi-constant if the maximum precentage difference between the properties computed over the density range [0.40,0.80] with the mean property computed at the relative density of 0.55 is lower than 10%. All ratios are considered quasi-constant as the condition aforementioned is fulfilled. Furthermore, the positive definiteness of the stiffness tensors is verified for the whole density range.

3 DETERMINATION OF THE ELASTIC PROPERTIES AT THE MESOSCOPIC SCALE

At the microscopic scale, the bibliographic data and the multiple hypotheses done on the properties of Pinus pinaster (Ait.) allow to propose two different material models for both initial and final woods taking into consideration their variability into the stem according to their corresponding relative density.

At the mesoscopic scale, the representative volume element (RVE), which can be seen as a lamellar composite, is modelled by an alternation of growth rings composed by both initial and final wood of varying width. The well-known numerical homogenisation method based on the strain energy of periodic media [21] is then employed to compute the mechanical properties of 3D cubic FE-model of the RVE of wood specimens extracted from several positions in the modelled logs of Pinus pinaster (Ait.).

This technique is based on the use of periodic boundary conditions (PBCs) to calculate the equivalent stiffness matrix of the material at the mesoscopic scale. However, PBCs cannot be applied directly to the lamellae at the mesoscopic scale because of growth ring patterns. Hence, lamellae are separated into several elementary cubes of relatively small dimensions to consider growth rings as rectangular parallelepipeds and to apply the homogenisation technique.

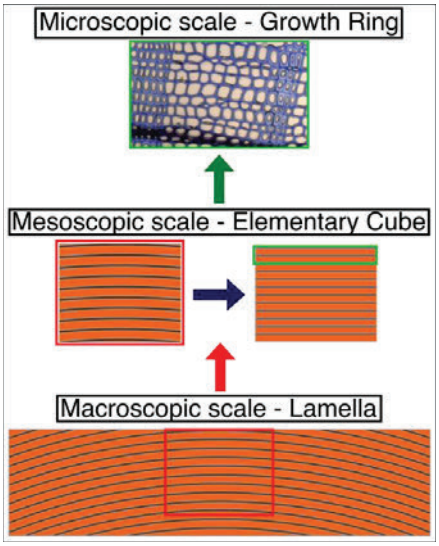

Figure 2 : *Multi-scale modelling of Pinus pinaster (Ait.) Glulam (Microscopic scale image adapted from [22])*

To consider the growth rings as rectangular parallelepipeds, a trigonometric study is realised on the elementary volumes considered as cubes of dimension h. The condition will be fulfilled over the whole range R ∈ [0;150]mm if the dimension h respects the following inequality h≤ 12mm.

The homogenisation procedure will then be coupled with a stochastic approach, the Monte-Carlo method, to efficiently compute the mesoscopic properties impacted by the overall variability.

The following assumptions are made to determine the effective properties at the mesoscopic scale:

• linear orthotropic behaviour defined in a local cylindrical reference system for all phases of initial and final wood;

• perfect bonding condition at the phases interface is considered.

3.1 The numerical homogenisation method

The geometry used for the RVE is the one depicted in Figure 2 with a cube considered as a lamellar composite. The geometric variable parameters used are the dimension of the cube h, the position of the centroid of the RVE R, the properties of the rectangular parallelepiped approximating the growth rings RW and FWp depending on the distance to the pith. The volume of the RVE is defined in Equation (7) in a local Cartesian reference system (O; x_1, x_2, x_3) defined at the centre of the RVE, with a_1, a_2, and a_3 the length of the RVE sides along the x_1, x_2, and x_3 axis, respectively.

$$V_{\mathrm{RVE}} = a_1\, a_2\, a_3 \; = h^3. \qquad (7)$$

The generation of synthetic logs is first coded in Python® environment. The parametric FE-model is then created within the commercial FE code Ansys®. 20-node solid elements SOLID186 with three Degree of Freedom

https://doi.org/10.52202/069179-0062

(DOF) per node have been used. The "Layered" element option has been selected to create and mesh only the RVE volume and model each ring as an equivalent layered section with 3 integration points per layer. In the 3D case, the generalised Hooke's law for the equivalent elastic material corresponding to the RVE can be written as:

$$\begin{Bmatrix} \bar{\sigma}_1 \\ \bar{\sigma}_2 \\ \bar{\sigma}_3 \\ \bar{\sigma}_4 \\ \bar{\sigma}_5 \\ \bar{\sigma}_6 \end{Bmatrix} = \begin{bmatrix} \bar{C}_{11} & \bar{C}_{12} & \bar{C}_{13} & \bar{C}_{14} & \bar{C}_{15} & \bar{C}_{16} \\ \bar{C}_{21} & \bar{C}_{22} & \bar{C}_{23} & \bar{C}_{24} & \bar{C}_{25} & \bar{C}_{26} \\ \bar{C}_{31} & \bar{C}_{32} & \bar{C}_{33} & \bar{C}_{34} & \bar{C}_{35} & \bar{C}_{36} \\ \bar{C}_{41} & \bar{C}_{42} & \bar{C}_{43} & \bar{C}_{44} & \bar{C}_{45} & \bar{C}_{46} \\ \bar{C}_{51} & \bar{C}_{52} & \bar{C}_{53} & \bar{C}_{54} & \bar{C}_{55} & \bar{C}_{56} \\ \bar{C}_{61} & \bar{C}_{62} & \bar{C}_{63} & \bar{C}_{64} & \bar{C}_{65} & \bar{C}_{66} \end{bmatrix} \begin{Bmatrix} \bar{\varepsilon}_1 \\ \bar{\varepsilon}_2 \\ \bar{\varepsilon}_3 \\ \bar{\varepsilon}_4 \\ \bar{\varepsilon}_5 \\ \bar{\varepsilon}_6 \end{Bmatrix}, \quad (8)$$

where $\bar{\sigma}$ and $\bar{\varepsilon}$ are the stress and strain tensors expressed in Voigt's notation, respectively associated with the equivalent homogeneous solid and as such are volume averaged, see [23] for more details.
The goal of this method is to evaluate all the components of the stiffness tensor $\bar{\mathbf{C}}$ by applying successively 6 load cases to the cubic RVE through classical PBCs [21].

After determining the components of the volume-averaged stress tensor (according to the procedure presented in [23]), the components of the elasticity matrix at the mesoscopic scale are calculated, for each set of PBCs, as:

$$\bar{C}_{\alpha\beta} = \frac{\bar{\sigma}_\alpha}{\bar{\varepsilon}_\beta} \text{ with } \beta = 1,2,\dots,6, \quad (9)$$

and $\bar{\varepsilon}_\gamma = 0$, with $\gamma = 1,2,\dots,6$ and $\gamma \neq \beta$.

Furthermore, it is possible to evaluate the effective elastic moduli of the composite material from the compliance tensor $\bar{\mathbf{S}} = \bar{\mathbf{C}}^{-1}$, as shown below [23].

Three Young's moduli:

$$E_1 = \frac{1}{\bar{S}_{11}}, E_2 = \frac{1}{\bar{S}_{22}}, E_3 = \frac{1}{\bar{S}_{33}}.$$

Three shear moduli:

$$G_{23} = \frac{1}{\bar{S}_{44}}, G_{13} = \frac{1}{\bar{S}_{55}}, G_{12} = \frac{1}{\bar{S}_{66}}.$$

Three Poisson's ratios:

$$\upsilon_{23} = -\frac{\bar{S}_{32}}{\bar{S}_{22}}, \ \upsilon_{13} = -\frac{\bar{S}_{31}}{\bar{S}_{11}}, \ \upsilon_{12} = -\frac{\bar{S}_{21}}{\bar{S}_{11}}.$$

Three Chentsov's coefficients:

$$\mu_{23,31} = \frac{\bar{S}_{45}}{\bar{S}_{55}}, \ \mu_{23,12} = \frac{\bar{S}_{46}}{\bar{S}_{66}}, \ \mu_{31,12} = \frac{\bar{S}_{56}}{\bar{S}_{66}}.$$

Nine mutual influence coefficients:

$$\eta_{1,23} = \frac{\bar{S}_{14}}{\bar{S}_{44}}, \eta_{1,31} = \frac{\bar{S}_{15}}{\bar{S}_{55}}, \eta_{1,12} = \frac{\bar{S}_{16}}{\bar{S}_{66}},$$
$$\eta_{2,23} = \frac{\bar{S}_{14}}{\bar{S}_{44}}, \eta_{2,31} = \frac{\bar{S}_{15}}{\bar{S}_{55}}, \eta_{2,12} = \frac{\bar{S}_{16}}{\bar{S}_{66}},$$
$$\eta_{3,23} = \frac{\bar{S}_{14}}{\bar{S}_{44}}, \eta_{3,31} = \frac{\bar{S}_{15}}{\bar{S}_{55}}, \eta_{3,12} = \frac{\bar{S}_{16}}{\bar{S}_{66}}.$$

Moreover, the degree of anisotropy is now available by defining 9 independent symmetry criteria f_a, expressed in [%], reposing on the effective mechanical properties, as presented in the following. A criterion f_a is considered valid if its value, expressed in [%], respects the condition $f_a \leq 1\%$.

Two criteria on the Young's moduli:

$$f_1 = \frac{|E_3 - E_2|}{E_2}, f_2 = \frac{|E_1 - E_2|}{E_2}.$$

Two criteria on the shear's moduli:

$$f_3 = \frac{|G_{31} - G_{23}|}{G_{23}}, f_4 = \frac{|G_{12} - G_{23}|}{G_{23}}.$$

Two criteria on the Poisson's ratios:

$$f_5 = \frac{|\upsilon_{31} - \upsilon_{23}|}{\upsilon_{23}}, f_6 = \frac{|\upsilon_{12} - \upsilon_{23}|}{\upsilon_{23}}.$$

One criterion on the relationship between previous properties:

$$f_7 = \frac{\left| G_{23} - \frac{E_2}{2(1+\upsilon_{23})} \right|}{G_{23}}.$$

Two criteria on the Chentsov's and mutual influence coefficients sets μ and η, respectively:

$$f_8 = max(|\mu|), f_9 = max(|\eta|)$$

4 NUMERICAL RESULTS AT THE MESOSCOPIC SCALE

4.1 Convergence analyses

To validate the accuracy and effectiveness of the FE model of the RVE, convergence analyses on the RVE size and on the mesh size are realised on the equivalent elastic properties results while optimising the computational time. The study is realised in the case of the mean values of physical parameters on the whole range of distance to the pith R.
The details of these sensitivity analyses will be presented during the speech. In the case of the RVE size, for a supposed constant mesh size of $e_{size} = 0.5$mm for 3D element, an optimal RVE size of h = 8mm is selected which respect the condition for rectangular parallelepiped rings. Furthermore, this condition allows to superimpose the local coordinate cylindrical reference system to the local Cartesian reference system. In the case of the mesh size convergence, for a RVE size of h = 8mm, the optimal mesh size is constant and equal to $e_{size} = 1\text{mm} = h/8$. Here, the study is realised on the mean values of physical parameters for only the smaller growth rings at $R >$ 100mm. The computational time needed for 1 simulation is about t = 3.0 seconds.

4.2 Monte-Carlo Method

The Monte-Carlo (MC) method is commonly used to estimate the probabilistic distribution of simulation results and have already been used in the case of natural material [12]. In our specific case, for a RVE volume positioned at a certain distance to the pith R, the variability of physical parameters and mechanical properties at the microscopic scale induce uncertainty on the resulting effective properties at the mesoscopic scale, which can be assessed thanks to the MC method coupled with the numerical homogenisation technique. The probabilistic distribution is supposed to follow a normal distribution for the resulting elastic properties. The MC method applied in our study relies on four main steps.

• Step 1: The parametric FE model takes into consideration the variability of each input parameter, as presented in Section.2.
• Step 2: In the statistical domain, it is mandatory to obtain information on a given population by performing a random sampling. Its main purpose is to select a statistically representative number of samples of our studied population.
• Step 3: The homogenisation process is carried out on each sample to obtain the probabilistic distribution of the equivalent elastic properties at the upper scale at a given distance to the pith R.
• Step 4: Step 1-3 are repeated for some values of R in the range R ∈ [4,150]mm with an increment of 1mm. The number of samples n adequate in the case of our study has been estimated by studying the convergence of equivalent elastic properties mean and standard deviation of RVE volume over the whole range of R for different values of n. For the sake of brevity, this analysis is not presented here and will be discussed during the speech. The number of samples to achieve convergence is n = 250. Hence, the whole MC method takes approximately t_{tot}= 30 hours.

4.3 Numerical results for the effective properties.

In this section, the results of the numerical study are presented. To show the effectiveness of the proposed approach, a comparison between our numerical model and the analytical model of Reuss-Voigt over the range of interest R is accomplished. Furthermore, scientific literature data of interest are juxtaposed to the results as further comparison term. They are taken from various studies such as [15,16,24,25,26,27,28]. Over the whole range of R, only the criteria f_8 and f_9 are verified. Therefore, the homogenised material at the upper scale can be considered as an orthotropic material. For the sake of brevity, only the equivalent properties E_1 and G_{23} are presented in Figure 3.

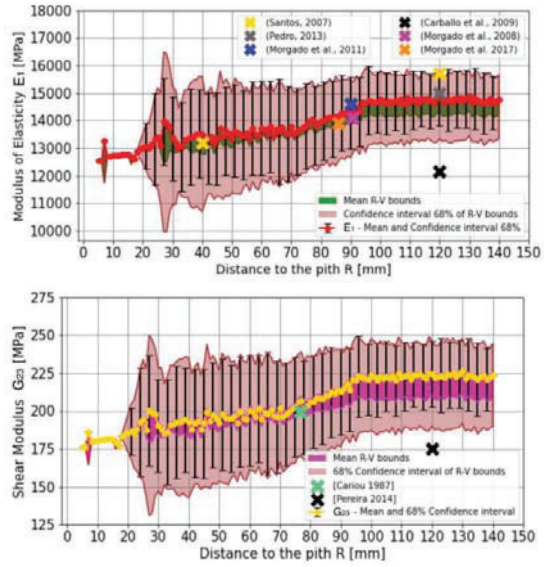

Figure 3: *Numerical results for the equivalent properties* $\boldsymbol{E_1}$ *and* $\boldsymbol{G_{23}}$ *over the whole range [5,140]mm versus experimental results.*

5 LAMELLAE PROPERTIES AT THE MACROSCOPIC SCALE

The purpose of this section is to obtain the equivalent mechanical properties of lamellae at the macroscopic scale. The lamellae are rectangular parallelepipeds of dimensions $A_1 = 500$mm, $A_2 = 95$mm, and $A_3 = 24$mm, along the X_1, X_2, and X_3 axis, respectively, of a global Cartesian reference system (O; X_1, X_2, X_3) defined at the centre of the log.
The lamellae and the RVE positions are defined by the position of their centre, respectively by the distances L, R, and the angle φ in the cylindrical reference system (O; L, R,T) with L the longitudinal axis, as illustrated in Figure 4.

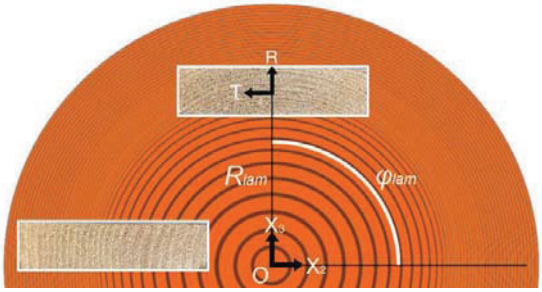

Figure 4: *Reference systems and position of the lamellae in the log.*

In Section 4, the equivalent properties of Pinus pinaster (Ait.) have been computed at the mesoscopic scale thanks to a homogenisation technique coupled with a stochastic approach. These properties are dependent only of the distance to the pith of the volumes R and are independent from the angle φ.
As the X_1 direction has no influence on the lamellae and cubes properties, we will consider only a section of dimensions $A_2 = 95$mm and $A_3 = 24$mm to describe the lamellae in the plane (O; X_2, X_3). To estimate the properties at the mesoscopic scale, we propose to discretise the lamellae as a combination of elementary sections with respect to their corresponding local orientation in the cylindrical reference system.
Finally, approximation methods resting on the utilisation of NURBS surfaces are used to compute the lamellae equivalent properties at the mesoscopic scale from the discretised mechanical properties found in Section 4.

5.1 Non-uniform rational basis-spline (NURBS) hyper-surfaces theory

This section gives a brief reminder of NURBS surfaces theory. These entities generalise the B-Splines surfaces, which generalise the Bézier surfaces [29]. Originally employed in Computer Aided Design (CAD) in the 1990's, these entities are now used in multiples domains, such as topology optimisation [32, 33, 34], shape optimisation [31, 38], anisotropy field optimisation for variable stiffness composites [36, 37], and surrogate model generation [30].

https://doi.org/10.52202/069179-0062

In this work, the NURBS surfaces entities are used as response surfaces (or surrogate models). Their aim is to fit the discrete mechanical properties of a material section or Target Points (TP) to homogenise and render a proper physical interpretation over the entire section. In other words, NURBS surfaces are used as approximation surfaces to fit the TP scalar data identified by their coordinates (X_2, X_3).

NURBS surfaces are used to approximate a model $M : \mathbb{R}^n \mapsto \mathbb{R}^m$, where $n = 2$ and $m = 12$ correspond to the dimensions of (X_2, X_3) coordinates, and to the dimensions of the set of desired mean and standard deviation mechanical properties extracted from the numerical study of Section 4, respectively. In the present case, these properties are the Young's moduli, the shear moduli and the corresponding standard deviations.
The parametric explicit form of each coordinate of a NURBS entity with only two input parameters reads:

$$s_b(u_2, u_3) = \frac{\sum_{i_2=0}^{n_2} \sum_{i_3=0}^{n_3} N_{i_2,p_2}(u_2)\, N_{i_3,p_3}(u_3) \omega_{i_2,i_3} P_{b,i_2,i_3}}{\sum_{i_2=0}^{n_2} \sum_{i_3=0}^{n_3} N_{i_3,p_3}(u_2)\, N_{i_3,p_3}(u_3) \omega_{i_2,i_3}} \tag{10}$$

with $s_b(u_2, u_3)$ the NURBS output b-mechanical property $(b \in [1, m])$ evaluated at the normalised input coordinates $(u_2 \in [0,1], u_3 \in [0,1])$. $n_k + 1 \;\; (k = 2,3)$is the number of control points (CPs) along the u_k parametric direction. ω_{i_2,i_3} corresponds to the weight assigned to the CP of indices i_2, i_3 . In this case, it is taken equal to 1 for every CP. P_{b,i_2,i_3} represents the $(n_2 + 1)(n_3 + 1)$ CPs coordinates. $N_{i_k,p_k}(u_k)$ $(k \in [2,3])$ are the basis functions of degree p_k (equal to 2 in our study) and are evaluated recursively with the Cox de Boor algorithm, based on Bernstein's polynomials [35]. For more information on this matter, the interested reader is referred to [29].
Each timber section is discretised with $N_{TP} = N_2 N_3$ TPs and the number of CPs of the NURBS entity vary as $N_{CP} = \delta\, N_{TP}$. Employing the surface fitting algorithm of [30], the CPs drive the NURBS surface across each output to obtain the distribution of the equivalent elastic properties of the lamellae at the macroscopic scale.

5.2 Sensitivity of the results to the number of target points and control points.

Firstly, a NURBS of degree 3 and $\delta = 1/4$ is applied to the input mechanical properties at the mesoscopic scale computed in Section 4 to smoothen the input curves. For the sake of conciseness, this interpolation process is not presented in this paper and will be presented during the speech.
To validate the interpolation method to compute the lamellae effective properties at the mesoscopic scale, convergence analyses must be made in terms of number of TPs and CPs. As the section geometry is defined in a Cartesian reference system, the TP and CP are also defined in the same reference system and are distributed uniformly across the directions X_2 and X_3.

The results of the sensitivity analysis allow to achieve convergence for a number of TPs equal to $N_{\mathrm{TP}} = 75 \times 30$ for all typologies of lamellae studied.
Regarding the number of CPs, the convergence is achieved with $\delta = 2/3$ to maximise the coefficient of correlation.
The precision of the NURBS surfaces is evaluated by comparing the relative differences between input and output values (a set of TPs different from the one used to determine the approximating NURBS entity). As the relative difference is under 2% for every mechanical properties, the interpolation method is validated.
Finally, defining the TPs and CPs in a Cartesian reference system induce variability of the output properties according to φ (should depend solely on the distance to the pith R) and is evaluated to 5% for a constant value of R.

5.3 Lamellae properties at the macroscopic scale

The NURBS entities are used to compute the equivalent properties of lamellae of two typologies. The first typology is a lamella whose centre is positioned at $R_1 =$ 50mm and $\varphi_1 = 0$ while the second is positioned at $R_1 =$ 80mm and $\varphi_1 = \pi/2$ and are presented in Figure 5. Only the input data (TP) and the output NURBS effective properties for the mean longitudinal modulus are presented for the sake of brevity.

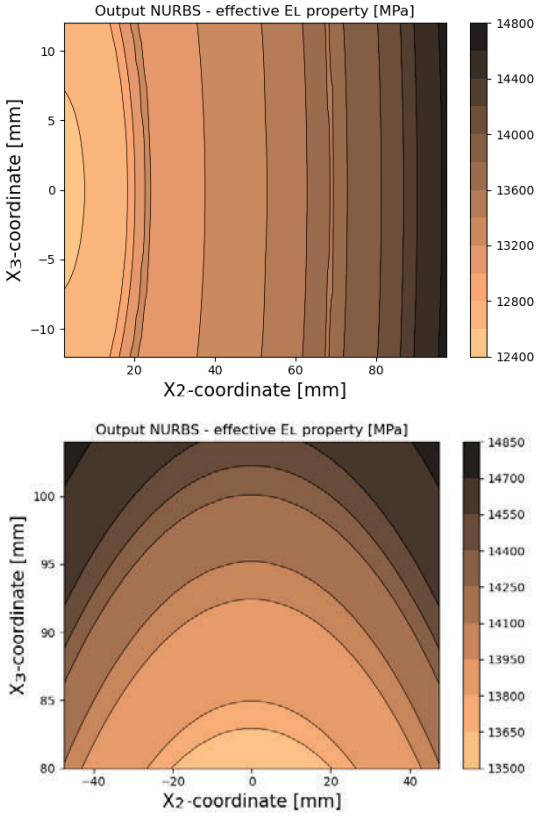

Figure 5: *Output NURBS effective properties (longitudinal modulus) of two typologies of lamellae at the macroscopic scale.*

6 CONCLUSIONS

Effective elastic properties of lamellae of Pinus pinaster (Ait.) at the macroscopic scale have been computed. The model took into account the several sources of variability and their propagation across the scales.

The scientific literature allowed to propose several models of elastic behaviour dependent on the density for the initial and final wood at the microscopic scale.

Numerical composite homogenisation techniques have been used in the case of elementary volumes considered as lamellar composites of initial and final woods.

The "Strain Homogenization Technique" has been used on the RVE to homogenise the effective properties at the mesoscopic scale (including the associated variability).

The lamellae are then discredited into several data reference. An approximation method reposing on the use of NURBS entities has been used to model the elastic behaviour of some configurations of lamellae.

This work focuses on computing homogenised properties to be used for Pinus pinaster (Ait.) instead of the classical softwood properties classically chosen.

These properties adapted to the case of Pinus pinaster (Ait.) can be imported into a model representing multiples configurations of glulam at the macroscopic scale by taking into account the finger-jointing and gluing of the components.

The next step would be to model the impact of grain angle, conical angle, micro-fibril angle, reaction wood, log shape, and centred pith on the results as additional sources of variability to better represent the reality of wood growth.

SIZE EFFECT OF LARGE GLUED LAMINATED TIMBER BEAMS – CONTRIBUTION TO THE ONGOING DISCUSSION

Christoffer Vida[1], Markus Lukacevic[2], Georg Hochreiner[3], Milena Stavric[4], Josef Füssl[5]

ABSTRACT: The effort to experimentally test glued laminated timber (GLT) beams is tremendous, especially for large beams. Such beams are increasingly used to realise wide-span timber structures, but experimental investigations of large beams are missing. In the literature, numerical simulation studies can be found instead to estimate the influence of the beam size. However, these studies come to partly different conclusions regarding the size effect, which confirms the high influence of the modelling strategy. Therefore, we conducted an extensive simulation program covering more than 8000 simulations to research the size effect, including large GLT beams of up to 3300 mm depth.

The developed modelling concept considered the morphology of timber boards deterministically and accounts for discrete cracking to simulate the bending strengths of GLT beams subjected to four-point bending tests. We predicted the size effect on the characteristic bending strength for two commonly used strength classes. We found that the strength decreased with increasing beam size. The results showed that the strength decrease is not only caused by the beam depth but also the length. Furthermore, the influence of different global failure criteria was investigated, with which the results from the existing studies could successfully be reproduced.

KEYWORDS: Glued laminated timber, XFEM, Size effect, Global failure criterion

1 INTRODUCTION

Glued laminated timber (GLT) is a building material suitable to realise a large variety of wide-span structures, e.g., hall constructions as well as office or apartment buildings. In recent decades, the dimensions, especially the beam depth, of GLT beams have increased continuously. The versatile use of GLT requires a comprehensive understanding of the mechanical behaviour and effective properties of the material. However, there is a debate among experts about the influence of the size of GLT beams on their bending strength.

This so-called size effect on the characteristic bending strength $f_{\mathrm{b,k}}$ can be described by applying the commonly used factor k_{h} to a characteristic reference bending strength $f_{\mathrm{b,k,ref}}$:

$$f_{\mathrm{b,k}} = f_{\mathrm{b,k,ref}} \cdot k_{\mathrm{h}} \,. \tag{1}$$

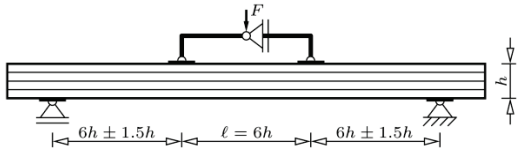

Figure 1: *Four-point bending test setup for a GLT beam according to DIN EN 408 [1] with the depth h and length ℓ.*

According to DIN EN 1995-1-1 [2], $f_{\mathrm{b,k,ref}}$ is provided in DIN EN 14080 [3] ($f_{\mathrm{m,g,k}}$) for beams with the reference beam depth $h_{\mathrm{ref}} = 600\,\mathrm{mm}$ of individual strength classes. The experimental test setup for GLT beams, according to DIN EN 408 [1], is a four-point bending test (Fig. 1), where the beam length is always proportional to the beam depth. Further, the factor k_{h} in [2] is only applicable for smaller beams, reading:

$$k_h = \min\begin{cases}\left(\dfrac{600}{h}\right)^{0.1} \\ 1.1\end{cases}, \tag{2}$$

with a maximum strength increase that is limited to 10 %.

The power law given in Eq. (2) is consistent with the one for wooden members presented by Bohannan [4] based on Weibull's strength theory [5]. Colling [6] also proposed considering the beam volume V and the loading configuration. Here we focus on the size effect k_{h} based on the volumes that reads as:

$$k_{\mathrm{h}} = \left(\frac{V_{\mathrm{ref}}}{V}\right)^{1/m}, \tag{3}$$

where V_{ref} is the reference Volume.

The effort involved in the experimental testing of larger GLT beams is tremendous. Thus, experimental investigations on the size effect in the literature [7–9] focused on smaller GLT beams with depths up to

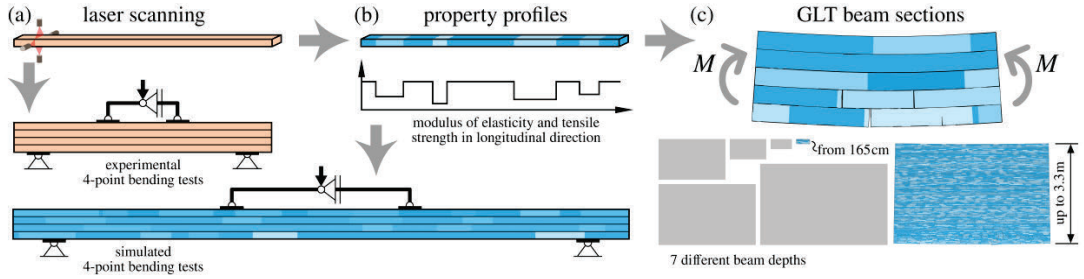

Figure 2: *Modelling concept that was based on (a) GLT beams assembled by real timber boards [8], (b) GLT beams reconstructed by virtual boards using derived material property profiles of real wooden boards [13], and (c) GLT beam sections employed to estimate the size effect [12].*

600 mm. For the larger sizes, numerical studies were conducted, e.g., by Frese and Blaß [10] and Fink et al. [11], covering beam depths up to 3000 mm and 1200 mm, respectively. These studies, however, provided partly contradictory results.

Therefore, we conducted an extensive simulation campaign to study the size effect for beams having depths up to 3300 mm [12]. The applied approach was based on a previous approach that simulates the entire loading process of GLT beams subjected to four-point bending tests [13]. Herein, we present the modelling concept that enabled us to predict the size effect for different beam depths and lengths. Furthermore, global failure criteria similar to the ones used in the literature [10, 11] could be implemented and investigated, which will be presented in detail in [14].

The present paper gives an overview of these studies. The structure is as follows: Section 2 presents the modelling concept to simulate the bending strength of GLT beams subjected to four-point bending tests. The investigation of the size effect and different global failure criteria is presented in Section 3. The paper closes with conclusions and an outlook.

2 MODELLING CONCEPT

The modelling concept builds upon a set of virtual boards to assemble GLT beams (Fig. 2). An experimental study [8] on GLT beams provided the morphological details of real wooden boards based on surface laser scans (Fig. 2a). This enabled the virtual replication of each individual board with deterministic material properties, as outlaid in [15]. The approaches by Frese and Blaß [10] and Fink et al. [11] used, in contrast, stochastic methods to construct the boards and their material properties. Vida et al. [13] presented a modelling approach to simulate the entire loading course of GLT beams subjected to four-point bending tests (Fig. 2b). For the study on the size effect [12], the approach was adjusted to suit the research scope and its efficiency was increased by reducing its model size (Fig. 2c). There, only a beam section anywhere between the two loading points of a four-point bending test was considered, which allowed applying the constant bending moment M directly.

An overview of the procedure deriving the used material properties is presented in Section 2.1. Section 2.2 describes the modelling approach for beam sections before Section 2.3 continues with its validation. The realisation of different beam lengths is discussed in Section 2.4.

2.1 MATERIAL PROPERTIES

The material properties were based on the deterministic estimation procedure presented by Kandler et al. [15]. Therein, the boards were virtually reconstructed and parted in sections. The section length ℓ_s was based on the corresponding knot configuration in the real wooden board, and thus the sections were of individual size (Fig. 3). Each section refers either to defect-free wood, so-called clear wood, or to sections with single large knots or knot clusters, referred to as knot sections.

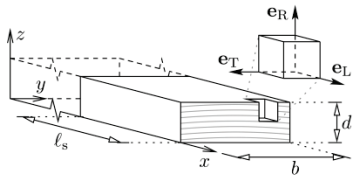

Figure 3: *Board section with homogeneous material properties. [13]*

The material properties of each section were constant, and the material behaviour was orthotropic. The stiffness properties for the clear wood sections were based on a micromechanical multiscale model proposed by Hofstetter et al. [16]. The model used density and moisture content as the primary input parameters. Consequently, each board had its own individual stiffness tensor $\mathbb{C}$. A separate FE approach [15] estimated the longitudinal modulus of elasticity (MOE) $E_{L,i}$ for each knot section i individually. The stiffness tensor $\mathbb{C}$ was then modified along the board by $E_{L,i}$. The tensile strength in longitudinal direction $f_{t,i}$ was assumed to be $55\ \mathrm{N/mm^2}$ for the clear wood sections of all boards. However, the clear wood strength represents an upper strength limit having only a minor influence on the load-bearing capacity [13]. Within knot sections, $f_{t,i}$ was estimated by the knot-area ratio according to the study presented by Lukacevic et al. [17]. Finally, the section-wise constant effective MOE $E_{L,i}$ and tensile strength $f_{t,i}$ in the longitudinal direction were provided for each board by two material property profiles (Fig. 4a,d). Two strength classes, T14 and T22, were considered.

https://doi.org/10.52202/069179-0063

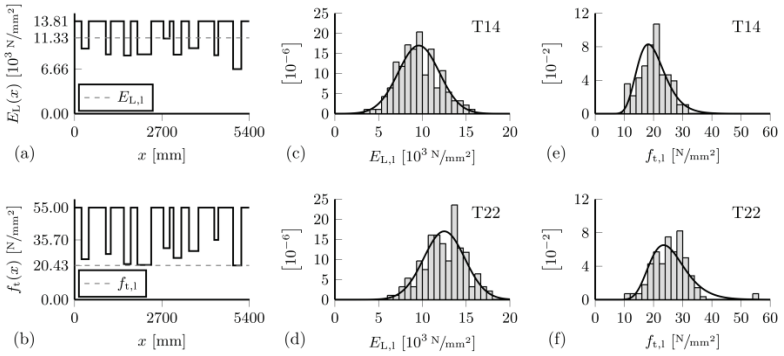

Figure 4: *Example of a board's property profiles providing (a) the effective longitudinal MOE $E_L(x)$ and (b) the effective tensile strength $f_t(x)$ as well as histograms considering all boards and PDFs fitted by maximum likelihood estimations for (c,d) the MOE $E_{L,l}$ and (e,f) the tensile strengths $f_{t,l}$, separate for both strength classes T14 and T22. [13]*

In total, 140 boards of each strength class were available. The board's length was 5400 mm, the width 90 mm, and the thickness 33 mm. The longitudinal MOE of an entire board $E_{L,l}$ considered all sections i of the board as a chain of linear springs:

$$E_{L,l} = \frac{\ell_{tot}}{\sum_i \frac{\ell_{s,i}}{E_{L,i}}} \quad \text{with} \quad \ell_{tot} = \sum_i \ell_{s,i}\,, \tag{4}$$

where $\ell_{s,i}$ is the length corresponding to the section-wise constant $E_{L,i}$ from its stiffness profile (Fig. 4a). Figure 4c,d shows the histograms and the fitted normal probability distribution functions (PDFs) of $E_{L,l}$ according to Eq. (4) for both strength classes T14 and T22, respectively. The board tensile strength $f_{t,l}$ is assumed as the lowest strength $f_{t,i}$ of section i within the strength profile of the considered board (Fig. 4b):

$$f_{t,l} = \min_i \{f_{t,i}\}\,. \tag{5}$$

Figure 2e,f shows the histograms and the fitted log-normal PDFs of $f_{t,l}$ according to Eq. (5) again for both strength classes, respectively. A comparison of the characteristic tensile board strength and the mean longitudinal board MOE to the values according to DIN EN 14080 [3] is given in Tab. 1. Generally, the simulated values are lower than those specified in the standard. The underestimation could be due to different board lengths in the test setup, especially regarding the strengths.

2.2 MODELLING APPROACH

We used a non-linear FE approach to simulate GLT beam sections (Fig. 5) by employing the FE software Abaqus [18]. Details about the approach are published in [12]. The beam layout was assembled by the virtually reconstructed boards from Section 2.1, and the beam structure was designed to be homogeneous. Consequently, only boards corresponding to strength class T14 or T22 were used to simulate beams of strength class GL 24h or GL 30h, respectively. The boards within a beam were arranged by a uniformly distributed pseudo-random process of the following steps:

1. Random picking a full-length board from the entire pool of virtual boards.
2. Random longitudinal displacement of the board within the GLT beam section to define the start and end positions of the lamella.
3. Random choice of the lamella's orientation in the GLT beam layout.

Typically, restrictions on the length of boards are reversed by connecting individual boards with finger joints. Herein, weak points due to finger joints were neglected. We assumed that the structural behaviour and failure is covered by the random allocation of natural weak spots, as it was found by experimental studies [7, 19].

The beam section (Fig. 5) was modelled with the variable length-to-depth ratio ℓ/h, where $h = k \cdot 33$ mm depending on the number of laminations k. The length $e = 100$ mm was added on both ends to avoid disturbing the area of interest by load application effects. The constant bending moment M was applied at the reference points R_1 and R_2 by prescribing a reversed rotation. During the loading, the cross-sections at both beam ends stayed planar. The beam width b was according to the used boards, and the symmetry in the

width direction was exploited to reduce the model size further.

We considered different kinds of local failure mechanisms within the approach, i.e., discrete cracks in the vertical and horizontal direction as well as plastic deformations. All failure mechanisms could only take place within the region of the length ℓ as marked in Fig. 5.

The vertical cracks could occur within the lamellas on the tensile side, and the horizontal cracks between all adjacent laminations building up the beam section (Fig. 5). Both crack directions enabled the formation of a continuous crack over multiple laminations. Two vertical cracks with a horizontal offset and in adjacent laminations could be connected by a horizontal crack. Their implementation is briefly outlined in the following:

- *Vertical* cracks were realised within the framework of XFEM, which was proposed by Tapia Camú and Aicher [20]. The application of XFEM enabled an element to split into two parts with planar and opposing crack surfaces. The split was initiated by an initiation criterion, i.e., the tensile stress in the centroid of an element exceeding the tensile strength $f_{t,i}$. The maximum traction stress t^* between the crack surfaces was, thus, $f_{t,i}$. A linear traction–separation (t–δ) law (Fig. 6a) governed the interaction between the crack surfaces in conjunction of a constant fracture energy $G_{f,v} = 30\ \mathrm{Nmm/mm^2}$.
- *Horizontal* cracks were implemented with cohesive surfaces. The traction–separation (t–δ) relation between the two parts was linear elastic until the initiation of damage and its evolution (Fig. 6b). The maximum traction stress t^* is set to $5.0\ \mathrm{Nmm/mm^2}$ and $6.0\ \mathrm{Nmm/mm^2}$ for transversal tensile stresses and shear stresses, respectively. An uncoupled stiffness tensor defined the traction t between the surfaces and their separation δ. A constant fracture energy $G_{f,h} = 0.6\ \mathrm{Nmm/mm^2}$ was used.

The applied constant properties were assumed because of the lack of available data, e.g., for the fracture energies.

The plastic deformations in compressive zones were considered by implementing ideal plastic behaviour with a multisurface failure criterion [21–23]. The relevance of plastic deformations on the load-bearing capacity was assumed to be limited to smaller beam depths based on an experimental study [8]. Thus, ideal plasticity was only implemented for beams consisting of a maximum of 20 lamellas corresponding to a depth of 660 mm (Fig. 5).

The applied global failure criterion determined the load-bearing capacity M_{max} by the first load decline of at least 3 % from the so far maximum total load M. Finally, the calculated bending strength of the beam reads as:

$$f_b = \frac{6\,M_{max}}{bh^2}, \tag{6}$$

where the dimensions b and h can be found in Fig. 5.

Next is the validation of the approach. The influence of the element size and the plastic deformations on the bending strength are additionally discussed in [12].

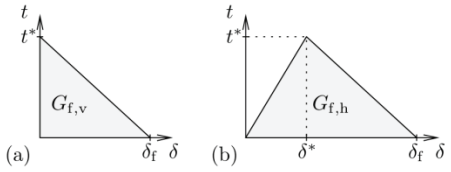

Figure 6: *Traction–separation (t–δ) law with the area representing the fracture energy G_f for (a) vertical cracks and (b) horizontal cracks, where t^* and δ^* are the traction and separation at damage initiation, respectively, and δ_f is the separation at fully evolved damage. [13]*

2.3 VALIDATION

To validate the approach, we compared the results of 40 tested GLT beams with simulation results, i.e., the effective MOE E_{GLT} and bending strength f_b (Fig. 7). The experimental study [8] focused on GLT beams with well-known knot morphology without containing any finger joints. The beams were manufactured using the same boards from the virtual reconstruction process presented in Section 2.1. Thus, it was possible to recreate each tested beam with the unique beam layout and material properties for the simulations.

The validation covered two strength classes, i.e., GL 24h and GL 30h, and two beam sizes with 132 mm and 330 mm depth. The different beam configurations were classified by four types, A, B, D, and E, designated according to their strength class and number of lamellas:

https://doi.org/10.52202/069179-0063

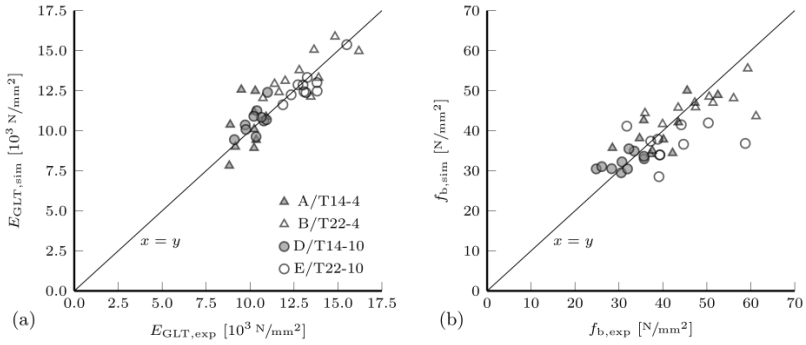

Figure 7: *Comparison of experimental results (subscript exp) to simulation results (subscript sim) for (a) the effective MOE E_{GLT} and (b) bending strength f_b. [12]*

A/T14-4, B/T22-4, D/T14-10, and E/T22-10. The test setup of the experiments was according to DIN EN 408 [1].

The simulations reconstructed the tested beams in the range between the two loading points with a dimensional ratio $\ell/h = 6.0$. The simulation results successfully reproduced the characteristics of the experimental results for the different strength classes and beam sizes, as shown in Fig. 7.

2.4 CONSIDERATION OF DIFFERENT DIMENSIONAL RATIOS

The ratio of beam length to depth ℓ/h, also referred to as dimensional ratio, influences the structural response, as presented in [12]. This was shown by simulating beam sections having ratios ℓ/h of 6.0 and 1.5 for beam depths of h of 165 mm, 330 mm, and 660 mm. However, the larger dimensional ratio requires larger finite element models for which the computation time of the nonlinear calculations became quite long. Therefore, the bending strength prediction of different dimensional ratios based on models having only a ratio of $\ell/h = 1.5$ would be very valuable.

The applied solution to this problem was to estimate the bending strength of larger dimensional ratios $p \times 1.5$ in the following way:

$$f_{b,i} = \min\left\{f_{b,(i-1)\cdot p+1}, f_{b,(i-1)\cdot p+2}, \cdots, f_{b,(i-1)\cdot p+p}\right\}, \quad (7)$$

with $i \in \{1, \ldots, \lfloor n/p \rfloor\}$, where n denotes the number of simulation results from models with $\ell/h = 1.5$ and $\lfloor\cdot\rfloor$ is the floor function that rounds the included number to the nearest smaller integer.

A rough validation was done by comparing the PDFs (Fig. 8) corresponding to the simulation results having the ratio ℓ/h of 6.0 and 4×1.5. The PDFs of f_b were log-normal distributions fitted by maximum likelihood estimations. Considering the simplicity of Eq. (7), the agreement with the simulation results was surprisingly good. The maximum deviation of the mean bending strength was 3.3 % and of the characteristic bending strength 2.2 %. Consequently, the influence of different dimensional ratios can be estimated by this method.

3 COMPUTATIONAL STUDY ON THE SIZE EFFECT

To study the size effect on the bending strength of large GLT beams, we carried out an extensive simulation campaign that is summarised in the following and presented in detail in [12]. The study covered beam sizes ranging from 165 mm up to 3300 mm for two strength classes, i.e., GL 24h and GL 30h. The number of simulations performed depended on the beam size but was the same for both strength classes (Tab. 2). All simulations were carried out with a dimensional ratio of $\ell/h = 1.5$ using the 140 virtually reconstructed wooden boards of each strength class from Section 2.1.

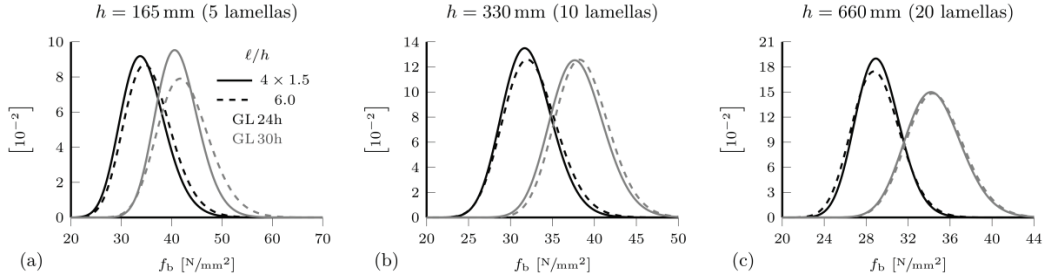

Figure 8: *Comparison of PDFs for the bending strength f_b obtained from simulations with the dimensional ratios of 6.0 or 4×1.5 covering both strength classes for three beam depths: (a) 165 mm, (b) 330 mm, and (c) 660 mm. [12]*

https://doi.org/10.52202/069179-0063

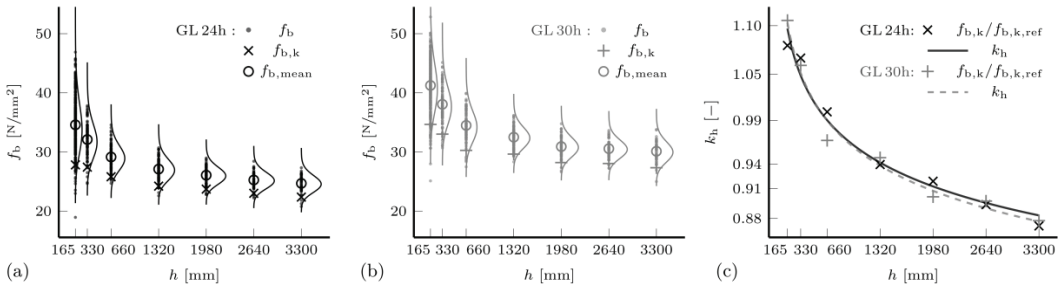

Figure 9: *Bending strength f_b values and PDFs obtained from simulations with the beam depth h and a dimensional ratio of 4×1.5 for strength classes (a) GL 24h and (b) GL 30h, which are used to derive (c) the factor k_h commonly used to describe the size effect. [12]*

The study [12] covered GLT beams having fixed dimensional ratios (Section 3.1) and variable dimensional ratios (Section 3.2). Additionally, the influence of the applied global failure criterion was investigated (Section 3.3), and the results will be published in [14].

Table 2: *Studied beam depths with the corresponding number of lamellas and simulations. [12]*

Depth h (mm)	Lamellas k (–)	Sample size[a] (–)

1980	60	300
2640	80	200
3000	100	200

[a] For each strength class with $\ell/h = 1.5$

3.1 BEAM SECTIONS WITH FIXED DIMENSIONAL RATIO

The test setup, according to DIN EN 408 [1], always requires a dimensional ratio $\ell/h = 6.0$ for the maximum loaded range. Consequently, the beam length ℓ increases when increasing the depth h. The effective bending strengths were calculated using the simulation results in conjunction with Eqs. (6) and (7) to obtain representative results for the required dimensional ratio $\ell/h = 6.0$.

The effective bending strengths decreased for both strength classes with increasing beam size (Fig. 9a,b). The decrease was present for the mean and characteristic bending strength, $f_{b,mean}$ and $f_{b,k}$, respectively. The mean and characteristic values were obtained from the two-parameter log-normal PDFs, which were fitted to the entire sample by maximum likelihood estimations. Additionally, the PDFs showed a decreasing variation with increasing beam size. The decreasing variation results in a lower decrease of $f_{b,k}$ compared to $f_{b,mean}$.

On the level of $f_{b,k}$, the size effect k_h according to Eq. (3) was clearly present for the entire range of simulated beam sizes (Fig. 9c). For the analytical solution represented by Eq. (3), the characteristic reference bending strength $f_{b,k,ref}$ and the power law parameter m were fitted to the simulation results by the least squares method. The reference depth h_{ref} was set to 600 mm according to DIN EN 14080 [3].

The characteristic reference bending strengths $f_{b,k,ref}$ found through fitting overestimate the values provided in DIN EN 14080 [3] by about 7 % and 4 % for GL 24h and GL 30h, respectively (Tab. 3). The found parameter m is quite similar for both strength classes having a mean value of 26.2.

Both strength classes showed about the same decrease. The largest simulated beams ($h = 3300$ mm) showed a reduced $f_{b,k}$ of about 12 % compared to $f_{b,k,ref}$ (Fig. 9c). For smaller beam depths than h_{ref}, the predicted k_h agrees well with the modification according to Eq. (2) from DIN EN 1995-1-1 [2]. Additionally, our results agreed very well with two experimental studies from the literature testing beams with depths of about 300 mm and 600 mm. Aasheim and Solli [7] and Schickhofer [9] identified k_h as 1.07 and 1.04, respectively. For the same beam depths, our approach predicted k_h to be 1.05. The result was obtained using the mean value of the parameter m corresponding to both strength classes in Eq. (3).

Table 3: *Characteristic reference bending strength $f_{b,k,ref}$ and power law parameter m fitted to the simulation results. [12]*

	$f_{b,k,ref}$ (N/mm²)	m (N/mm²)	$f_{b,k,ref}$ (N/mm²)	m (N/mm²)
Load drop	25.74	27.00	31.23	25.38

3.2 BEAM SECTIONS WITH DIFFERENT DIMENSIONAL RATIO

As already pointed out, the test setup, according to DIN EN 408 [1], defines a fixed ratio of the length ℓ between the two loading points and the beam depth h. However, the dimensional ratio ℓ/h of GLT beams is determined during the design process and might not coincide with the fixed dimensional ratio of the experiments. Therefore, investigating the size effect on $f_{b,k}$ for different dimensional ratios ℓ/h is highly relevant for practical application.

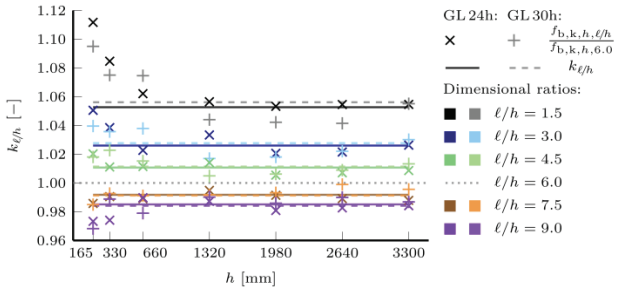

Figure 10: *Comparison of the normalised values $k_{\ell/h}$ of each individual beam depth h: the scatters refer to the simulated results in conjunction with Eq. (7), and the horizontal lines are according to Eq. (3). [12]*

The different ratios ℓ/h were realised using the procedure presented in Section 2.4. The simulation results stemmed from the models having a dimensional ratio of 1.5. For each of the seven simulated beam depths h, five different lengths ℓ were investigated, covering ratios ℓ/h ranging from 1.5 to 9.0. The obtained characteristic bending strengths $f_{b,k,h}$ for each ratio of a specific beam depth h were normalised by $f_{b,k,h,6.0}$ of the same beam depth h with a ratio $\ell/h = 6.0$ (4×1.5). This normalised value is herein denoted as $k_{\ell/h}$.

The simulation results indicated that the ratio ℓ/h heavily influences the bending strength of a GLT beam (Fig. 10). By changing the ratio for a specific beam depth h, the investigated beam length changes. When looking at a particular beam depth, the characteristic bending strength of a beam with a shorter length was smaller than that of a longer length. Especially beams with a depth smaller than 660 mm showed a more pronounced influence of the dimensional ratio ℓ/h. For each individual ratio, the larger beams showed an almost constant factor $k_{\ell/h}$. Consequently, the same size effect is present for only changing the beam length or depth. The horizontal lines in Fig. 10 render the results of Eq. (3) in conjunction with the results provided in Tab. 3. The simulation results agreed well with the analytical concept.

3.3 INFLUENCE OF THE APPLIED GLOBAL FAILURE CRITERION

The applied modelling approach enabled the investigation of different global failure criteria for each simulation. This was possible by simulating the entire loading process and determining the load-bearing capacity afterwards. The size effect on $f_{b,k}$ of large GLT beams had been estimated before by Fink et al. [11] and Frese and Blaß [10]. However, their results diverged from each other. To investigate the influence of applied global failure criteria, we implemented similar criteria within our approach. The modelling strategies of each approach were different, making a completely identical description of the failure criteria impossible, e.g., due to a different mesh size or the implementation of discrete cracking. Nevertheless, we tried to implement the criteria as closely to the proposed one as possible. The implementation of the global failure criteria and the main differences between the modelling strategies will be discussed in detail in [14].

The applied global failure criterion defined the simulated load-bearing capacity M_{max} used to further calculate the corresponding bending strength f_b according to Eq. (6). Additional to our already presented load drop criterion (Section 2.2), we implemented the following global failure criteria:

- The global stiffness reduction criterion is met by the first global stiffness reduction of at least 1 % compared to the initial global stiffness of the first loading increment. The global stiffness is calculated in each increment with the current bending moment and rotation. The load-bearing capacity is then the maximum load during the loading before the criterion is fulfilled. This implementation is similar to the criterion applied by Fink et al. [11].
- The first crack initiation criterion focuses only on the initiation of the first crack in the outermost tensile lamination to identify the load-bearing capacity. The load-bearing capacity is then the maximum bending moment observed during the entire simulation up to this point. During the loading process, an arbitrary number of cracks can occur within the other laminations of the beam. This criterion is comparable with the one used by Frese and Blaß [10] and Frese [24].

The estimated individual trends of the size effect k_h for each global failure criterion (Fig. 11) agreed very well with the results presented in the literature. The stiffness reduction criterion predicted basically no influence of the beam size on $f_{b,k}$, which agrees with the result presented in Fink et al. [11]. The first crack initiation criterion resulted in a decrease only a bit larger than proposed by Frese and Blaß [10]. The characteristic bending strengths of all criteria were taken from fitted log-normal PDFs.

4 CONCLUSION AND OUTLOOK

The development of reliable modelling concepts is of significant importance to effectively investigate wood products such as GLT beams. In the present study, a comprehensive simulation campaign of more than 8000 simulations could predict the size effect for large GLT beams of up to 3300 mm depth. It was further shown that not only the beam depth influences the characteristic bending strength but also the beam length. The size effect,

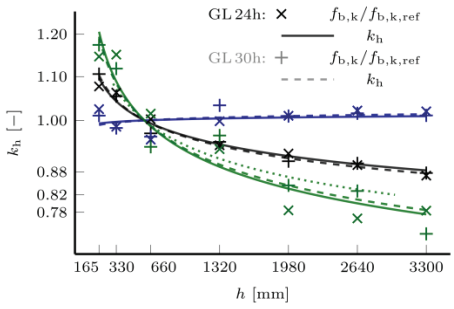

Figure 11: *Size effect k_h according to Eq. (3) based on three different global failure criteria: (i) the load drop criterion in black, (ii) the system stiffness reduction criterion in blue, and (iii) the first crack initiation in the outermost tensile lamination criterion in green compared to (iv) the proposed result by Frese and Blaß [10] with the dotted line in green. [14]*

including changes in beam length and depth, could adequately be described by the concept proposed by Colling [6], at least for beams with depths greater than 660 mm. Additionally, results of numerical studies from the literature could be reproduced by using corresponding global failure criteria.

Numerical simulations offer an efficient way to perform extensive parameter studies of different kinds to make reasonable predictions. Nevertheless, simulation results need to be carefully validated as they might heavily depend on their modelling strategy. Experimental testing of such large GLT beams is unfortunately missing, which would strengthen the value of such studies.

As for future research focus, the aim is to obtain section-wise constant fracture energies for individual knot sections, which then can be used to replace the for now constant one. This could be achieved by employing the so-called phase-field method [25, 26], which is one of our main current research focuses.
