Finally, the fourth specimen of each configuration was equivalent to the third one, however 15 mm thickness gypsum boards were attached with of 8 x 75 mm drywall screws over the plywood sheathing, to evaluate the contribution of the non-structural sheathings. A brief list of the specimens is presented in Table 1.

2.2 TEST SET-UP

A reinforced-concrete reaction wall and a strong floor were used to carry out the tests. As shown in Figure 2, a H500x500x246 mm steel beam was connected to a 250 kN capacity hydraulic actuator, to distribute the load to the specimens in two points, by means of load-transfer plates, as shown in Figure 1. Rollers were placed under the diaphragms to braced them, avoiding out of plane displacements. Load cells were attached to a 4000 mm long W10x48 reaction beam and placed near to the corners of the unloaded chord of each diaphragm. Four angle brackets supported the 4 meters long reaction beam and were also anchored to the strong floor using post-tensioned steel bars, thus ensuring that the friction between steel plates and strong floor was greater than applied load by the hydraulic actuator.

The adopted set-up was designed to position the specimens in a flat manner, parallel to the strong floor, and placed over steel bars to allow the diaphragm to move under in-plane loads. Each test was instrumented with eleven linear variable displacement transducers (LVDT), to measure different displacements, such as those in the unloaded chord beam, between sheathing panels, displacement in the angle brackets, among others. A system connected to a PC was used to collect the data.

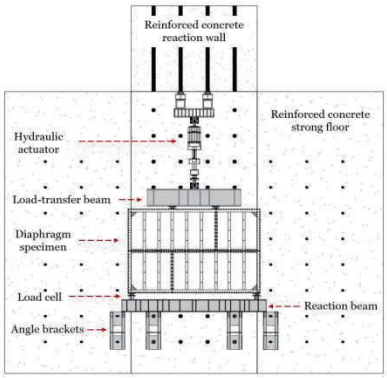

Figure 2: *Plan view of test set-up. Taken from [27].*

2.3 LOADING PROTOCOL

Tests were carried out based on the guidelines provided by the ASTM E455 standard [23]. SL – OSB and SL – PLY specimens were tested according to a loading protocol (force-controlled) based on [9], as shown in Figure 3. Both tests were performed considering a design load of 50 kN, however, to evaluate the stiffness degradation at low/high load levels, the SL – OSB specimen started the loading protocol at the fifth cycle, and loaded to the failure at the end. Conversely, the SL – PLY specimen started the loading protocol at the very first cycle and loaded to the failure after the fourth 1x design load cycles. Stiffness results can be found in [27].

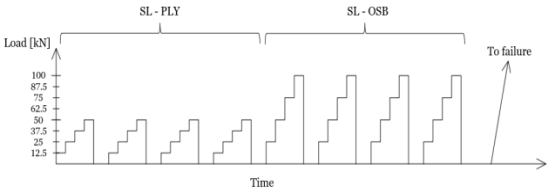

Figure 3: *Loading protocol for SL-PLY and SL-OSB specimens.*

The rest of the specimens were tested under a monotonic loading protocol, all of them displacement-controlled, with a displacement rate of 5 mm per minute. Load was stopped when the peak load dropped by approximately 20%.

3 NUMERICAL MODELING

Numerical models are a valuable tool for researchers when studying the nonlinear response of structures since they provide the means to overcome the physical and resource limitations of lab testing. However, numerical models also require a validation process against real specimens to measure their reliability level, precision, and prove that they meet the minimum requirements for structural engineering, beings this latter especially relevant when unconventional systems or solutions are studied. Therefore, this section presents a nonlinear numerical model for the timber diaphragms tested as part of this research project, validates its results against the test data presented in previous sections, and carries out additional analyses to better understand the nonlinear response of industrialized timber diaphragms. The numerical model has been developed employing the M-CASHEW software built by [24] and following the modeling guidelines proposed by [25].

Timber beams were represented using Euler-Bernoulli frame elements (elastic response) that have 3 degrees-of-freedom at each node. An elasticity modulus E = 11.4 GPa was considered for the sawn lumber model, based on the experimental results reported by [25]. Also, an elasticity modulus of 11.5 GPa were employed for I-joist beams according to [28], and 9.3 GPa for LSL, according to values declared by the manufacturer. Besides, the frame elements employed a corotational approach in the numerical formulation. Nailed connections were modeled employing zero-length spring elements with 3 degrees-of-freedom per node. The so-called MSTEW model proposed by [29] for nonlinear timber connections was employed in the X and Y direction, whereas a zero-stiffness element was considered for rotations. It should be noted that the elements used for the directions X and Y employed the true-oriented approach developed by [24] with the aim of avoiding overestimated values for the diaphragm's capacity and stiffness, as has been found by prior investigations [29,30]. The governing parameters for the MSTEW model were computed by nonlinear minimization techniques from the test data on nailed connections similar to [31].

The sheathing panels were modeled by means of shear rectangular elements with 5 degrees-of-freedom: one for rigid-body rotation, two for in-plane shear deformation, and two for rigid-body translation. Note that panels' rigid behavior consider the bearing between them. Based on the experimental data from [25], a shear modulus G = 1.3 GPa was used when modeling the OSB panels, and G = 0.5 GPa when modeling plywood panels, according to Table C4.2.3A of SDPWS [14]. When conducting analyses with the model, a displacement-controlled approach was employed along with a norm displacement increment test as convergence criteria. Besides, up to 20 iterations were conducted at each load step and the residual tolerance was set as 1e-6 kN. Full details on the modeling approach can be found in [25] and [27].

4 RESULTS AND DISCUSSION

4.1 FAILURE MODE

The diaphragms presented failure modes related to fasteners, as usually shown in the literature [5-13]. All specimens failed due to pull out of the nails in the edges of the panels (Figure 4a, 4c), crushing of OSB panels, cutting of drywall screws (Figure 4d) and a non-expected failure in the loaded chord of SL-PLY specimen (Figure 4b). The frame structure appeared to remain undamaged, particularly in the unloaded chord beam. Steel angles in each specimen prevented undesired end-beam to chord-beam joint failure, allowing them to exhibit typical ductile failure modes.

The smooth shank nail used in SL diaphragms led these specimens to show failure modes associated to pull out of the nails, due to their low friction resistance. In case of SL-PLY/GWB, no shear cracking was seen over the gypsum boards. Conversely, the main failure was due to the cutting of drywall screws and pulling out of the nails attaching the edges of the plywood underneath, as shown in Figure 4d.

Most of the investigations on I-joist diaphragms have considered nail spacings not closer than 102 mm, and employing 10d sheathing nails [11-13], which increased the probability of flanges to split. Thus, this paper attempted to reduce nail spacing, reducing the nail diameter at the same time, minimizing as much as possible the probability of splitting without decreasing shear capacity. As shown in SL specimens, failure modes on IJ specimens were also due to pull out of nails and crushing of panels by nails head. IJ-OSB, IJ-PLY and IJ-PLY/GWB specimens showed ductile failure modes as previously mentioned, although IJ-PLY also presented brittle failures located at blocking, like those reported in [13]. As well as in SL-PLY/GWB, the failure mode of IJ-PLY/GWB was partially due to the cutting of drywall screws, added to local gypsum failures and detachment, as reported in [31]. No cracking of global gypsum panels was reported, as shown in Figure 4e. Further results are available in [27].

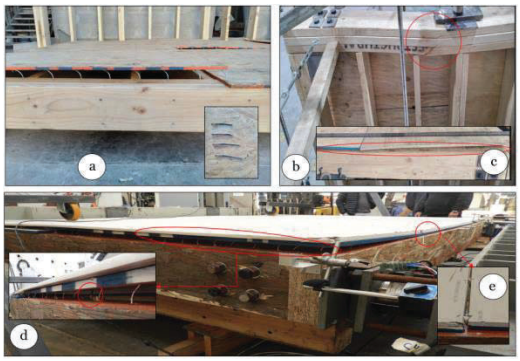

Figure 4: *Typical failure modes of diaphragm specimens.*

4.2 FORCE-DISPLACEMENT RESPONSE

The monotonic and envelope curves are plotted in Figure 5. The y-axis located in the right shows unit shear capacity, which is the peak capacity divided into 2 and then divided into the width of the diaphragm. Initially, the monotonic response was approximately linear up to drift values (midspan displacement divided into half mid-span length) of about 0.2-0.5% for SL specimens, and up to 0.6% for IJ specimens [27]. Bare specimens appeared to behave virtually elastic according to Figure 5.

Beyond the mentioned drifts, the structural response turned to be highly non-linear, mainly due to the local deformation of nails. A summary of the main results is listed in Table 2, which includes peak capacity on each test (F_0), elastic stiffness (K_0), yielding load (F_y), yielding displacement (δ_y) according to ASTM E2126 [33] and ductility ratio (μ), which was obtained as δ_u / δ_y. Note that ultimate displacement δ_u was omitted from Table 2 due to space constraints.

4.3 AXIAL CHORD TENSION EQUATION CHECKING

The most common way for modeling diaphragms analytically, and to estimate their chord tensions comes from principles of engineering, where the diaphragm is assumed as a deep and thin beam, thus the sheathing panels act as the web, supporting the shear, and the chords act as flanges, supporting all the axial tension, which is usually estimated as M/W, where M is the flexural moment diagram along the chord, and W is the width of the diaphragm. Thus, this research included two specimens (SL-OSB and SL-PLY) to assess how well this assumption fits with the experimental results. Both specimens were instrumented at the unloaded chord with one strain-gauge each, as shown in Figure 6. To consider the contribution of both straps, the axial load measured in each strain-gauge was. The comparison was evaluated at the shear allowable design of each specimen: for SL-OSB (4 kN/m), the experimental axial chord tension indicated 7.4 kN, with a theoretical tension of 5 kN, thus showing a 48% of percentage difference. For SL-PLY (shear limit of 4.5 kN/m), the experimental measurement recorded a value of 6.6 kN, in contrast to 5.5 kN from the theoretical estimation, showing a 20% of percentage difference. Such percentage differences confirmed thw well-functioning of such an assumption, and in particular the M/W equation, even though experimental results appear to be slightly higher. These underestimations may be attributable to the axial load duplication, since axial loads at the instrumented strap were probably higher than those at the non-instrumented strap, due to the eccentricity with respect to the shear resistant zone, i.e., the sheathing panel. Further research needs to be carried out on this topic.

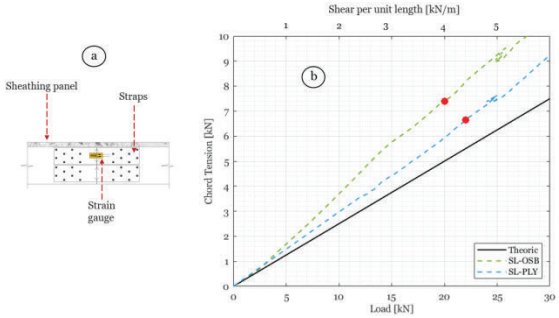

Figure 6: *Chord tension measurements versus theorical M/W estimation: (a) shows the location of strain gauge and in (b) is shown the measurements up to the starred allowable design limit.*

4.4 DESIGN IMPLICATIONS

This section compares the experimental results with the estimations of strength and stiffness provided by SDPWS [14]. This section is intended to evaluate how well code provisions adjust with the experimental results reported in the present investigation. Even though SDPWS standard is only applicable to diaphragms uniformly nailed, and just with one type of sheathing per specimen, PLY/GWB specimens were also Ied in this section, but not deeply discussed.

4.4.1 Strength

The nail sizes and sheathing panels used in this research were chosen for being commonly used in the Chilean industry, however, they were not coincident with North 5merican configurations, then they were not applicable to meet SDPWS [14] available unit shear capacities. Thus, two different methods to obtain unit shear capacities (v_{SDPWS}) were employed in the present research. The first consisted of choosing the more similar configuration from Table 4.2A of the SDPWS [14] standard. Thus, considering 6d common nails (2.87 mm in diameter) and 9.5 mm (⅜ in) sheathing panels, nominal unit shear capacities were taken from 4 – 6 in nailing pattern (785 plf) and 2.5 – 4 in nailing patterns (1175 plf) to compare with SL specimens and IJ specimens, respectively. In contrast, the second method consisted in estimating allowable unit shear capacities for each specimen by means of Johansen's theory [34], as explained in [9]. Following these approaches, experimental and theoretical shear capacities for each specimen were shown in Table 3. Experimental unit shear capacities for SL specimens were between 78-96% larger than those proposed in SDPWS [14], while for IJ specimens the experimental to SDPWS [14] nominal contrast were between 68-114%. Allowable unit shear capacities were obtained by dividing experimental and SDPWS nominal values by 2.8, as suggested in [14]. Conversely, Tissell & Elliot [9] method was chosen to properly estimate allowable unit shear capacity for each specimen, allowing to take into account the accurate variables for every specimen, such as nail size, sheathing thickness, among others. Such a method allowed to calculate the allowable unit shear capacity of

each specimen through their Johansen's yielding mode [34], multiplied by the nails separation. Table 3 shows in its lasts two columns the allowable unit shear capacity derived from [9] method. As it can be highlighted from Table 3, conventional SL specimens reached experimental-allowable unit shear capacities between 61-100% higher than those proposed via [9] method, while conventional IJ specimens exhibited experimental-allowable unit shear capacities between 144-172% higher than those proposed via [9] method. On the other hand, since both experimental and SDPWS nominal results were divided into 2.8, percentage variance are the same as those presented above.

Table 3: *Nominal and allowable unit shear capacity.*

Test	Nominal		Allowable (ASD)		
	v_{exp} kN/m (plf)	v_{SDPWS} plf	v_{exp} plf	v_{SDPWS} plf	$v_{T\&E}$ kN/m (plf)
SL – OSB	22.5 (1540)	785	550	280	4 (275)
SL – PLY	20.5 (1400)	785	500	280	4.5 (310)

IJ – PLY/GWB	41.6 (2850)	-	1020	-	-

* T&E: Tissell & Elliot [9].

4.4.2 Stiffness and deflections

The stiffness of a uniformly nailed diaphragms may be indirectly calculated from SDPWS Eq (4.2-1), which is usually employed to calculate the mid-span displacement within linear range. This equation is relevant since it allows to predict whether the diaphragms will behave rigidly or flexibly in contrast to the lateral force resisting system underneath, according to principles such as those published in [4]. The mid-span displacement is calculated as follows:

$$\delta = \frac{5vL^3}{8EAW} + \frac{vL}{4G_v t_v} + 0.188Le_n + \frac{\sum x\Delta_c}{2W} \quad (1a)$$

$$\delta = \frac{5vL^3}{8EAW} + \frac{0.25vL}{1000G_a} + \frac{\sum x\Delta_c}{2W} \quad (1b)$$

Equation (1a) includes bending, panel shear deformation, nail slip, and chord splices slip, while Eq. (1b) eases the use of the first equation by combining both shear flexibilities, generating an apparent diaphragm shear stiffness G_a, which is a function of nail slip in the linear range. Under the same logic as in section 4.4.1, since no SDPWS [14] configurations are exactly coincident with those carried on in this research, G_a values were calibrated with the monotonic and cyclic (envelopes) sheathing-to-framing tests presented in [27], which were used to determine the nail slip e_n in equation C4.2.3-3 in SDPWS [14], and presented here as Equation (2):

$$G_a = \frac{1.4v_{ASD}}{\frac{1.4v_{ASD}}{G_v t_v} + 0.75e_n} \quad (2)$$

where $G_v t_v$ correspond to shear stiffness of wood structural panels. Due to the lack of precisely information, values from Table C4.2.3A from SDPWS [14] were taken, where 14.6 kN/mm (83500 lb/in) and 7.5 kN/mm (43000 lb/in) were considered for 11.1 mm thickness OSB and 15.1 mm thickness plywood, respectively. G_a values were tabulated in Table 4, which also shows all the parameters considered for each of the 4 conventional specimens tested to be used in Equation (1b).

Table 4: *Mid-span displacement comparison at allowable design levels.*

Tested Specimen	SL – OSB	SL – PLY	IJ – OSB	IJ – PLY
L (mm)	3663	3663	3663	3663
L (ft)	12	12	12	12

δ_{exp} (mm)	1.69	2.56	2.59	3.22
$\delta_{SDPWS}/\delta_{exp}$	1.81	1.87	0.75	1.21

Load-displacement curves were calculated for each specimen presented in Table 4 and were plotted against the corresponding experimental results. As shown in Figure 7, each conventional specimen (uniformly nailed and with one sheathing) was plotted until the corresponding allowable shear limit, defined in Table 3 and Table 4 in the y-axis, while the x-axis was limited to 0.27% drift, equivalent to 5 mm of mid-span displacement. Note that most of specimens behaved

https://doi.org/10.52202/069179-0447

slightly stiffer than their corresponding SDPWS [14] prediction, being the only exception the specimen IJ – OSB, whose percentage difference was about 25%, probably attributable to a poor nailing process. These outcomes may provide a first overview of how conservative this equation is for estimating mid-span displacements inside the linear range for Chilean industrialized diaphragms. Although not a fair comparison, non-conventional specimens which included gypsum boards were included in Figure 7 with the purpose of showing the difference in contrast with conventional systems.

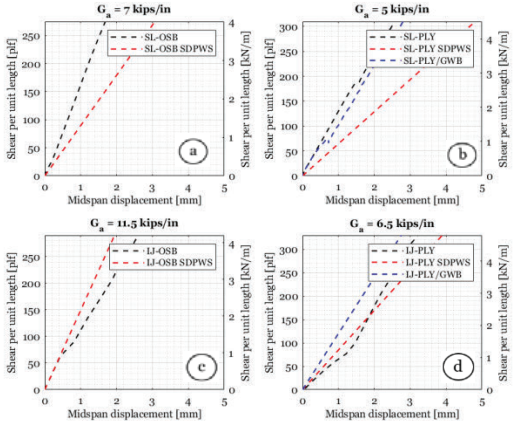

Figure 7: *Measured and calculated mid-span displacement curves for allowable design levels: (a) SL-OSB specimen, (b) SL-PLY and SL-PLY/GWB, (c) IJ-OSB specimen, and (d) IJ-PLY and IJ-PLY/GWB specimens. Adapted from [27].*

4.5 NUMERICAL MODELING

This section had the purpose of confirm the well-functioning of the M-CASHEW [24] software at modeling diaphragms with different configurations, including different types of nails, panel sheathings, among others. To address this purpose, 5 out of the 6 diaphragms experimentally tested – which are presented in Table 5 - were contrasted versus numerical models. Note that SL-OSB specimen was excluded from this comparison, because its loading protocol, as shown in Figure 3, produced notorious creep, mechanism which is not possible to reproduce by M-CASHEW [24]. Thus, this section considered monotonic analyses and one cyclic analysis (SL-PLY) with little to no creep. Loading set-up used in numerical models was to that used in experimental tests, i.e., the protocol suggested by ASTM E455 [23], applying the loads in the north-south direction.

The good agreement between experimental results and numerical models can be appreciated in Figure 8 and Table 5, which shows the comparison between global stiffness, peak capacity, ultimate displacement, and ductility. As previously mentioned, The IJ-OSB specimen showed an unexpected low stiffness, which was confirmed by its numerical model contrast, showing a clearly stiffer behavior within the linear range, although capacity and ductility appeared to be consistent with its corresponding experimental result.

The PLY/GWB specimens, i.e., those sheathed with gypsum over a plywood panel, were modeled only considering the plywood panel, since gypsum board did not appear to add any shear capacity. In this line, drywall screws were modeled directly as springs over plywood panels, attaching them to the framing underneath. These results have proven the feasibility of M-CASHEW to properly model light-frame diaphragms, as shown in Figure 8. It should be highlighted that the deformation of sheathing-to-framing connectors was the main flexibility source, while those attributable to framing were negligible [27].

5 CONCLUSIONS

An experimental campaign was carried out on 8 full-scale industrialized timber diaphragms, proving its feasibility to withstand in plane shear loads without showing severe damage. The main conclusions of the present investigation are listed below:

Strength results resulted to be consistent with the recommendations provided by SDPWS [14], while experimental chord tension measurements suggest that an enlargement factor of 30% should be applied to chord tension obtained by mechanic principles. Anyway, more research on this topic must be performed to confirm such statement.

Experimental results showed that OSB-sheathed specimens were between 20-40% stiffer than those sheathed with plywood, regardless the framing. Also, I-Joist diaphragms results showed that those sheathed with 15.1 mm thickness plywood performed 27% stronger than those sheathed with 11.1 mm thickness OSB, consistent to Johansen's theory [34]. Likewise, I-Joist diaphragms developed larger peak capacities than sawn lumber diaphragms, which suggests that the more quantity of nails, the larger peak capacity, no matter if these nails have smaller diameters. Conversely, experimental results showed that sawn lumber diaphragms – sheathed with 2.9x65 mm nails - performed stiffer (between 10-70%) than their I-Joist counterparts – sheathed with 2.5x50 nails -. Thus, considering that I-Joist bare frame performed 100% stiffer than sawn lumber bare diaphragm, and that sawn lumber sheathed specimens contained less nail quantity than I-joist sheathed specimens, this leads to the conclusion that in plane stiffness is mainly controlled by nail diameter, while peak capacity is mainly controlled by nail quantity [27].

Peak capacity and in-plane stiffness were increased by using gypsum boards over plywood panels with 8x75 mm drywall screws. In fact, an increase of 15% was reached in the peak capacity, while a 20% improvement was noted in stiffness, particularly considering I-Joist specimens results.

Although the M-CASHEW [24] software had been mainly used to reproduce light-frame walls behavior until this research, with limited investigations attempting to predict diaphragm's structural response, this research proved the feasibility of M-CASHEW [24] to accurately predict mid-span displacements all the way to failure for different monotonically and cyclically loaded diaphragms. A more comprehensive discussion of these results is going to be available in literature soon.

Finally, these experimental results (which are deeply discussed in [27]) will serve as the basis for the inclusion of light-frame diaphragms in the Chilean regulation code [26]. Unit shear capacities, as well as the well-functioning behavior of mid-span displacement equations presented in here will experimentally support their adoption in the mentioned code.

FEASIBILITY STUDY ON LONG-SPAN CLT-GLULAM COMPOSITE FLOORING SYSTEM CONNECTED WITH BAMBOO-TENON SHEAR CONNECTORS

Yue Diao[1], Cristiano Loss[2]

ABSTRACT: The rise of cross-laminated timber (CLT) became a cornerstone for the development of mass timber high-rise buildings and for large applications of timber products in construction. The design of CLT floors is often hinged upon meeting the vibration and deflection requirements under serviceability limit states. As a result, thick and material-intensive sizes of floor members can result from the design to fulfil the minimum stiffness requirements.

A long-span composite flooring system made of CLT panel and glulam ribs is a structurally optimized and cost-effective solution. In this paper, a feasibility study of a 12-meter composite flooring system consisting of CLT slab and glulam ribs jointed through bamboo-tenon shear connectors was conducted. The flooring system was designed to achieve performance objectives per the National Building Code of Canada, focusing on office spaces. Finite element modelling was used to investigate the behaviour of connectors under push-out shear forces. A parametric study of the shear connector was then carried out. Impacts of the material properties of mortise-tenon on the behaviour of the joints were discussed. Further, the structural performance of the composite system was investigated under several case scenarios. Specific design recommendations for adopting bamboo-tenon as the shear connector in composite systems were provided.

KEYWORDS: Bamboo connectors, CLT composites, flooring systems, long-span floors

1 INTRODUCTION

1.1 COMPOSITE FLOORING SYSTEMS

The acceptance of composite flooring systems started with the growth of reinforced concrete-based and concrete-steel composite floors. In Europe, design provisions of such composite floors have been included in Eurocode 4 [1]. More recently, research has been conducted with the aim of replacing concrete slabs with CLT panels. With specific reference to the timber-timber floor composites, general design guidelines of a fully connected CLT-glulam ribbed system have been discussed in the proceeding of the joint Conference of COST Action [2]. Several long-span timber floor solutions using inclined self-tapping screws as shear connectors have been studied in Europe [3]. Research has been conducted to investigate new connection systems; the result of metal fastener combinations employed in timber composite floor structures can be founded in [4]. It has been shown that these mechanically connected composites can be designed assuming full composite action. However, with the increase in floor span, the number of metal fasteners used, the on-site labor costs and the construction time increase along with it, making larger span timber flooring systems less attractive in practice. Therefore, there is an urge to develop high-structural performance connection systems for timber composite floor systems.

1.2 MODERN CARPENTRY JOINTS

The advancement of automation technologies in the wood industry, namely computer-numerically-controlled (CNC) machining technology, increased the level of prefabrication of CLT structures. As a result, CLT panels can be manufactured as wall and floor elements and quickly assembled on-site. These technologies also increased the possibility of using CNC machining carpentry joints to serve as the connection system in mass timber construction. Studies of carpentry joints used in modern timber frame structures have been conducted by Tannert et al. [5] and Claus and Seim [6]. More recently, the castellation CLT joints have been studied by Brown et al. [7]. Schmidt and Blass [8] have investigated the behavior of hardwood connectors serving as in-plane shear connectors for CLT walls.

1.3 ENGINEERED BAMBOO PRODUCTS

Bamboo is a rapidly renewable biomaterial with similar environmental benefits and mechanical properties as timber. Full culm bamboo can be applied as a structural

https://doi.org/10.52202/069179-0448

material in low-rise residential housings in countries with rich bamboo resources, such as the Philippines, Colombia, Ecuador, China, and India. In recent years, significant efforts have been devoted to the characterization of the mechanical properties of engineered bamboo products, such as laminated bamboo lumber (LBL), parallel strand bamboo (PSB), and bamboo laminated veneer lumber (BLVL), aiming to expand their application as load-bearing members in buildings and eventually, incorporate them into the building code. However, other factors of using bamboo material in the built environment must be addressed, such as the fire protection strategy, the connection design approach, and its long-term behaviour.

1.4 OBJECTIVES

Seeing the technological developments in the wood industry and needs for a sustainable building environment, this paper aims to develop an engineered bamboo shear connectors for wood composite floorings. Due to enhanced mechanical properties of engineered bamboo, it is anticipated that such bamboo-tenon connectors are suitable candidates for CLT-glulam floors intended for long-span usage. Besides, the design value of the bamboo-tenons remains in the elastic region, aiming to prevent the irreversible damage in local areas of timer members for future deconstruction and reconstruction purpose.

2 CLT-GLULAM RIBS COMPOSITE FLOORING SYSTEM CONNECTED WITH BAMBOO SHEAR CONNECTORS

2.1 CLT-GLULAM FLOOR

A 12-meter timber composite flooring system consisting of a 3-ply CLT panel and glulam ribs connected by bamboo-tenon shear connectors was designed to fulfil the static performance objectives per the National Building Code of Canada (NBCC) [9]. A non-structural concrete topping was placed on top of the CLT panels and counted as dead load only. The flooring system was modular designed, assumed sitting on continuous mass timber vertical load-bearing elements or hybrid timber-based frameworks. The structural elements are illustrated in Figure 1.

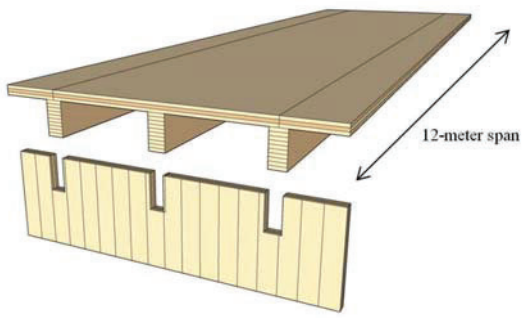

Figure 1: *CLT-glulam composite flooring and its end supports*

2.2 BIO-BASED TENON-TYPE SHEAR CONNECTORS

The three-piece tenon-type shear connector requires grooving into both the CLT and glulam ribs and is made of engineered bamboo products, as shown in Figure 2.

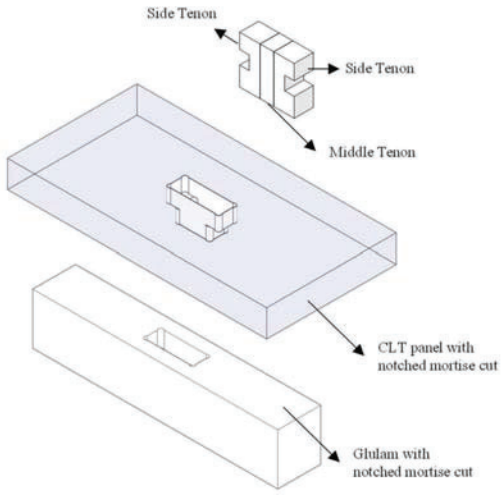

Figure 2: *Three-piece bamboo-tenon shear connector and CLT-glulam with mortise cuts*

The geometry of the tenon was inspired by the traditional joinery technique combined with CNC-machined carpentry joints used in modern timber structures. The sides of the tenon are symmetrical pieces with grooved profiles to accommodate CLT panels. The middle piece is used for tightening the mortise-tenon joint. The entire connector is embedded in mass timber members and covered by non-structural floor components, as described in Section 2.1. The corners of mortises in CLT and glulam were routed as rounded circles (i.e., notches in the figure). It is a feature of modern CNC machine drilling and provides a buffer area at the corner of the mortise-tenon contact region. Two engineered bamboo products were considered for the tenon material in this study, e.g., parallel strand bamboo (PSB) and laminated bamboo lumber (LBL).

3 MODELLING IN ANSYS

3.1 MATERIAL PROPERTIES

Mass timber products in this study., i.e., CLT and glulam, were modelled using solid wood properties and assembled by layer's fibre orientation. Wood is assumed as an orthotropic material. The material properties of PSB and LBL were described using the transversal isotropic and orthotropic models, respectively. This difference is caused by their different processing procedure [10]. The fibre orientation of each material and corresponding axis directions in the modelling space are shown in Figure 3.

https://doi.org/10.52202/069179-0448

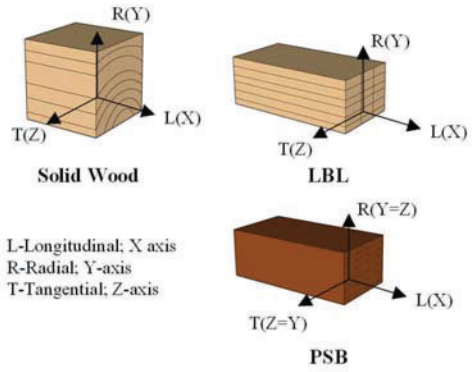

Figure 3: *Biomaterials fibre orientations and their axes in Cartesian coordinate system*

The elastic properties of wood were obtained from Wood Handbook [11]. The species of CLT and glulam are spruce (Sitka) and Douglas-fir, respectively. For details see authors' previous work [12]. The elastic properties of bamboo products are listed in Table 1 and Table 2, while more details can be found in [13, 14] and [15, 16] for PSB and LBL, respectively.

Table 1: *Elastic modulus of engineered bamboo products*

Product	E_x	E_y	E_z	G_{xy}	G_{xz}	G_{yz}
PSB	11890	3066	3066	1361	1361	746
LBL	9391	1440	1149	1365.08	1260.09	461.81

*Unit in Mpa

Table 2: *Poisson ratios of engineered bamboo products*

Product	μ_{xy}	μ_{xz}	μ_{yz}
PSB	0.411	0.411	0.115
LBL	0.25	0.2	0.42

Material properties under compressive and shear forces are the decisive parameters in tenon-type contact joints. Summarizing from [13-17], the constitutional law of wood and bamboo product is illustrated in Figure 4. It should be noticed that the stress-strain relationship of wood material under complex stress was well established for modelling with entire curve behaviour. In contrast, the studies on the stress-strain relationship of bamboo products most focus on describing the curve before failing.

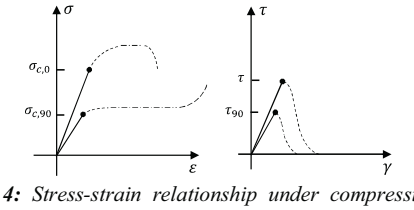

Figure 4: *Stress-strain relationship under compression and shear*

The bilinear isotropic hardening model is assumed to describe the behaviour of wood and engineered bamboo products in the plastic phase. Table 3 lists the tangent modulus of wood in compression, validated by the mean values of clear wood specimens from [18] and [19] for spruce CLT species and Douglas-fir glulam species, respectively. The tangent modulus and strengths of PSB and LBL under compression and shear forces were obtained from the mean value results from [13-14] and [15-16], respectively. σ_{xx}, σ_{yy} and σ_{zz} are the normal stresses; σ_{xy}, σ_{yz} and σ_{xz} are the shear stresses.

Table 3: *Properties in the plastic region (unit in Mpa)*

Item	CLT, Spruce	Glulam, D.-Fir	PSB, Moso	LBL, Moso
$E_{Tangent}$	123.20	149.60	2853.60	93.91
σ_{xx}	37.80	50.00	33.09	46
σ_{yy}	4.1	6.0	7.68	21.63
σ_{zz}	4.1	6.0	7.68	19.62
σ_{xy}	4.08	5.7	23.44	18.13
σ_{yz}	0.93	1.9	3.64	22.59
σ_{xz}	2.85	3.99	23.44	6.58

The Hill criterion, given in Equation (1), was applied as the failure criteria:

$$f(\sigma) = \sqrt{\begin{matrix} F(\sigma_{yy}-\sigma_{zz})^2 + G(\sigma_{zz}-\sigma_{xx})^2 \\ +H(\sigma_{xx}-\sigma_{yy})^2 + 2L\sigma_{yz}^2 + 2M\sigma_{zx}^2 + 2N\sigma_{xy}^2 \end{matrix}} \quad (1)$$

F, G, H, M, and N are material constants from the tests, defined by Equation (2)-(7):

$$F = \frac{1}{2}\left(\frac{1}{R_{yy}^2} + \frac{1}{R_{zz}^2} - \frac{1}{R_{xx}^2}\right) \quad (2)$$

$$G = \frac{1}{2}\left(\frac{1}{R_{zz}^2} + \frac{1}{R_{xx}^2} - \frac{1}{R_{yy}^2}\right) \quad (3)$$

$$H = \frac{1}{2}\left(\frac{1}{R_{xx}^2} + \frac{1}{R_{yy}^2} - \frac{1}{R_{zz}^2}\right) \quad (4)$$

$$L = \frac{3}{2}\left(\frac{1}{R_{yz}^2}\right) \quad (5)$$

$$M = \frac{3}{2}\left(\frac{1}{R_{xz}^2}\right) \quad (6)$$

$$N = \frac{3}{2}\left(\frac{1}{R_{xy}^2}\right) \quad (7)$$

R_{ij} are the yield stress ratios, defined by Equation (8):

$$R_{11} = \frac{\sigma_{xx}^y}{\sigma_y};\ R_{11} = \frac{\sigma_{yy}^y}{\sigma_y};\ R_{11} = \frac{\sigma_{zz}^y}{\sigma_y};\quad R_{11} = \sqrt{3}\frac{\sigma_{xy}^y}{\sigma_y};\ R_{11} = \frac{\sigma_{yz}^y}{\sigma_y};\ R_{11} = \frac{\sigma_{xz}^y}{\sigma_y} \quad (8)$$

https://doi.org/10.52202/069179-0448

Assuming the compressive strength in the main fibre direction as the reference yielding stress, σ_y, the generated yield stress ratios are listed in Table 4.

Table 4: *Yield stress ratios*

Item	CLT, Spruce	Glulam, D.-Fir	PSB, Moso	LBL, Moso
R_{11}	1.00	1.00	1.00	1.00
R_{22}	0.11	0.12	0.23	0.47
R_{33}	0.11	0.12	0.23	0.43
R_{12}	0.19	0.20	1.23	0.68
R_{23}	0.04	0.07	0.19	0.85
R_{13}	0.13	0.14	1.23	0.25

3.2 MODELLING AT THE JOINT LEVEL

One-meter-long solid-type joint models were built in the ANSYS workbench to investigate the joint shear performance under static push-out force. See Figure 5.

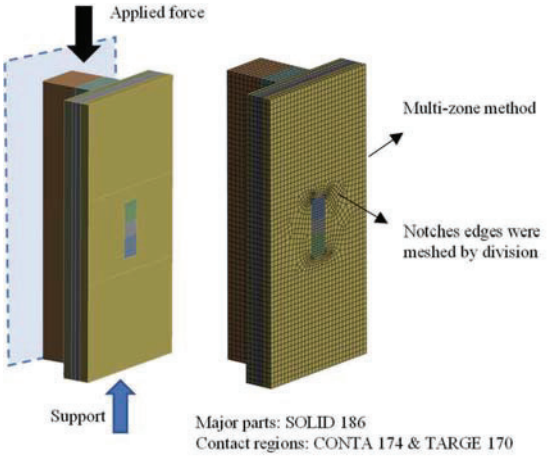

Figure 5: *Joint model*

CLT panel was modelled by layers bonded together. The crosswise layout was defined by a local coordinate system. Glulam was built as one united body and its material properties were defined by the global coordinate system. Both members were split locally to improve the meshing quality around the mortise. The tenon was orientated with the main fibre direction perpendicular to the shear force direction with a specific defined local coordinate system. Solid 186 element was employed in all bodies. The multizone meshing method was applied. To capture the mortise-tenon in detail, the meshing size around the contact area was refined. The mortise notch edges were divided into 5 segments. Face meshing was applied to the tongue of the CLT panel. The global and local meshing sizes were compatible and chosen for a high-quality finite-element meshing result. The overall meshing size of CLT and glulam were set as 18 mm whereas the meshing size of the tenon was set as 15 mm. The meshing quality was 0.94 on the average, with all the components meshed using hex elements.

The surface element was used to evenly distribute applied force to the loading area. Sub-steps were set for convergence after approaching the plastic region of materials. In sub-step 1 to 4, the force increment is 20 kN. After applying 80 kN to the model, 10 kN was applied per sub-step until the finish. Large deformation was allowed. A frictional coefficient of 0.5 was applied to all the contact surfaces within the model [20].

The parametric study was conducted to investigate the joint performance when varying material combinations of tenons and contact characteristics between tenon pieces. The studied schemes are listed in Table 5.

Table 5: *Parametric study scheme*

Scheme No.	Side Tenon	Middle Tenon	Contact
1	PSB	PSB	Bonded
2	PSB	PSB	Frictional
3	PSB	LBL	Frictional
4	LBL	LBL	Bonded
5	LBL	LBL	Frictional
6	LBL	PSB	Frictional

Note: Contact refers to between tenon pieces

3.3 MODELLING AT THE FLOOR LEVEL

The CLT-glulam rib flooring system was modular designed where one floor module consists of one CLT slab with dimensions of $105 \times 1200 \times 12000$ mm (thickness × width × length) and one glulam with dimensions of $175 \times 380 \times 12000$ mm (width × depth × length). Single floor module was built in ANSYS Workbench adjusting the modelling method used for the joint, with minor changes on meshing. The variation of timber products caused by it defects and product assembly process are not considered in this stage of investigation. However, to better capture the structural behaviour at the system level, the meshing size of the fully and not connected composite beams was set as 60 mm. This was compared with the theoretical results of applying the Gamma method to a simply supported CLT-glulam composite floor of the same configuration. Bonded contact was applied between CLT and glulam under fully connected situations, whereas frictional contact was applied for not structurally connected composite floors. The same frictional coefficient as the joint model was used. The proposed bamboo-tenon connected flooring system was built based on geometry imported from SolidWorks. The as-built floor models are shown in Figure 6.

The case study was conducted using the loading conditions listed in Table 6. The impact of supporting systems on the structural behaviour was studied, considering common office space usage; see cases 1 to 3. In these cases, a specified live load of 2.4 kpa is uniformly distributed on the floor. The serviceability of the proposed flooring system was compared under 1.0 DL + 1.0 LL load combinations. Extreme loading conditions, as per Notes A-Table 4.1.5.3 of NBCC, were also studied. Such cases as using proportions of the long-span floor as

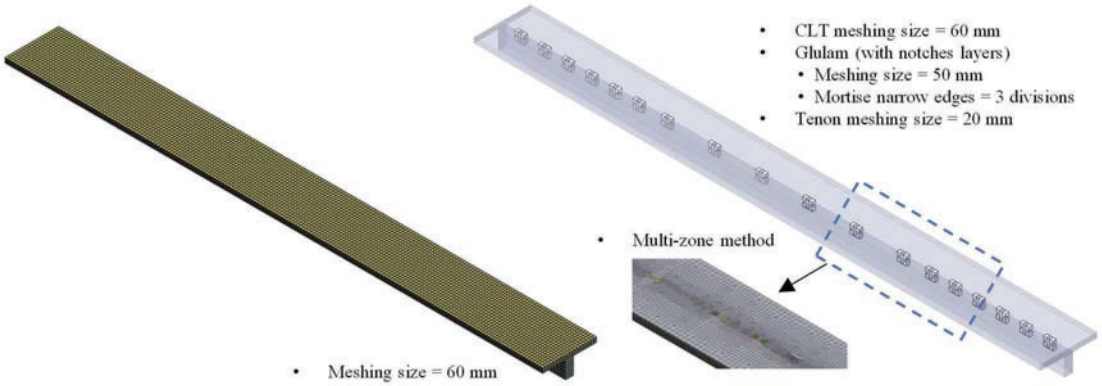

Figure 6: *Finite-element models of one module CLT-glulam composite floor (Left: full and not connected floor; right: proposed floor)*

Table 6: *Case studies of the flooring system*

Loads	Boundary conditions and loading areas
Uniformly distributed loads, q: 1.0 DL +1.0 LL	Case 1: Simply support
	Case 2: Fix-Roller
	Case 3: Fix Ends
Uniformly distributed loads, q: 1.25 DL +1.5 LL	Case 4: Simply support

	Case 6: Extra LL at both ends
	Case 7: Extra LL at one end

a temporary storage room for files or furniture. In these cases, an extra live load of 2.4 kpa was partially distributed on segments of the flooring system. See cases 4 to 7. The 12-meter span floor is divided into 4 segments of 3 meters. The flexural behaviour of the proposed composite flooring system under ultimate limit states and extreme loading conditions were investigated.

4 RESULTS AND DISCUSSION

4.1 LOAD-SLIP CURVES OF THE JOINT

Figure 7 shows the load-slip responses of the parametric study results extracted from the joint models at varying of the design scheme. The estimated elastic stiffness of the joints is specified in Table 7.

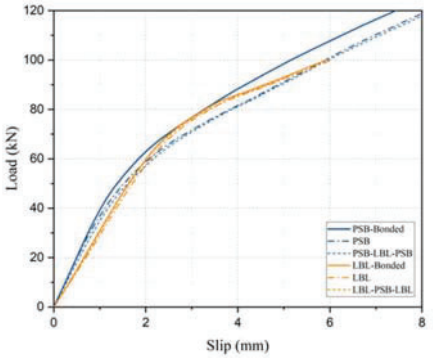

Figure 7: *Extracted load-slip responses*

Table 7: *Stiffness results of tenon joints*

Scheme No.	Tenon Configuration*	Stiffness (kN/mm)
1	PSB-Bonded	39.62
2	PSB	36.73
3	PSB-LBL-PSB	34.46
4	LBL-Bonded	30.89
5	LBL	29.11
6	LBL-PSB-LBL	30.69

*Side-middle-side tenon material

In schemes 1 to 3, PSB is designed to be directly in contact with the timber members. On the contrary, schemes 4 to 6 employ LBL as the side tenons in contact with the CLT and glulam members.

Within the PSB tenon groups, i.e., scheme 1 to 3, the internal bonded group hindered the sliding between tenon components, resulting in an increase of 8% on the overall

https://doi.org/10.52202/069179-0448

stiffness result compared to the pure PSB tenon group. The same effect occurs in the LBL-bonded and LBL groups, which shows a 6% increase of the stiffness. When changing the middle tenon material from PSB to LBL, i.e., from scheme 2 to scheme 3, the joint stiffness reduces by 21 % due to lowering the stiffness of the middle tenon. Interestingly, by changing the middle tenon from PSB to LBL, i.e., from scheme 5 to 6, the stiffness increased by 5%, closing to the boned group (scheme 4). The stress distributions under different loads are plotted in Figure 8.

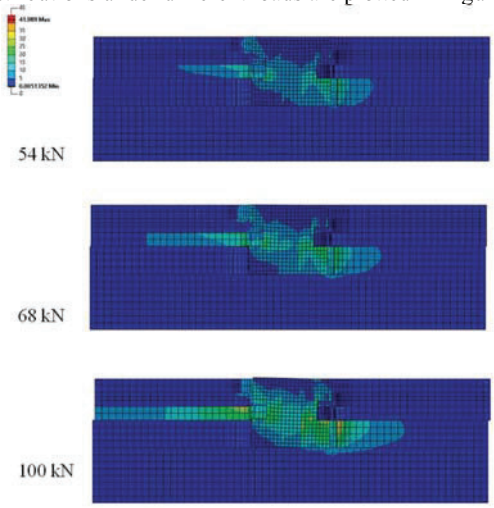

Figure 8: *Von-mises stress distribution of LBL-PSB-LBL tenon*

4.2 IMPLEMENTATION OF BAMBOO-TENON TO THE LONG-SPAN COMPOSITE FLOORING SYSTEM

By analysing the joint response under push-out shear forces, the LBL-PSB-LBL tenon (scheme 6) was selected for the proposed CLT-glulam flooring application. The proportional limit of 54 kN from the load-slip curves was assumed as the joint capacity. The flooring system was divided into three segments assuming different connectors spacing in each, in order to simplify the installation of the shear connectors. The amount and spacing of selected bamboo-tenon shear connectors are illustrated in Figure 9, and details are summarized in Table 8.

Table 8: *Bamboo-tenon distribution along the beam*

Segment	Starting point	Ending point	Amount per meter	Spacing	Edge distance
1	0	3000	2	300	300
2	3000	9000	1	800	400
3	9000	12000	2	300	300

Unit in mm

The composite efficiency of the proposed composite floor was investigated using Equation (9).

$$\eta = \frac{(EI)_{ef} - (EI)_0}{(EI)_\infty - (EI)_0} \quad (9)$$

Where $(EI)_{ef}$, $(EI)_0$ and $(EI)_\infty$ represent the effective bending stiffness from the proposed bamboo-tenon shear connector jointed composite flooring system, not connected composite floor and the fully connected composite floor, respectively.

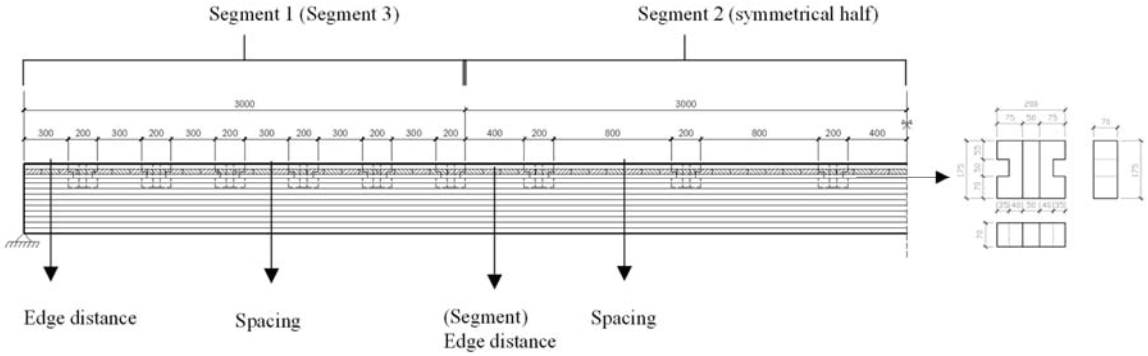

Figure 9: *Bamboo-tenon shear connector connected CLT-glulam composite floor*

4.3 CASE STUDIES OF THE COMPOSITE FLOOR UNDER SERVICEABILITY DEISGN

Figure 10 shows the case study results on the composite flooring system under serviceability loads (case study 1 to 3 in Table 6). All case scenarios were loaded to the prescribed loads. In the simply supported composite floor (case 1), the composite efficiency of the proposed flooring system is 50.79%. The supporting conditions significantly influenced the composite efficiency of the composite floor. Fixed support in this study has limited both the translations and rotations of the floor end elements. By moving into restrained supports, the differences in deflection between the floor with no and full composite action was shown reduced. Specifically, the composite efficiency of floors with fix-roller supports and the fixed ends support were 27.41 % and 14.69%, respectively. These indicate the benefits of implementing shear connectors become less remarkable when increasing the restriction from the supporting system.

A construction path was created on the CLT-glulam interface, going through the central line of the glulam top surface and penetrating through tenons if implemented. The shear stresses on the interface are plotted in Figure 10, (c). With tenons inserted, the shear stress on the interface shows an oscillating pattern, i.e., the stress increases when passing through a tenon, reaches the regional maximum value at the contact surface of mortise-tenon and decreases to zero when moving to the area where no tenon is inserted. For example, in case 1, the regional peak stress value occurs at 500 mm from the edge, which is also the end of the first inserted tenon. Also in case 1, the regional peaks value along the span shows the same decreasing trend as fully connected composite beams, i.e., the regional peak value keeps declining when approaching the mid-span of the floor. By changing the degrees of freedom at the supports, the maximum stress moved from the first tenon area to the 6th and the 5th tenon in the fix-roller and the fixed ends cases, respectively.

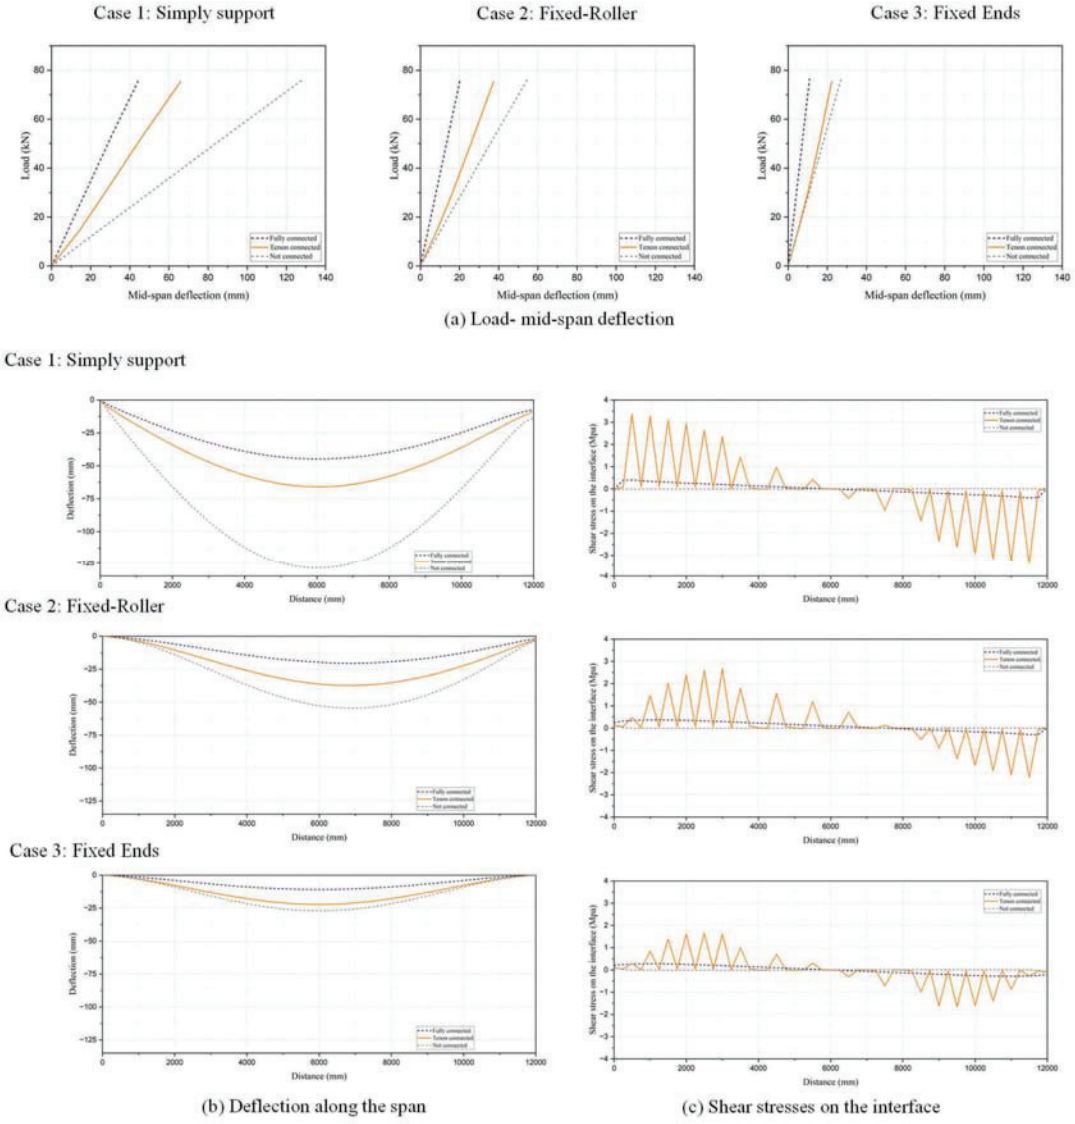

Figure 10: *Comparison on the flexural performance of the composite floors with different boundary conditions under serviceability loading conditions*

Figure 11 shows the case study results of long-span composite floors with extra partially distributed live loads with loading conditions listed in Table 6. The case study models were loaded to the design load as described in Table 6, case 4 to 7. A yielding point can be observed on the load-deflection curves. It should be noticed that this is caused by the deformation near the supporting area. Evidence can be found from the deflection along the beam curves, where a kink appeared near the supports. The stress distribution of the composite flooring system plotted in Figure 12 also illustrates this deformation. Besides, stress results were checked on all structural members. It shows all members remain in their elastic regions under the design value.

https://doi.org/10.52202/069179-0448

Compared to the simply supported with uniformly distributed loads case (case 1), the shear stress increased at the increasing of live load on the floor segments in other cases. For example, when adding an extra 2.4 kpa live load to each end, the peak shear stress increased from 4.16 Mpa in case 1 to 4.42 Mpa in case 6.

Among three extreme loading case scenarios, the extra live loading area on the middle segments causes more deflection of the structure and overall shear stresses on the interface. Therefore, this case scenario should be seen as the least favourable scenario under extreme loading conditions.

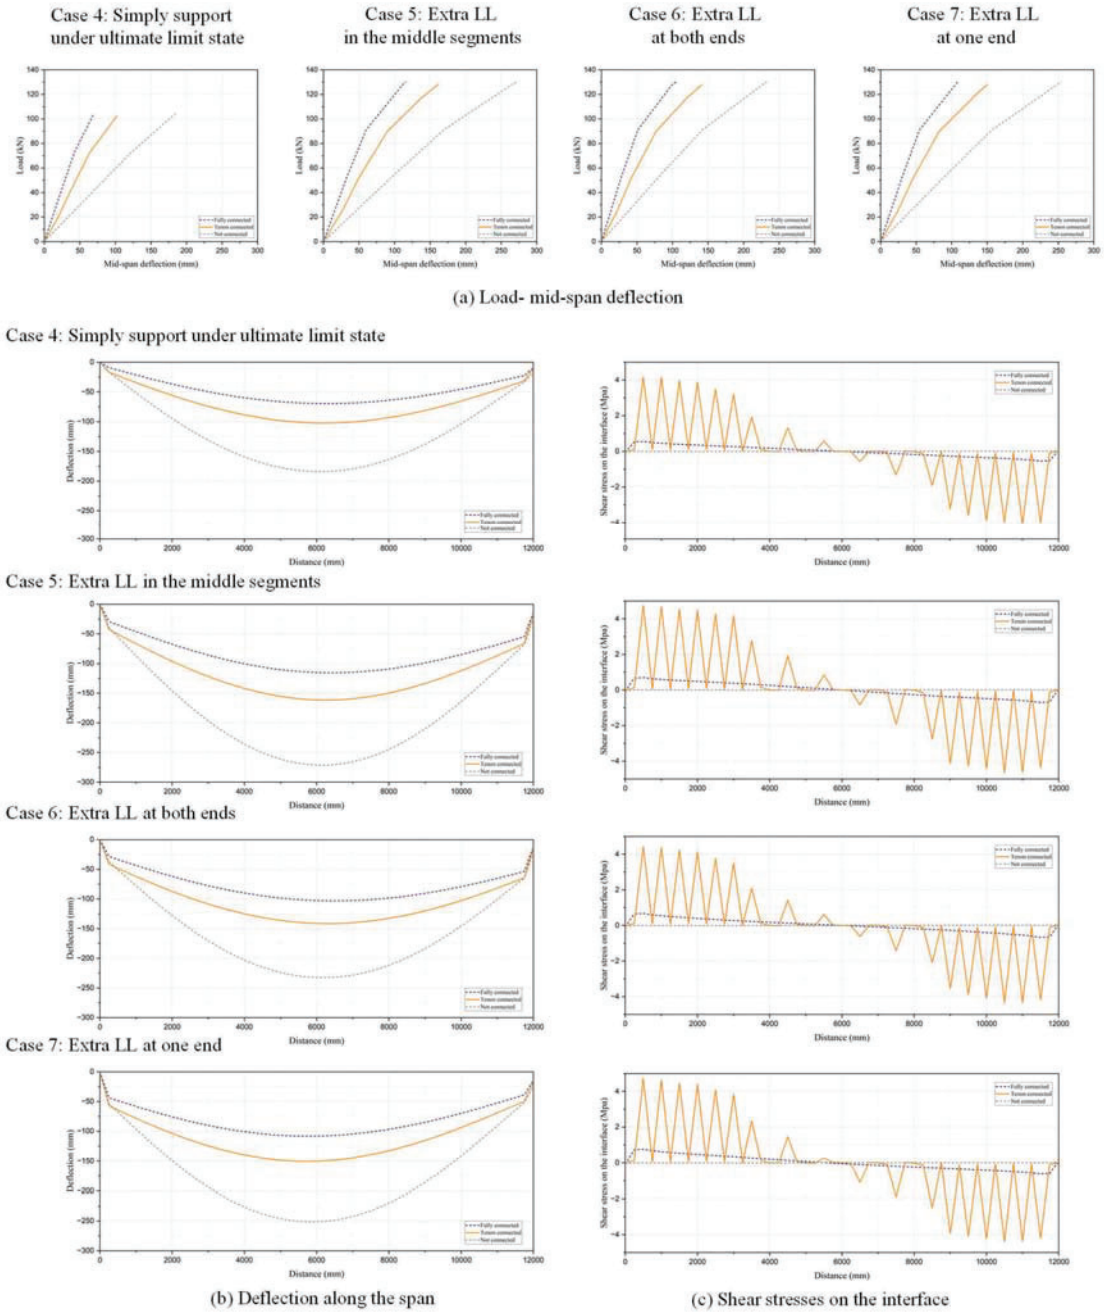

Figure 11: *Comparison on the flexural behaviour of the composite floors under ultimate limit state and extreme loading conditions*

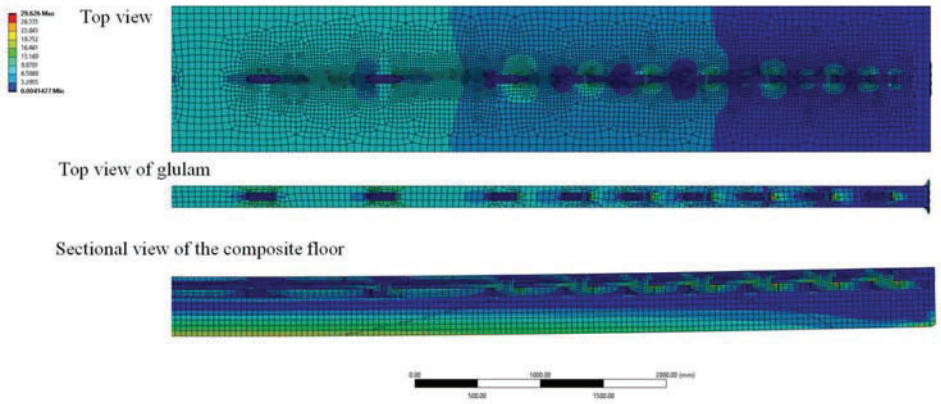

Figure 12: *Von-mises stress distribution of bamboo-tenon connected composite floor under ultimate limit state (half span, case 4)*

5 OVERVIEW

5.1 COMPARISON BETWEEN THE ANALYSIS AT THE JOINT LEVEL AND THE FLOOR LEVEL

The geometric feature of the bamboo-tenon, i.e., the tongue-and-groove cut, was generated for the purpose of quick assembly and disassembly. In one of the preliminary FEM simulations at the joint level, where bonded contact was applied to all the contact surfaces within the mortise-tenon, a quick distortion occurred on the glulam notches edge and the tongue of CLT panels, indicating the potential decrease of the overall joint capacity due to the existence of glue. Within the parametric study scope of this study (Table 5), the comparison between internal glued joint groups and the frictional connected joints showed a limited increase in the joint stiffness by internal bonding. Considering the costs of adhesives and the curing time, the internal glued joint was not chosen for the subsequent floor design.

However, the rotational behaviour of the tenon has a more significant impact on the global flexural behaviour when implemented in the long-span CLT-glulam flooring system. When the composite system undergoes deformation under bending, the rotational behaviour of the tenon leads to a detached mortise-tenon surface at the bottom. Therefore, the proposed tenon-type shear connector failed to efficiently transfer the forces between members as anticipated. A much lower composite efficiency is witnessed when analysing the proposed bamboo-tenon connected long-span composite floor.

This inconsistent results between the joint and the floor models indicates that special attention needs to be drawn to the rotational behaviour of tenon-type connectors. Specifically, tenon geometries and shape can be redefined with a new design to minimize the rotation of the bamboo-tenon under shear forces.

5.2 COMPARISON BETWEEN PROPOSED CONNECTOR AND SELF-TAPPING SCREWS

CLT construction using self-tapping screws as connectors has been studied and well implemented in practice. In the 7-meter CLT ribbed composite system studied by [21], 48 screws were used to engage floors with full composite action. For longer spans, the number of screws rises and can be around 80 to 90 [22]. In general, high level of composite action is guaranteed by reducing spacing of screws, as demonstrated by [23].

Using a specific selection of material combination, the number of shear connectors used to assemble a 12-meter flooring system can be as low as of 18 bamboo-tenons. Besides, the fabrication tolerance can be preciously controlled in the factory. As such, the proposed tenon-type connectors of this study demonstrate a structurally efficient solution.

5.3 LIMITATIONS OF MODELLING

Compared to the well-established knowledge on the behaviour of wood, the lack of harmony material testing methods on engineered bamboo products and reliable dataset of their mechanical properties led to uncertainty in the estimation of the bamboo-tenon connector capacity.

Besides, future modelling will benefit from the experimental test results of the joints, as well as the full-scale flooring tests. Limited by the knowledge and experimental database of the structural behaviour of tenon-type shear connectors, 3D floor models were used in this study. Further study can advance this modelling method by incorporating reliability analysis on the impacts of defects on the mechanical properties of structural members.

6 CONCLUSION

This paper mainly investigated the structural performance of a bamboo-tenon shear connector jointed long-span CLT-glulam ribbed composite flooring system. Specific recommendations for the bamboo-tenon design are concluded as follows:

1. Having a stiffness of 30.69 kN/ mm per tenon per joint and an elastic capacity of 54 kN under shear forces, the LBL-PSB-LBL tenon material combination is recommended for this three-piece tenon design;
2. A total number of 18 bamboo-tenon were implemented by segments in the proposed composite flooring system; however, the

https://doi.org/10.52202/069179-0448

rotational behaviour of the tenon reduced the composite efficiency;

3. By increasing the restrains of supports on the composite flooring system, the variance in the flexural behaviour of floors under full and non-composite action was shown reduced, resulting in less composite efficiency when implementing shear connectors;
4. Under extreme loading conditions, the extra live load partially distributed on the middle segments should be concerned as the worst-case scenario and should be prioritized.

This feasibility study demonstrates the potential of using bamboo-tenon as shear connector in CLT-glulam long-span flooring systems. Further optimization of the bamboo-tenon is needed. This research helps broaden the applications of engineered bamboo products in the future building environment.

ACKNOWLEDGEMENT

This research was financed by the Natural Sciences and Engineering Research Council (NSERC) of Canada through the Discover Program, grant number RGPIN-2019-04530, and Discovery Launch Supplement, grant number DGECR-2019-00265. STUDY ON FRAME DESIGN OF CONVENTIONAL WOODEN HOUSE

Tomoya Sahata[1], Naohito Kawai[2], Hideyo Tsukazaki[3]

ABSTRACT: This study assesses conventional Japanese architectural methods. Japanese houses constitute a framework with columns and beams. In addition to these structures, braces are installed to provide resistance to earthquakes and wind loads. A brace wall consists of foundations, columns, beams, and braces. Members are produced from standing trees. Therefore, the member length is constrained. For this reason, the lengths of timbers distributed in the market are 3–6 m. For horizontal members such as beams, the ends of the members must be connected to provide the necessary length for the building. For this study, we confirmed the effects on the strength and failure properties when joints were provided on beams that make up the brace wall. Results indicate that the joint of the beam placed on the 910 mm brace wall did not affect the maximum load, but had a slightly reduced initial stiffness.

KEYWORDS: Beam joint, Brace wall, Factual investigation, In-plane shear test, Structural analysis

1 INTRODUCTION

A conventional Japanese wooden house is made up of wooden materials such as columns and beams (Fig. 1). For an average-sized house, a joint is necessary to extend the beam length. As a rule, this joint should not be placed inside the wall to which the brace is to be attached, as presented in Fig. 2 [1]. However, when performing seismic reinforcement work, it might be necessary to install a beam joint on the brace wall [2]. Our drawing survey [3] results revealed that many beam joints in braced walls exist, even in new houses. Reports of past studies have described many findings from examinations of braced walls and beam joints. For braced walls, the effects have been confirmed of different species of braces and different types of joint hardware at the end of the braces on strength properties [4, 5]. Regarding joints, the effects of different species of wood, cross-sectional dimensions, and shapes of the joints on joint performance have been confirmed [6, 7]. However, the effects on brace walls have not been clarified when the beam joint is installed in the brace wall. Therefore, this study was conducted to elucidate the effects of beam joints of braced walls on strength and fracture properties. As described herein, a questionnaire survey related to the arrangement of the joints was administered to frame designers. After the configurations of loading tests and structural analyses were found, the beam joint effects on the strength properties of braced walls were assessed.

2 FACTUAL INVESTIGATON

2.1 OUTLINE OF THE ACTUAL SURVEY

A questionnaire survey was conducted of frame designers at wood processing (hereinafter, pre-cutting) factories with the aim of identifying trends in the arrangements of joints in beam members. The first survey targeted 108 pre-cutting factories with annual processing area of approximately 100,000 m^2 or more. The second survey was administered to 201 companies (including 64 pre-cutting factories targeted by the first survey) that mainly use software from three major pre-cut CAD manufacturers. The number of newly selected pre-cutting factories was 137. The total number of companies in the first and second surveys was 245. Table 1 presents results of the questionnaire collection. The combined collection rate for the first and second questionnaires was 24.1%. Interviews were conducted with 23 of the 68 respondents to assess their responses.

Table 1: *Questionnaire collection results*

Number	1st time	2nd time	Duplication	Total	Response rate Number of companies responding / Number of companies sent
Shipping companies	108	201	64	245	59 companies/245 companies (%) 24.1 %
Answer companies	24	35	–	59	
Respondents	24	44	–	68	–

2.2 LENGTH OF WOOD TO BE USED

Findings from the survey of the lengths of timber used for horizontal members are depicted in Fig. 3. Because the

https://doi.org/10.52202/069179-0449

same trend was observed for the horizontal structure of the first floor, second floor, and shed structures, they are presented together. As the figure shows, 4 m timber is the most commonly used material, followed by 3 m and 5 m. According to the interview survey, 3 m and 5 m timbers are used in the right places in relation to the positions of the columns and openings, perhaps because of the very low use of lumber longer than 6 m, the high price, and the reduced ease of installation on site.

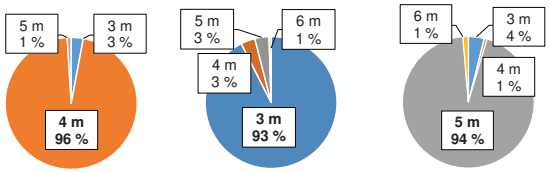

Figure 3: *Priority of specified length of horizontal member to be used*

2.3 TYPES OF JOINTS FOR HORIZONTAL MEMBERS

Results of a survey of the types of connections used for horizontal members are portrayed in Fig. 4 for the first floor, second floor, and shed sections together. Fig. 4 shows that more than 70% use the type B joining method. The type A jointing method is also often used for horizontal structures of the first floor. Type A joints are often used in the horizontal structure of the first floor because the foundation and base are connected by anchor bolts, which require no high bending performance. Furthermore, interviews conducted after the questionnaires were collected also indicate construction-related reasons, such as easier on-site assembly.

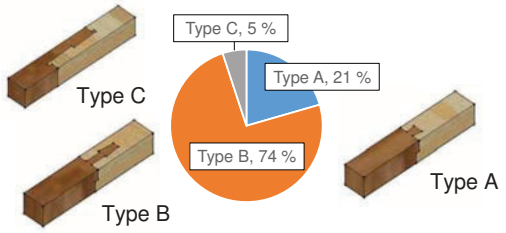

Figure 4: *Types of beam joints in horizontal members*

2.4 JOINT OF HORIZONTAL MEMBERS PLACED IN THE BRACE WALL

A questionnaire survey was administered to ascertain the actual situation of the frame design work. The relative positions of the brace and the beam joints in the brace wall are presented in Fig. 5. Joints of the beam in the brace wall are of three types: push up of the single brace (Fig. 5(i)); the opposite side of the push up portion of the single brace (Fig. 5(ii)); and the push up portion of the double brace (Fig. 5(iii)). Results of these investigations of the beam joints in the brace walls are shown in Fig. 6. The percentages of designers who responded "give special consideration" or "give consideration" were 74% in the case of Fig. 6(i) and 80% in the case of Fig. 6(iii). Those findings indicate that more than 70% of the designers responded that they would "consider" or "give consideration" to the push up portion of the brace in the brace wall. However, the interview survey results suggest that beam joints had to be placed at the push-up of the braces sometimes to prioritize the yield of fixed-length materials (mainly 3 m and 4 m).

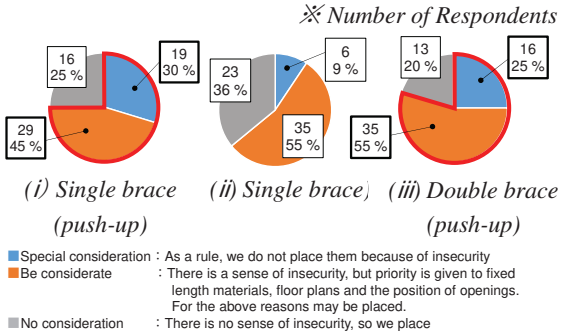

Figure 6: *Awareness of beam joints on the inside of brace walls*

3 IN-PLANE SHEAR TEST

3.1 SPECIMEN AND TEST BODY

Table 2 presents the specifications of members that constitute the test body. Fig. 7 shows the test body configuration: cross-sectional dimensions of the foundation and column are 105 × 105 mm; the beam is 105 × 180 mm; the studs are 30 × 105 mm; and the brace is 45 × 90 mm. The test body dimensions indicate a 910 mm wall length and a 2730 mm wall height. It is noteworthy that the 910 mm test body length is a traditional Japanese unit. The test body parameters reflect how to set the brace and presence and absent joint. The test body name is the following.

[Test body name] A – B

A: How to set a brace

B: Presence or absence of beam joint

Table 2: *List of physical properties of test materials*

Material name	Tree species	Air-dry density (kg/m³)	Moisture content (%)	Average annual ring width (mm)	Young's modulus (kN/mm²)
Foundation	Cedar	482	14	4.3	11.5
Column	RW laminated wood	496	14	–	11.5
Beam	RW laminated wood	471	15	–	10.5
Brace	Cedar LVL	369	11	–	8.3
Stud	WW laminated wood	432	11	–	11.8

Table 3 presents a legend for test body symbols. It lists the test bodies. The number of test bodies was three for each. The total of test bodies was 12.

DJ	**D**ouble	**J**oint	3

3.2 TEST METHOD

The test method was based on an allowable stress design for wood-frame housing [8]. The historical force was repeated three times with positive and negative alternating forces so that the apparent deformation angle became 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, and 1/50 rad, as presented in Fig. 8. Then it was pulled until the apparent deformation angle became 1/15 rad. As presented in Fig. 9, the relative rotation angle between the upper member and lower member of the beam joint is calculated using the displacement of two electrical displacement meters attached to the beam joint.

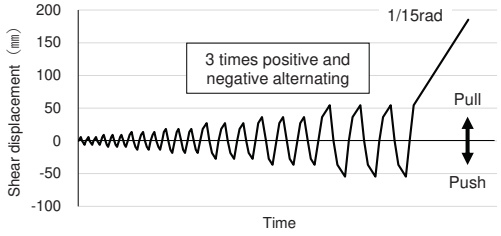

Figure 8: *Loading schedule for in-plane shear test*

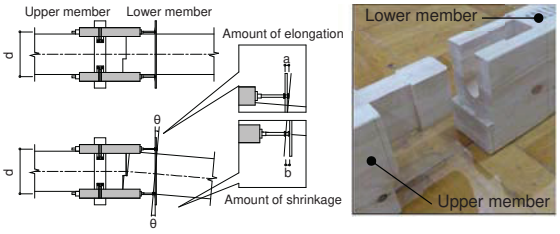

$\theta = (a - b) / d$

a,b: Displacement by displacement meter (mm)

d: Distance between gauge points (mm)

Figure 9: *Method of rotation angle calculation for beam joint angles of beams joint*

3.3 TEST RESULTS AND DISCUSSION

Fig. 10 shows the relation between the load and the shear deformation angle. Table 4 presents the maximum load and initial stiffness as calculated from the test results presented in Fig. 10. The maximum load and initial stiffness of the test body of the single brace (SN) are greater than those of the SJ. For the test body of the double brace, the maximum load and initial stiffness of DN are comparable to those of DJ. Table 5 shows the rotation angle of the joints at maximum load. From Table 5, it is apparent that the angle of rotation of the joint at maximum load is greater for SJ than for DJ. This greater angle can be attributed to the difference in the magnitude of the moment generated at the beam joint by the brace. In the case of the double brace, because the compression brace is joined to the tension brace at the midpoint of the lengthwise direction of the material, one can infer that the force pushing up the beam is less than that of the single brace because of the relaxation of the compressive force. Fig. 11 shows the test body at 1/15 rad. From the left side of Fig. 11, it is apparent that no marked damage has occurred to the beam joints. This finding suggests that the effect of the beam joints on the maximum load of the braced wall is small. Regardless of the presence or absence of beam joints, the failure of all test bodies terminated in buckling of the compression brace, as shown on the right side of Fig. 11.

4 STRUCTURAL ANALYSIS

4.1 OVERVIEW OF THE ANALYTICAL MODEL

The analytical model is the same as the test body, with SN, SJ, DN, and DJ. An example of an analytical model is portrayed in Fig. 12. The wall has 910 mm length and 2730 mm height. The model replaced the members with wires, with nodal springs placed at each joint. Rotational springs were incorporated at the column-head joints and at the column-leg joints. The braces were placed with axial springs according to the direction of the applied force. Braces were designed so that, because of horizontal loads, the braces would push the beams upward when compression forces were applied. The top edge of the brace was kept close to the right edge of the beam. To reproduce effects of the L-shaped brace fastening metal, shear springs were placed to connect the top end of the brace to the top end of the column. For the SJ and DJ analytical models, rotational springs were set at the beam connections. To simplify the analytical model, the inter-columns were not modeled. Structural analysis was performed using software (Wallstat pro ver. 5.0.0β10) [9].

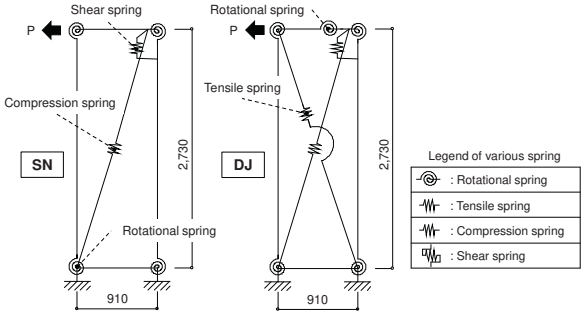

Figure 12: *Analytical model example (unit: mm)*

4.2 JOINT STIFFNESS AND INFLECTION POINTS

In-plane rotation tests were applied to calculate the rotational stiffness of the column head-column leg joint. The test body configuration of the column head is shown at the left panel of Fig. 13. The test body configuration of the column leg is shown in the right panel. Fig. 13 shows that the applied forces were alternating positive and negative. The rotation angle of the joint was calculated from the values of two displacement gauges, as presented in Fig. 14. The number of test bodies was six for both the column head and the column leg joints. The relation between the moments and joint rotation angles of the six bodies and the skeletal curves created based on the test results is presented in Fig. 15. The initial and secondary stiffnesses of the six bodies are presented in Table 6.

1	26.4	12.4
2	22.0	11.0
3	20.1	9.2
4	21.4	8.1
5	21.2	12.1
6	16.5	9.5
Average	**21.3**	**10.4**
Standard deviation	**2.9**	**1.6**

Axial force tests were conducted to elucidate the joint characteristics. The test bodies were constructed as presented in Fig. 16 with six test bodies. The axial force test results are shown in Table 7: the average values of tensile and compressive stiffness were, respectively, 23.0 kN/mm and 45.1 kN/mm. The rotational stiffness of the joint was calculated using the tensile and compressive stiffnesses obtained from axial force test results. The rotational stiffness (mountainous deformation) calculation method is depicted in Fig. 18. In the case of bending deformation of a joint, tension is borne by part A and compression by part B. The stiffness per unit area was calculated by dividing the tensile and compressive stiffnesses shown in Table 7 by the respective bearing area. The calculation results show that the stiffness per unit area was 16.7 N/mm^3 on the tensile side and 2.9 N/mm^3 on the compressive side. The neutral axis was found to be 82.5 mm from the bottom edge by solving the equation of equilibrium between the tension and compression sides. Therefore, the rotational stiffness is calculated as the sum of tensile and compressive forces, 127 kN.m/rad, assuming that the stress level increases uniformly from the neutral axis to the outermost circumference.

Tensile stiffness: 23.0 kN/mm
Pressure receiving area under tension: 1,381 mm^2
Tensile stiffness per unit area: 23.0 / 1,381 = 16.7 N/mm^3

Compressive stiffness: 45.1 kN/mm
Pressure receiving area under compression: 15,628 mm^2
Compressive stiffness per unit area: 45.1 / 15,628 = 2.9 N/ mm^3

Figure 18: *Method of calculation rotational stiffness of beam joints*

The compressive stiffness of the single brace was ascertained from the load–displacement relation: the results of the analysis of the frame model consisting of rotational spring at the column-head-column-foot joint were subtracted from the in-plane shear test results obtained for the brace wall (average of three bodies) in Chapter 3 (Fig. 19).

	Stiffness (kN/rad)
1st	687
2nd	489
3rd	208
4th	-450

4th	0.043

Figure 19: *Skeleton curve of compression brace in a single-braced wall*

The tensile stiffness of the brace portrayed in Fig. 20 was found by subtracting the analytical results obtained for the frame model consisting of rotational spring at the column head-column leg connections from the in-plane shear test results (average of three bodies) of the tensile brace wall shown in the same figure.

	Stiffness (kN/rad)
1st	296
2nd	80
3rd	9
4th	-79

	Inflection point displacement (rad)
1st	0.005
2nd	0.015
3rd	0.051
4th	0.085

Figure 20: *Skeleton curve of tensile brace*

We calculated the shear stiffness of the L-shaped brace hardware applied to the analytical model from the axial force of the brace and the displacement of the brace end found from results of in-plane shear tests of the brace wall (average of three bodies) (Fig. 21).

Figure 21: *Skeleton curve of L-shaped brace hardware at the top edge of the brace*

The compressive stiffness of the double braces was calculated from the results of the in-plane shear tests described in Chapter 3 and from results obtained for the single braces. A compression brace in a double-braced wall has higher strength performance than a compression brace in a single-braced wall because the tensile brace in a double-braced wall delays buckling of the compression brace. However, the tensile brace performance was assumed to be equivalent to that of the single braces. The skeletal curves of the compression brace of the double-braced wall are presented in Fig. 22. From the in-plane shear test results obtained for the double-braced wall, the relation between the load and shear deformation angle of the frame and tensile bracing was subtracted to obtain the skeleton curve of the compression bracing of the double-braced wall.

	Stiffness (kN/rad)

4.3 COMPARISON OF ANALYTICAL AND TEST RESULTS

Fig. 23 presents test results for each parameter and the analytically obtained results of the model with the previously described characteristic values. The test results and analysis results show general agreement. The developed analysis model is inferred as reasonable.

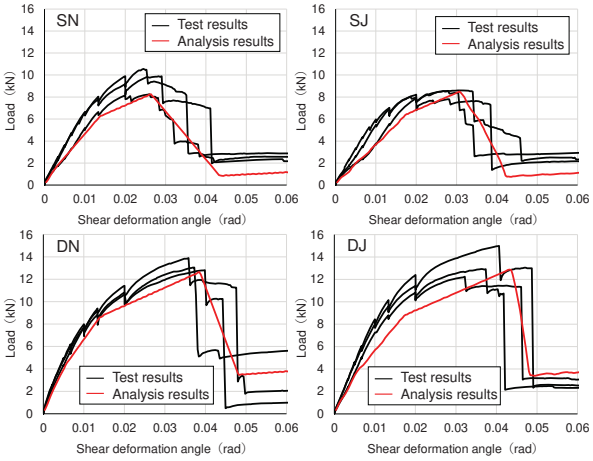

Figure 23: *Relation between load and shear deformation angle in test and analysis*

Fig. 24 presents analytical results obtained for single-braced and double-braced walls. Fig. 25 shows the strength properties obtained from Fig. 24 and the test results. From Fig. 25, the maximum load was almost identical in the test and analytical results. Regarding the initial stiffness, the analytical results showed smaller values than the test results, but the tendency of the initial stiffness to decrease with the joint was similar. The test and analysis results demonstrated that the initial beam stiffness was reduced when the beam joint was placed at the push up of the brace, although it did not affect the maximum load.

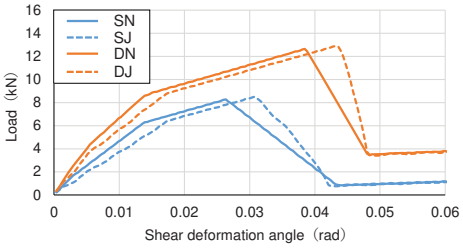

Figure 24: *Relation between load and shear deformation angle in analytical results*

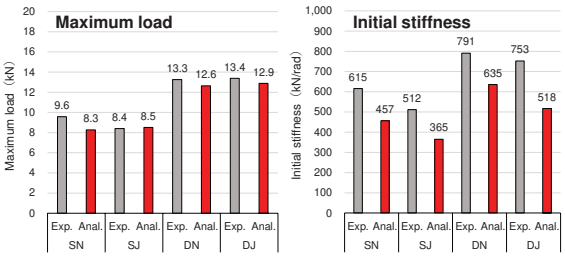

Figure 25: *Maximum load and initial stiffness of analytical and test results*

5 CONCLUSIONS

A survey was administered to frame designers. The responses indicated that more than 70% of frame designers have concerns about a beam joint at the push-up portion of the brace. In-plane shear tests of single-braced and double-braced walls were conducted. The applied force test results indicated reduction of the initial stiffness of the single-braced, 910-mm-long wall by approximately 20% when the beam joint was placed at the push-up portion of the brace. Structural analyses were conducted by creating an analytical model of the braced wall. Those analyses revealed a similar trend to that indicated by the experimentally obtained results, thereby confirming the beam joint influence analytically.

EXPERIMENTAL ANALYSIS OF A SCREW-GLUED SHEAR CONNECTION FOR USE IN MASS TIMBER COMPOSITE PANELS

Tyler Hull[1], Daniel Lacroix[2]

ABSTRACT: Ribbed or box section mass timber composite (MTC) panels offer a potential solution to the floor span limitations of conventional mass timber panels due to vibration. Glued connections have shown to be a viable shear connection in MTCs due to their high strength and stiffness. Investigated herein is the behaviour of a screw-glued connection of commercially available construction adhesive and self-tapping screws, to assess its viability to adequately transfer forces between the flanges and webs of MTCs. Shear tests on four 400mm long dimensional lumber T-sections yielded an average slip modulus of 17.63N/mm per mm^2 of glue, with an average yield stress of 4.59MPa and 3.47MPa from two bilinear data fit models. The connection was used to fabricate six 1.8m long dimensional lumber T-beams which were tested in flexure and used to validate a numerical model capable of capturing the behaviour. The results agreed well, with the average experimental midspan deflection being 0.98 of the average numerical midspan deflection. Overall, when used on a 10m HMT panel, analytical results using the γ-method indicated a nearly fully composite shear connection was achieved, and a vibration-controlled span of 10.4m was possible for the 455mm deep section.

KEYWORDS: Mass timber composite, screw-glued, shear connection, shear testing, experimental analysis

1 INTRODUCTION

1.1 BACKGROUND

Conventional mass timber flat slab floor systems, such as cross-laminated timber (CLT) panels on glulam beams, have difficulty rivalling the column spacing standard achieved by other commercially available floor systems due to the mass timber slab spans being limited by vibration and human comfort [1,2]. To achieve long floor spans using an all-wood system in structures where larger and open floor plans are needed (e.g., office, institutional, and high-end residential), designers have employed mass timber composite (MTC) ribbed (i.e., T-beams) and box (i.e., I-beams/hollowcore) panel floor systems (e.g., Catalyst, Spokane, WA, USA [3]; WoodIn, Waterloo, ON, Canada [4]). Figure 1 shows an example of a MTC ribbed panel consisting of a CLT panel for the flange that is connected to glulam webs through shear connections.

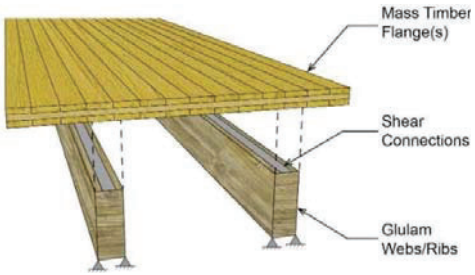

Figure 1: *Mass Timber Composite Ribbed Panel*

MTCs have shown the viability to overcome the current vibration and serviceability limitations of conventional mass timber flat slab floor systems (i.e., exceeding 7-8m), and be a viable all-wood long span floor system solution [5]. However, the shear connection (e.g., glue, self-tapping screws (STS)) has a crucial role in the transfer of forces between the flange(s) and the web. Due to vibration concerns at serviceability limit states often being the governing criteria in the design of MTCs, the shear connection's stiffness is critical to the overall element performance. Research has shown that glued connections [6] exhibit the highest shear connection stiffness; however, little research has been done on the types of glue to use, clamping procedures, and stiffnesses achieved in order to produce commercially viable bonds.

Montgomery [6] conducted a wide-ranging experimental study investigating the performance of 24 different shear connection options for hollowcore mass timber (HMT) panels through uniaxial tests on small-scale components and used the connection stiffness to numerically investigate their effects on, the behaviour of a 12.2 long HMT panel. It was observed that stiffer shear connections were necessary to achieve near fully composite action between the elements, thereby maximizing the efficient use of materials in the HMT panel, in addition to meeting the requirements for a 12.2m span. The identified connections were comprised of STS driven at an angle (30-45°), glue pressed, screw-glued, and perforated metal

[2] Daniel Lacroix, Assistant Professor, University of Waterloo, Waterloo, Canada, daniel.lacroix@uwaterloo.ca

https://doi.org/10.52202/069179-0450

plates with adhesive. Connections such as STS driven vertically (90°) were reported to not produce the needed stiffness to efficiently achieve adequate vibration performance at long spans [6]. Chen and Lam [7] investigated the performance of STS at 90° through numerical modelling and experimental testing on box panels comprised of CLT as top and bottom flanges, and dimensional lumber for the webs. As a result of the connection stiffness, the overall section exhibited minimal composite behaviour resulting in a highly non-linear stress distribution over the depth of the section, and tensile failure in the webs occurring rather than in the bottom flange [7]. While this connection proved to not be optimal for achieving the composite action needed for long span MTCs, good agreement was demonstrated between the numerical model and experimental results, thereby indicating the viability of numerical methods for predicting the behaviour of MTCs [7].

Jacquier and Girhammar [8] investigated CLT-glulam T-beams in bending for the purpose of developing a cassette (i.e., box) composite floor slab for use in multi-storey CLT buildings. In their study, STS driven at 45°, doubled-sided punched metal plates (DSNP), screw-glued, and a combination of STS and DSNP were utilized for the shear connection between the flange and web. The results between the experimental and predicted bending stiffness determined using the gamma (γ)-method, which is introduced in Annex B of Eurocode 5 [9], agreed reasonably well with the experimental results [10], thereby indicating that analytical methods such γ-method can be used to predict the stiffness of MTCs in design. This observation was also confirmed by Hull and Lacroix [11] who compared the results of the γ-method to finite element modelling results. The γ-method was able to reasonably accurately predict the bending stiffness of the MTC panel, with the main difference between the finite element model and γ-method being attributed to shear lag effects observed in the flanges [11].

Despite the fact that initial studies have showcased the potential of MTCs to be designed to meet long floor spans in a laboratory and numerical setting, adoption of mass timber long span floor systems by the industry has been hindered in large part due to the complications associated with implementing viable shear connections in manufacturing processes, particularly glued connections. This is primarily due to the fact that the glue bond can vary greatly depending on the type of glue used, the contact pressure, the glue line thickness, and environmental conditions during the assembly. Screw-gluing was shown to be a viable option for utilizing the high shear stiffness of glued connections without the need for large hydraulic presses [6,12]. However, the practical application of screwed gluing in manufacturing applications has been limited by the lack of knowledge on possible adhesive and screw configurations.

1.2 OBJECTIVES

The overarching aim of the larger research program is to develop fundamental knowledge of mass timber composites (MTCs) and the effects of connection detailing on their behaviour in order to develop design guidelines and aid in their adoption by industry. The research specific objectives of this study are to: 1. investigate the shear behaviour of a screw-glued connection made with a commercially available construction adhesive, 2. establish the flexural behaviour of dimensional lumber T-beams using the screw-glued connection, 3. validate a finite element model capable of capturing the connection behaviour and predict the flexural response of the T-beams, and 4. investigate the potential span capabilities of MTC panels using the screw-glued connection analytically. Due to the limited information on the behaviour of connections and the effects of stiffness on the degree of composite action, as well with relatively higher associated costs with mass timber products, dimensional lumber was chosen to first investigate the behaviour and feasibility of the screw-glued connection in MTC panels.

2 SHEAR PERFORMANCE OF SCREW-GLUED CONNECTION USING DIMENSIONAL LUMBER

2.1 METHODOLOGY

The potential of using screw-glued connections in MTCs is first evaluated on a total of four specimens consisting of dimensional lumber. The shear connection specimens were 400mm in height and consisted of 35mm x 200mm Spruce-Pine-Fir (SPF) No.1/2 flanges connected to 40mm x 160mm Douglas Fir-Larch (D.Fir-L.) webs using a screw-glued connection. The connection consisted of 6mm diameter (dia.) x 100mm long partially threaded self-tapping screws (STS) with washer heads spaced at 133mm centre-to-centre (c/c), as well as a 10mm wide bead of commercially available silane modified construction adhesive (Figure 2). A 10mm wide bead of adhesive to every 40mm wide of web surface area was deemed adequate to provide full-surface coverage and adequate squeeze out.

Figure 2: *Dimensional Lumber Shear Test Specimens*

Additionally, 25mm dia. washers were added beneath the existing washer heads of the screws as a measure to aid in evenly spreading the pressure distribution of the screw-gluing as well as to prevent local wood crushing under the

https://doi.org/10.52202/069179-0450

screw heads (Figure 2). This assembly of partially threaded screw and 25mm dia, washer was able to achieve a load of 4.5kN [13], resulting in an average clamping stress of 0.85MPa. The flanges were sourced from a local Ontario wood supplier whereas the webs were removed from an existing building in Waterloo, Ontario Canada and donated to the University. In their original size, the web members had widths varying from 88 to 90mm to depths of 195-200mm. To maximize the use of wood, each element was planed to the final web dimensions thus yielding two webs per piece of wood donated. It should also be noted that the adhesive used complies with existing regulatory strength and durability requirements as a sub-floor adhesive [14].

A 500kN universal testing machine was used to evaluate the screw-glued bond performance of the four specimens under monotonic loading. The slip between the web and flange was recorded using a linear variable displacement transducer (LVDT) on both sides of the web and the average slip between the LVDTs was used in the stiffness calculation.

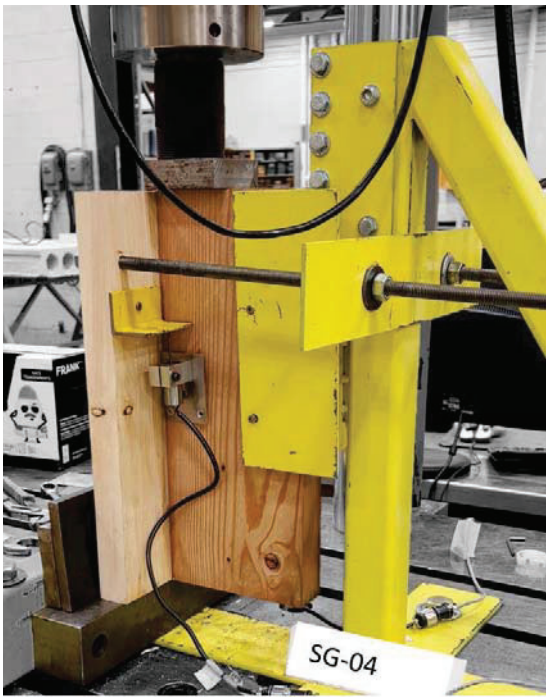

Figure 3: *Shear connection test setup*

The Standard Test Method for Strength Properties of Adhesive Bonds in Shear by Compression Loading (ASTM D905) [15] specifies a uniform loading rate of 5mm/min ± 25%, although the standard also states that there is no apparent effect on the bond strength for loading rates ranging 0.38 to 10.27mm/min. Additionally, the standard Test Methods for Mechanical Fasteners in Wood and Wood-Based Materials (ASTM D1761) [16] proposes a loading rate of 2.54 mm/min ± 25%. Due to the shear connection being comprised of adhesive and screws, a loading rate of 2mm/min was chosen which resulted in times to failures on average of 1.5 to 2 minutes. As shown in Figure 3, the flange of the test specimen rested on a solid steel block that was secured to the testing frame, while a reaction frame (yellow), with a roller along the web, was used to resolve the eccentricity between the load application point and flange bearing location. Two steel bolts with a steel plate were also used to prevent rotation if any local crushing occurred beneath the flange.

Following each test, the moisture of both the flanges and web were determined using a Tramex MRH3 pin-probe moisture and relative humidity meter. The webs and flanges had an average moisture content of 9.2% and 11.2% respectively, with a maximum deviation of ±1% moisture. To determine the specific gravity, smaller clear wood elements were cut off the flange and web of each of the shear specimens. The clear wood specimens were then oven-dried according to Density and Specific Gravity (Relative Density) of Wood and Wood-Based Materials (ASTM D4442) [17] in order to determine the specific gravity of each. The D.Fir-L web elements had an average specific gravity of 0.47 with a coefficient of variation (CoV) of 0.02, while the SPF flange elements had an average specific gravity of 0.40 with CoV of 0.05.

2.2 EXPERIMENTAL TEST RESULTS

From the experimental tests, three key parameters were determined for each specimen: 1. the maximum load averaged over to glue area to determine the glue bond shear strength, 2. the slip stiffness (k_s), and 3. the stiffness up until the maximum load (k_{Fmax}). Table 1 presents the individual and average values of the screw-glued connections as well as their CoV.

Table 1. *Shear connection load-slip results*

Specimen	Shear Strength [MPa]	Slip Stiffness, k_s [N/mm per mm^2]	Connection Stiffness at Max Load, k_{Fmax} [N/mm per mm^2]
SG-01	4.69	19.11	18.78
SG-02	5.85	15.55	13.29
SG-03	3.89	15.94	12.11
SG-04	3.43	19.91	16.29
Avg.	**4.47**	**17.63**	**15.12**
CoV	0.20	0.11	0.17

The slip stiffness (i.e., initial stiffness), which is key when designing MTCs for service level and vibration criteria, was determined as the slope between 10% and 40% of the maximum load as defined by EN 26891 [18,19] for mechanical fastener connections. The connection stiffness at maximum load (k_{Fmax}) was determined as the slope from the origin to the maximum load.

The shear strength of the screw glued bond averaged 4.47MPa, with a CoV 0.20. The high glue bond shear strength is a promising result as it indicates the composite connection can likely be designed for the strength of the wood material. The variation seen in the CoV of the shear

https://doi.org/10.52202/069179-0450

strength was attributed to specimens SG-02 and SG-04 where the difference in failure mode between these two specimens in the post glue bond failure observation can be seen presented in Figure 4. SG-02 (Figure 4a) shows a failure of wood fibre from both the web and flange indicating that the flange had a similar strength to the web, whereas for SG-04, the failure occurred almost entirely in the flange. Additionally, some wood decay was observed in the web at the top of the connection, as highlighted in Figure 4b.

(a) Failure plane of SG-02

(b) Failure plane of SG-04

Figure 4: *Representative failure of screw-glued shear connection*

In general, it is observed from Table 1 that the slip stiffness had less variation than the maximum load and provides encouraging results for the overall repeatability of the screw-glued connection given the number of variables that can influence the overall behaviour (e.g., lumber grade, stiffness, surface planning, glue vs. wood failure, moisture content, curing conditions).

Determining the yield point of timber-timber composites is another key parameter needed for design calculations. Two bilinear load deformations models were data fitted to each specimen and the bilinear models were then averaged together to obtain a representative bilinear model for the screw-glued connection. The first bilinear model used the methodology presented in EN 12512 [20], and although intended for joints made of mechanical fasteners, this method provided good representation for the behaviour of the screw-glued connection. In the EN 12512 model [20], two sloped lines are determined, with their intersection being the yield point. The first line is defined by the slip stiffness from Table 1, while the second line is a tangent with a slope based on Equation (1).

$$\tan\beta = \frac{1}{6}\tan\alpha \tag{1}$$

Where α is the angle formed by the slip stiffness line, and β is the angle formed by the tangent line. The tangent line is drawn on the load-slip curve where the slope of the tangent and load-slip curve are equal. The second bilinear model was proposed for its simplicity and relatively good agreement with the test data. Here, the yield point is determined where the slip stiffness line attains 75% of the maximum load. The second slope is then drawn between the yield point and maximum load point. Both models are demonstrated for specimen SG-04 in Figure 5: Load-slip curve of SG-04 with bilinear models.

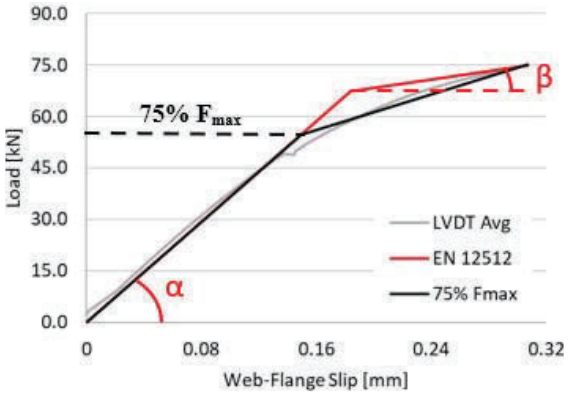

Figure 5: *Load-slip curve of SG-04 with bilinear models*

The average curves for the four specimens are presented in Figure 6, with the yield point results in Table 2. Generally, both models capture the behaviour well, with the EN 12512 [20] having a higher yield stress.

https://doi.org/10.52202/069179-0450

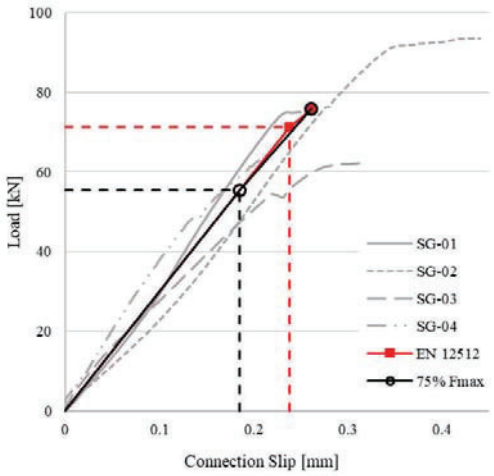

Figure 6: *Load-slip curves and averaged bilinear models*

The yield stress was determined by dividing the data fit yield load for each specimen by the 40mm x 400mm screw-glued area. Some variation is seen in the slip and load of the yielding point. This can be attributed to the variability in wood material shear strength, as well as stiffness, and its influence of the glue bond behaviour. The average yield stresses of 4.59 MPa and 3.47 MPa demonstrate the potential for structural viability of a screw-glued connection using a commercially available bead extruded silane modified adhesive by primarily achieving failure in the wooden elements first, as opposed to a pure glue failure being the dominating failure mode.

Table 2. *Yield point using bilinear models*

Specimen	EN 12512		75% F_{max}	
	Yield Slip [mm]	**Yield Stress** [kN]	**Yield Slip** [mm]	**Yield Stress** [kN]
SG-01	0.222	4.67	0.167	3.52

CoV	0.26	0.18	0.24	0.17

3 DIMENSIONAL LUMBER T-BEAM BENDING TESTING

3.1 METHODOLOGY

The dimensional lumber T-beams were 2m in length with a 1.8m clear span and consisted of an identical 35mm x 200mm SPF No.1/2 flange as well as a 40mm x 160mm D.Fir-L. web compositely connected using the screw-glue configuration tested in Section 2. Prior to each of the T-beams being assembled, the web and flange elements were each tested non-destructively to determine the modulus of elasticity, E. This was done by loading the elements in their T-beam orientation (i.e., the flanges on the flat and the webs on edge) in four-point bending and recording the midspan deflection using a string pot. The actuator load was increased up to 10kN and 2kN for the webs and flanges, respectively, to obtain a representative linear load-displacement curve to calculate the modulus of elasticity for each using classical Euler beam theory. However, since the midspan deflections recorded included deformations due to shear which results in the apparent modulus of elasticity, E_{app}. To get the true modulus of elasticity (i.e., shear free), E_{true}, additional analysis was required. Equation (2) was used to remove the shear deformations from the midspan deflection, where E_{true} could then be calculated using classical Euler beam theory.

$$\Delta_{shear} = \frac{\frac{P}{2}L}{3AG} \tag{2}$$

Where P is the actuator load, L is the clear span of the specimen (1.8m), A is the cross-sectional area, and G is the shear modulus taken as $E_{app}/15$ for the webs and $E_{app}/18$ for the flanges based on the lumber species and recommendations from Forest Products Laboratory's Wood handbook [21]. The results from the modulus of elasticity determination are presented in Section 3.2 in Table 3.

A total of six-dimensional lumber T-beams were assembled and loaded in four-point bending using the test setup shown in Figure 7. During the testing, the displacement at midspan was monitored using a string pot which passed through the table, while the slip between the web and flange was recorded using LVDTs located 0.3m and 0.6m from the midspan of the beams. Similar to the modulus of elasticity determination, the midspan deflection was used to determine the apparent and true stiffness of the beams, EI_{app} and EI_{true} respectively, based on the linear portion of the load-displacement curve.

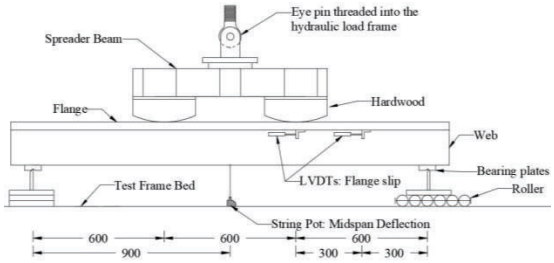

Figure 7: *Four-point bending test setup*

3.2 EXPERIMENTAL TEST RESULTS

The results from the modulus of elasticity determination for the flange and web elements of each beam are presented in Table 3. Overall, the flanges' modulus of elasticity was very consistent was an average E_{true} of 9062MPa, while more variability was seen in the average E_{true} of the webs of 13430MPa. This higher variation is attributed to the fact that the final web size was obtained by planing the original member to their final size, thus affecting the distribution of defects and grain deviation from member to member.

https://doi.org/10.52202/069179-0450

Table 3: *Modulus of elasticity results*

CoV	0.07	0.07	0.21	0.20

*Flange modulus of elasticity measured on flat

Key results describing the properties of each of the T-beams section are presented in Table 4. The maximum bending moment was determined by the maximum load reached in the test after the initial linear-elastic region of the load-displacement response. The average of this was 10.8kNm. However, considerable variation was observed and can primarily attributed to the variable grade of wood in the webs. Due to planing of the donated material into the final web sizes, some of them had less grain deviation and fewer defects as well as knots than others, thus resulting in increased flexure and shear strength in these specimens.

Table 4: *T-beam bending experimental results*

Specimen	Max Bending Load [kNm]	Apparent Stiffness, EI_{app} [Nmm^2]	True Stiffness, EI_{app} [Nmm^2]
SG-01	6.4	3.12E+11	3.96E+11
SG-02	13.7	3.33E+11	4.08E+11
SG-03	9.7	3.12E+11	3.72E+11
SG-04	10.3	4.21E+11	4.99E+11
SG-05	15.3	4.32E+11	5.03E+11
SG-06	9.4	4.07E+11	4.64E+11
Avg.	**10.8**	**3.69E+11**	**4.40E+11**
CoV	0.27	0.14	0.12

Nonetheless, lower CoVs were observed for the apparent and true stiffness of the sections. These are the primary focus of the experimental program as it is used in the comparison to the numerical modelling in Section 4, while also being indicative of the serviceability-level response, a key concern for future application in mass timber composites. The average apparent and true stiffness of the sections were found to be 3.69×10^{11}Nmm^2 and 4.40×10^{11}Nmm^2 respectively. Most of the variability in these results was attributed to the different modulus of elasticity of the webs, as the web modulus of elasticity was generally indicative of the overall stiffness of the assembly (i.e., T-beam). For example, lower modulus of elasticity sections such as SG-01 and SG-02 had lower overall assembly stiffnesses than the ones with higher modulus of elasticity sections such as SG-04 and SG-05. The experimental load-displacement curves of all six specimens are presented in Figure 8.

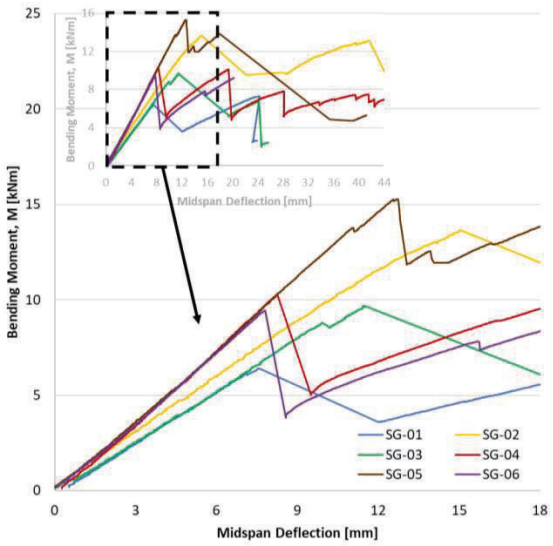

Figure 8: *T-beam load-displacement curves*

In general, due to the relatively short spans and increase section modulus of the T-section, the initial failure mode consisted of shear failure in the webs. This was followed by secondary flexural failures such as simple, splintering, and cross-grain tension in the web, while failure of the flanges was observed to either be due to compression yielding or simple tension. Figure 9 shows a representative T-beam at ultimate failure.

Figure 9: *Representative failure mode of T-beams*

4 NUMERICAL ANALYSIS

4.1 NUMERICAL MODEL DESCRIPTION

A numerical model was developed in *ABAQUS* finite element software [22] to capture the behaviour of the dimensional lumber T-beams and screw-glued connection. The assembly was generated using three separately defined elements; the SPF flange, the D.Fir-L web, and the loading blocks shown in Figure 10. The flange and web were modelled as 3D deformable solids, while the loading blocks were modelled as 3D rigid elements. The contact between the webs and flanges was modelled as a cohesive contact in the sliding direction and a "hard" contact in the normal direction. Boundary conditions were applied at the support locations

https://doi.org/10.52202/069179-0450

restricting all degrees of freedom except in-plane rotation, and in-plane displacement representing the roller end. The slip stiffness of the screw-glued bond, k_s, was used as the in-plane slip of the cohesive bond in the numerical model. Contact between the T-beam and the support blocks was modelled as a "hard" contact in the normal direction and a frictional penalty coefficient of 0.15 [23] in the tangential direction.

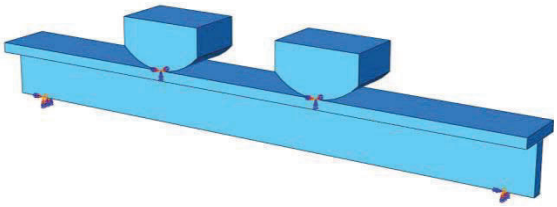

Figure 10: *Finite element model showing T-beam below two loading blocks and boundary conditions applied*

The wood elements are modelled as a linear-elastic orthotropic material using ABAQUS' engineering constants option, where the primary direction (1) represents the longitudinal direction of the wood grain and the two secondary directions (2) and (3) represent the two perpendicular to grain directions (i.e., radial and tangential). The experimentally determined true modulus of elasticity for each web and flange is used for the longitudinal modulus of elasticity, E_1, while the shear modulus G_{12} and G_{13} is taken as $E_{true}/15$ for the webs and $E_{true}/18$ for the flanges based on the lumber species and recommendations from Forest Products Laboratory's Wood handbook [21]. The Poisson ratios were also based on recommendations for each species group from Forest Products Laboratory's Wood handbook [21]. The remaining E_2, E_3, and G_{23} are based on CSA O86 [24] recommended values in term of E_{true}. The material parameters are summarized in Table 5.

Table 5: *Material parameter values used in ABAQUS model*

	Web Element	Flange Element
E_1 (MPa)	$E_{true,web}$	$E_{true,flange}$
E_2 (MPa)[1]	$E_1/30$	$E_1/30$
E_3 (MPa)[1]	$E_1/30$	$E_1/30$
ν_{12}	0.32	0.35
ν_{13}	0.35	0.35
ν_{23}	0.39	0.45
G_{12}[2] (MPa)	$E_1/15$	$E_1/18$
G_{13}[2] (MPa)	E1/15	E1/18
G_{23}[3] (MPa)	$G_{12}/10$	$G_{12}/10$

4.2 COMPARISON OF EXPERIMENTAL AND NUMERICAL RESULTS

The numerical model was run for each T-beam specimen, with the corresponding combination of web and flange true modulus of elastically, in order to validate the numerical results against the experimental results. For each T-beam, a specific bending moment and displacement point corresponding to an initial failure and the transition from linear-elastic to non-linear were carefully selected for comparison to the model. Thus, the loading in the model was increased until it reached the specific bending moment, $M_{specified}$, and then the experimental and numerical displacements were compared. The results of this comparison are summarized in Table 6. It should be noted the numerical model was limited to the linear-elastic stiffness of the T-beams and did not aim to predict ultimate failure.

Table 6: *Comparison of experimental (Exp.) and FE model deflections at midspan based on specified bending moment*

Specimen	**$M_{specified}$** [kNm]	**Exp. Deflection** [mm]	**FE Model Deflection** [mm]	**Exp./FE Model** [-]
SG-01	6.0	6.98	7.06	1.01
SG-02	10.8	11.15	11.27	1.01
SG-03	7.8	8.78	7.42	0.85
SG-04	9.9	7.95	7.30	0.92
SG-05	12.9	10.35	11.58	1.12
SG-06	9.0	7.42	7.18	0.97
			Avg.	**0.98**
			CoV	0.09

The numerical model agreed reasonably well with the numerical model, with the average experimental midspan deflection being 0.98 of the numerical midspan deflection with a CoV of 0.09. The deviation in SG-03 and SG-05 is not uncommon for dimensional lumber and can partially be attributed to the presence of localized defects in the wooden elements, lack of a continuous bond, and appreciable error in the properties (e.g., average slip stiffness used). The load-displacement curve for each of the experiment specimens, along with the numerical model response is presented in Figure 11: Load-deformation curve from experimental and numerical model results. Overall, the numerical model was deemed capable of capturing the screw-glued shear connection behaviour.

5 IMPLICATIONS ON MASS TIMBER COMPOSITES

To investigate the feasibility of the shear-glued connection studied in the current paper for use in MTC panels, the experimentally determined slip stiffness from Table 1 was analytically applied to a 10m long CLT-glulam HMT panel shown in Figure 12. The HMT panel consisted of four 80 x 245mm SPF 20f-E grade glulam webs and two 105 x 2400mm V2 grade CLT panels, with material properties taken from CSA O86 [24]. The γ-method, which has been shown to be an accurate method for determining the behaviour of MTCs in design [10,11], was used for this analysis.

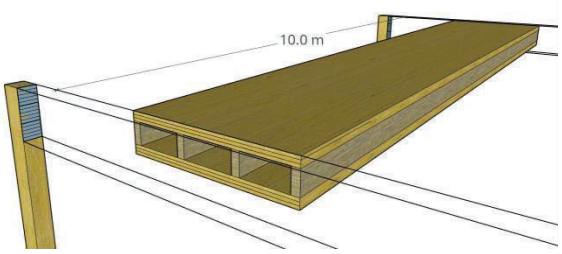

Figure 12: *10m hollowcore mass timber panel*

The results of the analysis are presented in Figure 13 where the screw-glued connection slip stiffness was able to achieve a high degree of composite action (>95%), thus resulting in an HMT panel that was able to meet the design criteria of a 10m span for stiffness requirements due to vibration demands. For comparison, a few select connections experimentally tested on CLT-glulam shear specimens by Montgomery [6] and Jacquier [10] are also presented in Figure 13.

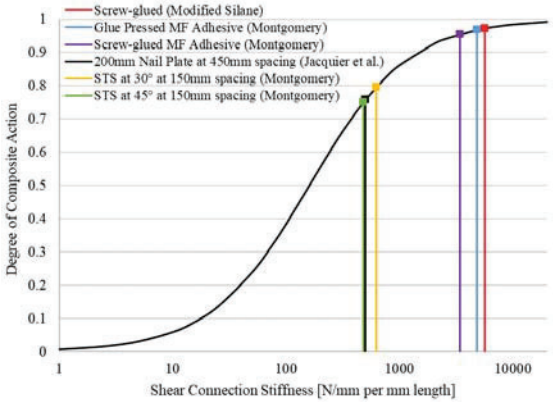

Figure 13: *Degree of composite action in HMT panel based on shear connection stiffness*

For the screw-glued connection, the HMT panel achieved a stiffness of approximately 105 x 10^{12} Nmm^2 which corresponded to a vibration-controlled span, according to the CSA O86 Annex A clause A8.5.3 [24] for the vibration-controlled span of CLT panels, of 10.4m. Overall, this indicated that the commercially available bead extruded silane modified adhesive and partially threaded STS is an easily applied, and structurally viable screw-glued connection for MTC panels, able to achieve high degrees of composite action.

https://doi.org/10.52202/069179-0450

6 CONCLUSIONS AND FUTURE WORK

Presented herein are the results of an experimental study investigating the behaviour of a screw-glued connection, with the goal of justifying it as a structurally viable shear connection for MTC panels. The connection consisted of 6mm dia. x 100mm long partially threaded STS with washer heads spaced at 133mm c/c, as well as a 10mm wide bead of commercially available silane modified construction adhesive on a 40mm wide web. Additionally, 25mm dia. washers were added beneath the existing washer heads of the screws as a measure to aid in evenly spreading the pressure distribution of the screw-gluing, as well as to prevent local wood crushing under the screw heads. The results have shown that the screw-glued connection was able to achieve a slip modulus of 17.63 N/mm per mm^2 of glue with a CoV of 0.11. The lower level of variation in the connection stiffness is encouraging for the overall repeatability of the screw-glued connection given the number of variables that can influence the overall behaviour (e.g., lumber grade, stiffness, surface planning, glue vs. wood failure, moisture content, curing conditions). Overall, when used on a 10m HMT panel, analytical results using the γ-method indicated a nearly fully composite shear connection was achieved and a vibration-controlled span of 10.4m was possible for the 455mm deep section.

Two bilinear models were used to represent the load-slip response and to determine the yield stress of the screw-glued connection. The first, based on EN 12512, provided an average yield stress of 4.59MPa while the second, based on yield occurring at 75% of the maximum load, provided an average yield stress of 3.47MPa.

The average apparent and true stiffness of the sections were found to be $3.69 \times 10^{11} Nmm^2$ and $4.40 \times 10^{11} Nmm^2$ respectively, with most of the variation in stiffness across specimens attributed to the different modulus of elasticity of the webs. Generally, higher webs stiffnesses were proportional to higher T-beam section stiffnesses. The experimental T-beam results were then compared to a FE model created to capture the behaviour. For each T-beam flange and web element, the modulus of elasticity was determined not destructively and used as input for the model. Overall, the numerical model agreed well with the numerical model, with the average experimental midspan deflection being 0.98 of the numerical midspan deflection with a CoV of 0.09. The numerical model was thus deemed likely capable of capturing the screw-glued connection behaviour and will be used on future numerical analysis of MTCs.

The screw-glued connection investigate herein has proven to be a structurally viable and easy to apply shear connection with great potential for use in MTC panels. Future work applies the current screw-glued connection, along with other promising shear connection candidates, to CLT-glulam shear specimens with the goal of determining the optimal connection based on connection stiffness and yield stress, constructability, and cost for use in the production of MTC panels in industry. The optimal three connection configurations are used in the fabrication of 15 CLT-glulam T-beams which, to the author's knowledge, will be one of the largest studies on MTC panels.

LOADING TEST OF CLT-SHEAR WALL CONNECTED WITH STEEL BAR－TIMBER COMPOSITE COLUMN DISSIPATING HIGH-ENERGY

Takumi Suyama [1], Riko Kawasaki [2], Atsuya Kawasoe[3], Tomokazu Yoshioka[4], Shinichi Shioya[5]

ABSTRACT: In light of the current climate crisis, there has been much recent interest in using timber structural members in large buildings, since timber is as renewable natural resource. Moreover, in severe earthquake prone zones, such as Japan, they are more desired on the grounds of light weight of timber members. We are developing a frame system formed by steel bar-timber composite members strengthened by deformed steel bars (i.e., rebars) using epoxy resin adhesive. We are also developing Cross Laminated Timber (CLT)-shear wall for the frame. One of the most excellent mechanical characteristics of CLT are its high shear stiffness and shear capacity. It is most advisable to use one long CLT panel as one continuous wall without cutting it at floor levels. This paper reports the application of the rotating shear plate concept to the CLT wall and experiment of the shear wall dissipating high-energy, by damper installed in a frame consisting of steel bar-timber composite columns and timber beams.

KEYWORDS: Shear wall, Cross-Laminated Timber, Composite timber, Column, Re-centering, Energy-dissipation

1 INTRODUCTION

One of the most excellent mechanical characteristics of Cross Laminated Timber (CLT) is its high shear stiffness and shear capacity. The structural component that can take advantage of that is shear wall. However, it is difficult to utilize fully the characteristics of CLTs, if they are cut and connected at floor level of each story in buildings, and they are also time-consuming and expensive. It is most advisable to use one long CLT panel as one continuous wall. The maximum dimension of one CLT panel available in Japan is 3.0 m x 12.0 m. It is possible to adopt the CLT as one 2-story to 4-story continuous wall. A mechanism is required to transfer the horizontal inertia force generated by the CLT slab during an earthquake to the shear wall. However, if the continuous wall yields in bending or rotates at its wall bottom, rotation, vertical misalignment deformation will occur at the connection between the slab and the wall above the second story. When the deformations are larger, it is currently difficult to transfer shear force between the slab and wall CLTs without damaging the connection during an earthquake. Future seismic design of buildings, on the other hand, will require performance to control damage and residual deformation. To control damage in slab-to-wall joints, a joint method that can only transmit horizontal shear force without restricting the rotation and the vertical deformation is desirable. Shioya has devised a shear key plate (rotational shear key) that allows rotation and transmits only shear forces in steel bar-timber composite column-beam connection [1]. Rocking wall is effective in reducing its residual deformation. Rocking CLT shear walls have already been developed [2], but the level of shear force that can be transmitted is extremely low, approximately 25% of the shear capacity of CLT wall. This paper reports the application of the rotational shear key plate concept to CLT shear wall and experiment of a shear wall dissipating high-energy by dampers, which are installed in a frame consisting of steel bar-timber composite columns and timber beams.

2 ARRANGEMENT AND AIM OF SHEAR WALL

Figure 1 shows a schematic diagram of assumed structure and shear wall, and its arrangement, where 3-story rigid-frame structure is assumed. Shear walls are placed in ridge direction. One-piece type of one CLT panel with a width of 3 m per one span (one-piece type) or two-piece type of two CLT panels can be assumed. Column is to be made of steel bar-timber composite column. The span in the ridge direction of building is assumed to be 3.6-3.8m and are connected with Glued laminated (Glulam) timber beams. The shear wall is assumed not to resist to axial forces from Dead load and Live load of building. Long-term loads are assumed to be resisted by the left and right columns of the shear wall.

The rotational shear key plate is incorporated so that its wall bottom performs as pin and is connected to RC foundation.

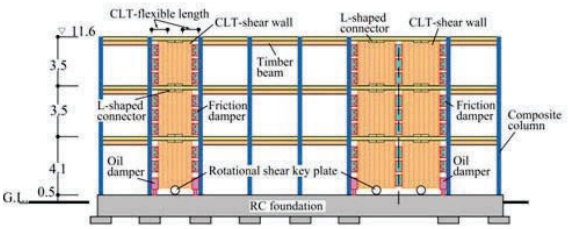

Figure 1: *Shear wall, damper, and rotational shear-key plate in a frame*

Shear wall and CLT slab are connected to each other with L-shaped angle steel and screws (hereinafter referred to as "L-shaped hardware joint") only over center segment of the span.

As the slab is not restrained by the shear wall over section between the L-shaped hardware joint and its columns, the slab is expected to absorb the vertical deformation between the CLT wall and the columns and not to be damaged over the section.

Friction dampers and oil dampers are installed between the CLT wall and the column, dissipating energy using the vertical deformation between them which is caused by the rotation of the CLT wall. The friction damper is expected to dissipate vibration energy mainly during big earthquakes, i.e., after 1/200 rad. and the oil damper is expected to dissipate the vibration energy during frequent small and medium earthquakes and vibrations caused by wind loads to improve the habitability in building.

3 FRICTION DAMPER AND ITS PROPERTY

The shape of the damper is shown in Figure 2. It consists of a steel plate/Part A, T-shaped steel/Part B, two ultra-high strength aluminium plate/Part C for sliding material, two filler steel plate/Part D, two splice plates/ Part E, two thick square washer/Part F and a high-strength bolt/Part G. In the experiment, high-strength bolts with an embedded foil strain gauge were used to accurately measure tension force of the bolts. Part A is inserted into a slit cut in the

Figure 4: *Shape and dimensions of specimen*

centre of the thickness of the CLT and secured with drift pins. Part B is fixed to the side of the column with self-tapping screws.

Figure 3(a) shows a set-up for cyclic reversed loading test to investigate the frictional characteristics of the damper. In the damper, friction force and energy dissipation generate on two sliding surfaces between web of Part B and ultra-high-strength aluminium plate/ Part C. The aluminium plate is fixed to the splice plate using sand blast. The friction force-deformation relationship is shown in Figure 3(b)-(e). The friction force can be assumed to be 1/2 of the vertical load F. Deformation as horizontal axis in Figure 3(c) is the sliding deformation of the aluminium plate, which means that the initial stiffness is higher than others and there is little slackness. The skeleton curve of the relationship can be seen such as a tri-linear curve and not an inverted S shape curve. Except Figure 3(c), the curves have an inverted S-shaped loop shape with initial slackness caused by clearance around the drift pin or the screw. This characteristic was anxious to lead to a deterioration in horizontal shear force-drift relationship of the shear wall.

4 LOADING TEST OF SHEAR WALL

4.1 SPECIMEN

Figure 4 shows configuration of specimen, which was scaled at 40% and modelled as a range from the first floor to center of the second story height in frame planned such as one CLT panel was to be fitted in one span in the three-story frame consisting of steel rebar-timber composite columns and Glulam timber beams.

The column was rectangular in cross section and made of steel bar-timber composite member, which was selected to be in the weak axis direction of the column in loading direction. CLT panel and the columns were connected by

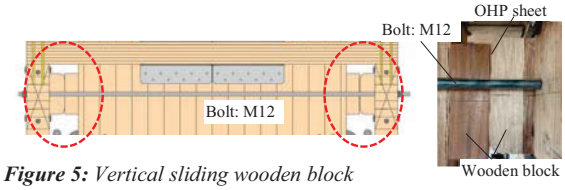

Figure 5: *Vertical sliding wooden block*

the friction damper mentioned in Chapter 3. No beam was employed to connect the left column and the right column. However, as shown in Figure 5, a pair wooden block was fixed to the column between the column and the CLT panel with tapping screws so that the interface of the wooden blocks could allow vertical sliding by being inserted a polyethylene terephthalate sheet. This prevents space between the columns and the CLT panel from closing, and separation between those is prevented by penetrating two long bolts through the columns on both sides and tightening those with washers and nuts.

This connectoin method is planned to be done at each floor, but in this specimen, it was also done near the top loading height.

Bottom of the CLT wall was connected to H-shaped steel flange as foundation by two pair-rotational shear key plates. However, in actual buildings, column bottom is planned to be anchored to reinforced concrete foundation by inserting column rebar into its ducts for the rebar and then grouting into the ducts.

Orthogonal beams were connected by glued-in-rod to the columns. The orthogonal beams were also made of steel bar-timber composite member. The second floor was made of the same CLT as the CLT wall and was connected to the CLT wall with L-shaped hardware joint. This was designed such that shear force could be transmitted from floor to wall. Two CLT slabs were connected by self-tapping screw to the orthogonal beams.

https://doi.org/10.52202/069179-0451

4.2 DETAILS OF SPECIMEN

4.2.1 Cross laminated timber (CLT)

The CLT had 84 mm thickness and consisted of 5 layers of 7 plies with lamina thickness of 12 mm which was width haggled. The strength grade was in accordance with cedar M60B of Japanese Agricultural Standard (JAS).

4.2.2 Column

The column adhered to cedar Glulam timber of E65F225 of JAS. Rebar was screw rebar with nominal diameter of D16 and yield strength level of SD390. The area ratio of tensile bars to column cross-section was 1.94%, and the ratio of the total rebars was 3.88%.

4.2.3 Connection of column bottom

Figure 6 shows detail of column bottom. The screw rebar coupler cut in 1/2 of the lengthwise direction was used as a nut. Nut/A was tightened on the column side with a lock nut. A steel plate was secured by wood screw to basement of the column, and then four dowel holes were drilled to match hole in the steel plate and four dowels were inserted. The column basement was fixed by tightening the screw rebar with nut B by passing the screw rebar and the dowel to upper flange of the H-shaped steel foundation. The steel plate was fixed to the H-beam with high-tension bolts.

4.2.4 Friction damper

Figure 7 shows detail of friction damper. High-strength aluminium plates (thickness=3.0 mm) are placed on both sides of web of T-shaped angle steel such as makes the joint surface slid. The tension of PC steel bar pressing the sliding surface was measured with a strain gauge embedded in the PC-steel bar. Splice plate was blasted on its one side to prevent misalignment with the aluminium plate. In addition, high-strength bolt was used to tighten splice plate to steel plate inserted into CLT panel to form friction joint between the splice plate and the inserted plate. Figure 8 shows shape and dimension of the inserted steel plate into CLT side face. The drift pin was made of hardened steel rod of S45C by heat treatment with a diameter of 12 mm.

4.2.5 Rotating shear key plate

Figure 8 shows a rotational pair-shear key plate (thickness = 9.0 mm). It was made of mild steel of SS400 and cut by laser-cut machine controlled with computer. Figure 10 shows set-up for the rotational shear key plate which consists of upper comb plate and lower comb plate.

Figure 11 shows the process of assembling of rotational shear keys. Upper two shear plates are friction-joined with high-strength bolts to both sides of the steel plate inserted to CLT-wall's bottom. Lower two shear plates are friction-joined with high-strength bolts to both sides of web of T-shaped angle steel secured to H-shaped steel foundation of reaction steel frame with high-strength bolts. The design of the pair shear key plate is based on magnitude of shear force and rotation angles to be allowed. The shear capacity of CLT wall of this specimen in design is 173 kN on the basis of its nominal shear strength and horizontal cross-section area considered wood ducts, and the pair-shear key plate can transmit shear force of approximately 1221 kN (= 9 x 1000/2 x 235/$\sqrt{3}$ x 2). Rotation angles of up to 3.3 x 10^{-2} rad. is to be allowable.

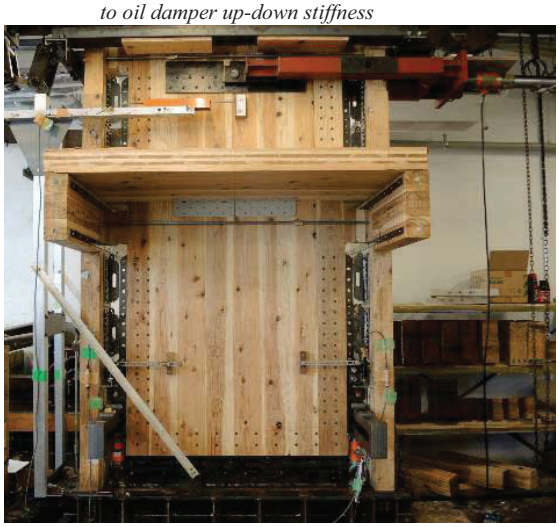

Photo 3: *set-up for loading*

4.3 LOADING

Figure 12 and Photo 3 show set-up for loading. H-beams of foundation were fastened to steel reaction frame with high-strength bolt, and repeated positive and negative cyclic horizontal force was applied at pin position at top of the CLT wall. No vertical load was applied to the columns. To prevent out-of-plane deformation of the top of the wall, two L-shaped steel beams sandwiched both side of the top of the wall, and the L-shaped steel beams and the reaction frame were connected by lateral braces. The lateral braces were joined so that the column heads were not restrained in loading direction. The loading protocol is shown in Figure 14. Orange colour indicates the force applied to check stiffness of specimen installed with each damper, and blue colour represents main protocol for seismic loading. The horizontal displacement at the top of the wall was controlled by deformation angle divided by 1691 mm of the height between the foundation and the displacement transducer. However, the initial 1-2 cycles were controlled by horizontal force.

4.4 MEASUREMENT

Figure 15 shows set-up for measurement of deformation and strain. The horizontal deformation of the wall was measured at the center of the wall width using displacement transducer attached to an aluminium frame fixed to the H-beam of the foundation, close to the height of the force point. Deformations of left and right dampers on the first story and the right damper on the second story, vertical up-down deformation of the CLT wall bottom, and the vertical deformation of CLT slab against the CLT wall were measured with displacement transducers.

Vertical axial strain and shear strain of CLT panel and vertical axial strain of timber near column bottom were measured with foil strain gauge (measuring length: 60 mm, long-term period measurement specification).

5 EXPERIMENTAL RESULTS

5.1 HORIZONTAL LOAD-HORIZONTAL DISPLACEMENT ANGLE RELATIONSHIP

Figure 17 shows horizontal force - deformation angle relationship. The deformation angle was calculated by dividing average horizontal displacement of the front and back near loading point by height of the displacement meter (1691 mm).

Horizontal force applied as reversed cyclic loading from the 4th cycle, experiencing each target deformation angle three times. The three cycles were observed to follow almost the same loop until the final deformation, and the cyclic loading did not cause any decrease in load capacity. The loops until the 30th cycle is shown in red and loops after the 30th cycle is shown in blue. Owing to loosening of the high-strength bolts of two splice plate of one friction damper connected to the top of wall from the 13th cycle to the 30th cycle, the relationship became loops such as it stiffs again after yielding.

This reason is considered that the stiffness is increased when the damper rotates owing to the loosening and the high-strength bolts strikes the side of hole in the splice plate and the inserted steel plate. After unloading at the time of recognizing the rotation of the splice plate, the friction damper was returned to be vertical and then the high-strength bolts were tightened.

Average shear stress obtained by dividing the maximum horizontal force of +110.4kN and -105.9kN at +1/50 rad. by area of horizontal cross section of CLT panel was 1.28 N/mm2. The average of those forces was 62% of shear capacity of the CLT wall bottom considering the deficiency by the drift pint and the inserted steel plate. As it may be possible to increase the horizontal loading capacity by increasing the tension of the PC steel bar in the friction damper, next work is going to reveal behaviour of the shear wall subjected to higher load levels by increasing the tension.

5.2 BEHAVIOR OF DAMPER

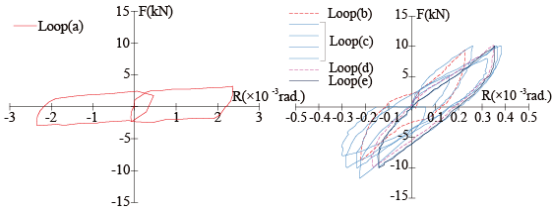
Figure 18 shows relationship of vertical shear force Q_D per a damper and sliding deformation δs between the inserted steel plate and the T-shaped angle steel. Q_D was calculated by the following Equation (1).

$$F \cdot h = 4 \cdot Q_D \cdot \ell \quad (1)$$

where F is horizontal force; h is height (1813.5mm) of the force point from rotational center of the rotational shear key; ℓ is horizontal distance (1100 mm) between the right damper and the left damper.

At first, the right-first damper on the lowest height from the bottom slid and yielded at -16.52kN in the fourth cycle; next, the right-third damper was done at -21.93kN in the seventh cycle; the left-first damper was done at -23.95kN in the tenth cycle, as well as the right-first damper.

As well as the horizontal force - deformation angle relationship, the relationship of damper was observed to



(a) Loop at step adding only rotational shear-key plate (b) Loops at steps adding each damper

Figure 16: *Lateral force-deformation angle Relationship*

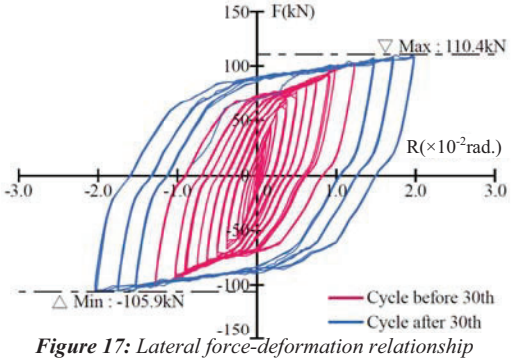


Figure 17: *Lateral force-deformation relationship*

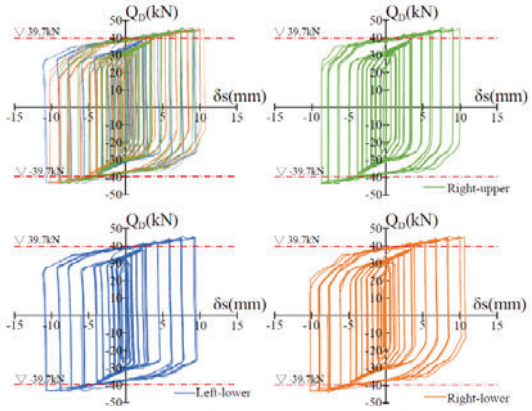

Figure 18: *Friction force/Q_D – slip relationship/δ between Part A –T-shaped angle steel*

be that of an increase in friction force after 1/68 rad. was observed. The maximum of sliding deformation of dampers during the final cycle of loading was+10.75 mm for the right-first damper; -11.22 mm for the left first damper; +9.97 mm for right third damper. The deformation of damper at higher position tended to be smaller, and the deformations of right and left dampers were to be close.

Figure 19 shows the relationship between tension change of the PC steel bar and sliding deformation in the damper. The target initial tension was selected to be 40.0 kN. The damper on the left side of the fourth row is considered to have loosened the PC steel bar due to the loosening of the high-strength bolt. Excluding this damper, the third row has the largest reduction, and the reduction became smaller as it approached the wall foot. It can be inferred that the frictional force might have been greater for the

right damper for the reason that the left damper has a greater reduction in tension than the right damper.

Figure 20 shows variation of sliding deformation of CLT and inserted steel plate against the horizontal force. It is an inverse S-shaped relationship with stiffness increasing from ±0.2 mm. The explanation of these is that after clearance of steel plate and its drift pin and clearance between drift pin and hole for itself in CLT closing, those resist each other. However, even maximums of sliding were negligible small.

Figure 21 shows variation of sliding deformation of the T-shaped angle steel against column. The maximum deformation in the final cycle was +1.333 mm at the right first damper; the left- first, +2.120 mm and the right third, +0.806 mm. A value of 0.75 mm sliding deformation is shown in the figure as a single vertical line, which roughly correspond clearance of hole in the T-angle steel and the neck of taping-screw. This also can be explained as clearance of those might have closed.

5.3 ENERGY DISSIPATION

Figure 22 shows variation of amount of energy dissipated by loops of each target deformation angle.

Although amount of energy at the same target deformation angle increased slightly in the second and third cycles compared to the first cycle, there was little difference in the amount, and there was no degradation of absorbed energy owing to the repetitive loading.

Figure 23 shows variation of the equivalent viscous damping constant he. The value calculated for reinforced concrete structure are represented by solid black lines.

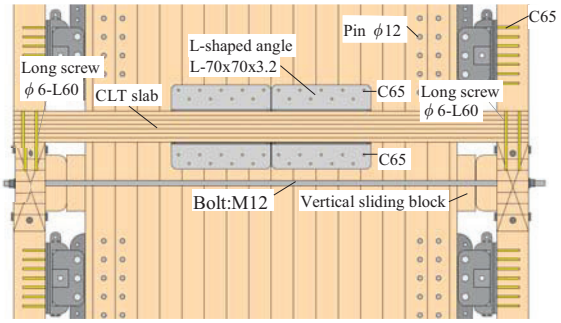

Figure 26: *Connection of CLT floor and CLT wall*

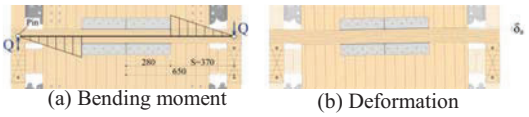

(a) Bending moment (b) Deformation

Figure 27: *Condition of CLT slab as CLT wall rotating*

This shear wall exhibited extremely high energy dissipation performance compared to RC, with performance of more than 10% from the initial deformation level and 40% at 1/50 rad.

5.4 WALL BOTTOM ROTATION

As shown in Figure 15, vertical displacements of CLT wall against the H-shaped steel of the foundation were measured on both left-hand and right-hand of the wall, by using transducers fixed to the lowest steel plate inserted into the CLT. Figure 24 shows variation of rotation angle of the CLT bottom calculated from the displacement, compared to the displacement angle as shear wall, i.e., drift. The rotation angle accounts for approximately 90% of the drift. Figure 25(a) shows variation of up-down displacements versus shear force. Figure 25(b) shows variation in the sum of two displacements at each side. This sum means vertical elongation at the rotation center of the rotating shear plate. Even when the drift increased up to 1/50 rad, the sum was less than ±0.8mm. This

https://doi.org/10.52202/069179-0451

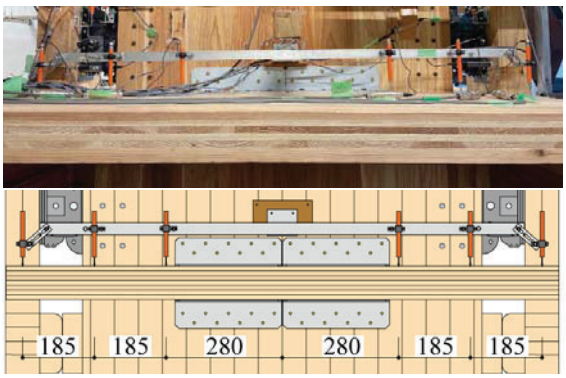

Figure 28: *Set-up for displacement*

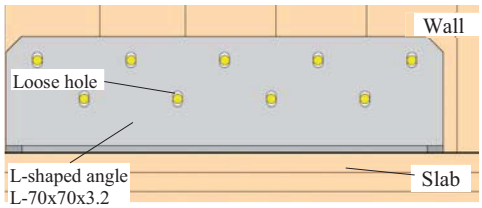

Figure 29: *Rotation-allowing angle steel*

demonstrates that the rotational shear key might have hardly elongated in vertically direction. This suggests that the left-hand dampers and the right-hand dampers might have slid as well, that sum of damper friction forces at each side might have been approximately same, and that the rotational shear key might not have been subjected to great tensile force in vertical.

5.5 VERTICAL DEFORMATION AND DAMAGE OF CLT SLAB

Figure 28 shows setup for measuring vertical displacement of the slab. An aluminium angle with displacement transducers attached were fixed to the CLT wall. The deformation measured is vertical deformation of the slab perpendicular to the aluminium angle.

The vertical deformation of the slab at each measured position against horizontal line passing through the fixed position of the aluminium angle can be approximated by the following Equation (2).

$$y_i = x_i \cdot \theta - \delta_i \quad (2)$$

where y_i and x_i are referred to Figure 30; θ is drift; δ_i is displacement of the transducer.

Figure 30 shows the distribution of the vertical deformation of the slab at a drift of +1/50 rad. The one dot chain line represents an inclination of drift=1/50 rad. This can be regarded as the inclination of the aluminium angle to which the displacement transducers were fixed. Vertical displacements of top surface of the slab can be calculated by using Equation (2), a distribution of which is shown by red solid line.

Even at the positions of the left and right boundaries of the L-shaped angle steel joint, values of the red line are different from those of the one dot chain line.

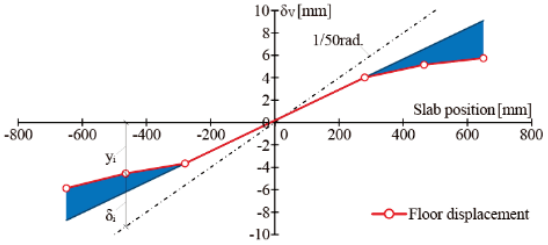

Figure 30: *Vertical displacement of floor*

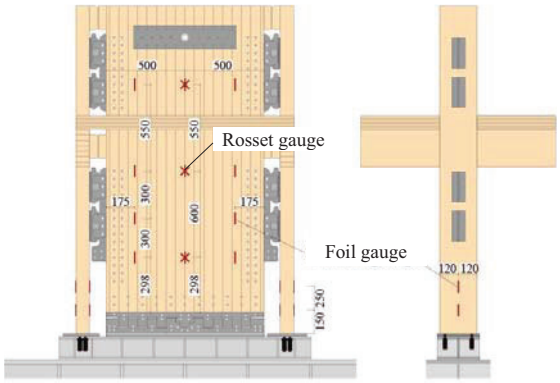

Figure 31: *Set-up for measurement of strain gauge*

This means that sliding deformation occurs between the CLT wall and the CLT slab over range of the angle steel joint. This may result from clearance between the screw holes and screw diameters at the joining angles and torsional deformation between the wall and the slab. The extent that the slab is deformed within range except the angle steel joint can be regarded as blue areas.

If the deformation of the slab is less than allowable value, no damage is expected to occur. The maximum values at drift=1/50. were 2.87 mm on the left side and 3.35 mm on the right side. In this experiment, the slab was not damaged even when the deformation reached 1/50 rad. This argues that this proposed system can significantly absorb the vertical deformation between column and wall, preventing the slab damage.

In the future, it is necessary to develop a method to estimate the deformation and damage deformation of slabs.

5.5.1 ROTATION-ALLOWING ANGLE STEEL

However, it is considered difficult to quantitatively estimate and design those factors. If the screw holes on the wall side of the angle steel are made vertical long holes as shown in Figure 29 so that the rotation of the wall is not restrained at the joint surface between the angle and the wall, the rotation of CLT wall and the vertical deformation caused by the rotation of wall bottom can be absorbed and the damage of CLT slab can be prevented, with transmitting transverse shear force by earthquake motion. Next experiment is planned to adopt the modified angle steel with the long holes.

https://doi.org/10.52202/069179-0451

5.6 SHEAR FORCE OF COLUMN

As shown in Figure 31, column strain was measured using foil gauges. Bending moment of column at each height position can be calculated by multiplying cross-sectional secondary moment of column by its curvature which is calculated using the strain of the foil gauge, as well known[3,4]. Shear force of column can be also calculated as gradient of two bending moments of lower and higher positions of the columns.

In the calculation, it was assumed that Young's modulus of timber is 6500N/mm^2 and that of rebar is 2.05x10^5 N/mm^2, which are nominal values of each. Figure 32 shows shear force vs drift relationship for the columns, comparing the horizontal force of the shear wall. The left and right columns resisted elastically up to 1/50 rad. At 1/50 rad. the positive force on the left column reached 9.5% of the horizontal force, and the negative force on the right column did 7.2%.

5.7 VERTICAL FORCE ON ROTATIONAL SHEAR KEY PLATE

Axial force of column can be calculated from strain of the strain gauges as well as bending moment. Figure 33 shows variation of sum of axial forces of the left and right columns. The sum must have been resisted by the rotational shear key plate. Although there is possibly some error because of Young's modulus of timber assumed as the nominal value, the sum at 1/50rad. is 6.6% of the column axial force calculated from the maximum horizontal load, which is extremely small. From this result, also, it can be seemed that the left and right friction dampers might have slid in good balance.

5.8 SHEAR STRESS-STRAIN RELATIONSHIP OF CLT WALL

As shown in Figure 31, shear strain was measured at three different heights by a rosette gauge (measuring length: 60 mm). Figure 34 shows average shear stress-shear strain relationship. Shear stress was defined as horizontal force divided by horizontal cross-sectional area of CLT wall. Shear strain was calculated from diagonal strain for simplicity; Figure 34(a) shows those up to initial ±3 cycles. Slope of the stiffness at the loop is shown by single-dotted line. The slope is the shear modulus G_W. Figure 34(b) shows those up to the final cycle. The plastic strain is found to be larger in upper part of the wall. This reason cannot have been explained at this time.

The shear modulus of CLT is, in general, 300-500 N/mm^2, but this experimental value is 3.0-4.0 times higher than the values. This is partly because of the assumption that shear forces of column was ignored and horizontal force was resisted by only CLT wall. However, as mentioned above, the shear forces of the column might have accounted for only 8.4% of the total load, so other factors may be responsible.

Figure 35: *Distribution of vertical strain of CLT wall by bending*

5.9 DISTRIBUTION OF BENDING MOMENT OF CLT WALL

As shown in Figure 35, vertical axial strain of the CLT wall was measured at four heights with a foil strain gauge (measuring length: 60 mm). Strain values were extremely small, 0.019% at even maximum. Those cannot be analysed in detail considering the variation of wood, but those of the left side indicate tensile strain and those of the right-side do compressive strain. These results are the exact opposite against moment by horizontal force F under positive load. On the other hand, the strains near the rotational shear key and near the loading point will be smaller.

This can be explained as those positions are pins and bending moment is zero. These results can be considered

https://doi.org/10.52202/069179-0451

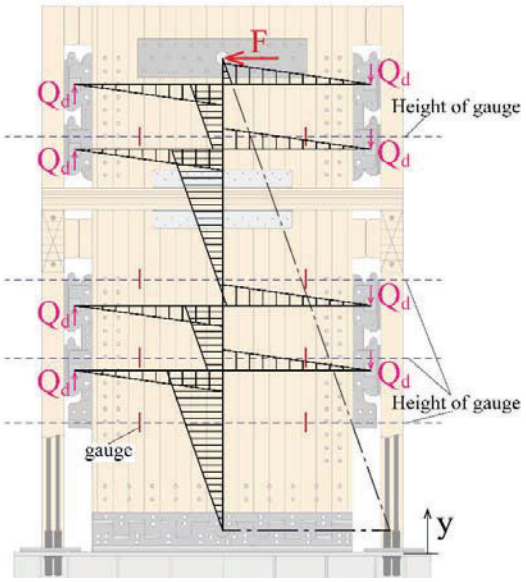

Figure 36: *Bending moment diagram for CLT wall*

to correspond to the distribution of bending moments in the CLT wall shown in Figure 36.

Moment by the horizontal force increases linearly as its height approaches the rotational shear key, as shown in one dot line, but bending moment of the CLT wall hardly increases because vertical friction force of each damper causes bending back. If shear force of columns is ignored because of it being small, horizontal shear force of the CLT wall can be considered constant regardless of height. Thereby, aspect of bending moment distribution of the CLT wall can be captured by assuming that the CLT wall bottom is pin. The heights of each strain gauge are represented by horizontal broken line. The left side is tensile, and the right side is compressive, corresponding to results of the strain in Figure 35.

These results demonstrate that the columns act as flange of wall and its CLT dose as web, similarly to H-shaped steel and that the columns resist against the bending moment of shear wall and the CLT wall dose almost against only the shear force. One of features of this shear wall is that the bottom of the CLT wall is connected to the foundation using rotational shear key plate, which significantly reduces bending moment of the CLT wall and perfectly suppresses damage of the CLT wall. The result of strain mentioned here is one of events supporting the features.

6 SUMMARY

In this paper, we proposed a shear wall system in which CLT panels are incorporated into a rigid-frame structure of steel bar-timber composite members, which authors have been developing, and revealed mechanical characteristic of the shear wall subjected to reversed cyclic lateral loading by a specimen scaled as 40%. The results are summarized as follows.

i) A friction damper so as to be installed between the CLT wall and the column and a connection method were proposed, and then it was confirmed that the damper can be easily joined. Although yield capacity of the damper increased with amount of its sliding deformation and the number of loading iterations, the capacity gradually converged to a constant value as the deformation increasing. Sliding deformation occurred in the joint between the damper and the CLT wall and in the joint between the damper and the column owing to clearance of holes in the drift pin or holes in self-taping screw, but the amount of deformation was almost negligible in the deformation of the shear wall.

ii) The rotational shear key plate was proposed to transmit shear force as the bottom of the CLT wall rotating, and it was confirmed that the plate could be easily joined to the CLT wall and that the incorporated CLT-shear wall allowed the rotation angle as planned.

iii) The shear wall yielded by sliding of friction damper at approximately 1/400 rad., and then produced elastoplastic history loops that generated extremely abundant energy dissipation and hardly degraded with repetitive loading.

iv) The maximum horizontal force in this loading test was 110.3 kN at 1/50 rad. This was 1.31 N/mm^2 at the average shear stress of CLT wall, which was 1.72 N/mm^2 when considering deficiency of joint drift pins and inserted steel plates at the wall bottom.

v) No failures were observed up to 1/50 rad. in this specimen by incorporating friction dampers and a rotational shear key plate and by making the best use of the steel bar-timber composite columns of flame.

vi) As it may be possible to increase the horizontal capacity of the shear wall by increasing tension of the PC steel bars, next work is going to reveal behaviour of the shear wall subjected to higher load levels by increasing the tension.

ACKNOWLEDGEMENT

This project was funded by Grant-in-Aid for Research-A in Japan and its experiment was conducted by all staffs of Shioya's laboratory. The authors gratefully acknowledge their work.

TIMBER VAULTS FOR ULTRA-LOW-CARBON BUILDING STRUCTURES

Shane Hossell[1], Will Hawkins[2], Antony Darby[3], Tim Ibell[4], Nicola Lines[5]

ABSTRACT: This paper explores the benefits of using curvature and arching action in timber flooring systems to reduce the embodied carbon and aid in material efficiency. In this paper, the embodied carbon of the proposed timber barrel vault system with granular infill is compared with a more conventional cross laminated timber (CLT) floor. The proposed barrel vault system is constructed out of curved glue-laminated timber that spans between supporting beams. Steel ties are used to restrain the horizontal thrust forces generated by the vault. A two-dimensional parametric optimisation of the barrel vault floor system and the CLT floor in terms of minimising embodied carbon was undertaken using a script written in MATLAB, analysed using matrix stiffness methods and optimised using a genetic algorithm. The analysis was carried out on spans ranging between 4m and 12m with the optimal solution dependent on the interaction between the fabrication stresses, arch height, and rod diameter. The resulting design for 4m to 12m spanning office floors results in a 35% to 41% reduction in embodied carbon compared to an equivalent CLT system.

1 INTRODUCTION

1.1 SUSTAINABLE MATERIAL EFFICIENCY

Building materials production emits around 10% of global energy-related CO_2 emissions, largely driven by cement and steel manufacturing [1]. To address this, the focus has shifted towards reducing embodied carbon in building materials. Embodied carbon factors are often linked to a unit volume or mass of material and therefore reducing the quantity of material results in concomitant reduction in the environmental impact of the building.

Floors typically account for 50% to 70% of a building structure's material consumption and weight [2]. Adding to this, floor area demand is predicted to increase by 75% between 2020 and 2050, with 80% expected to occur within developing countries [3]. Thus, material reduction in floors while maintaining safety is becoming even more critical to reducing overall embodied carbon in buildings.

Timber has recently re-emerged as an alternative for building structures with the introduction of mass timber products. Designers are increasingly turning to cross-laminated timber (CLT) panels as an environmentally friendly option for constructing buildings [4]. These panels, which are made from orthogonally bonded layers of sawn timber, have enabled faster construction through automated prefabrication, lower material uncertainty, and enabled longer spans made from timber. These benefits have consequently allowed CLT to be used in slab systems and walls. The simple and familiar geometries provided by CLT, and other mass timber products, have made it possible for the risk averse construction industry to adopt the material within their designs. Mass-timber buildings have also been shown to provide lower embodied carbon solutions when compared to steel and concrete [2]-[4] and, with the added advantage of biogenic carbon sequestration, this makes timber a viable solution to support a net-zero building industry.

However, CLT slabs are not optimal in their construction; the core material in a CLT slab does not contribute significantly to the member strength as it merely acts as a spacer between the extreme top and bottom fibres, which does most of the work [4]. Additionally, the cost of using timber in buildings is still seen as more expensive than designs utilising steel and concrete [2]. There are, therefore, numerous motivations for the efficient use of timber to ensure sustainability: to minimise fossil emissions during the construction stage, which are permanently released into the atmosphere; reduce cost; to ensure the sustainable use and distribution of a finite resource, which is under ever increasing demand.

New forests will be required for timber buildings to act as a carbon sink, which will threaten existing biodiversity and will increase competition for land. According to a comprehensive study by Mishra et al. [7] even if there is additional demand for timber in construction, the global

plantation area would need to expand by 100% by 2100 compared to 2020 with this figure increasing to 200% if 90% of all new urban dwellers were to live in timber buildings. Therefore, to ensure a sustainable supply of timber in the future will require a material first approach whereby existing timber designs are optimised for material efficiency based on the actual stress distribution within the member [8]. The challenge is to create flooring systems and design methods that balance low embodied carbon solutions with safety standards, while meeting the performance expectations.

1.2 COMPRESSION VAULTS: STRUCTURAL TIMBER INSPIRED BY NATURE

Unlike concrete and steel structures, timber beams are often governed by serviceability limit states (deflection or vibration) as opposed to strength, since their low mass-to-stiffness ratio results in thick floors and high material consumption. As a result of this, the low span-to-depth ratios required to satisfy serviceability requirements make it difficult to justify using timber beams for long spans.

Trees have evolved to be strong under combined compression and bending forces to support their own weight all while resisting the prevailing winds. This can be taken advantage of by developing vaulted floor systems that act primarily in compression and bending, with the geometric stiffness of the vault compensating for the low timber stiffness. The additional stiffness benefits of using vaults have been demonstrated by Hawkins et al. [9] in previous work on concrete **floors**, where increased structural efficiency resulted in significant reductions in embodied carbon, particularly for longer spans.

Curved timber structures are fabricated by bending initially straight lamellas to the specified curvature, before bonding them with adhesive to lock-in the curvature and enable composite action. Advances in laminating techniques and adhesives have enabled the creation of highly complex geometries, such as the Urbach Tower at the Remstal Gartenschau in Germany [10] and the work by Robeller et.al [11] on curved-folded thin shell CLT structures. During fabrication, high initial stresses can develop in curved timber structures, leading to overstressing under service loads if the lamellas are too thick [12]. However, the viscoelastic behaviour of wood causes the initial bending stresses to decrease over time, a process known as stress relaxation. As shown by Lara-Bocanegra et Al. [12], the initial bending stresses can decrease by 45% to 66% after two years, with the reduction largely depending on the initial curvature of the beam, moisture content and temperature.

1.3 AIMS AND OBJECTIVES

Considering the need for lower embodied carbon structures, this project aims to create a low carbon flooring system using the compression and bending strength properties of timber in combination with the stiffness benefits of vaults. The research compares the embodied carbon of conventional CLT floors with a timber barrel vault design and hypothesises that timber vaults will have the similar efficiency savings as concrete vaults, but with the advantage of simpler design and fabrication and lower embodied carbon. To equilibrate the compression forces in the vault, steel rods acting in tension are provided. This paper describes the preliminary feasibility investigation of using timber vaults as potential embodied carbon saving when compared with cross laminated timber floors.

2 METHODOLOGY

2.1 BASIC PARAMETERS

Two floor systems were adopted during the study with spans ranging from 4m to 12m. The first type of floor investigated in the study was a single span CLT floor designed to Eurocode 5 [13] and shown in Figure 1. The resultant embodied carbon calculated from the CLT floor was then compared to the proposed curved timber floor systems. An optimisation exercise using a genetic algorithm was carried out for the barrel vault flooring system, shown in Figure 2, which comprises of a single spanning parabolic arch supported on two glulam beams with steel ties to counter lateral thrust. Granular fill of earth, gravel or rubble provides a level top surface and is hypothesised to improve vibration and acoustic performance. The material used for all the timber elements was C24, with the properties adopted from EN 338:2016 [14] for sawn timber and EN 14080:2013 [15] for glue-laminated timber.

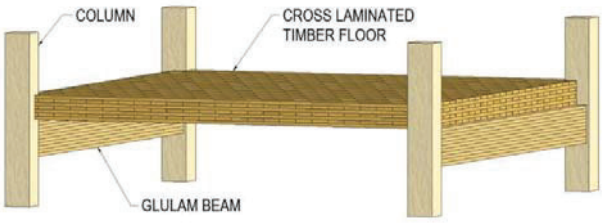

Figure 1: *Cross laminated timber floor*

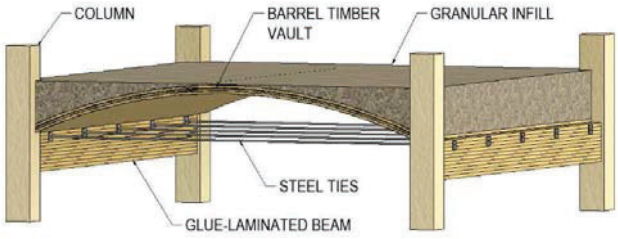

Figure 2: *Barrel vault timber floor*

2.2 DESIGN CRITERIA

Floor loadings were selected to represent a typical office design according to BS EN 1991-1-1 [16]. The design loadings included a live load of 3.5 kN/m^2 (2.5 kN/m^2 office loading and 1 kN/m^2 for movable partitions) and a superimposed dead load of 1 kN/m^2 with ULS partial load

https://doi.org/10.52202/069179-0452

factors of 1.5 and 1.35 respectively. The self-weight of the beams, arch and infill were included as permanent dead load with a ULS load factor of 1.35.

Deflections were calculated under serviceability limit state (SLS) under both short term and long-term loading in accordance with BS EN 1995-1-1 [13]. A limiting instantaneous deflection (ω_{inst}) of Span/300 and long-term deflection (ω_{fin}) of Span/250 was adopted in the designs. A partial load factor of 1 was used for both imposed and dead loads. To account for creep and moisture effects on deflection, a creep factor (k_{def}) of 0.6 was used under service class 1.

Two load patterns were considered, as shown in Figure 3. The first comprises a uniformly distributed imposed load over the full width of the floor to determine the maximum compression in the vault. The second load pattern consists of only applying the imposed load over half the floor to determine the maximum bending moment. The granular infill material was applied proportionally to the height of the vault.

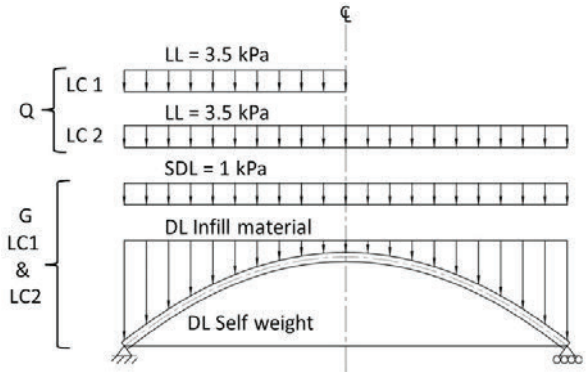

Figure 3: *Applied loading on the barrel-vault floor structure*

2.3 EMBODIED CARBON FACTORS

The focus of the study is limited to cradle-to-gate emissions (Modules A1-A3) and the embodied carbon and density values of the materials presented in **Table 1**. The carbon footprint of each floor design was calculated by summing the products of each material's quantity and its corresponding embodied carbon value.

The embodied carbon value for timber was sourced form an environmental product declaration (EPD 000124) [17] from a UK-based large timber merchant, which covers life cycle stages A1-A3, which includes tree felling, transport, processing, kiln drying, and finishing. The study assumed melamine-urea formaldehyde (MUF) resin, and its embodied carbon value was taken from Wilson [18] with a spread rate of 300 g/m^2 [19]. MUF resin was selected for the study based on consultations with glulam manufactures, as it is commonly used due to its cost-effectiveness and reliable performance [20], [21]. The embodied carbon value for the infill material was obtained from the Inventory of Carbon and Energy Circular Ecology [22].

Table 1: *Embodied carbon factors*

Material	Sawn timber (C24)	Adhesive (MUF)	Steel	Gravel infill
Density (kg/m^3)	420	-	7850	1835
Embodied carbon (kgCO_2e/kg)	115	1.775	1.55	0.00747

2.4 STRENGTH CAPACITY INCLUDING FABRICATION STRESSES

The design moment capacity, including fabrication stresses, shown in Figure 4, was calculated at each point along the length of the parabolic vault. The capacity was calculated at each point to avoid over conservatism, as the minimum fabrication stresses occur at the supports and the maximum occur at the centre of the vault. Equation 1 defines the height, u, of a parabolic vault with maximum height (h) and span (L). Utilising Equation 1 and its first and second derivatives, the curvature (K) and radius of curvature (R) at each point along the vault can be determined from Equation 2. Equation 3 determines the initial fabrication stresses at each point along the length of the beam using the Young's modulus of timber (E) and the moment of inertia of the lamella (I).

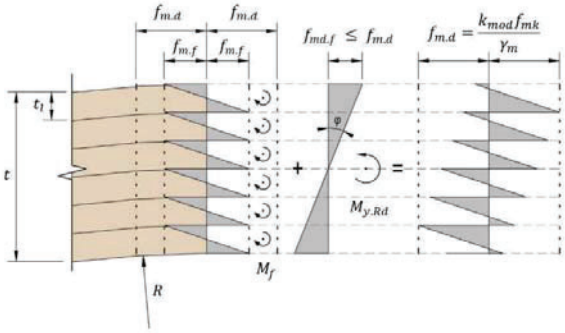

Figure 4: *Design load capacity in bending including fabrication and in-service stresses*

Stress relaxation was considered by reducing the initial fabrication stresses by 20%, which accounts for 1 week of relaxation, as adopted from Lara-Bocanegra [12]. The moment capacity of the section, Equation 4, was determined by limiting the maximum bending stress in the section to the design stress ($f_{md.f}$) as shown in **Figure 4**.

$$u = 4h\left(\frac{x}{L} - \left(\frac{x}{L}\right)^2\right) \quad (1)$$

$$K = \frac{1}{R} = \frac{|u''|}{[1 + (u')^2]^{\frac{3}{2}}} \quad (2)$$

$$f_{m.f} = \frac{KEI}{z_l} \quad (3)$$

https://doi.org/10.52202/069179-0452

The maximum additional stress capacity ($f_{md.f}$) was calculated by varying the curvature (φ) until the maximum design stress (f_{md}) within the timber was achieved. The maximum stress in the section occurs at the interface between the top and bottom lamellas and governs the moment capacity of the section. The utilisation of the section was calculated using Equation 5 using the calculated axial force ($N_{C.0.ED}$) and moment ($M_{0.ED}$) with the respective axial capacity ($N_{c.0.RD}$) and moment capacity ($M_{0.RD}$). The axial capacity incorporates the effect of buckling by including an instability factor (k_c).

$$M_{0.RD} = f_{md.f} Z_{xx} \tag{4}$$

$$\frac{N_{C.0.ED}}{k_c N_{c.0.RD}} + \frac{M_{0.ED}}{M_{0.RD}} \leq 1 \tag{5}$$

2.5 PARAMETRIC DESIGN OPTIMISATION OF THE BARREL VAULT

Optimisation studies date back over 50 years with genetic algorithms (GAs) being widely used and recognised in the optimisation of steel and concrete structures [23]. The optimisation study used in this paper comprises of a number of continuous and discrete variables, and the GA has proven to be a powerful tool when multiple interacting variables are used [24].

A two-dimensional parametric optimisation of the CLT floor and barrel vault in terms of embodied carbon was undertaken using a script written in MATLAB [25]. The vault design was optimised by considering the arch height, lamella thickness and steel rod diameter as continuous variables. The number of lamellas used in the parabolic arch and glulam beams was set as a discrete variable. The vault was discretised into a series of beams and nodes and analysed using matrix stiffness methods.

The genetic algorithm function in MATLAB [25] was used to find the optimal design as it is well-suited to handle both discrete and continuous variables by incorporating a penalty term into the objective function [26]. This penalty term transforms the constrained optimisation problem into an unconstrained one. During the optimisation process, the penalty function effectively penalises individuals in the population that violate the constraints more severely, guiding the search towards feasible solutions [27]. Figure 6 shows the optimisation process that was used for the vaults. The optimisation exercise evaluated a range of lamella thickness, steel rod diameters and arch heights for spans ranging from 4m to 12m.

The optimisation exercise is split into two branches. The first branch entails using the defined geometry for a specific set of input parameters to calculate the volumes and mass of the of each of the floor materials. The resultant mass of material is then multiplied by an embodied carbon factor and summed together to obtain the overall embodied carbon of the system. The second branch of the analyses performs a structural analysis of the system with the applied loading.

The capacity of the section, utilising the input geometry, is calculated, and used to determine the utilisation factors for each of the ultimate and serviceability limit states. With the increase in curvature of the beam there is a concomitant increase in fabrication stresses and therefore, to mitigate these stresses, the lamellas thickness needs to reduce. However, the fabrication of glue-laminated vault requires material to be planed off each of the faces of the lamellas to achieve a smooth surface to ensure adequate bonding between the layers. Conversations with glulam manufactures indicate that approximately 5mm of timber is planed off the top and bottom of the lamellas and 10mm is planed off each side irrespective of lamella thickness as shown in Figure 5. The tighter the radius of the lamellas, the thinner the lamellas need to be, and more material wastage occurs due to planing. This wastage has been included in the optimisation exercise.

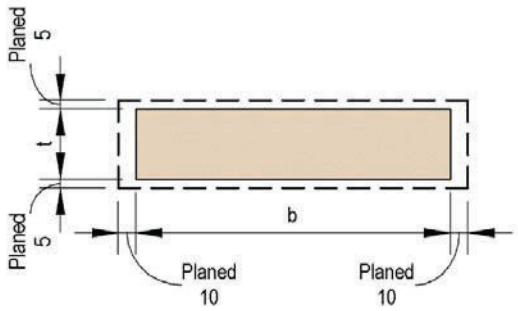

Figure 5: *Material wastage due to planing*

2.6 DESIGN OPTIMISATION OF THE CLT FLOOR

The cross laminated timber (CLT) floor system (Figure 1), was designed according to Eurocode 5 [13] and rests on two glulam beams. The equivalent stiffness was calculated using the gamma method to account for the orthogonal timber layers. The floor thickness was optimised by considering the lamellas thickness and number of lamellas.

The one-way spanning system was designed to meet both the ultimate limit states and serviceability limit states described in Section 2.1. Two CLT floor designs were considered; one that only met the deflection limits and another that satisfied both the deflection and vibration limits, to assess the impact of vibration in longer span designs. The vibration design of the CLT floor limited the natural frequency to 8Hz and satisfied the requirements of Eurocode 5 [13]. The embodied carbon calculation does not include fixings, columns, insulation, and other non-structural elements.

https://doi.org/10.52202/069179-0452

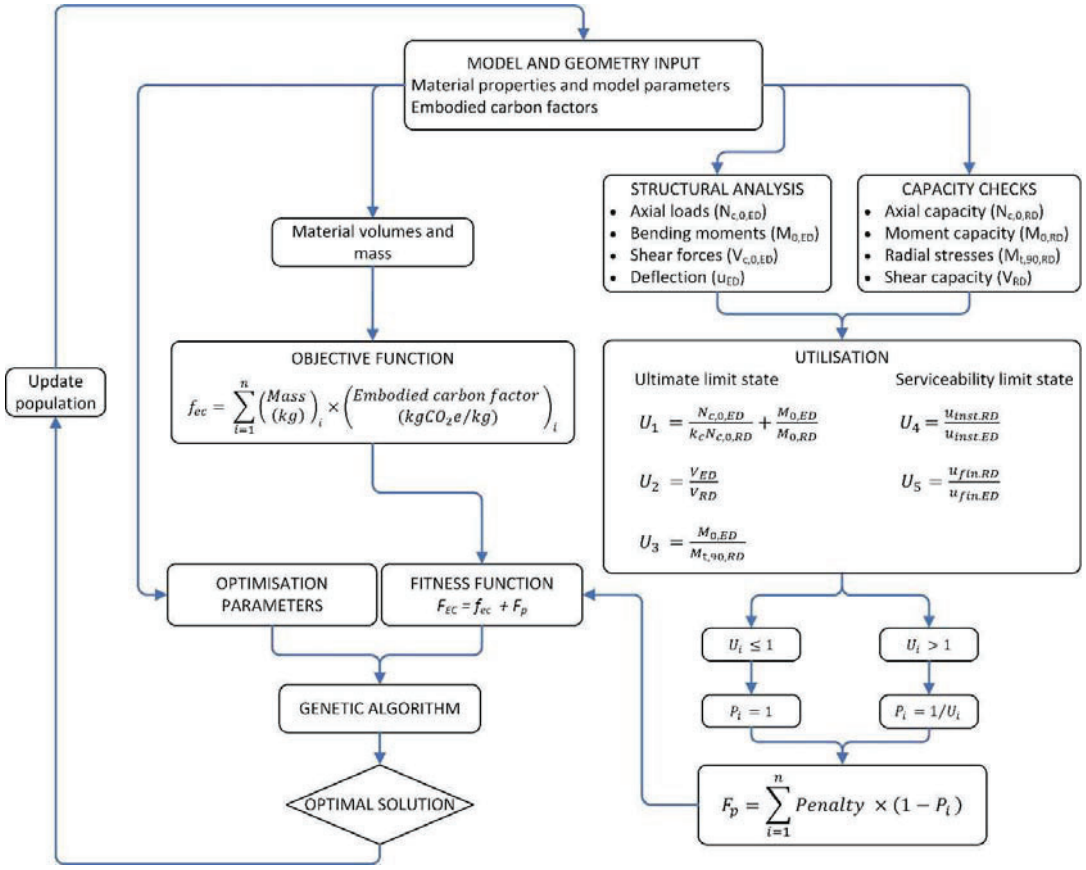

Figure 6: *Constrained optimisation process using Genetic Algorithms*

3 RESULTS AND DISCUSSION

The optimal embodied carbon solution for the vault system depends on the interplay between the arch height, rod diameter, number, and thickness of the lamellas. Figure 8 to Figure 10 shows the embodied carbon for an 8m span barrel vault compared to a CLT design, with and without vibration design. The optimal solution is indicated in the figures. The plots distinguish the embodied carbon contribution per square metre of the primary glulam beams, parabolic barrel vault, gravel infill and steel.

Embodied carbon with fixed arch height

The first investigation determined the impact of arch height on embodied carbon, with the results shown in Figure 8. The optimal arch height has a direct impact on the overall building height and solution feasibility. Using Section 2.5, the variables shown in Figure 8 were optimised for an 8m span and the lamella thickness of the primary glulam beams were fixed at 40mm to minimise material wastage. The CLT floor's embodied carbon, with and without vibration design, is also presented to show the magnitude of embodied carbon savings over the range of vault heights. The lowest carbon design occurs at a height of 0.6m (Span-to-height of 13). Near the optimal solution, there is minimal variation in embodied carbon. For instance, decreasing the arch height to 0.5m results in only a 2.45% increase in embodied carbon.

Embodied carbon savings decrease with increasing arch height, due to material wastage resulting from larger curvature causing higher fabrication stresses, which necessitates thinner lamellas.

For low arch heights, the steel rod diameter must increase significantly to control the horizontal thrust forces and ensure the design is compression governed over bending. Arch heights below 0.26m for the 8m span floor system produces higher embodied carbon than the CLT floor due to need for a large steel rod diameter required to restrain the horizontal thrust force produced by the shallow vault.

Embodied carbon fixed diameter of the steel rod

The second analysis examined the impact of rod diameter on embodied carbon, with the results presented in Figure 9. For an 8m span, when the steel rod diameter is less than 12mm, the system shifts from being compression governed to bending as the steel rod's utilisation is exceeded. At rod diameters exceeding 12mm, the steel rod has sufficient capacity to enable a compression governed vault system to form. Also, with rod diameters exceeding 12mm, the strength utilisation of the steel rod decreases and only the stiffness affects the optimal solution. This shift to a compression system results in a 150mm decrease in vault thickness, as shown in Figure 7(b), and a corresponding reduction in embodied carbon.

https://doi.org/10.52202/069179-0452

Figure 7(a) shows that the optimal solution is achieved at the minimum diameter of the steel rod (greater than 12mm) that results in negligible fabrication stresses. Rod diameters between 12mm and 21mm require vault heights that result in high lamella curvatures, leading to residual fabrication stresses that reduce the bending capacity of the section.

For rod diameters greater than the optimal diameter of 21mm, the vault thickness remains relatively constant with only a minimal variation of 1.7 $kgCO_2e/m^2$ between a rod diameter of 21mm and 70mm. This indicates that increasing the rod diameter beyond 21mm has little effect on the embodied carbon of the vault, which is also seen in Figure 9.

Strength vs Deflection

During this analysis, the optimal solution produced by optimising for strength alone (Combined bending and compression with buckling), and deflection alone, is compared with the optimal solution found by considering both strength and deflection design requirements. The results are shown in Table 2.

Strength and deflection have competing objectives to minimise embodied carbon: strength aims for a solution with low arch height, and large number of lamellas to minimise fabrication stress, while deflection seeks a high arch height to maximise the beneficial properties of the geometric stiffness of the vault but still considers the weight of the fill material. The deflection only optimal solution considers both live load distributions (full live load and half the live load). Additionally, the deflection only solution also aims for a solution with the minimum number of lamellas that results in the lowest possible waste. Therefore, in this problem, the solution tends to the maximum lamella thickness.

To satisfy both strength and deflection requirements, the optimisation compromises between the two solutions. The height of the arch is predominately governed by deflection, while the number of lamellas is determined by the fabrication stresses. The increase in arch height from the strength optimal solution causes the lamella to become thinner resulting in additional material wastage. The optimal solution based solely on the deflection only criteria results in the lowest embodied carbon solution at the optimal rod diameter, due to there being no fabrication stress constraints. The quantity of embodied carbon is then followed by the strength only solution.

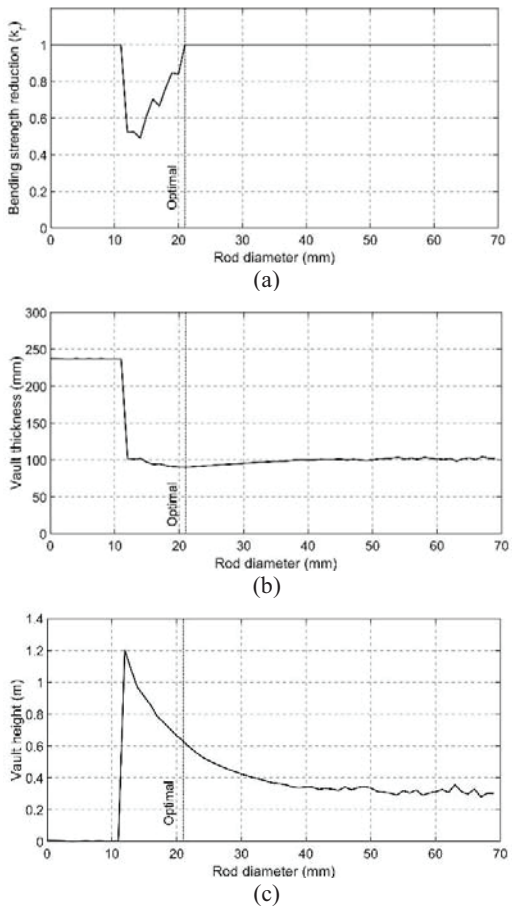

Figure 7: *Results for an 8m span parabolic vault showing, (a) The vault thickness with increasing rod diameter, (b) Vault height, (c) Bending strength reduction*

However, meeting both criteria results in a higher embodied carbon due to the increase in arch height from the strength only optimal solution and number of lamellas from the deflection only optimal solution.

Embodied carbon fixed lamella thickness

Figure 10 presents the results of the optimisation analysis by fixing the lamella thickness and limiting it to between 2mm and 40mm. The analysis indicated that the optimal number of lamellas is 3 with an optimal lamella thickness of 30mm for an 8m span.

Table 2: *Parabolic vault optimisation results for an 8m span barrel vault at the optimal rod diameter*

Optimisation constraint	**Arch height (m)**	**Lamellas (no.)**	**Lamella thickness (t) (mm)**	**Embodied carbon ($kgCO_2e/m^2$)**	**Utilisation**		
					Strength (incl. buckling)	Instantaneous deflection (ω_{inst})	Long term deflection (ω_{fin})
Strength	0.38	3	33	35.19	1	1.93	2.18
Strength + Deflection	0.56	3	30	36.84	1	0.9	1
Deflection	0.60	1	78	29.10	>> 1[1]	0.9	1

1) Fabrication stresses utilises most of the section's capacity

https://doi.org/10.52202/069179-0452

lamellas results in a sudden drop in the embodied carbon due to a reduction in fabrication material wastage. The choice of lamella thickness and number of lamellas is shown to not influence the embodied carbon in the primary beams.

Embodied carbon with increasing span

The analysis was repeated for spans between 4m and 12m with the results presented in Figure 11. Utilising the barrel vault floor system results in a reduction in embodied carbon between 35% and 41%, compared to the equivalent CLT floor when only considering strength design, buckling and deflection. However, at spans exceeding 5m, vibration governs the design of the CLT floor, and therefore it is likely that the barrel vaults will need to be checked and designed for vibration as well. It is worth noting that the diameter of the steel rod is determined by its stiffness rather than its strength. The strength utilisation of the steel rod in all the spans was around 50%, thus using higher strength steel is unnecessary.

Design considerations

The analysis showed that incorporating curvature in the floor design saves embodied carbon when compared to a traditional CLT floor design. However, there are several aspects that have not been considered that could make the floor system more inefficient, which include:

- Vibration. However, adding granular fill to the system is likely to enhance its damping properties and, when combined with the geometric stiffness of the vault, may prove more advantageous than a CLT floor system when vibration dominates the design at long spans.
- Fire design was not considered in the analysis and could result in additional embodied carbon in the design of the vault structure with the addition of a charring layer or other fire-resistant systems. This would also be necessary for the CLT system.
- The fabrication of curved timber members presents several challenges that may impact the feasibility of the floor solution. The production costs of curved timber members may be higher, as the process will be more labour intensive and require more resources compared to CLT floor fabrication. Additional design and fabrication of the connection between the steel rod and the timber beam is required, and the addition of fill entails an additional construction activity on site, which could increase construction time.
- Overall height of the optimal vaulted floor system is typically higher than the equivalent CLT floor and this may impose a constraint on the overall building design.
- Self-weight bending of the steel tie rod has not been considered which may lead to a reduction in geometric stiffness of the tie and therefore the floor as a whole.

However, several aspects which may improve efficiency have also not been considered in this preliminary investigation, including the following:

- Utilising double curvature in the form of groin vaults could eliminate the need for primary beams and provide a more efficient solution. This was demonstrated with concrete groin vaults in the research undertaken by Hawkins et al. [9].
- The addition of prestress. As shown in [28], the addition of prestress reduces the maximum vertical displacement.
- Optimising the form of the vault to reduce the bending moments caused by the gravel infill.

4 CONCLUSIONS

This paper investigates the potential of using timber barrel vaults as a low carbon alternative to CLT floors, by shifting the primary load resistance from bending to compression. A curved timber barrel vault system with granular infill is proposed, using glued, curved lamellas spanning between straight glulam beams, which span between columns. The horizontal forces generated by the vault is restrained by steel ties. An optimisation exercise using a genetic algorithm with a penalty function was performed, using both discrete and continuous parameters, to evaluate the performance of the system. Finally, the proposed system was compared to a CLT floor for a typical office design with spans between 4 to 12m. The key conclusions of the investigation are as follows:

- Compared with an equivalent CLT floor, the proposed barrel vault system provides a significant embodied carbon saving of between 35% and 41% across the analysed spans.
- The optimal design of the proposed timber vault solution is achieved when both strength and deflection utilisations are equal to one, which occurs at an optimal span-to-height ratio between 13 – 14.
- The arch height is predominantly governed by the deflection criteria with the number of lamellas determined by the fabrication stress.
- The optimal solution is dependent on the balance between the arch height, rod diameter and fabrication stresses. The optimal solution occurs at a maximum arch height that results in no stress reduction due to fabrication stresses, which is balanced by a steel rod with sufficient stiffness.
- The restraint by the tie at the optimal solution is dependent primarily on the stiffness of the material.

This paper shows that introducing curvature into timber floors provides a feasible and efficient solution to lowering embodied carbon. The process followed during the research shows a method that structural engineers can implement to optimise the reduction of their embodied carbon in buildings.

5 FUTURE WORK

To potentially achieve greater savings, the glulam primary beams can be removed by replacing the barrel vault with a doubly curved groin vault system, especially for longer spans. The next step is to analyse groin vaults and optimise their design by including vibration, acoustic performance, and fire design. This includes the form of the vault, the ease of fabrication, connection details, and coordination with building services to develop a cost-efficient solution. The study will also investigate the type and quantity of infill material that is needed to meet vibration and acoustic requirements while reducing the dead load. Furthermore, the potential of vaulted floor systems will be explored by comparing them with other efficient timber flooring systems that are currently on the market.

SEGMENTED COMPOSITE SECTIONS WITH WOOD DOWELS

Matthias Brieden[1]; Max Braun[2], Werner Seim[3]; Kristina Schramm[4], Philipp Eversmann[5]

ABSTRACT: Recent research approaches try to expand the scope of application of timber construction elements. Possibilities to reduce the material consumption and raise the automatization level are also gaining interest to an increasing degree. Segmented sections with wood connectors are predestined for this challenge because of their modular character. Analytical, numerical and experimental investigations are conducted to assess the effects of different geometrical and material parameters. The results provide a strong basis to understand and improve the effectiveness of these sections.

KEYWORDS: segmented sections, elastic composite, modular engineering, robotic fabrication, wood dowels

1 INTRODUCTION

Questions of the consumption of resources, efficient material usage, recyclability and sustainability at large are gaining significant importance within the construction sector. In addition, experts and the public are focusing increasingly on aspects of automatization, modular production and robotic fabrication. Accordingly, civil engineering in general and timber engineering in particular should also take these topics into account. [1]
A current research project at the University of Kassel is being carried out by the Chair for Timber Structures and Building Rehabilitation together with the Chair of Experimental and Digital Design and Construction. The project includes both numerical studies about the effective use of material and experimental studies to develop new types of connections with wood dowels.
The overall objective of this optimization process is to develop new types of slab and wall elements by using beam sections of limited length, which should be taken from reused or recycled materials as far as possible, and addresses all those aspects. Timber engineering can provide here an important contribution to the urgent questions of sustainability and resource consumption. [2]

2 GENERAL SET-UP

The research activities deal with segmented box-type elements. The section is symmetric and composed of two oriented strand board (OSB) panels, forming the upper and the lower layer of the element, and the web beam section, for which structural timber (KVH) C24 is used. Due to the "second-usage approach" of the project, other timber products and different strength classes may also be considered in the future. The connection between the upper and lower OSB panels and the web section is realised by wood dowels. These fasteners can be arranged in several set-ups, including various distances or angles. The general set-up can be seen in Figure 1.

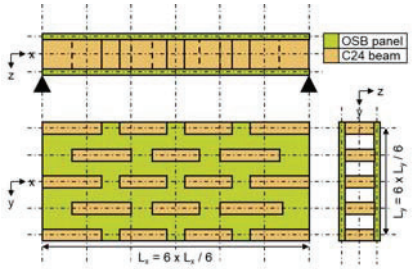

Figure 1: *General set-up*

3 METHODICAL APPROACH AND MODEL DEVELOPMENT

3.1 GENERAL

Both numerical and experimental investigations are part of the research. Whereas the numerical calculations provide the possibility of determining the influences of a huge number of different parameters systematically (e.g. geometry, material combinations, fasteners), the experimental testing should help to validate and calibrate the numerical models.
Analytical methods for composite sections can be found in EC 5 [3]. Several comparative studies with the analytical calculations are performed to check and verify the basic numerical approach. The pros and cons of different types of modelling can be found and assessed by varying the level of composite elasticity (between no and rigid composite). Finally, a numerical model has been developed and validated.

3.2 SET-UP AND PARAMETERS

As a first step, a construction element with a segmented beam was investigated (Figure 2).

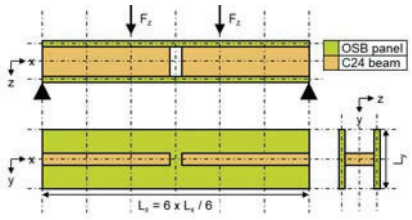

Figure 2: *Set-up for first step*

The materials considered are OSB panels and C24 beams; wood dowels at variable distances and slip moduli are applied for the fasteners. Dimensions and properties are listed in Table 1. The gap length is 2.0 cm.

Table 1: *Geometrical and material parameters*

		OSB	C24
Width	$L_y=b_y$	360 mm	60 mm
Height	$L_z=h_z$	24 mm	200 mm
Moe	$E_{0,mean}$	198 kN/cm^2	1,100 kN/cm^2
Density	ρ_{mean}	600 kg/m^3	420 kg/m^3

The wood dowels have a length of ℓ_{td} = 10.0 cm and a diameter of d_{td} = 1.0 cm; the distance between these fasteners is set to e = 2.0 cm. The static system is a single-span beam with a length of L_x = 2.0 m. The beam is loaded with two vertical forces of F_z = 10 kN. This arrangement represents a four-point bending set-up.

3.3 SELECTED RESULTS AND DISCUSSION

The deformation curve was determined numerically for each variation of the set-up. The results are shown in Figure 3 exemplary for K = 15.00 kN/cm. The curve for a non-segmented element is included as a reference. The other curves represent the three parts of the cross-section.

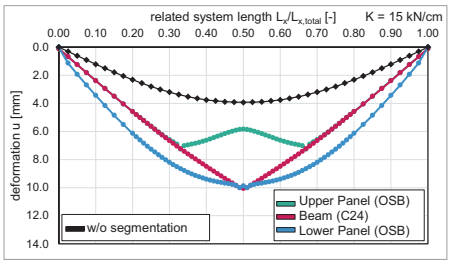

Figure 3: *Selected results*

The points where the load was applied ($L_x/L_{x,total}$ = 0.33; $L_x/L_{x,total}$ = 0.67) can easily be identified because of the contact between the upper panel and the beam. The upper panel separates itself from the beam between these points; the transmission of tensile forces through the dowels was deactivated for this numerical calculation. The deformation curve of the beam – actually, due to the gap, there are two beams – is linear, but it shows a discontinuity at midspan. This discontinuity is caused by the segmentation which is located here. Regarding the lower panel, it can be seen that the curve is not linear. The beam and the lower panel do not act as a composite cross-section because of the deactivated tensile forces. The ends of both beams push against the lower panel at midspan, which initiates the detachment of the lower panel.

Table 2: *Deformation in midspan*

		deformation u	
		absolute	related
Reference		3.938 mm	100 %
Upper panel	*OSB*	5.834 mm	145 %
Beam	*C24*	10.059 mm	255 %
Lower panel	*OSB*	9.869 mm	251 %

The segmentation leads to deformations that are more than 2.5-times higher in relation to the reference curve. The numerical results in midspan can be found in Table 2.

3.4 FURTHER EVALUATIONS AND PARAMETRIC STUDY

In addition to the investigation of construction elements on a macro level, single components were also evaluated on a micro level, for example, the behaviour and load factor of the dowels. As part of this, the optimization of the arrangement of these components was conducted. Effects of inclined dowels, which are about to transfer tension forces, were considered.

The results of these experimental tests and more detailed information are published by Brieden et al. [4]. Against this background, the slip moduli of the different configurations of fasteners was selected for the further investigations.

Investigations into modified set-ups were conducted; in particular, the impact of multisegmented web beams was evaluated. Other types of constructions will be considered to grasp effects such as the warping of the upper layer,.

The approach described previously was transferred to the general set-up. Thus, the opportunity to evaluate different combinations and variations of segmented sections with elastic composite is enabled. The influence of missing web segments at different locations will be determined to outline different effects – such as the rearrangement of the load transfer from web to covering layer – within this step.

4 DESIGN OF TEST SPECIMENS

4.1 GENERAL

Three major layouts are considered to assess the influence of the different configurations.

The arrangement of the fasteners – total number, properties, inclination, distance, *inter alia* – are constant for all layouts. The loads applied are also constant.

https://doi.org/10.52202/069179-0453

4.2 DESIGN PARAMETERS

4.2.1 Geometry and elements

Each layout consists of two OSB panels and five C24 beams; the dimensions can be found in Table 3. The beams are arranged in five axes, all identical.

Table 3: *Dimensions of components*

		dimension [mm]		
		length L_x	width L_y	height L_z
Upper panel	*OSB*	4,600	1,250	25
Beams x)	*C24*	4,600	60	200
Lower panel	*OSB*	4,600	1,250	25

x) L_x for refence variation; otherwise segmented

As described in the previous sections, wood dowels are used to realise the connection between the different elements. The wood dowels have a length of ℓ_{td} = 10.0 cm and a diameter of d_{td} = 1.0 cm.

Table 4: *Slip moduli of fasteners*

	slip modulus K [kN/cm]	
	compression	shear
Perpendicular dowel (1 dowel)	1.25	9.00
Inclined dowel (2 dowels)	5.00	12.50

The slip moduli of the wood dowels depend upon the arrangement (perpendicular or inclined) and the particular direction (tension or shear), see Table 4.

Table 5: *Distance between fasteners*

		distance e [mm]	
		Axes I / III / V	Axes II / IV
Frist segment	X	50	50
	O	3×100|2×150|3×100	4×125
	X	125	125
	total	9 fasteners	5 fasteners
Second segment	X	125	125
	O	4×125	4×125
	X	125	125
	total	5 fasteners	5 fasteners
Third segment	X	125	125
	O	4×125	4×125|3×100|4×125
	X	125	125
	total	5 fasteners	12 fasteners
Fourth segment	X	125	125
	O	4×125	4×125
	X	125	125
	total	5 fasteners	5 fasteners
Fifth segment	X	50	50
	O	3×100|2×150|3×100	4×125
	X	50	50
	total	9 fasteners	5 fasteners

The total number of fasteners for each variation is 326, of which 100 are inclined. The position of the inclined fasteners results from the specimen's layout; they are located at the beginning and end of each single segmented beam and inclined by α = 15°. The detailed distribution can be found in Figure 4 and Table 5.

The distances between the particular dowels varies between e = 5.0 and 12.5 cm and can be found in Table 5. The inclined fasteners here are labelled "X", while the perpendicular ones are named "O". Moreover, the number of fasteners for the particular segment is listed.

More information concerning the wood dowels can be found in Brieden et al. [4].

4.2.2 Loads and load cases

A total of g_k = 1.0 kN/m² is considered for the self-weight of the elements. Furthermore, an additional self-weight, for example, floor construction because of vibrations, thermal or acoustic aspects, of Δg_k = 2.0 kN/m² is taken into account. Regarding the live load, p_k = 2.0 kN/m² is considered.

Two load cases are evaluated. A total load of $q_d^{ULS} = 1.35 \cdot (1.0 + 2.0) + 1.50 \cdot 2.0 = 7.0$ kN/m² is applied for the evaluation of the ultimate limit state, whereas the total load in the serviceable limit state is $q_d^{SLS} = 1.0 \cdot (1.0 + 2.0) + 1.0 \cdot 2.0 = 5.0$ kN/m².

Table 6: *Loads and load cases*

		load [kN/m²]	
		USL	SLS
Self-weight	g	1.35	1.00
Add. self-load	Δg	2.70	2.00
Live load	p	3.00	2.00
Total	q_d	7.00	5.00

Table 6 summarises the loads and load cases.

4.3 REFERENCE ELEMENT

A construction with two OSB panels and five C24 beams is considered for the reference element. An overview of this variation is presented in Figure 4.

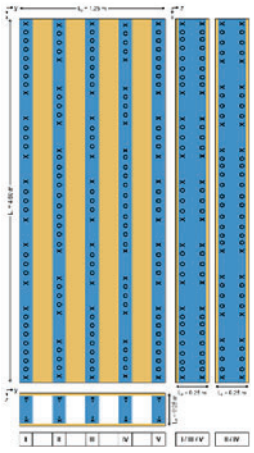

Figure 4: *Reference specimen*

The inclined fasteners in the figures are illustrated as "X" while the perpendicular ones are marked as "O".

The length of the beams is identical for all five axes – L_x = 4.60 m.

https://doi.org/10.52202/069179-0453

4.4 GAP SEGMENTED ELEMENT

The gap segmented element consists of two OSB panels and five segmented C24 beams. An overview of this variation is presented in Figure 5. A pair of inclined fasteners are applied ("X") at the beginning and end of each particular beam. The other (inner) fasteners are arranged perpendicular to the board surface ("O"). The gap between the single segments has a width of 5 cm.

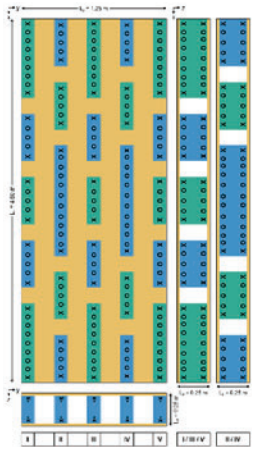

Figure 5: *Gap segmented specimen*

4.5 NOTCHED SEGMENTED ELEMENT

Furthermore, an element with two OSB panels and five notched segmented C24 beams is considered. An overview of this variation is shown in Figure 6. It is already known that a pair of inclined fasteners are applied ("X") at the beginning and end of each particular beam. The other (inner) fasteners are arranged perpendicular to the board surface ("O").

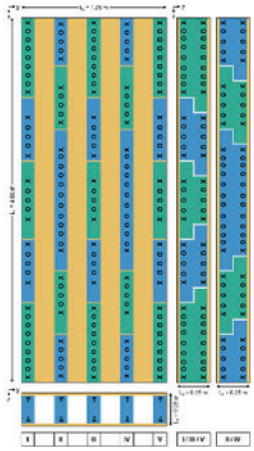

Figure 6: *Notched segmented specimen*

The gap between the single segments has a width of 5 cm, while the length of the notch is 10 cm.

5 NUMERICAL MODELLING

5.1 GENERAL

A numerical model of each variation was created for the investigations. The software RFEM 6 was used [6].
The OSB panels and the C24 beams were modelled as four node shell elements, whereas beam elements were used for the fasteners. An element size of 5.0 cm was chosen for the quadratic elements.

5.2 MODELS

5.2.1 Reference

Figure 7 shows the numerical model of the reference element without the upper panel for a clearer illustration. The support can be seen in addition to the five beams and the lower panel. The support was modelled with steel plates and should help to reduce local stress peaks.

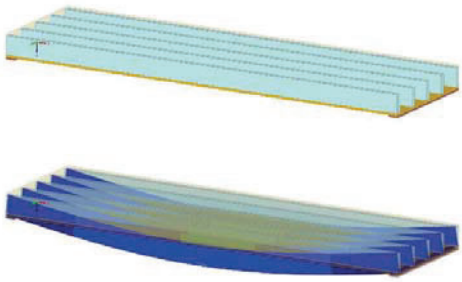

Figure 7: *Reference – model and deformations*

The second part of the figure shows the deformed model for the serviceable limit state (SLS).

5.2.2 Gap segmented

The model of the gap segmented variation is shown in Figure 8 in the same way as described previously. Here, the gaps within the five beams can be seen very well.

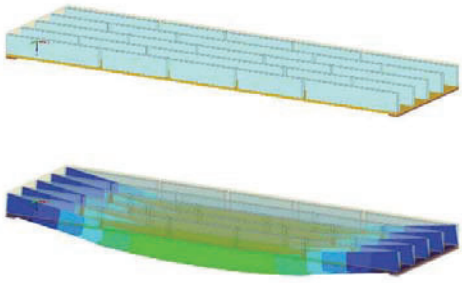

Figure 8: *Gap segmented – model and deformations*

The deformation can also be found in the figure. The relative deformation between the lower panel and the beams can also be seen for the outer edges. As the colours indicate, the deformation is higher for this variation.

5.2.3 Notched segmented

Finally, the numerical model for the notched segmented variation can be found in Figure 9. The notches are also depicted.

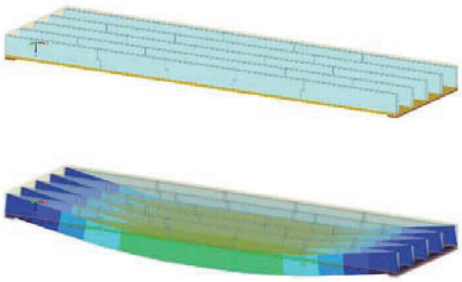

Figure 9 *Notched segmented – model and deformations*

An illustration of the deformed element for the SLS is shown in the second part of the figure.

5.3 RESULTS

5.3.1 General

As mentioned in section 4.2.2, two cases are considered. For the first one – the ultimate limit state – the stresses occurring (bending stress, shear stress and connection force) for the different components of each element are determined and compared. Exemplary, the bending stress in midspan and the connection force are presented in the following. In order to investigate the SLS performance, the deformations of the panels are considered and discussed later on.

5.3.2 Ultimate limit state

Cross-section

The distribution of axial stresses at midspan (L_x = 2.30 m) is illustrated in Figure 10 to Figure 12. The diagrams show the stress as a function of the element height L_z. The different colours of the lines represent the particular axes as labelled in Figure 4 to Figure 6; the axes indicate the position in the y-direction (Axis I: L_y = - 0.625 m to Axis V: L_y = + 0.625 m).

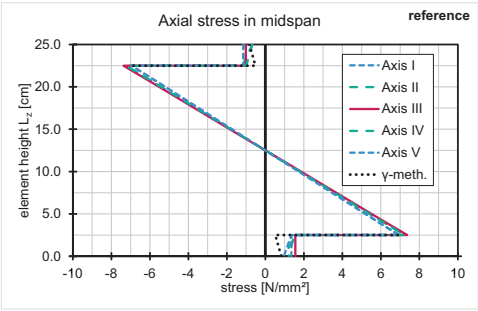

Figure 10: *Ultimate limit state (ULS) – reference – bending stress in midspan*

The different parts of the cross-section, i.e. upper panel, beam, lower panel, can be identified by their dimensions and orientations. The lower panel is located at the bottom of the diagrams (L_z = 0.0 … 2.5 cm); the upper panel can be found at the top of the diagrams (L_z = 22.5 … 25.0 cm); the results for the beams can be seen in between (L_z = 2.5 … 22.5 cm).

In addition, the corresponding bending stresses, which have been determined analytically with "Gamma Method" according to EC 5 [3], are shown for the reference model in Figure 10.

As the diagram illustrates, the stress at the different axes for the reference model only differ very slightly. The maximal stress comes up to $\sigma_{max}^{panel} \approx 1.3$ N/mm² for the panels, and $\sigma_{max}^{beam} \approx 7.4$ N/mm² at the joints (L_z = 2.5 and 22.5 cm) between the panels and the beams for the beams.

Concerning the comparison with the analytical results, some deviations can be found. Regarding the panels, for example, the values do not fit completely. These differences might be caused by the assumptions and simplification that are necessary for the analytical calculation – for example, a homogeneous fastener distance of e = 12.5 cm has been assumed for the "Gamma Method" in contrast to the distances applied for the numerical investigation (see Table 5).

Nonetheless, the agreement between the analytical and the numerical results is obviously good.

Figure 11 shows the stresses occurring for the gap segmented variation. Compared to the reference variation, the stresses in midspan for the beams are significantly lower, while it is vice versa for the panels. This is because of the different load transmission caused by the segmentations of the beams. Considering the illustration in Figure 5, it can be seen that the beam segments in axis I, III and V in midspan are shorter than the ones in axis II and IV. This leads to a higher stress in the latter beam segments, see the green lines in Figure 11. Due to the segmentation of the beams, a load shifting from the beams to the panels occurs.

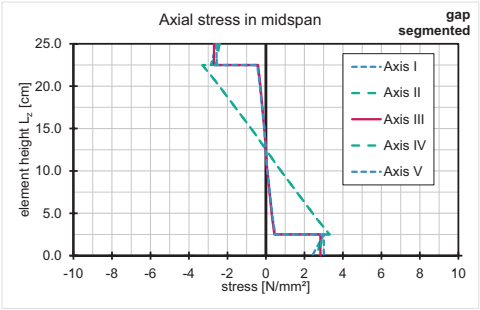

Figure 11: *ULS – gap segmented – bending stress in midspan*

The values of the maximal stress come up to $\sigma_{max}^{panel} \approx 3.0$ N/mm² for the panels, and $\sigma_{max}^{beam} \approx 3.5$ N/mm² at the joints (L_z = 2.5 and 22.5 cm) between the panels and the beams for the beams.

Figure 12 illustrates the axial stresses in midspan for variation notched segmented sections. Again, the load shifting effects can be seen. In comparison with the gap segmented variation, the stress in the panels reduces, whereas for the beams, it increases. Concerning these results, the influence of the notched segmented sections can be seen. The notching of the beams creates a different load transmission.

https://doi.org/10.52202/069179-0453

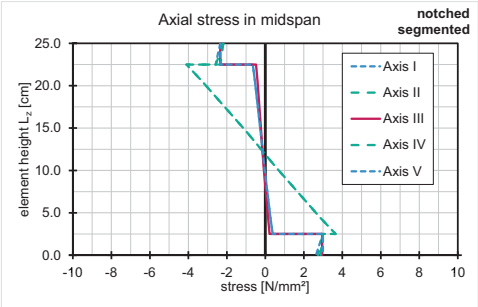

Figure 12: *ULS – notched segmented – bending stress in midspan*

The values of the maximal stress come up to $\sigma_{max}^{panel} \approx 2.5$ N/mm² for the panels, and $\sigma_{max}^{beam} \approx 4.1$ N/mm² at the joints ($L_z = 2.5$ and 22.5 cm) between the panels and the beams for the beams.

Fasteners

In order to evaluate the performance of the fasteners, in spite of considering each single dowel, the total number and the corresponding load was investigated.

These results can be found in Figure 13, which shows the load – here, the normal force – of the fasteners grouped for each variation.

Concerning the results, a distinction between fasteners with tensile force and those with compression force is necessary. As the diagram shows, the maximal tensile force is lower than $F_t = 0.7$ kN, while the compression force goes down to $F_c = -3.0$ kN. This means that the relation of the maximal tensile to the maximal compression load is about one to four.

	reference	gap segmented	notched segmented
0.7 kN … 0.5 kN	0%	4%	0%
0.5 kN … 0.3 kN	0%	5%	2%
0.3 kN … 0.1 kN	2%	19%	4%
0.1 kN … 0.0 kN	24%	27%	39%
0.0 kN … -1.0 kN	66%	41%	50%
-1.0 kN … -2.0 kN	10%	6%	7%
-2.0 kN … -3.0 kN	0%	2%	0%

Figure 13: *ULS – fasteners – normal force*

About a quarter of the fasteners are tensile loaded for the reference variation. Although only 45 % and 55 % of the gap and the notched segmented variation, respectively, are under compression, the majority of the tensile loaded fasteners – 46 % and 43 %, respectively – are loaded with less than $F_t = 0.3$ kN.

The main part of the fasteners for all three variations was loaded with $F_c = 0.0 \ldots -1.0$ kN.

5.3.3 Serviceability limit state

Panels

The results of the investigation of the SLS – here, the total deformation of the panels – are presented as surfaces in Figure 14 to Figure 16.

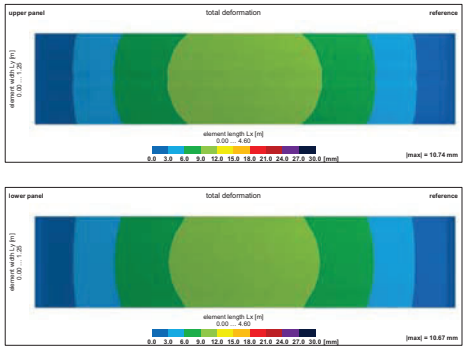

Figure 14: *SLS – reference – panels – total bending deformation*

The diagrams show the deformation of the upper and the lower panel as well as the maximal value. As expected, the difference between both panels is not significant.

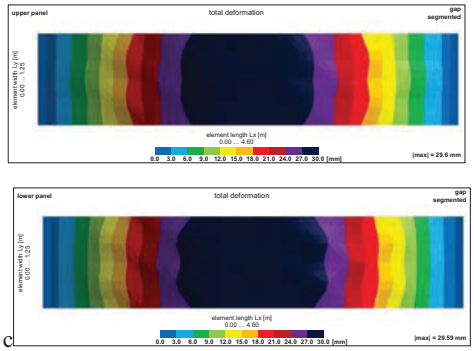

Figure 15: *SLS – gap segmented – panels – total bending deformation*

As the diagrams indicate, the deformation is maximal for the gap segmented element. The relation between the maximal deformation of the variations is 1.0 to 3.0 to 2.5.

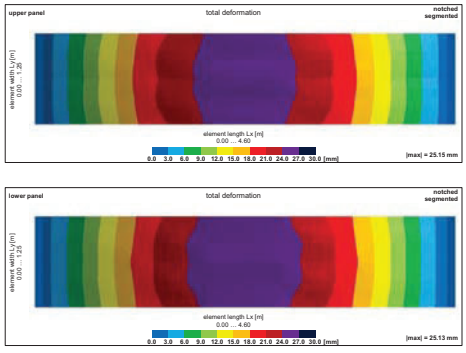

Figure 16: *SLS – notched segmented – panels – total bending deformation*

6 EXPERIMENTAL INVESTIGATIONS

The results of the numerical investigations indicate that this is a promising approach and experimental testing of macro-scaled specimens is actually conducted and evaluated. These tests and the detailed analysis of the measured and documented results are currently being done at the University of Kassel.

7 CONCLUSIONS AND OUTLOOK

Promising results have been achieved to date. Analytical and numerical approaches for different types of segmented beams were used and compared with good compliance. Further investigations were conducted against this background.
The methodology, development and selected results as well as additional information concerning the further investigations are presented within this paper.
The current results and findings in combination with experimental testing on a micro and macro scale will enable new and further application areas for segmented composite sections.

ACKNOWLEDGEMENT

The results presented were achieved within the DFG research project “Additive robotic assembly techniques for timber construction – Computational design and integrated structural joining methods”. This project is funded by “Deutsche Forschungsgemeinschaft”. The work would not have been possible without this support.
The authors would like to thank the funding agencies, colleagues named in the bibliography and representatives of the companies involved in the project, as well as the associated project committees for their contributions.

LIGHT-FRAME TIMBER SHEAR-WALLS WITH DIAGONAL BOARD SHEATHING: EXPERIMENTAL AND NUMERICAL INVESTIGATION

Alessandro Setti[1], Daniele Casagrande[2], Andrea Polastri[3], Riccardo Fanti[4], Maurizio Follesa[5], Ezio Riggi[6]

ABSTRACT: The lateral stability of Light-frame timber (LFT) shear-walls is typically ensured by the nailed connection between the wooden frame elements and the sheathing wooden panels, e.g. Oriented Strain Boards (OSB), whereas hold-downs and angle brackets are typically adopted to limit the rigid body rotation and sliding of shear-walls. A valuable alternative to wooden panels in the sheathing of LFT shear-walls is given by diagonal boards. Wooden boards are typically 45° inclined and fastened to frame members, on one or both sides, by means of nails. This paper presents a numerical and experimental study of LFT shear-walls with diagonal board sheathing through extensive experimental campaign and finite element modelling. Monotonic tests were performed on six full-scale LFT shear-walls whereas monotonic shear tests were conducted at connection level to determine the mechanical properties of sheathing-to-framing nailed connections. The results showed that shear-walls sheathed on two sides, with boards which are 90° oriented one to the other, are characterized by significant in-plane shear resistance and can be considered as a feasible alternative to traditional LTF with wooden sheathing panels.

KEYWORDS: Light-frame shear-wall, diagonal sheathing board, lateral load, timber constructions, nailed connection.

1 INTRODUCTION

Light-frame timber (LFT) structures are certainly one of the most spread structural system used for low-to-mid-rise timber buildings worldwide. The lateral load resisting systems in such structural type is typically composed of LFT platform-type shear-walls which are designed to resist both vertical and lateral loads. The lateral stability of LFT shear-walls is typically ensured by nailed connection between wooden frame and sheathing elements, typically wooden panels such as e.g. Oriented Strain Boards (OSB) or plywood. Hold-downs and angle brackets are typically adopted to limit the rigid body rotation and sliding of shear-walls, especially in seismic prone areas, where lateral forces can reach particularly severe intensity.

Several comprehensive studies have been conducted to investigate the mechanical behaviour of traditional LFT shear-wall subjected to lateral loads. The seismic behaviour of shear-walls sheathed with OSB panels was investigated in the CUREE project ([1], [2]) through full-scale shear-wall tests and full-size building shake table tests. Salenikovich and Dolan [3] investigated the monotonic and cyclic behaviour of shear-walls with different aspect ratios showing that sheathing-to-framing connection mechanical properties and connection spacing have large influence on the shear-walls' response. The NEESWood project [4] provided essential outcomes obtained from shake table tests on two-storey and six storey buildings that lead to define the seismic behaviour of low-to-midrise LFT buildings in North America, through the development of a performance-based seismic design approach. Tomasi et al. [5] and Casagrande et al. [6], within the SERIES project, investigated the seismic response of two three-storey LTF buildings braced with LFT shear-walls sheathed with OSB or gypsum panels by means of shaking table tests.

A valuable alternative to wooden panels, for sheathing LFT shear-walls, is given by diagonal boards. Wooden boards are typically 45° inclined and fastened to the frame members by means of nails (Figure 1a). LFT walls with diagonal board sheathing had been largely used for many decades in the construction of low-rise buildings primarily in North America and a revival of such structural type is being observed also in Europe nowadays. However, limited information on their mechanical behaviour is available in literature. Partial designed models have been developed and limited provisions have been included in Standard documents [7] The mechanical behaviour of light-frame timber walls with diagonal board sheathing has been studied since the late 1950.

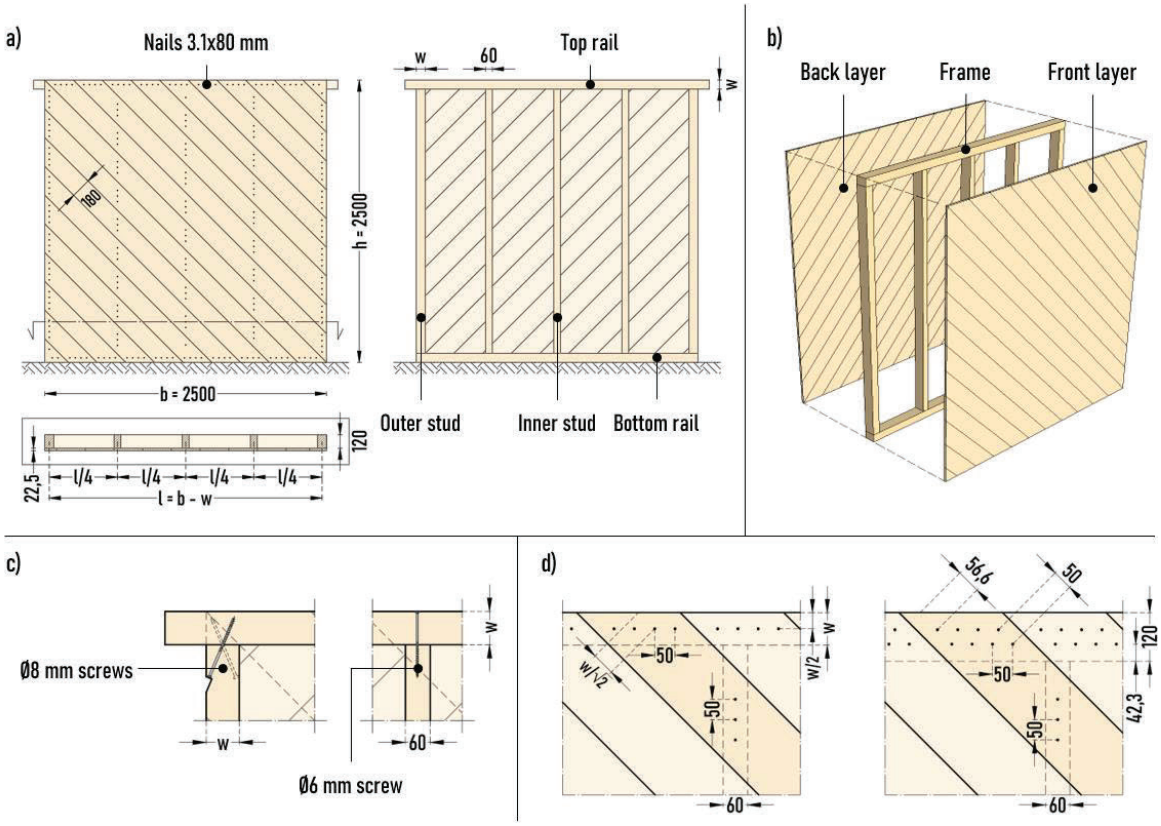

***Figure 1**: Shear-wall types and geometries: a) single sheathing board layer (1s) and general dimensions; b) double crossed sheathing board layers (2s); c) frame member connections; d) sheathing-to-framing nail layouts.*

Doyle [8] conducted an experimental campaign on seventeen shear-walls characterized by: different number of sheathing layer (single or double layers), type of boards (full-length and jointed) and corner with or without reinforcements The results provided by single sheathing layer walls showed that the overall mechanical behaviour depended on stresses which are acting within the boards: shear-walls with boards subjected to tension were stiffer and stronger than shear-walls with boards subjected to compression. Similar outcomes were obtained by Ni and Karacabeyli [9] in Canada by means of both monotonic and cyclic tests on sixteen shear-walls. The influence of different parameters was studied: sheathing layer configurations (either single or double layer), type of mechanical anchor, magnitude of vertical loads and reinforcements.

This paper presents a numerical and experimental study of the mechanical behaviour of LFT shear-walls with diagonal boards sheathing through experimental and numerical analyses. Monotonic tests were performed on six LFT shear-walls whereas monotonic shear tests were conducted at connection level to determine the mechanical properties of sheathing-to-framing nailed connections. Numerical finite element models were implemented to predict the mechanical behaviour of tested shear-walls.

2 EXPERIMENTAL CAMPAIGN

2.1 SHEAR-WALL TESTS

The shear-walls were assembled at the mechanical test laboratory of the Institute of Bioeconomy (formerly Ivalsa) of the National Research Council of Italy. Monotonic tests were carried out on six 2.50x2.50 m LFT shear-walls sheathed with boards (Figure 1a and 1b). Either 80x120 mm (type A) or 120x120 mm (type B) solid wood members were used as frame outer members (rails and outer studs) whereas 60x120 mm members were adopted for inner studs. The specimens were assembled using C24 wooden members; studs were spaced at quarter length of shear-wall (l) defined as the difference between the base of the wall (b) and the width of the frame perimeter member (w). A couple of crossed and inclined semi-threaded screws (8x160 or 8x200 mm) were adopted to ensure connection between rails and outer studs whereas a single semi-threaded screw (6x160 or 6x200 mm) was adopted as connection between rails and inner studs (Figure 1c). C16 boards (width 180±20 mm and thickness 22.5mm) were placed inclined 45° with respect to the timber frame and connected to the frame by means of either four or eight 3.1x80 mm ring nails. Three nails were used to connect the boards to the inner studs (Figure 1d). Sheathing-to-framing nailed connection layouts were adopted in accordance with the provisions reported in Eurocode 5 [10]. Sheathing boards were placed on either one side (1s) or both sides (2s) of the wall frame; this latter

https://doi.org/10.52202/069179-0454

configuration had boards placed on one side 90° oriented from boards on other side of the frame (double crossed layers) as shown in Figure 1. Test set-up used for full-scale shear-wall experimental campaign is shown in Figure 2. Specimens were anchored to the steel foundation by means of a couple of special mechanical anchors designed to fully prevent sliding and rocking of the specimen. Such anchors consisted of 15 mm thick steel plates provided with slotted holes where a special hold-down was connected by a steel dowel in order to allow free rotation of the specimen. These steel plates were bolted to the steel foundation element and the special hold-downs were connected to lateral side of outer studs by means of 5x70 mm LBS screws (30 or 60 screws were used for 1s or 2s shear-wall type respectively). As shown in Figure 2, lateral load was applied by means of a horizontal hydraulic jack through a steel top beam equipped with thick angular steel plates at top wooden rail ends to transfer the load from the hydraulic actuator to the top rail of the wall. Additional restraints were provided at the top of the wall specimen, on both sides, to prevent out-of-plane displacements of the wall and buckling.

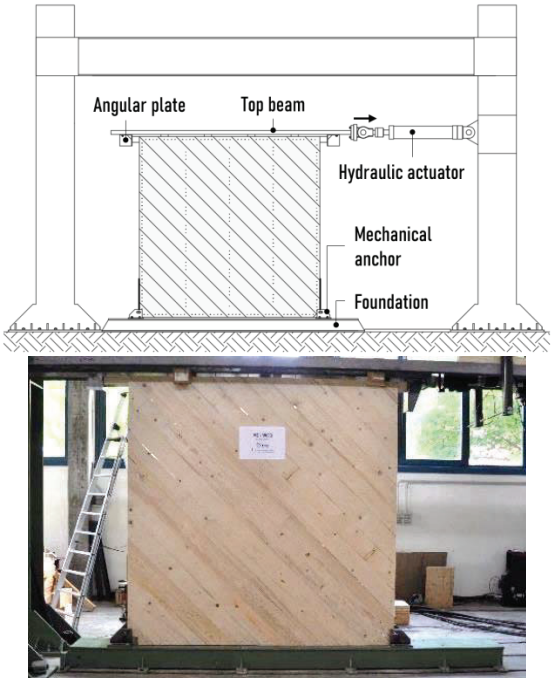

Figure 2: *Set-up of full-scale shear-wall tests.*

The instrumentation layout is represented in Figure 3. Linear Variable Displacement Transductors (LVDT) were used to measure the top horizontal displacement δ_T (M1), and the sliding of the specimen δ_B (M2) at the foundation level; two vertical LVDTs were placed in correspondence of ground anchor to measure the up-lift δ_V (M3 and M4) of the specimen. Finally, two diagonal LVDTs were placed to measure diagonal deformation of the frame (M5 and M6). The list of specimens used for experimental campaign is reported in Table 1.

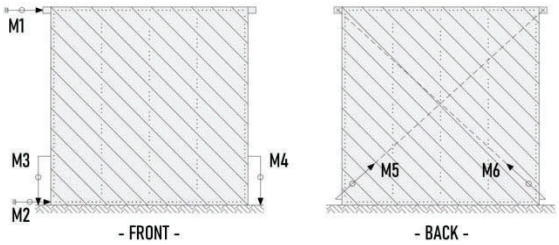

Figure 3: *Instrumentation layout for full-scale shear-wall tests.*

Each specimen reported an alphanumeric label: the sheathing layer configuration (1s or 2s) was identified; the next letter ("C" or "T") depended on stress which was acting within diagonal boards during the test (compression or tension respectively), see Figure 4; the last part identified the sheathing-to-framing nail configuration which depended on both the number of nails adopted (either four or eight) and on the dimensions of frame perimeter members (defined with letters "A" and "B").

With regard to W001b, the specimen used in test W001 was strengthened by means of an angle bracket at the upper corner (Figure 5). The purpose of this solution was to create a corner reinforcement (CR) in order to prevent failure of the perimeter member connection, thereby increasing in-plane strength capacity.

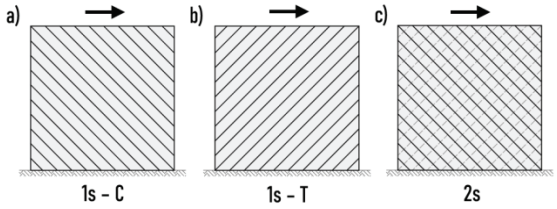

Figure 4: *Laying direction of boards compared to load direction used for W001 and W001b (compression) (a), W002 (tension) (b) and W003, W004 and W005 (c).*

Monotonic test procedure was defined in accordance with EN594. The test protocol consisted in a linear displacement with a constant speed of 0.2 mm/s imposed to shear-wall until 100 mm displacement (measured from hydraulic actuator LVDT) was reached or failure of the specimen occurred.

Table 1: *Full-scale shear-wall tests.*

Test	Label	Frame perimeter members
		width x depth
[-]	[-]	[mm]
W001	1s – C – 4A	80 x 120
W001b*	1s – C – 4A – CR	80 x 120
W002	1s – T – 4A	80 x 120
W003	2s – 4A	80 x 120
W004	2s – 4B	120 x 120
W005	2s – 8B	120 x 120

**specimen W001 stiffened with a further corner reinforcement (CR).*

https://doi.org/10.52202/069179-0454

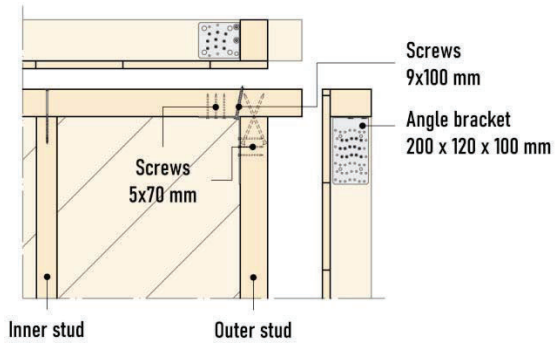

Figure 5: *Details of corner reinforcement used for W001b specimen (1s – C – 4A – CR).*

The results obtained with the experimental campaign are reported in
Table 2. Load-displacement curves are shown in Figure 6. The relative displacement δ was calculated with equation (1); in particular the sliding and the rocking of the specimen (δ_R) were subtracted from the top horizontal displacement.

$$\delta = \delta_T - (\delta_B + \delta_R) \quad (1)$$

The rocking displacement component δ_R is taken equal to δ_V as the aspect ratio of shear-walls is 1:1.
The results obtained from "1s" wall configuration (single sheathing layer) showed that in-plane strength capacity was dependent on the direction of the sheathing boards. As the matter of fact, two completely different behaviours from W001 (1s – C – 4A) and W002 (1s – T – 4A) were observed. During test W001, the shear deformation imposed by the external load was forcing the boards in compression stresses creating a diagonal compressed "strut" within the sheathing layer which led to the failure of the connection at the upper corner (Figure 7a). The concentrated forces caused relative displacements both in vertical and horizontal directions between the outer frame member. In addition, the shear-deformation caused the separation of the boards (Figure 8a).

Conversely, in test W002, the sheathing boards acted in tension. The stress configuration leads the frame perimeter members to compress each other (Figure 7b). Besides, shear deformation caused the contact between each board, generating collateral stresses in perpendicular direction which were acting in opposition to the movement of the specimen and which allowed the shear-wall to reach a maximum force almost four times greater than that obtained for shear-wall with boards subjected to compression (W001) (Figure 8b). The specimen has demonstrated a quite linear behaviour until the end of loading protocol and failure occurred in sheathing-to-framing connection,

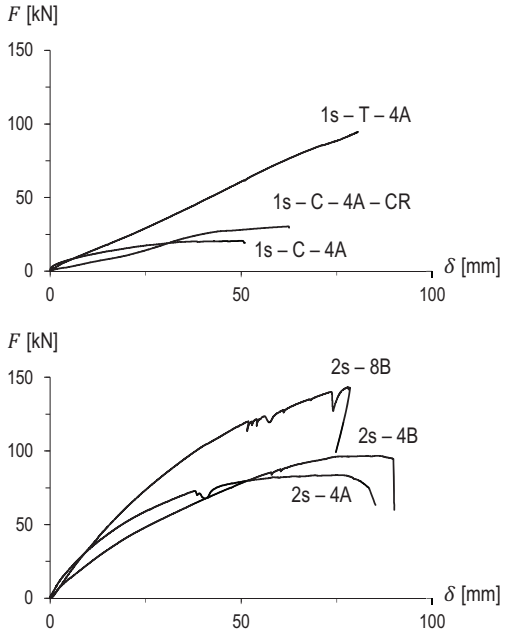

Figure 6: *Load-displacement curves from full-scale shear-wall tests.*

- *δ_{max}, F_{max} peak point of load-displacement curve;*
- *δ_u, F_u ultimate curve point defined as the displacement at 80% of maximum load post peak or displacement limit of test protocol;*
- *K is stiffness assessed as the slope of the straight line passing from the origin of the axes to the yield point that was defined according to provisions reported in EN12512 (intersection between the secant between 10% and 40% of the maximum load and the tangent to the capacity curve with 1/6 slope of the secant line);*
- *μ ductility defined as the ultimate and yielding displacement ratio.*

**not reported as unreliable values (see Table 1).*

https://doi.org/10.52202/069179-0454

It is worth mentioning that specimen W001b (1s – C – 4A – CR, wall with corner reinforcement) increased in-plane strength capacity of almost 50% compared to W001; failure occurred due to angular bracket yielding used to reinforce the corner connection (Figure 7c).
Significantly different responses were obtained from "2s" wall configurations (double crossed sheathing layers) tests compared to "1s" configurations, providing greater strength capacity and stiffness. Double crossed tests provided a strength capacity almost four-to-seven times greater than W001.

Figure 7: *Wall frame corner detail: a) failure of W001 frame perimeter members connection; b) no visible failure occurred for W002; c) failure of W001b by yielding of angle bracket. Pull-out of frame perimeter members connection for W003 (d), for W004 (e) and W005 (f).*

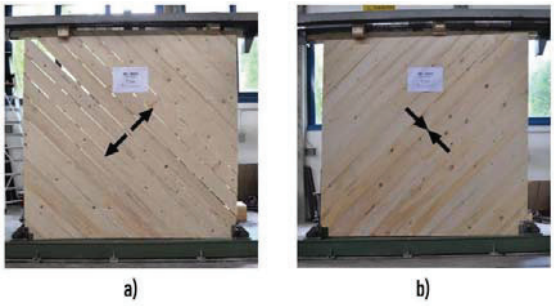

Figure 8: *Shear deformation: a) W001 sheathing boards tend to separate; b) W002 sheathing boards tend to contact.*

Load-displacement curves obtained from "2s" wall configuration tests showed a decreasing trend of the slope due to the progressive withdrawal of the screws which connected frame perimeter members on the left corner during the tests (Figure 7d, 7e and 7f). Similar mechanical behaviour with a decrease of stiffness during the test was observed in "1s" wall configuration with boards subjected to compression stresses. (see Figure 7a).

2.2 CONNECTION LEVEL TESTS

Experimental monotonic tests were carried out at connection-level on sheathing-to-framing nailed connection. These tests were designed and performed in order to characterize the mechanical behaviour of board-to-stud nailed connection and with the aim of collecting input parameters for the numerical model. The three sheathing-to-framing connection configurations used on full-scale shear-wall experimental campaign (see Figure 1d) were tested as reported in Table 3. Three specimens were tested for each configuration. Monotonic tests were carried out in accordance with the loading protocols defined in EN26891 [11].
Test set-up adopted for experimental campaign is represented in Figure 9: four LVDTs were placed to measure relative slip of nails between frame wood element and the two boards. Test protocol consisted in a linear displacement with a constant speed of 0.08 mm/s imposed to top CLT element until failure occurred or 80% of load post peak was reached. Load-displacement curve was drawn through mean displacement and force measured by a 600 kN load.

Table 3: *Sheathing-to-framing connection tests.*

Test	Configuration	Solid wood element		Board	
		width	depth	width	depth
[-]	[-]	[mm]	[mm]	[mm]	[mm]
001	4A	80	120	180	22
002	4A	80	120	180	23
003	4A	77	120	173	21.5
004	4B	120	120	182	22.5
005	4B	120	120	184	22
006	4B	120	120	182	23
007	8B	120	120	180	22.5
008	8B	118	116	170	22
009	8B	118	116	195	22

The results and load-displacement curves are reported per single nail in Table 4 and Figure 10, respectively.
In Table 5 it has also reported the mean values of peak load and load measured at 15 mm displacement on the three sheathing-to-framing configurations. The mean values of the reached maximum strength decrease, increasing both the number of nails and the cross section of frame member. Load-displacement mean curves obtained from connection-level tests were used to characterize sheathing-to-framing connection behaviour for numerical analyses.

3 NUMERICAL ANALYSES

Numerical finite element analyses were conducted through the commercial software SAP2000 [13], see Figure 11, in order to predict the mechanical behaviour of LFT shear-walls with diagonal board sheathing.

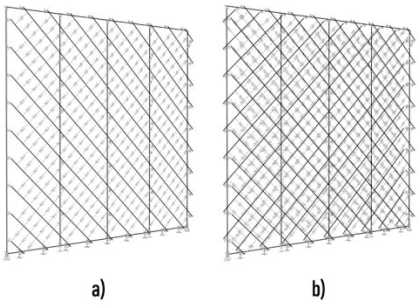

Figure 11: *Numerical model developed for "1s" (a) and "2s" (b) shear-walls.*

Orthotropic material was used to define the properties of wooden members (both frame member and diagonal lumber). The axial and bending stiffness of the solid wood members were set assuming an elastic modulus $E_{0,mean}$ = 12200 MPa .Furthermore, perpendicular to the grain and shear moduli were defined in accordance with EN338 [14]: $E_{90,mean}$ = 390 MPa and G_{mean} = 690 MPa.

Wooden frame and sheathing boards were modelled through "frame" elements. Outer and inner studs were connected to top and bottom rails by means of "non-linear links". Bottom rail was hinged to each end and provided by "line springs" along the frame object and resisting under compression only, in order to simulate the presence of the foundation. Sheathing boards were connected to the frame members by means of "non-linear links" whose mechanical behaviour was obtained by the sheathing-to-framing connection tests. Furthermore, boards were connected each other in perpendicular direction through "gaps" equal spaced in order to simulate the contact between the boards and taking into account the perpendicular to the grain compression forces due to shear-wall deformation.

Lateral increasing force in correspondence of top rail was imposed through non-linear static analyses. As an example, Figure 12 represents the comparison between experimental analysis and numerical results for specimen used in test W003 (2s – 4A).

It is noteworthy to mention that the distribution of stresses within sheathing boards was constant along each single board but with a decreasing trend moving gradually from the diagonal boards to the shorten ones.

4 CONCLUSIONS

An experimental campaign and a numerical investigation, on the mechanical behaviour of LFT walls with diagonal sheathing boards was conducted.

Results showed that shear-walls sheathed on one side (1s, single sheathing layer shear-walls) demonstrates a completely different behaviour in terms of resistance and stiffness, based on stresses which acting within sheathing boards, showing how the lateral resistance is strongly ruled by board laying direction. Corner reinforcement could be provided in order to avoid early failure in the connection between perimeter wood members of "1s" shear-wall, the reinforcement increases lateral resistance.

Regarding shear-walls sheathed on two sides with boards placed on one side 90° oriented from boards on other side of the frame (2s, double crossed sheathing layer shear-wall), the results showed that are characterized by significant in-plane shear resistance comparable to traditional LFT walls braced with wooden sheathing panels. The finite element model gave reliable results in terms of capacity curve if compared with these obtained from full-scale shear-wall tests, confirming that the model developed can be used to predict the mechanical behaviour of light-frame timber shear-walls with diagonal board sheathing.

SEISMIC PERFORMANCE OF CLT SHEAR WALL INFILLED HYBRID STEEL MOMENT FRAME WITH CONCEALED STEEL PLATE AND DRIFT PINS CONNECTIONS

Hiroshi Isoda[1], Richard Yip Je Too[2], Kazumi Kanazawa[3]

ABSTRACT: In Japan, the recent introduction of Cross Laminated Timber (CLT) started gaining attention because of its ability to perform under seismic activities. The increasing of utilization of timber in mid-rise buildings became possible followed by the change in height limit of fire-proofed timber buildings (e.g., Steel-CLT hybridization) in the Building Standard Law. However, the design method of such hybrid structures in Japan has yet to be generalized and it has become an obstacle for structural designers. In this paper, a series of models for hybrid steel moment frame (SMF) CLT shear walls structures are presented for the non-linear incremental displacement analysis. The model was verified by the experiment results and can potentially serve as an appropriate method to design future CLT-Steel hybrid structures.

KEYWORDS: Cross Laminated Timber, Hybrid Structures, Lateral Performance, Cyclic Tests

1. INTRODUCTION

Hybrid systems require an application of 2 or more materials and enable the benefits of each material to be applied to seismic force resisting systems. For instance, in timber and steel hybridization, the ductility of steel provides significant post-yield deflection capability, allowing the structure to dissipate seismic energy during earthquakes. On the other hand, the timber infill can increase the stiffness of the system, which can reduce the fundamental period and drift values in seismic vulnerability. [1]

Recently, many researchers are beginning to focus on research topics regarding steel-timber hybrid buildings. In Canada, research on steel-timber hybrid system was conducted [2]. The proposed system consists of a steel beams with wooden shear wall infills connected to the studs via nails. In China, a hybrid system consisting a steel frame with wooden shear wall infill was proposed, in which nails were also used to connect the wooden shear walls [3]. From the results, it was observed that the timber infill could contribute to the increase of stiffness and strength of the structure significantly. Nonetheless, ultimate failures like panel tear out and bending of nails were observed. The failures show that the stiffness and strength of the connection is inadequate, indicating that the system could resist more load if properly designed with stronger connection, as well as with stronger infills.

To overcome such problems, a new steel-timber hybrid system is proposed in this paper. It utilizes concealed plate with drift pin (DP) connections as the wall-to-frame connection and cross laminated timber (CLT) as the infill wall for better seismic performance. The advantages of using DP connectors is that, it can have high ductility like nails and screws, while also maintaining its high rigidity. In Japan, the research on steel-timber hybrid system utilizing concealed steel plate with DP connection was initially conducted by Fukumoto et. al. [4]. However, the system consists of steel tie bars as well, which are exposed, and fire safety would become an issue. Because of this, newly developed wall-to-frame connection was proposed that consists of only DP connections with concealed steel plate inserted into the pre-opened slit in the CLT panel.

In 2018, Kanazawa et. al. [5] reported the results on this type of hybrid system for the first time. In 2019, 4 new types of specimens were additionally introduced, of which the results have not been reported anywhere else. On top of that, in Japan, the standard seismic design methodology for such hybrid system has not been generalized. Therefore, this paper will compare and discuss the results of all 2018 and 2019 specimens and also to propose an analysis model that can trace the cyclic behaviour of the system. The model could serve as a fundamental design methodology with the aim to accelerate the promotion of such hybrid system. It should be noted that the presented contents in this paper are a part of the journal paper accepted for publication, written by Richard et al [6]. For more information, please refer to the paper listed in the reference.

2. DESCRIPTION OF TEST SPECIMENS

Figure 1 and 2. shows the naming method of the specimens and the detailed figure of the standard hybrid specimen FM-S60-32, respectively. Figure 3 and 4. show the specimen overview of tests conducted in 2918 and 2019, respectively. It should be noted that the CLT-steel hybrid frame experiment was conducted at 1/2 scale. The size of the specimens is 3600mm and 2000mm between

the center of steel columns and steel beams, respectively. The steel column is SN490B graded with size of RH-300x300x10x15 for all specimens. Column and beam connections are rigidly welded and reinforcing ribs were appropriately placed in
each specimen. The CLT panel used in the experiment is made of Japanese Cedar, which is 1531mm in height (1631mm for FS-S60-32), 1100mm in width (1075mm for FM-S60-32-S) and 105mm in thickness. At the wall-to-frame connection, concealed steel plate and DP connections are applied. To further connect the concealed steel plate to the steel frame, several bolts were used. The length and the DPs were 105mm and 10mm, respectively. The thickness of the concealed steel plate was 6mm. Moreover, non-shrink mortar was also infilled in between the CLT panel and the frame, to increase fire safety as well as to cover the uneven surfaces of the steel beam for better distribution of the compression load from the CLT panel.

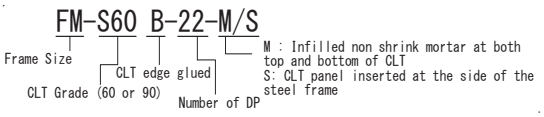

Figure 1: *Naming method of the specimens*

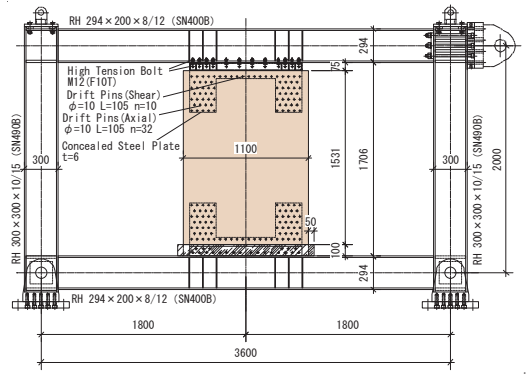

Figure 2: *Detailed figure of FM-S60-32*

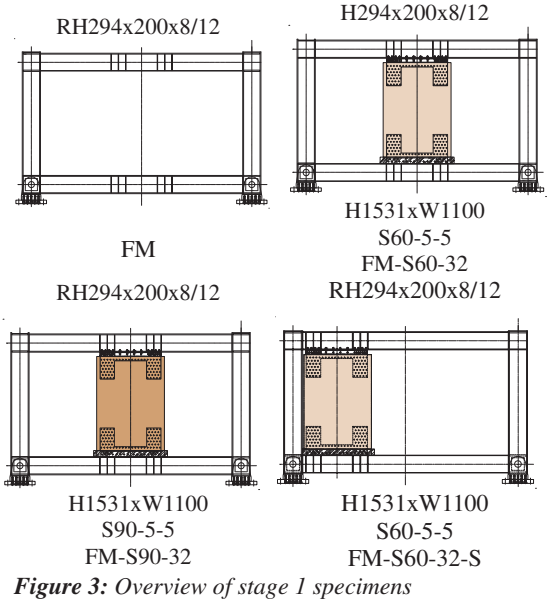

Figure 3: *Overview of stage 1 specimens*

In this paper, a total of 8 specimens, including 2 steel bare frame and 6 CLT-steel hybrid specimens with different configurations were prepared and investigated. The parameters of the hybrid specimens, including the descriptions are listed as follows:
1. Stiffness grading of CLT panel(S60 or S90): Specimen that consists of CLT infill with higher grading (S90) was introduced to investigate its effectiveness in the hybrid system, compared to the lower graded CLT (S60).

2. Edge gluing between the laminas in the CLT panel: To investigate the difference in the amount of contribution to the overall shear resistance due to the increased performance provided by the edge gluing in the CLT shear wall.

3. Positioning of CLT panel: To investigate the effectiveness of the shear force resisted by the infilled
CLT shear wall when it is placed at the side of the steel frame.
4. Number of drift pins (22 or 32): To investigate the influence of the number of drift pins (32+10+32 or 22+14+22 configuration) on the lateral performance of the hybrid system.
5. Position of infill non-shrink mortar: To investigate the effect of a higher stiffness option due to the stronger compressive strut formed in the CLT shear wall.

6. Size of the steel beam (FS:RH-194x150x6x9 or FM:RH-294x200x8x12, both SN490N graded): To investigate the capability in energy dissipation which occurs through the yielding of the steel beam.

3. TESTING METHODS AND DATA ACQUISITION

Figure 5. illustrates the setup of the cyclic loading test and the measuring positions for data acquisition. The test specimen was pushed and pulled by two hydraulic

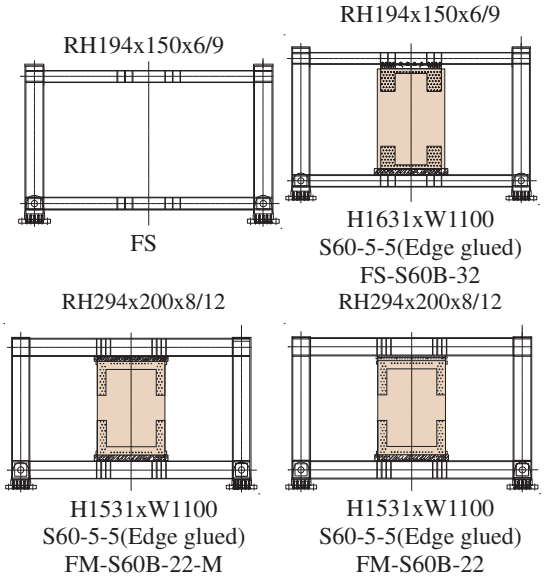

Figure 4: *Overview of stage 2 specimens*

https://doi.org/10.52202/069179-0455

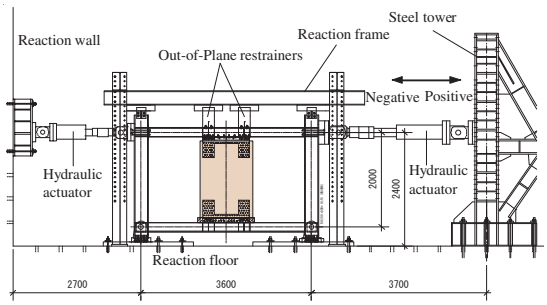

Figure 5: *Configuration of cyclic loading test*

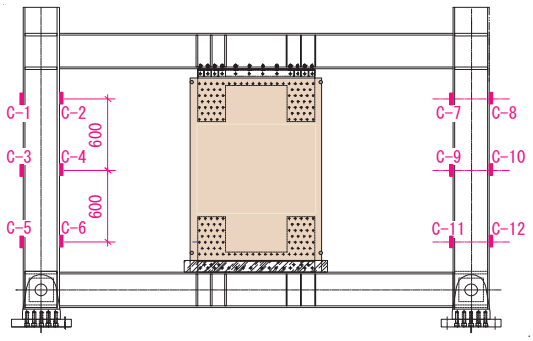

Figure 6: *Position of strain gauges on steel columns*

actuators from both sides of the frame. Out-of-plane restrainers were set above the top of the steel beam to prevent out of plane deformation. The steel frame was also fixed to the reaction floor.

The horizontal displacement δ was measured at the centre of top steel beam. The drift angle R is calculated by δ/H, where H is the distance between centre of the beams (=2000mm).

To evaluate the shear force in each of the steel frame and the CLT infill, the following equations were used. The shear force resisted by the steel frame (Qc) can be obtained by adding the shear forces in the left (Q_{CL}) and right (Q_{CR}) steel columns. The shear force in each steel column was determined using Equation (1).

$$Q_{CL} \text{ or } Q_{CR} = \frac{M_{top} + M_{bottom}}{h} = \frac{(\varepsilon_{top} + \varepsilon_{bottom})EZ}{2h} \quad (1)$$

In Equation (1), M_{top} and M_{bottom} are the bending moments of the top part and bottom part of each steel column, ε_{top} and ε_{bottom} are the strain values recorded using strain gauges located at the top (C-1, C-2 and C-7, C-8) and bottom (C-5, C-6 and C-11, C-12) of the steel columns, respectively, shown in Figure 6. E is the elastic modulus of steel (2.05×10^5 N/mm^2), Z is the section modulus of the steel columns (1.35×10^6 mm^3), and h is the vertical distance between the strain gauges (1,200 mm).

In the CLT-Steel hybrid wall system, the total shear force (Q) was resisted by two components, the steel frame and the CLT shear wall. Therefore, from the load-sharing by the two components, Q_{CLT} can be acquired by using Equation (3).

$$Q_C = Q_{CL} + Q_{CR} \quad (2)$$

$$Q_{CLT} = Q - Qc \quad (3)$$

It should be noted that both stage 1 and 2 test specimens were subjected to different cyclic loading protocol of controlled angular displacement with cycles grouped in phases, as indicated in Figure 7. Even though the loading protocols were different, the obtained results for both stages were essentially the same. The first phase for 1/200 rad contains only 2 full reversed cycles for stage 2 specimens, while others contain 3 cycles. Finally, the loading will be terminated at final pushover at 1/10rad, where the specimens are expected to fail.

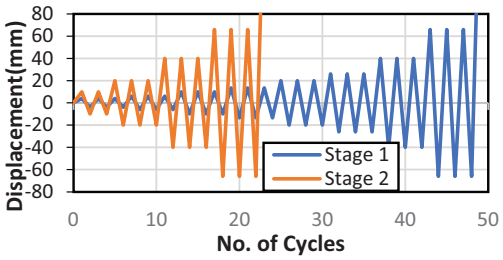

Figure 7: *Loading protocol*

4. RESULTS AND DISCUSSIONS.

4.1 Load-Displacement Properties

Figure 8. summarizes the load-displacement hysteresis curves of all specimens. From the figures, it can be observed that with the exception of FM-S60-32-S, the CLT-infilled specimens with FM beams experienced strength degradation at an angular deformation of around 1/50 to 1/30 rad due to the shear failure of the CLT infill. It can be said that the shear capacity of the CLT infill was fully utilized. As for FS-S60B-32, strength degradation did not occur because one of the two steel beams yielded and buckled markedly at 1/30 rad, which led to out-of-plane deformation of the CLT infill. All the specimens were tested successfully, per the loading schedule, except for specimen FM-S60-32-S, for which the test had to be terminated prematurely because of the large compression flange local buckling of the beam. Overall, almost no slip behaviour was observed among the hysteretic behaviour of the specimens with CLT infill, an outcome that was similar to the hysteretic behaviour of the steel frame specimens. This shows that the steel frame was dominant in terms of the behaviour of the hybrid system.

Table 1 summarizes the specimens' maximum capacity and initial stiffness. The table shows that the installation of the CLT panel significantly increased the maximum load capacity and initial stiffness of the steel bare frame. From Figure 8 and Table 1, the following principal conclusions can be drawn:

1. When comparing specimen FS-S60B-32 and FM Frame to FS frame, the results show that same amount of increase in maximum capacity and initial stiffness were obtained in both cases. Considering that there was no strength degradation occurred in FS-S60B-32, it indicates that by

https://doi.org/10.52202/069179-0455

infilling a CLT panel into a slender frame, the hybrid system is capable of increasing the stiffness while still maintaining the ductility.

2.When comparing FM framed hybrid specimens to FM frame, the results show that the reinforcement effect in maximum capacity and initial stiffness by the CLT infill is lower compared to FS-S60B-32. Although strength degradation occurred in FM framed hybrid specimens, the amount is not large overall, demonstrating that the lateral load was shared by both the steel frame and the infill, which worked closely together to resist lateral load.

4.2 Typical Failure Modes

In this section, the typical failure modes of the hybrid systems are presented. At 1/100rad, noticeable displacement at the DP connections was observed in specimens with fewer DP connectors. Due to the yielding of DP connectors, specimens FM-S60B-22 and FM-S60B-22-M were observed to undergo early failure at the wall-to-frame connection, of a type that involved compressive buckling at the concealed steel plate as shown in Figure 9(a). Between 1/50 and 1/30rad, all specimens except specimen FS-S60B-32 underwent shear failure along the grain of CLT's lamina, as shown in Figure 9(b). Because of the early yielding of DP connectors, specimens FM-S60B-22-M and FM-S60B-22 showed particularly significant failure in the CLT shear wall, which split in half vertically in the middle as shown in Figure 9(c). However, in the case of FM-S60B-22-M, the lateral load was maintained even after the splitting, as the mortar at top and bottom constrained the potential rocking motion of the split CLT, thus enabled each broken section to continue to resist lateral load individually.

At large deformations (1/50 rad~1/10 rad), the steel frame began to display yielding evidence, thereby demonstrating the capability to dissipate energy through plastic deformation. While yielding of the steel frame was observed in all specimens, it is noticeable that the DPs in specimens with 22+14+22 configurations underwent yield deformation before yielding of the steel frame; this proved the capability to dissipate energy at smaller deformations. After the experiments were concluded, almost all the specimens with infilled CLT shear walls were observed to have experienced the separation of a CLT panel from a concealed steel plate at one or more locations, as shown in Figure 9(d). This was because of the repetitive bending deformation of the DPs under a growing angular cyclic displacement.

4.3 Load Sharing Effect

As described above, in the CLT-steel hybrid system, the shear force is jointly resisted by the CLT panel and the columns of the steel frame. In order to evaluate the effectiveness of the hybrid system's lateral load resistance, the percentage of shear force resisted by each of the subsystems was calculated for all specimens using the values of Eqs. (2) and (3); the results are shown in Figure 10. The percentage of utilized CLT shear capacity calculated using Eq. (4) is also shown,

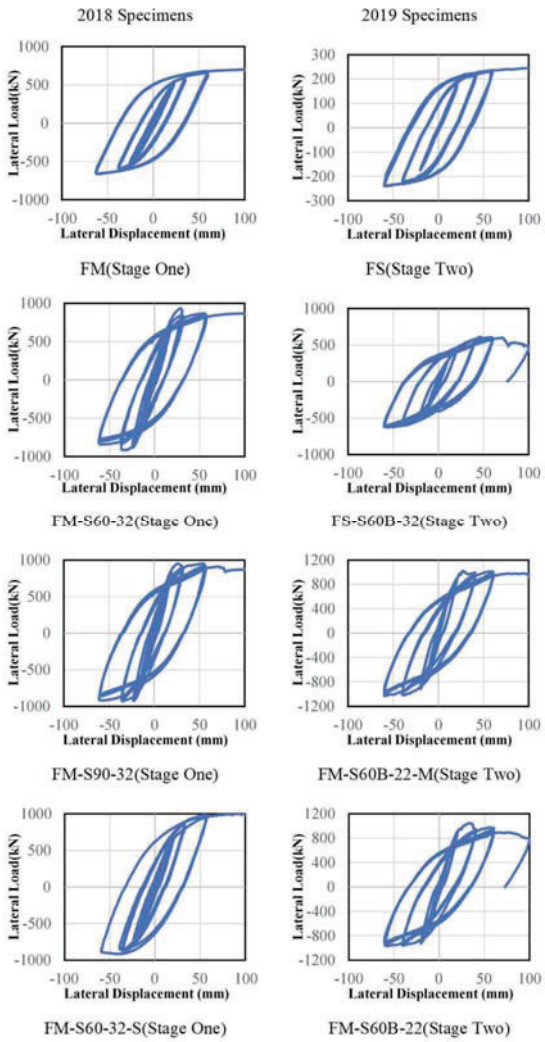

Figure 8: *Load-Displacement Skeleton Curves*

Table 1: Maximum capacity and initial stiffness

Specimen Name	Maximum capacity(kN)		Initial stiffness (kN/mm)	
	P_{max}	Compare to FS* or FM frame	K	Compare to FS* or FM frame
FS	247.5	-	8.5	-
FS-S60B-32	611.5	2.5*	25.6	3.0*
FM	791.3	2.9*	24.32	3.2*
FM-S60-32	931.7	1.2	46.08	1.9
FM-S90-32	931.7	1.2	51.88	2.1
FM-S60-32-S	1003.4	1.3	37.11	1.5
FM-S60B-22-M	1015	1.3	55.74	2.3
FM-S60B-22	1045	1.3	51.56	2.1

https://doi.org/10.52202/069179-0455

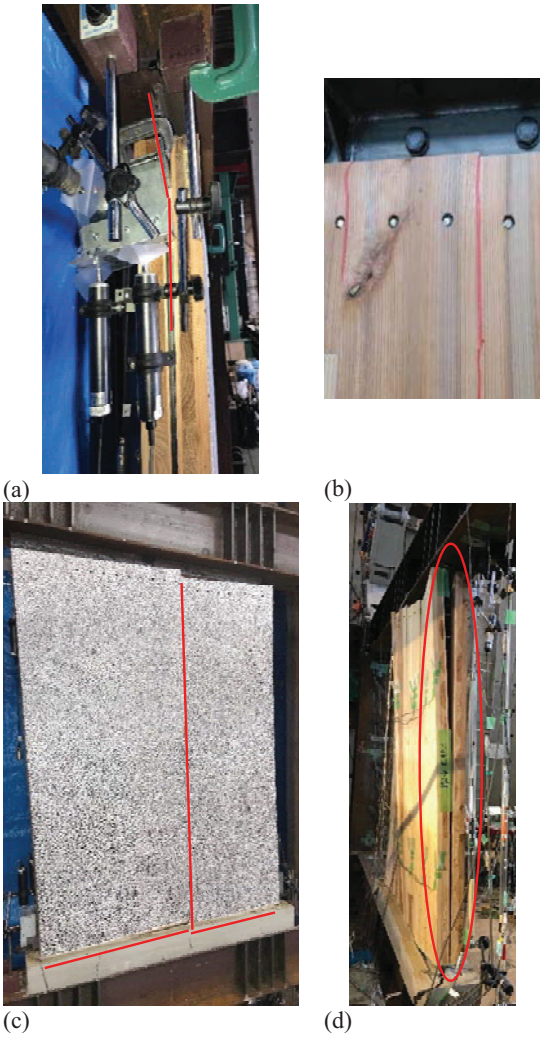

Figure 9: *Failure mechanisms*

$$Q_{CLT(\%)} = \frac{Q_{CLT}}{\min\{Q_s, Q_m\}} \times 100 \quad (4)$$

where, Q_{CLT} is the shear force resisted by the CLT during the test, and $\min\{Q_s, Q_m\}$ is the calculated CLT shear strength (268.9kN for S60 and 311.9kN for S90).

In the case of FS-S60B-32, at the initial cyclic deformation of 1/200 rad, 50% of the shear capacity of CLT was utilized. As the deformation progressed, the shear capacity was utilized up to 127% at peak. In terms of the sharing of resistance between the panel and the frame, the CLT infill resisted more than half of the shear force until almost the end of the experiment without any strength degradation. That was because, as compared with tests based on the FM frame, this specimen used the more slender FS beams. Because of that, this specimen was observed to experience significant torsional buckling at 1/30 rad, which led to the out-of-plane deformation of CLT.

For the other five specimens, a different result was observed. The shear capacity of the CLT was taken

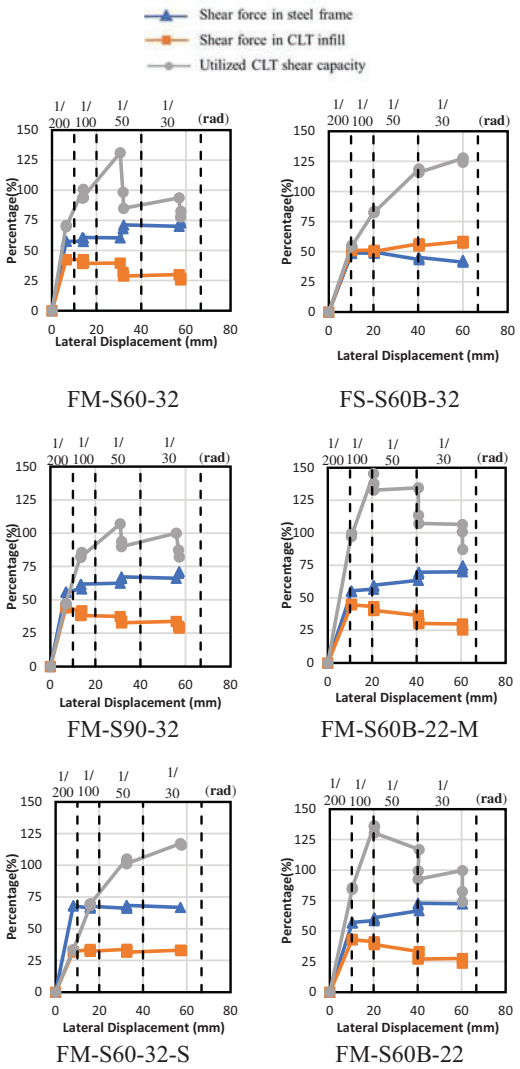

Figure 10: *Load sharing effect between steel frame and CLT infill*

advantage of at a comparatively smaller deformation, especially those specimens that had a 22+14+22 DP configuration. This is because of the early yielding of the DP connectors, which caused the CLT to deform more freely, a fact which also resulted in early shear failure of the CLT. Overall, the shear capacity of the CLT was utilized to beyond 100% (107~145%) in every specimen, proving that the utilization of the shear capacity of CLT infill was maximized. As for the sharing of the load, the steel frame resisted more than 50% of the shear force throughout the experiment because of the more robust beams, which were more capable of transferring the lateral loads to the steel columns. As observed in the discussion of failure mechanisms, the CLT could still resist some shear force even after shear failure. Due to the accumulation of damage, the percentage of force resisted by the CLT infill nonetheless decreased gradually, as shown in Figure 10.

https://doi.org/10.52202/069179-0455

5. NUMERICAL ANALYSIS

5.1 Analysis Model

A hysteresis model that can accurately reflect the hybrid system's behaviour was developed using a commercial software, SNAP V7.0 [7]. The analysis model for specimen FM-S60-32 is shown in Figure 11, as an example for the overall explanation. Figure 12 provides an overview of a series of elemental tests conducted to help define the parameters of each component in the model.

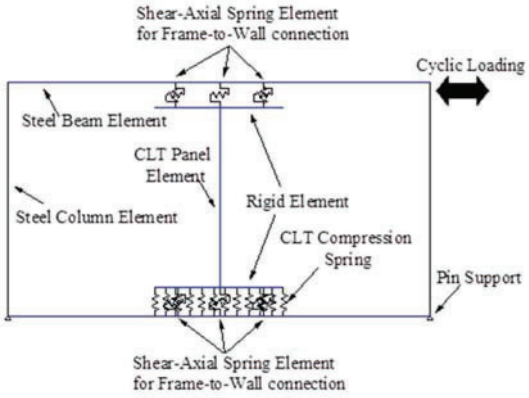

Figure 11: *Analysis model for specimen FM-S60-32*

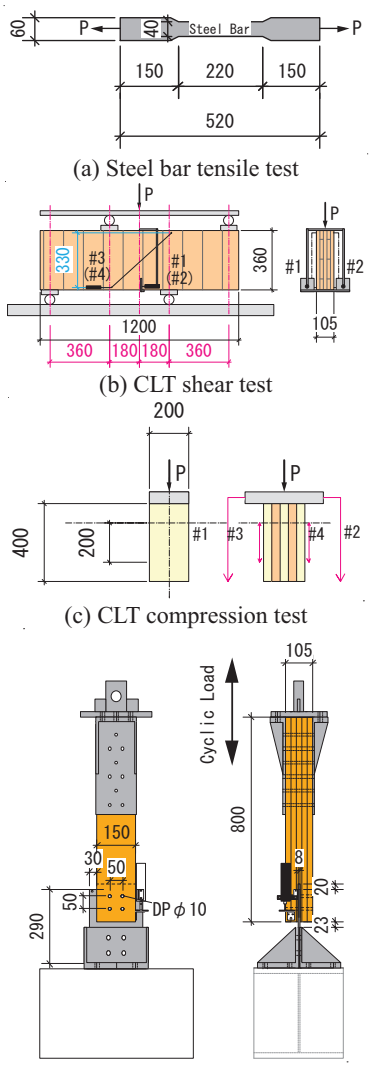

(a) Steel bar tensile test

(b) CLT shear test

(c) CLT compression test

(d) Drift pin cyclic test

Figure 12: *Overview of elemental tests*

Firstly, the hysteretic response of the steel frame was reproduced and confirmed through validation with the test results of the steel bare frame specimens. The bare frame model is basically the same as the example shown in Figure 11, minus the CLT infill elements. The hysteretic response of the steel frame was reproduced using the proposed modified Ramberg-Osgood model [8]. The parameter values used to define the steel frame model were obtained from the steel bar tensile test, illustrated in Figure 10(a). A good agreement between the experimental and analytical results was obtained, as shown in Figure 13.

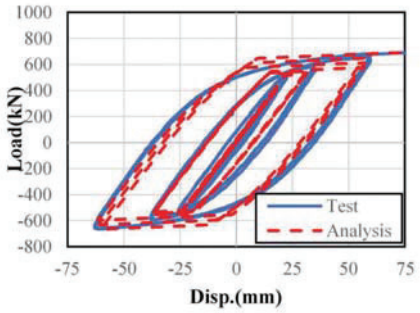

Figure 13: *Comparison between the test and numerical results of FM steel bare frame*

As for the CLT infill, it was modelled as an I shape with a vertical beam element in the middle and horizontal beam elements on the top and the bottom. During the experiments, strength degradation occurred due to the shear failure of the CLT infill. To reproduce such behaviour, the vertical beam element is defined as non-linear with model that allows strength degradation. The shear properties of the CLT infill were obtained from the CLT shear elemental test, illustrated in Figure 12(b). On the other hand, the horizontal beam elements were defined as rigid to allow effective load transfer between the CLT and steel frame through the DP connections in the numerical model. The contact surface between the CLT infill and the non-shrink mortar was modelled using a series of spring elements placed 100mm apart. Each of the bearing spring was adjusted to only resist compression and modelled as an elastic-plastic element, of which the parameter input was obtained from the CLT compression test illustrated in Figure 12(c). However, the bearing springs at the ends were considered to only have half the stiffness and yield strength, as each of the bearing springs is assumed to bear the compression load by a certain area.

Finally, the wall-to-frame connections (drift pin connections) was modelled using a series of axial-shear spring elements, which can resist both axial tensile and compression, as well as shear forces. The hysteretic behaviour of the connection was represented using the

https://doi.org/10.52202/069179-0455

modified NCL model, proposed by Matsunaga et al. [9]. As illustrated in Figure 12(d), the drift pin cyclic test was conducted to obtain the load-deformation relationships for

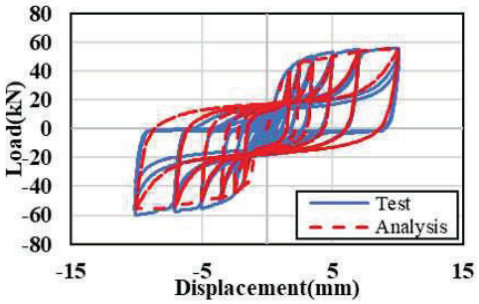

Figure 14: *Comparison between the drift pin cyclic test and calibrated numerical result*

the frame-to-wall connection. The elemental test results were then used for calibration to obtain the parameters of the modified NCL model. It can be seen from the comparison of the analysis result and the test result in Figure 14, the calibration went well as the model is capable of reproducing the slip and pinching behaviour of the DP connection under cyclic loading.

5.2 Modelling Results

The analysis model was subjected to the same loading protocol as the structural experiments. The predicted hysteresis loops, load sharing effect and cumulative energy dissipation (obtained by calculating the area under the hysteresis loops) of the hybrid system are shown in Figure 15, 16 and 17. Since the modelling results are similar for all specimens, only the results for FM-S60-32 specimen are shown.

From Figure 15, it can be observed that the plotting of the yielding of steel beam, shear failure of CLT and yielding of DP from the test and analysis results are in good agreements. Generally, the numerical results were able to reproduce the hysteretic behaviour of the hybrid system; a behaviour that is governed by the steel frame.

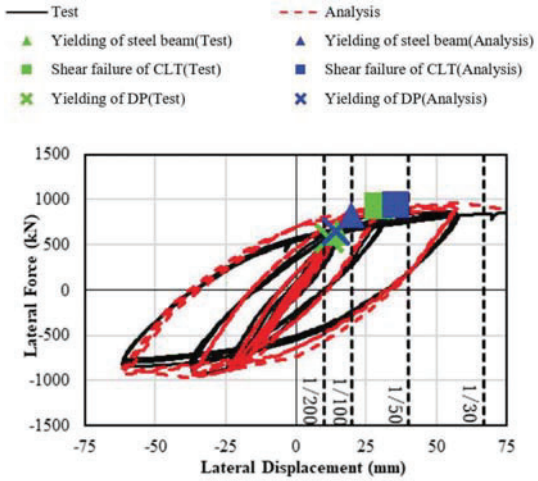

Figure 15: *Predicted hysteresis loops*

From Figure 16 and Figure 17, it can be seen that the model predictions were capable of capturing the trend of the load sharing effect between the two subsystems (steel frame and CLT) and also the cumulative energy dissipation at all test cycles.

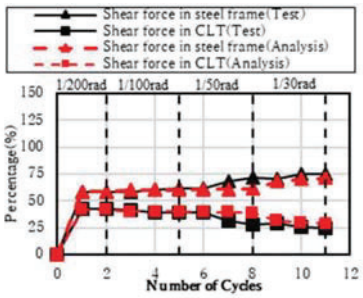

Figure 16: *Load sharing effect (Test vs. Analysis)*

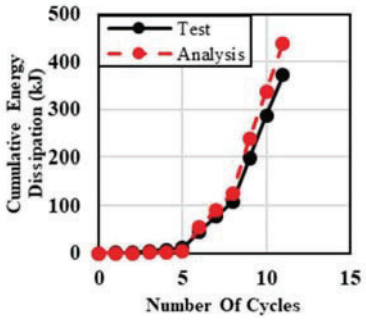

Figure 17: *Cumulative Energy Dissipation (Test vs. Analysis)*

6. CONCLUSIONS

This paper reports the experimentally observed and numerically simulated performance of a CLT-steel hybrid system using concealed steel plates and drift pins as wall-to-frame connections in different configurations. The load-displacement properties, failure mechanisms, equivalent viscous damping factors, and shear force sharing effect between the timber and steel subsystems were observed and discussed.

From the load-displacement properties, it was observed that significant increases in initial stiffness and maximum capacity for the bare steel frame could be obtained by infilling a CLT shear wall. At large deformations, most of the specimens were seen having an ultimate failure at the wall-to-frame connection, for example, shear failure of the bolted connection, buckling failure of the moment-bearing concealed steel plate, and detachment of the CLT panels from the moment-bearing concealed steel plate. As for the sharing of shear force between the CLT panel and the steel frame, the results showed that both of these components worked closely together to resist the lateral load. In general, the burden of resistance increased for the steel frame once damage developed in the CLT infill. Also, when the steel beam size was larger than the two under test (M frames as opposed to S frames), the steel columns could resist most of the lateral load due to the more effective transfer of load from the beam.

https://doi.org/10.52202/069179-0455

After the structural experiments were concluded, a non-linear finite element model was developed using SNAP V7.0 for the purpose of simulating the experimental results and as a basis for making further predictions. Three sub-models were made of the frame, the CLT panels, and the frame-panel connections, respectively, and combined to reproduce the experimental results accurately. The results of the numerical model did reliably agree with the experimental results. Such validation of the numerical model by the experimental results means that the model is a candidate to serve as a tool for designing such wood-steel hybrid structures, intended for applications as lateral load resisting systems for medium- to high-rise buildings in Japan. In addition, for further studies, the numerical model may be used to conduct seismic analyses to determine appropriate R-factors, which are required when designing such structures.

INVESTIGATION OF A NOVEL TIMBER-MORTAR CONSTRUCTIVE SYSTEM

Andrea Polastri[1], Riccardo Fanti[2], Pietro Rigo[3], Efrem Demarchi[4]

ABSTRACT: Timber constructions are well-know because are able to guarantee structural safety and easy assembling as well as high level of thermal insulation and living comfort. The new challenge is to enhance the use of local resources and starting to design the whole building in order to permit to dismantle and reuse/recycle the different elements/materials at the end of building-life. A constructive technology that can answer to all the aforementioned requirements is represented by a timber-mortar composite structures recently proposed. The use of timber-masonry structures belongs to the European tradition and different typologies of wooden frame infilled with masonry or with clay/mortar have been used all over the world. This paper analyses the mechanical behaviour of a new concept of timber frame wall infilled with lime mortar: experimental results show that, for low-rising buildings, the presented system is a valuable alternative to timber shear-walls (e.g. Light Frame Timber or Cross Laminated Timber). Furthermore, the studied system permits to use small-section timber elements that can be easily obtained sawing local wood; moreover, indoor air quality and living comfort are guaranteed using, for the whole construction, only few natural row materials such as wood, lime, clay and hemp.

KEYWORDS: Use of local wood, Wooden frame, Timber-mortar wall, Reuse-Recycle, Experimental test.

1 INTRODUCTION

In the last decades the use of timber in constructions has constantly increased, driven by the physical-mechanical properties of wooden products: the very high strength-to-density ratio of wood makes it extremely competitive for buildings constructions in seismic-prone areas. Moreover, the thermal properties of wooden panels can be exploited to improve energy efficiency of new residential buildings. Light-Frame Timber (LFT) and Cross Laminated Timber (CLT) represent the most widely used timber technologies, in particular, LFT give the possibility to prefabricate the entire wall (structure, insulation and also electrical and plumbing systems) while CLT panels are becoming strong engineered and industrialized products. Recently both research institutes and the productive sector have been starting to study and propose timber constructive systems able to ensured structural safety, high level of thermal/acoustic insulation and, at the same time, to improving the living comfort (i.e. optimal thermo-hygrometric indoor conditions and quality of air indoor). Contextually, the main challenge is to re-design the entire building process in order to increase the use of wood grown in areas close to construction site. The use of local resources (e.g. wooden row material) and an appropriate study of the end-of-life phases as the dismantling/disassembling and the reuse/recycle are critical points that have to be considered.

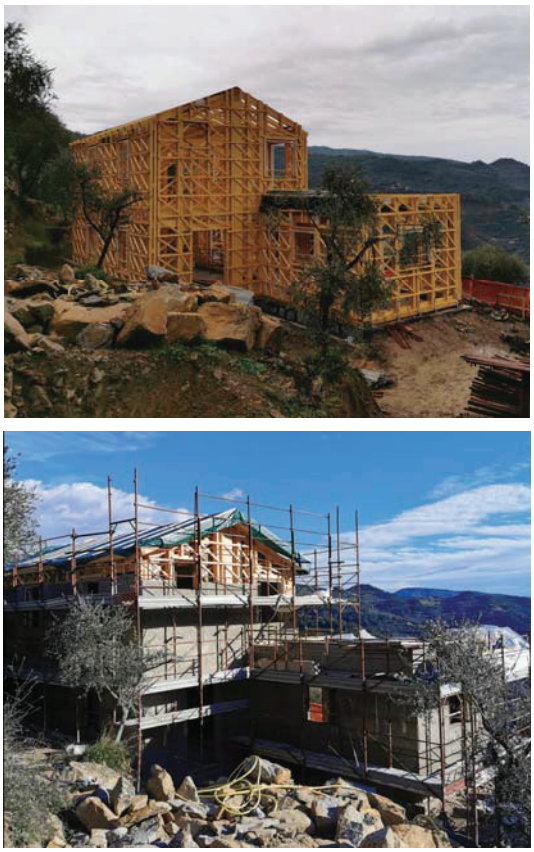

Figure 1: *Example of timber-mortar constructive system use; prefabricated only-timber frames assembled on-site (above) and building during the pouring of lime mortar (below)*

A valuable solution is to distinguish the different function of the building elements adopting engineered materials and high-technology connections for the bracing systems, able to guarantee the stability of the structure even in case of earthquake, while secondary elements could be obtained with timber elements composed by row wooden material. Another way is represented by the use of only-natural material (i.e. wood, mortar, brick, etc…) and, where necessary, steel connections which have to be separated and recycled as used-iron at the dismantle phase. With these materials it is possible to obtain all the building elements both structural/non-structural walls and horizontal floors/roof.

This paper will discuss the possibility to erect low-rising buildings with a novel constructive system named "*Nidus*" that belong to the second category being the whole building composed by timber elements infilled with mortar. More than 20 low-rise buildings (up to 3 storeys) have been realized in Italy in the last decade with this technology. Starting from the state of the art, the new timber-mortar system will be presented and results of an experimental mechanical tests campaign will be discussed.

2 STATE OF THE ART

Timber frame structures with masonry infill, also called "half-timber" buildings, have been used all over the world. The main reasons for this widespread diffusion are certainly the easy access to materials, the simple construction method and the good seismic response. Examples of this kind of structures can be found in many European countries, especially in seismic prone areas: "*fachwerk*" (North-Central Europe), "*gaiola pombalina*" (Portugal), "*casa baraccata*" (South Italy), "*lefkada*" (Greece), "*hatil, himiş* and *bağdadi"* (Turkey). Other examples of timber frames with mansory infill can be found in other regions all over the world: *"taq* and *dhajji-dewari"* (Kashmir, India), "*assam-type structure"* (Himalayan region), *"chuan-dou timber frame"* (Southwest of China), *"kay peyi"* (Haiti) and *"tapial, adobe and quincha"* (South and Centre America).

As pointed out by Langenbach [1], it's relevant to observe that some of these structural systems were specially developed and selected as earthquake-resistant construction. In Lisbon (Portugal), after a disastrous earthquake in 1755, the construction system called "*gaiola pombalina*" was used for the reconstruction of the city. This structural system consists of a three-dimensional wooden frame, braced with wooden elements and filled with stones and bricks. The inspiration for this technique came from the observation that the half-timber type constructions had withstood better the earthquake [1] than the "only" masonry structures, thanks to their deformability. In the southern part of the Calabria Region (Italy), after an earthquake in 1783, a system constituted by masonry reinforced with timber frames, called "*casa baraccata*", was indicated from the government as an essential requirement to ensure safety [2]. An comprehensive collection of articles concerning the seismic behaviour of *half timber buildings* in the Mediterranean area, experimental tests and numerical modelling is presented by Ruggieri et al. [3]

Recent seismic events (Turkey in 1999, Greece in 2003, Kasmir in 1967 and 2005, Haiti in 2010) have highlighted the good seismic response of these mixed constructions. For this reason, some research projects have been conducted in order to improve the knowledge regarding the seismic resistant behaviour of this kind of traditional wood frame structures. Makarios et al. [4] studied the seismic response of the traditional buildings of Lefkas Island in Greece observing a good seismic behaviour. Dogangun et al. [5] and Gülhan et al [6] observed an excellent seismic response of traditional buildings after the earthquake occurred in Kocaeli and Duzcedel (Turkey) in 1999. Kaushik et al. [7] reported about the better behaviour of traditionally constructed timber-masonry structures compared to reinforced concrete structures during the Sumatra earthquake in 2004. Kaushik et al. [8] observed that both masonry and reinforced concrete buildings showed poor performance during the Sikkim (India) earthquake of 2006, while traditionally constructed half-timber houses showed acceptable damage.

Several experimental studies on the behaviour of traditional half-timbered walls are available in literature. Four modules of a timber crossed frame without masonry infill and three identical modules with masonry infill have been tested by Ferreira et al. [9] under horizontal and vertical load and compared with numerical models. Three different types of half-timbered walls (unreinforced, retrofitted with GFRP sheets and filled with brick masonry) have been tested by Vasconcelos et al. [10], the latter showing high values of ductility. Half-timber walls build in real scale were tested under cyclic load by Poletti et al [11] considering two different infill typologies, as well as the possibility of having no infill, showing that the presence of infill increases the cyclic stiffness, as well as the energy dissipation and the ductility. Two full-size of a "*gaiola pambolina*" walls, were tested in a cyclic manner by Dutu et al. [12] showing a good in-plane behaviour of the timber–framed masonry system and significant deformation capacity. Meireles et al. [13] conducted cyclic shear testing to study the hysteretic behaviour of the interior wooden walls of the half-timber "*gaiola pambolina*" building in Portugal, showing non-linear load–displacement responses and high ductility. A full-scale replica of "*casa baraccata*" wall has been tested under quasi-static cyclic load by Ruggieri et al. [14] and Sandak et al. [15], at CNR-IBE laboratory in San Michele all'Adige – Italy. Ali et al. [16] conducted in-plane quasi-static cyclic tests on three full-scale "*dhajji-dewari"* building walls and monotonic tensile and bending tests on connections, showing that the masonry infill does not increase the lateral load capacity, but it has an effect on the energy dissipation capacity of the system. Two distinct geometrical variations of "*quincha*" were tested by Quinn et al. [17] with and without the infill, showing that the infill increases stiffness and capacity, 4.5 and 2 times respectively. Chand et al. [18] conducted an experimental campaign on seven different connections generally adopted in "*assam-type*" houses using cyclic tests and pull-out tests showing high deformability and ductile behaviour. Cyclic tests were

performed by Liang et al [19] on three "*Chuan-dou*" timber frame models with a scale of 1:2 with and without infill. Experimental analysis of seismic resistance of Haitian timber-framed structures with stones-earth infill called "*kay peyi*" were performed by Vieux-Champagne et al. [20] at CNR-IBE Laboratory demonstrating the high ductility of the filled wood structures.
Novel composite wooden-masonry or wooden-mortar walls have been proposed and used in different European countries. Bettini [21] studied the use of partitioned *adobe* infills in association with timber frames. Recent studies have highlighted the possibility to use hemp cement as infill in low-rise timber buildings [22-26].
All the aforementioned studies agree with the fact that the composite timber-masonry or timber-mortar structures lead to an optimal overall behaviour: framed timber structure is loaded by vertical/horizontal loads and, at the same time, confines the masonry/mortar infill which collaborate in order to stiffen the wall and to transmit the vertical/horizontal loads to the foundation; furthermore, the infill element is able to guarantee good thermal performances during the summer season, thanks to the mass given by infilled material.

3 THE COSTRUCTIVE SYSTEM

Nidus timber structure is given by "balloon-frame" prefabricated wooden truss elements (maximum width 2,5m) modules that are assembled at the factory and jointed together at the construction site.

Once defined the architectural concept of the building, timber prefabricated modules, that will compose the different walls, have to be designed. A complete 3D model (Figure 2) have to be implemented and all the wooden elements, needed to assemble the prefabricated truss, have to be drawn and verified.

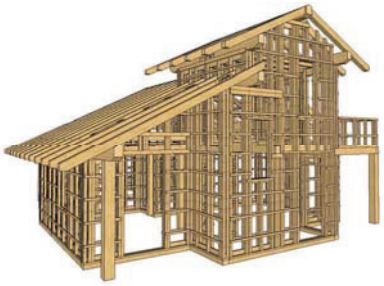

Figure 2: *Nidus constructive system, 3D model*

According to the 3D design, the carpentry/factory can cut manually or through a CAD-CAM process and CNC machines all the small-section wooden elements. Typically, the vertical wooden elements are 80mm x 80mm, while horizontal and diagonal are 80mm x 30mm. An horizontal beam is expected at the inter-storey level in order to support the floor beams (e.g. 160mm x 240mm) that will be inserted and screwed to the continuous vertical elements at the construction site.
Different members are jointed together with 5mm diameter screws according to the assembling drawings (Figure 3): the carpentry/factory can use the well-known steel modular frame developed for LFT prefabrication.

Figure 3: *Nidus balloon-frame prefabricated modules*

The preassembled elements, identified by a numerical code, that clearly indicate the position, can be easily moved by simply use of lifting belts. Once placed in the right position the studs are anchored to the pre-casted concrete foundation with commercial hold-down (uplift forces) and the bottom beams is connected to foundation with standard concrete bolts (shear forces). Modules can be screwed one to each other in order to avoid gap between the vertical elements. Typically the last horizontal closure is a standard timber inclined beams roof (Figure 4). By this doing in a couple of days the whole structure is erected.

Figure 4: *On construction site: Nidus modules assembled*

In order to obtain the complete wall-system, wooden-cement panels have to be stapled on the external faces of the timber frame. Finally, the empty area between panels is infilled with mortar composed by a mix of lime, perlite and hemp (Figure 5) characterized by a density equal to 350÷450 kg/m^3, as the softwood used for the structure.

Figure 5: *Detail of Nidus wall during mortar casting*

Is important to note that, according to the *Nidus* constructive systems, the casted lime mortar creates a continuous layer that wrap the entire building running both on the vertical external surface (walls) both on the external horizontal surface (roof) giving a unique layer of

https://doi.org/10.52202/069179-0456

thermal insulation and natural air tightness (no membrane/tapes are required), see Figure 6.

Figure 6: *Lime mortar casted in the space between floor beams (up) and on the top of the roof (below)*

4 FULL-SCALE TESTS

Full scale tests were carried out to investigate the mechanical behaviour of the timber-mortar wall system in particular *only-timber* frame (Figure 7, left) was tested according to the EN 594:2011 [27] monotonic procedure, furthermore complete *wall-systems* (Figure 7, right and Figure 8) were tested both according to monotonic and cyclic protocols, EN 594:2011 [27] and EN 12512:2001 [28], respectively.

Figure 7: *Full scale tests on only-timber frame (left) and complete-wall system (right)*

The *only-timber* specimen (Figure 7, left) is a timber frame composed by small wooden elements (vertical elements 80mm x 80mm, horizontal elements 100mm x 28mm and diagonal elements 60mm x 28mm) assembled with 5mm diameter screws. In order to realize the complete *wall-system* specimens (Figure 8), the procedure described in Section 2 was applied to two further *only-timber* specimens: external panels were stapled and the mortar was casted; two months later, tests were performed. Specimens were realized respecting exactly the procedure given by *Nidus* constructive system.

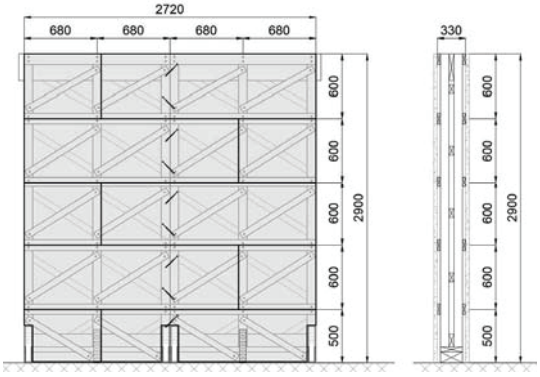

Figure 8: *Complete wall-system, geometry and connections*

Consistently with the provisions reported in EN 594 a series of transducers was applied to the tested specimens, as shown in Figure 9. A Linear Variable Displacement Transducer (LVDT), named LPM057, measured the horizontal displacement at the top corner of the wall. According to [27] these displacements are required to calculate the racking stiffness of the specimen. Two LVDTs (LPM052 and LPM053) measured the diagonal displacements of each module which forms the wall. A LVDT (LFV033) was placed at the centre of the wall in order to measure the relative vertical displacement between the two modules. Two LVDTs, LPM055 and LPM056, measured the uplift of the wall at the hold-downs positions, as shown in Figure 6. In cyclic test the same transducers were applied.

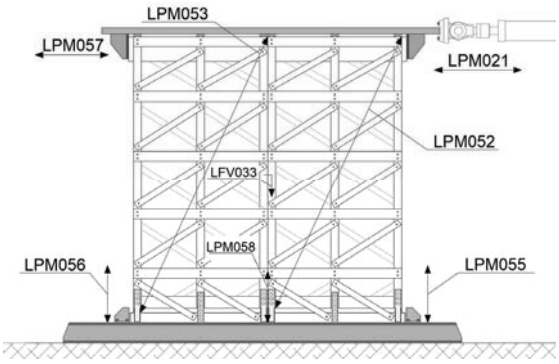

Figure 9: *The complete-wall system at the end the test*

The timber frame was anchored to the steel foundation with 4 couples of hold down (4 hold downs at both side of the wall), in order to avoid rigid rotation due to uplift forces, while the horizontal sliding is prevented by a steel rigid element (bolted to the steel foundation) in contact with the bottom wooden beam (Figure 10).
All the performed tests were stopped once reach the maximum displacement given by EN 594:2011 [27] equal to 100mm. At the end of the test the *only-timber* specimen did not show any failure because the high deformability of the structure given by the large displacements permitted by the ductile behaviour of the timber-timber screwed connections.

https://doi.org/10.52202/069179-0456

Figure 10: *The complete-wall system at the end the test*

Observing *complete-wall* specimens, both in case of monotonic and cyclic test, it was not possible to see any failure because the inner mortar layer was covered by the external panels. At the end of the tests, in order to identify possible local failures a visual analysis was performed removing a couple of panels: it was possible to recognize the cracks developed at the mortar-wood contact surfaces, see Figure 11.

Figure 11: *The specimens after the test: lateral panel removed in order to analyse mortar status*

The results of the experimental campaign were reported in Table 1 in terms of failure mode, stiffness k, maximum load F_{max} and corresponding displacement v_{max}. A comparison between load-displacement curves are reported in Figure 12.

Table 1: *Mechanical parameters of the tested specimens*

ID	wall-system	protocol	k [kN/mm]	F_{max} [kN]	v_{max} [mm]
1	only-timber	monotonic	0,3	21,6	96,6
2	timber-mortar	monotonic	5,9	82,7	87,8
3	timber-mortar	cyclic*	3,1	75,9	99,4

*mechanical parameters are referred to backbone curve of the first quadrant

Experimental results demonstrate, comparing the complete *wall-system* to the *only-timber* specimens, the high contribution to load-carry capacity (+400%) given by the infilled mortar; stiffness increases more than ten times. In particular, monotonic test on timber-mortar wall showed comparable strength and higher stiffness as the double-sheeted LFT, studied by Grossi et al [29,30], characterized by nails 2.8x60mm spaced at 50mm. Is noteworthy that LFTs showed high loss of strength, due to sheeting nail failure, in a range of top displacements between 40mm and 60mm. At the opposite the studied wall showed a continuous increase of strength until the end of the test (at an imposed displacement equal to 100mm).

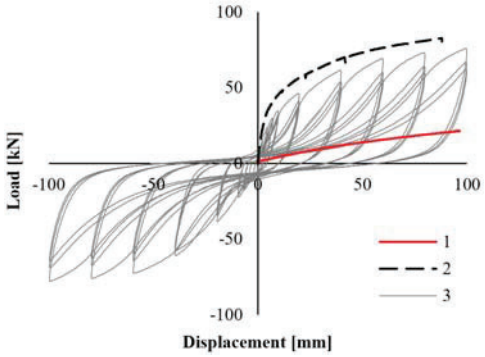

Figure 12: *Load-vs-displacement curves of monotonic and cyclic tests*

Figure 12 showed that the mortar infilled in timber-frame (complete *wall-system*) provided a not negligible contribution, in terms of strength and stiffness, associated with a good capacity of energy dissipation. These contributions are not considered in the design phase yet due to the lacking of a calculation method for *complete-system*. Nowadays practitioners design the timber-mortar walls as *only-timber* frame structure, consistent with EN1995:2004 [31] provisions and so, the contribution of the infilled mortar is neglected. The analytical calculation underestimates the strength, stiffness and energy dissipation capacity of the *complete-system;* hence further studies and tests are required in order to fully-characterize the mechanical properties of the presented constructive system.

5 CONCLUSIONS

This paper presents a new constructive system that uses timber frame structural walls infilled with lime mortar. Results of experimental campaign on a full scale shear walls are presented and discussed: the study considered both *only-timber* truss wall and timber-mortar walls. Monotonic and cyclic test were performed. Strength and stiffness showed by the complete timber-mortar wall are comparable with the mechanical properties of a typical LFT; furthermore an higher ductility was shown by timber-mortar walls. Timber-mortar constructions guarantee high comfort and quality of indoor living given by the use of only natural raw material, such as wood, lime, perlite and hemp. The presented constructive system can be considered as valuable alternative to traditional structural timber shear-wall for low-rising buildings.

SHEAR PERFORMANCE OF STRUCTURAL PARTICLEBOARD-SHEATHED LIGHT-FRAME WALL

Chul-Ki Kim[1], Min Lee[2], Kugbo Shim[3]

ABSTRACT: The National Institute of Forest Science developed structural particleboard (PB), which is made of domestic wood, to substitute for imported OSB (Oriented Strand Board) used as a structural sheathing panel in light-frame construction. To investigate whether structural PB could be used as sheathing panel of light-frame wall or not, shear resistance of light-frame wall sheathed with structural PB compared with that of light-frame wall sheathed with OSB. Shear resistance was evaluated using a hysteresis curve by applying a quasi-static load. Shear strengths of wall sheathed with OSB and PB were 7.9 and 8.7 kN/m, respectively. It was confirmed that secant shear modulus for OSB and PB walls at 40% of the maximum load was 2.4 and 3.7 kN/mm, respectively. In addition, ductility was shown as 8.3 and 10.0 in OSB and PB walls, respectively. It was confirmed that shear resistance of PB wall was higher than that of OSB wall. From the results in this study, it is considered that structural PB manufactured using domestic wood can be used for sheathing material of light-frame construction, and it is expected that it can contribute to the national carbon stocks.

KEYWORDS: Light-frame wall, Shear resistance, OSB, Structural PB

1 INTRODUCTION

Korean wood building market is a little bit small compared with North America, Japan and etc., but constant. Since 2009, about 10,000 houses per year have been commenced steadily. From the statics about total floor area commencement, small houses having a total floor area of about 100 m^2 dominate in Korean wood building market. Because of economical and easy-to-build construction, light-frame construction is normally used for small houses.

Problem is that imported wood or wood-based products are usually used for light-frame construction in Korea. So, that need to develop substitute for the imported products occurred in view of the carbon-neutral and increasing price of materials. Because of climate crisis, increase of construction material made by domestic wood is required. By using HWP (Harvested Wood Products), it can take advantage of compliance with UNFCCC (United Nations Framework Convention on Climate Change) through carbon fixation and GHG (Green House Gas) substitution effect. On the other hand, the price change of imported dimension lumber and OSB (Oriented Strand Board) increased rapidly after COVID-19. Compared with 2020, the price of dimension lumber and OSB after COVID-19 are 2.9 and 2.7 times higher in Korea.

The National Institute of Forest Science has developed structural particleboard (PB) to substitute for imported OSB since 2020. Considering the scale of PB industry in Korea, it was concluded that it was advantageous to make a structural PB first. In a previous study, it was confirmed plant production possibility for structural PB. In this study, therefore, the shear resistance of structural PB was investigated whether structural PB could be used as a sheathing panel in light-frame construction.

2 MATERIALS AND METHOD

2.1 WOOD FRAME MATERIALS

For wood frames, dimension lumber of 2 by 6 was used, and the species was SPF. the grade of dimension lumber was 2 and better. The Structural PB was manufactured to be suitable for domestic industry conditions. A MFU (melamine-urea-formaldehyde) resin adhesive and isocyanate were used to provide water resistance. The ratio of the surface layer to the middle layer of the structural PB was 40:60, and the target density was set to 700 kg/m^3. The hot press conditions were a temperature of 200 ℃ and a time of 7.3 s/mm, and the amount of pressure was 50 kgf/cm^2. OSB imported from North America for rate sheathing was also used to compared to structural PB. The span rating of OSB was 24 per 16 inches.

2.2 ASSEMBLY WOOD FRAME

To assemble wood frame, nailing such as nail size, number of nails, nailing spacing, etc. was done in accordance with ASTM E72. Sheathing panel was attached to the dimension lumbers by using 8d common nail at 150 mm one center at the center of a panel and at 300 mm one center at the edge of a panel, respectively. In case of nailing distance from the edge of panel, different nailing distances for each panel were used for preventing occurrence of failure in the edges. For OSB, nailing distance from the edge of panel was 10 mm, on the other hand, the nailing distance was 15 mm for structural PB. Total size of shear wall was 2,440×2,440 mm. The center distance between studs was 610 mm. Figure 2 shows shear wall configuration.

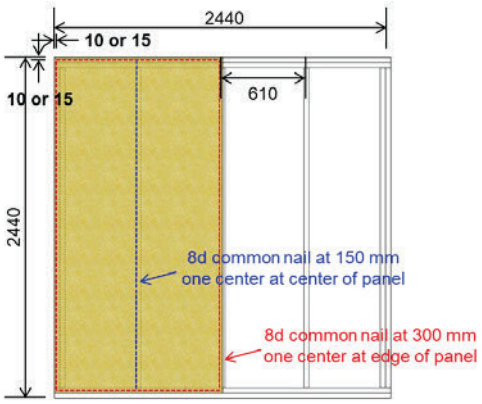

Figure 2: *Shear wall configuration (unit: mm)*

2.3 EVALUATION OF SHEAR RESISTANCE

Two hold-downs and anchor bolts were installed to fix test equipment (Dongyang, Korea). To prevent bulking during evaluation of shear resistance, four lateral supports were set up as shown in Figure 3. ISO 16670 protocol as quasi-static load in accordance with ASTM E2126 was applied to evaluate shear resistance. In the protocol, ultimate displacement was 83.3 mm, and it was determined from previous static shear wall test. The displacement pattern consists of phases, each containing three fully reversed cycles of equal amplitude, until 120 % of the ultimate displacement.

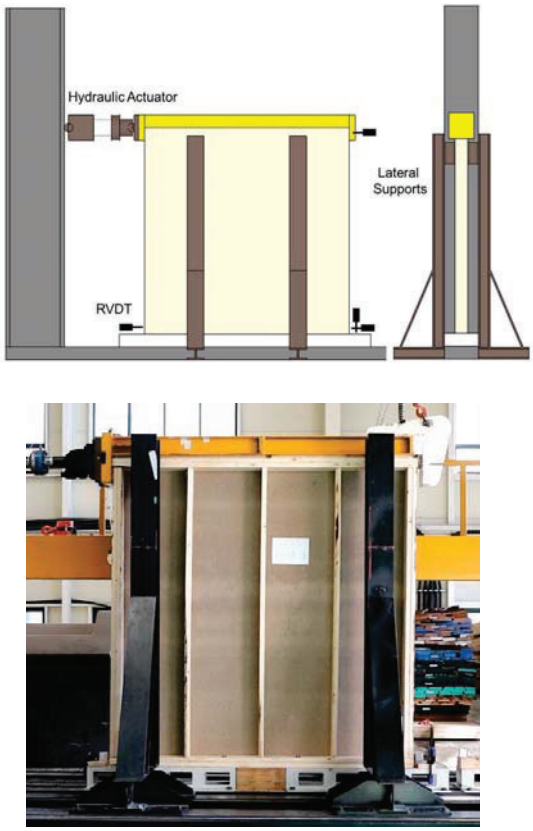

Figure 3: *Shear wall test setup (top) and picture (bottom)*

Envelop and EEEP (Equivalent Energy Elastic-Plastic) curve obtained hysteresis curve were used to calculated shear resistance such as shear strength, secant shear modulus at 0.4 of peak load and peak load, and ductility ratio. Each value for evaluating shear resistance was calculated as follows,

$$v_{peak} = \frac{P_{peak}}{L} \tag{1}$$

$$G' = \frac{P}{\Delta} \times \frac{H}{L} \tag{2}$$

$$D = \frac{\Delta_u}{\Delta_{yield}} \tag{3}$$

where, v_{peak} = shear strength (N/m), P_{peak} = maximum load resisted by the specimen in the given envelope (N), L = length of specimen (m), G' = shear modulus of the specimen obtained from test (N/mm), P = applied load, 0.4 of peak and peak load, measured at the top edge of the specimen (N), Δ = displacement of the top edge of the specimens as applied load based on test (mm), H = height of specimen (m), L = length of specimen (m), D =

https://doi.org/10.52202/069179-0457

ductility, Δ_u = ultimate displacement (mm), Δ_{yield} = yield displacement (mm). Detail calculation of shear resistance of wall can be confirmed in ASTM E2126.

3 RESULTS AND DISCUSSION

Figure 4 and 5 shows hysteresis, envelope, and EEEP curve for light frame shear wall sheathed with OSB and structural PB, respectively. As it was considered that the difference of positive and negative envelop curve was small for both shear wall sheathed with OSB and structural PB, average envelop curve was used to calculate shear resistance. The maximum difference of peak load was 8% for structural PB shear wall in the group of shear wall test.

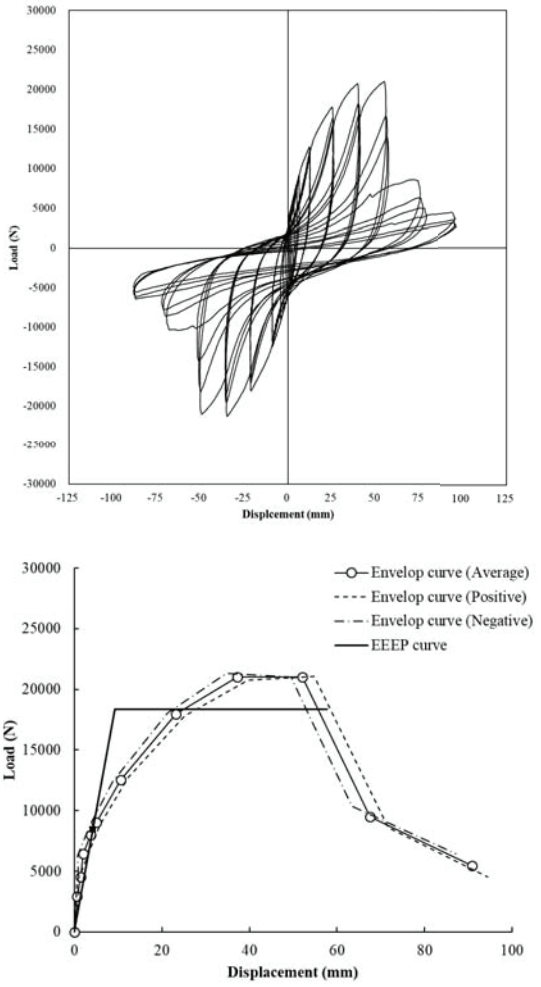

Figure 4: *Results of shear wall test of OSB sheathed light-frame wall*

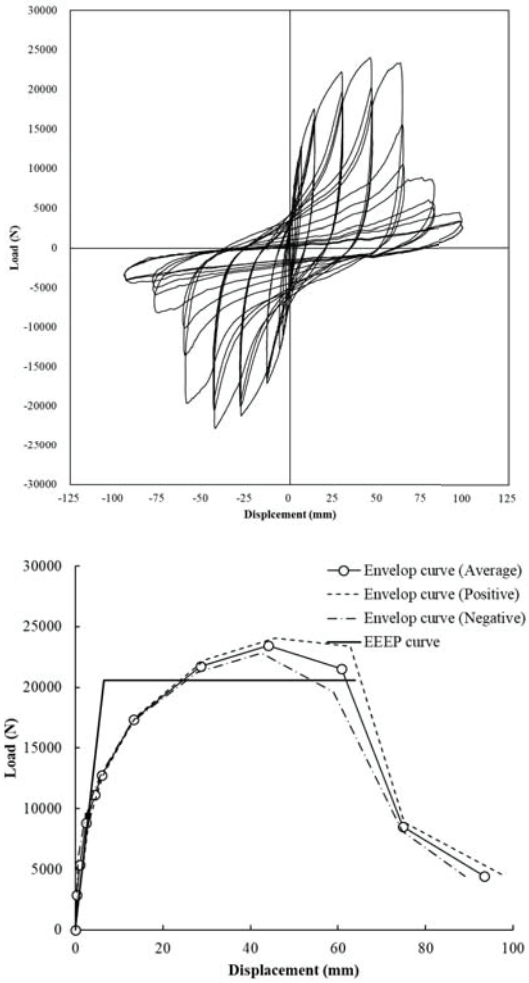

Figure 5: *Results of shear wall test of structural PB sheathed light-frame wall*

Table 1 presents the average shear resistance of wall according to the type of panel. Shear strength and secant shear modulus at 0.4 of a peak load for OSB wall were 7.9 kN/m and 2.3 kN/mm in the first order of cycles, respectively. The order of cycles means a sequence among three fully reversed cycles of equal amplitude in ISO 16670 protocol. As the order of cycles increased, shear strength decreased in case of OSB wall. But the result of ductility was inconsistent. As the order of cycles increased, ductility of OSB wall increased. The shear modulus at peak load was nearly constant regardless of the order of cycles. The shear strength and secant modulus at 0.4 of a peak load for structural PB wall were 9.0 kN/m and 3.0 kN/mm in the first order of cycles. Results of shear strength, shear modulus, and ductility according to the order of cycles is consistent in the case of that OSB wall.

https://doi.org/10.52202/069179-0457

Table 1: *Average shear resistance of wall*

Type		v_{peak} (kN/m)	G (kN/mm)		D
			$0.4P_{peak}$	P_{peak}	
OSB	Cycle 1	7.9	2.3	0.5	8.3
	Cycle 2	7.1	2.7	0.5	9.9
	Cycle 3	6.7	2.9	0.4	10.6
PB	Cycle 1	8.7	3.7	0.5	10.0
	Cycle 2	8.1	3.4	0.6	10.8
	Cycle 3	7.3	3.7	0.6	11.9

The difference of shear strength between the first order cycles and the third order of cycles was 1.28 kN/m for OSB shear wall, and 1.43 kN/m for structural PB shear wall. From the difference, it was concluded that structural PB shear wall had better toughness property than OSB shear wall. As Toothman (2003) reported toughness is positive relation with energy absorb, it was considered that structural PB shear wall had advantage considering the ground motions produced by earthquakes. It was confirmed that shear resistance of structural PB wall is better than that of OSB wall for all order of cycles. It meant that structural PB wall has higher load capacity with less displacement and higher energy absorption capability.

Figure 6, 7, and 8 show failure mode during shear wall test. Regardless of the type of panel, the same failure modes were detected. One was nail shear failure between wood frame and panel, the other was bending of wood frame members within an elastic region.

Figure 6: *Failure mode (Nail shear failure) during OSB shear wall test*

Figure 7: *Failure mode (Nail shear failure) during PB shear wall test*

Figure 8: *Failure mode (bending of stud in wall) during PB shear wall test*

In this study, the walls anchored fully by holddown were test. Because of that, uplift forces are transferred from the sheathing into the studs and then directly into the foundation (Seaders *et al.*, 2008). Therefore, it was concluded that the location of nail shear failure was sheathing-to-stud at edge of wall. Nail shear failure in structural PB shear wall occurred frequently compared with OSB shear wall. Moreover, Nails in the structural PB did not pull out as easily. So, it enabled the friction to continue to dissipate more energy in case of structural PB shear wall.

Because structural PB is more brittle than OSB, nailing distance from the edge of panel in structural PB is 5 mm more than that in OSB. The expected nail shear failure was achieved by increasing the nailing distance from the edge of panel in PB wall. From the results of failure modes, the theory for estimating shear resistance of OSB wall might be used to predict shear performance of structural PB wall.

4 CONCLUSION

Compared with OSB wall, shear resistance of structural PB wall was higher. In the first order of cycle, shear strength, shear modulus and ductility of structural PB wall were 1.1, 1.3 and 1.1 times higher than that of OSB

https://doi.org/10.52202/069179-0457

wall. It is expected that structural PB made by domestic wood can contribute to achieving carbon neutral in the building sector.

Deployable Wood Structures for Disaster Relief and Military Use

Jayson Leonard[1], Weichiang Pang[2], Michael Stoner[3], Dustin Albright [4]

ABSTRACT: Rapidly deployable structures may be used to speed up the recovery after natural disasters and to provide shelters for military personnel in hostile zones. The recent unforeseen disruptions caused by the COVID pandemic highlighted the needs for temporary testing centers or backyard pop-up offices. This paper investigates the development of deployable wood structures via four key factors, namely (1) deployability, (2) transportability, (3) functionality, and (4) cost. Currently, the military does not have an optimum design that excels in all the previously mentioned criteria. This study aims to design a rapidly deployable structure for emergency response such as disaster relief with the potential for military applications. This research begins by covering existing deployable shelters used for disaster relief and military applications. Next, it presents several alternative designs using different materials and different functionality. Then, it addresses how these new designs compare to the existing shelters in each category. Finally, it discusses tests performed on the folding mechanism being used throughout the design of a deployable wood structure. As a result of the study, new designs are shown to be competitive with the existing ones. The results of an experimental study of how hinges perform as structural elements will be discussed.

KEYWORDS: Cross-Laminated Timber, Deployable Structure, Disaster Relief, Military Shelters, Hinge

1 INTRODUCTION

As a society, we have all come to realize it is not always possible to know when disaster will strike. Disaster can take the shape of many forms including but not limited to, natural disasters, man-made disasters, war, and more recently, pandemics. When these events happen there is potential for people to be displaced from their homes and resources to be overwhelmed. This immediately calls to action the need for new structures, such as temporarily shelters and medical facilities. To build one of these from the ground up can be time-consuming and demanding for labor and materials. Therefore, the use of prefabricated or deployable structures could be put into place instead. The two primary uses for these structures investigated in this study are post-disaster and military applications.

The U.S. military currently has both expandable and non-expandable rigid wall tactical shelters. For easier reference, National Stock Number, which is an identifying number assigned to materials and items, is used by the U.S. military to identify a shelter. One example of an expandable unit is shelter designated NSN 5411-01-136-9838, an expandable unit with interior dimensions (expanded) of 18’ 4” L x 21’ 6” W x 7’ 1” H (Figure 1). The nonexpanded exterior dimensions are 19’ 11” L x 8’ W x 8’ H. This unit has a weight of 6900lbs and an assembly time of only 30 minutes with four soldiers. These units are designed to have dimensions consistent with a standard ISO shipping container of 20’ L x 8’ W x8’ H. This allows for easy and consistent transportation methods. These units are also made from steel which gives the units a rugged and durable finish. Along with traditional transportation methods, the military may also drop these units from aircraft with parachutes.

Figure 1: *An Example of Expandable Rigid Wall Shelter (NSN 5411-01-136-9838)*

The U.S. military also utilizes soft wall shelters as a means of less permanent shelter. The soft wall shelters are typically a stretched fabric supported by either a frame or pressurized air. An example of a frame-supported soft wall shelter is NSN 5419-01-465-3025EJ. The dimensions for this unit assembled are 20’ x 32.5’. The weight of this unit is 1250 lbs., and the erection time is less than an hour with four soldiers. An example of an air-supported soft wall shelter is the Airbeam tent NSN 8340-01-558-8707 (Figure 2). This structure is supported by a series of Airbeams that are inflated onsite. The weight of this structure is around 1000 lbs. With the supplied compressor, the erection time is only 15 minutes with four

2 DESIGN OF STRUCTURES

The goal of this research is to design prefabricated and rapidly deployable structures using wood, a sustainable and renewable material. There will be four distinct shelter designs that fall under two separate categories. The two categories are construction material and deployment strategy. The material choices are light-frame wood construction or cross-laminated timber (CLT). The deployment strategies include non-foldable (static) and foldable (dynamic).

The need for rapidly deployable structures can be seen in many different environments and cases. This played a large role in the design of the structures and was one of the first areas of concentration. On the civilian side of this research, the expected mode of shipment is by land through the use of semi-trucks. In order to make shipment of these units as easy and seamless as possible, ISO standard shipping sizes played a large role in the design footprint (ISO, 2020). A twenty-foot-long unit became the basis of design due to standardization and practicality. The most typical 20 ft long shipping container is 8 ft wide x 8.5 ft tall. Another standard-size shipping container is known as the “high cube” container. These containers are 20 ft long x 8 ft wide x 9.5 ft tall. By moving up to the high cube size, the structures become more liveable and comfortable with more headroom. Table 1 shows the key dimensions of the static and dynamic structure types. The static unit does not fold; therefore, the folded dimensions are not applicable for this unit type.

Table 1: Dimensions of the Static and Dynamic Structures

Unit Type	Deployed			Folded		
	Length	Width	Height	Length	Width	Height
Dynamic	20'	19' 5"	8' 3"	20'	6' 8"	8' 3"
Static	20'	8'	9' 6"	NA	NA	NA

2.1 Static Unit

The static unit follows a shipping container-like design that conforms to ISO high cube dimensions. The unit is 20’ long x 9.5’ tall x 8’ wide. These units can be fitted out to take a role such as a housing or medical unit. Figure 1 shows a static unit being used as a temporary housing structure. With around 160 sq. ft. of living space, the unit is not abundantly spacious, however, the space that is provided is highly functional.

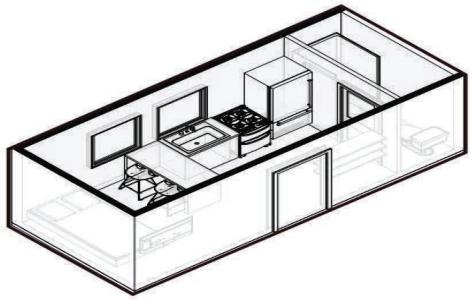

Figure 3: *A Floorplan for a Static Unit.*

2.2 Dynamic Unit

The dynamic unit is 20’ long x 8’-8” tall x 7’-3” wide when folded. When the unit is unfolded, it is 20’ long x 8’-8” tall x 21’-8” wide. Figure 2 shows one of many possible finished floorplans for a dynamic unit. The structure is supported only by the exterior walls allowing for the interior to be fully customized by the end-user. The top series of images shows the folding process. The bottom left image shows an exploded view of the entire unit, while the bottom right image shows the plan view of the floorplan.

By having both a static and a dynamic unit, users can choose based on their needs. For example, the end-user may prefer to have a static unit because it can be completely finished before shipment. Since the unit does not fold, all furnishings and finishes can be done before the end-user receives the unit. Also, there is no additional work once the unit is set on a foundation because the unit does not need to be unfolded. A dynamic unit may be chosen because they provide a larger liveable space that requires less room for storage and transportation.

When designing the dynamic unit, one of the first parts that needed to be figured out was how these units would expand and contract. There are many different strategies and designs that have been used in the past to achieve this task. For this research, continuous hinges were used as the folding mechanism. In addition, the hinges are designed to carry structural loads, namely, shear and uplift forces. By choosing hinges, the method of deployment would be through foldability of panels about the axis the hinge lies. This deployment method had many impacts on the design of the structure. One of which is the dimensions of each panel. Getting the structure within the ISO shipping standard sizes while also maximizing useable space took careful planning. Figure 3 shows the foldable unit in its final deployed state and locations of hinges needed for folding mechanism and for shear strength.

https://doi.org/10.52202/069179-0458

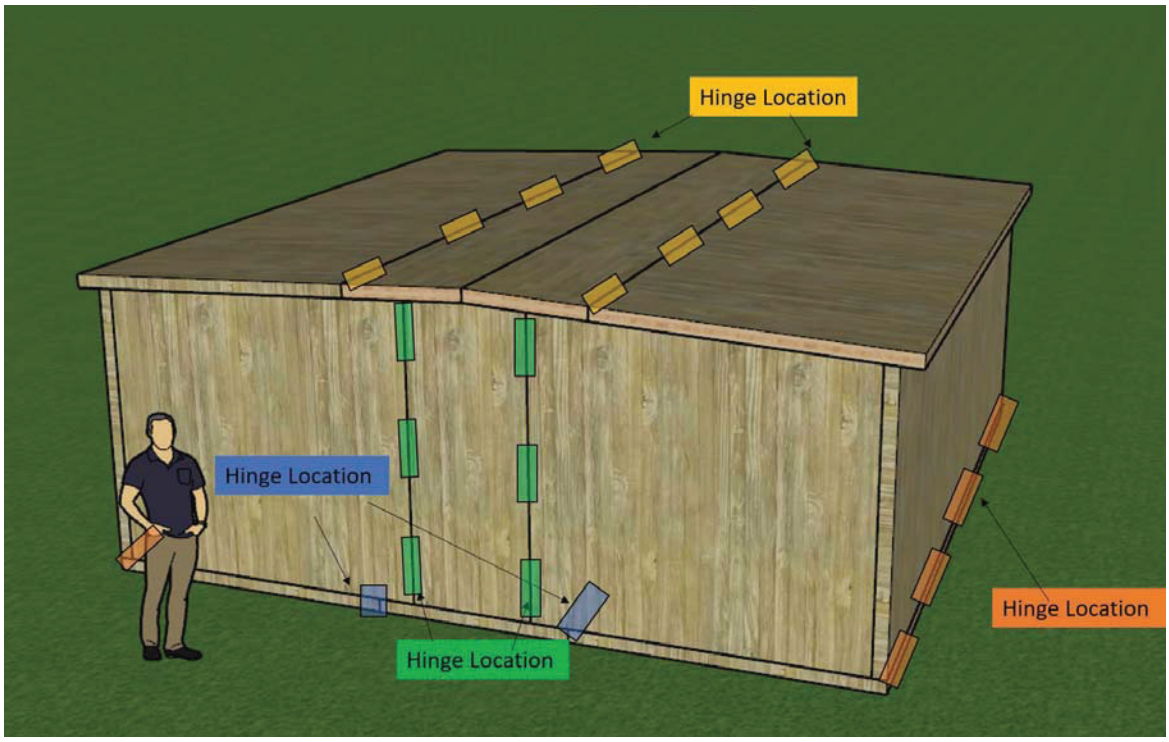

Figure 3: *Foldable Unit in Final Deployed State and Locations of Hinges Required for Foldability and Shear*

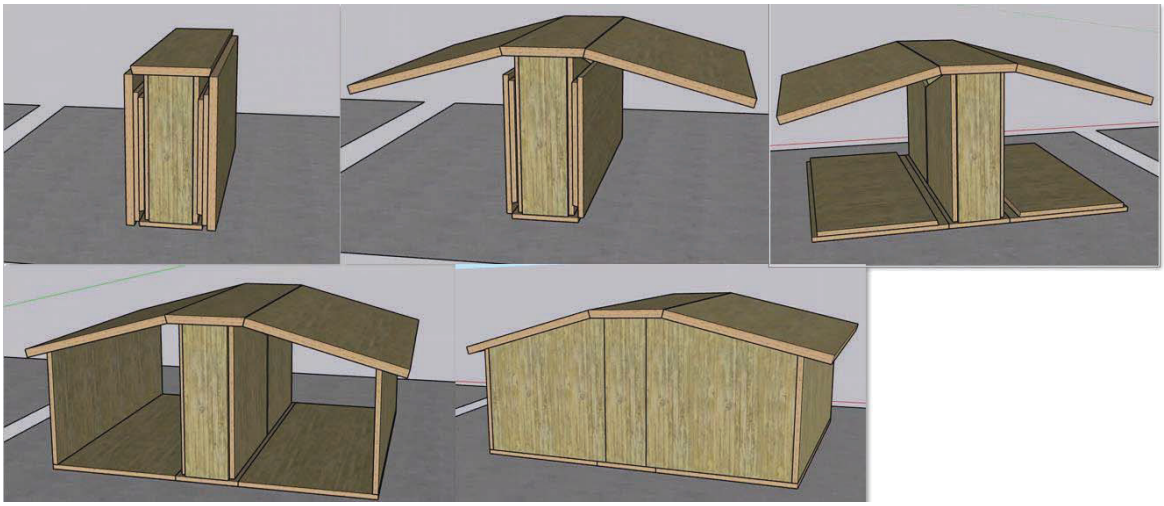

Figure 4: *Process of unfolding the dynamic unit.*

2.3 Light-Frame and Cross-Laminated Timber

Two materials are considered for both the static and dynamic units, namely light-frame wood and cross-laminated timber (CLT) panels. Light-Frame units are designed with traditional 2x dimension lumber or sawn lumber. The CLT units are designed using 3- and 5-ply Southern Yellow Pine CLT panels.

The static and dynamic units, each has its advantages and disadvantages. The light-frame units will be lighter than the CLT units allowing them to be transported and deployed more easily. Also, the light-frame units will have wall cavity space than can be filled with insulation which can provide a more comfortable and energy-efficient shelter. Light-frame units are also easier to hide electrical and plumbing within the walls. Also, since light-frame uses less wood than CLT, the final costs of these units are expected to be less than their CLT counterparts. The CLT models are much stronger and can be used in more extreme conditions. For example, CLT units should be able to provide greater resistance to threats such as blasts and ballistics.

https://doi.org/10.52202/069179-0458

3 EXPEIRIMENTAL TESTING

3.1 Hinge Testing

This research also contains load testing on hinges that will be used within the dynamic structures. The hinges' main role is to provide a means of rotation for individual panel elements. Typically, the hinges would be ignored as structural elements, however, there is potential to expand the use of the hinges to act as shear and hold-down connections for the wall panels. The hinges would also need to be able to take the moment and shear applied by the wall members during deployment. Therefore, by gathering data on the strength of the hinges, one will be able to identify the capacity of the hinge connections.

A series of tests were performed on hinges to determine the structural load carrying capacities. There were two hinge types that were used for the testing in this research, continuous style hinges, also known as piano hinges, and residential butt hinges. Table 2 shows the hinge types and properties. For simplicity of naming and referencing, each hinge type may either be referred to as hinge A or hinge B throughout this research. Figure 5 shows some key dimensions of each hinge type.

Table 2: *Hinge Properties.*

	Hinge	
Property	A	B
Hinge Type	Continuous	Butt
Leaf Thickness	0.12"	0.0855"
Pin Diameter	3/8"	15/64"
Length	12"	4"
Width	5"	4"
Screw Diameter	0.25"	0.137"
Screw Length	3.5"	1"

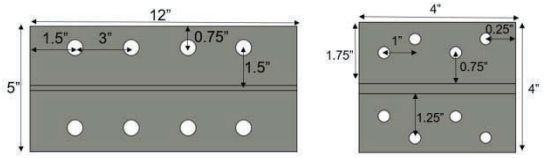

Figure 5: *Key Dimensions of the continuous hinge (left) and the butt hinge (right).*

Each hinge type was tested in two directions, loading parallel and perpendicular to the pin. Parallel to the pin tests will be referred to as shear tests, and perpendicular to the pin test will be called tension tests. Figure 6 shows a conceptual drawing of the directions each hinge was tested in. Multi-directional strength properties are important because the deployment stage will induce forces on the hinges. By completing these tests, the hinges could be incorporated into the structure's strength rather than ignored when in the deployed state. Along with the load tests performed on the hinges, there was also a material test performed on the leaf of each hinge. The material test provided key materialistic properties such as ultimate stress, yield stress, and modulus of elasticity of the steel used in the hinges. All these properties are important metrics when describing how a structural element performs. A summary of the load tests performed on the hinges can be found in Table 3.

Table 3: *Summary of Tests Performed on Hinges*

Test No.	Loading	Hinge Type
1A	Shear	A
1B	Shear	B
2A	Tension	A
2B	Tension	B

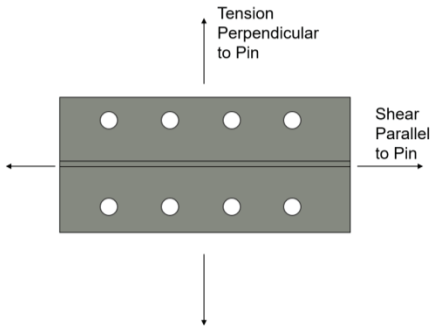

Figure 6: *Testing Directions on Hinges.*

3.2 Shear (Parallel to Pin) Test

Shear tests were performed on the continuous and butt hinge and are referred to as Test 1A and 1B, respectively. The shear tests were done to gather data on how these hinges would perform when loaded in the direction parallel to the pin. One way this type of loading could be observed in a structure is when shear is transferred from wall to floor panels. Both tests, 1A and 1B, were performed with cyclic loading. Cyclic loading is when a load is applied in one direction, then removed and applied in the opposite direction. The loading setup in both shear tests was set to follow CUREE standard loading protocol. Cyclic loading is often chosen over monotonic loading, single-direction loading without load removal, because it may represent loading caused by wind gusts or earthquake accelerations better. Figure 7 shows a conceptual drawing of the test setup for Test 1A (Shear of Continuous Hinge). Figure 8 shows the picture of Test 1A. 3-ply southern yellow pine CLT panels were used as the main member throughout these tests.

The string potentiometers were used to measure localized displacement, and the actuator was used to measure forces and displacements of the entire system. A displacement-controlled reversed cyclic loading protocol was utilized to perform the shear test. Figure 9 shows the force vs. actuator displacement of Test 1A. The figure also shows the expected design strength as well as measured stiffness. For the continuous hinge, Simpson Strong-Tie SDS screws were used to fasten the hinges to the CLT panels. The manufacturer provided the design ASD values, which are displayed in blue. The ASD value was then multiplied by the format conversion factor (K_F of NDS) to show a

https://doi.org/10.52202/069179-0458

non-factored LRFD value (green line). A strength reduction factor was not used because the goal was to try to estimate the test peak value rather than a design value. Figure 10 shows the failure mechanism of Test 1A.

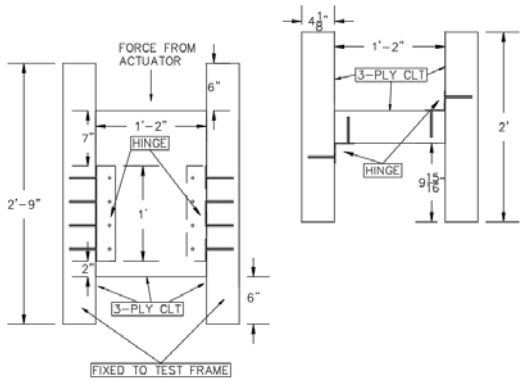

Figure 7: *Setup for Shear Test of Hinge Connection.*

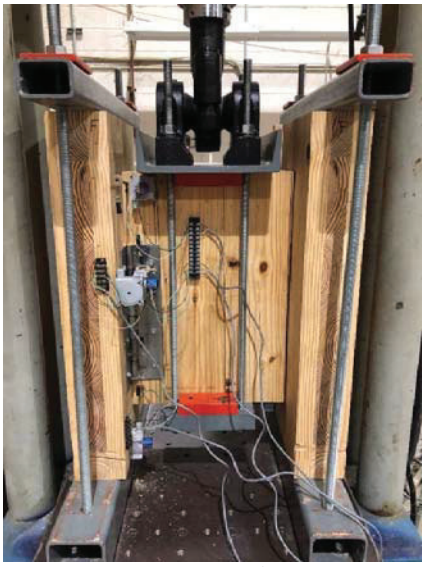

Figure 8: *Test 1A Setup and Instrumentation.*

The ultimate strength, yield strength, and initial stiffness of each hinge connection were determined from the test (Table 3). The ultimate strength was determined by identifying the peak force for the push and pull cycles. The yield strength was determined by offsetting the initial stiffness by 5% of the screw diameter (ASTM, 2018). The initial stiffness was determined by taking the slope of the initial part of the curve.

Table 3: *Summary Results of Shear Test 1A*

	Hinge A		
	Push	Pull	Average
Ultimate Strength (kip)	9.06	6.72	7.89
Yield Strength (kip)	5.08	3.12	4.1
Initial Stiffness (kip/in)	35.62	35.68	35.57
Initial Stiffness (kip/in)	18.1	21.9	20.0

Figure 10: *Failure in Test 1A*

3.3 Tension (Perpendicular to Pin) Test

Tension tests were performed on the continuous and butt hinge and are referred to as Test 2A and 2B, respectively. The tension tests were performed to gather data on how these hinges would perform when loaded in the direction perpendicular to the pin. Loading conditions that could cause these forces on the structure could be through deployment, raising panels into place, and forces that act normal to the panels, such as suction caused by wind. Both tests, 2A and 2B, were performed with monotonic loading, which is when a load is applied in one direction at a constant rate until failure. Monotonic loading was chosen for this direction because compression toward the pin would not provide useful or practical data. Figure 11 shows the test setup for Test 2A.

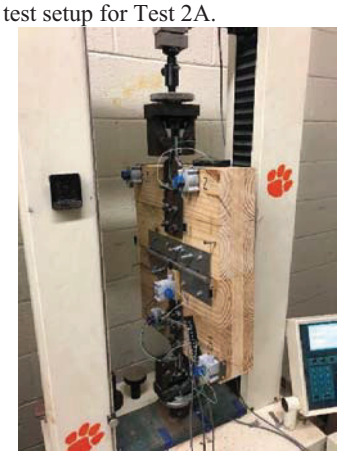

Figure 11: *Test 2A (Tension of Continuous Hinge)*

4 PERFORMANCE MEASURES

Both the static and dynamic units were designed for gravity loads (live and dead loads), wind and seismic loadings. The results from the hinge tests were used to design the dynamic units. Four designs were produced from this study: (1) Static Light-frame Unit, (2) Static CLT Unit, (3), Dynamic Light-frame Unit, and (4) Dynamic CLT Unit. Four metrics were used to measure the performance of each of the four designs. These metrics are (1) Deployability, (2) Transportability, (3) Cost, and (4) Building Envelope Resistance. By providing each structure design with a score in each category, the end user can quickly determine which structure will best suit their needs. Some of these categories could be subjective; however, the goal of the scores is to relate the structures relative to each other. Scoring in each category ranges from 1 to 4. A score of 1 means the structure did not perform relatively well in that category. A score of 2 or 3 means that the structure performed about on average in that category. A score of 4 means that the structure performed the best.

4.1 Deployability

Deployability is a measure of how easy it is for the structure to be deployed. Factors that affect deployability include weight, time to assemble/erect, and required tools. Deployability is an important metric as it relates to ease of use. The concept of disaster relief is to be able to provide assistance in a quick and easy manner. If a structure requires specialty tools or labor to be usable, it would not be considered especially deployable. Another reason deployability is important is that in remote areas, there may not be access to large machinery to lift the panels to unfold the unit. As a full-scale model was not in the scope of this research, assembly time could not be measured. However, estimation could be made from similar-sized structures used in the military. Also, an exact time deployment is not as important as the general time between each structure as this scoring system is only meant to compare relatively between each four structure designs. A score of 1 in deployability would be because a structure is lightweight, requires very little if any work upon arrival, and does not require special tools or machines.

https://doi.org/10.52202/069179-0458

4.2 Transportability

The transportability category is a measure of how easy it is to transport these structures. Another consideration is how many structures can be shipped on one truck. Transportability is a function of the weight and size of the unit. All these units were designed to be within ISO standard shipping sizes. The maximum weight of a step deck trailer is 45 kips, and the maximum dimensions are about 50 ft long x 8.5 ft wide x 10.5 ft tall. This limits both the static and dynamic units to two units per shipment. However, when looking at shipment in terms of square feet per shipment, the dynamic units has clear advantage. The light-frame dynamic unit scored the best because it is relatively lightweight and can deliver more usable square footage than its static unit counterpart. The CLT dynamic unit scored the worst because it weighs the most.

4.3 Cost

Cost is important because it shows the feasibility of implementing these structures on a wide scale use. As with any product, the price can fluctuate depending on the materials used in production. Also, the price can be reduced when built in large quantities. However, for this research price of a single unit will be estimated at the current prices. The current price for 3-ply southern yellow pine CLT is around $39 to $44 per sq. ft. (J. Gouge, personal communication, January 19, 2022). For the CLT structures, a cost of $40 per sq. ft. was used as this is within the expected price range. These prices do not include the assembly of the units.

4.4 Building Envelope Resistance

Building envelope resistance is an important category for consideration in both civilian and military sectors. Some factors that could be used in this category include debris impact resistance, insect resistance, and fire resistance. Some factors that may play a larger role in military use are ballistic and blast resistance. The latter two factors will be used to create a score for each structure in this category.

The ballistic performance of the CLT panels was estimated using the THOR CLT model introduced earlier and shown in equation 2.5.2-1. The calculation was performed for a half-inch diameter steel ball projectile. The estimated striking velocity that can be resisted by a 3-ply southern yellow pine CLT panel is 1650 fps. Modern firearms do not use spherical steel balls as projectiles, and therefore these results are difficult to compare to real-world ammunition types. However, comparing the striking velocity to the velocities shown in Figure 2.8, it can be estimated that the CLT structures may show ballistic performance around the III-A NIJ rating. This roughly means that the CLT structures could be able to all common handgun bullets. Level III-A exceeds or meets most law enforcement agencies' requirements in the U.S. (T. Muszynski, personal communication, June 27, 2022). The light-frame walls are built up from ½ in. dry wall and 7/16 in. OSB sheathing with studs spaced at 24 in. O.C. The light-frame walls will provide practically zero ballistic resistance. These walls will not even meet the lowest NIJ rating of level I.

4.5 Performance Measure Summary

Each structure was assigned scores in the categories of deployability, transportability, cost, and building envelope resistance. A radar chart shown in Figure 13 was made to show each performance category for all structure types together. This chart makes it easy to see which units perform best in each category and helps the end user determine which unit is right for their purposes. If a structure type has a higher score, it means that it performs comparatively well in that category.

5 CONCLUDING REMARKS

This research has contained the design of four types of rapidly deployable structures using different materials and deployment strategies. These units could be used in many different environments for multiple purposes; therefore, variety is important. There have also been tests performed on multiple hinges that will be used to gather important parameters. Moving forward experimental testing on the hinges will be completed and a better understanding of their behavior will be discussed.

GLUED TIMBER TRUSSES

Tuomo Poutanen[1], Markku Karjalainen[2], Valtteri Paananen[3], Jouko Tanskanen[4]

ABSTRACT: Current timber trusses are mainly made using steel fasteners, nail plates, or dowels with slotted plates. Glued timber trusses are applied commercially by two companies: German PERI produces trussed joists for concrete casting and Canadian Barret Structural makes trussed joists for residential floors. These trusses are based on finger joints made using a cursor. Recently, a Finnish company Teeri-Kolmio Oy started manufacturing glued trusses for residential floors with the joint processed using a saw blade. The such joint enables deep chord routings up to through the chord, long fingers, large web-chord glue areas, minimal timber splitting, and high resistance and reliability. There are further special characteristics. Top chord support is possible without hangers. The truss can be manufactured as a long billet, stored at lumberyards, and cut for actual needs. The truss can be manufactured without open routings and water pockets. The truss is strong and reliable and can be applied for the roofs of commercial buildings up to about 30 m spans. Our study shows that the trussed roof is more cost-effective than the glulam roof which opens a promising new business possibility.

KEYWORDS: Glue, Truss, Joist, Billet, Trimming, Visual joint

1 INTRODUCTION

The glue is the cheapest, stiffest, and often the strongest timber fastener. The truss is the most effective structural model in horizontal structures with the least material and the best flexibility. Timber is a renewable structural material.

Prefabrication and automation are demands for effective construction. It means that the horizontal structures are made of joists with uniform height. The glued timber truss is the most cost-effective and ecological horizontal joist with uniform height.

Timber trusses are mainly applied for floors and roofs. The floor trusses are always parallel chord trusses with uniform height. Roof trusses are normally pitched. The authors believe that the parallel chord trusses gain market in the roofs, too, as such trusses are well suited to off-site construction and prefabrication and further suit well for attic roofs.

Currently, timber trusses are not applied to roofs. In this article, calculations are presented which show that glued timber trusses have potential in roofs, especially in long-span commercial roofs, with spans normally 15-25 m but up to about 30 m. Our study shows that the trussed roof is more cost-effective than the glulam roof which opens a promising new business possibility.

Consequently, the glued timber truss has potential.

This article focuses on timber trusses with uniform height made of timber and glue only. Timber trusses with steel connectors are touched as a comparison only [1-5].

1.1 LIGHT TIMBER TRUSSES

Light trusses are made of small timber members like sawn wood. Current light timber trusses are mainly made of nail plates. The global market exceeds €10 bill. The glued trusses play a minor role, apparently less than €0.2 bill.

The glued joint has some advantages over the nail plate joint:

- In a glued joint the web chord load path has only one shear joint, but two shear joints are needed in the nail plate joint. Thus, the glued joint is more cost-effective in this regard.
- The glued joint has a lower slip due to a more rigid joint and a lower number of shear joints.
- The glue cost per share area is only about 5 % of the nail plate but the effective shear resistance of the glued joint is about 50 % less. Further, excess timber is needed in the glued joint due to web fingers. The overall glued joint cost is less than the nail plate joint cost.
- In a nail plate joint the web width must be the same as the chord width, which normally is not optimum regarding the web resistance. Especially, in the parallel chord nail plate trusses, the web width, about 100 mm, is defined due to the joint resulting in about a twice bigger web volume and cost than needed for the web resistance. The glued truss lacks this deficiency.
- Glued trusses are mainly used concealed. The glued joint does not require the precise timber cross-section and the planing is not needed,

https://doi.org/10.52202/069179-0459

while needed in the nail plate trusses. For this reason, the glued timber truss has a 5…10 % timber cost advantage.
- The fire resistance of the nail plate truss is defined by the negligible fire resistance of the nail plate. The fire resistance of the glued truss is defined by the wood charring.
- The nail plate truss has poor resistance in the open air. The glued truss can be used in the open air, the resistance is normally defined by the wood, not the joint.

On the other hand, the nail plate joint has advantages over the glued joint:
- The glued joint needs finger routing in the web and in the chord with excess cost. However, this cost is negligible in automatic manufacturing.
- The finger routings in chords weaken a little the chord resistance. This issue is negligible as the chord routings make only local defects in timber analogous to knots. The primary design criteria in trusses with uniform height are deflection and joint resistance, and the chord resistance is secondary.
- It is difficult to implement the glued joint in complicated cases like pitched trusses. On the other hand, the nail plate joint is flexible and can easily be implemented in complicated pitched trusses and frames.

The glued joint is most suitable for standardized applications like parallel chord trusses with uniform height. Implementing a glued joint to pitched trusses is challenging.

1.2 ROBUST TIMBER TRUSSES

Robust timber trusses are made of robust timber members like glulam. The authors made a study to obtain a robust timber truss using only glue in the joint, patent US2008092988. The joint needed sophisticated CNC processing and did not reach the commercial market.
There are research studies for robust timber truss joints made of glue and steel rods or plates. However, such trusses have not gained a significant commercial market.
The current robust timber trusses are made of dowels with slotted steel plates. Such joint has high material and labor costs and therefore the commercial competitiveness is not good regarding other alternatives like steel trusses.
Current primary girders are placed normally 4…6 m apart from each other where a secondary structure is needed. An alternative concept is explained here: the trusses are about 0.5 m apart from each other. A secondary structure is not needed. This article explains that this glued timber truss roof concept offers a profitable business potential as it seems to be more cost-effective than the glulam roof.

1.3 RISK REVIEW

Glued timber trusses are applied commercially little though the high potential. This is apparently due to the perception of the unreliability of the glued joint. The resistance of the glued joint is prone to timber defects like knots and inclined fiber and the resistance of the glued shear joint. The glue must be spread reliably, and the glue must not be decayed. One inproper joint may be fatal for the overall resistance of the truss. Thus, the glued joint must be subjected to strict quality routines analogously to welded joints in steel trusses.
The current manufacturers of glued trusses for the structural market have secured quality issues by proof-loading each commercial glued truss to 1.5…1.8 times the allowable i.e., characteristic load. This quality routine makes a more reliable outcome with a proper proof load than in the code-based design, but it makes considerable excess cost and is difficult in trusses made as a billet and in long-span roof trusses.
The authors believe that proof-loading is not necessary when careful quality measures are taken:
- The basic principle of a glued timber joint is that the failure should not occur in the glue line. It is possible to fulfill this requirement in the glued truss joint.
- The timber quality on webs and especially on the web fingers is critical. Therefore, the webs should be appropriately graded to avoid critical defects, especially big knots.
- The chords should be graded too analogously to the grading of the flanges of I-joists.
- In the glued joint the glue must be spread all over the joint and the glue must not be decayed. The glue cost in the truss is negligible and therefore it is feasible to overdesign the glue joint in critical cases for example by limiting allowable mean glue shear stress to a low value, e.g., about 0.3 N/mm^2 for the characteristic load. The glue cost in the glued truss is little and the overall effect is negligible.
- It is beneficial to make the joint and the fingers big when small knots in the timber are allowed as they play a negligible role.
- The glue should be spread using a robot to exclude human errors and further, an automatic camera checking should be applied to secure the outcome.
- In critical points like truss ends, multiple adjacent webs may be applied to reduce stresses and increase reliability. The web cost in a glued truss is negligible and therefore multiple webs make only a minor excess cost.

1.4 WOOD MATERIAL

Any sawn wood with minor defects especially minor knots like spruce is suitable for glued trusses. Glulam, LVL, and other glued products are feasible, too.

2 EARLIER GLUED TIMBER TRUSSES

There were three glued truss concepts on the market, one based on finger joints and two based on lap joints.

2.1 DSB

DSB, patent US2780842, is the first commercial glued timber truss manufactured in Germany for floors and roofs in multiple plants from about 1950’ through 1970’.

https://doi.org/10.52202/069179-0459

The production was terminated apparently due to quality assurance issues.

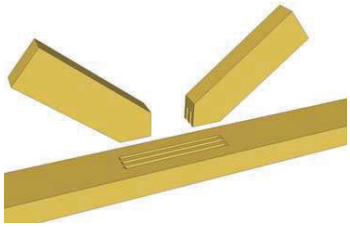

Figure 1: *DSB joint, the fingers are not tapering and the webs are not connected to each other.*

2.2 IU-TRUSS

Finnish inventor Pertti Purontakanen filed a patent FI54008 in 1979, for a glued timber truss where the chords are double planks, webs are planks and are inserted between the chord planks, and 3 mm plywood is between the chord plank and the web plank. The purpose of the plywood is to avoid stress peaks in the glue joist and to simplify the glue application as the glue is spread on the plywood. A batch of trusses was stacked on top of each other and pressed together using a hose and air pressure.
IU-truss was on the Finnish market for about a decade. The production terminated due to stability issues of the upper chords and webs causing a roof collapse at least in one case. In the IU-truss, both upper chord planks must be nailed to the battens to avoid lateral buckling.

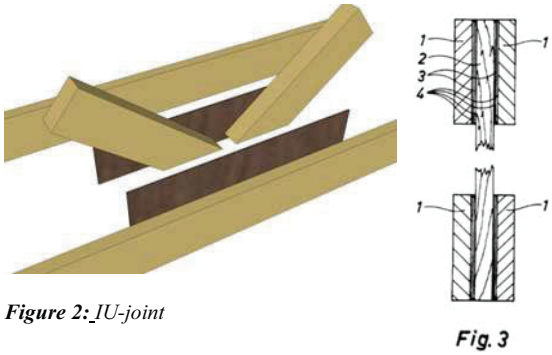

Figure 2: *IU-joint*

Fig. 3

2.3 A-TRUSS

Finnish inventor Arvo Hyvärinen developed A-truss which is like a nail plate truss, but the nail plates are replaced with birch plywood glued to chords and webs. The assembly of the A-truss is the same as in the IU-truss. Although the A-truss is more expensive than the nail plate truss, the A-truss was on the market for two decades. The A-truss fabricator specialized in complicated cases which the connector truss fabricators opted not to do. One may think that the resistance of the A-truss is doubtful, but the authors do not know of one failure with these trusses.

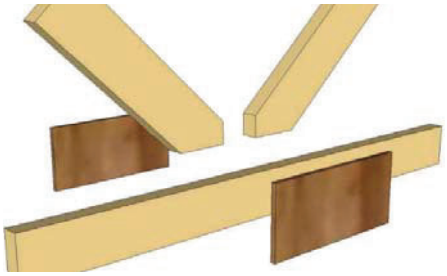

Figure 3: *A-joint*

3 CURRENT TIMBER TRUSSES

Nakashima et al [4], patent JP2014055406A, developed an interesting joist which is a combination of truss and I-joist.

Figure 4: *Nagashima's joist*

There are three glued timber trusses on the market, all based on finger joints.

3.1 PERI

The PERI truss, patent CH306573, is like the DSB-truss, but the webs in the joint are connected to each other by a finger joint with tapering fingers. The PERI-joint has high resistance which is due to deep chord routing and high chord thickness, about 60 mm. The PERI-truss is used as a joist for concrete casting. The PERI-truss is currently exploited extensively on the market.

https://doi.org/10.52202/069179-0459

Figure 5: *PERI-truss and joint*

3.2 TRIFORCE

A more improved product with a tapering finger joint in the web-chord joint and in the web-web joint was developed in Canada some 30 years ago, patent CA2335684, https://www.openjoisttriforce.com/. The web cross-section is rectangular 38*38 mm^2, and the chord routing is shallow, 16 mm. This joist has established a solid position in the residential floor market in the US and Canada. It is produced in standard lengths with an option for 600 mm trimming on one end.

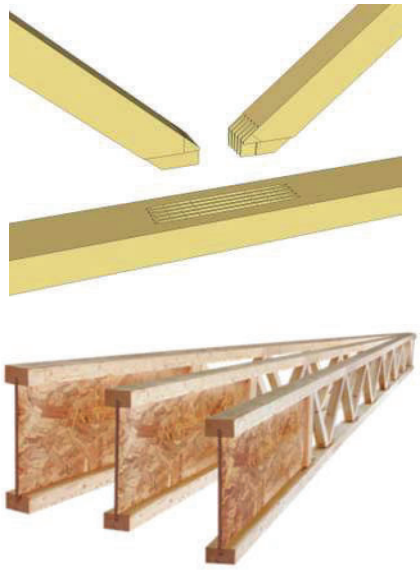

Figure 6: *Triforce joint and truss*

3.3 G-TRUSS

G-truss is the latest glued timber truss on the market explained in more detail in the next paragraph, www.gjoist.com, www.tk-palkki.fi

4 G-TRUSS

The authors started the glued truss development more than 20 years ago. In the beginning, the focus was to develop a joint suitable for light and robust trusses without open routings [1, 2]. A patent US7975736 was granted to a joint where routings were processed using a cursor moving in the axial direction. This embodiment did not reach the commercial market.

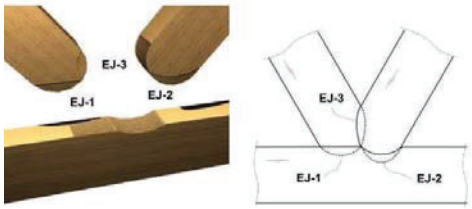

Figure 7: *Glued truss joint, US7975736, suitable for light and robust trusses.*

In 2014-2017 the authors realized a development project where more than 10 joint models and more than 300 full-scale trusses were tested [3]. Innovations were made and three patents were granted EP3620588, US11162262, and US11220821. The new truss was named “G” glued truss and glued joist.
The G-truss consists of some new features:

4.1 Simplicity

All webs in the G-truss are similar and there are no verticals. There are only three different timber member types in each truss. Upper chord, lower chord, and web. All mortise routings in the chords are similar and all tenon fingers on the web ends are similar, too. Thus, the timber members are easy to make and assemble.
The simplicity applies to the structural design, too. As the web pattern is the same along the truss, the resistance also is the same along the truss. The G-truss can be turned upside down. These features are significant in a truss manufactured as a billet.

4.2 Saw blade routing

The fingers in the joint, the tenon web fingers, and the mortise chord fingers are processed using a saw blade. The fingers are tapering and therefore the processing is made in two steps in two saw inclinations, as shown in Figure 8. The saw blade makes a good surface for gluing and a small knot in the finger does not make any timber splitting.

https://doi.org/10.52202/069179-0459

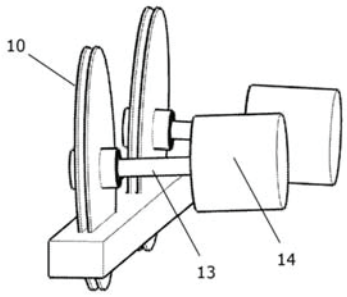

Figure 8: *The saw blade routing is processed in two steps to obtain the tapering fingers.*

4.3 Trough routing

The web finger punches the chord, which results in a big joint. The joint size is the maximum possible i.e., the whole overlapping area of the web and the chord. In such a joint, a small knot is not critical. The web-chord glue area is large meaning small shear stress in the glued shear joint. The mean glue shear stress for the characteristic load is about 0.3…0.5 N/mm^2

4.4 Only one or two fingers per web

In the glued timber truss joint the resistance of one web finger decreases when the number of fingers per web increases on the web. The G-web has only one or two fingers per web and therefore the web finger is effective.

4.5 Upper chord support

The upper chord support is possible without a hanger as the web finger is long and reaches above the support. This feature makes about a 20 % cost advantage in cases when the hanger can be avoided.

Figure 9: *The G-web finger punches the chord.*

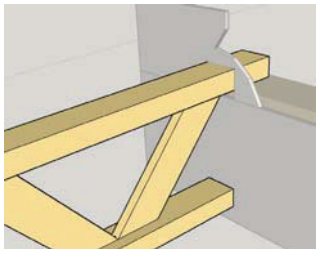

Figure 10: *The upper support is possible without a hanger.*

4.6 Free web layout

The webs in the G-truss may be connected to each other as is normal in a truss, but the webs may be apart from each other. This enables two features missing in a normal truss where the web pattern and the node points normally are fixed:

- The node points within the truss can be fixed to match the extra support along the truss and thus the reinforcement of the truss is not needed in the support. The extra support may be on the bottom chord or on the top chord.
- The crosswise opening which may be excessively big can be fixed arbitrarily. It is possible to fix a continuous crosswise opening along adjacent trusses for MEP or to assemble a crosswise girder inside the adjacent trusses.

The web layout normally means that the webs make an X-pattern. In this embodiment, the supports and the openings in a truss may be fixed to fully match the actual situation in the building. Figure 11 shows a truss with a special web layout.

In a normal truss, the webs and the chords have no or negligible moment stresses. When the webs are fixed apart from each other in the chord joint, excess and harmful moment stresses are induced, in the joints, webs, and chords. These excess stresses set some demands on the joint and the truss.

- The joint must be reliable and strong.
- Normally at least one extra web is needed in critical cases to shear the excess stresses to multiple webs and joints.

In the G-truss, the webs may be fixed apart from each other as the joint is strong and an extra web may be fixed anywhere along the truss.

Figure 11: *A truss with a special web layout.*

4.7 Billet manufacturing

Current trusses are manufactured for fixed length (with eventual trimming option at ends) with supports at bottom chord ends. G-truss can be manufactured as a long billet like I-joist and solid joist and cut arbitrarily to make multiple working trusses. Each joist can be supported at

https://doi.org/10.52202/069179-0459

the bottom chord, top chord, between chords, or along the truss.

Figure 12: *A billet truss that can be cut for multiple working trusses.*

If the support does not match a node point reinforcement is needed at the support. Figure 13 shows a reinforcement when the support is in the upper chord at the joist end. OSB panels and steel U-rail are nailed on the chord edges.

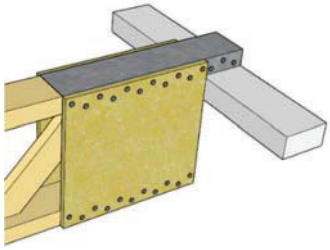

Figure 13: *The billet truss can be cut arbitrarily, if the cutting point does not match a node point a reinforcement is needed. The upper support reinforcement is realized by fixing OSB-paned and steel U-rail.*

5 FLOOR TRUSSES AND JOISTS

The global timber floor joist market is about €5 bill. The I-joist is the market leader with a 50 % market share due to low material cost, simple manufacture, and the option for billet manufacturing.
The floor sets many special demands for the joists. The current joists match differently these demands.

5.1 Horizontal openings

The residential floor often includes MEP installation. The space between the joists can be utilized for MEP. Often the installation across the joists is needed, too when crosswise openings are useful. A truss has crosswise openings without extra cost. Such openings are not possible in the solid joist and I-joist perforation is limited and causing extra cost.

5.2 Support

Floor joists are mostly supported at the lower edge. However, the hanging support suits better, especially for the supporting beam and normally for the wall structure, too. The truss can be supported at the upper chord which allows the advantages of the hanging support. A hanger corresponding to about 20 % excess cost is needed in the I-joist and in the solid joist.
Hanging support is an increased trend in construction. It is especially useful in off-site construction and in prefabrication.
G-truss can be supported at the top chords without a hanger.

5.3 Cross bracing

Walking on the floor makes impact loads which should be distributed to multiple joists to avoid harmful local deflection and vibration. Therefore, there should be a cross-bracing "strong back" like a 50*150 mm^2 board across the joist which shares the impact load with multiple joists. Such cross bracing is impossible in the I-joist and in the solid joist and therefore these joists need some greater height to compensate for the missing cross bracing inducing excess cost.

5.4 Billet manufacturing

I-joist and solid joist are manufactured as a billet, kept in stock, and cut to actual need which is effective regarding logistics and the overall economy. G-truss is the only truss that can be manufactured as a billet which is due to the high joint resistance.

5.5 Vertical openings

The residential floor virtually always has a vertical opening like a staircase or chimney where joists hitting the opening are cut and excess joists are fixed by side of the opening. Cross beams are needed to support the cut joists. Currently, the cross beams are fixed at the perimeter of the opening and fixed by the faces of the excess joists. G-truss has three characteristics that enable a simple and flexible structure:

- The cross beams can be fixed inside the G-trusses i.e. they need not be by side of the opening. For this reason, the cut beams may run beyond the cross beams to make overhangs. Cutting of the overhangs is arbitrary and therefore the form of the opening is arbitrary, for example, a circle. Currently, the form of the opening can be rectangular only.
- The cross beams are not supported at the faces of the excess joists, but inside them, which denote simple joints e.g. hangers are not normally needed.
- The crossbeam may be excessively long to be supported by multiple joists and thus sometimes extra joists are not needed.

Figure 14 shows the principle of the new structure.

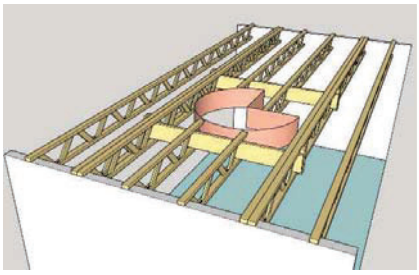

Figure 14: *the principle of the new opening structure.*

https://doi.org/10.52202/069179-0459

5.6 Costs

The special features explained above have cost effects different for each joist.
Figure 15 shows approximate costs for a typical 6 m residential floor.
G-truss has the least material cost and has no excess costs regarding the special features.
In this Figure, the factory price of the G-truss is €7/m. The high price is due to patent royalties and good profit for the licensee manufacturer.
In the long run, the factory price of the G-truss and the I-joist should be about the same.
Approximate CO2 emissions are given, too, the G-truss is the most effective in this regard.

	G-joist	I-joist	Metal web joist	Plated joist	Wood joist
Material	3.2	3.5	5.0	5.5	9.0
Manufacturing	2.3[1]	1.0	2.0	2.5	-
Overhead costs	1.5	1.5	1.5	1.5	-
Factory price	**7.0**	**6.0**	**8.5**	**9.5**	**9.0**
1.Perforation	-	0.5	-	-	0.5
2.Support	-	1.0	≈0.5	≈0.5	1.0
3.Cross bracing	-	0.5	-	-	0.5
4.Billet opt	-	-	1.0	1.0	-
5.Openings	-	0.5	0.5	0.5	0.5
Reference price	**7.0**	**≈8.0**	**≈9.5**	**≈10.5**	**≈11.0**

Current market		**2 500 MC**	**2 500 MC**		

Figure 15: *Approximate floor joist costs, €/m at 6 m span.*

6 ROOF TRUSSES

The global roof demand is huge. Currently, timber is competitive in residential roofs mainly via the nail plate truss. Steel and concrete dominate the commercial roof market.

6.1 RESIDENTIAL ROOFS

The nail plate timber truss dominates the residential roof market due to its low cost and flexibility to accommodate multiple geometric and structural forms. However, the nail plate truss has some deficiencies:

- The nail plate truss needs height which means that the prefabrication of the roof is not feasible. The roof must be constructed on-site from prefabricated trusses.
- The nail plate truss is not effective for a house with an attic, either the truss will be very expensive, or the attic space is limited.
- A roof opening in a nail plate truss roof is complicated and expensive.

Glued timber trusses are not currently applied in residential roofs. Joists with uniform height, I-joists, solid joists, or nail plate trusses are sometimes applied for residential roofs. The glued joist would be more cost-effective.
Off-site construction and prefabrication are strong drivers and trends in construction. Therefore, the authors believe that the joisted roofs gain market.
The mono-pitch residential roof is the most cost-effective for the glued truss as it suits the offsite manufacturing of panel components. A double-pitched roof can be prefabricated effectively too if the joists can be fixed parallel to the ridge. Ridge beam plus joists along pitches are feasible, too.

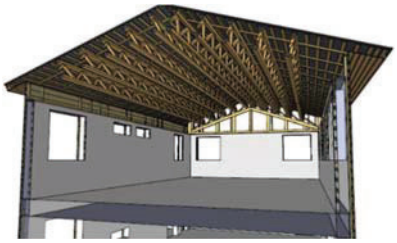

Figure 17: *Pitched roof can be constructed effectively using joists by fixing the joist parallel to the ridge.*

6.2 COMMERCIAL ROOFS

The nail plate truss can be applied for commercial roofs up to about 30 m spans. The truss cost is low, but the roof can't be prefabricated. The expensive on-site construction work deteriorates the overall economy.
The glued truss enables roof prefabrication and automation and is feasible in long-span commercial roofs where strict deflection and dynamics demands are missing. The feasible height of the glued truss is about span over 25. The reliability without proof loading is obtained using the measures explained above. The overall economy is good and there is commercial competitiveness even with proof loading.
Next, two commercial buildings are compared regarding roofs, one building has a G-roof, and the other has a consistent glulam roof [5]. The walls and roof of both buildings are rigid diaphragms to resist horizontal forces. The columns in the glulam building resist the vertical forces only.
The snow load is 2.2 kN/m^2. The net inner height is 5.2 m, and the width is 18 m. In both cases, the roof consists of 2.4 wide and 18 m long prefabricated elements. The measures of the glulam girder is 1164 mm…1440 mm*190 mm, GL30c, c/c 6 m.
The 18 m long G-truss has a height 780 mm, chords are 60*195, and webs are 45*73 doubled at the ends.

Figure 18: *The 18 m long G-truss*

Figure 19 shows the cross-section of the G-roof element. Soft mineral wool insulation or loose insulation is applied to enable simple application in spite of the inclined webs. Semi-hard insulation panels are at the sides to make a good seam between the elements.
We see that the basic structure is flexible:

- Additional trusses can be fixed in cases when extra resistance is needed e.g., in point loads or in roof openings.

https://doi.org/10.52202/069179-0459

- A crosswise girder for extra support, crosswise overhang, or point load may be added.
- The G-truss can be supported at the top chord which is beneficial in the beam support.
- The G-roof element can be fixed to the wall or a beam by processing above the element, with no fixing nor sealing below the element needed.
- The sealing between the elements is simple, only the upper membrane must be fixed onsite.
- The seam includes a big assembly tolerance, though it is air and moisture tight.

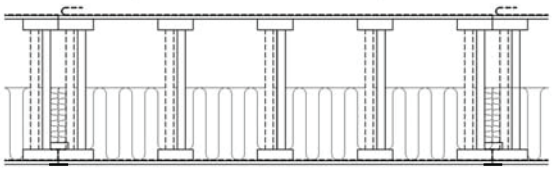

Figure 19: *Cross section of 2.4 m wide roof element of G-roof. The element includes five G-trusses.*

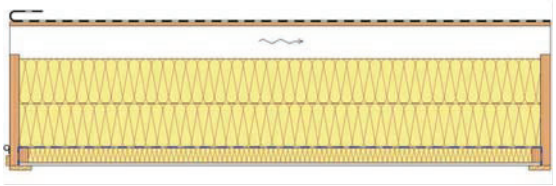

Figure 20: *Cross section of roof element supported on glulam beams, such element is dominantly used in Finland, disclosed in LVL Handbook, Figure 2.39 https://proofer.faktor.fi/epaper/LVLHandbook_2020/#76.*

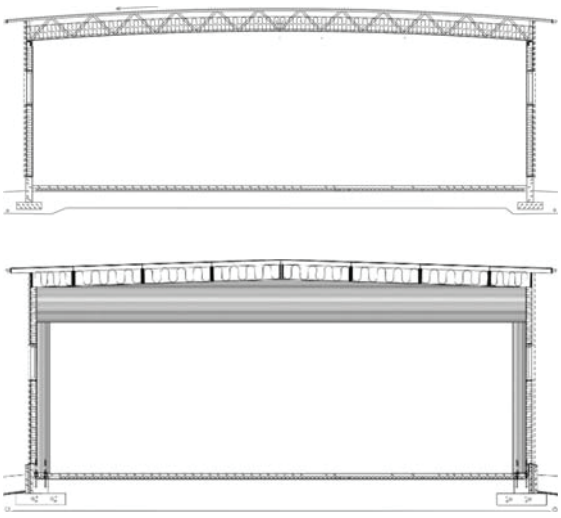

Figure 21: *Cross section of the G-building above and the glulam building below, the net inner height is 5.2 m and the width is 18 m. The wall height of the glulam building is 6864 mm, and 5920 mm in the G-building. The overall roof height in the G-building is about 50 % less. The glulam building has a secondary and normally harmful building volume between the beams, 25 % of the net volume.*

Table 1 includes wood volume, approximate wood cost, and approximate CO2 emission for the G-roof and for the consistent glulam roof in 18, 24, and 32 m spans. The calculation is based on the sawn timber cost €300/m^3, and glulam and LVL cost €600/m^3. The assembly cost of the G-truss is €3/m [5]. The table includes the wood cost only, the lower and the upper cladding and the insulation are the same in both structures and these costs are excluded.

We see that in all cases the overall wood volume is about the same in all alternatives, but the G-roof is about €20/m^2 cheaper as the G-roof consists of low-cost sawn timber only. The G-roof has lower CO2 emissions.

In the G-buildings, there are further advantages resulting in lowers costs not considered in the figures of Table 1:

- The wall area is less.
- The volume of the building is less requiring lower heating/cooling costs.
- Columns and column foundations are not needed when the roof is supported on walls.
- The secondary structure of the roof costs less. In both cases the assembly of the 2.4 m*18 m roof element is manual. The assembly of the G-element costs less as it has only 8 wood components per element whereas the glulam roof element, FigSure 20, has 75 wood components.
- The construction work is simple including the walls, and the roof only, the building skeleton, columns and girders, and the column foundations are not needed.

The factors listed above make further benefits for the G-building and the overall advantage is about 10 % of the overall cost of a commercial building.

Table 1: *Comparison, G-roof vs glulam roof [5]*

	Span (m)	18	24	32
G-roof	Wood (m^3/m^2)	0.061	0.106	0.195
	Wood (€/m^2)	25.6	37.9	64.8
	CO2 (kg/m^2)	4	5	8
Glu-lam	Wood (m^3/m^2)	0.078	0.104	0.179
	Wood (€/m^2)	43.2	58.0	103.2
	CO2 (kg/m^2)	8	9	14

7 DISCUSSION

The G-trussed joist used in residential floors seems to be more cost-effective than other timber joists. The cost advantage is €1-3/m i.e., €2-6/m^2. The high floor cost is an Achilles heel in timber engineering, especially in long spans. In this regard, the G-truss increases the competitiveness of timber engineering.

The authors believe that the joisted roofs gain market due to prefabrication and automation. The G-truss apparently is the most cost-effective joisted roof structure.

G-truss economically reaches long spans up to about 30 m. There are two prefabricated wood elements that reach long spans, too: LVL box slab https://proofer.faktor.fi/epaper/LVLHandbook_2020/#76 and modified I-joist-box-slab https://www.kielsteg.com/. Both are more expensive than the G-truss, as in these elements the wood plus glue cost is about 100 % higher, and the CO2 emissions are manifold. Further, these slabs have difficulties in thermal insulation, assembly at the

https://doi.org/10.52202/069179-0459

site, vertical and horizontal openings, supports, crosswise connections, air circulation, crosswise girder, and crosswise overhangs.

The G-truss seems to be sufficiently economical to undercut the costs of the current dominant structural model of commercial buildings: a skeleton arrangement plus a secondary structure. Thus, the G-truss has the potential to change the construction paradigm.

G-truss roof is competitive against steel and concrete roofs, too. Thus, the G-truss increases the competitiveness of timber in construction.

Only floor and roof glued trusses are addressed here. However, glued trusses are feasible in other applications, too like bridges, scaffoldings, railings, joists for concrete casting, and studs.

The truss is a complicated structure; however, the G-truss is simple, and it goes in for prefabrication and onsite automatic construction:

- The G-truss is flexible, therefore residential floors can be built with no excess labor regarding special issues like support, openings, and cross-bridging.
- Residential roofs can be built offsite using automation with negligible onsite labor and enabling effective use of attic space.
- Commercial buildings can be constructed without a skeleton.

Timber structures are more design intensive than concrete and steel. The authors have worked with codes and suggested modified allowable stress design. It simplifies the timber codes and makes considerable material savings when the excess reliability for the loads with low variability is removed [7].

8 CONCLUSIONS

Glued trussed joist is feasible for residential floors due to its low cost and flexibility and seems to be more cost-effective than other timber joists.

The nail plate timber truss dominates the residential roof market mainly due to its flexibility for multiple geometric forms. However, the nail plate truss poorly suits prefabrication and construction automation. If the roof can be constructed using joists with uniform height the glued truss is a feasible option.

Our study shows that the glued truss roof in commercial buildings up to about 30 m spans is more cost-effective with lower CO2 emission than a consistent glulam commercial building. In this regard, the glued truss may change the current construction paradigm.

The glued timber truss simplifies timber engineering.

3DP BIOWALL – CIRCULAR ECONOMY IN WOOD CONSTRUCTION THROUGH ADDITIVE MANUFACTURING OF FULLY RECYCABLE WALLS

Benjamin Kromoser[1], Sara Reichenbach[2], Roman Myna[3], Raphaela Hellmayr[4], Bernhard Reinholz[5], Rupert Wimmer[6]

ABSTRACT: To further increase the environmental potential of renewable raw materials, a new construction concept for fully recyclable bio-based wall elements assembled by additive manufacturing, called 3DP Biowall, is presented. The proposed concept considers the entire life cycle from material converting, to manufacturing and application, over to recycling and restarting a new construction phase. With the help of this method the materials are kept significantly longer in a closed material cycle, with conceptually no waste production. A fully biobased material mixture of wood particles and Biomix (sodium lignosulfonate and starch) is used. The present paper describes the basic approach, first production experiments as well as the achieved mechanical performance within compression and flexural tests performed with first test specimens. Furthermore, the potential of the closed material loop approach is assessed through an LCA and by comparing the 3DP Biowall to other well-known exterior wall systems. All production life cycle phases were regarded and experimentally investigated. The successful production tests and the achieved mechanical characteristics prove the feasibility and potential of the new approach. The performed LCA points out further optimisation potential regarding the mixture with the starch component having a comparatively high impact at the environmental footprint of the material mixture.

1 INTRODUCTION

There are different approaches to obtain resource-efficient constructions, for one by choosing an appropriate material, for the other by optimizing the structure and furthermore by optimizing the production processes [1]. New methods and processes can be found throughout the industry and in literature, with renewable materials and additive manufacturing showing great potential (e.g. [2]). Unfortunately, most additive manufacturing concepts for production of whole building components or buildings rely on the use of mineral-bound materials such as mortar or concrete which have a very high environmental footprint. To push forward a more sustainable building mentality other materials have to be brought into the equations, with wood constructions showing great potential as wood is able to partly store CO_2 during the tree's growth phase.

However, wood is also a limited resource and currently a considerable amount of the processed raw material ends up in a secondary stream and directly used as an energy source. In 2019, approximately 40% of harvested trees was not used for sawn timber products [3].

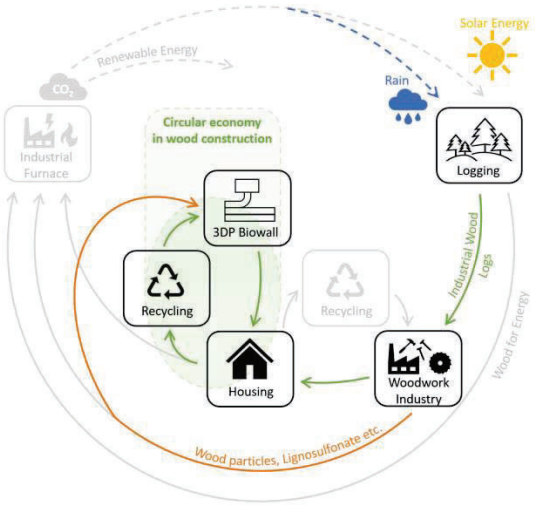

Figure 1: *Circular economy in wood construction based on* ***[4]****, including the future 3DP Biowall concept.* ***[5]***

[6] Institute of Wood Technology and Renewable Materials BOKU, Austria, rupert.wimmer@boku.ac.at

https://doi.org/10.52202/069179-0460

This together with material consumption surpassing the growth of population significantly [6], reveals that a circular approach, structure optimised design and use of secondary streams for manufacturing construction components is indispensable. The newly presented 3DP Biowall construction concept combines the high environmental friendly potential of grown renewable raw material mainly coming from secondary streams (e.g. wood particles, lignosulfonate) including a completely new binding concept [5,7], which allows for a closed-loop process (Figure 1), with a new production strategy resulting in new truly resource-efficient construction method.

2 MATERIAL CONCEPT

Various boundary conditions were set for the printing material to be used within 3DP Biowall: (1) A pure mixture of grown renewable materials, (2) Preferably side stream resources; (3) Recyclability of the end product, as well as (4) Ability to be extruded and develop a sufficient bond to the previously deposited layer. The resulting material mix consists of diverse wood particles (Figure 2c) and a bio-based binder (consisting of industrial starch and lignosulfonate, Figure 2 a) and b), respectively) which can be mixed in a dry state before water is added within the printing process.

The use of lignosulfonate adhesives has a long tradition in commercial use for paper glues. As technical lignins are not able to act as a binder without crosslinking agents or other additives [8], the material is currently mainly burnt for energy production processes [9]. The hydrophobic behaviour it shows due to its aromatic moieties, together with the presence of the hydroxyl groups suggests its compatibility with starch, a renewable resource that is also often used within adhesives production, especially for the paper industry. When applying starch as wood adhesive, the biggest challenge is its water resistance.

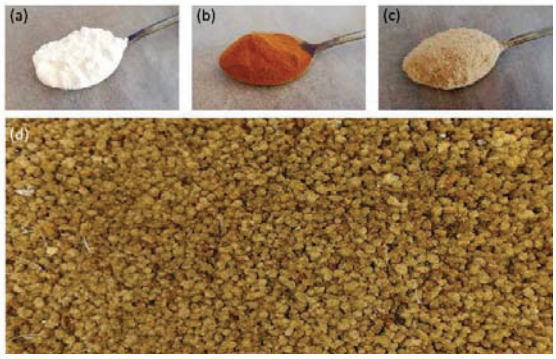

Figure 2: *Components for biobased wall systems* ***[5]***

The results of blending starch and lignin show very good mechanical behaviour for wood bonding as well as full recyclability [7], while the hydrophilicity can be adjusted using different measures. Within in the bio-based binder lignosulfonate acts as a dispersant, whereas the use of starch ensures the strength development of the bond line.

For good adhesion a homogenous distribution of the particulate mixture is critical. This can be supported by using triboelectric charging, where different components receive opposite charges. The created electrostatic potential attracts the individual Biomix and wood particles to each other. Unlike commonly used 3D-printing techniques, which are either based on thermoplastic melting and solidification or chemical reacting of fluid material, the proposed production method is based on dry extraction with minimal water dispersion afterwards.

3 PRODUCTION CONCEPT

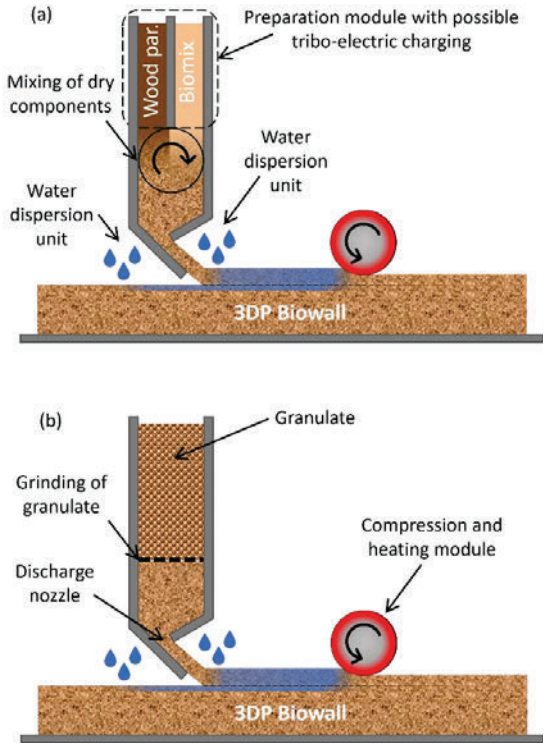

Figure 3: *Printing head concept for a (a) fully-integrated production (b) granulate-based production* ***[5]***

Two concepts (Figure 3) for the material preparation and the printing head are being developed to provide a continuous printing process of the 3DP Biowall. The first approach is a fully integrated production (a), where mixing of all components is implemented in the printing head for immediate application. The second approach is a granulate-based production (b), with the granulate (Figure 2(d)) produced beforehand. Advantages and disadvantages of both production processes are listed in Table 1.

Within option (a) the dry materials (wood particles with Biomix) must be mixed properly in dry state before the extrusion (Figure 3 (a)). Integrating a triboelectric mixing device into the printing head could be a promising supplement resulting in a more homogeneous distribution.

https://doi.org/10.52202/069179-0460

To ensure proper bonding, the bottom layer and the extruded mixture need to be moistened e.g., using water vapor prior to compressing and heating.

Table 1: *Assets and drawbacks of a (a) fully integrated production (b) granulate-based production* ***[5]***

	Fully integrated	Granulate based
Advantages	• Well suited for dry recycled wood components • Easy (automated) adaption of process parameters (mixture ratio) • Higher degree of compression possible, therefore ideal for hollow wall elements • Very homogeneous distribution of the different materials resulting in higher compression strength • All work steps are integrated in one tool • Shorter time frame from shredding to printing	• Fresh wood particles (high moisture content) can be directly used in granulate production without drying • Easy storage and transport, simplifying the printing on site • Can be used for other applications, e.g. ceiling filling • The high moisture content of the wood particles results in significantly less water consumption • Printing head has a simple design, therefore robust and reliable • Production of granulate can take place e.g. at sawmills, creating further added value
Disadvantages	• Materials have to be dried for transport otherwise they can be affected by rot • Higher complexity of the printing head • High water consumption	• Mixing ratio of individual components cannot be adapted in the printing head • Additional crushing unit needed in the printing head • Lower degree of compression possible

For the granulate-based production (Fig. 3 (b)), the granulate is produced directly after gathering of the wood particles, e.g. in the saw mill. By mixing the fresh wood particles with the Biomix-blend, a process of self-agglutination of the components is initiated. The adjustment of size and properties of the granulate is done either via variation of raw materials and mixing proportions or by choosing different process parameters.
The 3D-printing process allows Biowalls to be designed and produced with variable thicknesses and densities. Either a solid or hollow wall structure is conceivable, while the latter allows for an addition of further materials to match desired criteria like thermal insulation, fire resistance or sound insulation. Even complex and structural optimised patterns are achievable by applying selective material distribution/moistening/curing.
For that, the following aspects need to be considered and optimised in the printing process: (1) used material composition (Biomix – wood particles mixing ratio), (2) layer thickness, compression force and temperature as well as their interaction to obtain a homogeneous structure, (3) amount and time at which water is added for optimal wetting of the Biomix– wood particles mixture without clogging the printing nozzle, as well as the (4) production speed.
The independent development of the printing head and carrier system allows for an application und various conditions, e.g. on-site construction with a robot or portal system or off-site using an indoor robot system, as shown in Figure 4.

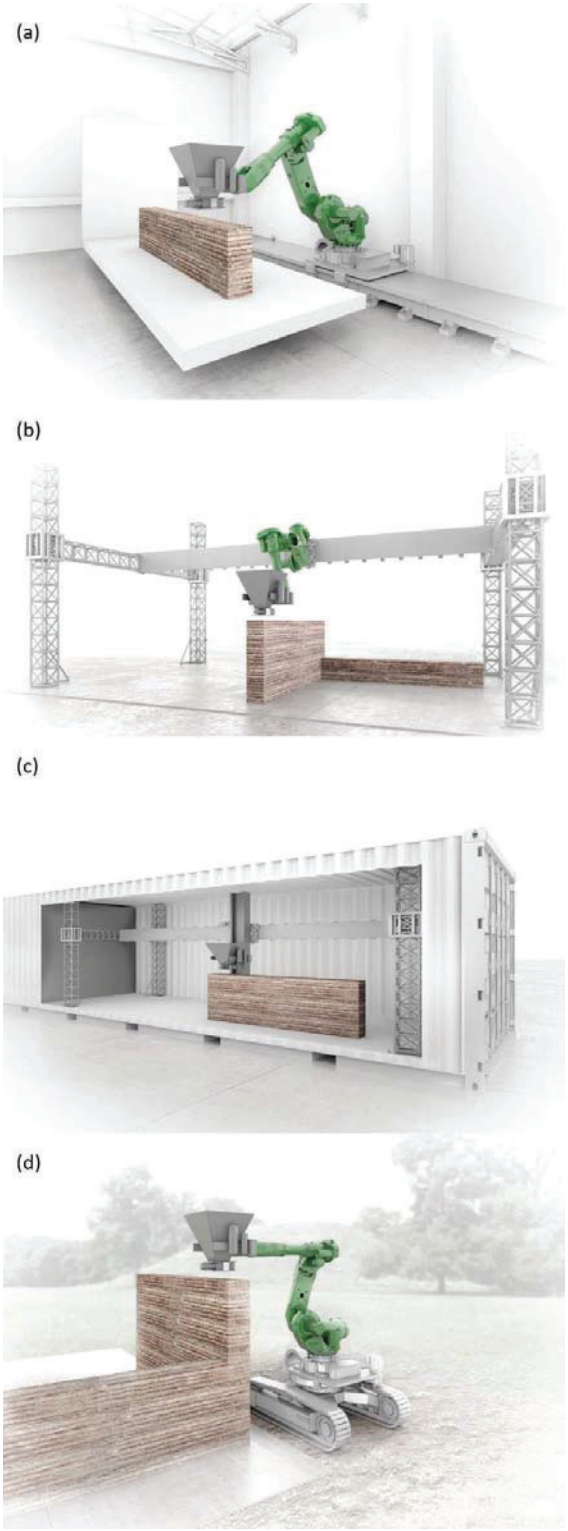

Figure 4: *Illustration of possible carrier systems for the printing head and construction strategy* ***[5]***

https://doi.org/10.52202/069179-0460

The successful implementation on the indoor robot-system of the institute is shown in Figure 5(a). This setup allows to study the fully automated production in future under constant laboratory conditions.

4 RECYCLING CONCEPT

As the 3DP Biowall is completely bio-based, reusing the material offers great potential. In comparison with well-established wood products, the material of the 3DP Biowall is designed for direct and true recycling (without downcycling or the addition of supplemental material) and therefor is in line with the shown principle of a circular economy (Figure 1). To reopen the created glue lines, an optimised disaggregation process needs to be defined, in which moisture treatment together with mechanical disintegration take place without changing the size or form of the wood particles. An essential step towards a fully reuse of the recycled material is a proper separation of the wood particles from each other. This leads to a conceptionally endless process, where multiple printing of 3DP Biowalls without the addition of adhesives is conceivable. As the used material is neither harmful to humans nor the environment, pyrolysis or composting could be a possible end-of-life scenario.
3DP Biowalls are not foreseen to replace the current solid wood applications, but rather to give the opportunity to increase the yield rate by means of using secondary material streams.

5 PRELIMINARY DATA AND ENVIRONMENTAL IMPACT

The data derived from first preliminary experiments on 3DP Biowall specimens consisting of a 1:1 mixture of dry wood particles and Biomix (50% sodium lignosulfonate and 50% corn starch). In addition to this blend, further Biomix variations were prepared adding sodium chloride and ash.
The production of small-scale specimens (Figure 5(c)) followed the four specific steps for each layer:

I) Application of water onto the bottom layer using high-pressure spray guns
II) Distribution of the dry mixture with constant layer thickness as shown in Figure 5(b)
III) Application of water onto the new layer with low pressure to not disrupt the particles
IV) Compression of the new layer using a hydraulic press at temperatures higher than 150°C

The process was repeated until the specimen height reached 40mm. After production it was stored at standard conditions (20°C and 65% rel. hum.) for one week before being cut [5].
The developed prototype of the printing head allowed a semi-automatically production of the specimens, with only step (IV) needed to be done manually. Currently the integration of automated compression and heating in

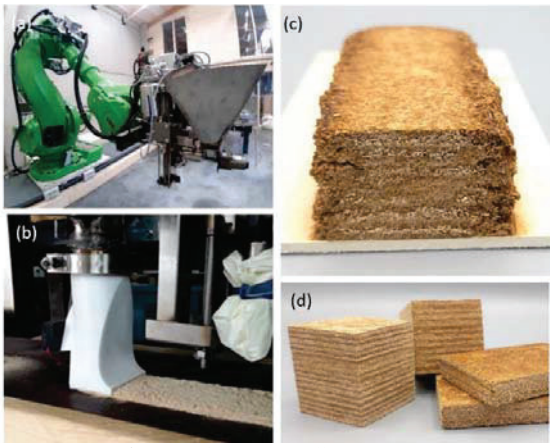

Figure 5: *Production of 3DP Biowall specimens* ***[5]***

order to automate the entire process are being developed and tested. A variety of small-scale specimens with different compression, amount of water to dry material ratios and various additives (NaCl and Ash) were produced and tested against their fire resistance, their water sorption behaviour and mechanical behaviour, including flexural and compressive strength. For the flexural strength measurement prisms with the dimensions of 160mm by 40mm by 40mm were tested, before being cut to 40mm cubes for the subsequent compression tests. The cubes can be seen in Figure 5(d). The alternating shade of color is a consequence of boundary layer development between the printed layers during the process.
The results, including the Young's modulus, are shown in Figure 6 with the Biowall specimens named Biowall or Regular, NaCl or Ash.

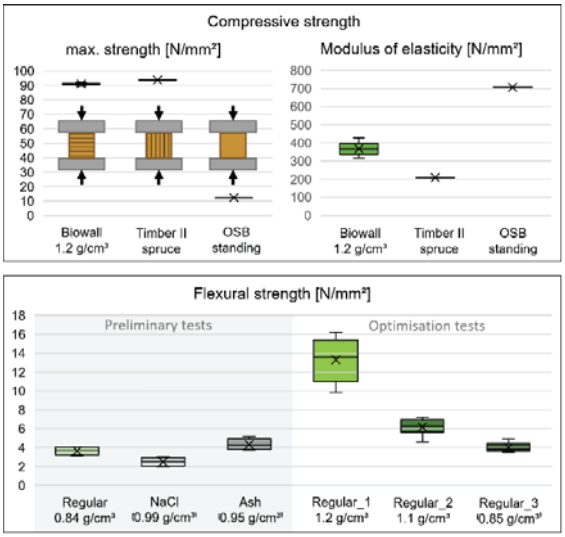

Figure 6: *Mechanical properties* ***[5]***

Within the DVS measurement different relative humidity levels (from 0 % to 95 %) were set until equilibrium and the mass of the sample (10mm x 10mm x 1.5mm) was continuously recorded by a microbalance in the device. The results of the DVS measurement are presented in Figure 7 and show a wood like behaviour. The Biowall samples reached a 15% higher fibre saturation point compared to solid wood; a characteristic that is linked to lignosulfonate and its hydrophilic behaviour.

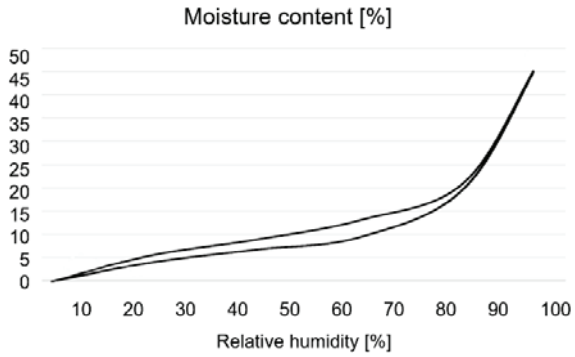

Figure 7:*DVS measurement* ***[5]***

The single flame source test results according to EN ISO 11925-2 were very promising. As a reference solid spruce was chosen. The 40mm by 40mm by 150mm samples were placed directly to the flame source having a 45° tilted orientation plane, with an exposure time of 30s. No ignition occurred for the Biowall specimens. The average flame size was 18mm x 40mm, showing anisotropic behaviour. Additionally, the time required resulting in a flame front height of 150mm was evaluated. After 30 min exposure the flame front had a height of 80mm without ignition, so the test was stopped. The reference sample showed a flame front of 2.5mm by 8.1mm after only 30 seconds with the height of the flame front exceeding 150mm after 3 min.

In addition to these tests the material was subjected to microscopic analysis. The images show the interaction between the two ingredients of the Biomix (Figure 8 (a)) and the dispersion of the binder within the saw dust when dry-blended (Figure 8 (b)). The tensile shear stress of Biomix was investigated in [7], and showed promising properties compared to urea formaldehyde, a conventional adhesive in wood industry.

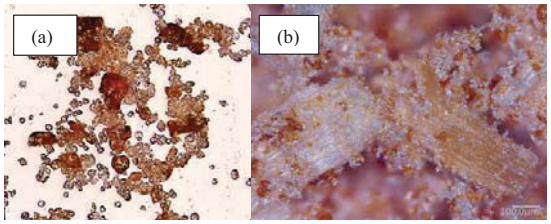

Figure 8: *Microscopic images* ***[5]***

In order to make a statement on the resource-efficiency and the ecologic aspect of the newly developed material an LCA focussing solely on the material production (Figure 9) was conducted. In a second step the material was considered within the boundaries of a constructed exterior wall system including insulation. In comparison with other well-known exterior wall systems (Figure 10) with similar U-values the environmental indicators consistently decrease with every further recycle cycle and therefor proof the closed material loop approach.

Within this paper only the Global Warming Potential (GWP) in kgCO2-equivalent and Primary Energy Non-Renewable - Total (PENRT) in MJ are presented with further environmental impact indicators discussed in [5]**.** Evaluating the material itself a distinction is made between primary and secondary resources, where secondary resources are by-products or even waste and primary resources products produced specifically to obtain that specific resource. The analysis shows the high impact of starch on each indicator. Therefore, to reduce the environmental footprint alternatives need to be considered, to either substitute the starch completely or partly.

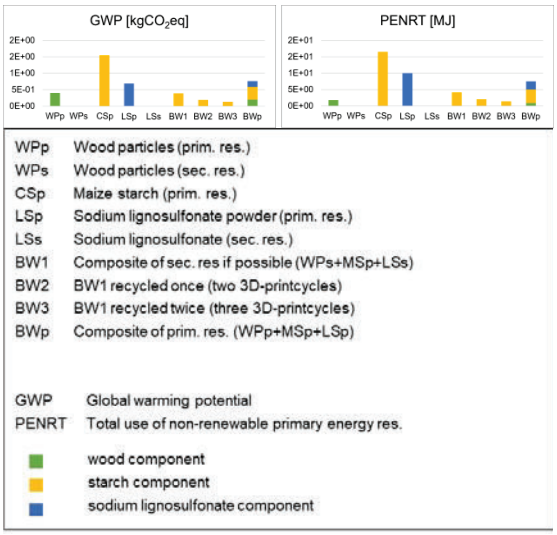

Figure 9: *LCA of the material (wood+Biomix)* ***[5]***

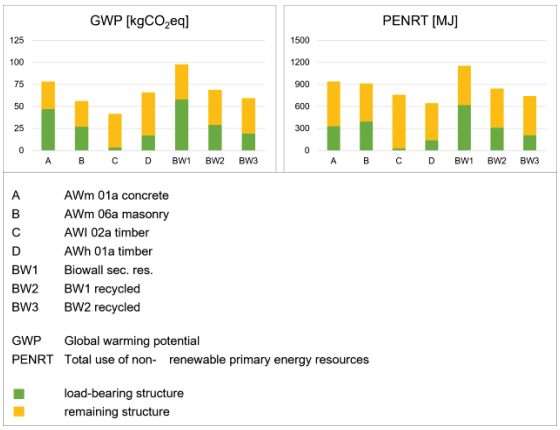

Figure 10: *LCA of complete wall systems* ***[5]***

https://doi.org/10.52202/069179-0460

Compared to wall systems that are currently in service, see Figure 11, the environmental evaluation for the production phase per functional unit of 1m^2 wall the 3DP Biowall showed elevated values of both GWP and PENRT, when not considering recycle cycles. Recycling the Biowall composite drives these values down on every cycle.

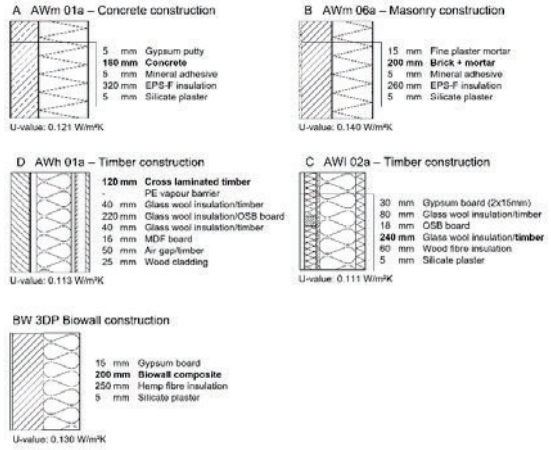

Figure 11: *Cross sections of considered wall systems* ***[5]***

6 THEORETICALLY FEASIBLE PROJECTS

According to Austrian standards no differentiation between one and four storey building is made in terms of the fire resistance requirements of load-bearing structures. Therefor and in order to show economically and environmental feasibility the mechanical properties of the introduced 3DP Biowall should developed in such a manner so that the wall system can be used for these types of buildings.

Examples for such state-of-the-art buildings, made of timber, are "Kleiner Prinz" in Munich (GE) and "Max-Mell-Allee" in Graz (AT), with both having four floors and built using timber frame construction technique with outer walls similar to the wall type awrhhi01a-03 [10]. Based on these designs a maximum design compressive load under normal conditions of around 60 kN/m arises. For this load case the resulting compression stresses and height decreases of the 3DP Biowalls with different wall thickness are summarised in Table 2 based on the model as shown in Figure 12, where the height H is 3 meters.

The stresses for the assumed load are lower than 1N/mm^2 while the mean maximum strength of Biowall under compression is around 90N/mm^2 according to Figure 6. This gap of order two suggests that not only four storey buildings but buildings with even more than four floors can be designed with the 3DP Biowall.

The modulus of elasticity for calculating the compression strain and therefor the compressions is also taken from Figure 6 and approximated with 350N/mm^2. Here again the authors are aware of the 350N/mm^2 not being the characteristic value typically used in a proper dimensioning tasks. The maximum compression is about 5mm for a 100mm thick Biowall and therefore of one magnitude smaller than the expected reduction in height as a consequence of drying shrinkage and creep for a two storey log cabin with a 94mm thick wall made of softwood [11].

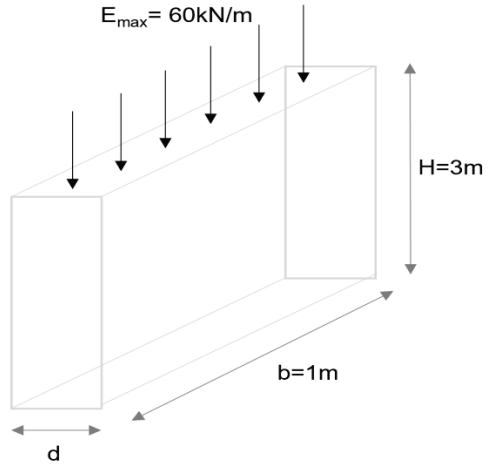

Figure 12: Wall model used for calculation

Taking into account the thermal resistance of the complete wall system, Figure 11 suggests to combine a 200mm thick Biowall with a 250mm hemp fibre insulation. For this Biowall thickness stress and strain are halved.

Table 2: *Stress and Compression for Biowall*

Thickness d [mm]	100	200	300	400
Stress [N/mm2]	0.60	0.30	0.20	0.15
Strain [mm/m]	1.71	0.86	0.57	0.43

The Biowall section can also be split into two pieces sitting on both sides of the insulation layer with each part having a thickness of for example 100mm. This would also increase the flexural stiffness by a factor of approximately seven as well as the sound insulation.

Additionally it is conceivable to replace the hemp fibre by Biowall material with less density as outboard sections of the wall. The material characterisation regarding is thermal insulation potential is part of the project too and will be done in future work.

7 CONCLUSIONS

The positive results of the first preliminary tests and the LCA show that, although challenging obstacles like the further development of the material mix, the production process and the optimisation of their interaction must be overcome to be truly competitive in terms of both environmentalc and economic reasons, 3DP Biowall has the potential to establish closed material loops and implement automation within the construction process, resulting in wood being used in a completely new form full of possibilities.

SEISMIC ANALYSIS OF A MULTI-STORY TIMBER-CONCRETE BUILDING AND DESIGNING FOR REUSE

Sivert Lie[1], Themistoklis Tsalkatidis[2]

ABSTRACT: This research paper seeks to investigate the seismic performance of a hybrid timber-concrete building with multiple stories and explore the possibility of designing for reuse in low-seismicity regions. The building design incorporates hollow-core slabs (HCS) as flooring, a cross-laminated timber (CLT) panel core, and moment-resisting timber frames (MRTF). Various types of beam-to-column connections (BCC) from prior research are adopted in the MRTF. Modal response spectrum analysis of the building is conducted using the Eurocode 8 method, which takes into account the effect of connection ductility. The connections are assessed based on several factors, including story drift, on-site construction ease, disassembly ease, and the reuse potential for beams, columns, and connecting element. The advantages and disadvantages of the concept are discussed. The results show that a higher rotational stiffness in beam-to-column connections shifts the buildings first torsional mode to a higher mode and lower frequency, but generally lowers the reusability of the structural components.

KEYWORDS: Design for reuse, seismic design, disassemble, connections, sustainability, hollow-core slab

1 INTRODUCTION

The construction industry and the production of structural elements contributes to significant parts of the global carbon dioxide production [1]. The need for sustainable buildings that meet the demands from increasing population worldwide and limiting the increasing global temperature due to greenhouse gasses, requires structural engineers to adapt traditional methods of design into more environmentally friendly solutions. While being a large part of a building's mass [2], the use of innovative and emerging materials is generally considered harder for structural elements than for other parts of the building [3]. Recently, the concept of designing for reuse has been implemented in several projects with promising results.

Designing for future reuse increases the possibility of reusing structural elements in order to reduce the carbon footprint of a new building and the waste production from a demolished building. Combining sustainable materials like timber with reused concrete elements can be an important part of reducing the global climate emission from the construction industry, where the production of structural elements is responsible for a share of 15% [4]. The concrete production is a large part of this share due to the high number of concrete projects [5].

The yearly production of Hollow-core slabs (HCS) has been reported to reach 150 million cubic meters per year [6]. The concept of reusing HCS has only been implemented in niche projects until now, but a newly published standard NS 3682:2022 describes the process of demounting, documenting, and evaluation of the element quality [7]. Traditionally, HCS has been regarded as a diaphragm [8]. However, designing HCS with the goal of facilitating disassembly and reuse may necessitate the development of novel methods for interconnecting elements and for connecting to the supporting structure.

The concept of reusing timber elements has not been implemented in a large scale and it is relatively new. This is reported to be due to several factors, including the aging of timber, duration of load and load intensity. The general view, however, is that the bending strength and stiffness are not, or only marginally, affected by this, but investigation is difficult due to large natural variability of timber [9].

Timber-concrete buildings have been extensively investigated, and light-frame wood buildings have shown great resistance against earthquake, due to low mass [10] and ductility of nails [11]. When using engineering wood products in construction, such as glulam or Cross-laminated timber (CLT), the mechanisms for seismic energy dissipation are different than for steel or concrete buildings [12]. Seismic design of moment-resisting timber frames (MRTF) necessitates the incorporation of ductile failure in connections to enable energy dissipation, as timber exhibits brittle material characteristics. For structures located in low-seismicity regions, this approach can be combined with design for future reuse of structural components.

2 METHOD

The suggested method is based on a reference building, preliminary designed according to Eurocode 5 [13], using an ULS utilization ratio of approximately 70% for critical elements.

https://doi.org/10.52202/069179-0461

A numerical model of the building is modelled using SAP2000 [14], where beams and columns are modelled as frames with orthotropic material parameters. CLT is modelled as orthotropic thin shell with material property calculation according to [15]. HCS are modelled as thin shell with membrane thickness corresponding to the element height and bending thickness as 92% of the membrane thickness. To ignore the transverse bending stiffness, a modification factor is applied to reduce the transverse bending stiffness contribution to 1% of the longitudinal stiffness, creating a one-way slab. Table 1 shows the materials, the mass density of structural elements, and loads applied to the structure.

Table 1: *Weight and density of elements and applied loads.*

Element	Weight/Density
HCS 200 mm	271 kg/m^2
HCS 320 mm	425 kg/m^2
Glulam beam and columns	460 kg/m^3
CLT wall-panels (5-L, 200 mm)	440 kg/m^3
Additional dead load	1 kN/m^2
Snow load	2.8 kN/m^2
Live load	3.0 kN/m^2

2.1 REFERENCE BUILDING

The 8-floor reference building is shown in Figure 1. The central core consists of CLT-panels and the remaining bearing structure is glulam beams and columns, working as MRTF, with beam dimension of 480x765 mm^2. Column dimensions vary from 480x900 mm^2 for columns in grid A/F and E/F, and 480x720 mm^2 in grid B/C and D/C. HCS works as the separating floor. The top floor is +34 295 mm, and the general story height is 2.8 m. The first floor differs with a story height of 7 695 mm in grid A/F and E/F, and story height of 4980 mm in grid B/C and C/D. The global X- and Y-axis is parallel with gridline F4 and A1, respectively.

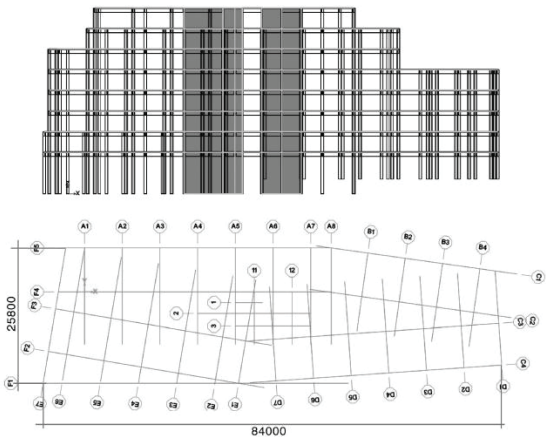

Figure 1: *Outline of reference building and grid.*

2.2 BEAM-TO-COLUMN CONNECTIONS

Several types of beam-to-column connections (BCC) from available research are implemented in the model. The connections are adjusted to fit the dimensions of the structural elements in the reference model, and all connections are based on continuous columns and intermediate beams. All connections are implemented in the analytical model as rotational springs at the beam ends. Two reference connections are made in order to investigate the effect of stiffness of the connections and get comparable extreme values. Pinned connection has springs with zero rotational stiffness, while the rigid connections are implemented with infinite rotational spring stiffness. The rotational stiffness K_R for each connection is based on the analytical formulation found in the respective research.

Following the results from experimental testing where the inclusion of lateral springs did not affect the results relatively much [16], lateral springs are set as rigid in all connections to get comparable results. Rotation of the connection about the column longitudinal axis is neglected as the HCS are assumed to prevent this motion.

Each connection is classified as either pinned, semi-rigid, or rigid according to EC3-1-8 [17], where the stiffness of a typical beam element is used. As the column distances are different in the two global directions, two classification values are used for X and Y, with beam length $L_{b,x}$ = 7200 mm and $L_{b,y}$ = 8400 mm, respectively.

2.2.1 Bolted connection

The determination of K_R for the bolted connection (BC) is based on traditional calculation methods described by EC5 with bolts and slotted steel plates [13]. Using the slip modulus of a single fastener K_{ser} and the corresponding radius from center of rotation r_i, the rotational stiffness in ULS is found using Equation (1):

$$K_R = \sum_{i=1}^{n} \left(2 \cdot \frac{2}{3} \cdot \frac{\rho_m^{1.5} \cdot d}{23} \right) \cdot r_i^2 \tag{1}$$

where ρ_m is the mean density of the connected element and d is the diameter of the bolt. The rotation point is assumed in the center of gravity of the bolts in the beam.

2.2.2 Top-and-seat steel angles connection

The top-and-seat steel angles connection (TS) is evolved from [18], using steel angles on both sides of the column for intermediate BCC connections. The calculation of the rotational stiffness K_R is based on formulation from [19, 20], and is seen in Equation (2):

$$K_R = \frac{h_b^2}{\frac{1}{K_{top}} + \frac{1}{K_{bot}}} \tag{2}$$

https://doi.org/10.52202/069179-0461

where h_b is the height of the beam. K_{top} depends on the bearing stiffness of the column face K_{cc}, axial stiffness of the bolt K_B and the tensile stiffness of the angle horizontal leg K_t. K_{bot} does not include the axial stiffness of the bolt as it is assumed that the bolt has no withdrawal stiffness. The springs are added as a series of springs. K_{CC} is expressed in Equation (3):

$$K_{CC} = \frac{E_{90}\, b_c\, l_{eff,cc}}{h_c} \tag{3}$$

where E_{90} is the modulus of elasticity perpendicular to grain, b_c is the width of the column, $l_{eff,cc}$ is the effective length of the area in compression and h_c is the depth of the column [21]. K_B is expressed in Equation (4) according to [22], using the modulus of elasticity for steel E_s, the cross-sectional area of the bolt A_b and the effective length of the bolt L_b. n is the number of bolts considered to contribute to K_R.

$$K_B = \frac{A_b\, E_s}{L_b} \cdot n \tag{4}$$

K_t is found using the steel angle dimensions and the distance from the critical yielding point to the vertical bolt [22], as seen in Equation (5):

$$K_t = \frac{E \cdot p \cdot t}{a'} \tag{5}$$

2.2.3 Glued-in steel rods connection

The calculation of K_R for the glued-in steel rods connection (GIR) is found using the tensile stiffness of glued-in rods for the tensile stiffness K_{tens} of the connection. The compressive stiffness K_{comp} of the connection is found adding a series of springs where the shear stiffness of the column K_{CS} is expressed by [21], the transverse stiffness of the column K_{CC} as in Equation (3) and the stiffness of the glulam beam in compression K_{BC} defined by [23]. Based on an adapted version from [21], an equation for the rotational stiffness is shown in Equation (6):

$$K_R = \frac{z_{eq}^2}{\frac{1}{K_{tens}} + \frac{1}{K_{comp}}} \tag{6}$$

Where z_{eq} is the equivalent lever arm between the tensile and compressive resultant. K_{tens} is found using the effective stiffness of a rod row and the distance from the bolt row to the center of compression [21]. The design of this connection leads to the connections showing great ductility in experimental testing [24].

2.2.4 Inclined threaded rods connection

The inclined threaded rods connection (ITR) is adopted from [25] and consist of screwed in rods in both the column and beam. The rods are fastened with steel rings, and the rings work as load transferring between the beam and column.

The calculation of K_R is based on component-method, where the stiffness contribution at the column side $K_{ax.c}$ is found using the axial stiffness $K_{ax,l0}$ and the withdrawal stiffness $K_{ser,ax}$ of the rods. Compliance terms S_{xx} and S_{xy} are used to consider the angle of rods. By converting from at point load to a uniformly distributed load acting on a clamped beam, the expression for the stiffness contribution at the column side $K_{R,C}$ is expressed in Equation (7):

$$K_{R,C} = \frac{h_b^2}{\left(S_{xx,c}^{c_1-c_2} + S_{xx,c}^{c_3-c_4}\right) + \left(S_{xy,c}^{c_3-c_4} - S_{xy,c}^{c_1-c_2}\right) \cdot \frac{3h_b}{L_b}} \tag{7}$$

For the stiffness at the beam side $K_{R.B}$, the lateral stiffness K_v of the rod is included in the compliance terms to consider the global direction of the rods:

$$K_{R,B} = \frac{h_b^2}{\left(S_{xx,b1} + S_{xx,b2}\right) + \left(S_{xy,b2} - S_{xy,b1}\right) \cdot \frac{3h_b}{L_b}} \tag{8}$$

The stiffness contribution from the steel rings $K_{R,con}$ is found through numerical analysis and provides 484 kN/mm and 600 kN/mm in compression and tension, respectively [25]. This leads to the equation for K_R seen in Equation (9):

$$K_R = \left(\frac{1}{K_{R,C}} + \frac{1}{K_{R,B}} + \frac{1}{K_{R,con}}\right)^{-1} \tag{9}$$

2.2.5 Overview of rotational stiffness

By applying the dimensions of the structural elements described in 2.1, where some of the connections depend more on the orientation and dimensions of the column, the rotational stiffness for each connection is presented in Table 2. Notation 1 indicates connections located at grid A/F or E/F, while notation 2 refers to grid B/C and C/D, see Figure 1. For the TS, GIR and ITR, four planes of rods are used, and for the bolted connection 16 M16 bolts are placed in a rectangular formation.

Table 2: *Calculated rotational stiffness of investigated connections.*

Connection	Global direction	K_R [kNm/rad]	Rigidity-class
Pinned		0	Pinned
Rigid		∞	Rigid
Bolted		5 629	Pinned
Top-and-seat steel angles	X Y_1 Y_2	49 961 26 684 30 191	Semi-rigid
Glued-in steel rods	X_1 X_2 Y_1 Y_2	53 481 33 938 50 741 38 669	Semi-rigid
Inclined threaded rods	X Y_1 Y_2	51 606 58 705 54 970	Semi-rigid

2.3 CONNECTION HOLLOW-CORE SLABS

The slab consisting of HCS is assumed as a diaphragm with rigid interconnections in the numerical analysis. The connection between HCS to timber beams is based on the connection of a timber-concrete-composite from [26], using vertical glued-in rods glued in the glulam beam and casted together with the HCS. This connection is implemented as a hinged connection in the numerical analysis.

2.4 MODAL RESPONSE SPECTRUM ANALYSIS

Modal response spectrum analysis (MRSA) is done according to EC8 [27] for each connection case, where the value for peak ground acceleration (PGA) is assumed for a building located in Oslo, Norway. This leads to a ground acceleration of reference ground acceleration of 0.3 m/s^2.

As the building is vulnerable for torsional effects, the Complete Quadratic Combination (CQC)-method proposed by EC8 is used for combination of modes. The seismic effect in the global directions X and Y is combined by adding 30% of the seismic effect from one direction to the other.

For a building in seismic class IIIa and ground type D, the parameters Type 2 design response spectrum is shown in Table 3. The average joint absolute drift for each connection case is found. A behavior factor of q = 1.5 is used for the design spectrum for all connection cases except GIR, where q = 2.5.

Table 3: *Parameters for creating Type 2 elastic spectrum.*

Ground type	S	T_B [s]	T_C [s]	T_D [s]
D	1.8	0.1	0.3	1.2

3 CONNECTION EVALUATION

The results from the analysis show that less rigid connections lead to a torsional mode being present at a lower frequency. Increasing the rigidity of the BCC leads to torsional modes being present at higher frequency and less participating modes. The comparison of results from the MRSA for each BCC indicates that increasing the rotational stiffness increases the absolute- and interstory drift.

3.1 PINNED CONNECTION

For the pinned connection, the modes and corresponding contributing mass are listed in Table 4. The first mode is a torsional mode, and the cumulative mass participation ratio exceed 90% in mode 6.

Table 4: *Modes and participation ratio for pinned connection.*

Mode	Period [s]	m_X [%]	m_Y [%]	m_{RZ} [%]
1	2.81	0.1	0.0	70.4
2	1.442	1.1	76.4	0.0
3	1.286	78.2	1,1	0.1
4	0.794	0.1	0.0	17.5
5	0.415	12.1	1.4	0.0
6	0.403	1.5	12.5	0.1
	∑	**93.5**	**91.4**	**88.3**

For the MRSA of the pinned connection, the average story displacement is shown in Figure 2, with a maximum drift of 30.7 mm at the top story. The maximum interstory drift of 5.5 mm is found in story 1 with seismic loading in global Y as the dominant load.

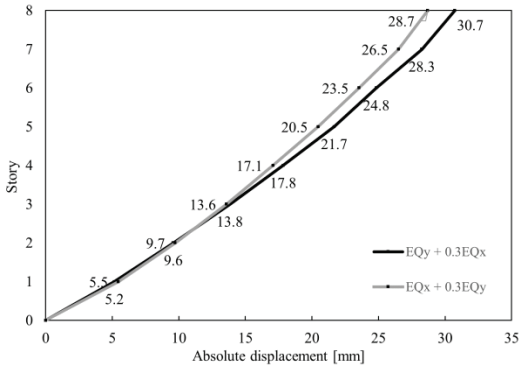

Figure 2: *Average story displacement for pinned connection.*

3.2 RIGID CONNECTION

For the rigid connection, the modes and corresponding mass participation ratios are listed in Table 5. The first torsional mode occurs at mode 3 and the cumulative mass participation ratio exceeds 90% in mode 5.

https://doi.org/10.52202/069179-0461

Table 5: *Modes and participation ratio for rigid connection.*

Mode	Period [s]	m_X [%]	m_Y [%]	m_{RZ} [%]
1	1.184	21.2	64.4	1.3
2	1.065	59.1	23.1	4.3
3	1.003	4.7	0.0	81.7
4	0.349	2.3	6.2	0.0
5	0.318	7.0	2.0	0.0
	∑	**94.3**	**95.7**	**87.3**

For the MRSA of the rigid connection, the average joint absolute drift is shown in Figure 3, with maximum drift of 46.7 mm at the top story. The maximum interstory drift of 14.4 mm is found in story one with the seismic loading in global X as the dominant load.

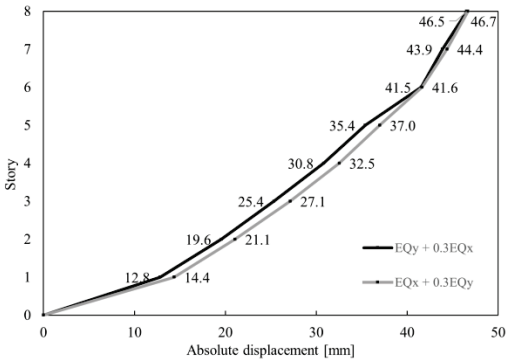

Figure 3: *Average story displacement for rigid connection.*

3.3 BOLTED CONNECTION

For BC, the modes and corresponding contributing mass are listed in Table 6. The first mode is a torsional mode, and the cumulative mass participation ratio exceed 90% in mode 6.

Table 6: *Modes and participation ratio for BC.*

Mode	Period [s]	m_X [%]	m_Y [%]	m_{RZ} [%]
1	2.407	0.1	3.0	72.1
2	1.401	0.0	75.5	2.3
3	1.245	80.6	0.0	0.1
4	0.734	0.1	0.0	14.6
5	0.409	2.9	10.1	0.0
6	0.387	9.6	3.1	0.1
	∑	**93.3**	**91.7**	**89.2**

For the MRSA of BC, the average story displacement is shown in Figure 4, with a maximum drift of 25.9 mm at the top story. The maximum interstory drift of 5.4 mm is found in story 1 with seismic loading in global X as the dominant load.

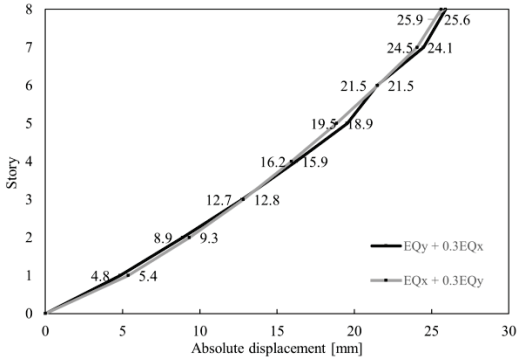

Figure 4: *Average story displacement for BC.*

3.4 TOP-AND-SEAT STEEL ANGLE CONNECTION

For TS the modes and corresponding contributing mass are listed in Table 7. The first torsional mode occurs at mode 3, and the cumulative mass participation ratio exceed 90% in mode 6.

Table 7: *Modes and participation ratio for TS.*

Mode	Period [s]	m_X [%]	m_Y [%]	m_{RZ} [%]
1	1.303	0.0	68.2	13.2
2	1.126	81.8	0.2	2.2
3	1.121	2.3	12.2	65.2
4	0.394	0.1	10.5	1.4
5	0.344	0.1	1.2	9.4
6	0.340	10.2	0.1	0.1
	∑	**94.5**	**92.4**	**91.5**

For the MRSA of TS, the average story displacement is shown in Figure 5, with a maximum drift of 23.6 mm at the top story. The maximum interstory drift of 6.1 mm is found in story 1 with seismic loading in global X as the dominant load.

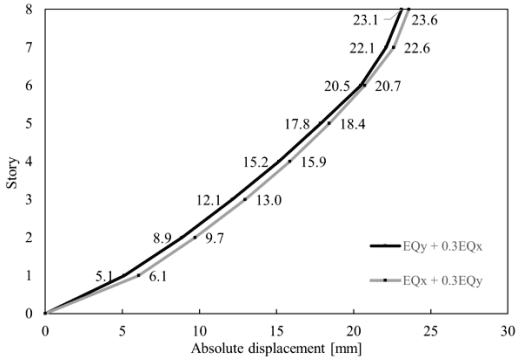

Figure 5: *Average story displacement for TS.*

https://doi.org/10.52202/069179-0461

3.5 GLUED-IN STEEL RODS CONNECTION

For GIR, the modes and corresponding contributing mass are listed in Table 8. The first torsional mode occurs at mode 3, and the cumulative mass participation ratio exceed 90% in mode 6.

Table 8: *Modes and participation ratio for GIR.*

Mode	Period [s]	m_X [%]	m_Y [%]	m_{RZ} [%]
1	1.283	0.2	69.8	11.9
2	1.122	83.8	0.0	0.6
3	1.110	0.4	11.2	68.8
4	0.391	0.2	10.8	0.8
5	0.340	0.4	0.7	0.8
6	0.332	9.7	0.1	9.3
	∑	**94.6**	**92.6**	**91.7**

For the MRSA of GIR, the average story displacement is shown in Figure 6, with a maximum drift of 16.7 mm at the top story. The maximum interstory drift of 3.9 mm is found in story 1 with seismic loading in global X as the dominant load.

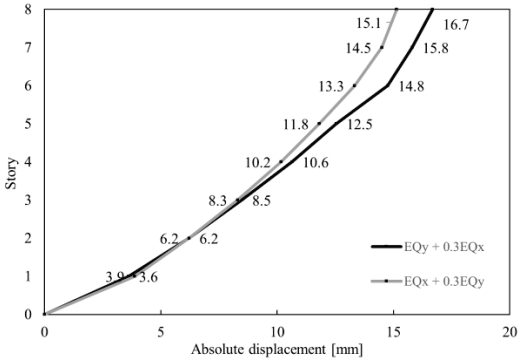

Figure 6: *Average story displacement for GIR.*

3.6 INCLINED THREADED RODS CONNECTION

For ITR the modes and corresponding contributing mass are listed in Table 9. The first torsional mode occurs at mode 3, and the cumulative mass participation ratio exceed 90% in mode 5.

Table 9: *Modes and participation ratio for ITR.*

Mode	Period [s]	m_X [%]	m_Y [%]	m_{RZ} [%]
1	1.246	3.6	71.4	7.6
2	1.120	80.7	3.0	0.7
3	1.092	0.0	7.4	74.1
4	0.384	2.3	8.6	0.1
5	0.339	7.6	2.5	0.4
	∑	**94.2**	**92.9**	**82.9**

For the MRSA of the inclined threaded rods connection, the average story displacement is shown in Figure 7, with a maximum drift of 24.6 mm at the top story. The maximum interstory drift of 6.3 mm is found in story 1 with seismic loading in global X as the dominant load.

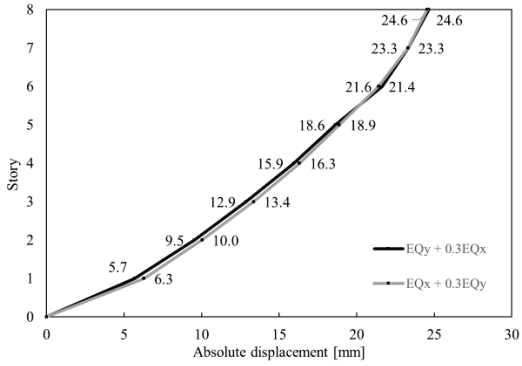

Figure 7: *Average story displacement for ITR.*

4 DISCUSSION

In addition to the numerical results presented, each BCC is discussed based on several parameters: ease of construction on-site, ease of disassembly, reuse potential of beams, columns and connecting elements and aesthetics of connection.

4.1 STRUCTURAL BEHAVIOR

The absolute displacements from the MRSA are calculated using the average joint displacements in each floor. For connection cases where two torsional modes are present before the cumulative mass participation ratio exceeds 90%, the internal variation in joint displacement is higher than connections with only one torsional mode.

By comparing the result from the MRSA with E_Y as the dominant seismic load, Table 10 shows that the tendency is that connections that offer lower rotational stiffness has the first torsional mode outside of the spectrum where the pseudo-acceleration is significant.

For a building in an area with low value for ground acceleration, this means that a connection with low rotational stiffness can be a better option with regards to seismic performance.

Table 10: *Comparison of first torsional mode, torsional mass participation ratio, and the corresponding pseudo-acceleration.*

Connection	T [s]	m_{Rz} [%]	a_g [g]
Pinned	2.810	70.4	0.008
Rigid	1.003	81.7	0.034
BC	2.407	72.1	0.008
TS	1.121	65.2	0.031
GIR	1.110	81.2	0.019
ITR	1.092	74.1	0.032

https://doi.org/10.52202/069179-0461

4.2 EASE OF CONSTRUCTION ON-SITE

The ease of construction on-site is critical for efficient construction process of a building. BCC with an extensive process with necessary high precision is time consuming and harder to construct on-site.

ITR is rather comprehensive to construct and require high precision to acquire the rotational stiffness from the numerical formulation. The effect of different rod-to-grain angle than used to calculate the rotational stiffness affects the rotational stiffness significantly [25]. Following this, the insertion of rods in both the beam and the column should be done in a controlled environment (typically off-site) and leads to low on-site flexibility.

The same applies to GIR because contact between the beam and column faces is critical. This is due to the spring stiffness of the column face, K_{cc}, which is one of the decisive parameters for the rotational stiffness. As a result, the mounting process is time-consuming and has minimal tolerance for errors both in production and during assembly. However, if the on-site margin of error is within the tolerance limits and the necessary off-site preparations are completed, the assembly process may be time-effective.

4.3 EASE OF DISASSEMBLY

The ease of disassembly is critical for efficient tear-down of buildings and possibility for reusing structural elements. Connections with more permanent connecting elements, typically glue or welds, are considered having lower reuse potential [28] and a relatively low reversibility [29].

This leads to GIR being a less suitable alternative when considering possibilities for future reuse of beams and columns. The structural performance of this connection depends on the withdrawal capacity of glued-in rods, making the reversibility of the connection, without causing damage to the column, beam, or rods, low.

Conversely, connections that utilize bolts and screws as connecting elements require less time for disassembly [29]. This implies that the traditional bolted connection, the steel angle connection, and the inclined threaded rods connection may all be relatively easy to disassemble.

4.4 REUSE POTENTIAL OF BEAMS, COLUMNS AND CONNECTING ELEMENTS

The reuse potential for the components in each BCC is discussed, where the potential is based on the possible failure mode of the BCC, and the affected area of the beam and column. The reuse of connected and connecting elements is based on the possibility of reusing components of the connection. Connections with more permanent connecting elements, typically glue or welds, are considered having lower reuse potential [28].

One issue with the traditional type of timber connections, like BC, can be residual displacement caused by non-linear behavior of the timber under initial load. This happens due to imperfections in the timber surface facing the connector and occurs even if the dowels are tightly fitted [30]. This means elements involving bolts should be checked for damages, and most probably the portion of the elements with bolt holes should be deposited. Bolted connections should also generally be designed for ductile failure of the connector [13] and due to this requirement, the bolts should not be reused for structural purpose. The possibility of removing the affected portion of the beam and column is incidentally the cased for all connections discussed, but especially relevant for GIR, as the rods are time-consuming to remove.

ITR can have the highest potential for reuse, but this requires designing the next project based on the available beams and columns. This concept is referred to as stock-constrained design [31].

4.5 REUSE OF HOLLOW-CORE SLABS

To include HCS in the design of a sustainable building, the design process should evaluate if the building is going to be designed using an existing stock of materials, designed for future reuse. The optimal solution would be to combine these two concepts, but as for HCS, the concept of including already existing elements seems to be the better option. The reasoning behind this is the large amount of already produced HCS.

The HCS should be connected to the timber beams using the same concept as for glued in shear studs, creating a timber-concrete composite. This is shown to reach good shear capacity [26] and can also be utilized to reduce the necessary cross-sectional area of the timber beams due to timber-concrete-composite effect.

4.6 EVALUATION OF THE CONCEPT

The advantages with the concept of reusing and designing for future reuse is described to be of significant value. Utilization of already produced structural elements introduce a potential of reducing significant amounts of global greenhouse gas emissions. The disadvantages are, on the other hand, what significantly raises the threshold to fully utilize the potential reduction of environmental burden the construction of a new building.

For structural elements, the process of tearing down a building often implies rough treatment for vulnerable elements like timber. To facilitate future reuse of these elements, the process needs to be changed from demolition to disassembling. The integration of disassembling will increase the time consumption of tearing down a building significantly and consequently increasing the cost.

To implement connections with higher rotational stiffness more suitable for modular buildings, the concept of stock-

constrained design may be an effective method to utilize already produced elements. However, when using this method, the design of the new building is restricted by available materials. This could lead to a lower utilization of available land area, and implicit meaning a higher cost per area.

5 CONCLUSION

In this paper a modal response spectrum analysis according to EC8 is done for a reference building consisting of a variety of beam-to-column connection from available research, hollow-core slabs as separating floor and a CLT-core.

The results of the presented study show that a higher rotational stiffness in beam-to-column connections shifts the buildings first torsional mode to a higher mode and lower frequency, but generally lowers the reusability of the structural components. Therefore, in the cases where the reusability is prioritized, the evaluated connections with higher rotational stiffness beam-to-column connections may not be the best alternative. However, according to the findings of the numerical investigation, it is possible to combine design for seismic loadings in low-seismicity regions with designing for future reuse by selecting beam-to-column connections with appropriate characteristics. Overall, this is a promising option for the design of future projects.

DEVELOPMENT OF TEMPORARY STRUCTURE USING CLT PANEL: INVENTION OF CONSTRUCTION AND VERIFICATION BY CONSTRUCTION EXPERIMENT

Hiroaki Kubotera[1], Toshiaki Sato[2], Yohei Aioi[3] and Kazuo Niikuma[4]

ABSTRACT: Temporary buildings have the advantage of being able to meet sudden demand. In recent years, the demand has been affected not only in the event of a disaster but also due to COVID-19 infection. This paper shows a temporary structure that can be used repeatedly for the purpose of constructing a temporary building using Cross Laminated Timber (CLT), and confirmed its practicality through construction experiments.

KEYWORDS: CLT, Temporary Construction, Experimental Study

1 INTRODUCTION

Buildings are divided into temporary buildings and permanent buildings according to the period of use, and in particular, temporary buildings have the advantage of being able to meet sudden demand. In recent years, the demand has been affected not only in the event of a disaster but also due to COVID-19 infection, and the Japanese government has approved the use on the street for the purpose of taking out and installing terrace seats, so temporary buildings are also used in restaurants. Under these circumstances, wood is lightweight and easy to process, and deterioration does not pose a major problem on the premise of dismantling and repairing, so it has the potential as a material for temporary buildings. From the perspective of creating demand for timber in Japan, it is meaningful to aim for the general spread of wood-based materials in the field of temporary construction, where a large amount of demand can be expected from local governments and private companies.

Against this background, we designed a temporary structure that can be used repeatedly for the purpose of constructing a temporary building using Cross Laminated Timber (CLT), and confirmed its practicality through construction experiments. The developed temporary structure is composed of CLT panels with four corners machined and steel joints, which facilitates on-site assembly.

2 DESIGN OF TEMPORARY STRUCTURE USING CLT PANELS

2.1 OUTLINE OF STRUCTURAL SYSTEMS

The temporary structure developed in this paper is composed of four CLT (3-layer, 3-ply, Japanese cider) panels with the same cutting at the four corners and a steel joint with a truss mechanism. Fig. 1 shows the elevation of the temporary structural system on each side, and Fig.2 shows an image of using as restaurant on the street.

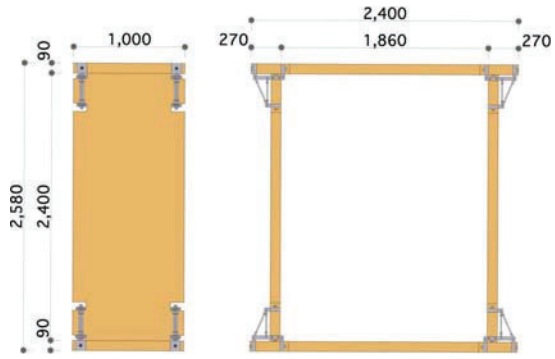

***Figure 1**: Elevation of temporary structural system*

***Figure 2**: Image of terrace seats with the developed unit as the core*

https://doi.org/10.52202/069179-0462

In Fig. 1, The truss mechanism resists the horizontal force in the frontage direction, and the wall itself resists in the direction of the wall orthogonal to it.

Temporary buildings, which are supposed to be demolished in a certain period of time, consume resources faster, so consideration must be given to material reuse and material recycling, and this project also emphasized this. In particular, the dimensions and fabrication of the four CLT plates were standardized for convenience in repeated assembly and disassembly as a temporary unit, and the shapes of the eight steel joints were also standardized for easily removal.

2.2 COMPONENT DESIGN

All CLT panels are processed in the same way to ensure reusability. At the prototype stage, as shown in Fig. 3, we considered a plan to provide tenons with notches at the four corners of the CLT, and a plan to replace the tenons with steel materials. In consideration of restraint, we adopted a plan to make a through hole at the position where the tenon was supposed and pass a bolt (diameter = 16 mm) through it. As a result, the rattling caused by the error of wood processing can be corrected by tightening the nut. The outline of the processing of the entire CLT panel is as shown in Fig. 4.

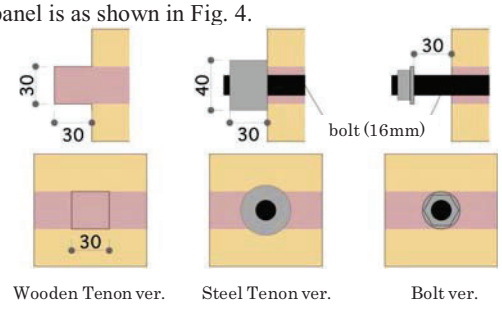

***Figure 3**: Wood processing and trial production of joints*

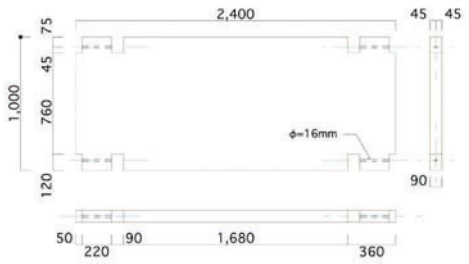

***Figure 4**: Outline of CLT panel processing*

Fig. 5 shows an outline of the steel joint and the parts of each part constituting the joint. All parts are made of steel (ss400) and are integrated into one joint with four pins, which can be easily assembled and disassembled by attaching and detaching them. In order to reduce the cost of electric discharge machining, the member B was divided into three parts and fixed with M8 countersunk screws. For member C, since it is a truss mechanism that applies only axial force to the member, it is necessary to use a pin joint, and rod end bearings are used at both ends of the M10 bolt.

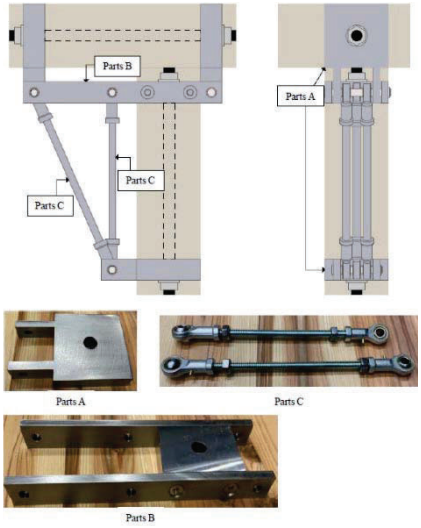

***Figure 5**: Steel joint configurations and parts*

In the design of this joint, the dimensional error of each member was also examined in consideration of on-site work. Compared to wood processing, steel processing causes almost no dimensional error, so for the hinge part that is completed only with steel, the hole diameter and hinge pin diameter are both 10 mm, and a hinge pin with a negative tolerance was selected. The through hole of the bolt, which is expected to be affected by the processing error of the wood, was 0.5 mm larger and the wood was processed. In addition, in order to absorb dimensional errors in the CLT cutting process, the bolts of part C are designed to have a margin of 5 mm between the rod end bearings, and the length of the entire member C can be adjusted by fastening the bolts during construction.

3 INVESTIGATION OF STRUCTURAL PERFORMANCE

3.1 OVERVIEW OF INVESTIGATION

The temporary units proposed in this research do not examine the basic conditions that the building must satisfy, such as ensuring fire resistance and fixing methods to the ground. Safety based on allowable stress calculations against long-term loads and rarely occurring loads and external forces, with the goal of ensuring performance equivalent to temporary structures according to the Japanese Building Standards Law, considering the assumed usage. We decided to verify the Tables 1 & 2 list the mechanical properties of the steel and wood used in the study.

***Table 1:** Mechanical property of steel*

Steel type	Reference strength [MPa]	Long-term allowable stress		Short-term allowable stress
		σ	τ	
SS400	$F = 235$	$F/1.5$	$F/1.5\sqrt{3}$	F

https://doi.org/10.52202/069179-0462

Table 2: *Mechanical property of Wood*

Species	Design strength [MPa]			
	Comp-ression	Tensile	Bending	Shear
Japanese cidar	17.7	13.5	22.2	1.8

Structural performance was confirmed by the following procedure. Since this temporary structure is a composite structure of wood and steel, we first verified the safety of the steel joints against the assumed external force, and then modelling the joints on the upper part of the unit as a static rigid frame assuming rigid joints. Considered the safety of wood. According to the design guidelines for temporary structures, when the scale is small, the external force assumed in the design against snow load and wind load is often reduced, but with reuse in mind, each member should have a certain amount of surplus performance. Therefore, we decided not to conduct this study.

3.2 EVALUATION OF STRUCTURAL PERFORMANCE

Fig. 5 shows the mechanical model of the steel joint. In the actual design, bolt fastening force is generated against the steel plate sandwiched between the stud bolts (φ = 16 mm) passed through the CLT, but this model ignores that effect as an evaluation on the safe side. Then, consider only the effect of preventing the bolt from coming off.

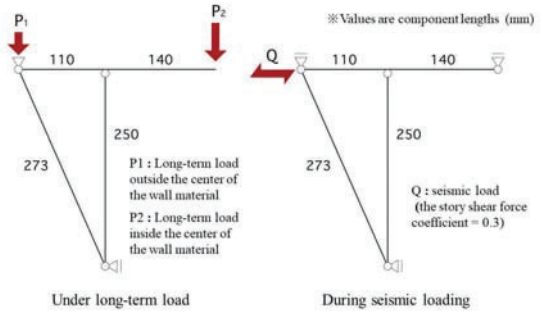

Figure 6*: Mechanical model of steel joints*

Regarding the long-term load P shown in Fig. 6, the dead load is generally calculated as a uniformly distributed load. The conditions were set such that the portions inside the wall material act on both ends of the joint as concentrated loads P_1 and P_2, respectively. Assuming a cedar density of 0.38 and a gravitational acceleration of 9.8 [m/s^2]

$$P_1 = 0.38\times10^{-6}\times500\times225\times90\times9.8 = 37.8\ [\mathrm{N}]$$

$$P_2 = 0.38\times10^{-6}\times500\times975\times90\times9.8 = 163.4\ [\mathrm{N}].$$

Similarly, regarding the seismic load Q in Fig. 5, the dead weight of the ceiling material, two wall materials, and steel joints (approximately 9.0 kgf) is assumed to be the fixed load used to calculate the story shear force, and the story shear force coefficient was set to 0.3 as a safe side evaluation. From the above conditions

$$Q = 0.3\times W/2 = 415\ [\mathrm{N}].$$

The reason for dividing by two in the above formula is that when the unit is viewed from the frontage direction, it is assumed that the two steel joints at the front and back will simultaneously resist the seismic load.

Table 3 shows the maximum stress in each member of the steel joint as a result of the investigation based on the above. From the results shown in Table 3, all values are well within the allowable stress shown in Table 1, confirming its safety.

Table 3: *Maximum stress of steel joints members*

Load	Member	σ_{max} (axial) [MPa]	σ_{max} (bending) [MPa]	τ_{max} [MPa]
Only dead load	Diagonal	5.2	–	–
	Vertical	4.8	–	–
	Horizontal	–	0.52	7.7
Seis mic force	Diagonal	13.2	–	–
	Vertical	12	–	–
	Horizontal	–	1.4	19

Following the investigation of the steel joints, Fig. 7 shows the mechanical model used for investigation of CLT panel.

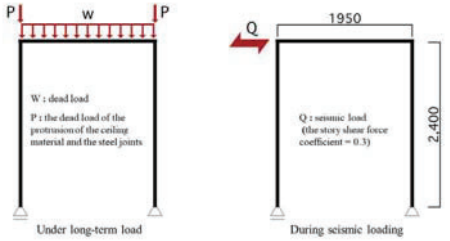

Figure 7*: Mechanical model for investigating CLT panel*

Regarding the long-term load shown in Fig. 7, the uniformly distributed load w in the figure represents the dead load of the ceiling material, and the vertical load P represents the dead load of the protrusion of the ceiling material and the steel joints. Each value is

$$w = \frac{0.38\times10^{-6}\times1000\times1950\times90\times9.8}{1950} = 0.34\ [\mathrm{N/mm}]$$

$$P = \left(0.38\times10^{-6}\times1000\times225\times90 + 9.0\times2\right)\times9.8 = 252\ [\mathrm{N}]$$

https://doi.org/10.52202/069179-0462

The seismic load Q shown in Fig. 7 is the same as in the investigation of steel joints, but since it is a model of the entire unit here, it is set to 830 N before dividing by two. Table 4 summarizes the maximum stress generated in the CLT based on the calculation results of the stress in each part based on the above discussion. As with steel joints, all values in Table 4 are within the allowable stress shown in Table 2, confirming its safety.

Table 4: *Maximum stress of CLT panel*

Load	Member	σ_{max} (axial) [MPa]	σ_{max} (bending) [MPa]	τ_{max} [MPa]
Only dead load	Wall	6.5×10^{-3}	–	–
	Ceiling	–	5.6×10^{-3}	0.12
Seismic force	Wall	1.2×10^{-2}	1.4×10^{-2}	1.5
	Ceiling	9.2×10^{-3}	1.7×10^{-2}	1.5

As the final part of the member study, the results of other parts such as bearings and pins, as well as the buckling of bolts, are summarized below. The bearing used this time has a radial static load rating of 13.2 kN. It can be seen that there is sufficient margin even when compared with the axial force of 1445 N, which is the largest stress shown in Table 3, 18.4 (N/mm2), multiplied by the cross-sectional area of 78.5 mm2 of member C (Fig. 5).

According to the results in Table 3, the largest force acting on the pin is the axial force acting on the diagonal member, which is 13.2 [MPa] x 78.5 [mm^2] = 1036 N. These are divided into two components, vertical and horizontal. We evaluated the stress generated in the hinge pin using two simple beam models. Fig. 8 shows the dynamic model used in the study of the pin, and Table 5 shows the calculation results using it.

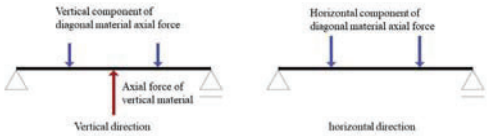

Figure 8*: Mechanical model for evaluating hinge pin stress*

Table 5: *Maximum stress of hinge pin*

Direction	σ_{max} (bending) [MPa]	τ_{max} [MPa]
Horizontal	41.2	4.29
Vertical	78.5	9.71

The hinge pin adopted in this research is carbon steel S35C for machine structural use. Although this is stronger than SS400 material, the maximum stress of the hinge pin is within the allowable stress of SS400 shown in Table 1, so the safety can be confirmed.

The double-ended bearing material (member C) does not become plastic within the design load range, but confirms that buckling does not occur within the elastic range. The buckling stress σ_{cr} is generally obtained from the following equation.

$$\sigma_{cr} = \frac{\pi^2 E}{\lambda^2} \text{ where } \lambda = \frac{L_k}{i} \qquad (1\text{-}1, 2)$$

In the above equations, E : Young's modulus, λ : slenderness ratio, L_k : buckling length, i : cross-sectional secondary radius. The buckling length L_k is the same as the length of the member because the double-end bearing material can be regarded as a double-end pin. As the Young's modulus of SS400 is 205 [GPa] and member cross section is circular with a diameter of 10 mm,

$$\text{Diagonal}: \sigma_{cr} = \frac{\pi^2 \times 2.05\times10^5}{(273/2.5)^2} = 169\ [\text{MPa}]$$

$$\text{Vertical}: \sigma_{cr} = \frac{\pi^2 \times 2.05\times10^5}{(250/2.5)^2} = 202\ [\text{MPa}]$$

is calculated. Comparing this with the stress shown in Table 3, it is considered that buckling does not occur within the range of the design load this time.

4 VERIFICATION OF EFFECTIVNESS BY CONSTRUCTION EXPERIMENT

4.1 OUTLINE OF CONSTRUCTION TEST

A construction experiment was conducted to verify the effectiveness of the temporary unit. At the design stage, we were thinking of a procedure to assemble the unit with the unit laid on its side, and then pull the roof panel to raise it. However, in this experiment, from the viewpoint of ensuring construction space and safety, we adopted the method of attaching the wall panel first and joining it with the roof panel with a crane as shown in Fig. 9.

In this construction experiment, it took about 2 hours to rework the wood part due to the small error of the hinge part. The actual assembly time was about 30 minutes, and After the completion of the construction experiment, no distortion or twisting was observed in the entire unit within the range of visual observation. It was confirmed that it was very stable under the load of its own weight, which is enough to lift the whole with a crane, and no large gaps were found in the joints.

4.2 EXAMINATION OF PROBLEMS SEEN DURING CONSTRUCATION

(a) Hinge part

First of all, the poor workability of the hinge part was a problem. At the design stage, there was no dimensional leeway in the hinge part, but with only the negative tolerance of the hinge pin, the workability was poor, and there were some cases where the pin did not pass through.

https://doi.org/10.52202/069179-0462

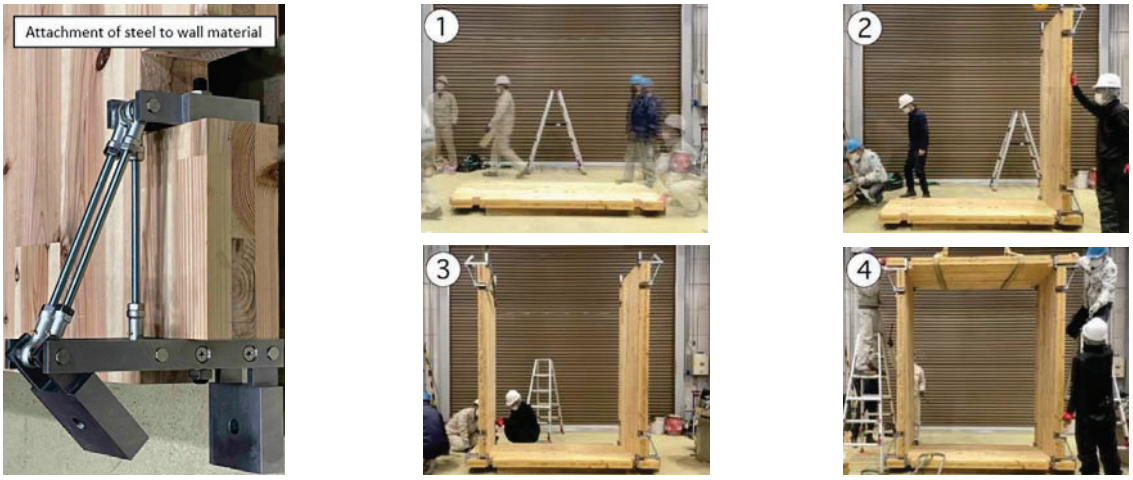

***Figure 9**: Procedure of construction experiment*

We think that the diameter of the through holes at both ends of the member B should have been designed to be 0.5 to 1 mm larger.

(b) Weight

The second point is the problem of weight. In this construction experiment, a overhead crane was used, so there were no particular weight problems, but considering the actual operation as a small-scale temporary unit, it is necessary to consider the possibility of assembling and dismantling only by human power. Especially, the weight of CLT is a problem, and at present it is about 85 [kgf] per piece even after processing, which is likely to adversely affect workability. In order to be able to flexibly respond to changes in shape and processing during the design process, including the steel joints, there was an aspect of giving a margin to the cross section of each member at the initial stage of selecting members. Considering the surplus performance, it may be necessary to reconsider the thickness of the laminated board and the cross-sectional area of each steel material to optimize the weight.

(c) Machining accuracy

The CLT prepared in this study was not pre-cut at the factory, but was hand-processed at the site. A particular problem was the machining error in machining the 16mm through-hole for the stud bolt to pass through, which exceeded the expected error in the design stage. The cause was thought to be the storage method of the CLT before processing, and about 2 mm of warpage occurred in the long axis direction during processing. In manual drilling, it is difficult to keep vertical and horizontal, but warping made this process even more difficult. As a result, in this construction experiment, as shown in Fig. 10, the hole drilled during processing was expanded to a maximum of 21 mm and assembled. If the steel joints are assembled first, as in this case, the error absorption performance of the steel cannot be fully demonstrated, so it can be said that it is necessary to improve it to absorb the deformation of the wood after processing, assuming reuse.

***Figure 10:** Through hole in CLT before and after modification*

(d) Truss members

When I checked the condition of each part after the unit was assembled, it was found that among the members (member C) with bearings attached to both ends in the steel joint, six at the bottom of the unit were clearly in a state where no axial force was generated. The reason is that the initial deformation of the wall material during assembly is within the error absorption range assumed at the design stage, and no force is generated in the member in the first place, or the stud bolt passed through the CLT is tightened with nuts from both sides. Therefore, it is conceivable that the force is concentrated on the bolt and the horizontal member (member B). Since the load is only due to its own weight, it is a matter of speculation. It is considered desirable to have a design that can adjust the axial force before and after assembly by applying two chamfers between materials for right-hand and left-hand threads.

https://doi.org/10.52202/069179-0462

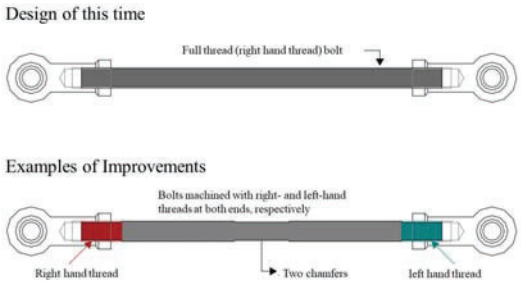

***Figure 11**: Example of improved ended bearing members*

5 CONCLUSIONS

In this study, we designed a temporary unit using a CLT panel and confirmed its effectiveness from construction experiments. The findings obtained are as follows.

1) Even with CLT panels, it is more difficult to secure machining accuracy than steel materials, and appropriate error management is required.
2) It was a rather heavy unit to assemble manually after undergoing construction experiments. It is necessary to consider whether to assemble with heavy machinery and to optimize the dimensions and weight in consideration of the balance with the structural performance.

ACKNOWLEDGEMENT

We would like to our sincere gratitude toward the technical staffs of faculty of engineering in Kyushu University for their assistance in fabricating the components of this temporary unit, and also the staff of PLAM Co. Ltd. help our works with the wood processing and unit assembly work in construction experiment.

APPENDIX

(A) Processing CLT Panel

Figure A shows how the notch was processed manually by a skilled carpenter. The notch portion was processed by first making cuts from both sides of the laminated board using a circular saw, and then using a multi-tool to cut the portion that could not be completely cut due to the circular saw.

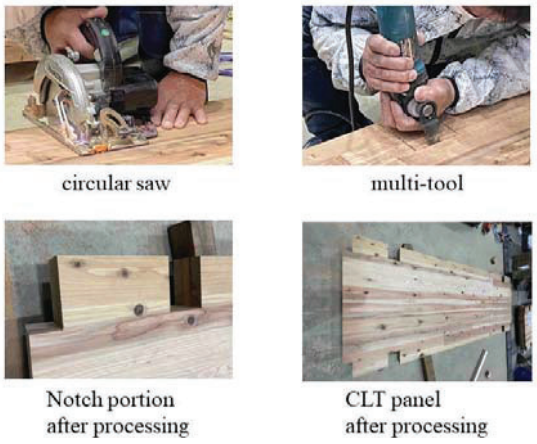

***Figure A**: Photos of the notch being processed*

(B) Records of construction experiments

On January 18, 2022, we conducted a construction experiment of a temporary unit using CLT panels, which is the subject of this research. The experiment was conducted in a large-scale experimental facility at a university. The experiment is roughly divided into the steps shown in Fig. B, and the records of each step are summarized as supplements.

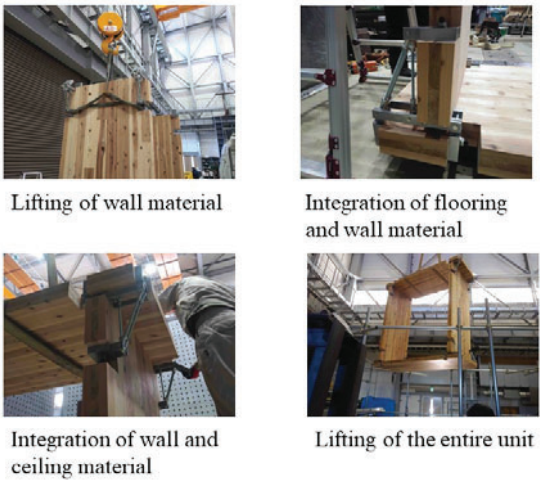

***Figure B**: Experiment process and photos*

(1) Lifting wall panels

The wall panels were lifted by an overhead crane by attaching a belt to the notch of the CLT panel. The ceiling material was lifted by passing two belts through the middle of the material. The overhead crane used here has a capacity of 4.8 tonf.

(2) Integration of floor and wall materials

Regarding the unification of the flooring and wall panels, in this construction flow, the wall panels were constructed while they were being lifted by an overhead crane. We were able to put it in place. However, since it

is difficult to secure means to replace cranes at actual sites, this point needs to be examined in the future.

(3) Integration of ceiling and wall materials

Regarding the integration of the wall material and the ceiling panels, in the previous procedure, there were two steel joints. As a result, it was confirmed that the error was concentrated in the final joint and the stud bolt could not pass through. As mentioned above contents, the expansion of the through hole of the CLT panel was made the largest in this part, and it is necessary to review the assembly error.

(4) Movement of the whole unit

After completing the construction experiment, the entire unit was moved by an overhead crane. In the study of structural performance shown in this paper, such a situation is not assumed, but for example, when a temporary unit is assembled at a factory and then transported to the place of use, there is no situation in which the entire unit is lifted and moved. Easy to imagine. This time, as shown earlier, there was a considerable amount of leeway in the stress generated in the members, so there was no deformation of the unit within the scope of visual confirmation even after the move, but in the future, we will be able to operate under such special conditions. It is considered necessary to conduct a safety evaluation as well.

World Conference on Timber Engineering Oslo 2023

HOW TIMBER BUILDINGS CAN BE DESIGNED FOR DECONSTRUCTION AND REUSE IN ACCORDANCE WITH ISO 20887

Ylva Sandin[1], Marlene Cramer[2], Karin Sandberg[3]

ABSTRACT: There is a need for a shift towards circular economy in the building and construction sector. Design for deconstruction and reuse (DfDR) and design for adaptability (DfA) have been suggested as means to facilitate reuse of buildings and diminish waste and material consumption. A standard, ISO 20887:2020, has appeared to support the implementation of DfDR/A. One objective of this study is to demonstrate timber building design examples that can be considered consistent with the standard and designs that should be avoided. Another objective is to examine if there are important aspects of DfDR/A for timber buildings that are insufficiently covered by ISO 20887:2020. The broader, long-term aim of the work is to remove thresholds to DfDR/A by providing support for designers and industry in applying the standard. The principles and strategies in ISO 20887:2020 are illustrated with practical examples from case studies, organised in a searchable database.

KEYWORDS: Disassembly, adaptability, circular economy, timber building, ISO 20887

1 INTRODUCTION

1.1 BACKGROUND

Greenhouse gas emission, raw material consumption and waste production from the building sector is huge [1]. If buildings (or their parts) were reused to a higher degree, material consumption and waste production could be minimised. For timber buildings, it is currently not viable and economic to extract timber for reuse [2]. The design philosophies *design for deconstruction and reuse* (DfDR) and *design for adaptability* (DfA) have been suggested to facilitate reuse of buildings, and a standard, ISO 20887:2020 (hereafter referred to as ISO 20887), has been published to support the implementation of these philosophies [3]. As this publication is recent, using it in timber building design is not yet standard practice. Also, the standard is comprehensive and general, and it needs to be interpreted. There is a need for showing timber building solutions that are in line with the standard and solutions that should be avoided.

1.2 AIM AND OBJECTIVES

The broader aim of the study is to support circular economy by removing thresholds to DfDR/A.
The objectives are:

- To show how the principles and strategies of ISO 20887 can be interpreted and fulfilled in practical timber building design.
- To examine if there are important aspects of DfDR/A for timber buildings that are insufficiently covered by ISO 20887.

2 METHOD

2.1 GENERAL METHODOLOGY

Case studies were carried out, where timber building designs were examined with respect to DfDR/A. The resulting advantages and disadvantages were then used to illustrate the ISO 20887 design principles. The study included three steps:

1. *Data collection in case studies*. Interviews were carried out to identify what manufacturers, builders and designers consider as advantages and disadvantages to DfDR/A in the design of timber buildings [4-6]. Drawings and documents were studied. Field studies were carried out. The result is a list of advantages and disadvantages, illustrated by pictures and design drawings.
2. *Interpretation of ISO and re-evaluation.* First, the structure of the standard was analysed. Thereafter, the advantages and disadvantages identified in step 1 were re-evaluated to identify

[1] Ylva Sandin, RISE Research Institutes of Sweden, Sweden, ylva.sandin@ri.se
[2] Marlene Cramer, Edinburgh Napier University, UK, m.cramer@napier.ac.uk
[3] Karin Sandberg, RISE Research Institutes of Sweden, Sweden, karin.sandberg@ri.se

https://doi.org/10.52202/069179-0463

which principle(s) in ISO 20887 they illustrate, if any. The result is a set of documented experiences from using the standard.

3. *Establishing a database of design examples*. Design examples were organized to illustrate the ISO design principles specifically for timber buildings.

2.2 COMMENT ON CASE STUDIES AND THEIR METHOD

Six practical deconstructions and eight simulated deconstructions of timber buildings in different European countries were analysed. All case studies represent modern timber buildings with different building systems (post and beam, volumetric or planar modules and either mass timber or light timber frame). The practical deconstruction and reconstruction cases (all in Sweden) include a hall (post and beam, mass timber), an office building (volumetric, light timber), a residential building (volumetric, mass timber), two pavilions (one with planar elements, mass timber and one with post and beam structure, mass timber). Four of them are illustrated in Figure 1, the fifth is shown in Figure 2.

Figure 1: *Four of the studied practical deconstructions. Photos: Masonite Beams (above left), Olof Mundt-Petersen and Oskar Linderoth (above right), IsoTimber (below left), Folkhem (below right).*

The simulated cases all regarded industrially produced systems and residential buildings in two stories: three light timber systems, one mass timber system in planar elements and one a combined post and beam/light timber system.

As the different designs were evaluated in interviews, the identified advantages and disadvantages are somewhat subjective and do not necessarily represent a comprehensive list of strengths and weaknesses in each case study. Especially in the simulated case studies, only information that was volunteered by third parties and interpreted based on informed assumptions could be included in the analysis, without the option to verify it in full scale deconstructions or in laboratory. Nonetheless, it is expected that each case study captures the most important aspects of DfDR/A. All interviews involved knowledgeable people. On average, there were 3-4 people per case study who participated with different competences and experiences in construction and deconstruction. One of the simulated deconstructions involved a person who had disassembled and reassembled a similar building and now lives in it.

Figure 2: *A hall with post and beam structure, that first served as a temporary market hall and later became a sports hall. The photo shows the hall in its first use. Photo: Ylva Sandin*

2.1 LIMITATIONS

The study concerns *loadbearing structures* of timber buildings. The focus of the case studies was on DfDR, and although some of them gave considerations also to DfA, the gathered examples do not capture a comprehensive overview of DfA designs.

3 RESULTS AND DISCUSSION

3.1 DATA PRESENTED

In this section, one of the case studies, concerning the deconstruction and reconstruction of a hall, is first presented as an example of the case study method (section 3.2). Then, advantages and disadvantages to DfDR that were identified for that case are given (section 3.3). Thereafter, the ISO 20887 is presented, and examples are given of how data from the hall case can be re-evaluated with respect to the standard (section 3.4). It is then shown how the standard could be enhanced with a database of design examples (section 3.5). Finally, some reflections on the ISO 20887 following from the evaluation of all case studies are given (section 3.6).

https://doi.org/10.52202/069179-0463

3.2 CASE STUDY EXAMPLE: TEMPORARY MARKET HALL

A temporary hall was erected at Östermalmstorg in Stockholm, Sweden, to enable the traders in the market hall "Östermalmshallen" to continue their businesses while the hall was renovated. The temporary hall was designed by Tengbom architects and was in use as market hall 2016-2020 (Figure 2). It has a post and beam structure of glulam and LVL (Laminated Veneer Lumber). The building was disassembled in spring 2021 (Figure 3) and reassembled in spring 2022 as a sports hall in Mölnlycke, Sweden (Figure 4). The entire frame was reused, as were all the façades. Much of the installations and other layers were also reused (see also [5] and [7].)

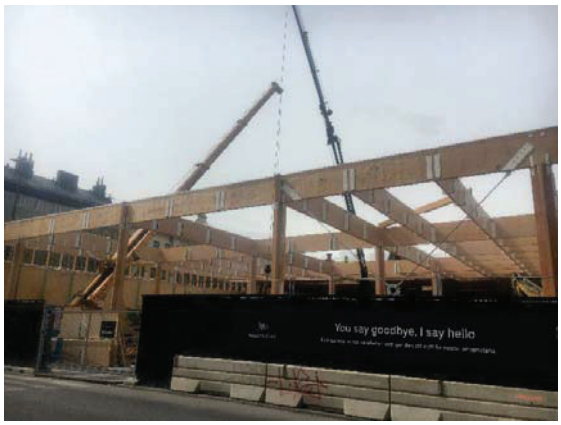

Figure 3: *The hall is disassembled, April 2021. Photo: Andres Zabala Mejia.*

Figure 4: *The hall during reconstruction. Photo Ylva Sandin.*

For this case, data was collected on four occasions. First, one of the architects that had worked with the design was interviewed. Then, the deconstruction site was visited during disassembly and the project manager was interviewed. On a third occasion, the project manager was interviewed on video during reassembly and finally the reconstruction site was visited during reassembly and both the project manager and people from the construction firm were interviewed. The deconstruction and reconstruction sites were documented in photos.

3.3 IDENTIFIED ADVANTAGES AND DISADVANTAGES TO DFDR

When asked about advantages of the design, based on their experiences from deconstruction and reassembly, the project manager and construction firm mentioned the following.

3.3.1 Advantages

Adaptable to new use: The transformation from market hall to sports hall was successful. The post and beam system was flexible and adaptable to the new use. Posts could be moved without changing their dimensions. Roof beams affected by larger stresses, following the change of post position, were reinforced with steel fittings (Figure 5). Lengths of posts were adjusted with steel details. Steel details were considered as positive aesthetic expressions, showing that the hall is reused.

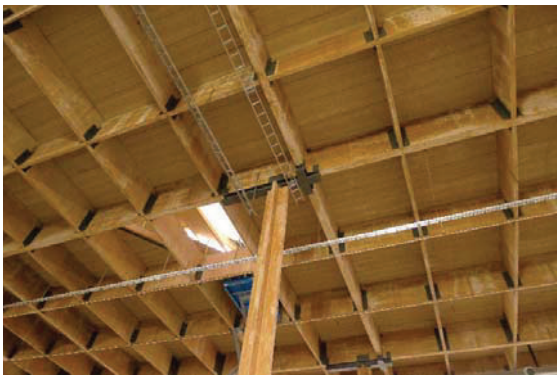

Figure 5: *A roof beam adapted with steel as bending moment changed when a post got a new position. Photo: Ylva Sandin.*

No waste: All parts of the loadbearing structure were reused – there was no waste (ignoring waste that did not concern the structure, particularly roof insulation.) Posts and beams were robust and durable. There were only minor marks on them from disassembly and transport, nothing major.

Prefabricated frame: The frame was prefabricated, and the disassembly process could be done as the assembly in reverse order. The roof was originally designed to be lifted into place quickly, in a narrow and busy urban environment.

Easily accessible and readable frame: The loadbearing and sound absorbing wood wool roof elements were attached one at a time and lifted. After this, the beams and posts were easily accessible, visible, and understandable. It was largely obvious how it would be dismantled.

Bolted connections: Beam-to-beam connections and beam-to-post connections were bolted, and the bolts were removable (Figure 6). There were no unforeseen connectors in the post and beam system.

https://doi.org/10.52202/069179-0463

Figure 6: *Bolted connections could be undone. Photo Andres Zabala Mejia.*

Separable services: Mechanical and electrical services were independent of the frame and could be easily separated.
Documentation available: Original documentation and drawings were available, and the design was consistent with the drawings. Half of the original drawings could be reused; the new parts were just added.
Transportability: It was easy to transport the parts. An advantage of the LVL beams was that they provided smaller dimensions than glulam would have done.

3.3.2 Disadvantages

Extensive planning needed: It was time consuming and difficult to make plans for numbering, labelling and logistics. A logic way to number and label the parts of the structure (having for example more than one thousand roof elements) had to be found, considering how and in what order parts were to be dismantled, transported, and stored. This was pointed out as something that could have been thought of and documented already in the original drawings.
Invisible screw heads: The loadbearing wood wool roof elements were connected to roof beams with countersunk screws. The exact position of screws was not known but had been decided on site during original assembly and carpenters had made slightly different choices. At deconstruction, screw heads were therefore not easily visible and had to be searched for, which was time consuming.
Stabilising members optimised for original location: Some elements in the outer walls were included in the stabilization for wind load, but were not dimensioned for the new, higher wind load at the new location. They could easily have been oversized at low cost to take larger wind loads.
Walls dismantled with difficulties: Connections in the façade walls were hidden and difficult to dismantle. They had to be sawn apart.
Fire protective layer sensitive to moisture: The fire protection treatment for indoor use on the LVL beams was sensitive to moisture. It became sticky when wet and cracked when it dried.
Physical labelling: Once labelling of all the roof beams was done, it turned out to be hard to see the labels when beams were unloaded and stacked on the re-assembly site.
Weather protection of sensitive beams: It was difficult to plan how the LVL beams should be covered from rain during dismantling.
Adaptation for reuse with high aesthetic requirements: High ambitions for the aesthetics with the ambition that the reconstructed building should still be a beautiful, was a challenge. New steel reinforcements had to look good while at the same time signalling reuse. The property owner and architect did not want to change dimensions and they wanted to preserve the symmetry and other architectural qualities. All additions had to fit and could not be too much or too visible.

3.4 INTERPRETATION OF ISO 20887 AND RE-EVALUATION OF PROPERTIES

3.4.1 Presenting the ISO 20887

The standard presents three *principles for DfA* (Versatility, Convertibility and Expandability) and seven *principles for DfDR* (Ease of access to components and services, Independence, Avoidance of unnecessary treatments and finishes, Supporting re-use (circular economy) business models, Simplicity, Standardization and Safety of disassembly). Important advice is also given under the headings *General disassembly principles* and *Documentation and information*. The standard states that each of the principles should be examined on five *levels of analysis* (Systems, Elements, Components, Sub-components, and Materials). In this study, only one level per case is considered for analysis, based on relevance with respect to reuse scenarios. For example, the temporary market hall was analysed on the elements level as it was deconstructed into assemblies and components for reuse in a similar building. Apart from principles, the standard presents *strategies* and *guidance*.

3.4.2 Re-evaluation of advantages and disadvantages

The recorded advantages and disadvantages discovered in the interviews were compared to the principles and guidelines of ISO 20887. An interpretation was made of how each aspect corresponds to the ISO. This was done for all cases. Examples are shown here from the analysis of the temporary market hall.
Table 1 shows aspects of the design that can be interpreted as compliant with the standard, and Table 2 shows aspects that can be interpreted as inconsistent with the standard. Data from all cases was re-evaluated in a similar way.

https://doi.org/10.52202/069179-0463

Table 1: *Advantages to DfDR and connection to ISO 20887. Examples from case study on temporary market hall.*

Advantage	Compliant with principle/guideline
Adaptable to new use	• Versatility, convertibility and expandability
No waste	• Supporting re-use (circular economy) business models: Reusability
Prefabricated frame	• Supporting re-use (circular economy) business models • Simplicity • Standardization
Easily accessible and readable frame	• Ease of access to components and services • Simplicity • Safety of disassembly
Bolted connections	• Independence: Reversible connections
Separable services	• Independence: General
Documentation available	• Documentation and information
Transportability	• General disassembly principles

Table 2: *Disadvantages to DfDR and connection to ISO 20887. Examples from case study on temporary market hall.*

Disadvantage	Inconsistent with principle/guideline
Extensive planning needed	• Documentation and information
Invisible screw heads	• Independence: Reversible connections • Ease of access to components and services • Safety of disassembly
Stabilising members optimised for original construction	• Convertibility and expandability
Walls dismantled with difficulties	• Independence: Reversible connections • Ease of access to components and services • Safety of disassembly
Physical labelling	• Documentation and information
Weather protection of sensitive beams	• Supporting re-use (circular economy) business models: Reusability • General disassembly principles
Adaptation for reuse with high aesthetic requirements	• Versatility and convertibility

The analysis of advantages and disadvantages and their comparison to principles and strategies in ISO 20887 is somewhat ambiguous - some properties could be associated with many principles and for others it was less obvious (but not impossible) to find any match in the standard. For example, solutions and problems around intermediate storage of recovered parts were usually interpreted to fit under *General disassembly principles*, though the ISO does not make explicit mention of storage requirements.

3.5 ILUSTRATING THE ISO 20887 PRINCIPLES AND STRATEGIES

Having re-evaluated the results according to the ISO 20887 design principles, a catalogue illustrating principles and strategies with practical examples from the studied cases was attempted using the general structure in Figure 7. This catalogue is a text document, aiming to fulfil the first objective of this study.

General disassembly principles
- Example 1
- Example 2
- ---

Ease of access to components and services
- Example 1 etc.

Independence
- Example 1 etc.

Avoidance of unnecessary treatments and finishes
- Example 1 etc.

Supporting re-use (circular economy) business models
- Example 1 etc.

Simplicity
- Example 1 etc.

Safety of disassembly
- Example 1 etc.

Standardization
- Example 1 etc.

Figure 7: *Principles and strategies in ISO 20887 can be illustrated with practical examples from the studied cases to form a catalogue, showing how the abstract principles can be treated in practice.*

Some of the designs in line with *General disassembly principles* found in case studies and stored in the catalogue are:

- *Example 1: Lifting points are marked out physically on the structure for future disassembly.*
  This can be done with paint or, in some cases, by leaving lifting loops in the structure during assembly, which will efficiently show where elements are supposed to be lifted, Figure 8.

***Figure 8**: Lifting loops in an element. Photo: Ylva Sandin.*

- *Example 3: Members are designed for easy transport*
  Members can be designed to have dimensions that are practical to handle. In the temporary market hall case, it was pointed out that choosing LVL instead of glulam for some members led to less heavy members, Figure 9.

***Figure 9:** Laminated veneer lumber beams (right). Photo Andres Zabala Mejia.*

- *Example 2: Modules are designed for easy transport.*
  The structure can be modular, with dimensions optimised for transport and handling, Figure 10 and Figure 11.

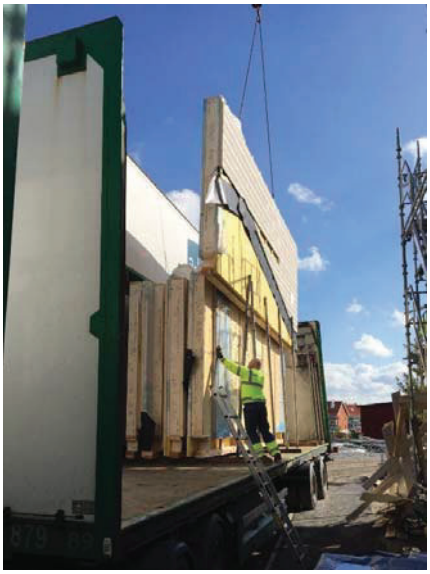

***Figure 10:** Modules designed for efficient transport: planar wall elements. Photo: Derome.*

***Figure 11:** Modules designed for efficient transport: volumetric modules. Two modules can be transported with one vehicle. Photo: Masonite Beams.*

However, the amount of data in the catalogue became unpractical to handle as a text document. Many design examples were obtained from the case studies, showing both designs in compliance with the standard and designs that are inconsistent with the standard.
To store and arrange the large amount of data, the study uses a web application for data management (Notion). Data can thereby be sorted and filtered, for example by case or by ISO principle, Figure 12-Figure 14.

https://doi.org/10.52202/069179-0463

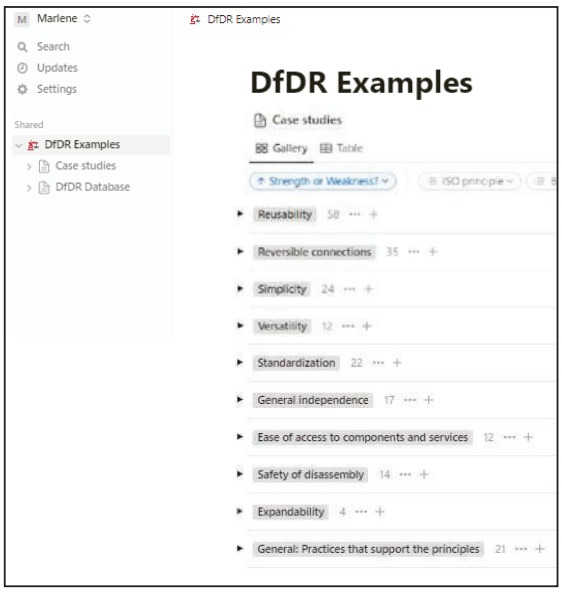

Figure 12: *Data is stored case by case and tagged to be sortable and filterable by ISO principle. A data management tool (Notion) is used.*

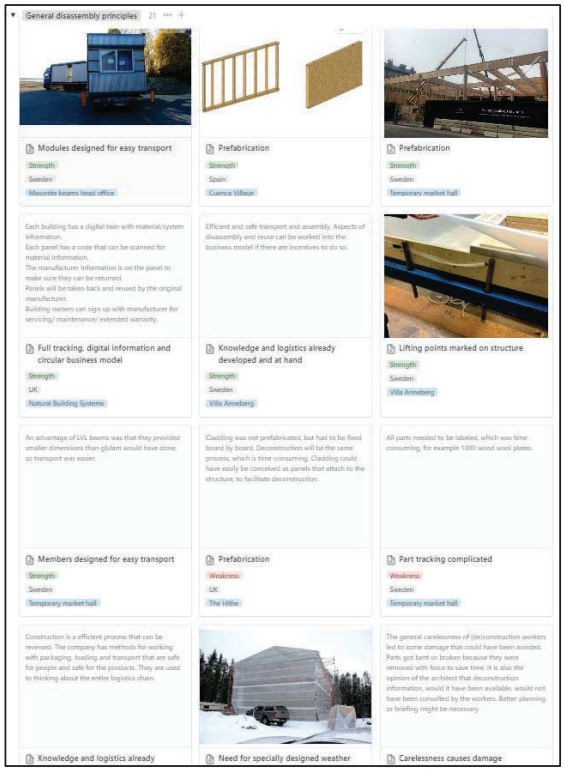

Figure 13: *Filtering data by choosing "General disassembly principles" will show case study data associated with this aspect. The picture shows a small sample of the data associated with this aspect.*

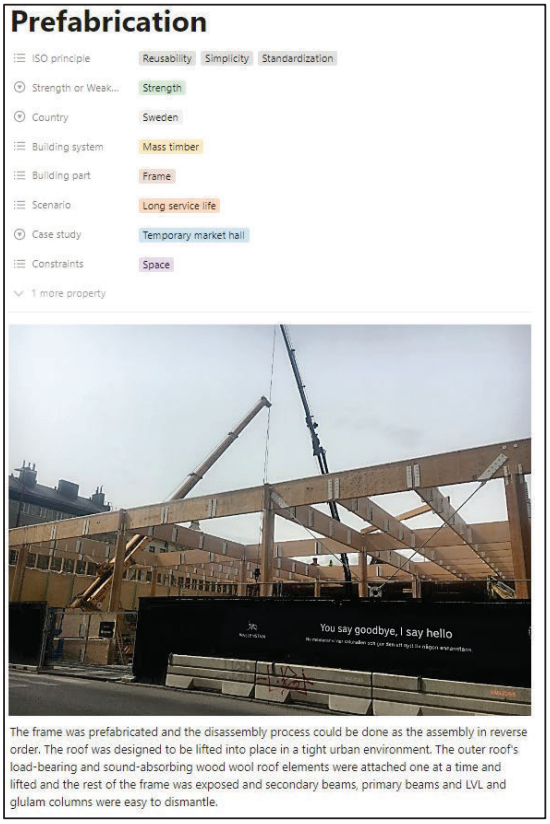

Figure 14: *Each design example is tagged under different headlines, e.g. country or building system, to allow users to filter for relevant context*

Storing the data this way makes it possible to get an overview of cases, see patterns and find inconsistencies. As an example of an inconsistency found, I-beams were judged reusable (compliant with the ISO) in two cases, and not reusable (inconsistent with the ISO) in another case. For one of the cases, the property owner pointed out that knowing the brand of the beams was an important basis for judgement and that having a personal knowledge of the product made it possible to rely on its reusability. This indicates that further investigations might be needed to find out if there are differences in quality of beams or differences in viewpoints between persons. It would be valuable to further study the effect of age on different timber materials.

The database is a prototype and a suggested methodology for collecting more data. Data from nine out of the fourteen case studies has been added to date (February 2023) and the work is ongoing.

More case studies should be carried out and data be added to the database, so that several examples of each type of timber structure is included.

The database is specific to timber construction. The intention is to show a multitude of examples, some describing practical experience, and show that contrasting views and evidence might exist. Contrasting views also

https://doi.org/10.52202/069179-0463

suggest that lessons from the case studies might only apply to a certain building system, deconstruction scenario or regional context, and the database should allow to filter examples according to these criteria.
As researchers, property managers and manufacturers might seek different types of information and sort data in different ways, it is important at this stage to involve different stakeholders in a dialogue on the kind of data and sorting possibilities, as the work with collecting more data goes on.

3.6 REFLECTIONS ON THE ISO 20887

3.6.1 Examining if important aspects are insufficiently covered

Our second objective of the study was to examine if there are important aspects of DfDR/A for timber buildings that are insufficiently covered by ISO 20887. The result is ambiguous.
On the one hand, the standard *can in fact be said to cover the important aspects* identified in case studies. None of the stakeholders in any of the case studies set out to incorporate the ISO principles in their design, yet all design examples (advantages/disadvantages to DfDR) could be assigned to one or more of the ISO principles.
On the other hand, important aspects *are not explicitly treated*. The standard is generic and independent of structural material and cannot list design examples for every building type or civil engineering works. The specific and tangible aspects of DfD/A that emerge from case studies will not be found in the standard. It remains abstract and needs to be interpreted.
Some timber specific advantages/disadvantage not explicit in the ISO are given below.
Transportability. In several case studies, interviewed persons stressed as a significant advantage, that the structure (or rather its deconstructed parts) was well adapted for transport. As timber is a light material, this property might be characteristic to timber structures and should be recognised as a large benefit when choosing structural system for a building.
Designing for transportability is included in the standard, but the aspect is rather hidden. It is not a principle but mentioned among several practices that can support general disassembly principles: "When possible, materials and components, which can be easily, safely, and more cost-effectively replaced or removed and transported, should be used. […] Components that are sized to suit the intended means of handling should be used. Various possible handling options at all phases of assembly, disassembly, transport, reprocessing, and reassembly should be considered." (ISO 20887, section 5.3.1.)
Reversible connections. One of the principles in the ISO is Independence and a sub-category of this is Reversible connections. While it is easy to intuitively understand that this is important, it is not very clear how the principle shall be interpreted in practical timber construction. The standard (section 5.3.3.2) states that "Reversible connections can be disconnected and/or disassembled for easy alterations and additions to structures.". The interpretation of the principle was repeatedly discussed in case studies. The cases showed that bolted joints, screwed joints and nailed joints might all be considered reversible as bolts can be removed and the others can normally be sawn apart without causing damage to the connected members, although fasteners themselves will not be reusable. For timber structures, we suggest that "reversible connections" might be defined as connections that can be separated without damaging the connected members (at least not to a degree that generates waste or makes substantial refurbishment necessary). Thus, the choice of connector does not necessarily define the reversibility.
Handling moisture. It is crucial to protect a timber structure from moisture during disassembly, temporary storage, and reassembly. The ISO does not give explicit advice on weather protection and storage but whether timber parts are protected or not might strongly influence their reusability.

3.6.2 Some comments on the reinterpretation of the case study examples

The DfDR strategies are interconnected. Each design example found in case studies was assigned to 2.6 ISO principles on average. The reinterpretation of the case study examples gave insight in the relative importance of each design principle for the sample, Figure 15. *Reusability*, a sub-category to Supporting re-use (circular economy) business models, was by far the principle most design examples were assigned to, followed by *Reversible connections*, a sub-category to Independence.
Some principles were well matched in design examples, others were more problematic. Some examples are shown below.

Good match: *Reusability*
Case study examples that were assigned to this principle mostly covered one of four aspects:

- The condition of recovered parts, i.e. damage and remaining service life
- The generality of recovered parts and the resulting freedom in reuse options, e.g. the size and shape of recovered panels
- Barriers to reuse, e.g. timely and costly reconditioning, storage, adaptation
- Verification or available information for materials

All four aspects are mentioned in the ISO, although they could be more clearly separated and linked to examples.

Slight mismatch: *General Independence*
Under this principle, the standard mostly highlights the merits of independent layers, i.e. separating layers with different expected service lives. Although the case studies did not explicitly work with the concept of layers, design examples fit the principle well and mostly concerned:

- Independent installations

https://doi.org/10.52202/069179-0463

- Separating the vapour control layer
- Independent façade

One difference between the description in the ISO and the case study observations was noted: While the ISO described the most important layers to be separable should be the most reusable ones, the case study examples showed problems were related the accessibility of the least reusable layer. This was because most cases targeted assembly reuse, and the least reusable layers often need to be accessed for replacement.

An aspect that is not explicit in the standard is the advantage of self-contained assemblies. It became clear that independence is as much about keeping similar parts together as it is about keeping different parts apart. Self-contained functional units are more easily separated and independently reusable, e.g., self-contained pods are more independent upon recovery than open panels that need to be finished with additional materials.

Stark mismatch: *Avoidance of unnecessary treatments and finishes*

The ISO states that treatments which would limit reuse should be avoided. Timber preservative and fire-retardant treatments generally do not limit its reuse options, but they should still be avoided where unnecessary to limit environmental impact (which is out of scope of this study). Finishes that hide the wood surface might limit visual inspection methods for verification, so these should be avoided as well. The ISO might need to clarify the motivations for avoiding different finishes and give specific examples relevant to different materials.

The principle was also interpreted more widely as avoidance of unnecessary components and finishes, so that recurring examples could be assigned:

- Avoidance of sensitive materials, e.g., the vapour control layer, though by no means unnecessary in all types of timber construction, can be eliminated in vapour-open systems, avoiding the use of damage-prone materials.
- Avoidance of wet construction methods, e.g., foundations can be minimised when designing lightweight structures.
- Avoidance of excess connectors, e.g., avoiding the need for unplanned connectors by providing temporary bracing during construction

Although most design examples could be matched to the ISO principles reasonably well, there is quite an amount of work left to do to adapt the standard to reflect the real world rather than the real world to illustrate the standard. Future guidelines to the standard could aim to include a wider range of strategies, so that common design considerations are made obvious to designers. It would be necessary to analyse a wide range of buildings and civil engineering works, in a similar way as in this study, to get a better understanding of the most important strategies, without it becoming too comprehensive.

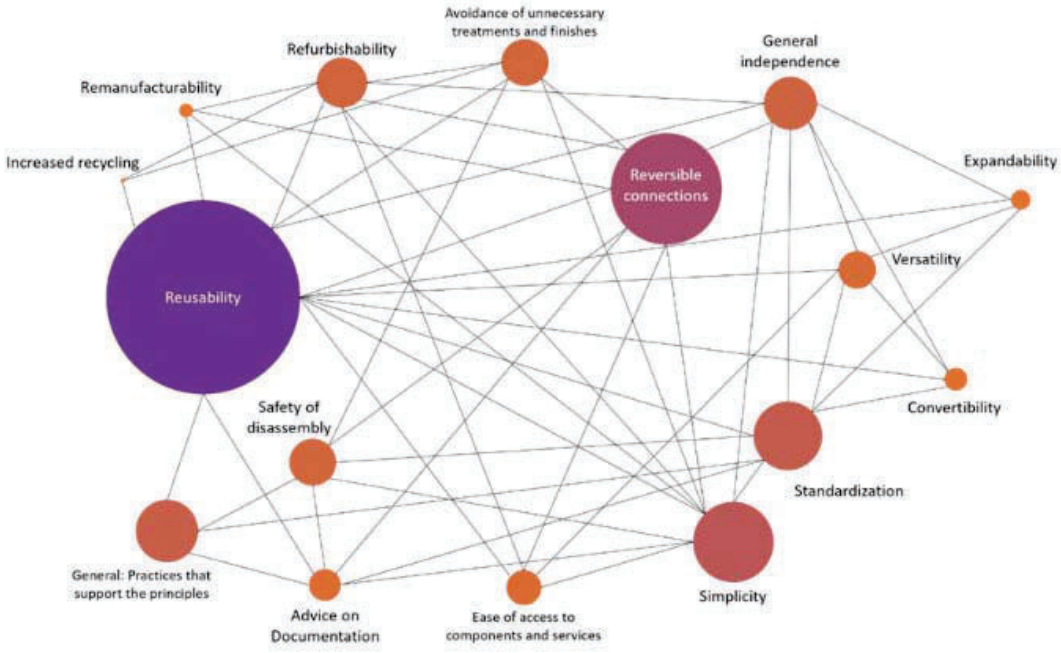

Figure 15: *ISO 20887 principles and their connection as given by data from nine case studies on timber structures of different sizes and types. The size and colour of the circles indicates how many examples were assigned to each principle and a connection was added between circles when at least one example illustrates both principles.*

4 CONCLUSIONS

The case study approach [4] resembles a top-down approach: An existing design is evaluated for its advantages and disadvantages to DfDR/A. This involved gathering the right expertise and discussing the design, its future deconstruction and reuse, recording advantages and disadvantages. This method was used in case studies simulating deconstruction and was found to be an easy, pragmatic, and inspiring process that provoked ideas for modified designs. The case study method results in specific design examples, but also reveals general DfDR/A barriers and solutions in the given context.

A bottom-up approach for developing new designs adapted to DfDR/A is described in ISO 20887. The standard follows a broad and holistic approach, including decision-making, design principles, documentation, and implementation of DfDR/A. It is, however, not easy to apply in practice.

When the DfD/A design examples gathered with the case study method were re-evaluated to fit under the ISO 20887 principles, it became clear that the standard reflects the overarching principles of DfD/A design well. Keeping the aim of the ISO, to give an overview of DfD/A principles for all buildings and civil engineering works, in mind, it is still not feasible to fully represent all these different structures with examples, and the standard will likely remain somewhat general and abstract.

Both approaches combined can provide valuable support for designers in creating and evaluating deconstructable designs. The result of this work is a non-exhaustive database of specific examples illustrating ISO 20887 design principles. A database that focuses on timber buildings, to narrow down the scope and become more accessible, can complement the ISO and provide the link between DfD/A principles and the real world. The database draws from reality rather than from abstract principles, and it does not only show the many good solutions that have been developed already but also mistakes from the past, to help avoid pitfalls even with best intentions. This study is only the beginning, providing design examples for the loadbearing structure of nine timber buildings. Further examples are needed, covering all chapters of the standard and more building types, layers, and levels. As the continued collection of case studies progresses, the experiences will form a base for guidelines showing how the ISO can be interpreted for timber buildings.

ACKNOWLEDGEMENT

We wish to express our thanks to RISE Research Institutes of Sweden and to ForestValue ERA-Net Cofund (with funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N° 773324) for supporting the work, partly mase possible through the InFutUReWood project.

PUSH-OUT TESTS ON CONNECTIONS FOR DEMOUNTABLE AND REUSABLE STEEL-TIMBER COMPOSITE BEAM AND FLOORING SYSTEMS

Alfredo Romero[1], Jie Yang[2], François Hanus[3], Hervé Degée[4], Christoph Odenbreit[5]

ABSTRACT: Engineered timber panels made of laminated veneer lumber (LVL) can represent an alternative to concrete in a typical steel-concrete composite beam and the entire flooring system. The performance of LVL in strength reaches values, which are comparable to concrete. In addition, and according to policies to reduce greenhouse gas emissions and resources depletion (e.g. the European Commission´s Green Deal) the construction sector demands more and more circularity in construction. On that basis, the research project "Prefa-SeTi" (FNR Grant 15695062) investigates the load bearing- and displacement behaviour of steel-timber composite beams and especially the shear connection between the steel and timber. The work pursues a development, which was started within the European REDUCE project (RFCS GA 710040), which investigated solutions for composite structures in steel and concrete, and the demo project "Petite Maison" of Esch2022 the European Capital of Culture. In "Prefa-SeTi", nine push-out specimens were tested to investigate three newly developed shear connections. To comply with circularity, the connections are dismountable and robust enough to protect the structural elements from damage at serviceability limit state. This paper presents the demountable timber connectors and results of the push-out tests. Along with the results and the respective discussions, the paper outlines the tested mechanical properties of the LVL, the push-out test setup, and the testing procedure.

KEYWORDS: Shear connection, push-out test, steel-timber composite, demountable, reuse, circular economy, LVL

1 INTRODUCTION

Timber is a renewable material with strength properties which are comparable to concrete. Therefore, engineered timber products such as LVL can represent an alternative to concrete in steel-concrete composite beam and flooring systems. In addition, timber is ideal for prefabrication, fast erection, and deconstruction.

The policies targeting carbon neutrality and minimization of resources depletion such as the European Commission's Green Deal and the United Nation's Sustainable Development Goals are pursuing a transition towards a circular economy. The construction sector is not an exception to this; consequently, the sector demands more circular solutions.

Currently, most design and construction procedures are not well suited for deconstruction and reuse of the structural components. To cope with this issue, recent studies, such as the REDUCE project [1] have developed demountable and reusable solutions for steel-composite structures [2]. The research project "Prefa-SeTi" (FNR Grant 15695062) pursues a development, which started within the European REDUCE project (RFCS GA 710040) [1]. This project investigates the load bearing- and displacement behaviour of steel-timber composite beams and especially the shear connection between the steel and timber.

In composite structures, the shear connection is a key element which transfers shear forces between the components to achieve effective composite action. The existing steel-to-timber connections (e.g. screws, bolts, C-type connectors, adhesives, and their combination) have setbacks when the target is deconstruction and reuse of the components of steel-timber composite flooring systems. Therefore, within the framework of "Prefa-SeTi" three demountable shear connectors were developed and their load-slip response were investigated through push-out tests. Along with the results and the respective discussions of the tests, this paper outlines the tested mechanical properties of the LVL, the components of the demountable shear connections, the push-out test setup, and the testing procedure.

2 LAMINATED VENEER LUMBER (LVL)

LVL is made of veneers with a thickness of 3mm, bonded together with weather-resistant phenolic adhesive (see

[1] Alfredo Romero, ArcelorMittal Chair of Steel Construction at the University of Luxembourg, Luxembourg, alfredo.romero@uni.lu
[2] Jie Yang, ArcelorMittal Chair of Steel Construction at the University of Luxembourg, Luxembourg, jie.yang@uni.lu
[3] François Hanus, ArcelorMittal Steligence®, Luxembourg, francois.hanus@arcelormittal.com

https://doi.org/10.52202/069179-0464

Figure 1). The dimensions of the final LVL product are not limited by the dimensions of the raw material, and small-diameter logs can be used to produce large LVL members. When veneer logs are peeled to produce veneer, any natural defects in the wood, such as knots, are dispersed. This together with the lamination effect, significantly reduces the impact of defects and results in homogeneous properties. Thus, the variance on the properties is smaller, this translates in a smaller partial safety factor for design calculations, and therefore, higher design strength values compared to other timber products such as cross laminated veneer lumber (CLT).

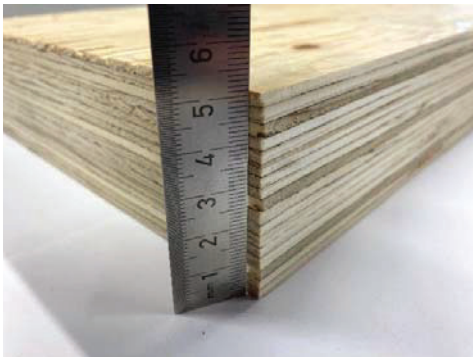

Figure 1: *Laminated veneer lumber (LVL).*

There are two main types of LVL products depending on the veneer layup: LVL with all veneers oriented in the same direction (e.g. LVL-P) and LVL with approximately 20% of veneers oriented crosswise at 90° with respect to the grain direction (e.g. LVL-C).

The mean and characteristic values of some mechanical properties of the LVL products commonly used for structural design are given by the LVL manufacturers. However, the reports of the tested mechanical properties and the respective stress-strain and load-deformation curves are hardly available. Berschoten [3] reported mechanical properties of LVL made of New Zeeland's Radiata pine and Chybinski et al. [4] reported some mechanical properties of European LVL-P panels.

To the knowledge of the authors there are no references dealing with the mechanical characterisation of LVL panels made of Scandinavian spruce wood with crossbanded veneers. Therefore, in this contribution we present mechanical properties obtained in tests of Kerto-Q panels (i.e. crossbanded LVL-C). The tests were done according to the European standards EN 408 [5] and EN 789 [6].

Wood is an anisotropic material but for engineering purposes it is considered as orthotropic. Hence, in the material testing campaign conducted within the framework of this research project, the orthogonal directions were defined as shown in Figure 2.

The mean strength values as well as elasticity modulus in the three orthogonal directions are presented in Table 1 for compression and tension. The mean stress-strain curves are shown in Figure 3 for compression and tension.

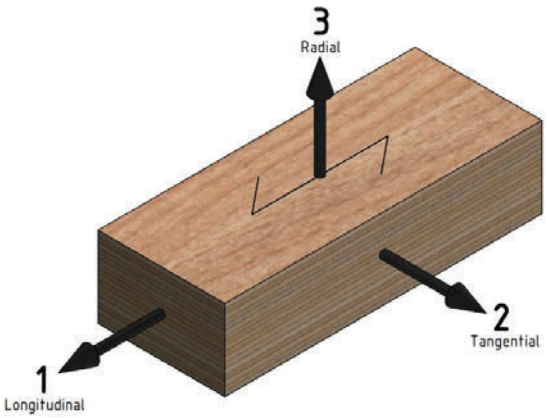

Figure 2: *Orthogonal directions of the LVL.*

Table 1: *Mean strength values and elasticity modulus of LVL made of spruce wood (Kerto-Q)*

Strength		Modulus of elasticity	
Symbol	Value [MPa]	Symbol	Value [MPa]
$f_{c,1}$	40.41	$E_{c,1}$	7 917.08
$f_{c,2}$	11.14	$E_{c,2}$	1 764.47
$f_{c,3}$	3.99	$E_{c,3}$	95.49
$f_{t,1}$	37.76	$E_{t,1}$	10 680.01
$f_{t,2}$	8.33	$E_{t,2}$	2 199.90
$f_{t,3}$	0.56	$E_{t,3}$	92.05

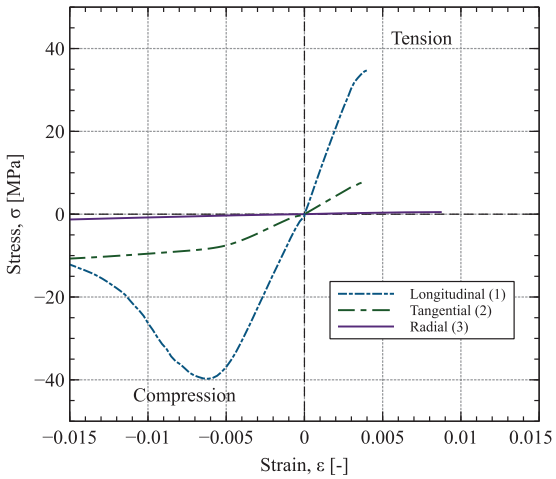

Figure 3: *Mean stress-strain curves of LVL for uniaxial tension and compression in the three orthogonal directions.*

These tests show that the strength of LVL in compression in the direction of the grain (i.e. $f_{c,1} = 41.03\ MPa$) reaches values which are comparable to concrete. Therefore, this material could represent an alternative to concrete in steel-composite beams and flooring systems.

https://doi.org/10.52202/069179-0464

3 THE DEVELOPED DEMOUNTABLE SHEAR CONNECTORS

Steel-to-timber connections with screws and bolts alone or in combination with C-type connectors and/or glue allow for deconstruction of STC structures. However, the drilling effect of screws and the preloading of high-strength bolts lead to damages in the timber elements which hinders the reusability of the structural components. Hence, alternative shear connectors are needed to develop structural solutions complying the principles of circular economy.

The three connections presented in this paper were developed to comply circularity and are robust enough, to protect the structural elements from damage at serviceability limit state (SLS).

The three demountable connections were denominated as follows: Shear Connection -Type 1 (SCT-1), -Type 2 (SCT-2), and -Type 3 (SCT-3).

These connections consist of a part embedded in the timber, the "shear connection device" (see Figure 4), and removable parts (i.e. bolt, washers, nut). The shear connection device consists of a steel-tube (S460) fitting the drilled hole in timber, at the steel-timber interface the connection is reinforced by steel elements welded to the tube: (i) a round steel plate (S460), (ii) a geka connector or (iii) a rectangular steel plate (S460) with four inclined screws, respectively for each connection type (see Figure 4). The details of the connections are shown in Figure 5 to Figure 8.

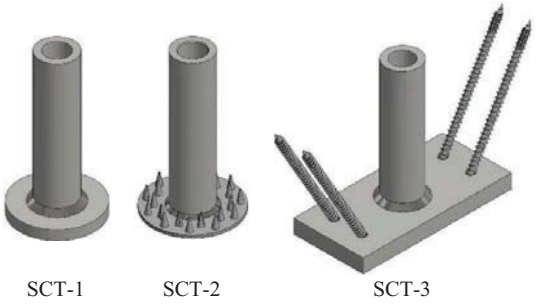

Figure 4: *Shear connection devices developed in Prefa-SeTi project.*

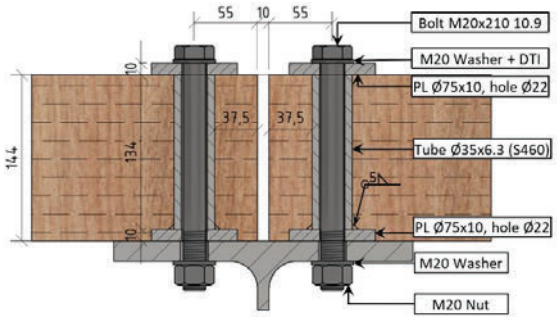

Figure 5: *Details of shear connection type 1 (SCT-1).*

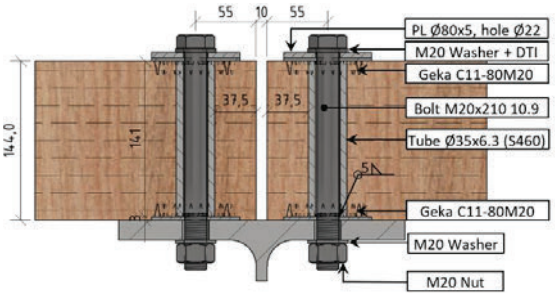

Figure 6: *Details of shear connection type 2 (SCT-2).*

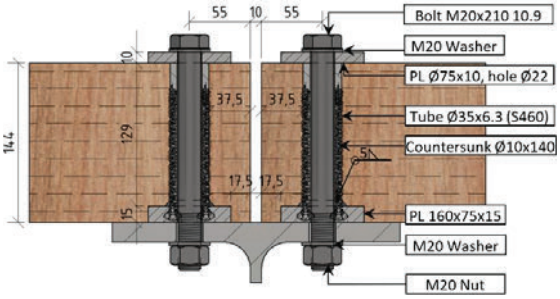

Figure 7: *Details of shear connection type 3 (SCT-3), transversal cut.*

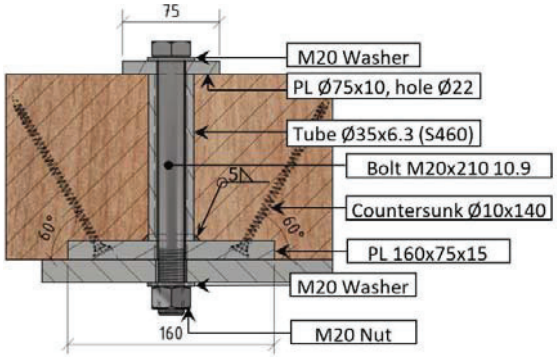

Figure 8: *Details of shear connection type 3 (SCT-3), longitudinal cut.*

The steel tube reinforces the hole, increases the surface in which the forces are transferred to the timber, and allows to achieve the preload of the high-strength bolts while preventing crushing of the timber.

4 EXPERIMENTAL PUSH-OUT TESTS

4.1 TEST SERIES

The load-slip behaviour of the connections was investigated through a series of push-out tests. Three identical specimens of each connection were tested. Therefore, in total 9 push-out tests were performed in this testing campaign. A summary of the test series is presented in Table 2.

https://doi.org/10.52202/069179-0464

Table 2: *Mean strength values and elasticity modulus of LVL made of spruce wood (Kerto-Q)*

Test series	Connection	Test IDs	Specimen IDs
Push-out test series 1	Type 1 (SCT-1)	POT1	POT1-1 POT1-2 POT1-3
Push-out test series 2	Type 2 (SCT-2)	POT2	POT2-1 POT2-2 POT2-3
Push-out test series 3	Type 3 (SCT-3)	POT3	POT3-1 POT3-2 POT3-3

4.2 SPECIMEN DETAILS

The connections were installed and tested in Kerto-Q LVL (LVL-C) plates made of spruce wood with dimensions of 650x300x144mm. The grain direction of the plates was aligned with the load direction.

The steel profile used in the setup was a standard European section HEB 260 (S355) with a length of 700mm.

The connections were installed symmetrically in both flanges of the beam. In total, 8 shear connectors were installed in each specimen, 4 connectors in each flange of the steel beam arranged in two rows. The spacing between the two rows of connectors was 250mm.

Partially threaded bolts M20x210 grade 10.9 were implemented in the connections. These bolts were preloaded at 70% of their ultimate tensile strength. This preload was achieved using a calibrated torque wrench plus a certain nut rotation. In addition, direct tension indicators (DTI) were used to ensure the minimum preload was reached.

The specimen details and dimensions are shown in Figure 9 and Figure 10.

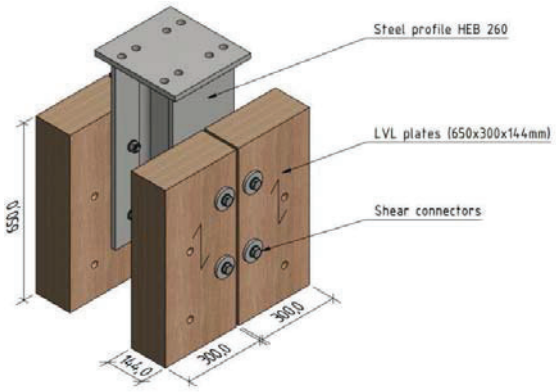

Figure 9: *Main components and dimensions of the push-out test specimens.*

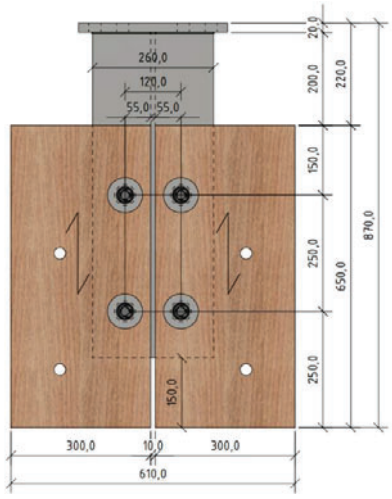

Figure 10: *Dimensions of the push-out test specimens.*

4.3 TEST SETUP

The specimen was placed on a thick steel block covered by neoprene strips (see Figure 11 and Figure 12). Steel L-profiles fixed with threaded rods were used to prevent the opening of the gap between the timber plates in the bottom of the specimen and a steel plate was used on the top to prevent the closing of the gap. Similar L-profiles were placed in the parallel faces of the timber plates to prevent the parts from falling apart once the connection was lost. In this case, a gap of 3 mm between the timber plates and the L-profiles was left to allow detaching of the timber from the steel beam.

Linear Variable Differential Transformer (LVDT) sensors were installed to measure the relative displacements between the steel beam and the timber plates in the direction of the load (measuring the slip) and perpendicular to the load (measuring the timber plates detachment from the beam flanges). Figure 11 and Figure 12 show the push-out test setup.

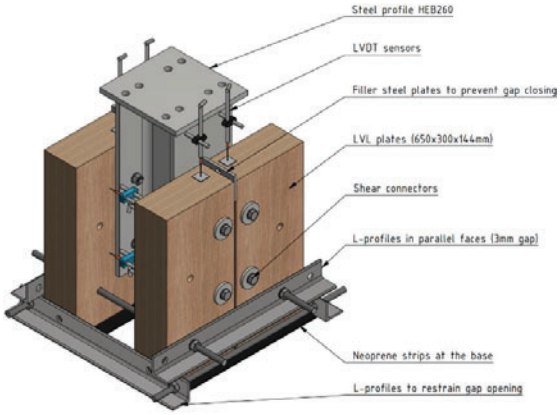

Figure 11: *Components of the test setup.*

https://doi.org/10.52202/069179-0464

Figure 12: *Push-out test setup.*

4.4 LOADING PROCEDURE

To define the loading procedure a maximum load of 1200kN was considered. This loading procedure consists of an initial load to reach 40% of the maximum estimated load (480 kN) and then 25 cycles between 5% (60 kN) and 40% (480 kN) of the expected maximum load (1200 kN) at a frequency of 1 cycle per minute. Subsequent loading and unloading steps were carried out. For two of the specimens of each series the load was stopped when the failure of the connection or the maximum displacement was reached, for the remaining specimen the load was stopped at a displacement of about 40mm.

The initial loading/unloading steps along with the 25 cycles were performed in force control mode, the subsequent loading/unloading steps were carried out in displacement control mode. Figure 13 shows the time history of the loading procedure.

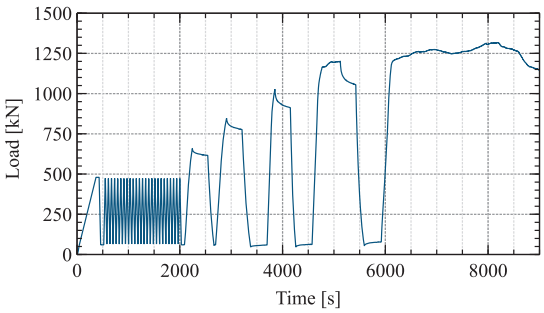

Figure 13: *Time history of the loading sequence.*

5 RESULTS AND COMPARISSON

5.1 RESULTS

The load slip curves of the three push-out test series are shown in Figure 14 to Figure 19.

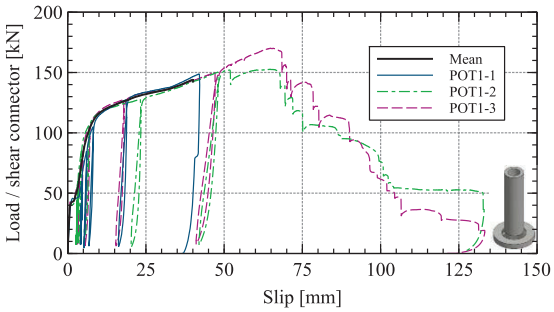

Figure 14: *Load-slip curves up to 150mm slip of push-out tests series 1 (POT1) of shear connection type 1 (SCT-1).*

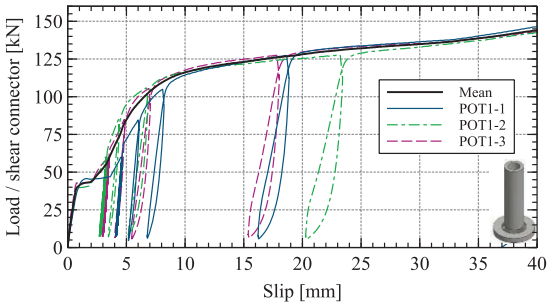

Figure 15: *Load-slip curves up to 40mm slip of push-out tests series 1 (POT1) of shear connection type 1 (SCT-1).*

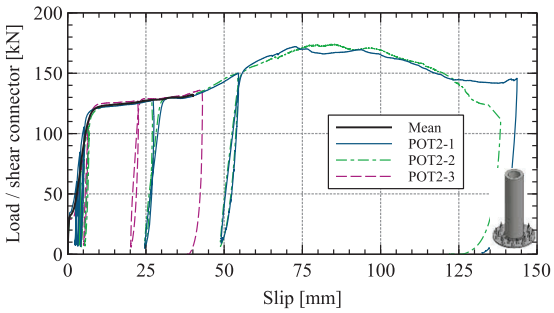

Figure 16: *Load-slip curves up to 150mm slip of push-out tests series 2 (POT2) of shear connection type 2 (SCT-2).*

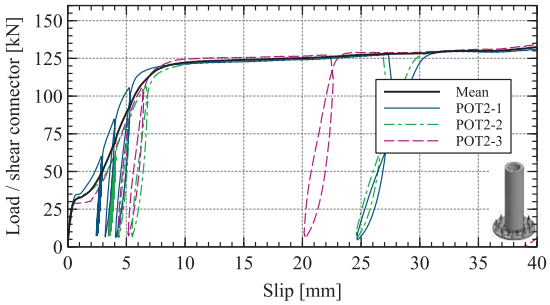

Figure 17: *Load-slip curves up to 40mm slip of push-out tests series 2 (POT2) of shear connection type 2 (SCT-2).*

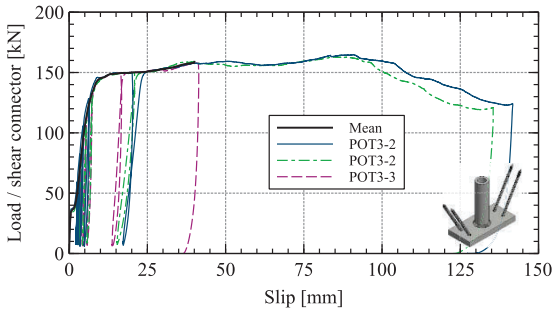

Figure 18: *Load-slip curves up to 150mm slip of push-out tests series 3 (POT3) of shear connection type 3 (SCT-3).*

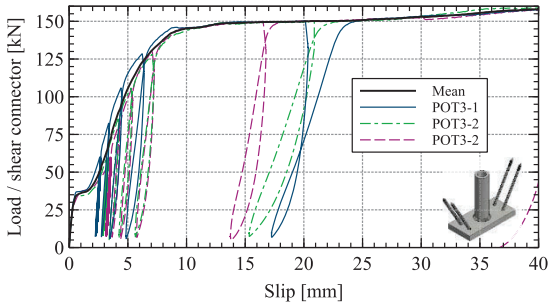

Figure 19: *Load-slip curves up to 40mm slip of push-out tests series 3 (POT3) of shear connection type 3 (SCT-3).*

The three connections showed large deformation capacity. The load-slip behaviour and the stiffness of the connections is different in terms of magnitude for each connection type. However, the three connections follow a similar pattern in their load slip behaviour.

Due to the preload of the bolts, the three connections have an initial slip capacity, when this slip capacity is reached, there is a slip of about 2-4mm with no increase in load because the bolt moves within the hole until there is contact between the bolt and both the flange of the beam and the inner surface of the connection device. After contact, there is bearing and shear in the bolt and then, there is embedment of the connection device in the timber plate.

Figure 20 is a longitudinal cutting of SCT-1, this figure illustrates the typical deformed shape observed in the three shear connection types. The veneers closer to the steel-timber interface crushed and one plastic hinge appeared in the connectors.

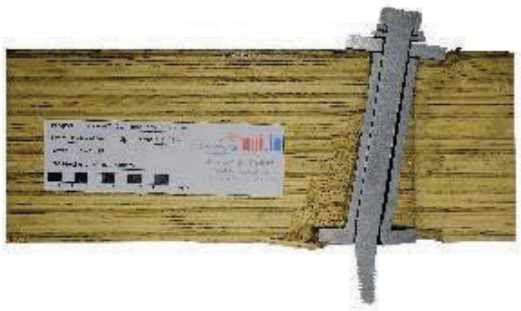

Figure 20: *Longitudinal cutting of SCT-1 showing the deformed shape after the test.*

5.2 COMPARISSON

SCT-1 and SCT-2 exhibited similar behaviour in the initial loading stages, whereas the SCT-3 showed higher stiffness. However, higher peak loads were reached with SCT-2. In addition, only in some specimens of SCT-1 the bolts failed, in SCT-2 and SCT-3 the tests were stopped because the maximum possible deformation (about 140mm) of the test setup was reached.

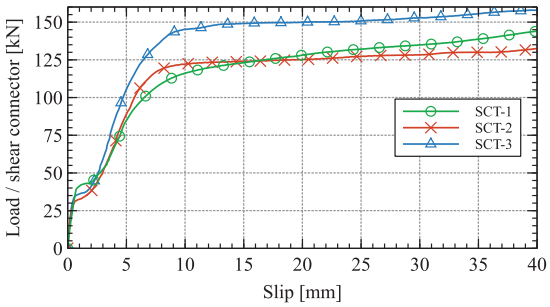

Figure 21: *Comparison of the mean load-slip curves of the three shear connections.*

6 CONCLUSIONS

The main conclusions of this contribution are the following:

- The three newly developed connections are capable of withstanding significant deformations and can bear loads of comparable magnitude. To illustrate, at a 6mm slip, SCT-1, SCT-2, and SCT-3 had average loads of 96kN, 104kN, and 120kN, respectively.
- The connections presented in this paper comply with the principles of circular economy.
- The novel connections, unlike existing steel-to-timber connections allow to reach the required preload for high strength bolts while preventing premature damages in timber due to crushing of the timber in the radial direction. Meaning the slip resistance can be activated.
- The use of crossbanded LVL prevented the occurrence of splitting failure. This demonstrates one of the benefits of using this type of LVL compared to non-crossbanded LVL and other timber materials which are known to be susceptible to this type of failure, as shown by other researchers in similar tests [7,8].
- The behaviour of the connections is non-linear, it is characterized by (i) an initial stiff response until the slip resistance given by the bolt preload is overcome, (ii) when the slip resistance is overcome, there is sliding friction, which results in a small displacement of about 2-4mm with no increase in the load until contact bearing between the bolt and both the steel flange and the connection device starts, (iii) then there is bearing and shear in the bolt and embedment of the connection device in the timber, which produce a monotonic increasing branch in the load-slip curve.
- Further studies will be useful to determine the influence of certain parameters such as the thickness of the timber plates, bolt size and grade, size of bottom steel plate, connectors arrangement, etc.

STRUCTURAL PERFORMANCE OF TIMBER-CONCRETE COMPOSITE FLOOR ELEMENTS WITH DECONSTRUCTABLE CONNECTORS AND ITS POTENTIAL FOR REUSE

Mohammad Derikvand[1], Gerhard Fink[2]

ABSTRACT: By incorporating design methods that allow for disassembly, buildings can be deconstructed at the end of their service life, thereby supporting the principles of circular economy and reducing waste. This paper provides a summary of the latest research advances by the research group for Wooden Structures (Aalto University) on the development and mechanical characteristics of a deconstructable connection system for timber-concrete composite (TCC) floors. This includes an overview of the experimental investigations conducted to date, focusing on the performance of the proposed system both at the connection level and at the floor level. At the connection level, the paper highlights the experimental investigations on the static and cyclic shear properties, as well as the ease of deconstruction after being exposed to substantial loads. Additionally, the floor level examination includes an overview of the bending properties, vibration characteristics, and deconstructability after reaching the failure point. A subsequent experiment is also reported here on the flexibility of the deconstructable connector for reuse and the influence of pre-existing concrete cracks on the performance of prefabricated TCC floors. The paper concludes with an outlook on the future of designing for deconstruction of TCC structures, as it not only reduces the environmental impact of construction but also allows for the efficient reuse of valuable resources.

KEYWORDS: Timber-concrete composite, cross-laminated timber, design for disassembly, vibration, four-point bending, cyclic shear test, self-tapping screws

1 INTRODUCTION

Deconstructable timber-concrete composite (TCC) structures combine the advantages of both timber and concrete in such a way that would allow for the structure to be disassembled at the end of its service life. This eases the process of recycling or reuse of the materials, which makes it a more environmental-friendly option compared to conventional forms of TCC structures. Therefore, deconstructable TCC structures are gaining more attention because of their potential to reduce waste and the environmental impact of buildings [1-5]. However, they are relatively new in the field of construction and the connector options for such structures are limited on the market, especially for the cast-in-situ construction method (i.e., the wet-dry system). Accordingly, the current knowledge on certain attributes of deconstructable TCC connectors is quite limited, specifically regarding their mechanical performance such as long-term static or dynamic properties or even their ability to be disassembled and taken apart at the end of their service life.

A number of factors play a major role in determining the efficiency and success of a deconstructable TCC connector. This includes technical requirements, such as the resistant of the connector against loads and environmental exposures factors such as humidity and temperature fluctuations without a considerable decrease in its performance; practicality factors, such as simplicity and easy installation effort, if possible, without additional training for the construction worker and without requiring specialized tools; versatility factors, such as suitability for various construction methods; market success factors, such as cost-effectiveness and viability for the target market in comparison to the regular connectors.

Considering the above factors, a deconstructable TCC system has been recently developed at the research group for Wooden Structures (Aalto University, Finland) using self-tapping screws. In this paper, the research activities related to the development and experimental investigations of the deconstructable TCC system are shortly summarized and discussed. Furthermore, a test report is provided which highlights both the potential of the deconstructable connector for reuse and the importance of preventing concrete cracks in prefabricated deconstructable TCC floors. The paper also highlights the outlook of the topic of design for deconstruction of TCC structures, with emphasis on raising awareness about the benefits of deconstructable connection systems to promote their use in sustainable construction projects.

2 DECONSTRUCTABLE TCC CONNECTOR

The existing deconstructable TCC connectors in the literature have been made using either screws or bolts [e.g., 3,4,6,7]. In most cases, the mechanical performance of the proposed connectors has been investigated only either for a certain type of construction or for a certain floor type. Therefore, the versatility aspects remain to be demonstrated.

Our project at Aalto University was initiated by evaluating various deconstructable connector prototypes. To be able to disassemble a TCC connection in general, the following two conditions were found to be vital:

1. The connector inside the concrete must be accessible. The connectors in a regular TCC system are normally covered by concrete and cannot be reached.

2. The connector must be removable. Some connectors are not removable even if they can be accessed inside the concrete, e.g., glued-in plates or glued-in steel rods.

Considering these conditions, self-tapping screws were selected as the target connector, as they can be removed if they can be accessed. To enable the accessibility, the upper parts of the screw must be protected from being covered by the concrete. The design and the material type of the protection layer were investigated during the prototyping. One of the early prototypes consisted of a protective layer (or plug) made with polyvinyl chloride (PVC) and a lid and a level adjuster made of silicon rubber. Several versions of this prototype were tested during the preliminary investigations, see the results here [8]. Overall, the connector was easy to use; however, it did not provide sufficient shear properties compared to a regular screw, which was attributed to the design and the material type of the protective layer.

After the pre-investigation, it was decided to use a thin protective layer that mimics the shape of the screw threads. To accomplish this, heat-shrink tubing (HST) was chosen as it is cost-effective and can create a thin layer around the screw threads by shrinking around them when heated. The configuration of the connector is shown in Figure 1.

For cast-in-situ fabrication of TCC floors and prefabrication in the wet-dry system, the connector can be used in the same way as a regular screw, in which the connector is first driven into the timber component, then concrete is poured on top.

For prefabrication in the dry-dry system, the connector is inserted into the base of a formwork before pouring concrete to create the slab. Once the slab has dried, the screw is detached, the slab is then laid on top of the timber member and the screw is reinserted through the connector hole in the slab into the timber.

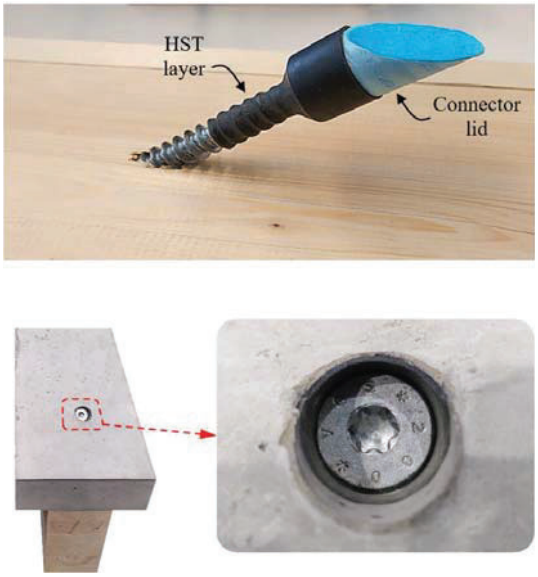

Figure 1: *The deconstructable connector components (top); a glulam-concrete composite connection made with the connector (bottom).*

In both wet-dry and dry-dry construction methods, the TCC system can be deconstructed by removing the screw from the connector hole in the concrete section. Once the screw is removed, the timber component and the concrete slab can then be separated.

3 EXPERIMENTAL INVESTIGATIONS OF THE TCC CONNECTOR

In the following sections a summary of the experimental investigations on the deconstructable TCC connector is presented.

3.1 SHEAR TESTS OF THE CONNECTOR UNDER STATIC LOADS

In an early study [1], the static shear strength and stiffness of the deconstructable connector concept were evaluated on several glulam-concrete composite connections. The focus of the study was on the wet-dry construction system, however, the application in the dry-dry system was also investigated to confirm the versatility of the connector and its potential for use in different types of construction. Other test variables included insertion angle, screw type and diameter, and screw arrangement.

A push-out shear test set-up was used to load the connection specimens (Figure 2). At the end of the tests, some of the tested connections were evaluated for deconstructability by removing the screw from the assembly.

https://doi.org/10.52202/069179-0465

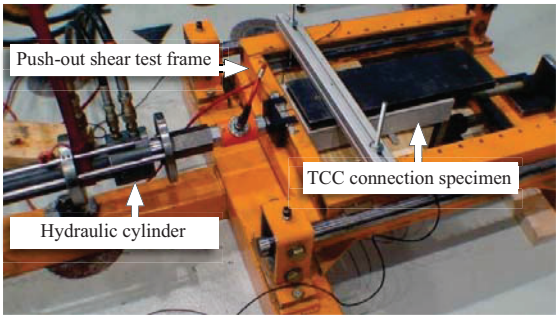

Figure 2: *Example cyclic load-slip curve of a deconstructable connector.*

The strength and stiffness of the deconstructable connections were relatively similar to those of identical connections made with regular self-tapping screws. The difference between the shear properties of the two connector types was the lowest when the connectors were inserted at 30˚ angle. Furthermore, it was demonstrated that the deconstructable connectors with 30˚ insertion angle can still be disassembled even if 15 mm slip is reached at the timber-concrete interface under loading. However, this level of slip prevents the disassembly of the connectors with a larger angle of insertion.

3.2 SHEAR TESTS OF THE CONNECTOR UNDER CYCLIC LOADS

In an ongoing study, the shear properties of the deconstructable connector were evaluated in a CLT-concrete composite system under cyclic loading. One objective was to determine how much the cyclic shear properties of the deconstructable connector might differ from those of a regular screw. Another objective was to evaluate the deconstructability of the connector at the end of cyclic loading.

For the shear tests, the push-out load set-up shown in Figure 2 was used. Several load levels within the serviceability range were applied, where the lower load level represented the dead load on the structure in an office floor and the upper load level represented the combination of the dead load and possible live loads. Each specimen was loaded up to about 130 k load cycles. They were then disassembled, reassembled, and then loaded to failure.

The results of the study showed that the trends in the load-slip behaviour of both types of connections were similar. An example load-slip curve during the cyclic loading of a deconstructable connection can be seen in Figure 3. The deconstructable connections were able to reach the same initial level of shear stiffness as the regular connections, which was likely due to the same CLT-concrete interface characteristics.

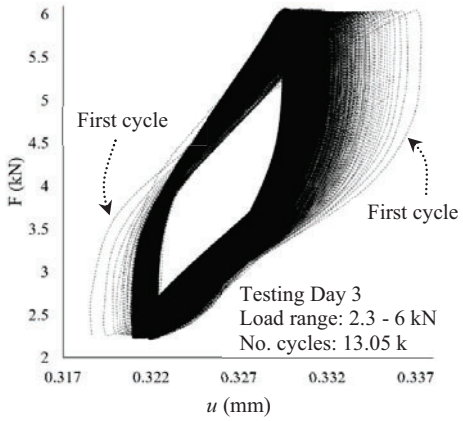

Figure 3: *Example cyclic load-slip curve of a deconstructable connector.*

As the cyclic test progressed, the shear stiffness increased as a result of the wood fibers hardening at the screw contact points but this also led to an increase in accumulated slip. Interestingly, the accumulated slip for the deconstructable connections was found to be lower than that of the regular connections during the cyclic loading.

The disassembly and reassembly processes of the connections were straightforward because no detectible plastic hinge had been formed in the connectors. After the reassembly process, the deconstructable connections retained 70% of their initial shear stiffness and their load-bearing capacity remained comparable to that of the regular connections.

3.3 BENDING TESTS OF A CLT-CONCRETE FLOOR ELEMENT

Following the completion of the test at the connection level, the effectiveness of the deconstructable connector was further evaluated in a CLT-concrete composite floor system, see [2]. To do this, a number of composite CLT-concrete beams, representing a strip of a full-scale floor, were constructed using the new connector. The properties of the beams were experimentally evaluated, including vibration performance, bending properties, interface slip, failure modes, and ease of disassembly. A control group of composite beams made with regular self-tapping screws was also fabricated and tested to provide a point of comparison. During the fabrication of the specimens, concrete was poured in such a way that a 3-mm concrete layer would form above the connector's lid. As a result, the composite beams made with both deconstructable and regular connectors were visually identical (Figure 4).

https://doi.org/10.52202/069179-0465

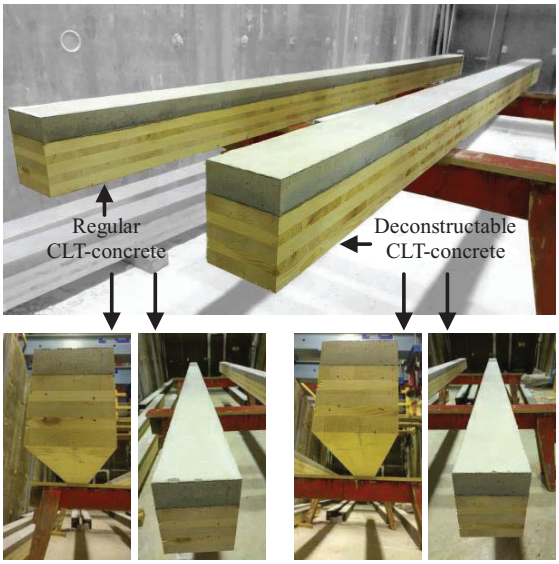

Figure 4: *The visual characteristics of a deconstructable and a regular CLT-concrete composite beam tested in: [2].*

Overall, the study found that the natural frequency, bending strength, and bending stiffness of the deconstructable composite beams were similar to those of the beams made with regular screws. Furthermore, the connectors inserted at a 30˚ angle did not show any detectable signs of plastic deformation, even after undergoing significant deformation under bending load. This indicates that the new connector system is able to maintain its deconstructability even under large loads.

4 DECONSTRUCTABLE CLT-CONCRETE FLOOR MADE WITH REUSED ELEMENTS

After the completion of the tests in the previous study [2], the deconstructable CLT-concrete composite beams were disassembled; one example is shown in Figure 5. A subsequent experiment was then undertaken aiming to connect one of the disassembled concrete slabs, with pre-existing cracks, to a fresh CLT beam using the self-tapping screws that were also disassembled in the previous study. The objectives were to a) evaluate the effect of concrete cracks on the performance of the system and b) demonstrate the ability of the connector for reuse in a disassembly-reassembly process. The composite beam was fabricated using 5-layer CLT with the dimensions of $b \times h \times l = 145 \times 130 \times 4000$ mm^3. The dimensions of the concrete slab were $b \times h \times l = 145 \times 55 \times 4000$ mm^3. The concrete slab contained multiple cracks along the span due to the previous bending tests (as shown in Figure 6).

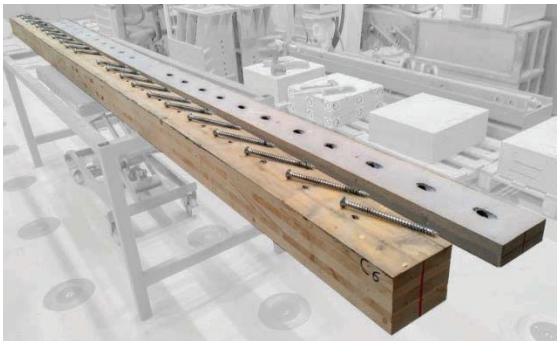

Figure 5: *A CLT-concrete composite beam deconstructed after destructive bending test.*

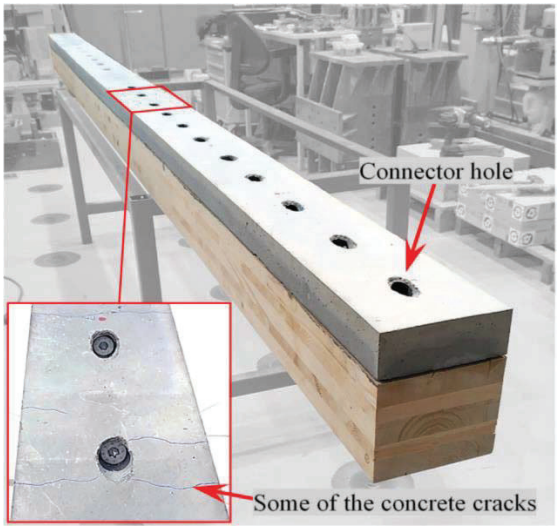

Figure 6: *The composite beam with concrete cracks.*

The first eigenfrequency (f) and the damping ratio (ζ) of the CLT beam prior to the assembly process and those of the composite beam with cracks were measured from several points along the beams using a hammer, an accelerometer, a charge amplifier, and a dynamic signal analyzer. The effective bending stiffness (EI_{eff}) of the CLT beam was measured in the elastic region prior to the assembly process using a four-point bending test set-up in accordance with EN 408 [9]. The bending properties of the composite beam with cracks were also measured using the same test set-up; however, the loading continued until after the failure point was reached.

The vibration characteristics of the pure CLT and the composite beam with cracks are given in Table 1. The results of the vibration test on the composite beam without cracks from the previous study [2] are also presented as a reference. The composite beam without cracks is the same one from which the concrete slab and the screws reused in the new beam were obtained.

https://doi.org/10.52202/069179-0465

Table 1: *The vibration characteristics and bending performance of the beams.*

Characteristics	CLT	CLT-concrete	
		With cracks	Without cracks
f (Hz)	18.3	18.8	19.8
ζ (%)	2.9	5.6	3.1
EI_{eff} (kN.m^2)	227.6	677.9	898.7
F_{max} (kN)	-	27.6	28.9

The first eigenfrequency (f) of the composite beam with cracks was only 2.7% higher than that of the pure CLT beam and about 5.3% lower than that of the composite beam without cracks (Table 1). Nevertheless, the damping ratio (ζ) was considerably higher for the composite beam with pre-existing cracks. The higher damping ratio is a result of cracks and related gaps in the concrete which can further dissipate the vibration energy.

The load-deflection curves of the composite beams with and without concrete cracks as well as that of the pure CLT beam are illustrated in Figure 7. The maximum load carrying capacity (F_{max}) of the composite beams were relatively similar. However, F_{max} was governed by the finger joint failure in the bottom lamella and, therefore, is not discussed further. The most apparent difference in the load-deflection curves of the two composite beams appeared at the initial stages of the loading. The composite beam without cracks exhibited a nearly linear trend up to F_{max}. The composite beam with cracks, however, initially exhibited a larger deflection up to approximately 15 kN load level. Afterwards, the slope of the load-deflection curves of the composite beams was relatively similar up to the failure point. The composite beam with cracks exhibited a significantly higher bending stiffness than the pure CLT beam. Nevertheless, the bending stiffness was lower than that of the composite beams without cracks.

Overall, this preliminary experiment provided a quantitative comparison between the performance of TCC floor elements with cracked and uncracked concrete slabs. The results tend to indicate that the benefits of the composite system are considerably minimal when cracks exist in the concrete slab. Therefore, it is important to reduce the likelihood of crack development during transportation and assembly of TCC structures, especially when the dry-dry system is used and the concrete slab is prefabricated and transported separately.

Furthermore, this experiment demonstrated the flexibility of the deconstructable connector for disassembly-reassembly process. This can offer some advantages in TCC structures such as e.g., flexibility for repairs or design changes in buildings, in addition to its potential for easing the reuse process of the materials at the end of service life.

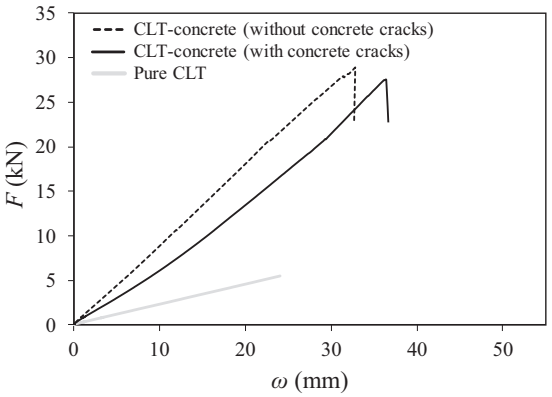

Figure 7: *Load-deflection curves of the beams.*

5 CONCLUSIONS AND OUTLOOK

Overall, the research works summarized in this paper have demonstrated the performance of the deconstructable TCC connection system, making it a viable alternative for applications where easy disassembly is of interest. This can be important not only for improving the circularity aspects of regular buildings, but also for other applications such as for temporary structures or for future design changes or repairs in buildings.

Although it was demonstrated that deconstructable solutions can be highly effective, to realize their true potential and promote their use, more needs to be done to educate and raise awareness in the field of design for deconstruction. For this, various strategies such as establishing design for deconstruction guidelines as well as providing training programs and other educational resources for designers and builders could be considered. Furthermore, showcasing and providing examples of successful deconstruction projects can help to educate and inspire designers and builders to create sustainable buildings that can be easily taken apart and recycled or repurposed.

ENVISIONING MASS TIMBER BUILDINGS FOR CIRCULARITY: LIFE CYCLE ASSESSMENT OF A MASS TIMBER BUILDING WITH DIFFERENT END-OF-LIFE (EOL) AND POST-EOL OPTIONS

Namhyuck Ahn[1], Christina Bjarvin[2], Mariapaola Riggio[1], Lech Muszynski[1], Laurence Schimleck[1], Catarina Pestana[2], Ambrose Dodoo[3], Maureen Puettmann[4]

ABSTRACT: The foundation of the circular economy in the construction sector is based on implementing the deconstruction and reuse of buildings, providing the potential for a closed loop of building materials within the supply chain. Mass timber buildings using large, prefabricated elements and certain types of reversible mechanical connections are deemed to have great potential for post end-of-life (EoL) options, including recycling and reuse. To fully characterize the benefits of reusing post-use mass timber in new construction projects, it is crucial to conceptualize a 'grave-to-gate' approach, including the complete analysis of post-EoL activities and impacts on the material's second life. In this study, a comparative life cycle assessment (LCA) including different EoL and post-EoL options for a virtual reference mid-rise mass timber building in the Pacific Northwest (PNW) of the United States was conducted. Among four different deconstruction and reuse scenarios examined in this study, a case of nearly complete reconstruction of a mass timber building for the second service life used as an idealized reference established an optimistic limit for reduction of global warming potential (GWP) by 13-41% compared to the 'demolish and landfill' decision, depending on the scenario. The demolition and landfill scenario had the lowest net impact since the GWMP calculations accounted for the carbon storage benefits in the landfill in addition to the carbon stored in the building.

KEYWORDS: Mass Timber, Circular Economy, Deconstruction and Reuse, End-of-Life, Life Cycle Assessment

1 INTRODUCTION

Opposed to the "use and dispose" linear economic model, implementing the circularity of materials in the construction industry (recycling/reuse) is a critical issue in carbon footprint discussions. In Europe, the Climate Regulation of 2021 [1] aims to reduce greenhouse gas (GHGs) emissions by at least 55% below 1990 levels by 2030 as an intermediate goal. In the same year, along with this ambitious goal of the EU, the United States also introduced the Climate Leadership and Environmental Action for our Nation's (CLEAN) Future Act to drastically reduce GHGs emissions to at least 50% below 2005 levels by 2030. Under the Buy Clean Actions [2], the U.S. government also plans to expand the development of life cycle assessment (LCA) data for building materials purchased for any federal-funded projects. There is a need for lower carbon footprint buildings, and mass timber has gained popularity as a sustainable alternative to traditional construction materials and has led to revolutionary developments in timber construction [3, 4].

1.1 MASS TIMBER BUILDING FOR CIRCULARITY

Mass timber buildings typically utilize large engineered wood panels custom-ordered and manufactured for load-bearing structures such as floors and walls [5]. Because of the lightweight nature of the material [6], mass timber construction requires smaller cranes than other construction types, such as precast concrete, while maintaining the required structural performance. Connection hardware is one of the important parts of mass timber buildings, and they heavily influence the structural performance of such buildings [7]. Panel assemblies usually have screws instead of nails and use bolts and plates for some connection systems. Depending on the type and number of connections, mass timber assemblies may be disassembled at the end of building's life and re-assembled in new construction. The presence of fewer, localized connections, in some mass timber designs may minimize damage to panels, thus facilitating reuse. Compared to the deconstruction of conventional wood light-frame buildings, which requires extra effort and time during the de-nailing process, deconstruction of mass timber buildings and recovering mass timber panels for

https://doi.org/10.52202/069179-0466

reuse rather than disposal at the end of the building's service life seems an attainable EoL scenario (Figure 1).

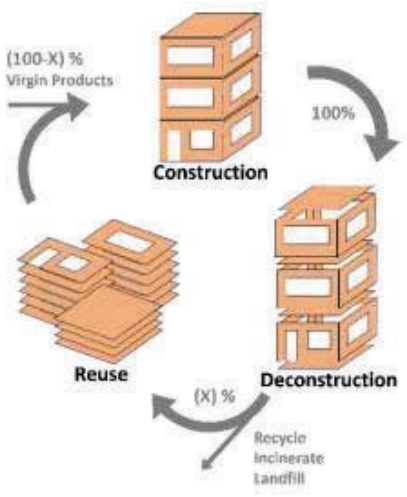

Figure 1: *Deconstruction and reuse of mass timber buildings.*

This is also well-aligned with circular economy principles that aim to maximize resource value and reduce environmental impacts. Moreover, the advantage of the reuse scheme is realized when the benefits of reusing mass timber panels are fully accounted for throughout their expected life.

1.2 LIFE BEYOND BUILDING END-OF-LIFE: EXTENDED LIFE CYCLE ASSESSMENT OF MASS TIMBER BUILDINGS

Conventional life cycle assessment (LCA) methodology is insufficient to assess the environmental impacts of mass timber building deconstruction and material reuse due to its focus on the first life cycle. Although the International Organization for Standardization (ISO) 14040 [8] defines module D to account for potential net benefits from reuse in ISO 14044 [9], it is still outside the system boundary. ISO 14044 instructs avoiding miscounting benefits from reusing by expanding the product system to the second product use [10]. Yet, it does not specify how these scenarios can be implemented, with or without a remanufacturing phase.

By extending part of the building material's lifespan at the end-of-life stage to the second lifecycle (Figure 2), there can be a proper evaluation of the circularity value of buildings that otherwise might have been overlooked [11]. For instance, if mass timber panels can be reused in another construction project after building deconstruction, the burden of producing panels from virgin timber can be avoided. Reusing panels instead of landfilling them also avoids the burden of panel waste processing. Moreover, reusing or landfilling panels can reduce the cumulative cradle-to-grave global warming potential (GWP) associated with the first building due to the carbon storage benefits of wood [12,13]. These benefits and avoided burdens can lower the environmental impacts of buildings, thus improving the potential of circularity as a viable option for sustainable construction. However, to fully account for the benefit of deconstruction and reuse, the first step is to incorporate this gate-to-gate impact into the system boundary.

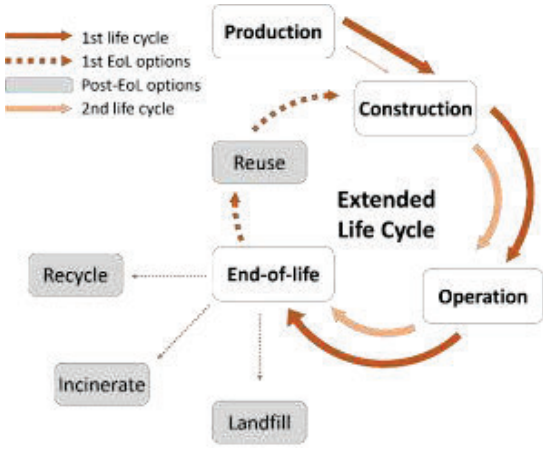

Figure 2: *Extended life cycle of buildings.*

While there have been attempts to address the benefit of reusing building materials at large using LCA [14-16], several studies have focused on timber-based buildings. LCA research investigating wood-cascading scenarios for glue-laminated timber beams in a virtual building indicated that reusing timber is beneficial as it provides the substitution effect for structural building materials [17]. However, the environmental impact assessment excluded construction, operation, and transportation stages for simplicity, and there was no comparison among different post-EoL options. Comparative LCA of CLT reuse, focusing on the second life [18], has also been conducted. Different CLT reuse rate scenarios were used to compare the avoided environmental impact of A1-A3 and C2-C4 modules on the overall carbon footprint. Again, this research also focused exclusively on the second life of mass timber panels, while there were no variations in post-EoL options. Recent work focuses on the first life of mass timber and EoL impacts after deconstruction [19]. In the research, various post-EoL options were implemented, including reuse, recycling, landfill, and incineration, using a dynamic LCA approach for comparison over two life cycles. Yet, the research focused more on the first life, leaving research needs for more in-depth analysis focusing on the second life with EoL alternatives to draw a comprehensive overview of circularity potential and its benefits for mass timber buildings.

1.3 OBJECTIVE AND SCOPE

The main objective of this study is to explore the circularity potential of mass timber buildings in their theoretical and practical reuse scenarios to help decision-

https://doi.org/10.52202/069179-0466

makers fully consider mass timber's carbon storage potential with its second life. Comparative LCA of a reference mass timber panel (MTP) building with various EoL and post-EoL options, including deconstruction, reuse, recycling, energy recovery, and landfill, are considered in this study.

2 MATERIALS AND METHODS

To analyze the environmental impacts of EoL and post-EoL options, we designed a comparative whole-building LCA of a reference MTP building, starting with the deconstruction and EoL processing of the first building and ending with the construction of a second identical building. In this manner, any recovered MTPs from the first building were assumed to be reused for the second building without changes in design.

2.1 REFERENCE BUILDING MODEL

The reference building for this study was based on mass timber building Type IV-C construction guidelines established in the 2021 International Building Code revision. The building was designed as an eight-story residential mixed-use building with a simple rectangular shape, a core elevator shaft, and stairs in the central space [20]. The building was designed to be located in the Pacific Northwest (PNW) region of the United States, and as such, it meets the building code requirements of that region. It was assumed that the first and second buildings were in the same Portland metropolitan area in Oregon. The study also included an ideal scenario, which reuses the foundation of the first building. This will be explained in detail in section 2.3..

With the specific region in consideration, seismic requirements were applied to the building design (e.g., a lateral force resistance system). For walls and floors, cross-laminated timber (CLT) was used, while glue-laminated timber (GLT) was used for the columns and beams. While mass timber products are mostly selected for building design, steel and concrete are also used in foundations and some structural elements. A conventional reinforced concrete structure with identical function and shape was designed for comparison with the reference mass timber building. Detailed building information is summarized in Table 1.

Table 1: *Description of the mass timber building used for LCA in this study.*

Type	Description
Building Use	Mixed-use
Construction Type	Type IV-C
Mass Timber Product Type	CLT (walls and floors), GLT (columns and beams)
Stories	8 (residential 6 + commercial 2)
Height	26 m
Total Floor Area	9,476 m^2

2.2 EOL AND POST-EOL OPTIONS FOR THE SYSTEM BOUNDARY

In this LCA, we set the system boundary to encompass EoL processing (module C) for the first building and production-and-construction (module A) for the second building. Either deconstruction or demolition was considered for the EOL option, depending on if panels were going to be reused or not. For post-EoL options, it was assumed that mass timber products (both CLT panels and GLT columns/beams) were reused (RU), recycled (RE), incinerated (IC), or landfilled (LF) in different proportions, depending on the case (Table 2). The whole system boundary information is summarized in Figure 3.

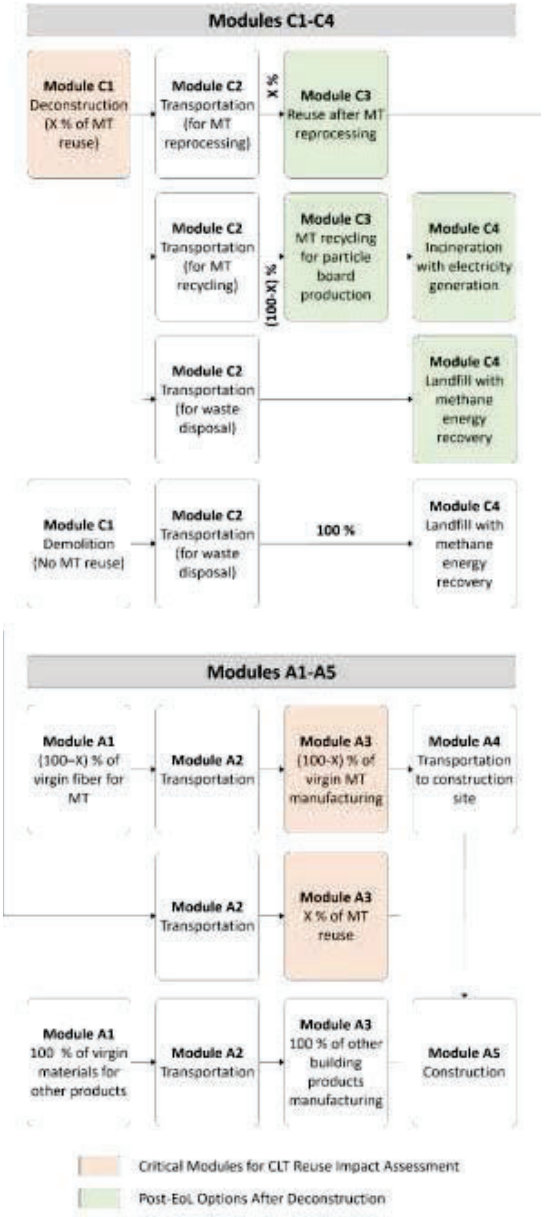

Figure 3: *System boundary applied to EoL and post-EOL of CLT in the study.*

https://doi.org/10.52202/069179-0466

In RU, mass timber products are reprocessed in the manufacturing facility located in Oregon and then transported to the new mass timber building construction site for a second life. Reprocessing for reuse included minimal treatment, such as cleaning, connection removal, and repackaging. The volume of panels required for the second building that was not satisfied by reused panels was made from virgin materials. In RE, mass timber products are recycled in the manufacturing facility in Oregon to produce particleboard for the general market. In IC, mass timber products are incinerated in the plant facility for electricity generation, while in LF, products are landfilled in the same facility with methane energy recovery.

2.3 DECONSTRUCTION AND REUSE SCENARIOS

Mass timber buildings are still relatively young compared to other building types, and almost none of the existing cases worldwide have reached the end of their service life. Consequently, few studies have investigated the potential reuse of mass timber panels for a new building design [18,19,21]. Based on this fact, the rate of use of recovered panels for the second building after the deconstruction of the first building was determined by hypothetical assumptions (Table 2).

Table 1: *LCA cases used in this study.*

Case		MT Deconstruction and Reuse	
		CLT	GLT
Ideal	1	90% RU 10% RE	
Optimistic	2	70% RU 30% RE	90% RU 10% RE
	3	70% RU 30% IC	90% RU 10% RE
	4	70% RU 30% LF	90% RU 10% RE
Conservative	5	50% RU 50% RE	90% RU 10% RE
	6	50% RU 50% IC	90% RU 10% RE
	7	50% RU 50% LF	90% RU 10% RE
No reuse	8	100% LF (construct a new mass timber building)	
	9	100% LF (construct a new reinforced concrete building)	

In 'conservative' scenarios, 50% of CLT panels used in the first building are assumed to be reused for the second building. 70% reuse is assumed in 'optimistic' scenarios because the reuse of CLT in the future may be easier than it is today because of continuous technological advancement (for instance, technology capable of separating CLT and concrete from a composite floor system without damaging CLT panels). In addition, a case of nearly complete reconstruction of a mass timber building for the second service life was used as an idealized reference to establish an optimistic limit for the reduction of global warming potential (GWP). In this scenario, it is assumed that 90% of the panels are recovered in an intact condition, which requires minimal on-site reprocessing (e.g., removing connectors and cleaning).

Notably, 90% of GLT beams and columns are reused in all cases except the demolition with 100% landfilling options (Cases 8 and 9). For all scenarios, connectors for mass timber products are assumed not to be reused for safety reasons.

In the ideal scenario, the building's foundation is also assumed to be reused. This is unrealistic in the legal and planning aspects of the project, but from the engineering perspective, it is a sufficiently possible scenario considering the durability of the concrete foundation. It is also a recommended practice, if possible, from the circular economy point of view. In this scenario, the distance between the reprocessing facility and the mass timber building was assumed to be the same as in other cases to avoid changes in impacts in module A4.

Two additional cases in which mass timber products were not reused, which were described as 'no reuse' scenarios in this study, were further analyzed for comparison. One is to construct a new identical mass timber building after the demolition of the first mass timber building, and the other is to construct a functionally equivalent building with a reinforced concrete structure. In both cases, all mass timber panels from the first building would be landfilled.

2.4 LCA METHODOLOGY

In addition to the GWP values associated with modules C and A, the module D benefits associated with storing carbon in mass timber for all cases were calculated using the Lashof accounting method [22]. For cases involving incineration or landfill EoL options, the benefit of replacing fossil fuels with biofuel generated during energy recovery was calculated.

LCA in this study was extended beyond the scope of conventional static LCA by adopting a dynamic approach, which accounts for the timing of different emissions generated in modules C and A over a period of 100 years. A previously created novel dynamic LCA model was used in this study to account for the radiative forcing caused by GHG emissions. The model emulates the atmospheric decay of the emissions over time, producing a dynamic LCA result [19,23].

3 RESULTS

We calculated the 100-year cumulative fossil GWP values, global warming mitigation potential (GWMP) values, and net climate impacts (the sum of the GWP and GWMP) in Modules C1 – A5 for each of the eight scenarios from Table 1 (Figures 4 - 7). The GWMP

includes benefits from carbon storage in wood products but not the benefits from energy recovery.

Comparing the two extreme scenarios (Case 1, "Ideal," and Case 8, "No Reuse") demonstrates the stark difference in GWP values when MTP materials are reused instead of landfilled (Figure 4). However, the "No Reuse" case had more carbon storage benefits because in this scenario, we accounted for the carbon stored in the landfill [13] *and* the carbon stored in the building, while in the Ideal case, we only accounted for the carbon stored in the building and in the recycled timber products. Bringing in virgin timber increases the GWP of the building, but it also increases the opportunity for carbon storage benefits. However, in both cases, the carbon storage benefits outweigh the GWPs, making the building a net sink for carbon due to the use of mass timber.

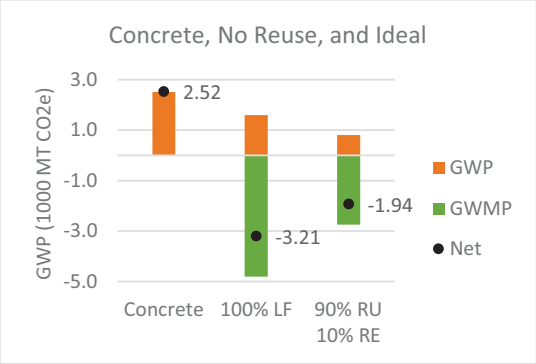

Figure 4: *Global warming potential (GWP), carbon storage benefits (GWMP), and net GWP values in Cases 8 (left) and 1 (right).*

Comparing the optimistic (70% reuse) and conservative (50% reuse) cases for each EOL option demonstrated similar differences. The optimistic cases had lower GWP values than the conservative cases, but conservative cases had more carbon storage benefits. These differences are shown in Figures 5-7. Comparatively, the GWP values associated with recycling are lower than those associated with incineration and landfilling.

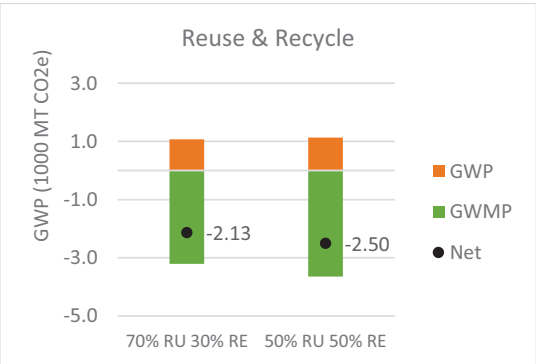

Figure 5: *Global warming potential (GWP), carbon storage benefits (GWMP), and net GWP values in Cases 2 (left) and 4 (right).*

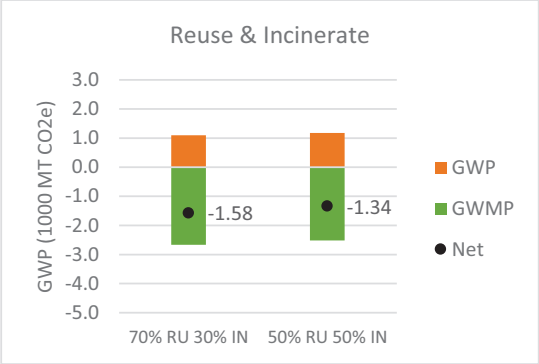

Figure 6: *Global warming potential (GWP), carbon storage benefits (GWMP), and net GWP values in Cases 3 (left) and 6 (right).*

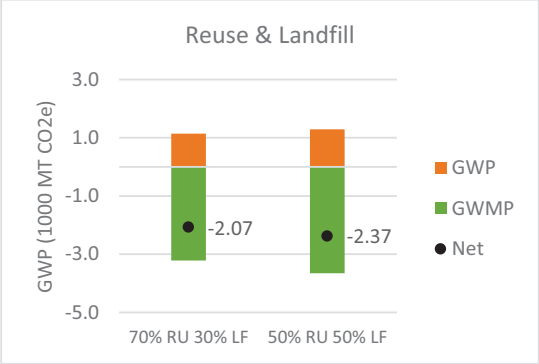

Figure 7: *Global warming potential (GWP), carbon storage benefit (GWMP), and net GWP values in Cases 4 (left) and 7 (right).*

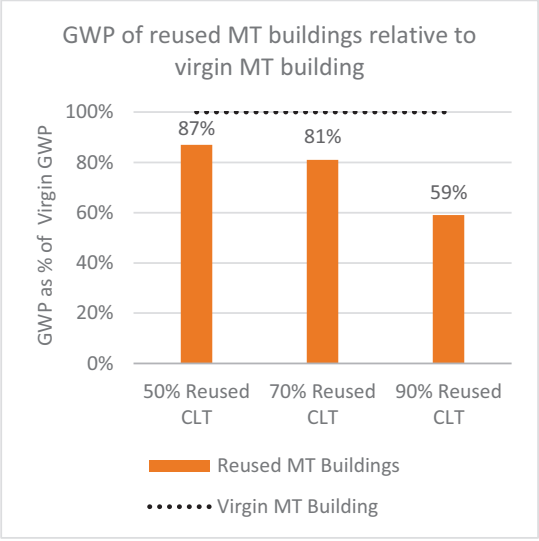

Figure 8: Fossil GWP of the 8-story mass timber (MT) building constructed from 50%, 70%, ***or 90%*** reused CLT as a percentage of the virgin mass timber building GWP.

https://doi.org/10.52202/069179-0466

Finally, the GWP values of the buildings constructed from reused timber in the Optimistic and Conservative cases are compared relative to the GWP of the virgin timber building (Figure 8). These GWP values are shown as a percent of the virgin MT building GWP, with the virgin MT GWP equaling 100%).

4 CONCLUSIONS AND FUTURE RESEARCH

This research analyzed the climate impacts of four different post-EoL options (reuse, recycling, landfill, and incineration) on the second life of a virtual mid-rise mass timber building in the PNW of the United States after four different post-deconstruction scenarios for the first life of the building (no reuse, conservative, optimistic, and ideal used to establish an optimistic limit for potential benefits). Although the presented analysis uses some oversimplified assumptions (e.g., reuse of the same foundations, reuse for the same design) and has demonstrable bottlenecks, this research indicates the aim for the mass timber industry on the path to the circular economy age and a vision of its potential impact on the environment. The study also demonstrates that reusing mass timber products may contribute to sustainable forest practices by reducing the pressure on harvesting, a value that cannot be fully expressed in conventional LCA approaches.

Compared to a conventional static LCA, using a dynamic LCA approach achieved by incorporating the temporal variations of GHG emissions and their atmospheric decay rates into LCA allows for a more realistic representation and a more comprehensive understanding of global warming impacts. This is particularly applicable to the *recycle* and *incinerate* EoL options predicted to generate emissions at different times throughout the time horizon instead of all at once.

Future research includes another round of analysis with a systematic approach to refined mass timber cascading scenarios and practical second-building design interventions with a different configuration than used in this presented study. In addition, observational research to gather information, such as the actual attrition rate of recovered panels from multi-story mass timber test structures, is also planned.

A REUSE-READY TIMBER SLAB-AND-COLUMN SYSTEM FOR MODULAR BUILDING STRUCTURES

Xavier Estrella[1], Alex Muresan[2], Dario Redaelli[3], Jan Brütting[4], Jonas Warmuth[5], Corentin Fivet[6]

ABSTRACT: The construction industry is a significant contributor to resource consumption and waste generation. To address this issue, component reuse has been proposed as a way to prevent valuable building elements from being discarded and avoid producing new ones. However, the lack of circular economy principles in existing structures makes it difficult to extract and exploit reusable components fully. This paper presents a new load-bearing timber system (Pixel Slab) designed for disassembling and reassembling multiple times over the building's lifespan. The system goes beyond the traditional concepts of modularity and reversibility, providing designers with a minimum kit of parts that can be used to make localized adjustments and accommodate a wide range of building designs – such as floor geometry, load conditions, and supports distribution – with little to no new material input. This allows for functional design requirements that are difficult to predict over the long term. The system also focuses on low-tech assembly and disassembly processes, embodied environmental impacts, and manufacturing costs, all of which aim to increase the potential for component reuse. The proposed timber solution proved to be particularly suited to increase the sustainability of short-lived buildings.

KEYWORDS: Component reuse, design for deconstruction, timber structures, circular economy, sustainable buildings, construction and demolition waste, material recovery.

1 INTRODUCTION

Over the last few decades, the construction industry has been at the center of ample criticism because of its role in the climate change emergency that societies face nowadays. Due to the high growth rates of newly built infrastructure and the widespread use of highly pollutant construction materials, the industry has been identified as responsible for 15% of the world's CO2 emissions [1] and one-third of the waste production [2]. Besides, recent research associates it with 50% of the exploitation of natural resources [3,4] and 36% of global energy consumption [5]. As the demand for new housing and civil infrastructure is expected to grow in the upcoming decades, measures are urged by private and public organizations to deal with such a multiscale challenge.

In this context, timber structures arise as an environmentally friendly strategy to tackle the aforementioned issues, providing the means to reduce the carbon footprint of the construction industry. For instance, previous studies have shown that the energy consumption of concrete houses is 60-80% higher compared to timber houses [6], and that the CO_2 production during the life span of a concrete building is 30-130 kg/m^2 greater [7]. In seasonal countries with cold winters and hot summers, it has been calculated that a timber house consumes around 15% less energy for heating/cooling when compared to a concrete or steel house, and over a period of 100 years, it is estimated that a timber house could reduce the net emissions of greenhouse gases by between 20% and 50% when compared to traditional systems [8].

On the other hand, the inclusion of Circular Economy principles into construction practices has also proved to be an effective approach to alleviate the environmental impact of new infrastructure. In particular, the reuse of construction components has been gaining traction lately [9], with the aim of keeping construction components in a closed loop at their highest value and extending their lifespan over several building cycles. This way, components are brought back into the construction supply chain with little/no maintenance after the initial structure reached obsolescence, minimizing new production and diverting valuable resources from landfilling.

The current practice of timber construction does not allow a straightforward inclusion of reuse techniques at the end-of-life phase of existing buildings. Therefore, once timber structures have reached obsolescence, their components are discarded or must undergo time/energy-consuming procedures to be reused in different building applications. And even though mass-timber structures generally employ reversible and standard connections that facilitate assembly/disassembly procedures, their future reuse potential cannot be guaranteed beforehand. This is mainly due to the lack of open-ended reuse principles in current timber construction practices, such as adaptivity to different architectural requirements and load conditions, use of standard and interchangeable components and connectors, embracing long-term purpose uncertainty, and easy repairability, replaceability, and transportability.

Therefore, this paper presents a novel timber slab-and-column system "Pixel Slab" designed for open-ended reuse over multiple life cycles. The system goes beyond the traditional wooden concepts of modularity and reversibility, providing designers with a minimum kit of parts that can be used to make localized adjustments and accommodate a wide range of building designs – such as floor geometry, load conditions, and supports distribution – with little to no new material input. This allows for functional design requirements that are difficult to predict over the long term. The system also focuses on low-tech assembly and disassembly processes, embodied environmental impacts, and manufacturing costs, all of which aim to increase the potential for component reuse of current timber construction practices.

2 MATERIALS AND METHODOLOGY

This study follows a Research-through-Design (RtD) approach in the development of the Pixel Slab system. The RtD methodology generates new knowledge through a systematic and iterative process of evaluating design results and feedback [10]. This approach combines theoretical concepts with design and development, allowing for exploratory ideas and a disruption of the status quo in a scientifically controlled environment. The RtD framework for this investigation, as shown in Figure 1, consisted of six main stages: (1) goals and functional requirements definition, (2) iterative design sessions, (3) conceptual design, (4) structural implementation, (5) feasibility analysis, and (6) full-scale validation.

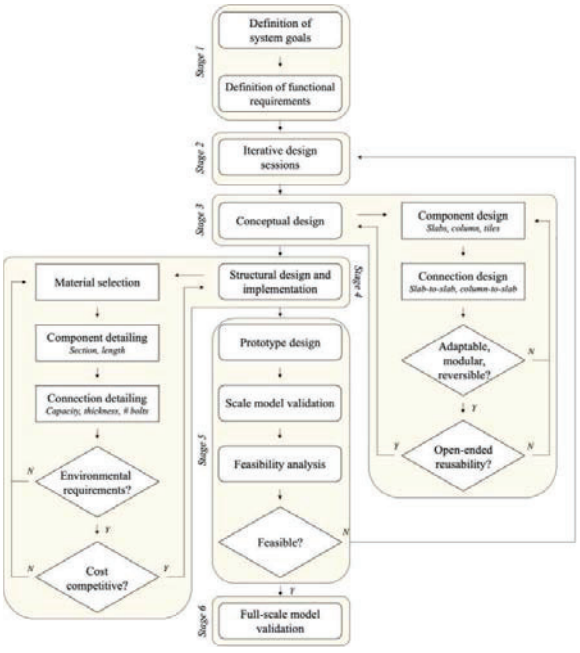

Figure 1. *Methodological workflow for the development of the Pixel Slab system.*

A set of system goals was defined early in the development of the Pixel Slab system aiming at guiding its design principles and requirements. Adhering to a downstream component reuse philosophy [9], the system aims to bridge the gap between reusability and its practical application in timber construction. At the same time, it incorporates Circular Economy principles into the design phase to account for future uncertainty and maximize the potential for open-ended reuse. The goal is to design timber structures that are easily repairable, replaceable, demountable, and transportable. Accordingly, the system goals are stated as follows, in descending order of hierarchy:

- To maximize the open-ended reuse potential of timber structures by implementing design-for-reassembly principles in such a way that it can meet unpredictable scenarios and boundary conditions.
- To minimize the detrimental environmental impacts related to manufacturing, handling, maintenance, and end-of-life.
- To reach manufacturing and operation costs that are competitive to conventional products in the long term and over several life cycles.

A comprehensive set of functional requirements was established to provide a clear research framework by considering past, present, and future reuse practices, and to establish the boundaries and conditions for the new timber solution. The requirements aim to ensure the structure's technical and economic appeal under various future scenarios and promote the open-ended reuse of the structural system and its components. To facilitate the implementation during the conceptual design phase, the functional requirements were grouped into three categories: (1) structural, (2) assembly and disassembly, and (3) versatility and modularity.

The structural requirements establish the scope and niche of the proposed timber system in terms of its intended applications and performance:

- To provide a load-bearing structural system for low- to mid-rise office or residential timber buildings.
- To create a continuous load path and carry vertical loads down to the foundation system. The system is not intended to carry horizontal loads and should be designed along with a lateral resistant system (e.g., core walls, bracing system, among others).
- To allow versatility of vertical load levels and spans between vertical supporting elements.
- To provide an effortless installation of vertical shafts, pipes, and non-structural elements.

Assembly and disassembly requirements define the design boundaries with the aim of maximizing the structure's reuse potential in unspecified future scenarios:

- To employ dry, readily accessible, reversible mechanical connections for assembling elements and components.
- To minimize the number of connections between elements, assemblies, non-structural components, and the main structural system.
- To maximize the use of standard connections across the different system levels (substructure, superstructure, flooring, and non-structural components).
- To employ only low-tech tools and procedures for assembling and disassembling. Likewise, to provide means for easy handling and transportation of components.

https://doi.org/10.52202/069179-0467

Versatility and adaptability requirements aim to ensure that the Pixel Slab system can be adjusted and reconfigured for future reuse scenarios, making it flexible and capable of being used in a wide range of applications:

- To allow open-ended re-arrangements of structural and non-structural components in the system.
- To employ interchangeable modular elements and connections, facilitating reorganization and replacement of system components.
- To allow unplanned inclusion or removal of openings across the floor layout, e.g., for staircases, elevators, shafts, technical installations, or building extensions.
- Not to restrict the inner partitioning layout and to ease parallel disassembly if modifications are required.

3 RESULTS: PIXEL SLAB

Figure 2 shows the resulting timber Pixel Slab system. It comprises slab elements set horizontally to create a lateral surface and column elements to transfer vertical forces to the foundations. Slab elements are made up of glue-laminated timber beams connected orthogonally to form a uniform flat grid. Individual beams are 80×240 mm spaced at 400 mm from their longitudinal axis. Beams are manufactured by gluing eight timber laths (80×30 mm each) with alternating discontinuities, as observed in Figure 3. This allows a grid-like slab with uniform properties in both directions. This configuration achieves spans of up to 6 meters based on the loading requirements specified in the Swiss SIA 261 standard [11] for office and residential buildings. Slabs are 2.4×2.4 m to facilitate handling, transportation, and storage. Besides, the beams' discrete placement results in a uniform distribution of slab openings that makes room for columns, vertical shafts, or non-structural elements, resulting in a low-weight solution compared to traditional flooring systems.

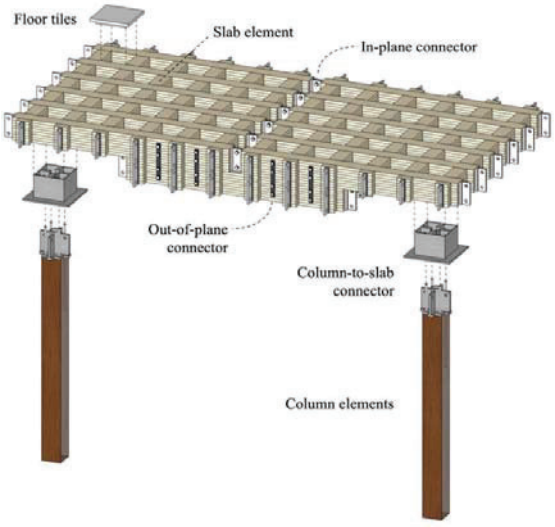

Figure 2. *Overview of the Pixel Slab system and its components.*

Flexible floor configurations can be designed by attaching slab elements with in-plane connectors, which transfer axial, bending, and shear loads between two adjacent slabs. In-plane connections were designed employing 240×83×15 mm steel plates grade S355, 660 mm long threaded steel rods grade 8.8, and two M27 steel bolts class 10.9, as per Figure 3. Threaded rods are embedded into timber into pre-drilled holes and glued-in employing epoxy resin, and subsequently welded to the steel plates. This way, in-plane connections are reversible and allow effortless construction, deconstruction, and reuse.

The structural capacity (strength and stiffness) of slab elements can be increased by stacking them vertically with out-of-plane connections, which are designed to bear the shear and axial loads that arise at the interface between slabs while not blocking the installation of vertical pipes or shafts through the openings. Out-of-plane connectors employ 380×60×5 mm steel plates grade S235 and four M16 steel bolts class 8.8, as Figure 3 shows. With this design, out-of-plane connectors provide a convenient and reversible method to reinforce areas that experience high demands or to accommodate longer spans.

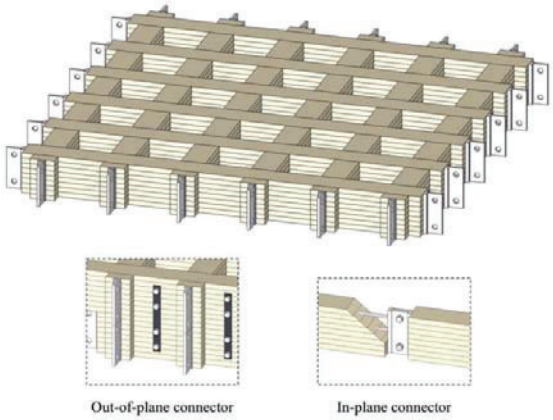

Figure 3. *Slab element with in-plane and out-of-plane connectors.*

Vertical loads are transferred across stories down to the foundation through conventional mass-timber columns. Forces between slabs and columns are taken by column-to-slab connectors that fit into the slab openings and nest the upper and lower columns, as Figure 2 depicts. Column-to-slab connectors employ high-strength steel and bolts, and their dimensions might vary based on the column sizing. Thanks to this versatile design, columns can be placed at any slab opening across the floor plan to accommodate different engineering or architectural requirements. It should be noted that the system described here is not intended to bear lateral loads, such as wind or earthquake, and should be designed as a gravity frame system without ductile capacity. Yet, the slab components must have adequate in-plane stiffness to effectively transfer lateral loads to the stiff core or bracing system.

Finally, floor tiles are installed on top of the slab elements to create a continuous surface for other finishing layers to be added, as illustrated in Figure 2. The dimensions of the floor tiles are designed to fit into one or multiple slab openings at once, with joint lines of minimum thickness to ensure proper sealing between components. This allows the tiles to meet technical requirements and fulfill non-structural functions such as smoke barriers or sound insulation. Tiles are attached to the slab components through reversible connections (i.e., bolts and nuts), allowing for future replacement of units and simple construction/deconstruction processes.

4 EXPERIMENTAL TESTING

A full-scale experimental campaign was carried out to evaluate the structural performance of the Pixel Slab system, and 19 different specimens were tested under bending load. Each specimen consisted of single-span components designed to be representative of the GLT beams used for the Pixel Slab system shown in Figure 2.

Beams were manufactured using mechanically graded GL32h timber with an elasticity module E = 13000 MPa and characteristic bending strength $f_{m,k}$ = 32 MPa. Single beams were 80×240 mm made up of 8 timber laths glued with polyurethane adhesive. The beams' span was 4800 mm, equal to the length of two Pixel Slab modules together. For double beams (laterally adjacent), the distance between their longitudinal axis was 400 mm. Besides, specimens had alternating discontinuous laths to simulate the discontinuity of orthogonally intersecting slabs. Finally, in-plane and out-of-plane connections were manufactured as per the specifications listed in Section 3.

Single-layer specimens ("S", "D", and "IP") were tested with a 4-point setup, while double-layer specimens ("OP" and "IPOP") with a 3-point setup. This was done to guarantee a bending failure in double-layer beams and not to reach the max shear strength. All tests used a 200 kN hydraulic jack fixed to a steel reaction frame and a loading beam was used to transfer the load from the jack to the specimens at the application points. For the 4-point setup, point loads were applied at 1800 mm from the beam ends.

Table 1. *Labelling and description of tested specimens.*

Test ID	Configuration	Description
S		Traditional GLT beam (×3).
D		Double beam with discontinuities (×4).
IP		Two discontinuous double-beams with in-plane connectors (×3).
OP(a)		Two stacked discontinuous double-beams with 11 out-of-plane connectors (×2).
OP(b)		Two stacked discontinuous double-beams with 6 out-of-plane connectors (×1).
OP(c)		Two stacked discontinuous double-beams with 90º and 45º screws (×1).
IPOP(a)		Two stacked discontinuous double-beams with in-plane and out-of-plane connectors (×4).
IPOP(b)		Two stacked discontinuous double beams only with in-plane connectors (×1).

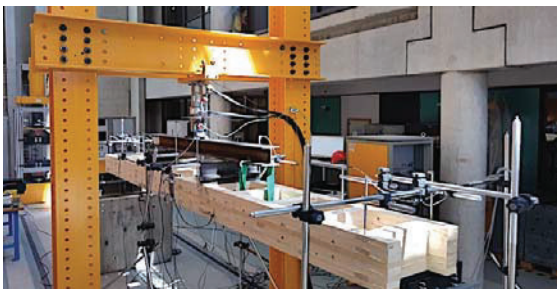

Figure 4. *Testing setup for "D" specimens.*

Specimens were installed on top of steel bearings and support beams placed 200 mm from the ends to allow free rotation under bending deformation. Displacement transducers (LVDTs) were installed to measure mid-span displacements, settlements at supports, slip between steel plates, and relative displacements between two stacked beams. Tests were conducted by applying load until the specimen's failure, defined as a 20% drop from the maximum recorded load. Figure 5 shows the force-displacement results for all "D" beams.

Test results showed that, when compared to traditional GLT specimens, beams with discontinuities had a reduction in the maximum moment M_{max} and elastic stiffness EI of 58.9% and 40%, respectively. This is mainly due to the presence of discontinuities along the longitudinal direction of the beam, which does not allow exploitation of the full cross-section and forces the continuous laths to take most of the tensile and compression stresses. Besides, the use of in-plane connections proved to be an efficient solution to join two GLT beams along their longitudinal axis, properly transferring axial, shear, and bending loads between the members. In this sense, employing glued-in rods showed to have a reinforcement effect on the capacity of the specimens, increasing the maximum moment M_{max} and elastic stiffness EI by 13.67% and 10.56%, respectively.

Finally, it was found that conventional beam design equations can be used to estimate the strength and stiffness of discontinuous GLT beams. To do so, the negative effects of the discontinuities can be considered as a reduction of the beam height, since fewer laths contribute to its capacity. To compute the maximum moment M_{max}, a reduced height h_{red} = 0.6×h was found to be consistent with the lab results. To estimate the stiffness EI, a reduced height h_{red} = 0.75×h is recommended.

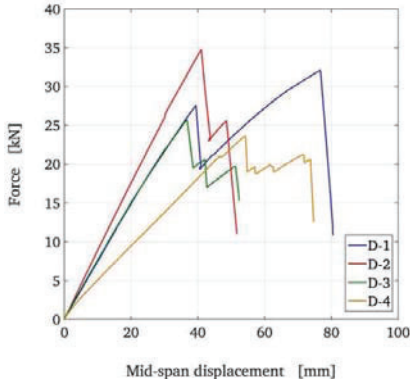

Figure 5. *Force-displacements data for "D" specimens.*

5 CHALLENGES AND FUTURE WORK

As part of the development of the Pixel Slab system, a full-scale prototype was manufactured following the specifications outlined in previous sections, as show in Figure 6. After conducting a set of detailed evaluations, results showed that the manufacturing processes do not require specialized knowledge and can be performed by traditional companies and assembly lines. However, more development is needed to further reduce the manufacturing costs of the connections and/or their quantity per linear meter of interface.

Additionally, the results confirmed that the construction and deconstruction process is straightforward and does not require particularly trained workers or special tools, making it well-suited for prefabrication and dry procedures. Yet, it highlighted the relevance of paying close attention to dimensional tolerances to prevent deformation of components due to manufacturing imperfections, thermal effects, and creep or shrinkage.

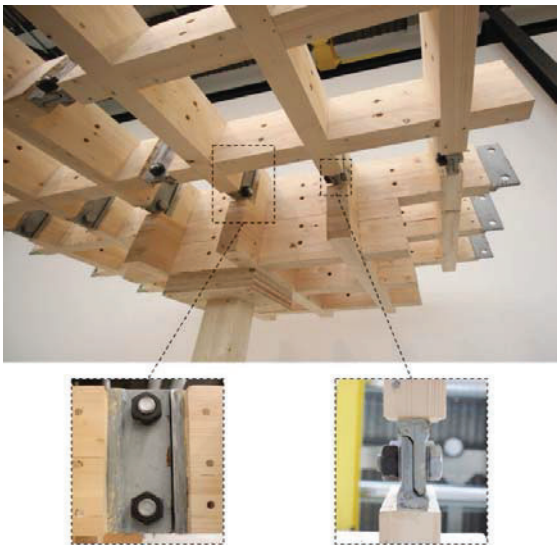

Figure 6. *Full-scale prototype of the Pixel Slab solution and connection details between beams.*

On the other hand, it is important to note that the full environmental benefits of the Pixel Slab system may only be realized over the long term. As part of the present research project, a preliminary life cycle analysis (LCA) was performed to compare the Pixel Slab system with a typical reinforced concrete system. The outcome of the analysis revealed that if only a single building lifespan is taken into account, the Pixel Slab system generates higher levels of emissions compared to the concrete solution. The primary reason for the higher emissions in the Pixel Slab system is the considerable amount of steel connections involved in the reusable solution. The production of steel accounts for a substantial portion of the total CO2 emissions. Nevertheless, when multiple lifespans are considered, the environmental impact per cycle of the Pixel Slab system decreases, and it becomes significantly lower than that of conventional systems. For instance, in a scenario with four lifespans, the emissions from the concrete system were ~80% higher compared to those generated by the Pixel Slab system. These results suggests that a potential entry market for the Pixel Slab are short lifespan buildings such as temporary classrooms or offices for ephemeral cultural or sport events.

These findings emphasize the potential of the Pixel Slab to decrease the carbon footprint in the construction sector. However, prior studies have highlighted that the emissions resulting from the disassembly and transportation of recovered components might have negative impacts on the environmental footprint [12–14]. This latter is largely due to the prominent levels of greenhouse gases associated with longer demolition periods, the use of heavy machinery, and the long-distance transportation of components (>1000 km) [12]. Further research is necessary to examine the relationship between these implications and the emission savings achieved through reuse, reduced landfilling and recycling, and lower production of new components.

6 CONCLUSIONS

This paper presents a new load-bearing timber system (Pixel Slab) designed for deconstruction and reuse over multiple building lifespans. The Pixel Slab system offers an alternative timber structural system for buildings designed for assembly and deconstruction by employing reversible connections and standardized components, with the main goal of increasing the open-ended reuse potential of building elements. In this sense, the proposed system incorporates a modular nature that provides constructors with an adaptable design framework with respect to floor geometries, spans, load conditions, and component distribution, making room for a diverse range of realistic solutions regarding architecture and engineering. Widespread implementation of the proposed solution is expected to support reducing global warming levels, resource depletion, and waste generation caused by the construction industry. The main features of the proposed system can be summarized as follows:

- The system is reversible and can be easily disassembled without damage to its components.
- The system is transformable into diverse floor plans and layouts since the columns' placement is highly flexible and slabs' thickness is reconfigurable.
- The system is adaptable and allows parallel assembly and disassembly, i.e., slab modules and tiles can be installed, removed, or replaced without disturbing adjacent components.
- The system allows full integration with non-structural components and sub-systems.
- No high-tech procedures and tools are required for the assembly and disassembly of the system and common equipment can be employed.
- Handling, storage, and transportation of components are facilitated due to compact dimensions.
- The construction process is dry and produces no waste on-site.

Future research is needed to propose standard procedures to estimate the residual properties of demountable elements and the environmental impacts of deconstruction and transportation related to disassembly and reuse. Likewise, further policy work that encourages reuse is still deemed necessary to boost reuse in the upcoming years.

ENGINEERED WOOD PRODUCTS MANUFACTURED FROM RECLAIMED HARDWOOD TIMBER

Daniel F. Llana[1], Violeta González-Alegre[2], María Portela[3], Justo García-Navarro[4], Guillermo Íñiguez-González[5]

ABSTRACT: The circular economy is commonly applied in recent years in order to reduce the amount of wood waste with many environmental benefits. The construction and demolition sector generates a large amount of wood waste that can be potentially reused or recycled into different wood-added-value products. The InFutUReWood and the RECOWERS European projects deal with reusing and recycling recovered timber as a structural material. One of the potential applications of recovered wood from construction and demolition sources is in manufacturing Engineered Wood Products (EWP). Twelve Cross Laminated Timber (CLT) panels and twelve glued-laminated timber (glulam) pieces from European oak were manufactured and tested in the present work. Four different 3-layer CLT panel configurations and two different 5-lamella glulam pieces configurations were manufactured using recovered and new European oak timber. The results show that there is significant potential in using recovered timber for manufacturing EWP. The modulus of elasticity of CLT panels and glulam pieces from recovered and new timber is similar while bending strength is lower in the case of EWP from recovered timber than from new timber, but still enough high for structural applications. The timber yield producing EWP from recovered timber is really low due to the great amount of wood waste generated during manufacturing.

KEYWORDS: cascading, circular economy, mass timber products, recovered, recycling, salvaged, secondary timber

1 INTRODUCTION

The circular economy is a new production model to reduce the amount of waste by reusing it or recycling it as added-value products, reducing the consumption of raw materials. The long-term carbon sequestration stored in timber constructions and the reuse of building materials contributes to the mitigation of climate change. Furthermore, the increase in timber demand for construction purposes in Europe will lead to a lack of enough new timber resources. Therefore, improvement of the circular economy model in the timber sector is absolutely recommended.

Several European projects dealt with this topic in recent years. The CaReWood project (2014-2017) [1] focused on the potential recycling of recovered timber in glued laminated products in order to replace sawn timber for different applications (furniture, window frames, mouldings and fittings). However, no promising results were found for structural applications in load-bearing construction elements, due to wood waste usually comes from different mix species, which it would be difficult and expensive to identify and classify [2].

InFutUReWood was a 3-year European project (2019-2022) that focused on design for deconstruction of timber structures; enhance the current demolition techniques to maximize the amount of recovered timber and recycling of current recovered wood as structural material in different mass timber products [3].

RECOWERS is a 2-year Marie Skłodowska-Curie Actions (MSCA) European project (2022-2023) that focuses on grading recovered timber from demolition for structural purposes [4]. There is a lack of a reliable classification or grading system that estimates the properties of recovered timber in order to reuse it for structural applications.

The construction and demolition sector creates a large amount of wood waste, much of which is nowadays used for energy recovery and panel manufacture [5, 6]. In the case of Spain, recovered wood is usually used in the form of chips for energy production and manufacturing particleboards [7]. Much of that wood waste has the quality to reuse or recycle in added-value structural products. Potential end-use structural possibilities include high-quality Engineered Wood Products (EWP) such as glued-laminated timber (glulam), solid wood panels, and Cross Laminated Timber (CLT) [8]. Previous tests on CLT from recovered mixed softwood timbers showed higher stiffness capacity and lower strength than CLT from new sawn softwood timber [9]. However, this was based on a limited number of tests.

The main objective of this paper is to compare the mechanical properties of CLT panels and glulam pieces manufactured from recovered European oak timber with CLT panels and glulam pieces manufactured from new sawn European oak timber.

2 MATERIALS AND METHODS

2.1 MATERIALS

From large cross-section (145 by 165 mm^2) European oak (*Quercus robur* L.) pieces recovered from a demolition of a 150-year-old house (Figure 1), recovered timber boards were sawn to a cross-section of 25 by 108 mm^2 (Figure 2).

***Figure 1**: Recovered timber pieces*

***Figure 2**: Recovered sawn timber boards*

Planed boards of final cross-section 20 by 100 mm^2 and variable-length from recovered and new European oak timber were used to manufacture CLT panels and glulam pieces. A total of twelve 3-layer (two external longitudinal layers and one internal cross-layer) CLT panels were manufactured. Three CLT panels were manufactured from recovered sawn timber, other three using recovered timber only in the longitudinal layers and new timber in the cross-layer, other three using recovered timber only in the cross-layer and new timber in the longitudinal layers and finally three more panels from new timber. Twelve 5-lamella glulam pieces were manufactured; six using recovered timber and six more using new timber. The number of CLT panels and glulam pieces, kind of timber and dimensions are shown in Table 1.

***Table 1:** CLT 3-layer panels and 5-lamella glulam pieces characteristics*

CLT panels					
No.	Kind of timber		Dimensions (mm)		
	Long. layers	Cross layer	Length	Width	Thickness *layer
3	R	R	1800	300	20*3
3	R	N	1800	300	20*3
3	N	R	1800	300	20*3
3	N	N	1800	300	20*3

Glulam pieces				
No.	Kind of timber	Dimensions (mm)		
	Lamellae	Length	Width	Thickness *layer
6	R	1900	100	20*5
6	N	1900	100	20*5

R: recovered timber
N: new timber
Moisture content: circa 15%

2.2 METHODS

Recovered and new timber European oak boards were planed until a final cross-section 20 by 100 mm^2 giving an aspect of ratio of 5. According to European standard EN16351 [10] when the board-dimension ratio is higher than 4, the bending test on CLT panels can be carried out over a span of 18 times the panel thickness. However, in order to avoid rolling shear, four-point bending test over a span of 24 times the thickness was conducted. In case of glulam pieces four-point bending test over a span of 18 times was carried out according to EN408 [11]. The test arrangement for CLT panels is shown in Figure 3 and for glulam pieces in Figure 4.

https://doi.org/10.52202/069179-0468

***Figure 3**: Four-point bending test set-up on a 3-layer CLT panel according to the standard EN16351.*

***Figure 4**: Four-point bending test set-up on a 5-lamella glulam beam according to the standard EN408.*

Density and Moisture Content (MC) were determined after mechanical testing from a slice. Density as mass by volume and MC according to EN13183-1 [12]

3 RESULTS

***Table 2:** Mechanical properties of CLT 3-layer panels and 5-lamella glulam pieces*

CLT panels						
Kind	MOEglo12		MOR		DEN12	
	Mean N/mm^2	CoV %	Mean N/mm^2	CoV %	Mean kg/m^3	CoV %
RRR	12106	4.95	44.74	20.02	769	3.06
RNR	11989	1.54	46.49	7.23	768	2.09
NRN	11180	6.72	72.80	2.60	761	2.48
NNN	11707	3.18	74.01	3.11	730	2.58

Glulam pieces						
Kind	MOEglo12		MOR		DEN12	
	Mean N/mm^2	CoV %	Mean N/mm^2	CoV %	Mean kg/m^3	CoV %
R	11175	7.00	38.11	15.76	770	4.59
N	11777	8.36	73.51	17.61	713	3.40

R: recovered timber
N: new timber
MC: circa 15%

Table 2 shows the results of static modulus of elasticity (MOEglo12), bending strength (MOR) and density (DEN12) obtained by mechanical testing adjusted to 12% MC according to EN 384 [13] of CLT panels and glulam pieces by the kind of timber (recovered and new) used for manufacturing.

Due to the small number of specimens, it was not possible to determine the 5º percentile of MOR and density. The lowest value of MOR was 35.81 N/mm^2 in the case of CLT panels and 31.87 N/mm^2 in the case of glulam pieces. The lowest value of density was 709 kg/m^3 in the case of CLT panels and 677 kg/m^3 in the case of glulam pieces.

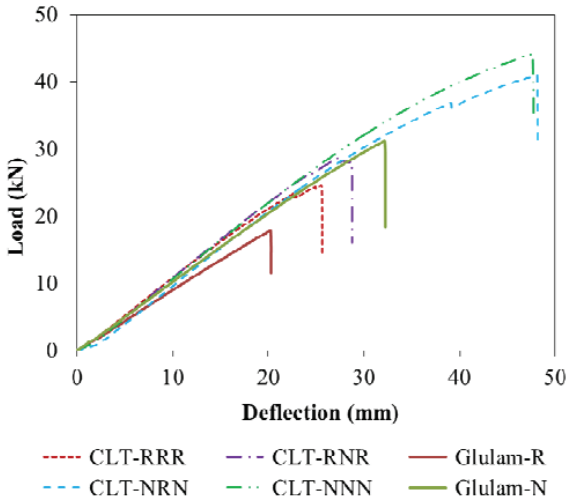

***Figure 5**: Load-deformation response in CLT panels and glulam pieces according their timber configuration (R recovered, N new timber).*

Fig. 5 shows load-deformation graphics for the four configurations of CLT panels and the two configurations of glulam pieces tested. The elastic behaviour was similar in all kind of configurations with recovered or new timber. However, the final load is higher by far in the case of CLT manufactured using new timber in the longitudinal layers (NRN and NNN) than those using recovered timber in the longitudinal layers (RRR and RNR) and also in the case of glulam pieces manufactured with new timber (N) is higher than those manufactured with recovered timber (R). In the case of CLT panels, it looks like that the material used in the cross-layer is not affecting the MOR values as was also reported by another author testing CLT from recovered timber [14].

https://doi.org/10.52202/069179-0468

***Figure 6**: CLT panel failure in tension*

Qualitative analysis of rupture sections was carried out after mechanical tests. All of the CLT panels and glulam pieces tested broke by wood failure in the tension face and the central third (between the two point loads), as shown in Figures 4 and 6. No failure differences were visually detected among CLT panels and glulam pieces manufactured with recovered and new timber. Other failures for example by rolling shear or glue-line were not reported.

In order to determine if there are statistically significant differences among the values of MOE and MOR obtained in the mechanical testing of different configurations of CLT panels and glulam pieces, ANOVA tests were carried out at a 95% of confidence interval (Figures 7 and 8).

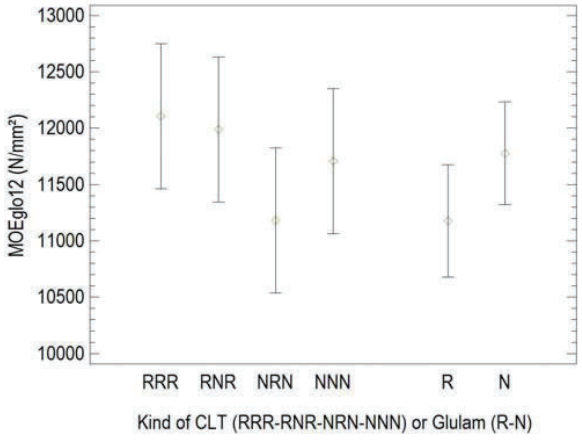

***Figure 7**: MOEglo12 ANOVA mean test for CLT panels and glulam pieces*

In the case of MOE (Figure 7), statistically non-significant differences were found at a 95% confidence interval among different kinds of CLT panels and glulam pieces timber configurations. The MOE of EWP manufactured with recovered European oak timber is not higher or lower than the MOE of EWP manufactured with new European oak timber.

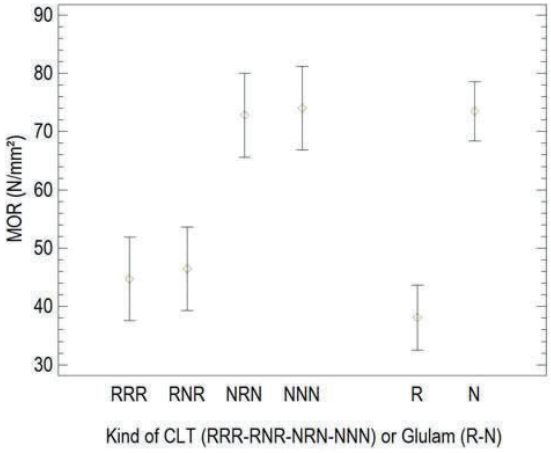

***Figure 8**: MOR ANOVA mean test for CLT panels and glulam pieces*

In the case of MOR (Figure 8), statistically significant differences were found at a 95% confidence interval between CLT panels manufactured using recovered timber in the longitudinal layers (RRR, RNR) and using new timber in the longitudinal layers (NRN, NNN), and also between glulam pieces manufactured from recovered timber (R) and from new timber (N). The MOR of EWP manufactured with recovered European oak timber is further lower than the MOR of EWP manufactured with new European oak timber.

In previous studies testing recovered solid-sawn timber was reported that MOE is not changing over time, while MOR is lower over time in softwoods and hardwoods species [15-17]. Some authors explained this MOR reduction due to the load history [18], others by the nails and holes present in old timber [16], others by the increase of brittleness in old wood [19] and others by the quality of the original timber [17]. Probably the reason will be a mix of all these explanations.

Regarding other authors testing EWP manufactured from recovered timber, Rose et al. [9] reported higher MOE and lower MOR in the case of CLT panels manufactured from a mix of recovered softwood timber species, while Arbelaez et al. [20] reported the same MOE but lower MOR testing CLT panels manufactured with recovered Douglas-fir timber.

Considering the reduction of the MOR in the case of recovered timber and checking the values obtained in the present study, the minimum values of MOR achieved, 35.81 N/mm^2 in the case of CLT panels and 31.87 N/mm^2 in the case of glulam pieces, are still enough for manufacturing EWP from recovered timber for structural purposes.

Regarding the timber yield of manufacturing EWP with recovered timber, the yield was really low. When boards were sawn from original recovered pieces, a great amount of sawdust is produced and most of the external parts of the pieces are not suitable for EWP because are

https://doi.org/10.52202/069179-0468

twisted or containing nails. Furthermore, some parts like holes or big cracks should be removed from the boards after sawing. Finally, boards should be planed to the final dimension not more than 24 hours before bonding. In the present study the final yield was around 13% because the original recovered timber was large cross-section. Other authors using as recovered timber medium size cross-sections obtained better yields. In the case of Irle et al. [2] manufacturing glue laminated products the yield obtained was around 30%. In the case of the InFutUReWood project manufacturing CLT panels in Ireland was around 28% [21]. In both cases the yield was approximately double than in the present study. That means that in the timber yield there is a great influence of the dimensions and condition of the recovered timber using for manufacturing EWP.

4 CONCLUSIONS

The results from the testing indicate the capability of the recovered timber from demolition sources to be used for the manufacturing Engineering Wood Products (EWP) in the present study Cross-Laminated Timber (CLT) panels and glued-laminated timber (glulam) pieces.

Four-point bending tests showed no significant differences between modulus of elasticity obtained in CLT panels and glulam pieces manufactured from recovered and new timber. While, bending strength was far higher in new than in recovered timber in CLT panels and glulam pieces. In the case of CLT panels only the kind of timber (recovered or new) used in the longitudinal layers is determining the differences in bending strength values.

In spite of bending strength values in CLT panels and glulam pieces manufactured from recovered timber are lower than in the case of new timber, these values are still high enough for structural applications of the manufactured EWP.

Recycling recovered timber in EWP produce a low timber yield (around 13% in the present study), with a great amount of wood waste generate during the manufacturing.

REUSE OF LOAD-BEARING TIMBER ELEMENTS – CASE STUDY OF A LOOKOUT TOWER IN LAUSANNE, SWITZERLAND

Jonas Warmuth[1], Xavier Estrella[2], Benoît Kälin[3], Johannes Natterer[4], Corentin Fivet[5]

ABSTRACT: The construction industry is jeopardizing Earth's environment; current mitigation efforts do not suffice; and additional sustainable strategies are required. One such strategy consists of reusing structural building elements over multiple service lives. In this context, this paper introduces a new framework for the design of timber structures made from reused structural elements. Beyond general approaches to reuse structural elements, the proposed framework provides a computational approach that supports architects and engineers in their design and decision making. In this course, optimization techniques such as Best-Fit heuristics are implemented to optimally utilize available stock elements in a new design. The introduced framework is applied to a real-world case study where a lookout tower is designed from timber elements salvaged from a soon-to-be-demolished lookout tower. Results show that a new design that makes optimal use of available stock elements and that meets architectural and statical requirements exists. In the long run, the introduced framework for the reuse of structural elements encourages the design of more sustainable structures with lower environmental impact.

KEYWORDS: Reuse, Structural Design, Computational Design, Life Cycle Assessment, Circular Economy

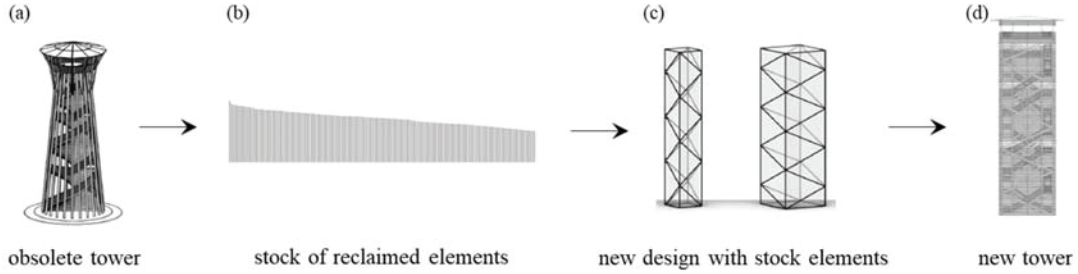

Figure 1. *Conceptual workflow for the design of a new lookout tower made from reused elements*

1 INTRODUCTION

The construction sector is responsible for a significant amount of global greenhouse gas emissions, resource exploitation and waste generation [1]. One way to remediate this detrimental condition and to reduce the environmental impact (EI) of built structures is the introduction of a circular economy and, associated with that, the reuse of structural elements in new structures. Apart from a few unique examples, however, this approach is rather the exception in today's building practice. The reason for this is that the conventional design approach is inverted in the case of reusing structural components, as the synthesis of a structural system (including topology and geometry) must comply with the geometric and static characteristics of the available elements. Consequently, this leads to challenges in everyday construction. One solution to this challenge is the use of computational tools, that make use of algorithmic formulations to assist the design with a fixed inventory of elements. An early computational approach was presented by Fujitani and Fujii [2] who optimized plane frames of fixed topology subject to given elements of known length and cross-section. Brütting et al. [3] presented structural optimization techniques to design truss structures from reused steel elements. Regarding timber, Bukauskas et al. [4] have developed a strategy based on heuristics to form-fit a stock of wood logs to statically-determinate trusses. Amtsberg et al. [5] presented a design-to-fabrication workflow using a geometric matching algorithm that makes best use of available tree forks. Huang et al. [6] employed the Hungarian Algorithm to design wooden geodesic domes from a stock of elements. Moreover, they provide a comparison of different algorithmic formulations for reuse-driven design in computational tools. In previous

work, Warmuth et al. [7] introduced a computational tool subject to support architects and engineers in designing structures with reused elements. This tool was built upon a mixed-integer-linear-programming (MILP) formulation to optimally assign stock elements to a given structure and was later extended by a Best-Fit heuristic to accelerate result generation. Their studies centred around the evaluation of steel and concrete as reusable materials. In this paper, the range of applicability is extended to timber structures, and the computational techniques from [6, 7] are implemented into a novel framework that allows for the design of timber structures made of reused elements in a flexible, interactive, and designer-driven workflow. The extension is demonstrated via a real-world case study, the new design of a lookout tower in Lausanne, Switzerland, made from an already existing tower on-site that became obsolete. Figure 1 shows the conceptual workflow for this: first, structural elements from the obsolete tower (Fig. 1a) are assessed and inventoried into a stock of elements (Fig. 1b). Then, a new design is developed based on the characteristics of the obtained stock (Fig. 1c) that leads finally to a new tower making optimal use of the available elements (Fig.1d). As per previous research on the topic [9, 10], it is expected that this significantly lowers the EI of the tower, the demand for resource mining, and waste production, compared to one built of new elements.

2 REUSE OF TIMBER

The goal in a circular economy is to maintain material, product, and components at their highest value for as long as possible. In case of timber, the amount of CO_2 emitted during combustion is equal to the amount absorbed by the plant during its growth, making timber a useful carbon sink [11]. In addition, reusing timber prevents its decomposition under anaerobic conditions, which would lead to the release of methane and contribute to greenhouse gas emissions [12]. And thanks to dismountable connections, timber structures are generally presenting high potential to be reused. Despite all these valid reasons to reuse timber, component reuse, regardless the material, is not the norm in building practice. The reasons for that are manifold. Conventional demolition processes tend to yield very little reusable material due to the use of heavy machinery. Reclaiming such material implies to process a meticulous disassembling of the structure that, as expected, has an impact on costs. However, Schultmann et al. [13] illustrate that environment-friendly dismantling and reuse strategies can even be advantageous from an economic point of view. In response to demolition costs, reusing timber has very variable cost implications, from cost savings of up to 80% depending on application and quality [14]. To ensure a safe reuse of timber components, their mechanical properties need to be assessed. In addition to natural aging phenomena of wood and duration of load, the presence of mechanical damage and biological attack must be considered. Although researchers seem to agree that aging has no, or only marginally, effects on bending capacities, the duration and intensity of the applied load have a direct effect on the material properties [15] and are known to cause strength reductions on a logarithmic scale [16]. The direction of loading should also be considered when assessing the remaining mechanical properties of reclaimed timber. Nevertheless, laboratory tests by Brol et al. [17] on 130 year old timber elements indicate that elements which worked as beams for many years can still be integrated in new structures as elements with axial loading. Moreover, Davis [18] states that timber is resilient over time and maintains much of its original capacities despite the effect of moisture, loading, temperature, and weathering [18]. And still, despite all these promising indicators to reuse timber, this strategy is rarely pursued today, albeit this was not always the case in the past. Küpfer & Fivet [19] state that dismantling timber structures and reusing their components were common practice before the Industrial Revolution. But due to new means of production and transportation, the common reuse and valorisation techniques were progressively abandoned. An example on how timber was reused in the past is shown in Figure 2.

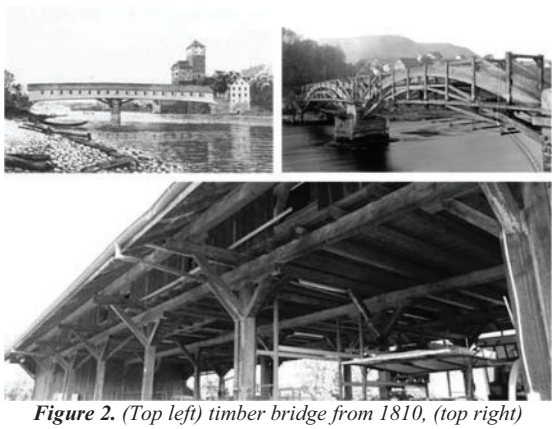

Figure 2. *(Top left) timber bridge from 1810, (top right) deconstruction in 1919, (bottom) new barn built in 1920 and still in use*

On the top left, a bridge can be observed that was built in 1810 in Eglisau at the German Swiss border to cross the river Rhine. After more than 100 years in service, it was decided to deconstruct it in 1919 due to a water level elevation of the river. Instead of landfilling its components after deconstruction, a new barn in Rheinhau, Switzerland, was built in 1920 from components of the deconstructed timber bridge. The barn is still in use and in good condition. The building is more than 100 years old but made from oak and spruce components that are over 200 years old. This simple illustration effectively demonstrates the mentality necessary for material-caring building practices.

3 DESIGN METHODOLOGY

The main objectives of this paper are (1) to introduce a new design framework and (2) to develop a case study i.e., the design of a load-bearing structure for a timber lookout

https://doi.org/10.52202/069179-0469

tower made of reclaimed elements. Again, it should be noted that the design of structures with reused elements from an available stock inverts the conventional design process. Typically, the structural layout determines the required elements to be manufactured. Instead, the design of structures through reuse describes the inverse: structure topology and geometry must be designed to make the best use of available stock elements. To achieve this goal, the workflow shown in Figure 3 is employed.

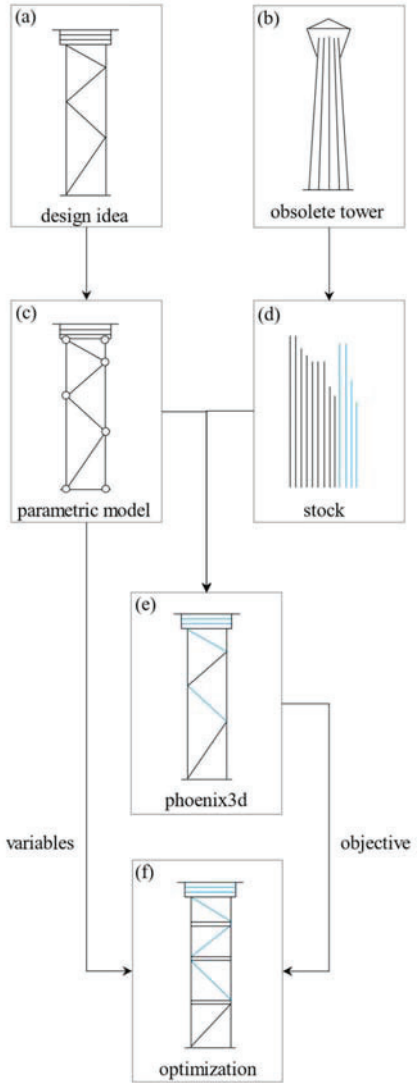

Figure 3. *Workflow of the introduced framework with new elements (blue) and reused elements (black)*

First, an initial design idea is conceptualised either by a hand sketch or a digital drawing (Fig. 3a). Based on this, a parametrized design model is created (Fig. 3c). In parallel, the source material from the obsolete tower (Fig. 3b) is identified and assessed. Once assessed, the stock of reused and new elements can be inventoried (Fig. 3d) where reused elements come from the obsolete tower and new elements are assumed to be available from new production. Assigning available stock elements to the parametric model such that the stock is utilized optimally is a time-consuming task when done by hand. Therefore, the computational tool Phoenix3D (P3D) [20] is assigned this process (Fig. 3e). P3D takes both the stock and parametric model as an input and returns the model with optimally assigned stock elements subject to minimize upfront global warming potential of the structure manufacturing. Finally, a global optimization process (Fig. 3f) modifies the set of variables of the parametric model such that the configuration with the least EI is found. More details of each step are given in the following sections.

3.1 PARAMETRIC MODEL AND STOCK IDENTIFICATION

The computer aided design software Rhino3D [21] is used to set up the parametric model. Included in Rhino3D is the visual programming plugin Grasshopper that takes care of the parametrization of the design idea. This allows a fast alteration of the design idea. Before setting up the parametric model, some constraints for the design have to be taken into account. For reasons of rationality, it was decided to allow only rectangular geometries. Moreover, the loadbearing structure is considered to be made of two sub-structures: an inner and outer truss. Furthermore, a tower height of at least 30 m is chosen to ensure a 360° panorama view, since the trees surrounding the tower have approximately this height. Within these constraints, the model can be created.

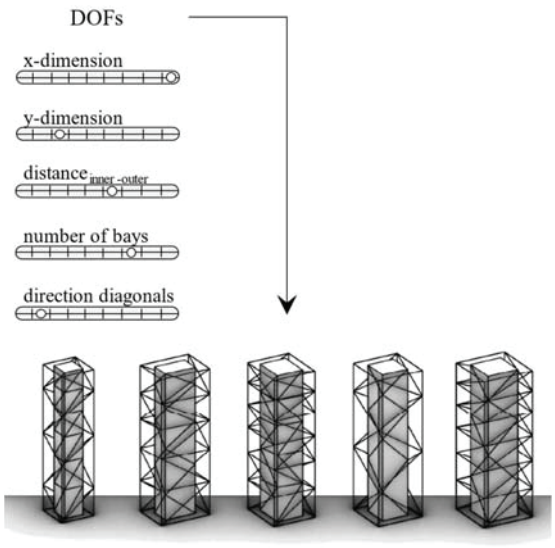

Figure 4. *Various tower configurations within the parametrization*

When setting up a parametric model, parameters, so called degrees of freedom (DOFs), have to be chosen. Ideally, the quantity of DOFs should be controlled in such a manner as to avoid losing control of the model, yet still allow for sufficient modification. The degrees of freedom

chosen in this case study are shown in Figure 4 and consist of the x- and y-dimension, the distance between inner and outer truss, the number of bays, and the direction of diagonals. In order to reuse structural elements and to employ P3D, a stock needs to be set up. This stock contains both reusable elements that were sourced from the obsolete tower (discussed specifically in Section 4.3) and elements that were newly produced. Reused elements have to be assessed for their mechanical and geometric properties. To retain the degree of complexity in this investigation, it is assumed that all available new elements are of same cross-section as available reused elements. Moreover, for new elements, only mechanical properties are taken into account because they can be provided in customized lengths.

3.2 STOCK ASSIGNMENT BY PHOENIX3D

The assignment of stock elements to the design model is here described as a discrete optimization problem and is carried out by P3D. P3D is an open-source tool to design optimum truss structures made from a stock of new and reused elements. It is implemented by the authors based on previous research in the field [8]. The core of P3D is moulded by two optimization algorithms: (1) a MILP formulation that delivers globally optimal results but is computationally expensive, and (2) a Best-Fit heuristic combined with a finite element analysis (FEA) of first order that delivers just close-to-optimal results but in real-time and with low computational costs. The objective function is to minimize EI which is computed by a Life-Cycle-Assessment (LCA). Details for the implementation of the optimization algorithms as well as the LCA can be found in [6, 19]. Figure 5 shows the workflow of the tool.

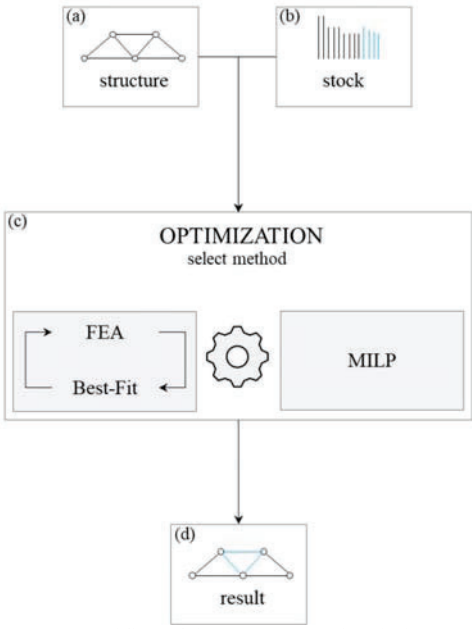

Figure 5. *Workflow of the computational tool Phoenix3D*

An initial intended structure serves as input (Fig. 5a) to which reusable stock elements are assigned as well as newly-manufactured elements (Fig. 5b). Subsequently, users can select which of the two optimization algorithms should be utilized to optimally assign the stock elements to the structure (Fig. 5c). As an output, the structure with the assigned stock elements is displayed (Fig. 5d) including statistics about the run optimization. Among these are the EI in [kgCO_2eq] and the percentage of reused and new elements in the structure, which will be used in Section 4 to assess the case study.

3.3 DESIGN OPTIMIZATION

Although P3D already optimally assigns stock elements to a given structure, the structure geometry itself can be modified as well to better fit to available stock elements. Thanks to the parametric implementation of the model, this can also be described as an optimization problem where the parameters of the model are serving as design variables and the computation of EI in P3D serves as an objective function (see Fig. 3). The tool used for this optimization is Wallacei [22], an evolutionary optimization and analytic engine for Grasshopper. Besides the objective of minimizing the EI, there are other factors that need to be taken into account. One is to utilize the available stock elements from the obsolete tower as much as possible because they would become waste otherwise. Another constraint considers aesthetic aspects of the design, which are evaluated by the designer. The compliance of these constraints is evaluated by the designer and therefore not subject of the optimization process. This means, however, that several iterations are necessary to end up at the final solution.

4 RESULTS: DESIGN OF THE SAUVABELIN TOWER IN LAUSANNE

In the following, results for a new design of the Sauvabelin lookout tower in Lausanne, Switzerland, are explained using the methods described in Section 3. Figure 6 shows the 20-year-old tower, now obsolete and in need of replacement.

Figure 6. *The Sauvabelin tower, October 2021*

For the case study, only the structural system is taken into account. However, it is aimed to apply common rules of

https://doi.org/10.52202/069179-0469

best practice for timber structures. This includes the protection of exposed elements from weather as well as homogeneous connection designs for constructive and economic reasons.

4.1 INTRODUCTION TO THE SAUVABELIN TOWER

In order to produce a viable project that addresses structural, architectural, societal, and environmental considerations, it is crucial to understand the importance of the existing tower. The Sauvabelin lookout tower was constructed in 2003 and since then has become a renowned landmark in the city of Lausanne located on the shores of Lake Geneva. Figure 7 depicts the tower during its construction phase. The overall concept encompasses a spiral staircase culminating in a viewing platform at its apex.

Figure 7. *Construction of the tower, 2003*

The Sauvabelin Tower, despite its popularity and emotional resonance among the residents of Lausanne, is slated for demolition due to considerations of safety and economy. The estimated service life was originally predicted to be 20 years. However, this projection of service life does not necessarily equates to the end of its structural components' service life. With proper maintenance and restoration, it is possible to extend the service life of the tower. Thus, between the years 2012 and 2017, the tower underwent maintenance work that involved the replacement of defective components. Figure 8 illustrates the replacement of the stair ends that were weathered.

Figure 8. *replacement of end parts of the stairs*

It is projected that the costs associated with maintaining the structure will continue to rise as the tower ages and reaches its revised estimated service life of 30 years in 2033. However, due to the design of the tower's structure, the maintenance costs would eventually surpass their limits, resulting in the tower's demolition. A potential solution to this scenario is to disassemble the tower now, salvaging its structural components that are still in good condition, and use them to construct a new tower that adheres to construction standards that prevent the elements from causing premature aging.

4.2 EXPLANATION OF AVAILABLE STOCK ELEMENTS

The stock of salvaged elements for this case study involves an evaluation of the current state of all structural components of the existing tower. The evaluation of the structural elements was conducted in September 2021 and was based on a visual inspection of the tower as well as information obtained from the original construction plans. As illustrated in Figure 9, the tower can be segmented into four categories of structural elements: the stairs, poles, stands, and roof. Each category is subjected to an individualized evaluation to determine its viability for reuse.

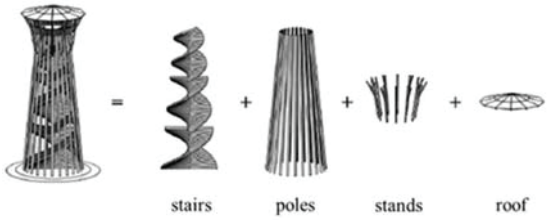

Figure 9. *Composition of the Sauvabelin tower*

The composition of the tower is comprised of 214 m^3 of timber, of which 141 m^3 are Douglas Fir and 73 m^3 are Spruce, sourced from nearby forests. The exact metrics can be viewed in Table 1.

Table 1. *tower composition*

	Stairs	Poles	Stands
Species	Douglas fir	spruce	Spruce
Amount	151	24	24
Cross-section	20/40cm	20/20cm	20/20cm
Length	6.0-12.0m	34.0m	8.0m

The tower's staircase comprises 151 steps, which range from 6.0 m to 12.0 m, with a linear distribution in between, and have been assigned a grade of C24 based on the Swiss construction code. It was found that, due to the maintenance work from 2012 – 2017, all steps can be reused, albeit in a different static configuration. As previously mentioned, research conducted by Brol et al. [17] has shown that reused timber elements can withstand a change in the direction of applied loading from bending to axial stress, which would apply to the proposed truss system in this case study. The tower features 24 poles forming its outer finish, however, due to their exposition and the presence of numerous metal connections that weaken their cross-section, these elements have been excluded from this study. The roof, which has a diameter

of 13.0 m and is comprised of elements with varying lengths and cross-sections, is in good condition and could be reused in its entirety. For the sake of simplicity and consistency, the decision was made to reuse only the staircase elements, which is the reason why the stands are also excluded, although they are in good condition and could potentially be reused.

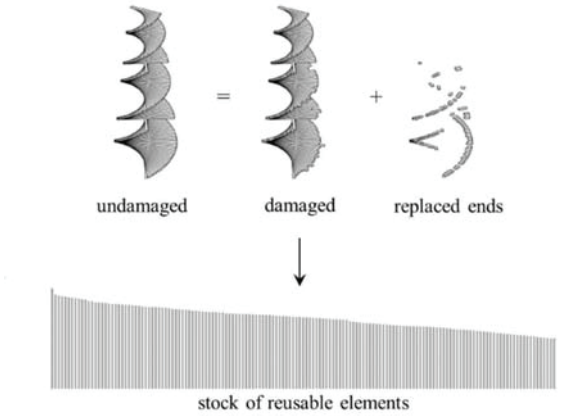

Figure 10. *Extraction of reusable elements from staircase of obsolete tower*

Figure 10 depicts the inventory of refurbished staircase elements that were installed during the previously mentioned maintenance work on the tower. The full stock comprises therefore 151 elements with a cross-section of 20/40 cm and varying lengths between 6.0 m to 12.0 m which results in a total stock mass of 54,319 kg considering a density of 530 kg/m^3.

4.3 DESIGN PROCESS AND FINAL RESULT

As outlined in Section 3, the goal of this case study is to reuse as many stock elements as possible to prevent them from being disposed in a landfill, while keeping the EI low.

Table 2. *results of iterations for tower design*

Iteration [-]	EI [kgCO_2eq]	Reused [kg]	Usage [%]
0	14,521	29,177	54
1	15,127	30,648	56
2	14,994	29,993	55
3	14,365	29,187	54
4	14,349	29,201	54
5	15,055	29,679	55
6	14,346	20,193	54
7	19,813	40,370	74
8	21,842	44,782	82
9	22,137	44,771	82
10	22,061	44,781	82
11	24,889	51,164	94
12	30,505	52,373	96
13	**24,564**	**49,504**	**91**
newly made	44,452	0	0

Although minimizing EI is a factor in the design process, it is not the only deciding one, i.e., designs with higher EI than other solutions may still be selected as the final design, as long as the EI is lower than a comparable tower made entirely of new components. Design decisions must balance construction and economic practicality with the aim of minimizing the EI of the structure, while considering personal design preferences. By employing the methods explained in Section 3, numerous suitable designs were found. The chosen designs were selected based on the designer's preferences and are listed in Table 2, including their EI in kgCO_2eq, weight of reused elements in kg, and the percentage of utilized stock elements. This usage is calculated by dividing the reused elements in kg by the total amount of reusable elements in kg, with the assumption that the difference is discarded and therefore waste. In Figure 11, the selected designs are represented on a graph, with the EI of the design shown on the vertical axis and the utilization of the stock on the horizontal axis. This visual representation shows that the optimal designs are located in the bottom right corner of the graph, where both a low EI and a high utilization of the stock elements are achieved.

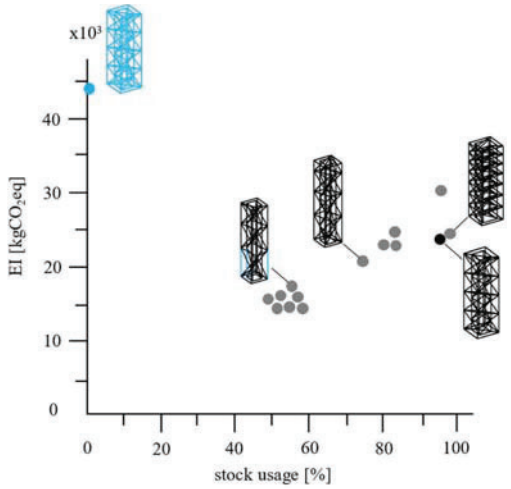

Figure 11. *Design iterations; black dot indicates final design, blue dot indicates final design made of entirely new elements*

After evaluating numerous designs through the optimization process described in Chapter 3, iteration 13 was determined to be the most suitable as the final design. This decision was made due to the high usage of old elements, corresponding to 91%. Furthermore, the design boasts a relatively low EI of 24,565 kgCO_2eq. Additionally, the design satisfied the aesthetic preferences of the designer. To validate this selection, in iteration 14, the EI of the final design was computed again, with the assumption that it was constructed solely using new elements. The results show an EI of 44,452 kgCO_2eq, indicating that the chosen design has a 45% lower EI compared to a comparable tower built entirely from new elements. The findings in Figure 11 also suggest a linear correlation between the EI and the stock elements used. This is likely due to the fact that only a few designs used

https://doi.org/10.52202/069179-0469

newly manufactured elements and were constructed almost exclusively with reused elements, resulting in a linear calculation of their EI through the corresponding LCA. Figure 12 presents renderings of the selected design to provide an understanding of how the new tower interacts with its environment. In addition to the outcome from iteration 13 shown in Table 2, a roof and cladding were added to protect the structural components from the weather.

Figure 12. *Renderings of the newly designed tower made of structural elements from the obsolete tower*

5 CONCLUSIONS

In conclusion, this study presents a novel framework for the design of timber structures from reused structural elements. The framework is validated through a case study of the Sauvabelin lookout tower in Lausanne, Switzerland. In this context, computational tools, such as Phoenix3D, can be employed to optimally utilize available stock elements. Results show that the introduced computational framework enables for the design of a new structures tailored to the available stock elements, i.e., making best use of available reused elements. Moreover, the proposed approach can significantly reduce the environmental impact of the new tower, with a reduction of 45% compared to a similar tower constructed entirely from new elements. The adoption of this framework has the potential to enhance sustainability in the construction sector and move towards a more circular economy.

VALUES OF RECLAIMED TIMBER

Maxence Lebossé[1], Franck Besançon[2], Gilles Halin[3], Alain Fuchs[4]

ABSTRACT: France's current 'wood wastes' management seems inefficient in settling on a durable reclaimed timber branch that would support reuse practices in architecture. We assume that there is a set of 'values' attached to timber members that should be revealed to estimate their market value better. Through the literature, we observe that the economy of a deconstruction project used to be considered significant, while embodied carbon is nowadays of major concern. Moreover, as Circular Economy and Cascading concept emerged, the meaning of durability has decreased in favour of reversibility that could guarantee a flow of material circulation. The problem is that these ideas involve probable rebound effects due to energy engaged in transportation and the transformation of reclaimed resources. Our reflection comes from a field study experience where we participated in the reuse process of timber members deconstructed from a textile mill. We observed that the lack of economy and the lack of 'values' identification resulted in depreciating the operation's efficiency, whose initial objective was to maximise the extraction and diffusion of reusable elements as much as feasible. Our research focuses on construction materials and massive structural timber members, which still seem challenging to reintegrate into new buildings.

KEYWORDS: Reclaimed Timber, Value, Reuse, Economy, Deconstruction.

1 INTRODUCTION

Since it appears as a solution to mitigate the environmental impacts of the construction sector, 'reuse' tends to become a current practice again [1]. Structural elements, such as timber joists, extracted from existing buildings must be able to respond to the direct competition of new timber products in terms of cost, availability, and traceability. Compared to past centuries, the reuse of reclaimed materials demands more information to fit contemporary norms and laws that rule the construction sector. Consequently, assessment, extraction, refurbishment and reintegration of reclaimed materials, which constitute the reuse process, should be considered interconnected, to ensure an optimised transmission of information and material in parallel between all stakeholders involved.

In France, less than 4% of what is qualified as 'wood wastes' produced by deconstruction and demolition worksites are reused or up-cycled. In contrast, it is estimated that 85% of that annual amount of 'wood wastes' comes from structural elements, including 46% with a section superior to 70x150 mm [2], and that a third are 'cut-to-length' [2]. Thus, let us think: is the supposed high potential of demountability of timber structures enough to make the use of reclaimed timber a current and effective architectural practice? It seems not. We wanted to gather assumptions about reclaimed timber members' values, to enlighten research on the subject. From a reduced perspective, the construction sector is about individuals producing materials that others will buy to construct buildings. Thus, we assume that the reuse process should aim to create 'values' attached to existing timber members, but, through a combination of architectural, technical, social and ecological aspects, not only from an economic perspective.

We observed that 'the economy' (also in the sense of minimising the use of material [3-4]) of deconstruction and reclamation was present in early studies from the 2000s [5-6]. An orientation of research that got sense since Architecture, Economy and Ecology are interdependent, deeply linked by their etymology, *'οἶκος'*, the ancient Greek term [7-8]. In France the construction sector weight (in added value) in 2021 is 5.7% of the Gross Domestic Product, even up to 30% if we enlarge to the industry sector and real estate branches which are also concerned by our habitat management [9]. This shows that the economy of the construction sector is deeply related to social and political aspects. Besides, family structure, population growth and ecological ambitions impact the development of the construction sector [10], and reuse has a role to play in it.

To build this paper we rely on readings based a wide span of texts related to reuse, timber, and sustainability. These different resources help us to analyse our case study, a textile mill deconstruction, in which we focus our attention on the reuse process of timber members.
To introduce our subject, part 2 emphasises that reuse is not an objective in itself but that it is more a solution to overcome a lack of durable uses. In a previous paper [11], we have exposed the fact that we should speak about 'resource' and 'deconstruction', instead of 'waste' and 'demolition'. Since architecture is about communication [12] we should be careful of the meaning of the terms we use. We will follow that idea by questioning concepts of circularity and cascading in part 3. Part 4 presents which 'values' are concerned, before concluding in part 5 in what way prices, market values, and deconstruction costs should be studied to support that subject.

2 SUSTAINABILITY AND DURABILITY

2.1 WHY RECLAIMING TIMBER

In France, two main reasons drive the development of strategies to reuse reclaimed timber. Both have got climate change for trigger. On the one hand, like other countries, France has introduced the obligation to assess the material composition of buildings that owners want to demolish or rehabilitate. Materials must be quantified, qualified and classified according to whether they should be reused, repurposed (up-cycled), recycled (down-cycled), or landfilled [13]. Thus, political decisions aimed to enhance better material sorting during deconstruction. This resulted in the potential availability of timber members that used to be discarded.

On the other hand, it is now commonly known that the construction sector can take advantage of timber construction to store carbon and allow us to build and renovate our dwelt environment in the future [14]. Additionally, climate change has already put and should increase, pressure on forests and thus can create tension around wood resources [15]. Thus, developing strategies to reuse timber could help in the future to be resilient to unexpected climatic events, therefore allowing us to pursue the development of the timber sector while limiting the pressure we put on forest regeneration [16-17]. Timber members susceptible to being deconstructed and stored in the building stock could be seen as a local source of timber, already extracted and manufactured.

2.2 HIERARCHY OF PRACTICES

Following the words of Fivet et al. [18], '*maintain in time an already manufactured capital*', in place, we could say, '*with effect to simultaneously contribute to the natural capital protection and the fulfilling of human capital*' there is a hierarchy, almost a moral one, in the way we now decide to manage our built environment. Preserve it, transform it, or expand it. Climate change effects challenge the construction sector to find ways to reduce its impact on our shared environment while guaranteeing access to comfort. Two interconnected parameters drive the evolution of practices, resource extractions and carbon emissions. The dilemma is that to reduce the energy consumption of already built square metres and future ones, we will need new resources, as the human population grows, and part of the building stock becomes technically obsolete. These resources will need to be as renewable and limited as possible, like the energy used for their extraction, transformation, and implementation. Consequently, following the 9 R's [19] principles, the reuse of construction material is not the priority. To sum up a transposition of that hierarchy of actions could be structured as follows:

- Stop building and preserve uses of existing ones.
- Rehabilitate and develop existing buildings.
- Redesign at different scales (from furniture to urban) with 'Design for…' principles [20-21].
- Use renewable materials that store carbon and emit few to be produced.
- Use fewer materials.
- If Adaptive Reuse is not feasible, reuse existing materials.
- If Reuse is not feasible, Up-cycle, Down-cycle, or Energy Recovery.

2.3 PRECARITY OF REUSE

All those perspectives of actions are part of a vast aim to turn our economic system toward a 'circular' dimension instead of a 'linear' one.

Stop building and preserving the existing as much as technically and economically feasible, by rehabilitation seems to be a robust solution. But adaptive reuse has three primary limits:

- The presence of polluted materials, asbestos, lead or hydrocarbons, can condemn building components to landfills.
- Deterioration of the building due to a lack of maintenance and abandonment can foster demolition or deconstruction instead of adaptive reuse.
- Inadequacy of uses between the existing and the future programme, at different scales, from room to the city block level, can tip the balance in favour of demolition or deconstruction at best.

If they credit the fact that demolition or deconstruction will happen, these three parameters should also warn us on the limits of the 'Urban Mining' concept; pollutions and deteriorations deeply influence sorting towards landfilling, energy recovery, or recycling in best cases.

2.4 REVERSIBILITY LIMITS, THE IKEA ANALOGY

Worldwide, craft timber structures, from Half-timbered houses [22-23] to Minka [24], including Maloca house [25] and their contemporary examples [26], follow a logic of prefabrication that include reuse aptitudes by default. They integrate a dimension of demountability deeply connected with the way wood is transformed into construction material, close to human scale, and assembled with reversible joints. But being made from wood is not a guarantee of reversibility for a building. Although the technicity of certain materials and of building composition has increased, it is not an indefectible sustainability label. The most famous and experienced example of the limits of reversibility is Ikea furniture items. These latter are not renowned for their ability to be disassembled multiple times without losing quality, degrading their structural abilities and their global durability. Even if they can easily be repurposed, transformed or adapted, a loss of pieces and integrity seems inevitable [27-28]. Following the Ikea case study, the material's quality and 'purity' are also part factors potentially condemning furniture pieces after dismantling. The closer a material is to its original form, the more it is reusable or repurposable, and the less it is losing quality or generates loss through time and use. For example, stone blocks, hewn wooden beams or earth are construction materials 'Close to Cradle' that might lose part of their unity but not their absolute integrity. During the documentation of our case study, we observed that the first-floor joists were not linked to the steel beams that support them (see Figure 1. a and 1. b). They were only placed and wedged by a notch cut at their ends. This design facilitates the deconstruction and allows to deconstruct by hand without involving machine assistance. Figure 1.a shows an operator lifting a joist with his right shoulder to 'denotch' it and sliding a wooden wedge between the joist and the steel beam. In Figure 1. b, we can see the second step of joist deconstruction, which consisted in using two ropes attached to

https://doi.org/10.52202/069179-0470

the joist extremity to take it down in two movements. Ikea's furniture reuse problem is not precisely proportional to building scale. Still, some reversible design strategies have weaknesses that we should consider, or at least assume as inevitable losses, such as screws and nails or wooden bars with sections inferior to 5 x 5 cm [29].

Figure 1.a et 1.b: *1.a shows joists 'denotching' from the I-steel beam. 1.b shows the descending of a joist with the rope system.*

3 SEMANTICS OF RECLAIMED TIMBER ECONOMY

3.1 CIRCULARITY AND CIRCULATION

3.1.1 Circularity. Feasible to what extent?

Since the reuse of reclaimed timber is inscribed in the scope of 'Circular Economy', we wanted to explore and precise some aspects of this concept regarding the 'values' we will develop in the following parts. 'Circular Economy' and 'Circularity' concentrate all the attention and seem to crystallise the economic frame of reuse practices [30]. Still, it must be used carefully because they are concepts with multiple interpretations [31-32]. It somehow glorifies an economic system we would like to see happen, but which demands massive socio-economic efforts, or can only stay abstract due to the limits of physics laws.

Even if wood, with other plant-sourced materials, seems to be the best example of an object that starts from a 'point' and could return to this same 'starting point', closing a perfect loop, it never strictly happens in practices. Even if the scenario of wood chips or ashes scattered on top of forest soil is not utopian, it depends on a rigorous protocol [33-34]. Bringing back, after centuries of use, the residues of a joist where the tree was first cut seem complex enough never to happen. Even more if it has been repurposed into furniture, then into particleboard, paper, to be finally burned. The closest architectural demonstration to the circularity concept is the Maloca house [25], which was built, reused, and burned in the same area.

3.1.2 Circulation. A concept that needs delimitation.

Another argument toward precautions with the use of the 'circularity' term is that the complete process briefly described earlier can make us drift from the first objective of sustainability of the circular economy, limiting resource extraction and carbon emission induced by increasing the time of first use. Circularity lets us think that, as we can 'close the loop', we can endlessly extract and operate natural resources. For reclaimed timber, a rebound effect of circularity is depicted by Ghyoot et al. [1] with the example of TerraMai, who collects reclaimed wood from Asia to South America to sell it in the USA. Similar globalised circularity was identified through interviews with carpenters or resellers who mainly bought reclaimed wood from Poland [35]. In addition to the impact of transport, this wood can also be crafted, implying energy consumption. Besides, as Ghyoot et al. exposed it, this migration of resources from developing to developed countries take part to destabilises the socio-economic systems of origins, mainly by depriving the local inhabitants of material resources that would still be useful to them. In those terms, we considered circularity and circular economy as a system in which materials can circulate or move or go through, in the sense of expressing a flow of products through time and space. But even there, the idea of movement keeps ambiguous statutes because movement and transportation imply energy whereas the immobility of things means 'continuity of use', which is less harmful to the environment.

3.2 THE STAIRCASE BEHIND THE CASCADE

3.2.1 Toward the 'tread' extension.

The cascading concept is much more honest on the downgrade aspect of material uses. As Niu et al. [36] propose, cascading is much more complex, suggesting that the materials can go up and down in terms of economic and 'use value'. But cascading keep the metaphor of water flow (waterfall), with water returning to this starting point, still support, like the loop of Circular Economy, an abstracted view of a much more complex system. Speaking of a 'staircase' seems clearer in depicting how we manage wood products through time and 'use value'. Step by step, a cubic metre of wood gets dispersed and disseminated in soil and air through different appropriation processes. At least, the representation of optimal sustainable use of a cubic metre of wood is not to go down the staircase, step after step but to extend as long as feasible the length of the 'tread', seen here as a platform, as figure 2 expresses it.

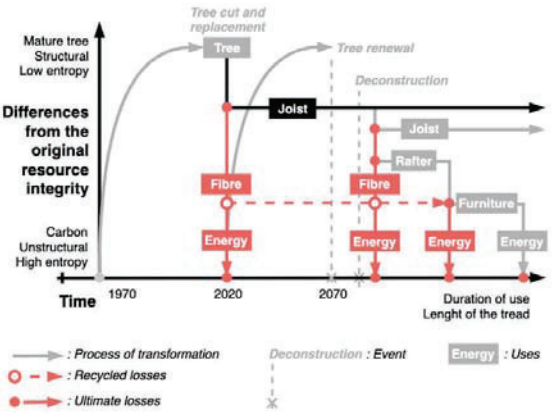

Figure 2: *Diagram of the 'staircase' of timber uses. It shows that the risers, as the steps, should be limited as much as possible, while the treads should be extended as much as possible. The joist black line illustrates the 'platform'.*

https://doi.org/10.52202/069179-0470

3.2.2 Designed to last and limit the entropy.

A sustainable conception of timber construction should find a way to combine all the 'Design for…' approaches [20].
Hazardous and composite materials have created disorders in reappropriating the building stock. Asbestos and lead are the more telling examples. Specifically for wood, treatment has brought more disorders; if we take into account that a better design should consider durability and design strategies not to put the wrong species in the wrong place, or at least to take on a limited lifespan. Glues or too-strong binders are the worst enemies of reuse. An example of this phenomenon is the up-cycling of brick panels in a housing project of 92 flats called Resources Rows, designed by the architecture firm Lendager Group and built in 2020 in Oerestad, Copenhagen [37].
A similar effect can be found in the car industry; where the increased complexity impacts building reliability through time and adaptability [38-39]. This points out the necessity to channel conception toward 'pure' and 'natural' material, closer to their original form when extracted. 'Closer to Cradle' may be better than Cradle to Cradle. Initiatives have taken a pathway in that sense [40-41]. The final challenge is not to see the log house as the best solution but to consider its parameters to integrate it into more creative solutions, such as the 'Breathing wall mass timber research project' supervised in the framework of the Rural Studio, in 2021 [42].

3.2.3 Definitions for wood that goes Up and Down.

A fascinating aspect of wood material is its transformability and appropriability faculties. That specificity opens a broad panel of potential futures for a single piece of timber.
To illustrate our thinking, we will use here the example of a floorboard piece. If reuse is not reached, it can be at best up-cycled or, in most cases, down-cycled. In France, it is estimated that on the annual average amount of wood waste of the construction sector, 48% is energy recovered, 42% is recycled, 7.5% is landfilled, and 2.5% is reused/up-cycled [2]. French legislation (Environment Code, Article L. 541-1-1) differentiates reuse (*réemploi* = re-employed) from up-cycling (*réutilisation* = re-utilisation) and down-cycling (*recyclage* = recycling). See Godina's lexicon [43], which depicts these terms toward 'universal' definitions. We see here how complicated it is to escape from terms that include '-cycling'.

- Reuse/*Réemploi* may not involve a radical transformation of the element, such as cuts. A floorboard must keep its original use, but it could be brushed, planed, varnished, etc.
- Up-cycling/Up-grade/*Réutilisation*, would mean here that our floorboard could becomes something between furniture and glue laminated beams.
- Downcycling/Down-grade/*Recylage* signifies that the floorboard will be crushed and, for example, used for particleboard production. Recycling, unlike Up-cycling, completely make the original timber piece disappear.

3.2.4 Where cascading gets blurred by prices.

Up- and Down-cycling blurs the cascading process. If we look for example at the market value of 1m3 floorboards and transform them into a chair with a similar design, niche products (Scrapwood Oak Chair) are seven times more expensive than mass products (Lisabo); see Figure 3. Mass products chairs keep the same value as a newly produced cubic metre of floorboards for the same volume of wood. On the contrary, based on volume unit, a cubic metre of glue laminated beam is worth less than one transformed into a chair or a cubic metre of reused floorboards.

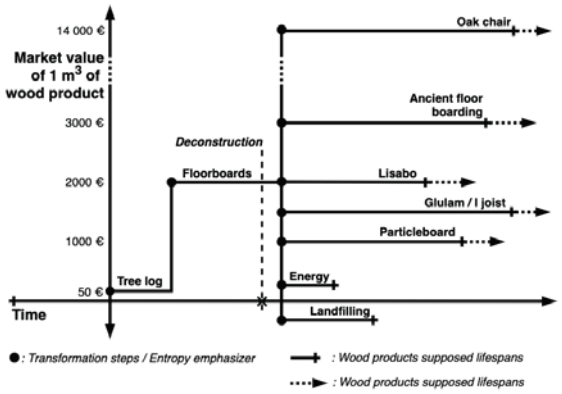

Figure 3: *Diagram of the market value of 1m3 of wood products market after their first use, here as floorboards, and from their original shape as a tree log.*

Consequently, we see that timber elements can go up and down through the 'cascade', see Figure 4, blurring the concept of cascading.

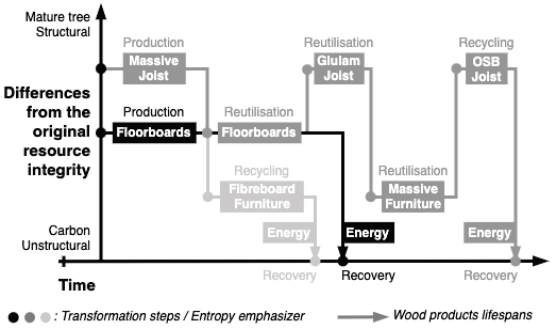

Figure 4: *Diagram of the three main scheme wood products lifespans, black: 'platform', dark grey 'crenel', light grey: 'staircase'.*

Up-cycling can contribute to down-grade the material (cuts, crushes, …) but can increase the value of the same cubic metre of wood. Oriented Strand Board or particleboard down-grade an original joist but can so up-grade if it is turned into an I-joist with panel web ('Steico Joist 45' professional price at a cubic metre, average web-based panel for glulam beam).
Up-cycle can save most wood resources, but not at no cost; material loss must be carefully considered in the transformation process. Student works involved in the research show that an average of 30% of the material will be lost in reappropriating the reclaimed timber. One group had to build furniture out of floorboards, and another a micro-house (4m2) based on a batch of cut-offs from our case study [35]. Other researchers identified a loss of up to 46% of the volume that will be recycled or recovered [44].

https://doi.org/10.52202/069179-0470

More recent work on the evaluation of timber purchase with the aim of up-cycling confirms these tendencies towards a range between 30 and 50% of loss in the reclamation of timber members produced before the 1950s, mostly not standardised. Consequently, as the original volume of wood is transformed, its virtual embodied carbon stock depreciates due to energy (and so related Green House Gas) involved in the transformation.

3.3 ON LIMITS OF BRAND-DUFFY SCHEMES

3.3.1 Layers that hide the need for durability.

Stewart Brand's scheme [45] (expansion of Frank Duffy's concept) conveys a misinterpreted general idea that the lifespan of materials (element, component) has definite lengths. Technical useful life is subject to multiple and variable factors influencing lifespan lengths. These include urban reconfiguration, frequency and degree of building occupancy, degree of climatic exposure, degree of rehabilitation, and natural wear of the material, all linked to 'uses' and, thereby, to the 'human factor'. Users also take part in determining the length of the lifespan with criteria of comfort, optimal use, norms, trends, and perception of wear.

All those criteria reveal that we must think about life expansion rather than life cycles that can legitimate a materials turnovers independently from useful life, a logic present in the office real estate industry.

3.3.2 Unusable or old-fashioned?

From Duffy and Brand's scheme perspective, what is not structural is not supposed to last more than decades [46]. But wood objects proved multiple times their ability to last after decades, if not centuries. Figure 5 shows examples of a dining room where most non-structural components are aged more than the supposed end of their lifecycle. The house containing these objects was built during the 1930s. The present owner, attached to the idea of limiting his environmental footprint, chose to perpetuate the use of objects that could be judged obsolete but still fit his needs.

Besides, this example introduces two values, sentimental and aesthetic. The first relates to our relationship with an object if it has an intimate story, as in our example case. The second one is related to artistic dimensions and subjectivity of taste, which is less present but not absent for structural elements. Thus, these two values are strong because they are the foundation of preservation and transmission, two parameters favouring continuity of use. Museums are the main manifestations of this statement, conserving objects defined as having high aesthetic value and being considered with a sentimental aspect by a population.

Let us again take the example of the 'Oak Chair in Scrapwood' design by Piet Hein Eek [46]. It supports the idea that if floorboards cannot be reused, they still have value after being up-cycled, with the assurance that a 500 € chair will probably last longer than or as long as the building that contains it or used to contain it.

Other concepts have tried to review the Brand-Duffy proposition from a more technical perspective [47] but keeping the structure of 'cycles', which conveys the idea of a substantial turnover of building components. Replacement should be possible essentially if it is technically necessary. Still, independently from a life cycle perspective, a wooden table can be used for decades, and tiles for plumbing are supposed to be reparable. Systems (HVAC) could be less machine aided by following passive principles [48-49], thus limiting maintenance and needs for components with rapid wear.

Figure 5: *M.dF's dining room. In the upper left is a classic example of 'Lundia' shelf in massive wood, dating from the late 1970s early 1980s; in the centre, the table is made with reclaimed planks and used as it has been since the 1930s; back in the centre, the double door in wood and glass (paint in white) is an original feature of the house since the 1930s; on the right, the sideboard is dated from the 1940/50s.*

4 VALUES OF A RECLAIMED TIMBER MEMBER

4.1 HISTORICAL VALUE

We start here with the most subjective value, as we introduced in part 3.3.2 and as know-how value expressing it in part 4.2, price and reclamation criteria depend not only on material aspects. Values attached to timber members also rely on their 'story'. Which building contains it? Has this building played a role in the site's historical background? A prominent example of that concept was brought to the public when Notre-Dame de Paris burned on April 19th 2019. More than losing a roof, a system dedicated to protecting the cathedral interior from climate contingencies, more than losing over 1500m^3 of wood, the cathedral loses her 'forest', the timber-frame nickname that emphasises roof personification and gives it a 'mystical value'. Moreover, the roof's members were precious archives of the medieval climate [50]. This gives more credit to the preservation of old pieces of wood present in buildings worldwide, or at least to the collection of data they contain. Historic value can be acquired after the first period of use, as an example of a barn built in 1920 in Rheinau (Swiss), reported by J.Brütting and C.Fivet [18-51]. The latter was constructed out of reclaimed timber members of a bridge built in 1810 in Eglisau. The historical value of the original bridge was transferred and developed by the fact that it became a barn, still in use a century after.

4.2 KNOW-HOW

Following the example of Bridges, the website 'Bridgehunter.com' [52] gathered at least 55 examples of bridges that were relocated, i.e. reused. More than a practical way of crossing a gap, these bridges stand for a legacy of timber engineering and are historical landmarks. With the idea that timber members have embodied immaterial values, we can assume that both crafted and industrial components and their elements can be characterised by their 'added values'. These added values stem from their design that 'contains' hours of conception to accomplish specific structural objectives (e.g. a span of a dozen meters) and hours of labour to transform wood to fit the design. Reclaimed timber members got added value for works already done and knowledge they can conserve and convey [53]. Since the medieval age, timber members have been included in chains of reclaimed materials [54]. At that time, timber reclamation might have been based on the aim of preserving a previous wood selection (related to strength grade), judged good for a structural purposed, still after reclamation. In addition, reuse interests must have been motivated by preserving the benefice of efforts made to extract and transform, by hand, a raw piece of wood into a usable member, indirectly including human energy and its apprenticeship [55]. Work, labour, as illustrated in Sebastião Salgado's book 'Workers' [56] or expressed in Graeber's theory of value [57], show how connected humans are or used to relate to what they produce, which is not only part of having an economic impact but also a cultural once.

4.3 EMBODIED CARBON

Notre-Dame de Paris fire can be supposed to have emitted over 1800 m ^{3} of C02. Following this example, embodied carbon in reclaimed timber can be seen as a value that must be part of its traceability when sold. Then, CO2 seems to be only the visible part of the iceberg of the environmental impact. It misses resources unextracted and unimpacted to produce new members (ozone, soils and water acidification, eutrophication, air and water pollution, abiotic resources depletion, fossil or not, unused energy, unproduced wastes, …). This lets us consider which values should be taken into account, whether there is a hierarchy, and how data can be collected, evaluated and transmitted concurrently to the element progression in the cascade/stairs, as represented by Figure 2. Recent advancements have been made toward assessing the environmental impact of reclaimed materials [58]. Nonetheless, the externalities of reuse still need to be investigated, by considering all the reuse process, which could entail, for example, deconstruction, milling, transportation, and implementation in the new project. All these activities also participate in increasing our entropy [59]. Furthermore, the environmental impact becomes even more complex if we include facts such as the renewal of biomass that occurred as long as a timber member remained in use and the induced avoided purchase of new products. Until now, the French Environmental Reglementation (RE 2020, see Decree n° 2021-1004) defines the framework for the Life Cycle Assessment (LCA) of new construction. In the LCA, reclaimed materials are currently worth 0 kg of CO2 by default. Thus, creating support to reuse initiatives might not remain a permanent rule. Here we saw that carbon value estimation and traceability would be necessary to reach an accurate LCA that integrates reclaimed timber members, to recognise the impact depicted above. Biogenic carbon could become part of a carbon market that would increase timber member market value.

4.4 MARKET VALUE AND USE VALUE

4.4.1 How much is it? About price estimation.

As we experienced through our field study, see part 5; price is a significant value parameter that could channel timber members toward reuse or not. In other words, value creates value. A low estimation and a lack of purchasers will limit the efforts of a preserved deconstruction, thus limiting in return the quality and the quantity of the timber members that could be sold. We hypothesise that the market value attributed to a timber member is also a label of its 'use value'. The higher the market value, the closer the timber member is to reuse. A lower price indicates a low aptitude to respond to the original use and to be competitive to new products and up- and down-cycling orientations [60].

As we will see in part 5.2.2, to evaluate the latent value of the timber stock of our case study, we align the latent market value of the building stock to the identified prices of the new and reclaimed products on the market by equivalence, as close as possible, by matching, length, section and species. We then adjust the latent value using coefficients: 1 (new, as new or with high historical value), 0.7 (reusable as it is), 0.5 (reusable with low processing) and 0.3 (reusable with high processing), 0.1 (up-cyclable).

4.4.2 Stock and logistics, blind spots of the reclaimed timber value.

The management of the reuse process takes part in adding or removing values, heightening the role and the aspects dual of stock and logistics. During their use, timber members are stored 'for free'. After deconstruction, the created supply of timber members must be protected from climate degradation (e.g. rain, UV, snow…) and eventual thefts (see part 5.2.1). When the protection used to be free, it can now cost to preserve the timber stock integrity. It could be said that value chains do not like storing 'useless' items, as demonstrated by numerous methods developed in the car industry and construction sectors, from Fordism to Lean construction [61]. If it is useless on the site, if it should be moved to find a use, or transformed to be used, it will cost, degrading profit margins, or at worse, diverting initiative in favour of reclamation towards recycling.

4.5 MECHANICAL PROPERTIES

The process of grade identification participates in attesting the value of timber members when facing insurance organisations who need proof of quality and durability/sustainability to ensure that the material will not be charged for the sinister in case of doubt. In that sense, if we look at the etymology of the term 'value', '*valere'* in Latin means to 'be strong' and to 'be valid for'. 'Strong for' (resistant enough), 'valid for' (mechanically adequate), structural purpose. What gives its value to a timber member is its faculty to bear loads. Values attached to mechanical properties are hard to evaluate in a context where we face 'unknown' pieces of wood, sometimes

https://doi.org/10.52202/069179-0470

without any load background and characterisation traceability. To complete the reuse of deconstructed timber elements, a grade datum is necessary for load simulation and structure design accomplishment. As we know, ageing has no significant incidence on bending strength and bending stiffness [62]. Nonetheless, this fact raises an important question concerning the sorting of timber elements to avoid reusing timber that does not enter the norms' criteria (NF EN 338, EC5). Variability of quality, from a mechanical perspective, engages us in developing strategies to avoid potential future disorders:

- Precise assessment methods to identify sources of 'de-grading', before and during the deconstruction.
- Evaluate timber mechanical properties of some pieces and extrapolate to sort them by similarities (dimensions, context of use, aspect, tree species, etc.) and create batches.
- Oversize structures made of reclaimed timber members.
- Consider a batch of timber members as part of one unique grade (C18, lower grade, for softwood and structural use, in our case).
- Evaluate timber mechanical properties of every piece to sort them individually.

Despite its seeming simplicity, this visual grading method is hard to apply on reclaimed timber following the norms ISO 9709:2018 and EN 14081-1+A1 due to aspects gaps with new timber products. A merging with approaches developed in EN 17121 should be interesting to elaborate a specific norm [63]. Another fact of poor adaptability of existing norms is the constraints induced by the reuse process. A strict application of the norms on reclaimed timber can take 5 to 10 minutes for two persons, without including handling time for and between each piece of wood. Therefore, visual grading of an entire timber stock from a building deconstruction can take days and cost enough to degrade the profit margin of the resale. Besides, the gap between norms conceived for brand-new timber products will reject reusable members. From our experiences, we see through visual grading a practice that could help to pre-classified batches of members before their machine grading based on significant characteristics. In our case study, we have experimented vibratory grading method based on MOE evaluation. Bending stiffness is determined by calculation after the caption of the frequencies with accelerometers. As the method is in the reliability assessment process, it is not relevant to give robust results. But trends are identified to avoid risks of keeping timber members inferior to the expected MOE, 7 kN/mm ^{2,} for structural members. Another trend identified is a division into 4 groups, see figure 6. One group is between 7 and 9 kN/mm ^{2}, a second between 9 and 11 kN/mm ^{2}, and a third from 11 kN/mm ^{2}. Each represents more or less a third of our sample batch, with the last of the 4 groups composed of timber members evaluated under 7 kN/mm ^{2}, representing less than 5% of the batch. The main problem is that MOR remains unknown, and mechanical evaluation must be completed to be reliable. But from our perspectives, MOR assessment is still constraining in determining grades, it demands heavy equipment and can generate losses. Therefore, we focus our research on non-destructive and reliable techniques. We try to maximise 'values' embodied in the timber members by preserving as many timber products as possible to sell them, so that they will be effectively reused and be able to transmit their 'values' once again.

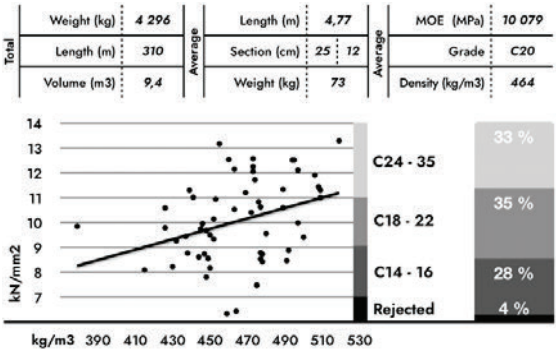

Figure 6: *In the upper part, the table gives general information on the joists batch studied. Lower part graphs depict the supposed strength grades and associate classes (EN 338), based on stiffness assessment with vibratory technique.*

5 AVOIDING FAILURES BY VALUATION

5.1 CASE STUDY CONTEXT

5.1.1 Description of the site.

Our case study is a textile mill, supposed to have been built around 1910 in Épinal, northeast of France. The specific part of the factory we studied was supposed to be designed for the offices of administrative activities. It then became a space for storing archives in the attic and first floor, and the last recent occupation of the ground floor was dedicated to a sewing workshop and a store. But still, we have not yet been able to track down the whole history of the building, which limits the structural analysis introduced in part 4.5.

The building was located in an urban renewal area; a part of the factory was kept, mainly shed volumes, to host economic activities. Our building was demolished to be replaced by a new collective housing project.

We estimate that over 80 m ^{3} were at least 'up-cycled'. The initial stock of wood was evaluated at 146 m^{3} in total, with 126 m ^{3} judged as healthy to be reclaimed for 'reuse', eliminating 17 m ^{3} damaged by fungi, insects, or polluted materials (tar mainly present on roof members) and 3 m ^{3} due to cut-offs.

5.1.2 Socio-economy of the project.

At the time of the field study, in spring 2021, timber product prices were rising unexpectedly. Meanwhile, reclaimed timber members extracted from our site were not affected by this phenomenon. Even the contrary happened while the reusability of the timber members was shared by all stakeholders taking part in the deconstruction.

In our case study, materials were proposed explicitly for sale to private individuals and not oriented towards private professional purchasers. However, in the early stage of the deconstruction, a sawmill offered to buy all the timber members' stock. That choice influenced the final rate of reuse and up-cycling.

We conclude from that experience that the more we divide the original stock by many uncertain buyers, the more we augment dispersion and loss of the resource. Besides, regarding the survey of the 'reuse practices', private individuals mainly up-cycled the timber stock, using joists as a post or cutting them in length for other structural purposes. Only floorboards were mostly strictly reused. This mismatch also provides evidence for the need for a method to define resource prices. On the one hand, sellers need to estimate the latent value of their timber stock to 'take the risk' of investing in deconstruction instead of demolition. On the other hand, buyers (companies) need timber members to be 'certified' to ensure their future clients that they are still safe to be reintroduced in new construction. Timber members are less susceptible to convince of their reusable faculties without 'values' attached and thus without investigation to create traceability.

5.2 LACK OF VALUE, LACK OF ECONOMY

5.2.1 If it is worth to be stolen, it is worth to be sold.

What could be seen as anecdotal looks relevant regarding the lack of values attached to reclaimed timber members. A batch of a hundred joists, part of timber members that were supposed to be reused, has 'disappeared', stolen, maybe reclaimed, by an anonymous person unmasked until now.

The main reason for this 'failures' was that the contractors did not achieve to include this batch in its new project, which was already drawn but still not under construction. Its original storage place, an empty yet still standing part of the textile mill owned by the town hall, needed to be evacuated, letting the joists batch outside, stored on the building site, with no protections, waiting to be reclaimed.

Disappearance, or thefts, advocate for the embodied value in what we could call a brownfield, industrial wasteland, or old building. Here, it points out that this joist batch has values, but these values were not taken into consideration enough to prioritise their final and effective reuse.

Another telling fact of the market value of elements waiting to be reclaimed is the need to close the access to the deconstruction site (also for security reasons) and the surveillance applied to avoid thefts. Recently we notably observed the change from human oversight toward camera-assisted monitoring to avoid guards' complicity with an organised group of thieves (EPFGE site visit).

5.2.2 What it costs and what it is worth.

For our case study, we compare the balance sheet of effective earnings, identified until now, with the potential earnings if prices have been better estimated and sales better organised to maximise profit, with no processing.

As Figure 7 shows it, after re-evaluation (with the method exposed in part 4.4.1), earnings from timber stock sales could have been able to finance its deconstruction and the connected practices linked to it, such as species analysis. Related to the cost of deconstruction, we observed that manual deconstruction is slower than mechanical deconstruction. The latter is ten times more expensive if we look at the cost per hour, circa 15 compared to 150€ from data we collected during the field study, with operators being paid following the French minimum wage at that time, 2021, taxes and fees included. Manual deconstruction involved punctual aids of equipment such as mobile scaffold towers, and portable power tools. Mechanical deconstruction involved equipment such as telescopic handlers or crane trucks.

As energy costs rise [64], we assumed mechanical practices would be less resilient than manual practices. Human portable size of construction materials could be allowed to keep a low cost of deconstruction in the future. Besides, if norms are respected, involving human work instead of machines participates in a more sustainable way of deconstructing also at a social level. At the same time, waste management and treatment costs are rising year after year [65]. Discarding a cubic metre of timber members costs 25€/m3 (0.5 wood density) in 2022; this does not include deconstruction costs and waste management up to the collection point. The global cost is estimated at 45€/m3 (0.5 wood density) [66]. As a comparison, we estimated that the average price for extracting a cubic metre of wood from our case study was around 322€ (including extraction of building layers to access timber members), while the estimated price of a reusable cubic metre of timber members was 465€.

Timber members types	Joists	Trusses	Purlins	Boards & Floorboards	Rafters	Total	Economic efficiency
Potential earnings at estimate prices	30 205 €	6 972 €	6 719 €	12 541 €	2 365 €	58 802 €	11 784 €
Potential earnings at effective prices	2 752 €	6 000 €	309 €	2 882 €	702 €	12 645 €	-34 373 €
Effective earnings at effective prices	1 397 €	0 €	197 €	1 180 €	480 €	3 254 €	-43 764 €
Deconstruction practices	Project manag.	Wood assess.	Manual decon.	Mechanical decon.	Waste manag.	Total	
Deconstruction costs for the timber stock	1 200 €	14 650 €	11 236 €	13 883 €	6 050 €	-47 018 €	

Figure 7: *This table present earnings differences and their impact on final economic efficiency of the deconstruction.*

6 CONCLUSIONS

Reuse of reclaimed timber is not guaranteed by the reversibility and appropriability of the wood material. The continuity of original use is in direct technical and economic competition with recycling and energy recovery. But reuse, compared to these, is still a relevant practice to limit our entropy. We introduced this paper with reflections on sustainability, durability, circular economy and cascading of wood products. These terms need to be more carefully used and reconsidered. We proposed that the lifespan of wood products and their representation should rely on the material integrity, rewarding the extension of the original use rather than steps of transformation. In response, we illustrated that idea with the concept of the 'staircase'. Based on observations we made during the deconstruction of a disaffected textile mill, we got interested in the role of values attached to timber members. After the deconstruction of our case study, we re-evaluated the estimated latent value of the timber stock and compared it with the effective cost of the work site. We also experienced grading practices that could give the right value to structural timber members. We found that taking care of the 'values' could optimise the reuse process and its effectiveness, by remunerating a preserving deconstruction with the earnings from reusable or up-cyclable timber members' sales. This paper only gives a glimpse of the subject of reclaimed timber 'values'.

https://doi.org/10.52202/069179-0470

These values need to be confronted with other field studies to get a comparison and collect price data that appear challenging due to the frequent approximation of stakeholders about the unit of time, volume, weight, costs, and prices. The full reuse of all the timber members extracted from our case study has not been completed until now. We will continue the restitution of research that is related to it by describing the final process of timber members' reintegration. We present here trends rather than final results, and future works will continue to investigate this theme through other deconstruction worksite visits, interviews and reviews. Assessment practices are at the heart of the creation of values. Wider research should be done to identify universal values and clarify the way they are assessed. A connection can be made with heritage approaches as they are similar in many ways.

World Conference on Timber Engineering Oslo 2023

CHALLENGES IN THE DESIGN OF A MODULAR MULTI-STOREY CLT BUILDING USING IRISH TIMBER

Hung Quang Phung[1], Conan O'Ceallaigh[2], Patrick J. McGetrick[3], Annette M. Harte[4], Rimjhim Kashyap[5]

ABSTRACT: Cross Laminated Timber (CLT) has been developed in recent years to the stage of automation in production, from timber classification, joining boards, applying adhesive, assembly pressing and CNC machining to form completed CLT panels. Volumetric buildings incorporating CLT are now being developed and completed, showing promising results as sustainable solutions for the construction industry. The majority of European CLT panel manufacturers use grade C24 timber, while countries such as Ireland also have an increasing supply of Sitka Spruce grade C16 timber which has been shown to be suitable for use in CLT. This paper presents elements of a larger research project and focuses on the preliminary design and development of a proposed modular seven-storey building in CLT manufactured from Irish timber, addressing the usage of CLT in volumetric modular construction. Challenges in delivering a building of this type are addressed in terms of building layout, loading arrangement, transportation, and structural design of panels. Design for deconstruction is also considered for the connections between the units to enable future reuse.

KEYWORDS: Modular construction, Circular economy, Cross-Laminated Timber (CLT), Irish timber

1 INTRODUCTION

The current level of housing demand and projected future population growth of 1.5 million people by 2051 in Ireland [1] places pressure on residential building construction – a requirement for an average rate of completion of 33,000 new homes per annum is projected within the next decade [2]. This figure has the potential to rise as high as 50,000 and is a significant challenge as current completion rates lie just under 30,000 per annum as of 2022 [3]. As the supply of raw material from Irish forests has been forecasted to double between 2017-2035 [4], there exist opportunities for the promotion and development of engineered wood product solutions for the sustainable construction of homes to both meet this housing demand and achieve lower building carbon footprints.

In parallel to this, the increase in the prominence of modern methods of construction over the past couple of decades, including automation and offsite manufacturing, has included the development of modular building systems. Modular building systems can generally be categorised into one of two types: 2D panellised, where components such as walls and floors are installed on site to form the building, or 3D volumetric, whereby whole finished modules are installed directly on site [5]. Where a project allows for repeatable building units (2D or 3D), these systems offer faster construction with reduced time on site, higher quality control and efficiency associated with factory assembly and prefabrication, and lower environmental impacts compared to traditional approaches. Developments in the automation of offsite manufacturing procedures have normalised low-rise modular construction, typically 4 storeys or less. However, Thai et al [5] note that modular construction for high-rise buildings is not yet as popular due to lack of design guidelines, inter-module connection techniques and sufficient understanding of structural behaviour, global stability and structural robustness of modular buildings. The majority of multi-storey modular buildings are constructed using reinforced concrete or steel (including cold-formed light gauge steel), or composite construction using both [5]; structural stability is typically provided by a steel bracing system, reinforced concrete cores or walls, or again, a hybrid of both.

Although concrete modular systems tend to have better fire resistance, water proofing and acoustic performance than steel systems, due to its heavier weight, modular concrete units incur higher costs for lifting requirements by crane, and can offer less flexibility in terms of design and connections. For these reasons, as modular buildings become taller, steel or hybrid systems can be preferred, particularly if 3D volumetric modules are being used to reduce internal finishing requirements on site. recently, developments in timber offer alternative solutions with similar benefits.

Harte [6] outlines the introduction to the construction industry of mass-timber products, such as Cross Laminated Timber (CLT), with excellent load carrying characteristics that over the past two decades have enabled timber to be used in larger and more complex structures, including modular construction. CLT panels for use in structures can be fabricated at lengths up to 16 m, widths up to 3 m and thicknesses up to 500 mm. Currently, the tallest all timber building in the world is the mixed-use 18-storey Mjøstårnet building in Norway, completed in 2019 and standing at 85.4 m [7]. Examples of modular mass-timber buildings include the 14 storey, 49 m tall Treet Building in Bergen, Norway which was completed in 2015 and was constructed using volumetric CLT modules achieving Passive House standard [7]. However, the majority of existing modular CLT buildings tend to be 7 storeys or less in height [8].

The success of timber modular construction to date has been reported as being dependent on local or regional production capacity and regulations [8], and its development has been focused primarily in Europe, followed by North America. Bhandari et al. [8] acknowledge that there is a need for a systematic review of modular CLT connection systems in terms of constructability, reuse and potential for rapid building deployment, including further study of the impacts of the transportation distance on cost and efficiency. Furthermore, with increasing demand for sustainable building solutions, international best practice in modular timber construction is expected to become more widespread.

The increased use of timber in construction has tended to be perceived as having the potential to make a significant contribution to reducing greenhouse gas emissions from the construction sector, particularly when it is being used in place of reinforced concrete or steel. This is becoming of greater significance now as many countries are introducing policies and initiatives that target net-zero emissions, such as the European Green Deal [9], with associated regulation and carbon footprint limits for new buildings. There has been limited research published on the lifecycle impact of modular volumetric CLT construction but recent research [10] has highlighted the significance of the energy production profile for this type of construction. The product, construction and end-of-life stages hold the most significant share of the building's lifecycle impact, while optimising the modular CLT building configuration and use of efficient fasteners can reduce the overall impact by around 5% [10]. The authors are also carrying out ongoing research on the lifecycle assessment of timber buildings and modular CLT construction as part of the wider Modular Mass Timber Building for the Circular Economy (MODCONS) project. This paper presents aspects of the MODCONS project on the preliminary design and manufacturing of a seven-storey residential building in CLT based on material properties of Irish C16 timber, following the volumetric modular approach. While 2D panellised solutions can offer flexibility, a 3D volumetric modular approach also offers a number of advantages, including the quality control and efficiency associated with factory assembly and reduced sitework. The volumetric approach also has the advantage of producing whole modular units that can be reused or refurbished, supporting a circular economy in construction and offsetting the need for virgin materials. European CLT panel manufacturers primarily use grade C24 timber, which has slower growth rates but higher strength than fast-grown Irish Sitka Spruce (*Picea sitchensis*) grade C16 timber. It follows that the capacity and opportunity for the increased supply of Irish timber to be used in added-value products in construction must be illustrated, supporting a reduction in the carbon footprint of the built environment [6]. The following sections outline the preliminary building layout and design including reuse, loading arrangements, transportation requirements, and the associated challenges.

2 DESIGN CONCEPT AND DEVELOPMENT

Following the current Irish building regulations (and associated technical guidance documents on structure, fire safety, access) [11], planning guidance [12] and European standards for actions on structures and structural design [13-16], the design of the volumetric units was developed assuming mass production of prefabricated units under factory conditions. The milestones of the preliminary design workflow are highlighted in Figure 1 below, beginning with (i) the selection of the volumetric construction method, (ii) the design and layout of individual modular units and plan design, meeting transportation requirements and internal sizes in line with the minimum area required by the local regulations [12], and (iii) structural design of the CLT panels required to transfer loads from the floors and ceilings to walls and foundations. Lifting systems and connections are also key considerations in the design for deconstruction targeting future reuse, however, limited discussion is provided here on consideration of these.

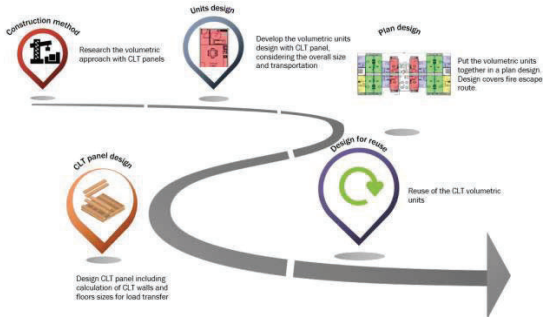

Figure 1: *Milestones of the design development*

2.1 SITE LOCATION

The site location for the seven-storey residential building was assumed in an urban location in Dublin, Ireland. The ground conditions and foundation design are not considered in this paper but based on existing

https://doi.org/10.52202/069179-0471

developments in this location, it is assumed that the geotechnical conditions will be suitable for the proposed building. The focus here is therefore on the building superstructure only.

2.2 ACCESS AND TRANSPORTATION

The design criteria for the CLT units are also informed by transportation within this urban location i.e. by access, size and weight limits. The modular unit height is limited at 4.65 m from ground to the top of the load being carried or top of the vehicle. This can be increased by a local authority permit [17]. The modular unit length is limited at 12 m + 3 m overhang for one piece [17,18]. This can be increased to 27.4 m with a permit from An Garda Síochana, and increased to more than 27.4 m with a local authority permit [17]. The modular unit width is limited at a maximum of 2.9 m (including a 300 mm overhang) [17,18]. This limit can be increased to 4.3 m with a permit from An Garda Síochana, and over 4.3 m with a local authority permit. Based on the above limitations and assuming the necessary permits are obtained, the size and dimensions of the modular CLT units were therefore limited to 4.3 m external width, 15 m external length, and 4 m in external height. Figure 2 provides an example illustration of the modular unit size for transportation, showing the unit overhang on the transporting vehicle. provides Supporting beams, not shown here, are also required to ensure the unit is supported by the walls during transportation.

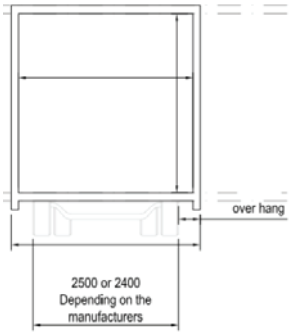

Figure 2: *Example illustration of modular unit transportation (not to scale, dimensions in mm)*

The maximum allowable modular unit weight is maintained below 24 tonnes to remain within transportation vehicle laden weight limits [19]. More detail on the weights of the designed modular units is provided in Section 2.3.

2.3 BUILDING LAYOUT AND MODULAR UNIT TYPES

The general arrangement of the building and plan layout design are dependent on the arrangement and combination of the volumetric unit types. Three apartment configurations were considered in the completed plan layout for the proposed seven-storey building, with a rectangular footprint on plan of 45 m × 25.32 m excluding balconies. The same floor plan (Figure 3) is repeated at all seven storeys, with reinforced concrete cores (3.48 m × 5.53 m on plan; 300 mm thick walls) located at each end of the building to provide access stairways, fire escape routes and lateral stability for the building structure. A central communal area is provided, meeting minimum area requirements [12]. Fire safety provisions and emergency access are based on Technical Guidance Documents B and K [11]. The stair cores are designed to be constructed on-site using reinforced concrete as a non-combustible material. The maximum distance from an apartment entrance door to the stairs is limited to 15 m. This plan is designed to ensure each bedroom receives natural light and it also allows for additional units and cores to be added.

To form the three apartment configurations, either single modular CLT units or a combination of units are employed. The four volumetric unit types designed are shown in Figure 4 – Types 1 (green) and 2 (yellow) are combined to form the two-bedroom apartments, Types 1 and 3 are combined to form the one-bedroom apartments, and Type 4 is a single studio unit (red). These exceed the minimum overall areas by at least 10% [12] while minimum widths of apartment rooms are also defined by [12]. A standardised width of 3.6 m is used for both one and two-bedroom apartments to reduce volumetric unit variation for manufacturing. However, for the studio apartment, a minimum internal width of 4.0 m is required. All modular units are l_e = 3.25 m in height, resulting in a total building structure height of 22.75 m.

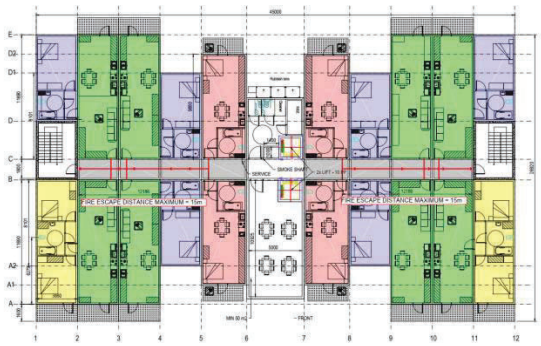

Figure 3: *Proposed building plan layout (not to scale, dimensions in mm)*

The units are designed to reduce the number of volumetric unit types required to form the building. This reduces structural variation, optimising unit standardisation to improve production efficiency. Furthermore, for the CLT panel supply chain, cost and time savings can be made when the same panel sizes can be ordered, manufactured and supplied in large quantities. The internal design of the apartments accommodates a standard plan layout. However, the skeleton frame of the volumetric units can be used with different interior designs of the apartments. This means the core CLT volumetric unit can be used in a different applications – allowing standardised mass production. Overall, the building consists of 12 apartments per floor, configured from 20 CLT modular units per floor, totalling 140 modular units.

https://doi.org/10.52202/069179-0471

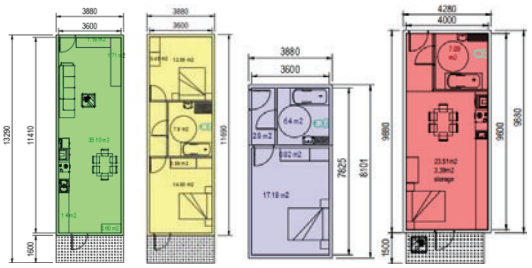

Figure 4: *Plan layouts of volumetric modular CLT units (a) Type 1 (b) Type 2 (c) Type 3 (d) Type 4 (not to scale, dimensions in mm)*

The estimated weights of the volumetric units are provided in Table 1; these values assume the prefabrication of the units including balconies for a conservative comparison with permitted transportation limits i.e. weight under 24 tonnes and length less than 12 m + 3 m overhang. All unit widths are under 4.3 m. Common practice would likely dictate site installation of balcony units post assembly of the building modules. Mobile cranes with suitable capacity are available for these modules and building dimensions, such as the Demag AC220-5.

Table 1: *Modular CLT unit dimensions and weights*

Type	External width (m)	External length including balcony (m)	Estimated weight (tonnes)
1	3.88	13.29	20.32
2	3.88	13.29	22.78
3	3.88	9.7	18.11
4	4.28	11.38	21.86

3 CLT PANEL DESIGN

3.1 LOADING

Figure 5 shows an indicative cross section for the modular CLT units, showing the proposed balloon arrangement of CLT panels for walls, floors and ceilings. This allows modules to be stacked on top of one another with gravity load transfer directly between walls, removing the risk of compression perpendicular to grain in floor panels in the more popular platform construction approach. For unit types 1-3, the clear span for floors and ceilings is the 3.6 m internal width, while for unit type 4, the clear span is 4 m. The floor and ceiling panel designs are based on the larger L = 4 m span.

The gravity loading acting on floors and ceilings is adopted based on [14], while wind loading is calculated based on the Irish National Annex to Eurocode 1 - Part 1-4 [14], giving a peak wind pressure of 1.27 kN/m^2. The characteristic variable action (unfactored imposed load) adopted for the unit floors is 2 kN/m^2 based on domestic loading, while the ceiling panels are designed for imposed loads of 0.6 kN/m^2 during the construction stage only. A flat roof is assumed with limited access for maintenance and repair only, with ceiling panels in units at roof level designed for an imposed load of 1.5 kN/m^2; this can be reduced to 1.0 kN/m^2 where permanent access to those panels is not provided. Including self-weight, the ultimate design loading for a 1 m strip of the floor is 4.47 kN/m. For the ceilings, the corresponding loading is 2.12 kN/m. All corridors and access areas are designed for an imposed load of 4.5 kN/m^2. Floors in corridors are to be supported by the CLT module walls and are included for loading calculation purposes only.

The preliminary wall design is based on the maximum gravity loading experienced by ground floor walls, allowing the resultant design to be used at any floor. It is assumed that the walls are encapsulated with plasterboard providing at least 60 minutes of fire resistance – this is expected to be a minimum requirement under current Irish practice. As the building is multi-storey, the total imposed loading on the walls has been reduced by a factor of 0.79 in accordance with Equation (6.2) of Eurocode 1: Part 1-1 [14]. These loads result in an ultimate axial design load on the wall of F_d = 112 kN/m. The ultimate transverse load acting on the wall due to wind, calculated using the peak wind pressure, is $q_d = 1.5 \times 1.27 = 1.91$ kN/m^2.

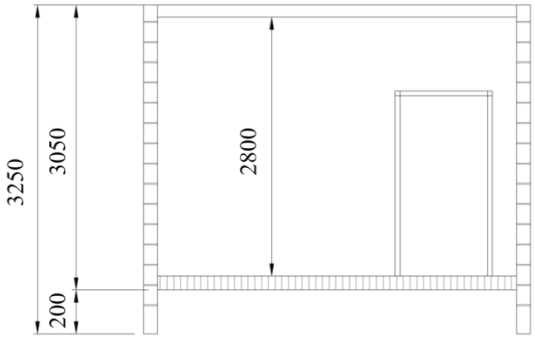

Figure 5: *Indicative cross section of volumetric modular CLT units (not to scale, dimensions in mm)*

3.2 MATERIAL PROPERTIES AND SOURCING

Irish Sitka Spruce (*Picea sitchensis*) grade C16 timber is assumed for the design of all CLT elements. While C24 grade timber is more commonly used for the manufacture of CLT in Europe, this study is intended to illustrate the feasibility of using locally sourced rather than imported timber, which at a minimum, can offer potential savings in transport emissions. This is also being investigated by the MODCONS team at University of Galway but is beyond the scope of this paper. The relevant adopted material properties for design in accordance with Eurocode 5 [15] are presented in Table 1 below, adopted from [20-22].

https://doi.org/10.52202/069179-0471

Table 2: *Material properties for C16 grade timber used for design*

Property	Value for C16	Unit
Characteristic bending strength, $f_{m,k}$	16	N/mm^2
Characteristic compressive strength along the grain, $f_{c,0,k}$	17	N/mm^2
Characteristic compressive strength perpendicular to the grain, $f_{c,90,k}$	2.2	N/mm^2
Characteristic shear strength, $f_{v,k}$	3.2	N/mm^2
Mean value of modulus of elasticity, along the grain, $E_{m,0,mean}$	8000	N/mm^2
Fifth percentile value of modulus of elasticity, along the grain, $E_{m,0,05}$	5400	N/mm^2
Shear modulus, $G_{0,90}$	500	N/mm^2
Rolling shear modulus, $G_{90,90}$	50	N/mm^2
Density, ρ	390	kg/m^3

3.3 PANEL DESIGN SUMMARY

Following the design approach based on beam theory [15,16] and outlined in [22], the assumed building layout shown in Figure 3, loading outlined in Section 3.1, and using C16 timber properties provided in Table 2, three common CLT panel build ups have been designed for the unit walls, ceilings and floors respectively for all unit types; these are summarised in Table 3. Service Class 1 is assumed. Values of k_{mod} = 0.8 for medium term actions [15, 22], k_{mod} = 0.6 for permanent actions [15, 22], γ_M = 1.25 [15] and k_{def} = 0.85 [22] are adopted for design calculations.

Table 3: *Summary of panel design*

Element	No. layers	Total thickness (mm)	Layer thickness (mm)	Layer orientation (degrees)
Walls	3	120	40	0
			40	90
			40	0
Ceilings	3	110	40	0
			30	90
			40	0
Floors	5	140	40	0
			20	90
			20	0
			20	90
			40	0

3.3.1 Floors and ceilings

The floor and ceiling panels both comfortably pass design checks for bending and shear, with low utilisation ratios. It is desirable at this preliminary stage to keep utilisation ratios below 75% for floors and ceilings. For example, for the CLT floor panel, the design bending strength, $f_{m,d}$ =10.24 N/mm^2 is considerably greater than the design bending stress σ_d = 2.96 N/mm^2. Similarly, the design shear strength, $f_{v,d}$ = 2.05 N/mm^2 is greater than the design shear stress, τ_d = 0.13 N/mm^2.

The critical design criteria for the floor and ceiling panels are deflections, which are limited to a maximum of L/250 = 16 mm here for the L = 4 m span [15]. The net final deflections are calculated here according to equation 7.2 of [15], reproduced as Equation (1) assuming zero pre-camber:

$$w_{\text{net,fin}} = w_{\text{inst}} + w_{\text{creep}} \quad (1)$$

where $w_{\text{net,fin}}$ is the net final deflection, w_{inst} is the total instantaneous deflection (variable + permanent) and w_{creep} is total deflection caused by creep (variable + permanent). For permanent actions, $w_{\text{creep,g}} = k_{\text{def}} w_{\text{inst,g}}$ and for variable actions, $w_{\text{creep,q}} = \psi_2 k_{\text{def}} w_{\text{inst,q}}$ where $\psi_2 = 0.3$.

For the floor panels, $w_{\text{inst}} = (w_{\text{inst,q}} + w_{\text{inst,g}}) = (4.24 + 1.16) = 5.40$ mm under variable and permanent actions, respectively, which is less than the corresponding limit of L/300 = 13.33 mm. The net final deflection $w_{\text{net,fin}}$ = (2.16 + 5.32) = 7.48 mm (< 16 mm). Reducing the outer layer thicknesses by a typical step size of 10 mm or greater would cause the section to exceed the 75% utilisation ratio in deflection thus no further changes are made to the section size and layers.

In terms of vibration serviceability requirements, the natural frequency of the floor is $f_{1,fl}$ = 12.93 Hz, and that for the ceiling is $f_{1,ceil}$ = 9.27 Hz, calculated using equation 7.5 of Eurocode 5 [15]. Both of these panels satisfy the simplified vibration serviceability calculation method in Eurocode 5 for residential floors however, it should be noted that the acoustic performance has not been assessed here - this is part of a larger task on the MODCONS project.

3.3.2 Walls

The wall design is more critical due to the loading accounting for vertical load from 7 storeys and wind loading. Following Clause 6.3.2 of [15] for combined compression (due to F_d) and bending (due to q_d), the 120 mm thick panel is checked for the 11.69 m long wall in unit Types 1 and 2. Due to openings for windows, the effective width, $b_{ef,}$ of the wall is taken as 6.5 m. Buckling is checked in the ultimate limit state according to Equation (2).

$$\frac{\sigma_{c,0,d}}{k_{c,y} f_{c,0,d}} + \frac{\sigma_{m,y,d}}{f_{m,y,d}} \leq 1 \quad (2)$$

where $\sigma_{c,0,d}$ is the design compressive stress along the grain, $f_{c,0,d}$ is the design compressive strength along the

https://doi.org/10.52202/069179-0471

grain, reduction factor $k_{c,y}$ can be obtained using equation 6.5 in [15], $\sigma_{m,y,d}$ is the design bending stress about the principal y-axis, $f_{m,y,d}$ is the design bending strength about the principal y-axis. $\sigma_{c,0,d}$ can be calculated based on a 1 m strip of wall (from the width b_{ef}) as $N_d/A_{x,net}$, as per [22]. Here, N_d = 201 kN is the vertical load and $A_{x,net}$ = 80,000 mm^2 is the cross sectional area of the two outer layers, giving $\sigma_{c,0,d}$ = 2.51 N/mm^2. $\sigma_{m,y,d}$ can be calculated as $M_{y,d}/W_{x,net}$, where $M_{y,d} = \frac{q_d l_e^2}{8}$ is the design moment due to wind loading and $W_{x,net}$ is the section's net moment of resistance. Here $\sigma_{m,y,d}$ = 1.95 N/mm^2. With $k_{c,y}$ = 0.43, $f_{c,0,d}$ = 8.16 N/mm^2 and $f_{m,y,d}$ = 7.68 N/mm^2, Equation 2 can be evaluated as 0.97 < 1, which passes but with a high utilisation ratio. Any further increase in thickness to reduce this utilisation ratio is not desirable as it would increase the weight of units beyond the 24 tonne transportation limit. However, further refinement of panel thicknesses is possible between unit types with consideration of the impact of increased variation in manufacturing.

3.4 CONNECTIONS AND DESIGN FOR REUSE OPPORTUNITIES

The common panel design for all units allows the modular units to be used in alternative arrangements i.e. the same unit can be used at any storey within this seven storey building. Furthermore, this also enables provision for reuse of the units at the end of, or during, the building's design life which supports the reduction of its environmental impact. While 2D panellised CLT systems may remain more popular and practical for construction, the whole unit reuse option remains an advantage for volumetric units. There are two options for reusing the units: (i) reuse the fully completed CLT units (with interior fit out) and (ii) reuse only the structural frame; the latter has been employed for volumetric construction in steel. However, associated challenges exist, for example, in the limited capacity to add new openings to walls, the detailing of demountable connections, maintaining overall building stability and modularisation of Mechanical and Electrical systems. Alternative solutions currently being assessed include straightforward options such as connections using screws instead of nails, no adhesive used to connect components to CLT, recessed lifting points located at the top of the unit wall panels etc. Connection groups currently being reviewed for this building system include:

- Alternative options for wall to floor and wall to ceiling connections, including standard angle brackets and timber rails above or below panels considering fire protection
- Inter-module connectors i.e. as part of the lateral stability system
- Connections for lifting and transportation
- Volumetric unit connection to substructures

4 CONCLUSIONS

This paper has demonstrated the feasibility and capacity of CLT panels manufactured using Irish C16 grade timber to be used in multi-storey volumetric modular residential construction. Due to a common CLT panel design between the four modular unit types proposed for use across all 7 storeys, wall panels at the ground floor level are the critical elements. However, the current design with 5-layer 120 mm thick wall panels provides flexibility to use the same volumetric modular unit at any of the seven floors. While 2D panellised systems grow in terms of popularity and standardisation, volumetric modular systems still hold the advantage of enabling reuse of a whole finished unit. The MODCONS project team's ongoing work involves the review the lifecycle impacts of this, considering the comparative ease of deconstruction of panellised systems for reuse. Furthermore, the proposed design, detailing, structural testing, and fire performance testing of connection systems for both volumetric and panellised systems using Irish C16 timber is ongoing.

ACKNOWLEDGEMENT

The authors wish to express their gratitude for the support and funding received from the Department of Agriculture, Food and the Marine's Competitive Research Funding Programmes, Project Ref: 2019R471 (MODCONS).

World Conference on Timber Engineering Oslo 2023

RE:SOURCE PAVILION – EXPLORING THE CIRCULAR USE OF WOODEN BUILDING MATERIALS

Ute Groba [1], Samuel Blumer[2]

ABSTRACT: The pavilion as a building task is a contested typology as both its functional life span and constructive durability tend to be limited. However, this ephemerality makes the questions of the materials' origin and the construction elements' later reuse a pressing issue which is of great importance for rethinking architecture of greater scale as well and render the pavilion a suitable format for study and exploration. This paper describes the conception, design and planned mounting of a timber pavilion as part of a master studio taught at The Oslo School of Architecture and Design. The pavilion is planned to be built and exhibited parallel to the World Conference on Timber Architecture 2023 in Oslo. Special focus is directed towards the implication of "disregarded" wooden materials for architectural design and constructive solutions. "Disregarded" wooden materials include cut-offs and cut-outs, materials found on waste sorting plants, pre-used materials from buildings soon-to-be demolished or erroneous deliveries. Specifically, the focus is on joining smaller members or members of varying sizes to larger load-bearing elements or to indoor and outdoor planes and surfaces. The paper discusses the insights this design task provided, highlights new questions that arose during the process, and suggests how these may inform timber architecture in general.

KEYWORDS: Timber construction, reclaimed wood, engineered wood, circular architecture, design for disassembly

1 INTRODUCTION

1.1 THE PAVILION AS A CONTROVERSIAL DESIGN TASK

The dichotomous demands towards sustainable building materials to be both permanent and ephemeral become overly apparent in pavilions as a building typology – permanent as materials are supposed to last long, and ephemeral as materials are supposed to be compostable (or combustible for energy production) instead of ending in landfills [1].

For many, the pavilion is a contested building task. As its function tends to be limited and its construction less durable, the pavilion may be criticised for its use of resources. However, the pavilion may also serve as a test bed for new architectural and constructive ideas and exhibit these to the public [2]. Bringing together the necessary expertise for non-standard design and construction endeavours may even initiate future collaboration.

When its materials have been pre-used or would have been discarded otherwise, and when the pavilion's functional and constructive conception allows for a relocation after its primary exhibition phase – in parts or as a whole, the critique of wasting resources is less apposite. Both using pre-used materials and designing the pavilion for later disassembly and reassembly may on the contrary provide an important opportunity to explore circular construction concepts that are not possible, feasible or common in full-scale buildings at present – either for logistic challenges, due to clients' short-time perspective and corresponding budget, or owing to expectations for the materials' visual and performative properties. The pavilion's focus on circular materiality also brings these issues to a broader public awareness, and if designed in an education context, equips future architects with a corresponding mindset and skills that they can bring to future projects.

1.2 FOUR CIRCULARITY FOCUS AREAS

Even when employing renewable resources that in addition store carbon, such as timber, the environmental benefits are maximized when the materials are in use as long as possible and when their use is planned in a cascading circle – not ending in a landfill[3] but feeding into energy or soil production [3]. This cascading circle may be understood as a perpetual succession of four use stages, or focus areas, that each tries to minimize material or energy losses along the way.

- *"Plan A":* The first focus should always be on extending a building's life span. This is supported by the construction's durability, the building's maintenance, the layout's and surfaces' adaptability and the building's overall lovability and acceptance [4].

[2] Samuel Blumer, sblumer ZT GmbH, Austria, samuel.blumer@sblumer.com

[3] Since 2009, landfills with biologically degradable materials such as wood are not allowed in Norway.

https://doi.org/10.52202/069179-0472

- *"Plan B":* If at some point, the building needs to be taken down, it should be possible to reuse it as a whole, or its components with the least modification and the least loss of material possible (design for disassembly) [5]. The re-use of building components is eased by access to their documentation or information about previous approval details (e.g. catalogued in a database). It furthermore requires the space and the logistics of storing and marketing them.

- *"Plan C":* When building components do not allow any further reuse, their materials' recycling will give them another life. Even when flagged as "upcycling" however, this new life is sometimes a dead end, for example when the materials' treatment only allows for later disposal in a landfill. The recycling of materials is supported by their non-toxicity and their separability into components.

- *"Plan D":* Materials should always be treated in a way that does not impede their later composting for soil amendment or their combustion for energy production. However, some paints or impregnations turn wooden materials into hazardous waste, and composites are often impossible to separate into their organic and inorganic constituents.

While previous "Timber Studio" courses at The Oslo School of Architecture and Design (AHO) have mainly dealt with "Plan A", this course's task has been designed to predominantly address "Plan B" and "Plan C". Focussing on wooden construction materials, the course paid special attention to their provenience (e.g. pre-used, cut-offs, waste, left-overs) and to their afterlife (not impeding composting or combustion). It furthermore engaged in design for disassembly and scenarios for subsequent uses.

2 METHODS

2.1 A DESIGN-BUILD MASTER STUDIO

The master's studio course *Re:Source Pavilion* was taught during the fall semester 2022 at AHO. It has developed the concept, program, design, construction, details, production and assembly plans of a wooden pavilion that is planned to be exhibited on a city-centre site during the World Conference on Timber Engineering 2023 in Oslo. Its 21 students from Norway and from abroad were at different stages of their master studies. The teacher team had special expertise in architectural design and theory, timber construction, parametric design, and static engineering. Both at a midterm review and at the final review, invited guest critics provided critical feedback.
The students worked with a variety of individual and group tasks, and in changing group constellations. Each student wrote one lecture report, presented one precedent analysis, and shared photographs of their favourite details from a study trip to Switzerland.
The students' playful first design task was individual as well. Each student got 1m of AHO terrace boards that had been retained when the school's deck got shifted during summer vacation. Only by subtracting material (grinding, sawing, cutting, sanding etc.), the students transformed their boards into something new, and formulated their thoughts in a short poem. The ensuing discussions among the entire group introduced a wide range of topics with relevance to the course's focus on wooden materials and their repeated use.
The students then suggested pavilion concepts in groups of 2, voted for which ones to refine, worked on pavilion designs in groups of 4, voted for which ones to continue with, and in groups of 7 contributed to develop the 3 final conceptual, spatial, and constructive pavilion designs that will be described more in detail in this paper. The diagram in
Figure 1 illustrates each student's path through the semester's group constellations.
Several efforts were made to foster the sense of contributing to the entire group's knowledge gains instead of individual achievements. As an example for the sharing of ideas across projects, when voting for the projects to continue with, the students would also point out ideas or aspects they would like to see followed up in later designs, without the project the ideas originated from claiming exclusive ownership to these. In the large final groups, each student developed an individual field of "nerd expertise", diving deeper into the different aspects of the project (e.g. parametric modelling; detail drawing; the logics of prefabrication, transportation, assembly and disassembly; or building and mounting 1:1 mock-ups).

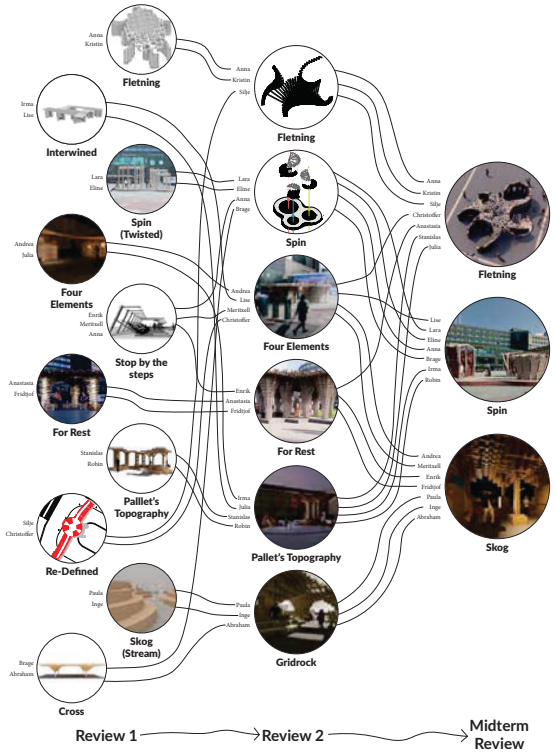

Figure 1: *21 students contributed to the projects in varying group constellations (Illustration: S. Corbevin).*

https://doi.org/10.52202/069179-0472

2.2 WORKSHOP EXPERIMENTS

A series of experiments in 1:1 scale was conducted at the school's workshop hall. In a first session, "disregarded" wooden materials reclaimed from waste facilities, a CLT producer and a disassembled, obsolete barn were joined into larger construction members.

The students' suggestion *Leftover Ceiling* created dowel-laminated slabs consisting of leftover boards with different formats and surface qualities, their edges aligned to a flush surface on one side and with a varied relief on the other side, imagining that the irregular side could remain visible in the room underneath (Figure 2).

To Glue or Not to Glue tested glue and wooden dowels as alternatives for joining pallet boards into thicker and longer elements that were used in a block construction and a cross-laminated floor slab (Figure 3).

Pillar and Beam made use of rescued plywood pieces to vertically join old components to longer columns. The plywood pieces were joint horizontally by adding simple top- and bottom flanges that only needed few screws to be held in place, resulting in wooden I-beams (Figure 4). This was also imagined to be a way to vertically join the ancient columns from pre-industrial barns that had been retrieved for this workshop.

Gradient Wall explored varying degrees of transparency by inserting plywood pieces in gradient angles between a top and a bottom beam made from CLT parts that had been cut out of CLT walls to create openings (Figure 5).

Stacked Triangles explored ways of joining boards into triangular segments and stacking these or connecting them in one plane (Figure 6).

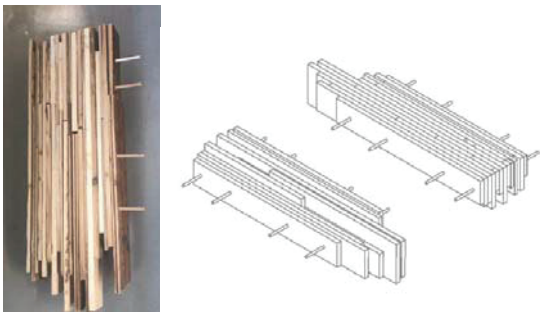

Figure 2: *Leftover Ceiling*

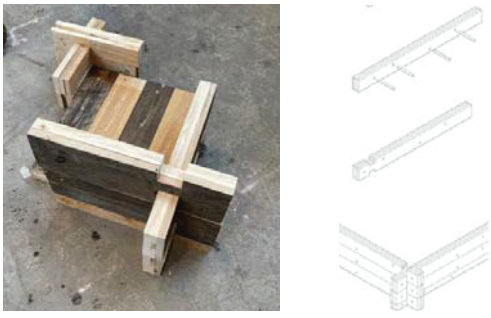

Figure 3: *To Glue or Not to Glue*

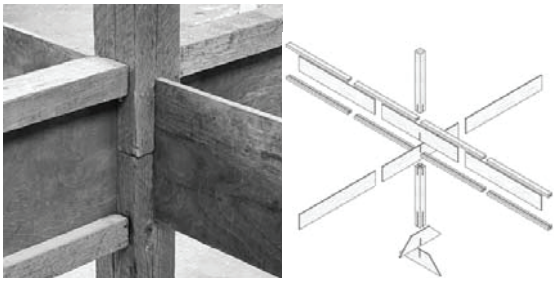

Figure 4: *Pillar and Beam*

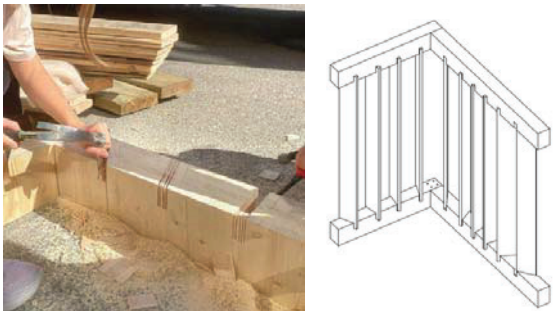

Figure 5: *Gradient Wall*

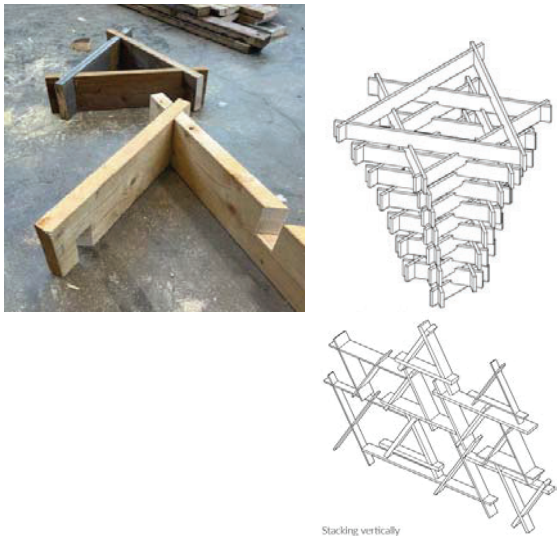

Figure 6: *Stacked Triangles*

As part of a later task, the students' pavilion designs were tested in 1:1 detail models, and a section of each of the three final pavilion designs was built as a full scale mock-up for the final review and exhibition at the AHO gallery (Figure 10, Figure 14, Figure 18).

https://doi.org/10.52202/069179-0472

3 RESULTS

3.1 FINAL PAVILION PROJECT 1: SKOG

"Skog" means forest in Norwegian, and the project departed from the wish to recreate the experience of being under a forest's treetop canopy, with the light filtered through different layers of leaves and branches, and an undulating forest floor beneath (Figure 7). From the outset, this intention was formulated and explored through hand drawings, a poem, various model iterations and digital visualizations.

The final project consists of 13 trees with a wooden gridwork symbolizing the tree crowns. The trunks consist of four square parts that are anchored in a base plate which is hidden in a modular stepped landscape. The landscape can be used as an informal sitting amphitheatre or during presentations and other events, and indicates areas for the exhibition of objects or prints (Figure 8). Due to the limited possibility of clamping the trees at the base, they were also connected to each other at the top. This creates a so-called social static system with a frame effect. In the case of local overload, the stress peaks are taken over by the neighbours.

The physical mock-up was made from left-over materials (2'x2' battens) after another course's concrete workshop at AHO (Figure 10). While the physical and digital models suggest standard 2'x2' formats in defined lengths, one can also imagine members with varying cross sections and/or lengths as well as surface qualities, especially in the places where these are only attached to the gridwork on two sides.

The students considered options to protect the gridwork's end-grain parts, either with a translucent roof plate or with small caps covering the horizontal cut faces. They finally decided to leave the wood unprotected and to embrace and exhibit its degrading process – possibly even at a secondary site in the forest where the construction materials originally came from (Figure 9).

3.2 FINAL PAVILION PROJECT 2: SPIN

Spin consists of three pavilion segments that can be rotated in order to create a wide range of spatial constellations that facilitate different activities, such as lectures, presentations and concerts, a pathway along the pavilion's differently treated panels or other smaller exhibitions, large audiences, smaller groups and coincidentally attracted passers-by. The rotation is made possible by mounting the pavilion segments onto the slewing rings from disused excavators. These are hidden in a stepped base plate construction (Figure 13).

With the wood stemming from an obsolete barn close to Oslo, the pavilion's dimensions are conditioned by the materials available. The students were able to make use of pre-existing 3D data of the barn's elements in order to maximize material efficiency. Former beams and columns make up the pavilion's load bearing frames (Figure 11). Wooden dowels are used for the pavilion's permanent connections, with rescued plywood parts reinforcing the joints (Figure 14). Demountable parts are joined by steel dowels. The old cladding makes a reappearance in the pavilion's vertical spaces between the frames. They are treated (sanded, oiled, painted, engraved, etc.) in various ways in order to show the wealth of options for processing or upgrading pre-used materials. Disused surfing sails are used to protect the wood from rain and to add colour to the design (Figure 12).

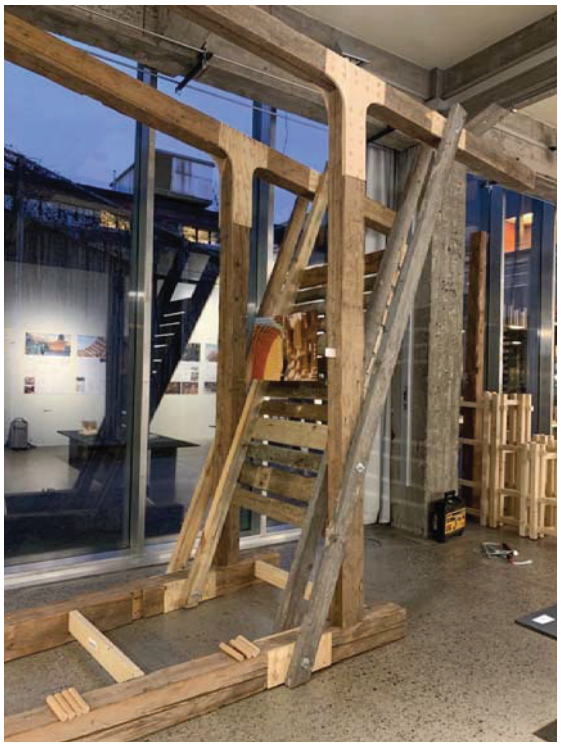

Figure 14: *Plywood parts reinforce the wood dowel connections (1:1 mock-up).*

https://doi.org/10.52202/069179-0472

3.3 FINAL PAVILION PROJECT 3: FLETNING

During the processing of wood into standardized industrial building materials, wood loses one of its original qualities, namely the organic shapes of the tree and its parts. This pavilion project's ambition was twofold: to create organic shapes with highly standardized industrialized wooden materials, and to mainly use short dimensions as more readily available from wood waste and cut-offs.

"Fletning" means weaving in Norwegian. By stacking rows of short, offset 2'x4' pieces ("wood bricks") with altering angles, the resulting semi-transparent walls allow glimpses through the construction that vary with every step when passing by (Figure 15). Towards the wall's top, the pieces gradually increase in length and create a cantilevering canopy (Figure 18). In some places, other walls' tops complete the geometry of an archway. Three such walls are arranged in a curved geometry that both ensures stability and creates subspaces for smaller exhibition sections, sitting areas or a podium. The structure's geometry has been parametrized in a digital model for full flexibility in the form-finding process. In order to compensate for the laterally projecting walls' lack of weight, the students suggest a disk-shaped roof element that is filled with earth for weighing down the pavilion against wind forces. It is clad with disused offprint metal sheets that mirror the construction and visually continue the pavilion's central space (Figure 16). Another option could be to omit the roof plate and to hide sandbags in the two podiums instead. The wall itself is made up of smaller ca.1m wide blocks that consist of 11 wood brick layers and weigh about 38kg each. They are joint by long wooden dowels that create a loose fit with the middle layers' holes and a tight and permanent connection with the outer layers. Stacks of these blocks are held together with steel rods, and these segments are joined with other stack segments (Figure 17).

Depending on the "re:source's" provenience – either from a waste facility or collected at a production facility – the materials' surface will either be weathered or more or less pristine. In contrast to most conventional products with the exposed surfaces aligned with the wood fibres' direction, here the end-grain's cut fibres face the visitor. If most pieces are cut to length, only a few weathered pieces will mix up the frontal view's colouring, but due to their angled placement, also the lengths' surfaces will be discernible. As only parts of the pavilion are protected by a roof, its walls will weather differently and increase the walls' visual homogeneity.

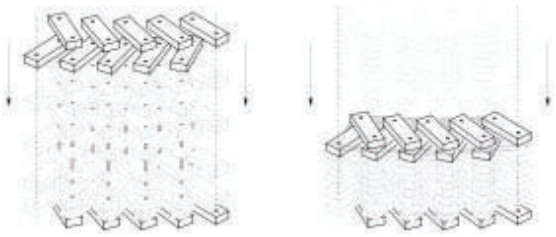

***Figure 15**: "Wood brick" layers are joined into a block and then stacked. Altering in orientation, they create varied transparency.*

***Figure 16:** Fletning's organic curves visually continue as a reflection in the roof disk (rendering).*

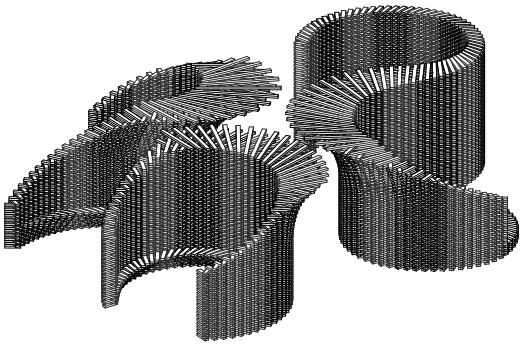

***Figure 17:** Wall segments are assembled into curving walls for stability and spatial differentiation.*

***Figure 18:** The "wood bricks" increase in length to create a sitting bench and to extend into a partial roof (1:1 mock-up).*

4 DISCUSSION AND CONCLUDING COMMENT

The work on the pavilion projects and the course's accompanying tasks addressed a number of issues that are specific for the design with "disregarded" wooden materials.

4.1 STRATEGIES TO JOIN SMALL PARTS INTO LARGER CONSTRUCTION MEMBERS

There is an element of unpredictability of the available sizes and qualities when harvesting disregarded materials. The students realized that shorter pieces were more common to find than long boards, panels, beams or large plates.
Different products were aimed at when joining small parts into larger construction members and thereby creating larger surfaces or increasing lengths and spans: planes (slabs), linear members (columns and beams), gridworks and bent surfaces with varying degrees of transparency.
Availability, fabrication, logistics and assembly on site were discussed and are mirrored in the resulting connections.

4.1.1 Permanent and disassemblable joints

The projects made a differentiation between permanently assembled construction members and joints between such members that need to allow for repeated assembly and disassembly.
Permanent connections typically involved glue or wooden dowels in places where a later dismantling was not considered relevant. For the wooden dowel connections, dried wooden poles were inserted into slightly more narrow pre-drilled holes. When the wooden poles adapt to the ambient moisture and expand, they permanently lock the parts together. It is difficult to dismantle connections with wooden dowels without destroying them. For example, the wooden dowel connections in *Spin* can only be removed by sawing them or by drilling them out. The wooden dowels permanently join beams and pillars into parts that still fit into a container and that can be raised by manpower.
Steel bolts in the connection details between these segments can be attached and detached repeatedly.
In *Fletning*, wooden dowels connect 11 layers of "wood bricks" into permanently joint blocks. Weighing about 38kg each, these can be handled by manpower. The stacked blocks are joined with removable steel rods and attached to other stacks.

4.1.2 Including diverging dimensions while minimizing cuts

Some of the workshop studies addressed the issue of minimizing adjustments to obtain equal formats when found materials differed in cross-section and/or length. Among the preliminary workshop experiments, *To Glue or Not to Glue* avoided the problem by basing their proposal on the components of standardized pallets. *Leftover Ceiling* aimed to expose the differing heights and lengths of the included reclaimed boards on one side, aiming to activate the visual and narrative potential of their product. *Stacked Triangles* also suggested versions where the boards circumscribed equal triangles while continuing outwards according to the found lengths.

Many of the pavilion projects were initially imagined with freely defined formats as usual in conventional projects where one can choose from a range of available formats and looks, and only later turned to embracing the unique and unpredictable qualities and dimensions of reclaimed wooden materials. However, also the final projects all have some potential to integrate found formats to a greater degree.

Skog: While the students aimed for a clear overall geometric shape and envisioned the pavilion with identical 2'x2' profiles, the canopy's construction system would also allow for integrating different lengths, resulting in a geometrically less controlled underside or top (or both). In contrast to other parts in the crowns' gridwork, its (at present) shortest pieces are only attached on two sides, which would allow for attaching other formats than 2'x2' cross sections as well. Visual consequences could be studied in the pavilion's digital model that served for visualizations and for a VR tour of the project.

Spin: The dimensions of an actual obsolete barn considered suitable as re:source co-defined the size and shape of the pavilion. As described above, the use of pre-existing 3D data of the barn's elements allowed the students to maximize material efficiency. With longer or shorter members available, for example from another obsolete barn, the pavilion's parametric model can be adjusted accordingly.

Fletning: Confronted with the complexity and laborious production of their pavilion, the students highlighted that 70% of their "wood bricks" were identical, while the rest differed in length. However, the key invention in mastering the complexity may lie in using the same drilling stencil with a defined distance between the holes for the dowel connections in all wood pieces, no matter their length (or even height if it is the same for an entire layer). Precision in the distance between these holes is of key importance for the pavilion's assembly, while – as is the case in *Skog* as well - precision in the components' length only matters visually.
The flexibility to include different formats (as long as they have the same height per layer) might alleviate one fallacy: the pavilion's design is based on cut-offs in the most common dimension, as these are most likely to find at waste facilities. However, this universally applicable format also makes these the most sought-after pieces. The further refinement of the design could integrate pieces that are less attractive for subsequent users.
Catering for a greater variety of lengths when minimizing cuts, one could align the pieces in a different way than in the students' project, for example creating several partial covers over each curve instead of the central area between the three curves, or creating random reliefs on one or both sides of the walls. Using the same basic design as the student's proposition but with random (found) lengths, the increasingly cantilevering walls would create vaults and

https://doi.org/10.52202/069179-0472

archways of a less regular geometry. These geometrical options may be explored in the pavilion's parametric model.

4.2 WEATHER PROTECTION

The pavilions feature different ways of handling the protection against weathering and decay. *Skog's* student team explored several options, but favours to expose the pavilion fully to the elements. *Fletning* suggests partial coverage, and *Spin* provides protection of all upright elements except for the base.
If the pavilions are no longer used as a temporary structure, adequate structural wood protection must be provided. The roofs should be constructed in such a way that the joints are not directly exposed to the rain.

4.3 ADDED WEIGHT

On an exposed site, high wind-induced uplifting forces occur. In order to compensate for wood's light weight and the lack of foundations in the temporary constructions, weight is added to the pavilions' roof or floor construction: the designs allow for adding sandbags, earth or other heavy materials in *Skog's* landscape, in *Spin's* base or in *Fletning's* roof plate or podiums. The added weight helps to fix the temporary pavilions in place against strong winds without the need of fastening them to a foundation on site.
Connecting several elements like in *Skog* or arranging connected frames in a half circle like in *Spin* additionally stabilizes the construction.

4.4 PROVENIENCE AND PROVENANCE

The re:sources' provenience as their place of extraction, or more precisely, retrieval, has been important – both as a justification for the pavilion as a building task, and as a specific area of investigation, as the materials' previous function, use, treatments, removal (cautious or careless) and storage all condition their visual and performative qualities as well as choices for their later processing and according use of tools in a technical perspective.
The material's previous life entails yet another dimension than just the performative one, which has been embraced in different ways in the student projects. In contrast to provenience as the exact location of retrieval, the term provenance is used to address the detailed history of an object, for example the different owners and exhibition or storage circumstances of an artwork. The materials used by the students all witness of their history, for example with traces of axe cuts from times before other tools were invented, with different layers of paint, with insect holes, with the overall roughening effect of weather exposure or the locally smoothing effect of repeated touch.
How these signs of previous life were valued differed – in some cases, they were consciously preserved and exhibited (e.g. in *Spin's* frames and parts of its cladding, or in *Fletning's* wood bricks), in other cases, they were ignored, evened-out or removed (e.g. in *Skog's* gridwork or in other parts of *Spin's* cladding).
The materials' provenience and provenance were of particular interest when discussing the use of obsolete barn materials, some of them from preindustrial times. The abundance of disused barns all over rural Norway most often leads to their demolition – in some cases, they at least serve for fire brigade exercises before turning to waste.
If the oftentimes quite solid materials can be used in constructions instead, even when just hidden between gypsum boards, they can still play an important load-bearing role and replace more harmful materials or ease the pressure on fresh wood. The same is true when cutting or planing the material to obtain parts that are straight or equal. Then, the old traces may still be discernible in part, while including the retrieved components mostly untreated will expose these qualities more fully.
In order to access a greater part of these narratives than only the visually accessible ones, some circular building projects label the materials with QR-codes for the visitor's information. This additional information beyond the architecture's mere atmospheric experience may even change the appreciation of the architecture's visual, experiential and functional qualities. What may be criticized in other cases is potentially valued when associated with the materials' previous life and the intentions behind their reuse.

4.5 PROJECT STATUS

The three final projects, together with the terrace board exercise and the workshop experiments, have been exhibited at the AHO gallery in December 2022 and are planned to be shown again during the conference.

It had been the wish of the WCTE arrangers to erect one pavilion at Oslo's Central Station during the World Conference on Timber Engineering in the summer of 2023. Out of the three final projects, a jury recommended *Fletning* to be built in full size for this purpose. The jury consisted of the course's external censor (Siv H. Stangeland from Helen&Hard), the course's teachers (3 architects and one engineer), a representative of WCTE and a representative of the engineering firm that was going to act as the responsible applicant (Sweco). The assessment criteria collectively agreed upon were the projects' poetic and conceptual approach, experiential qualities, functionality, resource use, originality and innovation, feasibility, disassembly and reuse options, and transferability of research insights.

At the point of this paper's submission deadline, the process of realizing the winning proposal has not started yet; an update will be included in the conference presentation.

4.6 EXPECTED CHALLENGES

A number of challenges are expected when realizing the winning proposal. *Fletning* is considered to be buildable, but intermediate storage and timing are expected to be the main challenges.
The manual assembly of *Fletning* has been tested by students in 1:1 mock-ups; it is relatively simple and can be done by untrained workers, but time-consuming and difficult to estimate for the pavilion's entirety. All larger pieces must be prepared in advance and their assembly

well-planned and tested, as the time window for mounting the pavilion on site is short. Possible unevenness of the site may complicate the pavilion's assembly somewhat. The storing of gathered materials and assembled parts will require adequate storage space over longer time. Security issues and possible vandalism need to be addressed carefully. The pavilion's after-life is not decided at the point of the paper's submission.

4.7 CONCLUDING COMMENT

The results of AHO's master's course *Re:Source Pavilion* showcase that vast architectural variety is possible when basing the design on readily available, disregarded wooden materials. Joining smaller and irregular pieces into larger construction members will be relevant for larger building projects as well. In the load-bearing parts of conventional projects, the formal and atmospheric potential of disregarded materials such as waste wood, cut-offs, cut-outs from CLT production and materials directly retrieved from obsolete buildings may not be fully taken advantage of.

The narrative and associative potential of discernibly reused materials may elevate their value for some, especially when their visually accessible qualities are complemented by information on their previous location(s), function(s) and modification(s).

In more rational (purely functional) assemblies, disregarded wooden materials may still play an important role in replacing more harmful materials and reducing the need for fresh wood, while at the same time maximising the life cycle and thus carbon storing benefits of wooden construction materials.

The necessary labour and related need for storage and transportation need to be carefully assessed in order to avoid the latent risk of promoting circularity for its own sake [6]. However, what is not established and competitive today (both budget-wise and in a LCA perspective) may become easier to achieve and more feasible in the future – both due to more established routines and systems, and potential legal changes.

ACKNOWLEDGEMENTS

The timber studio *Re:Source Pavilion* reflects the engagement and collaboration of a number of teachers without whom neither the pavilion as a built project nor as a contribution to architectural discourse would have been possible. Besides the paper's main author and course responsible Ute Groba, Samuel Blumer, Rune Veslegard and Moritz Groba have been part of the course's set-up and content and have contributed to this paper.

Likewise, the course students' ideas, explorations and work efforts are essential part of this endeavor. Thank you to A.B. Visiedo, J. Böttcher, S. Cornevin, F. S. W. Fønstelien, K. Guðmundsdóttir, R. Haugaas, L. B. Heidenreich, I. Jorganovic, C. I. Kirsby, L. B. Kjeldseth, N. A. G. Lerkerød, B. B. Lervåg, M. M. Barril, E. R. Martínez, P. R. García, A. M. Skelton, E. Svelle, A. Uusihärkälä, S. M. H. Vikene, A. Volkova and I. Wiig.

Furthermore, the course has been sponsored with materials for the workshop experiments and final mock-ups. Our deep gratitude goes to Omtre and Kristine Nore. We are also grateful for extra support during the pavilion's realization by sblumer GmbH.

ADAPTABILITY IN MULTI-STOREY TIMBER BUILDINGS – TOWARDS DIFFERENTIATED DURABILITY LAYERS IN ARCHITECTURE

Esther Vandamme[1], Mario Rinke[2]

ABSTRACT: The rise of multi-storey timber architecture has been recognized by multiple actors in the field. Most contributors discuss new timber buildings made with engineered wood products (EWP) almost entirely technologically, neglecting both spatial-architectural and organisational-functional aspects within buildings. Furthermore, even though today's timber structures are designed for longevity, studies show that more than half of all buildings are demolished not because of technical deficiencies but because of vacancy. This suggests that most buildings have an insufficient potential for adaptation.

This paper critically discusses current approaches of adaptability in timber construction and examine their relevance and effectivity within the larger theoretical framework of architectural adaptability. For this purpose, both areas are discussed based on existing literature and compared in their central aspects. Based upon three case studies in Europe, the principles of adaptability for timber buildings are visually traced and analysed.

In conclusion, precise demands for zones of changeability and permanence within the building can be predicted and timber components can be applied accordingly in a targeted manner. The paper proposes strategies for designing a timber construction that is differentiated according to the functional layers and designed to be able to adapt over time.

KEYWORDS: Circularity, Adaptability, Flexibility, Timber Engineering, Structural Design

1 INTRODUCTION

Thanks to new technology and advances in material research, wood is experiencing a renaissance as a modern building material. The ground-breaking improvements in engineered wood products (EWP) in the last decades have fundamentally changed timber architecture. Moreover, the rise of multi-storey timber architecture has been recognised by multiple actors in the field, i.e., architects, engineers, manufacturers and academics alike. However, most contributors discuss new timber buildings with four storeys or more almost entirely technologically, neglecting both spatial-architectural and organisational-functional aspects within buildings. [1] In general, studies show that more than half of all buildings are demolished not because of technical deficiencies but because of lying empty. [2, p. 421] Therefore, even though today timber structures made with EWP are designed for longevity, most buildings most have an insufficient potential for adaptation. As Geldermans (2016) notes, adaptability is a prerequisite for circularity, as it generates quality and added value.[3] This raises questions about the current discourse of adaptability in timber architecture regarding the actual circularity of a modern timber construction beyond the promising role of the biomaterial.

In recent years, a certain amount of important work have addressed the circularity of timber buildings. In general, Ellen MacArthur Foundation's definition of the circular economy as an 'economy that is restorative and regenerative by design, and which aims to keep products, components and materials at their highest utility and value at all times, distinguishing between technical and biological cycles' is accepted in architectural and timber engineering literature. [4, p. 5] In this respect, the six ReSOLVE Framework actions for the implementation of circular economy (Regenerate, Share, Optimise, Loop,

https://doi.org/10.52202/069179-0473

Virtualise, Exchange) are too broad to be directly applied as guidelines for the design of circular buildings. [5] Instead,, Cheshire outlines five design principles for applying circular economics: building in layers, designing out waste, design for adaptability, design for disassembly and selecting materials. [6] Similarly, in structural engineering, design for robustness, design for durability and design for repairability can be added as circularity strategies. [7] In this paper, we focus on adaptability following the findings of previous studies that 14% of the embodied greenhouse gas emissions can be prevented if a structure is reused instead of recycling its materials. [8, p. 9] Although referred to as 'flexibility' in several publications, [9], [10] we accept Schmidt and Austin's definition of adaptability as a capacity of a building to accommodate the evolving demands of its users and environment effectively, thus maximising value through life. [11]

While research on adaptability in architecture has developed a nuanced understanding of the gradual permanence of building layers throughout the lifespan of a building, the discussion on adaptable timber buildings mainly considers general technical aspects such as those of the building elements and connections. Besides these aspects, most literature neglects social and economic indicators. [12, p. 18] Hence, the architectural discourse can expand the technical discourse of adaptability of multi-storey timber architecture by taking into account social, cultural and economic indicators. In so doing, it can reveal strategies for designing a timber construction that is differentiated according to the functional layers and designed to evolve over time. In this way, building adaptability brings an overarching coordination layer to the design process, in which material and constructability decisions can then be coordinated explicitly concerning overall long-term goals. As consumer expectations, technological progress and competitiveness are increasing, the need for adaptability is likely to increase as well. [13]

The aim of this paper is to critically discuss the current approaches of adaptability in timber construction and examine their relevance and effectivity within the larger theoretical framework of adaptability in architecture. For this purpose, adaptability in timber engineering and architecture are discussed based on existing literature and compared in their central aspects. Subsequently, they are brought together in spatial diagrams in which the potentials and conflicting goals are described.

2 METHODOLOGY

For the purposes of this paper, the particular features of 'circularity' and 'adaptability' in timber engineering are analysed through a comprehensive literature review. Previous research on the topic of adaptability and circularity in timber engineering is searched for in the online databases Scopus, Jstor and Web of Science. The searches conducted in April 2022 requested the key words: timber AND engineering AND circular OR circularity OR adaptable OR adaptability, and was repeated in November 2023. Based upon these findings, the list of circularity facilitators in section 3 is distilled. These themes are examined with a focus on their inherent environmental goals and circular strategies.
Similarly, in section 4 the most significant approaches to adaptability in architecture are discussed. The canonical work of Schmidt and Austin, and Leupen and their references are taken as a starting point for the definition of adaptability. Additionally, the data-driven study of Ross (2016) and its preliminary results are a basis for a theoretical framework of adaptability enablers, complemented with the references of the theory of adaptability. This is followed by a critical positioning of the technical engineering approaches therein.
In section 5, the insights from key papers and books discussed here are supplemented by applications in practice that have been discussed and referred to by scholars. The most recent literature on the rise of timber architecture (from 2020 onwards) is taken as a base for the analysis of the trends and the identified indicators. These indicators are evaluated against three cases, chosen for their variety and exemplarity of the current trends. The case studies in Europe are multi-storey buildings of various sizes and functions which are illustrative of the circularity and adaptability approaches found in the literature. The analysis of the cases is based upon the published plans and sources cited. As visual feedback is important for experts in the field [14, p. 10], the principles of adaptability are visually traced, modelled and analysed. This diagrammatic approach is based on Leupen's visual studies and Rinke and Pacquée's concept of structural porosity. [15] The method proposed here illustrates the sustainability potential of EWP and their contributions to adaptability discussed from the literature and relates them to the permanence layers of adaptability in architecture.

3 TIMBER ENGINEERING ON CIRCULARITY

Since wood is part of the biological cycle of the circular economy, structural timber has a high inherent circularity potential. Other inherent environmental benefits associated with structural timber are carbon storage, renewability, lower energy demand, malleability, durability, visual quality, thermal conductivity, lightness and recyclability. [16, p. 141], [17, p. 3] This is proven by multiple life cycle assessments comparing mass timber structures with similar variants in other materials. Even though carbon sequestration could suggest that maximising the use of timber is the most sustainable, this renewable natural resource should be applied efficiently: reduce, reuse, recycle. [18, p. 25]

Nowadays, sustainability objectives generate many incentives for larger timber construction, supported by subsidies and a growing expertise. However, circularity in

 https://doi.org/10.52202/069179-0473

timber buildings is faced with several threats, organisable in three categories: market forces, regulations, and physical conditions. First, due to resources running out, the competitiveness for forest products plead for intelligent use of timber. [16, p. 145], [19, p. 8] Also, the low material cost gives little incentive for recycling [16, p. 149], [19, p. 7]. Studies focus on the environmental impact of reusing or reprocessing salvaged timber in mass timber products or (non-)structural applications. [12, p. 18], [20, p. 9] However, there are very few examples in practice where structural timber has actually been recovered and reused, and just like other materials, timber has been downcycled or recuperated for bioenergy in Europe. [21]

Second, national regulations are inconsistent relative to timber building construction. The absence of adequate guidelines in the current edition of The European Standard Eurocode 5: Design of timber structures is particularly pointed out, although a new version is in the making. [17, p. 7], [22]

Third, some technological risks are also to be considered. The assessment of the structural performance of elements for reuse is difficult. [19, p. 7] Seismic resistance, acoustics, moisture performance and fire resistance are yet to have universal solutions with predictable behaviour and efficiency. [1, p. 103] The overall costs and risks of this relatively new mode of construction can be higher than standard structure, leaving little room for circularity. [1, p. 134].

This newness also provides an opportunity for establishing the regulations and expertise with a circular viewpoint from the start.

To design for circularity, the benefits and risks need to be clearly identified. In current timber engineering research, the main facilitators or strategies for circularity are:

1. Disassembly potential connections [1], [7], [16], [18]–[20], [23]–[25]
2. Avoiding glues, non-compostable coatings or elements [16], [18]
3. Keeping timber inside the thermal and waterproofing system and eliminating risks from internal water damages [16], [23]–[25]
4. Standardising components or modularity [1], [20], [23], [25]
5. Certification of circularity and reuse [16], [19]
6. An independent building envelope [1], [18], [23], [25]–[27]
7. Durability and possibility to repair or replace the damaged parts [19], [20], [26]
8. Facilitating the adaption to increased loads [19], [26]

The abovementioned strategies for wood as a circular structural material can be seen as design for disassembly (1, 2, 4, 5, 6), design for robustness (8), design for durability (3, 5, 7), or design for repairability (3, 7). Although design experts rate design for deconstruction/disassembly as one of the least effective enablers for adaptability [2, p. 426] [24, p. 25], it is mentioned most in timber literature. These strategies primarily focus on the material and components level of circularity. Very few studies focus on the scale of a building for circularity and on design for adaptability although this leaves the most of the embodied carbon in place. [28]

As Campbell argues [16, p. 150], there is a need for mass timber construction research concentrating on durability and adaptability for buildings as a whole. Also, Ahn argues that there is a lack of expertise and knowledge on circular mass timber construction and stresses the lack of research attention in the timber construction sector directed towards public and stakeholder awareness for the circular economy. [20, p. 12]

In summary, it can be stated that the technical conceptualisation for adaptability is limited to the element and material level and that the elements are discussed here largely independently of their local and functional use in the building.

4 ADAPTABILITY IN ARCHITECTURE

The disposable building culture has been called upon by multiple authors in the twentieth century. Nowadays, many features of the built environment are purpose-built. Before adaptability became a research subject, many vernacular buildings were already genuinely adaptable to functional problems and responded to changes. [29] The foundations of adaptable architecture are is found in the early Modernist movement and applied in Europe in the housing crises following the first and second world war. [9], [30], [31, p. 158] In the early sixties, the Dutch architect Habraken proposed a participative concept for public housing and thereby introduced the terms ‘base building’ and an adaptable ‘infill’. [32] The Open Building design movement was based on this first work. [33]

The definition of adaptability from Schmidt and Austin as given above can be understood both as a characteristic to accommodate the demands without changes to a space - also known as polyvalence [31, p. 26]- or by altering the physical form of a space. Therefore, they introduce six types of change: adjustable as a change of task, versatile as a change of space, refitable as a change of performance, convertible as a change of use, scalable as a change of size, movable as a change of location. According to Schmidt and Austin, the structure of a building interacts with versatility, convertibility, and movability, but scalability could be added. Circularity is not mentioned in the book, however the concept of adaptability clearly is linked to the circular economy.[11]

Even though all types of adaptability are to a certain extent realisable for any building, universal adaptability is not realistic nor advantageous. [11, p. 274] Many design practices are wasteful and over specify for instance electrical services or one-system connections which could be outdated or unavailable promptly. [11, p. 7] Modelling

https://doi.org/10.52202/069179-0473

building adaptation is in a nascent stage. [34, p. 284] Data-driven models are rare, but Ross (2016) cites four enablers for adaptability based upon expert reviews: separation of building systems, whether interiors are free of structural elements, reserve capacity and as-built documents. [2] These four enablers are discussed in following points in detail.

4.1 Distinct Layers

One could go back to Laugier's primitive hut [35] and discern a structure and a protective layer as two separate building systems. Also, Semper's [36] four elements - hearth, earthwork, roofwork and enclosure – can be understood as the origins of the layer's theory. In a modern context, Duffy (1992) recognizes distinct elements of (office) buildings in a modern context: shell, services, and scenery. The literature on circularity mostly cites Brand (1995), who proposes buildings consisting of shearing layers. [31, p. 31] Schmidt and Austin later defined building layers as nominal categorisations that describe a building at a given scale that allow for the stratification (decomposition) of a building as a way of gaining further insight into how it will change over time. [11] The separation of building systems facilitates change, as adjusting one layer does not imply other layers have to be adjusted. The differentiated rate of change of the structure versus - for example - the scenery creates a hierarchy between the layers. To the layer model, ARUP (2016) adds a system level to cover more of the built environment than just buildings. The report crosschecks the ReSOLVE framework with the layers of Brand.[37] Leupen, in 2006, spatially related the layers in axonometric schemes and theorized the frame and the generic space as a less hierarchical model. [31] His layers: 'structure', 'skin' (building envelope), 'access' (circulation), 'service', 'scenery' (interior) are accepted in this paper. The distinction of these layers is seen as the first enabler for adaptability.

4.2 Spatial overcapacity

The literature is unanimous about adaptability due to spatial overcapacity. 'Loose fit' promotes a larger floor area than is strictly necessary for the first use.[38], [39] An open plan free of permanent objects in space allows for easy conversion, stated as the second enabler. Loadbearing walls should be minimized. [11, p. 21] [24, p. 25] Likewise, heigh ceilings allow for maximum daylight, other uses and intermediate floors. Structural typologies such as a short or a wide span, skeletal or massive structures are likely to persist, since they are the backbone of a building. [11, p. 73] Overcapacity could also mean extra storage space, a bigger window size or a predesigned fire safety division. [11, p. 4] For example, constructions built before 1970 often have this extra load-bearing capacity or large dimensions and are therefore favoured by developers for reconversion. [40, p. 4]
To conclude, spatial overcapacity is incorporating the third enabler 'reserve capacity' for facilitating changes. [13, p. 213] A wall-based or column-based structural system and its floor height are seen as key parts in adaptability. Therefore, the choice of a structural system has a significant impact on its adaptability. The equilibrium between over-dimensioning and reducing material use generates a potential conflict which has to be assessed case by case. [17]

4.3 Readability

Readability is about conveying a message to be adaptable. Hence, as-built documents – the fourth enabler - are vital deconstruction information in order to disassemble parts but also to assess load capacity, demolition or repair diagnostics. [20, p. 7] [24, p. 23] Sometimes, however, readability is understood as simplicity. Schmidt and Austin expanded the concept of legibility as a straightforwardness and implicitly clean and exposed joints. [11, p. 96] Others go further and focus on easily understood load paths and repeating thus predictable layouts and grids. [2, p. 422] [13, p. 215] However, when Hertzberger accepts the rigidity of a structure on which an identity can be based, he accepts a structure which suggest spatial possibilities. [32, p. 24]
Simplicity could bring in functional neutrality. For example, 'Solids' are designed as urban buildings with different functions in mind. [40, p. 7] This neutrality is seen as a means of adaptability. Nevertheless, Leupen mentions 'articulating the frame' as a way to give it cultural significance. By adding architectural expression instead of neutrality, the permanent gains meaning and therefore endurance, it becomes an intelligent ruin. [31, p. 33] Or as architect Mies Van de Rohe states: 'Only a clear expression of the structure could give us an architectural solution which would last.' [31, p. 63]

Even though many strategies like these four enablers can be applied at little or no raise of the construction cost – with standard construction methods and decrease in construction time [13, p. 216] - universal adaptability of an entire building is not reasonable nor useful. [11, p. 274] Adaptability has mostly been researched at a building level. [41, p. 118] Aside of these most effective enablers, we propose to add zones of changeability where adaptability in a building is most expected depending on changing demands.

4.4 Degrees of permanence

The theory of shearing layers can provide the framework for applicable design principles, but they mostly refer to a building as a whole. Therefore, the hierarchy of the circularity layers and their durability should be adjusted to their degrees of permanence diversified in a building. While the structure could be designed to last one hundred years, the services and scenery will most likely be adapted in about 15 years. [42] As argued by Rinke and Pacquée in [15], access routes in buildings are less likely to be adapted because of their essentiality. A differentiated look at the structure has to be adopted. The function of a space

 https://doi.org/10.52202/069179-0473

as an access route demands a more permanent structure than the division between two programs. The shearing layers that were previously conceived for the entire building would therefore have to be related to the specific functional zones of the building.
Rinke and Pacquée define the porosity of structural surfaces, related to the higher-level porosity of the building, as the capacity to open walls or slabs. They suggest specific zones of a building which could be designed for disassembly, as a hierarchy of substructures and demountable components. Therefore, they refer to the first half of the twentieth century, where material economy and post-war reconstruction demanded faster and cheaper modes of construction. Their critique on the layer model challenges the unitary view of an entire building without differences in zones of permanence. The load-bearing structure, the functional areas, the access routes and the horizontal and vertical circulation of supply and people are seen as more permanent. [15, p. 4]
As the circulation system and access are critically necessary, they rarely are subject to changes. Other authors also consider vertical circulation as necessarily permanent. For example, Habraken mentions the staircase as a lasting feature. [32, p. 184] To improve the flow of people and things, the location and the number of cores (service risers) are critical adaptability parameters because of their difficulty to change. [11, p. 73] [13, p. 215] According to Leupen, access has significance and permanence if it takes up an extra function, for example a gallery being more than a corridor. [31, p. 114] Access could thus be a permanent layer.
In contrast, Remøy and Van der Voordt see the plinth of a building as more subjected to change. Consequently the ground floor could be the ultimate place for adaptability investments such as ceiling height and open plan. [43, p. 4] Also, in the centre of a building, Leupen intends an adaptable structure with an open zone which could be filled in with a wooden floor or accommodate service risers. [31, p. 166] These two examples demonstrate strategies for more volatile zones of permanence.
A structure's adaptability characteristics should be adjusted to the degrees of permanence of the structural members in the building.

4.5 Non-physical aspects

Other aspects of adaptability which are rarely included in timber literature, but which are very influential, are location (such as social image, amenities, public transport) and non-physical values such as acquisition and operation costs. [11, p. 152] A building always has a social function and has the ability for social change. [11, p. 20] Many of the experts involved in multi-storey timber projects are motivated by social, economic, and environmental aspects of working with the built environment and its stakeholders. Process adaptability should not be minimised but falls out of the scope of this paper. [34, p. 275]

4.6 Adaptability in timber literature

The abovementioned enablers and the nuanced zones of permanence can be compared with the strategies for circularity in timber engineering literature identified in section three.
Firstly, in the list of facilitators for circularity the concept of layering is presented as the building envelope 'skin' independent of the 'structure.' However, the detachment of other functional building parts, such as Leupen's other layers: 'access,' 'service,' 'scenery,' regarding timber architecture are not discussed. Nevertheless, Kaufmann mentions layers of timber structures for maintenance, disassembly and recycling. [18, p. 27]
Secondly, overcapacity is revealed as a technical option to facilitate higher loads, but spatially only Jockwer points out the possibility to adapt according to the comfort demands regarding room size and structure, acoustic and interior performance. [19, p. 9], [26, p. 2] The open plan, in this paper identified as part of spatial overcapacity, is not to be found as a strategy in the timber literature on circularity.
Thirdly, readability of a structure or the exposure of structural members is not detected in studied literature. The cited certification of circularity fixates on labelling components, while a full as-built dossier or a straightforward structure which could make the whole timber building readable.
Lastly, the focus on components and design for disassembly in timber literature demonstrates the conceptual design mode, where the building exists as a whole and can be disassembled. It overlooks the possibility for gradual changes through zoning and corresponding degrees of permanence. The closest to this strategy is repairability, which seeks the replaceability of damaged parts in an intermediate scale between component and building.

As Brand mentions, the buildings which proved to be the most adaptable (like Amsterdam canal houses) are built upon knowledge acquired by centuries of trial and error. [11, p. 14] Therefore, the abovementioned existing research on adaptability could be a basis for analysing and frame the current trends of multi-storey timber construction.

5 CASE ANALYSIS

5.1 Adaptability in practice

The current trends in multi-storey timber buildings are studied in [1], [17], [44], [45]. Recent developments in practice like prefabrication, system construction and rigid structural grids are critically discussed against the background of the presented adaptability research. In the following, these trends are assessed against the enablers for adaptability and the degrees of permanence.

For risk mitigation and time saving, onsite works are increasingly minimized and prefabrication is introduced. Since most prefabricated projects are focussed on simple

https://doi.org/10.52202/069179-0473

assembly on site, disassembly can be designed in a similar fashion. In contrast, old-school timber framed buildings are not designed for disassembly because of the extensive fixing of materials to the frame. However, the adaptability of contemporary timber structures might depend on the size and development of the prefabricated units. The deconstruction effort and cost depend on the size and weight of elements, the number and type of connections, and their location in the building. Disassembly might require heavy construction equipment like cranes and temporary scaffolding, just like during the construction phase. [20, p. 2] The larger (façade) units can complicate disassembly since they often arrive fully equipped and watertight on the construction site. [1, p. 134] This might also complicate the readability of a timber structure. Furthermore, when services are hidden behind a structural lining, the adaptability or refitability will be restricted. Above all prefabrication targets, services as well as all layers should remain separable.

System construction is an important trend in timber construction. As Kolb described the size of the prefabricated units as room modules, wall or plan units, or small modules, one can discern volumetric, planar or linear (post and beam or frame) systems. [46, p. 44] The earlier multi-storey timber buildings are mostly constructed in a cross-laminated structural system. Volumetric and planar elements were the two most common structural systems. [17, p. 3], [44], [45, p. 22]
The first structural system, volumetric modules, is programmatically very specific, as it is limited to room spaces. Hotels, (affordable) collective housing projects, retirement homes and schools are the most frequent programs in volumetric modules. These specific programs do not imply a high possibility of convertibility. [45] The entire volumetric modules can be removed but these blocks are often too large for changes in individual demands. [19, p. 8] In a repetitive and enclosed structure made of volumetric modules, there is no possible diversification based upon degrees of permanence. At the moment, volumetric modules incorporate few architectural versatility and there is no market push towards the functional versatility of volumetric modules. [24, p. 21]
The second structural system of the early multi-storey timber buildings comprises planar structures. Mostly up to 10 stories, the CLT structures allow only limited spans and require many wood resources. [47, p. 27] The massive use of CLT between functional spaces or room modules with two load-bearing walls contradicts the spatial overcapacity, open plan and the degrees of permanence of architectural adaptability. Out of 350 studied projects in [45], 79% of the buildings with planar systems have residential programs. This suggests a limited convertibility.
From 2011 onwards, hybrid and frame structures are rising, especially in the tallest timber towers. [17, p. 3], [44], [45, p. 22] The open plan makes space for spatial overcapacity. Unsurprisingly, linear systems have more evenly distributed programs with a focus on commercial, which implies high convertibility. [45, p. 22] There is a shift from residential planar structures to commercial linear structures. This suggests that timber buildings are evolving towards more open plans and thus provide more adaptable structures.

However, the linear systems are very dependent on the spans for their plan layout. In multi-storey residential buildings, smaller spans are usually used in timber construction compared to conventional solid construction with reinforced concrete ceilings, resulting in rigid structural grids. [1, p. 25] Based upon the principle of spatial overcapacity, a large span is desirable for adaptability. One can argue that this would use more timber resources than a smaller grid. However, the total cost of a timber frame structure with a larger grid is lower, as there are fewer joints, and those are the most cost-intensive factor. [46, p. 90] Also, the optimal column spacing is material specific. Still, many grid layouts are based the historically used materials like concrete and steel and are therefore not efficient. [48, p. 1]
Nowadays, the grid layout of rectilinear volumes with regular flat extrusion is dominant in multi-storey timber structures. Probably because of the industrial (pre)fabrication processes and the resulting linear or rectangular geometries, any deviation turns out more costly. [47, p. 30] Often, when greater design freedom is needed, other structural materials are used. Svatoš-Ražnjević challenges how these rigid timber structures will adjust to complex urban contexts. [45, p. 29] The repetition of the grid might suggest a readability and an open plan. Indeed, the rigidity of the element geometry could accommodate adaptability and the high degree of modularity required. However, more combination systems and hybrid structures can multiply the possibilities for a structure based upon the degrees of permanence. The specification of the structural grid is crucial for adaptability and a weighted effort of the expectations of the owner, architect, engineer and contractor. [48, p. 8]

To conclude, in multi-storey timber structures, the practice focuses on efficiency and technological developments. Yet, currently in conventional high-end taller building typologies spatial design is part of the development and engineering focus. [49, p. 8] Moreover, the architectural expression is purely the exposure of timber as a material. [45, p. 4] The discussion of the current trends shows that developments in modern timber construction are very dynamic. Their limited reflection together with increasing longevity demands suggest that more complex design strategies need to be discussed and applied.

In the following section, three cases are analysed against the adaptability types of Schmidt and Austin and the identified adaptability enablers.

https://doi.org/10.52202/069179-0473

5.2 Adaptability Case Vodafone Headquarters

The Vodafone Headquarters in Newbury, United Kingdom, is an example given by Schmidt and Austin (2016) for all adaptability types except movability. It is a part of the campus designed by Fletcher Priest Architects. Since 2003 the headquarters have been made up of seven non-timber buildings linked by demountable footbridges. The building's layers are distinct, as the separation walls are movable, the cladding part of the skin is replaceable while it contains loadbearing elements, and there are several free-standing cores for circulation and services (fig. 1).

It offers great convertibility due to the generous provision of good daylight through a central atrium in a doughnut plan. This is part of the spatial overcapacity with an open plan, polyvalent spaces, and a column-based structure. The typical floor plan reads easily and consists of two connected rectangles. The campus buildings are standardised, although of different lengths. The scalability is demonstrated by its possibility to split a building up into two bays or per floor thanks to multiple access points. However, there is no compliance with the degrees of permanence as the structure is uniform throughout a building. The architectural expression of the structure has not been discussed in the literature. This case is featured as an exemplary project for the current understanding of adaptability in the architecture literature. [11, pp. 215–217]

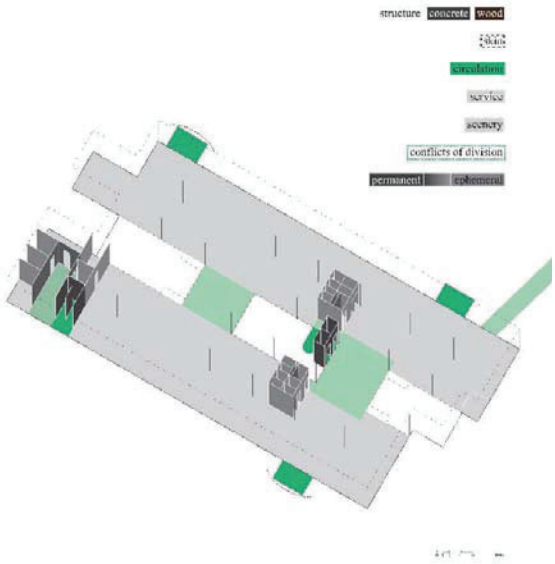

Figure 1: *Leupen 's layers and degrees of permanence on a typical floor of Vodafone Headquarters Newbury*

5.3 Timber Case Kajstaden, Västerås

In Västerås, Sweden C.F. Møller Architects and Bjerking designed a 2,400 m² tall building with a cross-laminated timber (CLT) structure. The CLT core provides structural stability to this nine-storey high housing block which opened in 2019. Thanks to the mechanical joints, the building is designed for disassembly. However, this building has little adaptability characteristics. The basic ceiling height of 2.5 m is generally limited with only an elevated ground floor and higher ceilings on the top floors featuring a spatial overcapacity. The façade 'skin' is loadbearing, and the structure is also the 'scenery' (fig. 2), which means that most conceptualised wall parts are directly translated into CLT panels. The division of the typical floor plan by load-bearing walls, however, might conflict with its versatility, as the load-bearing flat partition walls do not allow the floor plan to be rearranged at a later stage to accommodate larger units of use. Thus, there is no zoning according to the degrees of permanence, as the whole typical floorplan has a regular, non-hierarchical structural logic. The current size of the units, together with the given floor height, practically limits their use to residential. In the interior, there are no visible wooden surfaces, but the structure certainly has architectural expression in the façade.

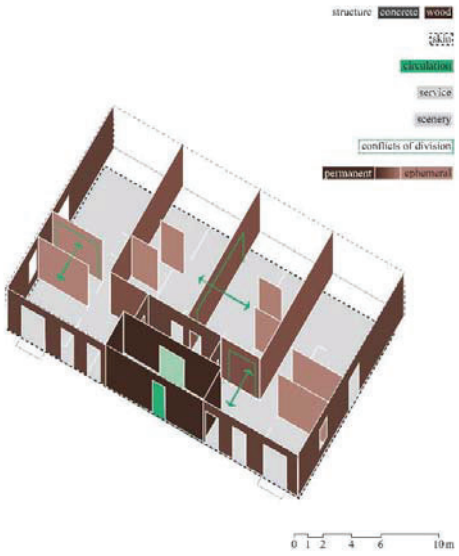

Figure 2: *Leupen 's layers, adaptability conflicts and degrees of permanence on a typical floor of Kajstaden, Västerås*

5.4 Timber Case Haut, Amsterdam

Team V and ARUP designed Haut as a housing timber-concrete structure in the Netherlands in 2022. The 21-storey building has a central concrete core and CLT load-bearing walls (fig. 3). The ceiling is left bare for appreciation of the hybrid wood-concrete slabs. The non-loadbearing façade is a detachable skin. The CLT walls divide the gross floor area of about 550 m² into eight spaces between 38 and 100 m². As Svatoš-Ražnjević writes, this post-and-beam construction at the perimeter with inner load-bearing walls might suggest "a link between heterogeneous structures and architectural

https://doi.org/10.52202/069179-0473

variety, or a compromise to achieve more flexible open spaces." [45, p. 16] Indifferent of the circulation, the same structural logic is applied to the whole semi-orthogonal floor. The combination of load-bearing walls and an undiversified structural logic with dispersed technical shafts might hinder its adaptability in the future. Even though the internal walls provide necessary stiffness against wind loads and torsion on the tower on serviceability limits, they are not necessarily always needed where rooms are divided. To detach the structure from the scenery and possible later circulation, some of the walls can be identified as conflicting with adaptability layers which should be reconsidered in an early design stage. This means that such walls, which delimit the corridor next to the lift or whole organisational segments of the building, are likely more permanent and thus well made of load-bearing panels. Other space-dividing walls between single room units, on the other hand, which could be removed to couple rooms later, should rather consist of frames that are then optionally filled.

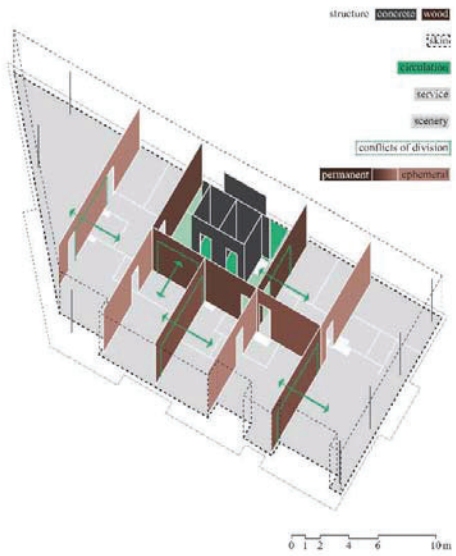

Figure 3: *Leupen 's layers, adaptability conflicts and degrees of permanence on a typical floor of Haut Amsterdam*

6 CONCLUSION

The premise of the paper has been that the design of multi-storey timber buildings has been discussed solely technologically. Even though timber is part of the biological cycle, experts need to work with the market forces, the regulations, and the physical conditions of wood to design for circularity. Circularity, as demonstrated in this paper, is considered very differently in engineering and architecture as both often refer to distinct levels of change. In timber engineering literature, circularity is focussing on design for disassembly and looking at components or materials regardless of their position in the building. In architecture, design for adaptability is based on several concepts, such as the separation of functional layers, providing spatial overcapacity and a readable plan layout. These strategies are not to be found in the timber literature. Also, mostly buildings are looked at here as a whole but omit the desirable diversification of adaptability according to the degrees of permanence.

The trends in timber buildings towards more prefabrication and volumetric modules are challenging the very concept of adaptability. However, there is a shift from planar residential structures to commercial linear structures, which suggests timber buildings are evolving towards more open plans and adaptable structures. The rectangular grid plan layout provides readability but might overlook architectural expression through its structure. The three cases exemplify the potential of adaptability concepts and demonstrate that more complex design strategies could be beneficially applied to timber architecture.

It is important to emphasize that the accessibility of the literature and availability of structural information on the case studies limit our findings.

The focus on material and components in the literature on circularity of timber architecture can be related to the massive influence and the relative newness of engineered wood products. Framing their potential for sustainable timber buildings within the conceptual architectural framework of adaptability, precise demands for zones of changeability and permanence within the building can be predicted and timber components can be applied accordingly in a targeted manner.

It would be insightful to apply the demonstrated methodology to contemporary multi-storey timber buildings which have been converted, but so far none are known. A post-completion analysis of timber buildings could significantly enhance circularity strategies in the field. Also, the stakeholders of these cases could be involved in further research on adaptability in timber buildings to better understand design conflicts.

PROPOSAL OF INTERACTIVE WORKFLOW FOR CIRCULAR TIMBER STRUCTURE DESIGN

Marcin Luczkowski[1], Sverre M. Haakonsen[2], Artur Tomczak[3], Bunji Izumi[4]

ABSTRACT: The methodology and design methods are often neglected and not discussed as indicators for the popularization of circular design. In this paper, which is part of ongoing research, we propose a design strategy and method for designing a building from reclaimed wooden elements, based on the actual building project case study in Oslo. The design method is a plugin for the Algorithms-Aided Design environment integrated with the database of available reclaimed elements. The plugin is based on algorithms suggesting suitable elements from the database in real-time. This helps the designer in tedious selection processes. Used in the concept and engineering phase of the building process, it can save time and rationalize design choices. The optimization objective is the structural performance and environmental impact of the final structure.

KEYWORDS: knowledge-based design, circular economy, timber structures, parametric modelling, algorithm aided design

1 INTRODUCTION

Timber products are light, relatively sustainable and have a good strength to density ratio. Increasing the usage of timber in construction is one of the priorities to decrease the environmental impact of the building sector[1]. The annual production of timber products is growing yearly worldwide, at the same time, timber production is limited by the sustainable forestry area in every country[2]. Some countries are already at the limit of their wood production capacity. Moreover, the use of timber is limited by the material price, which increased significantly in recent years [3].

Timber elements usually end their life being downgraded or burnt after the demolition of the building [4]. Downgraded timber elements sometimes come back to the building industry as plywood or other derivative products. Those products often require chemicals, such as glues, which make them structurally weaker, less sustainable, and sometimes more toxic. Every operation made to downgrade or even upgrade the timber product will lead to an increase in CO2 emission.

Today, the designed life span of the building is only 50 years [5]. The growing population of cities and changes in lifestyles require us to build higher and bigger buildings. In most of those buildings, the trouble with the structural system was not the leading cause of demolition[6]. Often the structural (load-bearing) elements are wasted, although they are in good technical condition and could be in use for the next decades. Timber elements are even great loss because the timber absorbs stresses with time, and it is rational to use it with a long lifetime.

To encourage engineers to involve circular economy aspects in the design, international standards have been created [7]. In those standards, it is highly recommended to pay attention to sustainability aspects of the structure already at the conceptual stage when it is still cost-effective. Our research group focuses mostly on conceptual timber design [8]. In this article, we want to show the study case in which the key concepts of the circular economy have been applied in digital design.

We observe a need for developing methods and methodologies to increase the usage of reclaimed timber elements in the building sector. The number of scientific articles, start-ups, and projects involving reclaimed timber is growing yearly. From a circular economy perspective, the ideal situation would be to extend the lifetime of buildings and not demolish but just renovate or repair them. Unfortunately, in many cases, the topology of the building must change. In this scenario, the reuse of deconstructed elements should be the priority.

The reusing of timber elements can be split in several steps. One of the most important is the timber classification. Many timber elements have been in use for decades. Timber properties can change due to rheology

and defects. Those information have to be set and preferably digitalized to be useful in common design process. After assessing all of the information, the database can be generated. The database should be usable in the design environment to provide an immediate feedback. It means that the access to the database should be provide directly from design software.

1.1 OBJECTIVES

The aim of this project is to show a possible change in the methodology of design by implementing a computational design method focused on using the available stock of reclaimed materials , also called Material Bank [9]). This project uses as a study case the design process for a small timber building in Oslo. The building called "Sletteløkka" is a timber extension of the existing building. It has its own supporting system built on the axial grid with a spacing of 2.5 meters. The length of the building is 10 meters, and the width is 5 meters. It has two stories with a floor height of 2.6 meters. The rooftop is placed 7.1 meters above the ground.

This project illustrates one possible computational method and methodology of conceptual design to reuse timber elements. Gathering the material stock (used elements), creating a digital material bank (a database with the digital representation of timber elements) and finally using a material bank in the conceptual and engineering design deliver several unknowns and important issues. How can we design from used elements? What is the best design strategy for the circular economy? How can the new technologies improve designing from material stock? How can we involve timber-specific mechanical properties and imperfections already in the concept design? How will reclaimed elements influence the structural and architectural performance of the building? Those are questions addressed in this work.

1.2 METHODOLOGY

This is a proof-of-concept paper describing an innovative strategy of supporting the design. In common design strategy, the decisions are in the linear form. Design steps must follow the decision made in the previous phase. Very often, choosing the cross-section of the elements is the last decision made by the architect or structural engineer. In design based on the circular economy, the geometry of the available reclaimed elements strongly impacts the design space. The designer has access to limited elements with limited shapes and sizes. Moreover, from an environmental perspective, the more reclaimed elements are used from material bank the more sustainable structure is. These facts demand implementing methodology with automated design methods. This design method should automatically map elements from the database with the building concept.
In a project like this, the methodology should use available design methods in the best way. This way, one of the challenges of designing with reused elements, namely the assignment of old elements to appropriate positions can be solved. The tool for matching old and new elements is a necessity in this project. Moreover, the whole concept design should be made in a more generative way. In this project, we used the Rhino/Grasshopper environment to apply a parametric workflow and to open the project for possible quick modification or optimization.

2 DESIGN AND WORKFLOW CREATION PROCESS

2.1 IDEA - BUILDING

The function of the building is a social, open-for-public space. With the help from the municipality of Oslo, volunteers and resident from Sletteløkka and Bydel Bjerke, together with the architects, initiated this project in 2019. Thereby providing a social space for all residents in the area. The architectural assumptions are to create an open and easy-access two-storey building. It should be accessible from both floors, and it should be easy to build. Since the neighbourhood society could be involved in erecting the building. One of the design limitations is that building from one side is touching the existing shop (see figure 1), but structurally it should be an independent structure. It means that the stiffness and structural performance of the structure does not depend on the surrounding structure.

Figure 1: *Front façade of the structure, on the right side of the structure, it is visible the existing shop building.*

However, the building is not as important as the materials which will be used to build it. The design team assumed to use as many reclaimed elements as possible. The reclaimed elements are used to create a primal structural system and also to use in not load-bearing elements. The façade system for the glass panels is produced from Japanese timber[7]. The elements used to create the structural system come from deconstructing an old barn in south Norway. In figures 2 and 3 the elements are marked with different colours and annotations, depending on their source. Norwegian timber has been reclassified as at least C30, and it can be used for structural elements. Timber from Japan is Japanese cedar (Cryptomeria japonica). It is a little bit weaker and elements from it has been dedicated only to transferring external forces to the main system.

https://doi.org/10.52202/069179-0474

Most of the elements have been 3D scanned from outside and physically tested on the macroscopic level.

2.2 IDEA - FRAMEWORK

The objective of this research is to find an appropriate design strategy to enable building it with reused elements. The design strategy, which follows and methods are algorithms, software, and tools which can lead to making this strategy as efficient as possible. Before it is explained how the framework has been applied, the assumptions are highlighted:

- In this project, the structural elements' database is known, but the design object can be adjusted. It is then needed to maximize the usage of those elements and, by this, increase the sustainability of the building
- The project is led by architects who would like not to change their habits to work in computational design. It is, therefore, necessary to implement a framework inside the design software, preferably with optimization working in the background.
- All the design decisions should be based on structural analysis. The algorithms should be using Finite Element Method (FEM) as the basic investigation tool.

Complying with these statements, the conceptual design is based on the parametric model made in Rhino and Grasshopper. Using this environment allows the inputs that define the geometry can be changed and adjusted. The axis spacing, floor height, roof angle or bracing position can be easily changed. The structural analysis of the structure is made in Karamba3D, which is merged with the parametric model. The outcome of Finite Element Analysis (FEA) is utilization and deformation. After creating an interesting topology of the structure and assigning sections, the matching algorithm is connected. After assigning the elements from the material bank one more time, the FEA proceeded. The last structural analysis is finally checking all the ULS and SLS criteria of the building (see the scheme of the framework in the figure 5).

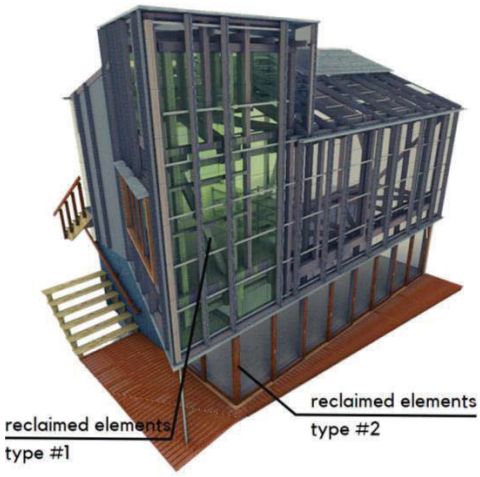

Figure 2: *General view of the structure with the facade, type #1 elements come from Norway, type #2 come from Japan.*

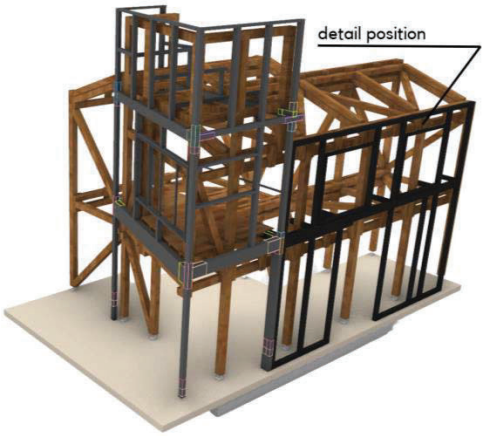

Figure 3: *General view of the structure without the facade, brown elements come from Norway, gray and black elements come from Japan.*

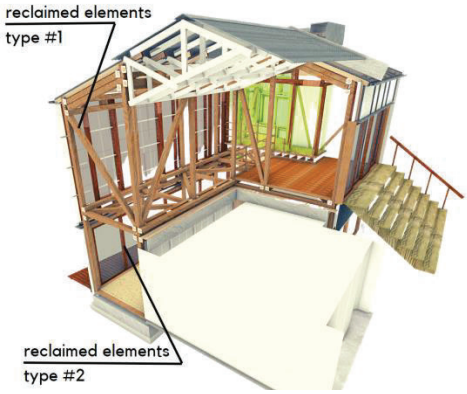

Figure 4: *General view of the structure from inside, type #1 elements come from Norway, type #2 come from Japan.*

https://doi.org/10.52202/069179-0474

The framework is oriented to maximize the usage of reclaimed timber elements in the structure from the available elements in the material bank. The algorithm to map the elements from the material bank has been created as a Python tool [Insert Artur et. al] with a wrapper for using it in Grasshopper. To create a material bank, we scanned (see figure 6) or measured available elements. The information about them are stored in a database which is available during the design and can be changed at any time. Since timber is an orthotropic material which has the best performance in the direction longitudinal to the grain, the decision was made to adjust optimization algorithms towards beam elements. It means that the axial direction of the elements is leading the matching algorithms. After scanning of reclaimed elements, the mesh is imported into Grasshopper where the length, and cross-sectional data needed for the material bank is extracted.

Figure 7 illustrates how different design options obtains different placement and amount of reclaimed elements in the database. This way, multiple options can quickly be evaluated and compared with regards to sustainability in addition to all other aspects. The idea of the framework is to deliver the designer a tool which, in real-time, will be reacting to topological changes in the building system. It means that if the designer changes the topology, the algorithm should automatically propose the best location of the available materials from the stock. The matching algorithm tries to assign the elements from the material bank to the design structure based on the specific features. The cross-section of the element from the material bank cannot be smaller than those from the structural analysis made before matching, and the length of the element cannot be shorter than the ones in the design model. Also, the algorithm to avoid locations of pockets (fabrication elements for detail generation) and imperfections cannot be in the sensitive places of beams and columns.

Figure 8 is a final presentation of the matching algorithm; each colour link is connecting elements from the databank to design model.

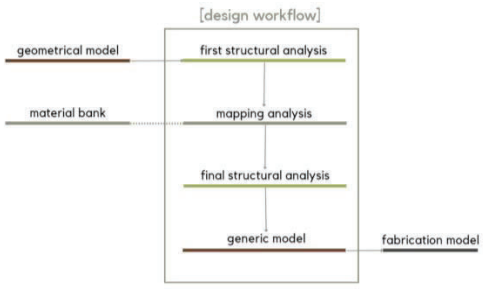

Figure 5: *Scheme of the framework.*

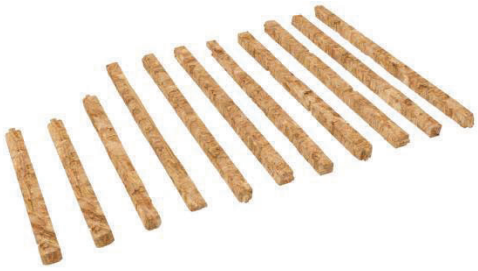

Figure 6: *Scans of reclaimed timber elements.*

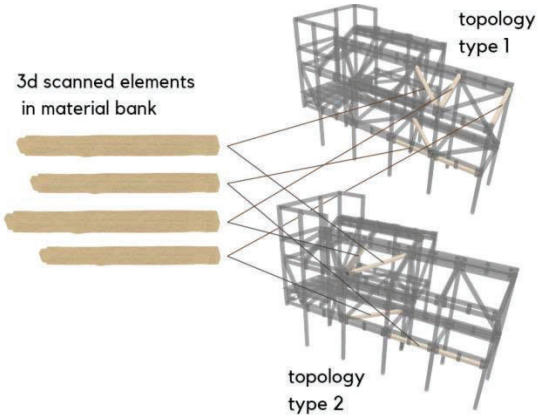

Figure 7: *The concept of the framework.*

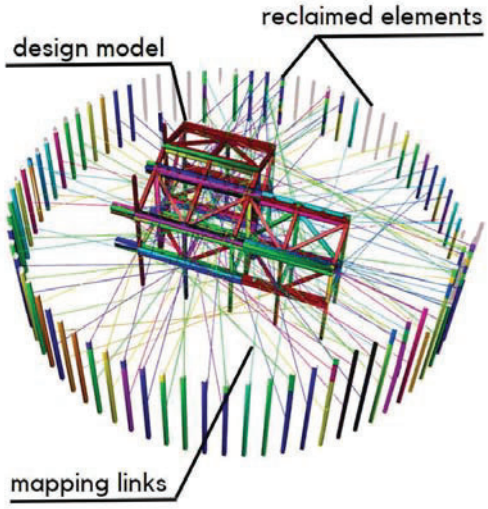

Figure 8: *The visualization of the matching produced by the algorithm.*

2.3 THE FINAL DESIGN

The timber building is designed to resist dead and live loads. The building is a public space category and has to resist 5kN/m2 on every floor. The snow load on the roof is estimated to be 3.8 kN/m2. The wind load of magnitude 0.3 kN/m2 is considered from three sides.

https://doi.org/10.52202/069179-0474

As mentioned before, the stock of timber elements origins from an old barn deconstruction. Figure 6 presents 3D-scans of some elements after deconstruction. The specialist categorized the timber quality as C30. A lot of elements have small imperfections, and the endings of the elements have the remains of the old joint systems. To see all those defects and judge if they comply with the architectural vision, we decided to include a 3Dscan of the material bank. Each element was scanned and represented with a 3D mesh with texture. What is also important, precise digital representation of the elements allow to involve the imperfections in the matching algorithm. matching

In this particular design, it occurred that the material bank was not covering all needed elements. The workflow allows for a combination of new and old elements. Importantly, the LCA calculations were made in real-time, giving the designer feedback about the current design's performance. Figure 4 presents the architect's desired structure together with the elements from the material bank (displayed in a circle around the model). The illustration depicts the final design which, at the moment the paper is written, waits for building acceptance by Oslo authorities.

3 CONCLUSION

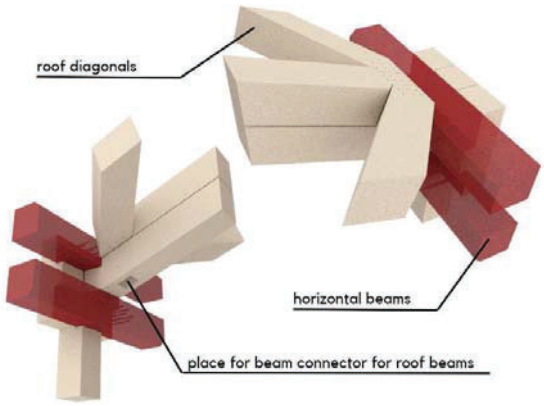

Figure 9: *Detail of the connection.*

The construction project is to be started before the summer of 2023. In this project, we do not only focus on the conceptual design and algorithms. The extra goal is also to measure the values of environmental and structural (displacement) performance.
The work made till now can be summarized in the following points:

• Creating an innovative design methodology, which quickly matches reclaimed elements from the material bank with the initial design model.

• Implementing several matching algorithms, in Python, and wrapped in a Grasshopper module to link it with parametric design.

• Visualizing the impact of using reclaimed elements by adding the 3D scanned meshes to the design model based on the results from the matching algorithms.

ACKNOWLEDGEMENT

The project is done thanks to great work made by architects and engineers: Ryoko Iwase, Toshikatsu Kiuchi, Sudarshan Khadka, Kozo Kadowaki and Alexander Eriksson Furunes, Makoto Isono, Lars Eivind Bjørnstad. The project is done in collaboration with OmTre company, who supply reclaimed timber elements and provide storage and testing facility. The Oslo Kommune was involved in finding the correct place for the project and support in financing the construction.

ENERGY DEMAND FOR THE DRIVING IN OF SELF-TAPPING TIMBER SCREWS AND ITS APPLICABILITY

David Glasner[1], Andreas Ringhofer[2], Gerhard Hubmann[3], Werner Braun[4]

ABSTRACT: The following paper proposes a test method to evaluate the insertion energy of self-tapping timber screws in order to gain data that can be used in life cycle assessments. The proposed test configuration is based on an established setup to test the torsional resistance for driving in screws. Experimental data show the usability of the test method to distinguish different screw types with regard to their energy consumption. It was found that the insertion energy is highly influenced by timber density, screw diameter and insertion length. This correlation was used to derive an empirical model to predict the insertion energy of Tenz® screws. Of course, the presented approach may also be adapted for other screw types and serve as a tool for screw comparison and optimisation. Furthermore, the insertion energy has the potential to serve as a key value in the quality control of screwed connections.

KEYWORDS: self-tapping timber screws, screw application, insertion moment, insertion energy, RILEM TC TPT

1 INTRODUCTION AND THEORETICAL BACKGROUND

The ongoing climate crisis has been a major topic in engineering and has also put a spotlight on energy consumption in construction. Although nowadays the energy demand for the production of construction materials and engineering products is relatively well known as it is vital for the life cycle assessment (LCA) of structures, lesser is known about the energy consumption during their application or usage. In timber engineering, one of these widely used products are self-tapping timber screws. The amount of energy needed to drive in a screw has not yet received much attention and as a result, the comparability of different products in regard to the demanded insertion energy is not given.

Furthermore, although some influencing factors on the insertion energy such as timber density and screw diameter have been hinted at in previous work (cf. [1]), their effect has not been quantified while other screw related characteristics such as screw type, head type and insertion length or timber related characteristics such as axis to grain angle and timber species did not receive any attention at all. Such information however may become very valuable in the future as the insertion energy has the potential to serve as a predictor for the withdrawal strength and the axial stiffness of a screwed connection (cf. [2]) and be therefore used in quality control.

In the following the insertion energy W is defined as the amount of work performed during the insertion of the screw, which is equivalent to the Integral of the power demand P during that process. In the scope of screw insertion, P can be determined in two ways:

- Measurement of voltage U and electric current I and calculation of the electric power demand of the electric drive with $P = U \cdot I$
- Measurement of insertion moment M and angular velocity ω and determination of the rotational power demand during the insertion process with $P = M \cdot \omega$

The determination of the electric power demand can be done relatively easy. However, the hereby calculated insertion energy also includes losses within the setup itself. As a result, the approach using M and ω is favourable for standardized testing as it only contains the energy demand of the screw-timber-interaction.

The synchronized measurement of the insertion moment M and the angle of rotation φ allows the calculation of the insertion energy according to Equation (1):

$$W_\omega = \int M \cdot \omega \, \partial t \tag{1}$$

where $\omega = \partial\varphi / \partial t$ = angular velocity. To be able to calculate the insertion energy without direct measurement of the angle of rotation, the following correlation between angular velocity ω, thread pitch p and insertion length l_i is utilised:

$$l_i = \frac{\varphi}{2\pi} \cdot p \rightarrow \frac{\partial l_i}{\partial t} = \frac{\partial \varphi}{\partial t} \cdot \frac{p}{2\pi} \rightarrow \partial t = \frac{\partial l_i}{\omega} \cdot \frac{2\pi}{p} \tag{2}$$

Inserting Eq. (2) in Eq. (1) yields:

$$W_l = \frac{2\pi}{p} \int M \, \partial l_i \qquad (3)$$

2 MATERIAL AND METHODS

2.1 Test setup and evaluation

On basis of the established test configuration for testing the torsional resistance when driving in screws provided in EN 15737:2009 [3], an adapted test configuration was developed to determine the energy demand as an additional property, see Figure 1.

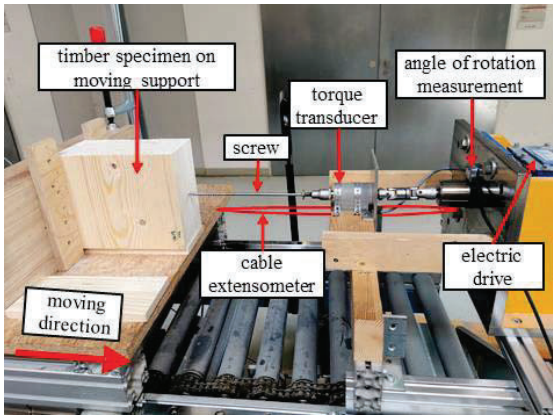

Figure 1: *Test configuration to determine the insertion energy*

The proposed configuration consists of a fixed electric drive and a moving support on which a timber block is placed. At the shaft of the electric drive a sensor to measure the angle of rotation as well as a torque transducer are installed. A pneumatic cylinder presses the moving support with the timber block against the screw, which is placed horizontally between timber and torque transducer. A cable extensometer, which is connected to both fixed and moving support, measures the insertion length.

During the tests in the scope of this paper, the pressure of the pneumatic cylinder and the renditions per minute of the electric drive were varied depending on the screw length but not recorded, as they show no influence on the insertion energy according to investigations in [2]. The dimensions of the timber specimens were chosen in agreement with the specifications given in EN 15737:2009 [3] meaning that the specimens were at least 20 d in length, 10 d in width and the screw length in height. Unless stated otherwise in one of the detailed descriptions of the test series in the following Sections 2.2 to 2.5, the timber specimens were made of spruce softwood (*picea abies*) with an almost equal mean density $\rho_{12,mean}$ of approx. 420 kg/m³ for all test series, which was done by matched sampling.

After the insertion test, the moisture content and density were determined according to EN 13183-1 [4] respectively ISO 13061-2 [5] on small scale specimens with a quadratic cross section and a length equal to the screw's insertion length. The small-scale specimens included the whole screw channel which was positioned in the centre of the specimen. For the evaluation, the density was corrected to a reference moisture content of 12 % according to ON EN 384 [5].

Figure 2 exemplarily shows the results of an insertion test carried out with a screw with a nominal diameter d_{nom} = 8.0 mm and a length l =240 mm in a piece of spruce softwood. The top graph shows the relationship M vs. t, which is used for the determination of the torsional resistance of driving in screws. The peak at the end of the driving in marks the insertion of the screw head in the timber. The middle graph shows power P vs. time t. The similar shape compared to the graph M vs. t is a result of the constant angular velocity for the majority of the test run. The bottom diagram shows the increase in insertion energy over time, which is equal to the area under the P vs. t relationship (marked in grey in the middle diagram). The insertion energy was then evaluated at two points: W_{shaft} including the insertion of screw tip, thread and shank but without the portion of the head insertion and W_{head}, including a flush head insertion to the timber surface.

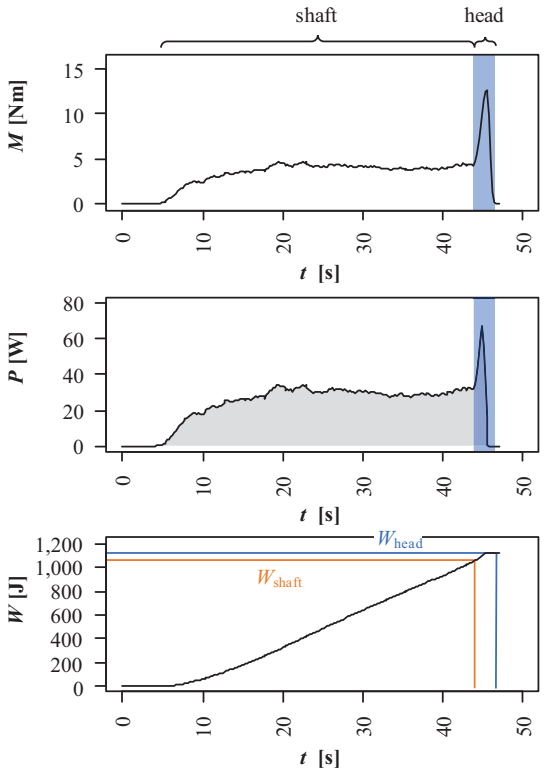

Figure 2: *M, P and W vs. t exemplarily for a TENZ® screw with d_{nom} = 8.0 mm and l = 240 mm*

2.2 Set 1: Comparison of different screw types from different manufacturers

The main aim of this set was to compare different screw types from different manufacturers with regard to the insertion energy. The tested screws are given in anonymized form in Table 1 and visualized in Figure 3. Groups one and two consist of partially threaded screws

with a nominal diameter of 6.0 mm respectively 8.0 mm;, the screw length was 160 mm respectively 240 mm. The test series were then compared to Tenz WBS screws of test series 29 respectively 30, see Section 2.3, Table 2. The Tenz screw of test series 23 with diameter 6.0 mm had a length of 240 mm; the insertion energy was therefore also evaluated at an insertion length of 160 mm. Group three included dry wall screws with diameters varying between 3.0 mm and 4.2 mm and lengths in the range of 35 mm to 70 mm. For a better comparison in-between this group, the insertion energy of the dry wall screws was evaluated at an insertion length of 30 mm.
All screws except for screw types one, nine and 18 had a countersunk head (CS) with or without additional features. Screw types one and nine had a staggered head with saw tooth, screw type 18 had a washer head (WH).

https://doi.org/10.52202/069179-0475

2.3 Set 2: Influence of density, length and diameter

The test series within this set were used to quantify the influence of timber density, screw length and screw diameter which have been identified to have a major impact on the insertion energy in [1]. For this purpose, three density classes were formed, which contained three test series each, one for each tested diameter. The test data of this set were also used to derive an empirical model to estimate the insertion energy for the whole Tenz screw portfolio. Consequently, additional test series were included on selected screws of type Tenz WS and Tenz DS. The test series of set 2 are given in Table 2 and depicted in Figure 4. The head types of all screws, except for Tenz WBS 8.0x600 mm which had a WH, were CS.

Table 2: *Test series of set 2*

	series	*n*	targeted ρ_{12}	d_{nom}	*l*	*p**

2.4 Set 3: Influence of axis-to-grain angle and head type

This test set served to investigate the influence of the axis-to-grain-angle α and the head type on the insertion energy. The tested screw type was Tenz WBS 8.0x240 mm with a pitch p =5.2 mm. A summary of the test series can be found in Table 3.

Table 3: *Test series of set 3*

2.5 Set 4: Influence of timber material

The investigation of different timber species and timber products was carried out in set 4. Within this set, Tenz WS 5.0x60 mm screws with p = 3.3 mm were used. The test series of this set are summarised in Table 4.

3 RESULTS AND DISCUSSION

3.1 Comparison of different evaluation methods

Figure 5 shows the residuals of the insertion energy of the whole data set calculated by Eq. (1) versus Eq. (3) for the insertion energy including screw head insertion (Figure 5 left) and without screw head insertion (Figure 5 right).

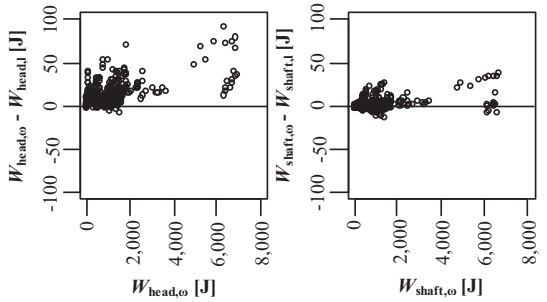

Figure 5: *Residuals for the insertion energy in dependence of the evaluation method. left: W_{head} including the head; right: W_{shaft} for the shaft only*

It can be seen that although the scatter does not show a trend along the tested spectrum, suggesting both calculation methods to be comparable, there is a shift to the positive side for the insertion energy including the head. This should be kept in mind when evaluating W_{head}. However, the knowledge of the thread pitch p is crucial for the applicability of Eq. (3) in both cases.
For the more detailed discussion in the remaining paper, the results of W_{ω} acc. to Eq. (1) will be discussed as it is seen as the more reliable method.

3.2 Set 1: Comparison of different screw types and manufacturers

The overall mean density $\rho_{12,mean}$ for test series of screws with d_{nom} = 6.0 mm of set 1 was 420 kg/m³. The minimum $\rho_{12,mean}$ of a single test series was 414 kg/m³and the maximum $\rho_{12,mean}$ was 424 kg/m³ indicating a successful matched sampling process. The average moisture content was u = 14.0 %. For more details regarding each test series, please refer to Table A-1 in the Annex.
Figure 6 compares the insertion energy of each test series of set 1 with diameter 6.0 mm with the corresponding Tenz screw (test series 29) which was for this purpose evaluated at an l_i of 160 mm. Except for series 1 and 5, statistically significant differences between Tenz and the other test series were found using unpaired two-sample t-tests assuming a significance threshold of $\alpha = 0.05$. Especially test series 3 differs from the other test series. Although not analysed in detail, this was the only series without any screw features (no compactor, cutter etc.) which could be the reason for the higher insertion energy.

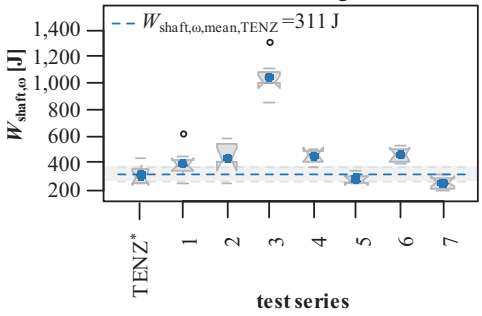

Figure 6: *Boxplots and mean values for $W_{shaft,\omega}$ of screws with d_{nom} = 6.00 mm and l =160 mm; 95%-CI for TENZ. *TENZ screw with l =240 mm was used and evaluated at an insertion length of =160 mm*

For the screws with diameter 8.0 mm, $\rho_{12,mean}$ of all series was 429 kg/m³. The minimum $\rho_{12,mean}$ of a single test series was 401 kg/m³ and the maximum $\rho_{12,mean}$ was 433 kg/m³. The average u was 14.2 %. A detailed summary can be found in Table A-2 in the annex.
The insertion energy results of each test series of this group can be seen in Figure 7. Again using unpaired two-sample t-tests statistically significant deviations can be found between Tenz (test series 30) and test series 8, 11, 12, 13 and 16.

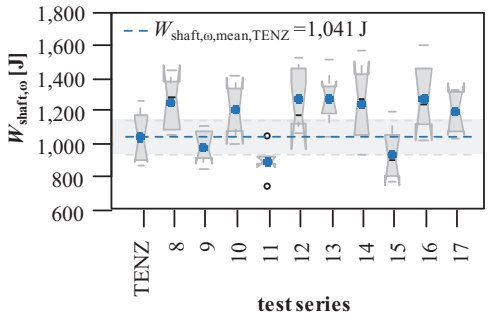

Figure 7: *Boxplots and mean values for $W_{shaft,\omega}$ of screws with d_{nom} = 8.00 mm and l =240 mm*

The timber specimens of the test series with the dry wall screws had an overall $\rho_{12,mean}$ of 414 kg/m³, the minimum density of a single series was 407 kg/m³, the maximum was 428 kg/m³ while the average u was 10.9 %. The main statistics of this set is summarized in Table A-3 in the Annex. Figure 8 shows the insertion energy of dry wall screws evaluated at a constant insertion length of 30 mm.

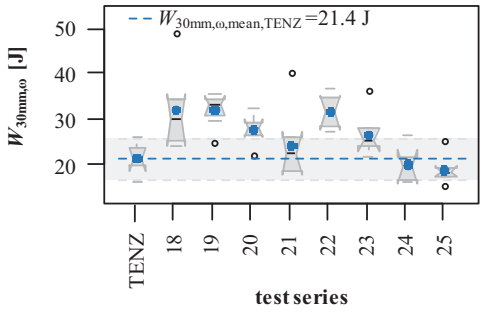

Figure 8: *Boxplots and mean values for $W_{30mm,\omega}$ evaluated at an insertion length of 30 mm for dry wall screws; 95%-CI for TENZ.*

Unpaired two-sample t-tests between Tenz and test series 18, 19, 20 and 22 showed a statistically significant difference while the difference to the remaining test series of this group were statistically insignificant.

3.3 Set 2: Influence of density, length and diameter

The main statistics of this set can be found in Table A-4 in the Annex.
During the execution of test series 36 with screws 8.0 x 600 mm, a bending of the screws was observed during insertion. As this was the only test series showing such behaviour, it is likely that the high slenderness of this specific screw is the reason for the bending. It is assumed that the bending causes the screw shank to press against the screw channel during insertion resulting in a higher insertion energy due to the increased friction.
As ρ, d and l were identified as the predominant factors regarding the insertion energy in a past investigation (see [1]), a nonlinear least squares regression analysis to describe $W_{shank,\omega}$ was made using the basic approach according to Eq. (4).

https://doi.org/10.52202/069179-0475

$$W_{TENZ} = W_0\left(\frac{\rho}{420}\right)^{k_\rho}\left(\frac{d_{nom}}{8.0}\right)^{k_d}\left(\frac{l}{100}\right)^{k_l} \quad (4)$$

Furthermore, it was assumed that the factors k_ρ, k_d and k_l are constant irrespective of the screw type (WBS, WS or DS). The initial regression was executed on the data of Tenz WBS screws though test data from test series 36 were excluded from this regression analysis due to the aforementioned bending effects. The resulting factors are $k_\rho = 1.713$, $k_d = 1.976$ and $k_l = 1.480$, which in the following were set to $k_\rho = 1.7$, $k_d = 2$ and $k_l = 1.5$. Based on these factors, screw specific nominal insertion energies W_0, definded as the insertion energy needed to drive in an 8.0x100 mm screw in spruce with density 420 kg/m³, were derived see Table 5.

Table 5: *nominal insertion energies W_0 for Tenz screw types*

screw type	W_0 [J]
Tenz WBS	267
Tenz WS	371
Tenz DS	496

The prediction of the empirical model is plotted against experimental data in Figure 9. An - especially in timber engineering - unusually high agreement between model prediction and experimental data is given ($R_{adj}^2 = 0.99$) when test series 36 is excluded. The correlation remains high even if series 36 is considered ($R_{adj}^2 = 0.95$).

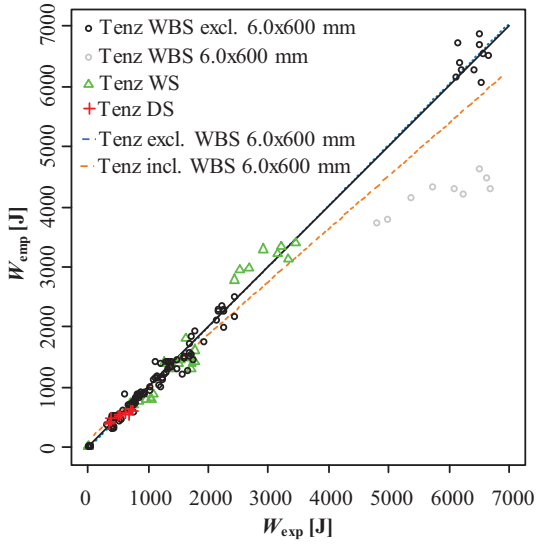

Figure 9: *Model prediction vs. experimental data for Tenz screws*

Figure 10 shows the accompanying residuals of the model. Overall, a uniform distribution of the residuals can be observed for the whole dataset (again excluding test series 36), confirming the general suitability of the model. Because the residuals for Tenz WS are also distributed without a recognizable trend along the tested spectrum even though the model's underlying factors (except for the nominal insertion energies W_0) were derived based on Tenz WBS screws it can be concluded that the assumption of the factors' independency of the screw type is valid. However, it remains uncertain whether this also applies for other screw manufacturers and especially for fully threaded screws.

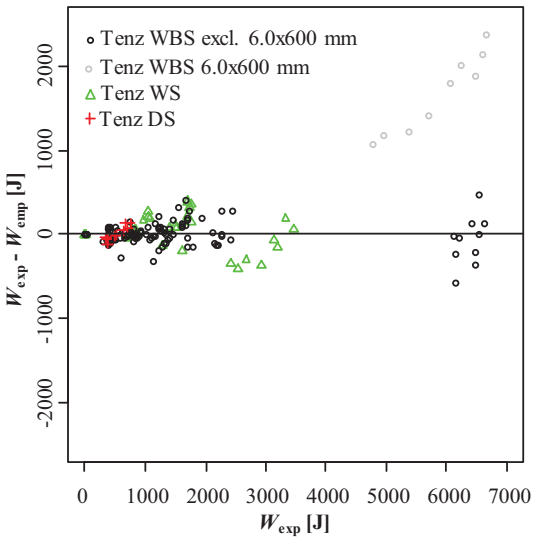

Figure 10: *Residual plot for data according to Eq. (4)*

3.4 Set 3: Influence of screw axis to grain angle and head type

A summary of the results of set 3 can be found in Table A-5 in the Annex. The mean densities of the respective test series range from $\rho_{12,mean} = 412 \div 423$ kg/m³ with a mean density of 418 kg/m³ of the total set 3. The average moisture content was 13.8 %.

Figure 11 shows the influence of the axis to grain angle α on the insertion energy. Between 90° (perpendicular to grain insertion) and 45°, a decrease of around 20 % of the insertion energy is observed. However, between 45° and 0° (parallel to grain insertion) no further reduction is given.

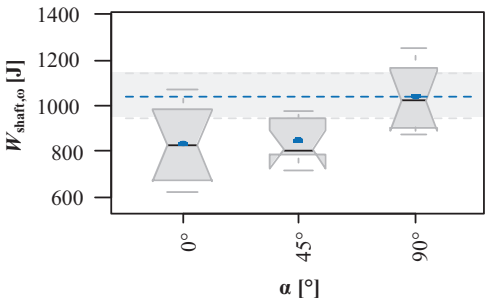

Figure 11: *Screw axis to grain angle α vs. insertion energy $W_{shaft,\omega}$*

The effect of different head types can be seen in Figure 12 with the head portion of the insertion energy calculated as $\Delta W_{head} = W_{head} - W_{shaft}$. In the presented case of an 8.0 x 240 mm screw, the CS placed level on the timber

surface results in an increase of the total insertion energy of approximately 10 % W_{shaft} ($W_{shaft,mean}$ = 1,041 J). However, if the CS is sunk 10 mm into the timber, the ratio ΔW_{head} / W_{shaft} is 25 %, which will increase even further for shorter screws. It is assumed that the higher ΔW_{head} of the WH compared to the CS mainly results from the larger diameter of the head though the shape of the head may also be of importance.

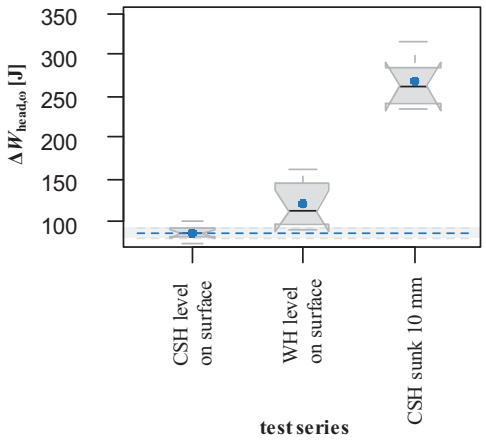

Figure 12: *Head portion of the insertion energy*

3.5 Set 4: Influence of timber material

In Figure 13 and Figure 14 the densities and insertion energies for set 4 are compared; a detailed summary of the test data can be found in Table A-6 in the annex. The low scatter of the densities of MDF board, beech and beech LVL results from the single specimens being manufactured from the same respective base material.

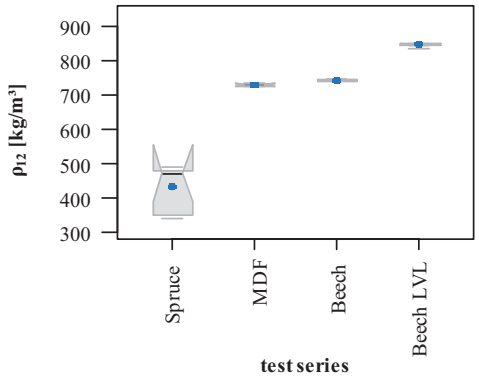

Figure 13: *densities of different timber materials of set 4*

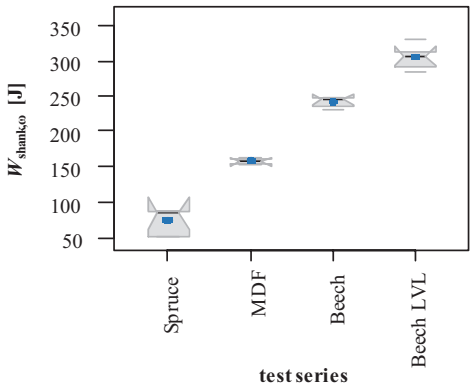

Figure 14: *insertion energy of different timber materials of set 4*

Based on the findings in 3.3, it comes to no surprise that the observation of an increased insertion energy with increasing density qualitatively is also true for different timber species and timber materials. However, when comparing the insertion energies in MDF and beech, they differ greatly even though the densities are very similar. This leads to the conclusion that the correlation between density and insertion energy is a material specific property.

4 SUMMARY AND CONCLUSION

This contribution deals with the insertion energy for screws, its influencing factors and possible applications. In the following, the main outcome of the paper at hand is summarized:

- The insertion energy of screws may become an important input factor for life cycle assessment of structures due to their widespread and still increasing use.
- A test configuration for the insertion energy is presented, which is based on the existing setup according to EN 15737:2009 for the torsional resistance of driving in screws by simply adding a measurement for the rotation angle.
- A simplified calculation method is derived that uses the correlation between insertion length, thread pitch and rotation angle that allows the evaluation of the insertion energy without direct rotation angle measurement. Both methods are equivalent if the head portion of the insertion energy is excluded and the exact thread pitch is known.
- Tests carried out with the mentioned configuration show a strong correlation between insertion energy and insertion length, screw diameter and timber density. The latter however can only be applied within a timber species/ timber product and the magnitude of the effect is currently only quantified for spruce.
- The insertion energy is highest when a screw is inserted perpendicular to the grain and is reduced

https://doi.org/10.52202/069179-0475

up to 20 % for axis to grain angles of 45° or lower.

- The correct placement of the screw has a great effect on the insertion energy, as the insertion of the head through inaccuracies during screw insertion significantly increases the energy needed.
- Regarding quality assessment of screw connections, the insertion energy may serve as an important benchmark due to its correlation with the density and subsequently with the withdrawal properties.

ACKNOWLEDGEMENT

This paper is based on the results of the FFG research program "Innovationsscheck-Plus", which received public funding from the Austrian Research Promotion Agency (FFG) and private funding from TENZ GmbH. Their support is thankfully acknowledged. It is linked to the work in RILEM TC TPT "Tests methods for a reliable characterization of resistance, stiffness and deformation properties of timber joints".

INFLUENCE OF THE SPECIMEN PREPARATION ON THE EMBEDMENT STRENGTH OF SELF-TAPPING SCREWS

Michael Gstettner[1], Andreas Ringhofer[2]

ABSTRACT: Due to their simple application and their wide-ranging applicability, self-tapping timber screws are either used for various types of connections or reinforcements in timber constructions. Apart from axial loading, self-tapping timber screws can be also loaded lateral, whereas the embedment strength f_h is one of the major parameters in the design process. The experimental determination of the embedment strength f_h, following EN 383, demands test procedures with thin timber specimen, whereas during the screw-application initial crack forming under specific conditions occur. As this has an unwanted and negative influence on f_h, a new way of specimen preparation was developed, with which initial crack formation can be excluded. Besides the presentation of this new method, the contribution also contains an experimental verification, which may lead to a significant modification of the current design model of f_h of self-tapping screws.

KEYWORDS: embedment strength, self-tapping screws, initial checks, novel preparation method, RILEM TC TPT

1 INTRODUCTION

Due to their versatile applicability and their simple installation without pre-drilling, self-tapping timber screws are frequently applied in contemporary timber constructions. Thereby, they are either loaded in axial or in lateral direction or in a combination of both. In the latter cases, their design according to Eurocode 5 [1] bases on the European Yield Model (EYM), where their yield moment M_y and the timber member's embedment strength f_h serve as main material properties. With regard to the embedment strength, there are two alternatives for a related calculation; one given in the present version of Eurocode 5 (where rules for nails and dowels are adopted for self-tapping screws in dependence of the size of their thread diameter) and one, which was specifically developed for self-tapping screws (c. f. Blaß et al. [2]) and is anchored in the majority of European Technical Assessments (ETAs) of self-tapping timber screws.
Comparing both approaches, especially the way how they consider the load-to-grain angle α, which is exclusively done by the Eurocode 5 approach, leads to a significant overestimation of experimentally determined f_h while for the ETA-approach (basing on Blaß et al. [2]) a high agreement between test results and model prediction was found, c. f. Gstettner [3]. In fact, this is surprisingly since the impact of the load-to-grain-angle α represents timber's well-known orthotropic material behaviour, established and successfully verified for f_h of other dowel-type fasteners such as dowels or bolts. The reason for the deviating behaviour, found for self-tapping screws, is discussed in Section 2.

2 RESEARCH ISSUE

Following the regulations according to EN 383 [4], aiming to avoid fastener's bending and to test a realistic application scenario, Gstettner [3] conducted screw embedment tests with a specimen-thickness $t = 2\,d$ without pre-drilling in advance. Thereby, the embedment strength f_h of several different screw types with their individual tip-characteristics applied in solid timber specimen with varying load-to-grain-angle (α), as well as the fastener axis-to-grain angle (ε), see Figure 1, was determined.

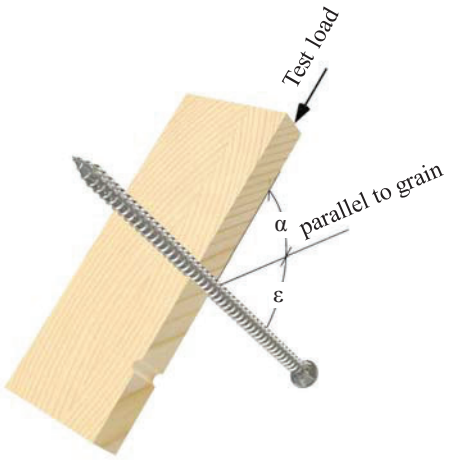

Figure 1: *Definition of the load-to-grain (α) and axis-to-grain angle (ε)*

https://doi.org/10.52202/069179-0476

In addition, to investigate an impact of the timber density on f_h, tests with three different timber-density classes of softwood were executed. In the frame of this campaign and especially for specific variations {α =var. | ε = 90°}, initial crack forming due the material displacement in the frame of screw insertion was observed. Thereby, the crack size and length were found to depend on the tip features of the screw. Results of some preliminary insertion tests indicate that RAPID® screws (8.0 x 220 mm, d_i = 5,2 mm), equipped with a tip-compressor and a half cut in combination with a low insertion speed, lead to crack formation in a tolerable amount. A related example is shown in Figure 2 (top). Even though this specific form of application was chosen, the crack formation due to the small specimen thickness according to EN 383 [4] still had a negative impact on screws loaded parallel to grain (α = 0° | ε = 90°). One consequence was that α did not influence the size of f_h at all. This observation is equal to the one made by Blaß et al. [2], with significant consequences for the regulation in currently valid ETAs of self-tapping screws, but stands in clear contrast to timber's orthotropic characteristics, as e.g. expressed by the Hankinson-formula, which rules the increase of f_h with decreasing α for laterally loaded dowels in EN 1995-1-1 [1].

To conclude: the challenge of the current determination of f_h for self-tapping screws is, that its empirical background bases on tests with comparatively thin specimens (aim: avoid fastener's bending during testing), which do not fulfil the minimum thickness requirements according to ETA and thus have a significantly negative impact on the initial crack formation. As pre-drilling turned out to be not a suitable alternative (note: pre-drilling leads to a differently pronounced densification of the timber surrounding the screw), the aim of the present investigation was to find a way of test specimen preparation, leading to a required specimen thickness according to EN 383 [4] on the one hand and avoiding initial crack formation as a consequence of a too thin specimen thickness on the other. The successful result of this finding process in form of a new specimen preparation method is shown in Figure 2 (bottom).

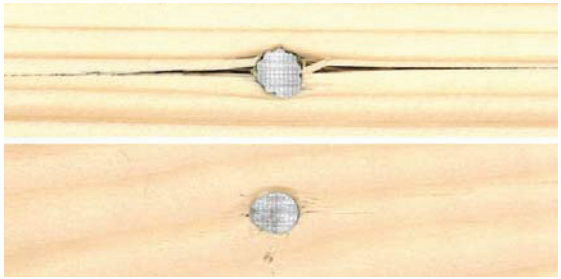

Figure 2: *Influence of the timber-specimen preparation on the embedment strength (f_h); (top) without- (bottom) with special specimen preparation*

The following sections comprise an explanation of this new method, the experimental programme to verify its impact on f_h as well as the gained test results and the proposals to modify the present approaches for determining f_h.

3 MATERIALS AND METHODS

3.1 OVERVIEW OF THE TEST PROGRAM

Inspired by the test program of Gstettner [3] an additional program in order to determine the influence of the specimen preparation process on the embedment strength (f_h), especially for α = 0°and ε = 90° was carried out. Next to a variation of the inner thread diameter (d_i) and the tip features, also the influence on the embedment strength (f_h) of three different application cases AC = {h | m | t} was investigated. Within each single test series, a minimum number of n = 18 tests was planned. The test program is shown in Table 1.

Table 1: *Overview of the test program, including the planned number of tests (n) within the test series*

⇩ Screw Type	AC ⇨	(h)	(m)	(t)
StarDrive	6.0 x 160	n = 18	18	18
RAPID®	8.0 x 220	18	18	18
RAPID®	8.0 x 240	18	18	18
RAPID®hardwood	8.0 x 320	18	18	18

3.2 MATERIALS

3.2.1 Timber Specimen

Due to its widely use in timber engineering and its status as a reference material in fastener testing, see EAD 130118-01-0603 2019 [5], pre-graded and kiln-dried structural timber lamellas with strength grade C24 acc. EN 338 [6] were used as a test material. They comprised a mix of Norway Spruce (*Picea Abies, Pinaceae*) and European Fir (*Abies Alba, Pinaceae*). Due to their similar mechanical properties, both wood species are treated as one assortment in practise. Within those lamellas, sections, free from any local growth characteristics (knots, pitch pockets, etc.) were used to gain high-quality preliminary timber specimen (t_{pre} = 40 mm), which were thereafter conditioned at 20 °C and 65 % relative humidity in order to reach an equilibrium moisture content u = 12 % according to SC 1 [1].

The dimensions $\{l_{(\alpha,\varepsilon,d)} \mid w_{(\alpha,\varepsilon,d)} \mid t_{(\lambda,d)}\}$ of the finished solid timber specimen are based on the regulations of EN 383 [4] for bolts and dowels, applicated in solid timber or wood-based panels, depending on the axis-to-grain angle α = {0° | 90°}, the nominal fastener diameter (d), as well as the slenderness (λ) as an ratio between the specimen-thickness (t) and the nominal fastener diameter (d). For specimen with {α = 0° | ε = 90°}, i. e. the load is applicated parallel to grain, while screw insertion is perpendicular to grain, EN 383 [4] proposes a specimen width $w_{(\alpha=0,d)} = 2\,a_1$, a length $l_{(\alpha=0,d)} = l_1 + l_2$ and a corresponding thickness $t = \lambda \cdot d$. To avoid fastener bending and to ensure embedding as a failure mode solely, λ was defined with 2. To prevent the specimen from further in-grain splitting during test execution, initiated throughout the screw application, additional 2 d were added to the distance to the loaded end (l_1). It is worth mentioning, that this setting was equal to the one by

https://doi.org/10.52202/069179-0476

Gstettner [3], enabling comparability to his investigations without this special form of specimen preparation. The final dimensions of the specimen are given in Table 2.

Table 2: *Dimensions of the finalised timber specimens*

		EN 383 [4]	Gstettner [3]
a_1	(unloaded edge)	$\geq 3\,d$	$7\,d$
l_1	(loaded end)	$\geq 10\,d$	$(10+2)\,d$
l_2	(unloaded end)	$\geq 10\,d$	$10\,d$
t	(thickness)	$(1.5 \div 4)\,d$	$2\,d$

In general, the new and improved specimen preparation process is based on the assumption, that the initial cracking mainly depends on the specimen thickness, see section 2. In order to enable screw insertion in a timber specimen with sufficient (practical) thickness to prevent initial cracking ($t_{pre} = 40$ mm) and to enable screw testing with the desired thickness according to EN 383 [4] ($t = \lambda \cdot d$), four major steps (A ÷ D), independent of the screw insertion {h | m | t}, were executed. Apart from a pre-drilling with a drill bit ($d_d = d + 2$ mm), which simplifies the removing of the slab (A) and the application of the self-tapping screw without predrilling thereafter (B), several circular saw cuts were carried out (C). For a perfect alignment of the self-tapping screw a specific template was used. To prevent the saw blade hitting the fastener, a safety distance was essential; the remaining wood material was removed with a chisel to complete the specimen preparation procedure (D), see Figure 3.

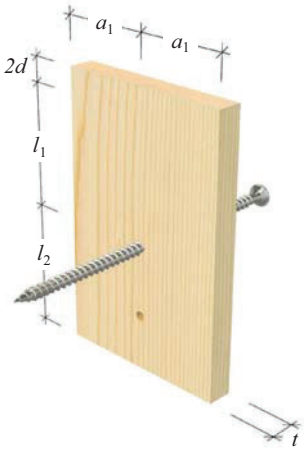

Figure 3: *Specimen dimensions, inspired by EN 383 [4]*

In order to cover the determination of the embedment strength f_h and to test a realistic application scenario of self-tapping screws without predrilling for three different cases {h | m | t}, different specimen application cases were carried out, see Figure 4. Whereas within case (h) the initial crack appears head-sided, i. e. the slab is removed on the side of the tip (see Figure 4, step A, highlighted **in blue**), both slabs are cut off for case (m), i. e. no initial crack occurs on both sides and for case (t) the initial crack occurs tip-sided, therefore the slab is head-sided removed (see Figure 4, step A, highlighted **in green**).

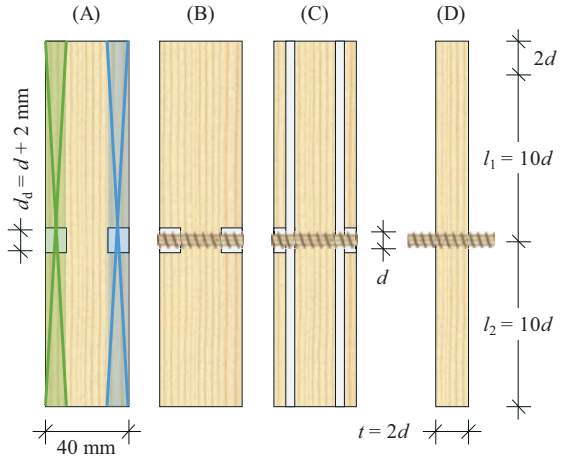

Figure 4: *Manufacturing process of the specimen*

3.2.2 Self-tapping screws

A self-tapping screw can be characterized as a hardened and coated carbon-steel rod, which consists of a head-part (h) including the drive, a middle member (m) with its thread and/or shank, as well as the tip (t), which are mostly equipped with varying features (*tf*). In the frame of the present investigation, four different screw types (ST1 ÷ ST4) according to ETA-12/0373 [7] were investigated, see Table 3 and Figure 5.

Table 3: *Thread specifications acc. to ETA-12/0373*

	d	d_i	P	l_t	*tf*
ST1	6.0 ±0.30	3.8 ±0.19	2.6 ±0.26	7.3 ±1.9	–
ST2	8.0 ±0.40	5.2 ±0.26	3.8 ±0.38	8.2 ±2.1	✓
ST3	8.0 ±0.40	5.2 ±0.26	3.8 ±0.38	8.2 ±2.1	✓
ST4	8.0 ±0.40	6.1 ±0.31	4.0 ±0.40	11.6 ±2.6	✓

Those differ once in their (nominal) outer thread diameter (d), inner thread diameter (d_i), thread pitch (p), tip-characteristics, including special tip-features (*tf*) and the coating; the latter responsible for corrosion-protection and added for easy application.

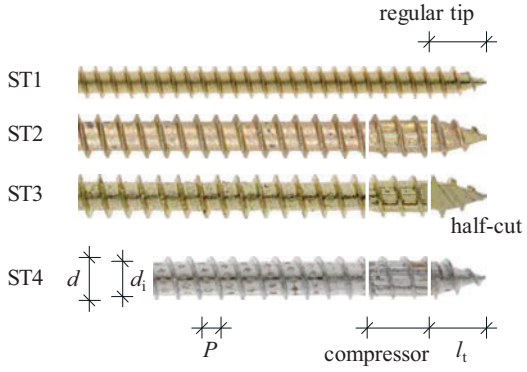

Figure 5: *Classification of self-tapping screws with their individual tip-characteristics (top to bottom: ST1 to ST4)*

Whereas the screw types ST1 (“StarDrive”, $d_i = 3.8$ mm) and ST2 ÷ ST3 (“RAPID®”, $d_i = 5.2$ mm) are designed for application in softwood, ST4 (“RAPID®hardwood”) with $d_i = 6.1$ mm is especially, but non-exclusively seen for application in hardwood. ST2 to ST4 are equipped with a tip-compressor, which shall decrease the insertion moment. While the tip characteristic of ST3 provides a half-cut, all other screw types are designed with a regular tip (see Figure 5).

3.3 TEST–SETUP AND EXECUTION

In order to determine the embedment strength f_h of laterally loaded self-tapping screws, full-hole embedment tests following EN 383 [4] were carried out. The test setup consisted of two load-bearing steel brackets ①, which were connected rigidly with the universal test rig lignum_uni_275 ② (ZwickRoell GmbH & Co. KG), see Figure 6. The timber specimen with its already applicated screw was thereby embedded in steel clamps ③, in which the shape of the screw-thread had been removed by milling in order to guarantee a perfect bearing during testing. To minimize fastener bending, the distance between the steel brackets and the specimen was kept as low as possible; only to allow a free side-deformation of the timber specimen. While testing, the force transmission between the test rig and the timber specimen was realized throughout a custom-made adapter ④, which was made of beech plywood. The local displacement measurement was realised by two displacement transducers ⑤ (type WA-L), which were aligned symmetrically to the test axis. Thereby the interaction between the test specimen and the transducers was achieved by a dowel ⑥.

Figure 6: *Image of the test-setup ST1 with its single steel-components; configuration {α = 0° | ε = 90°}*

With regard to the test execution, all tests were performed acc. to EN 383 [4], but without the recommended hysteresis loop. The max. test load should be reached within 300 ±120 s and is defined as $F_{max,i} = \max\{F_{w=5,i} \mid F_{max,w<5,i}\}$.

3.4 POST-PROCESSING

The embedment strength $f_{h,i}$ was calculated acc. to EN 383 [4] by the following Equation (1).

$$f_{h,i} = \frac{F_{max,i}}{d \cdot t_{i,sp}} \quad \left[\frac{N}{mm^2}\right] \tag{1}$$

Thereby, the specimen thickness $t_{i,sp}$ was determined after the test execution of every single specimen.

As main indicators of strength and stiffness properties, the timber density $\rho_u = m_u / V_u$ acc. to ISO 3131 [8] and the moisture content $u = (m_u - m_0) / m_0$ acc. to EN 13183-1 [9] of each specimen were determined using a small piece of the test specimens, taken next to the applied screw (see Figure 3). Minor deviations of the moisture content, influencing the wood density were adjusted by using Equation (2) acc. to EN 384 [10].

$$\rho_{12} = \rho_u \cdot (1 - 0.005 \cdot (u - u_{12})) \quad \left[\frac{kg}{m^3}\right] \tag{2}$$

whereas ρ_{12} is the moisture adopted timber density, ρ_u the timber density, determined immediately after testing, u the corresponding moisture content and $u_{12} = 12$ % the reference moisture content.
The embedment strength of every test series including a certain number of specimen n was subjected to an outlier adjustment ($\tilde{n}$), see Gstettner [3].

https://doi.org/10.52202/069179-0476

4 RESULTS AND DISCUSSION

4.1 TIMBER DENSITY | MOISTURE CONTENT

An overview of the main statistics for physical timber properties, such as the moisture content (u) and the wood density (ρ_{12}) is given in Table 4.

Table 4: *Main Statistics of physical timber properties*

	AC	$n = \bar{n}$	u_{mean}	$\rho_{12,mean}$	CoV[ρ]
		[-]	[%]	[kg/m³]	[%]

☐ research results of Gstettner [3]

For all test series, an average moisture content of $u = 12$ % (SC 1 acc. to EN 1995-1-1 [1]) was tried to reach. As a result, there are comparable moisture contents u_{mean} within the new series, while for the ones of Gstettner [3], higher moisture contents were observed. A longer storage of the new specimens under standard climate conditions (app. 2.2 years), led to a better converge to $u_{SC1} = 12$ %, as assumed. Regarding the timber density $\rho_{12,mean}$ a good match to $\rho_{mean,C24} = 420$ kg/m³ acc. to EN 338 [6] can be observed for all considered test series.

4.2 EMBEDMENT STRENGTH

In Table 5, the main statistics of f_h of the new test series are given in dependence of the screw type (ST1 to ST4) and compared with the reference ones of Gstettner [3]. Therefore, the ratio η according to Equation (3) is used to draw precise conclusions; here $f_{h,mean}$ is the average embedment strength of the test series with varying application cases {h | m | t} and screw types (ST1 ÷ ST4) while $f_{h,ref,mean}$ acts as a reference strength, taken from Gstettner [3].

$$\eta = \frac{f_{h,mean}}{f_{h,ref,mean}} \quad [-] \qquad (3)$$

☐ results of Gstettner [3]

First of all, the reference results of Gstettner [3] shall be discussed. In general, Gstettner [3] observed a regressive behaviour of the embedment strength f_h with an increasing screw diameter d. In addition, a significant reduction of the embedment strength was detected once for ST1 and also ST4, which was in fact not expected. It is assumed, that the initial crack forming during the screw application leads to this specific behaviour. ST4 is not equipped with a half-cut and has a higher inner thread diameter $d_i = 6.1$ mm, compared to ST3 ($d_i = 5.2$ mm). In case of ST1, there are no tip-features at all (see Figure 5).

Second and concentrating on the embedment strength as a consequence of the application cases {h | m | t} for all ST, significantly higher values of the embedment strength f_h compared to Gstettner [3] are given. The assumption of a positive effect on the embedment strength f_h by the new specimen preparation process is verified. This positive effect of the specimen preparation process on the embedment strength f_h is shown in Figure 7, exemplarily for ST1.

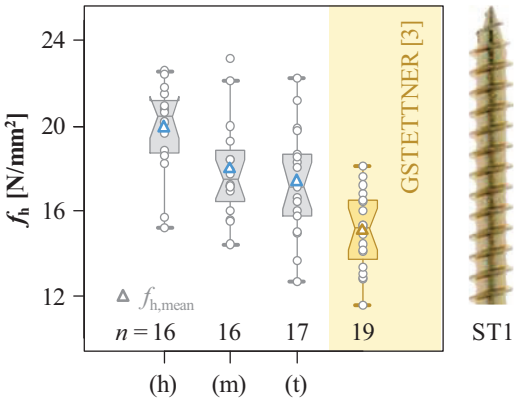

Figure 7: *Boxplot of f_h vs. application case for ST1, {d = 6 mm | d_i = 3.8 mm}*

Whereas the relative size of f_h for the application cases {h | m} of ST2 ÷ ST4 is almost equal, those of ST1 show a notable positive gap. With regard to the difference to the reference results and irrespective of the screw type, the application case (t) has the smallest increase of f_h compared to the results of Gstettner [3].

5 SUMMARY AND CONCLUSION

With focus on the lateral loading of self-tapping timber screws, an experimental research program was carried out to determine their embedment strength f_h. Thus, Gstettner [3] executed embedment tests using thin softwood specimen (t = 2d), following EN 383 [4]. Among others, a possible influence of the load-to-grain angle (α), screw axis-to-grain angle (ε), timber density (ρ) and several screw diameter (d) have been investigated. The outcomes of determining the embedment strength f_h for ST3, varying α are exemplarily shown in Figure 8.

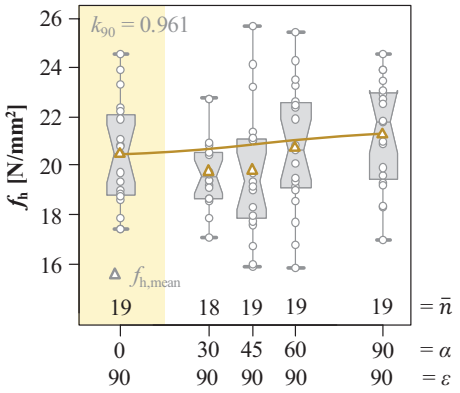

Figure 8: *Boxplot f_h vs. α for ST3, {d = 8 mm | d_i = 5.1 mm}*

Thereby, similar embedment strength (f_h) at a load-to grain angle α = 0°, compared to α = 90° was observed; which stands in a clear contrast to the general assumption of timber as orthotropic material. A negative impact of the specimen preparation and the application of the self-tapping screw without pre-drilling, especially for α = 0°, on the embedment strength (f_h) is assumed as a reason, see Gstettner [3]. Therefore, a new specimen-preparation process was developed, in order to disable an unwanted and negative influence of initial crack forming on the embedment strength. f_h, see section 3.2.1.

Within this experimental research, executed after the one of Gstettner [3], three different application cases, using various self-tapping timber screw types have been investigated. Whereas in application case (h) the initial crack appears head-sided and within (t) tip-sided, no initial cracks occur within the application case (m). In fact, a remarkable impact of the new and improved specimen preparation process on the embedment strength f_h, i. e. independent of all application cases {h | m | t} and the screw types {ST1 ÷ ST4} was observed, see Table 5. With focus on the application cases (h) and (m), barley no difference of the embedment strength f_h was observed, whereas in the case (t), where the initial crack occurs tip-sided, f_h converges to the test results of Gstettner [3]. Furthermore, with focus on the different screw types with their individual tip-features and different inner thread diameters (d_i), a significant influence on the embedment strength f_h was observed.

On this basis the following proposals can be made: Since the new and approved specimen preparation process led to significant increased embedment strengths f_h, an implementation of the specimen preparation procedure in the current standards EAD 130118-01-0603 2019 [5] and EN 14592 [11] is recommended. Whereas Gstettner [3] proposes a $k_{90} \approx 1.0$, for self-tapping screws with their individual tip characteristics and inner thread diameters (d_i), following ETA-12/0373 [7] for practical purpose, a factor k_{90}, see equation (4) and (5), considering the increase of the embedment strength f_h due to this new and improved specimen preparation is recommended.

$$f_{h,\alpha} = (k_{90} \cdot \cos(\alpha)^2 + \sin(\alpha)^2) \cdot f_{h,90} \quad (4)$$

$$k_{90} = \begin{cases} 1.10 & \text{for timber member head-sided} \\ 1.20 & \text{for timber-member tip-sided} \end{cases} \quad (5)$$

Thereby, k_{90} for head-sided timber members is determined throughout a minimum (see Figure 9), comprising the application cases (h) and (t).

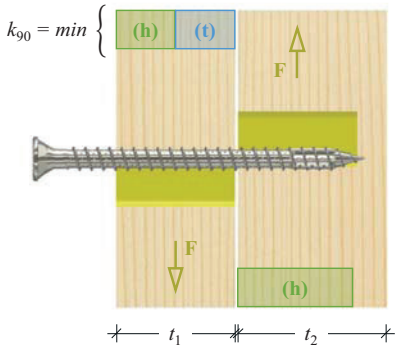

Figure 9: *Exemplary sketch of a timber-to-timber connection, executed with self-tapping screws*

It is worth mentioning, that the size of the embedment strength f_h was found to highly depend on the individual screw type, equipped with several tip-features and varying thread designs. Thus, a general applicability of k_{90}, shown in this contribution, can not be guaranteed. Therefore, further research work, also including a verification of α ≠ 0° is recommended, since it is assumed, that the initial crack forming does not influence at least specimen with α = 90°.

INFLUENCE OF TEST METHODS ON THE PARALLEL TO GRAIN EMBEDMENT STRENGTH AND FOUNDATION MODULUS CHARACTERIZATION

Caroline D. Aquino[1], Leonardo G. Rodrigues[2], Meta Kržan[3], Michael Schweigler[4], Zheng Li[5], Jorge M. Branco[6]

ABSTRACT: Different test setups have been reported in the literature for the determination of the embedment strength in timber elements. These variances hinder a straightforward comparison between available test data. It is difficult to determine if the source of variability lies in intrinsic timber properties or is related to the test protocol used. This paper aims to provide a better insight into the influence of embedment strength test methods, comparing experimental results from different test setups within the guidelines of EN 383 and ASTM D 5764-97a for Scots pine wood (*Pinus sylvestris*) and Spruce (*Picea Abies*). A robust statistical analysis was performed to identify statistically significant differences between the groups evaluated. The analysis of the parallel to grain embedment strength showed that the results differed between standards, pointing out the potential bias inserted in the embedment properties given their evaluation method. Moreover, the thickness of the specimen tests also proved to influence the yield and ultimate embedment strength for the wood species tested.

1 INTRODUCTION

The embedment strength, which is a property of utmost importance in dowel-type timber connections, is often determined through empirical expressions proposed in the literature. For instance, the European standard (Eurocode 5) [1] proposes an expression relating the dowel diameter and the wood density to the embedment strength, while the American Wood Council NDS [2] proposes an expression only based on the wood density. Nonetheless, because these empirical expressions are generalized, they fail to reliably predict the embedment strength for some wood species.

In that sense, alternative expressions have been studied based on experimental analysis of varying wood species [3,4]. The American standard, ASTM D 5764-97a [5], and the European standard, EN 383 [6], are the two most often used test standards for this purpose. The main difference between these standards is that ASTM D 5764-97a [5] allows for both half-hole and full-hole test specimens and bases the embedment strength on the yield load. On the other hand, EN 383 only allows for a full-hole test specimen and bases the embedment strength on the ultimate load capacity within 5 mm deformation. The two standards also reflect different dowel load conditions. Whereas the EN 383 standard loads the dowel on its ends, the ASTM D5764-97a [5] standard loads the dowel uniformly along its length. As a result, the EN 383 [6] test method is more likely to produce a bending effect than the ASTM D5764-97a [5], as reported in [7]. In terms of displacement measurement, EN 383 [6] recommends a local measure between the fastener and timber specimen, while ASTM D5764-97a [5] proposes a global measure between upper and lower support.

The standards also differ concerning the loading protocol. While ASTM 5764-97a [5] predicts a single loading cycle in displacement control, EN 383 [6] includes an additional cycle in load control of 40% of the estimated load-carrying capacity. This cycle was included to obtain the foundation modulus but at the expense of slightly conservative embedment values [8,9].

Moreover, when it comes to the thickness of the specimens, the protocols also differ. While EN 383 [6] proposes a range for the specimen thickness varying from

1.5 up to 4 times the dowel diameter, ASTM D 5764-97a [5] only defines a minimum value (the smaller between 38 mm and two times the diameter). The European standard defines a maximum value for the thickness mainly to avoid the bending of the dowel.

The variances between test protocols and specimen dimensions described hinder a straightforward comparison between available test data. It is difficult to determine if the source of variability lies in intrinsic timber properties or is related to the test protocol used. This paper aims to provide a better insight into the influence of embedment strength test methods, comparing experimental results from different test setups within the guidelines of ASTM D 5764-97a [5] and EN 383 [6].

2 MATERIALS AND METHODS

2.1 EMBEDMENT TESTS

This study investigates the effect of different test setups and protocols on the embedment properties of Scots pine timber. The influence of the thickness of the specimens, as well as the test configuration (load application) are investigated within the guidelines of ASTM D 5764-97a [5] and EN 383 [6]. A total of 264 specimens of Scots pine *(Pinus sylvestris*) were tested according to both standards for a dowel diameter (d) of 8 mm. Their minimum dimensions are shown in Figure 1 and Figure 2, respectively.

Within the scope of ASTM D 5764-97a [5], the height (h) and width (w) of the specimens were defined as h = 80 mm and w = 95 mm. Regarding the thickness (t), four different groups were tested: 20 mm, 25 mm, 30 mm, and 35 mm, whereas only one group with t = 20 mm was considered for EN 383 [6]. The height and width for the specimens tested according to the European standard were h = 160 mm and w = 65 mm. Mean and standard deviation values of oven-dry density (ρ) and moisture content (MC), calculated from mass and volume, are presented in Table 1.

Table 1. *Basic properties of Scots pine specimens tested according to ASTM D 5764-97a [5] and EN 383 [6] for a dowel diameter of 8 mm*

Thickness [mm]	N [no.]	ρ [kg/m^3]	MC [%]
ASTM D 5764-97a [5]			
20	53	500±48	11.5±1.0
25	52	495±58	12.1±0.4
30	45	511±49	11.7±0.8
35	60	497±51	12.0±0.6
EN 383 [6]			
20	54	522±69	11.2±1.3

An additional investigation was conducted regarding the method of load application within the scope of EN 383 [6]. Two test configurations - Setup 1 and Setup 2 - were evaluated (see Figure 2) since both were founded in the literature [10,11]. The main difference between setups lies in the load application. For Setup 1 the load is applied to the timber specimen while the dowel is kept fixed. For Setup 2, the load is applied on the steel dowel while keeping the specimen fixed. Scots pine (*Pinus sylvestris*) and Spruce (*Picea abies*) were tested for dowels of diameter 12 mm for both setups. Similar, mean and standard deviation values of ρ and MC are presented in Table 2.

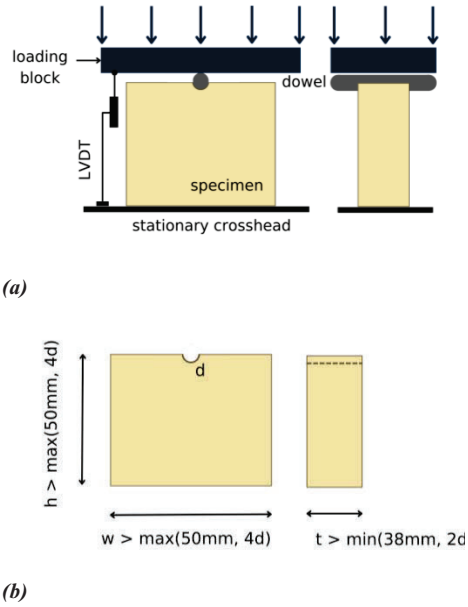

Figure 1: *(a) Test setup for ASTM D 5764-97a [5] and (b) corresponding specimen*

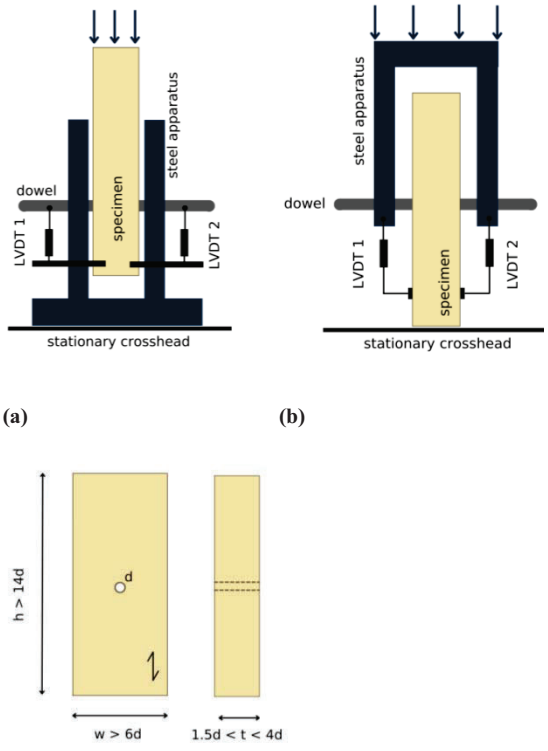

Figure 2: *Test setup for EN 383 [6] (a) Setup 1, (b) Setup 2, and (c) corresponding specimen*

The half-hole specimens tested according to ASTM D5764-97a [5] were loaded at displacement control at a constant rate of 0.02 mm/s. The test setup, presented in Figure 3, has a hydraulic actuator, equipped with a load cell of 25 kN, and a displacement range of 200 mm. To measure the joint slip, one linear variable differential transformer (LVDT) was fixed at the steel loading block. The tests were terminated at an embedment of one-half the fastener diameter or after the maximum load was reached.

The full-hole specimens tested according to EN 383 [6] were loaded into five different branches. The first part consisted of a loading branch, followed by a plateau where the load was kept constant and equal to 40% of the estimated capacity for 30 seconds. After, the load was diminished until it reached 10% of the estimated capacity and then kept constant for another 30 seconds. Thereafter, the test was performed under displacement control with a constant rate of 0.02 mm/s for specimens with dowels of 8 mm and 0.025 mm/s for dowels of 12 mm in diameter. Both loading and unloading branches were force controlled with a constant rate of 0.025 kN/s and 0.013 kN/s for dowels of 8 mm and 12 mm in diameter, respectively. The test setup, presented in Figure 4, has a hydraulic actuator, equipped with a load cell of 25 kN, and a displacement range of 200 mm. To measure the joint slip, two LVDTs were fixed on both sides of the connection. These two LVDTs were placed diagonally opposite the central timber member. The tests were terminated after the maximum load was reached or when the actuator displacement reached the threshold of 5 mm.

2.2 QUANTIFICATION OF PROPERTIES

The embedment properties retrieved from the recorded load-displacement curves for ASTM D5764-97a [5] and EN 383 [6] protocols, are shown in Figures 5a and 5b, respectively. A significant difference between these standards lies in the definition itself of embedment strength. While the EN 383 [6] definition is based on the ultimate load capacity, the ASTM D5764-97a [5] standard defines the embedment strength based on the yield load. The yield load is obtained by the intersection between the offset line of the initial linear portion of the load-deformation curve by a deformation equal to 5% of the fastener diameter. Nonetheless, if the offset line and the load-deformation curve do not intersect, the yield load can be regarded as the ultimate one. The ultimate embedment strength ($f_{h,u}$) and the yield embedment strength ($f_{h,y}$) were calculated according to Equation (1) and Equation (2), respectively.

https://doi.org/10.52202/069179-0477

$$f_{h,u} = \frac{F_{max}}{dt} \quad (1)$$

$$f_{h,y} = \frac{F_{yield}}{dt} \quad (2)$$

Although ASTM D5764-97a [5] does not make a reference to the initial or elastic foundation modulus (K_s), it can be interpreted as the slope of the initial linear portion of the load-displacement curve divided by the product of d and t. Nguyen et al. [12] computed K_s through a linear regression between 15% and 40% of the ultimate load. Xu et al. [13] considered the portion between 10% and 40% of the ultimate load, as recommended by EN 383 [6]. Santos et al. [7] only refer to the slope of the linear portion, not defining the4 range of load from which it was obtained. In this study, the portion between 20% and 30% of the ultimate load was chosen to be consistent with the approach adopted for the EN 383 [6] protocol based on the discussion of Van Blokland *et al.* [9]. The load at which the load-deformation curve deviates from a straight line fitted to its initial linear portion is known as the proportional limit load.

From the EN 383 [6] protocol, three foundation moduli were determined: the initial foundation modulus (K_s), related to the initial loading branch, and the elastic foundation modulus (K_e) related to the slopes of the unloading (K_{e-}) and reloading cycles (K_{e+}). According to Van Blokland et al. [9], non-linearity can be observed in the last part of unloading, which is between 10% and 20% of the maximum estimated force ($F_{max,est}$) in their tests. Therefore, to avoid this, the load levels between 20–30% of $F_{max,est}$ were used to obtain K_{e-}. Consistently, the same range was adopted for K_s and K_{e+}.

2.3 STATISTICAL ANALYSIS

A statistical software program (IBM SPSS Software, IBM, Armonk, United States) was used to perform the analysis with a significance level of 0.05. The normality of the data was diagnosed by the Shapiro-Wilk test and homoscedastic by the Levene test. A one-way Bonferroni analysis of variance (ANOVA) was performed to compare the embedment properties within different thicknesses tested according to ASTM D5764-97a [5]. Due to the non-normality of the data, bootstrapping procedures (1000 resamplings; 95 % CI, bias-corrected and accelerated - BCa) were implemented to obtain greater reliability of the results to correct deviations from the normality of the sample distribution and to present a 95 % CI for differences among means [14].

The statistical significance regarding the test protocol (ASTM D5764-97a [5] vs. EN 383 [6]) and setup (Setup 1 vs. Setup 2 from EN 383 [6]) was assessed via an independent t-test since data was diagnosed as normally distributed through the Shapiro-Wilk test and their variances was verified to be homogeneous by the Levene test.

3 RESULTS AND DISCUSSION

3.1 INFLUENCE OF THICKNESS WITHIN ASTM D5764-97a [5] PROTOCOL

The largest differences were found for the embedment strength, as a result of thickness. A p-value<0.001 was achieved in the analysis of variance for both $f_{h,y}$ and $f_{h,u}$. A post-hoc Bonferroni analysis indicated that the source of difference relies on the group with a thickness of 35 mm, which can also be noted by visually comparing the mean load-displacement curves shown in Figure 6 and the distribution of $f_{h,u}$ showed in Figure 7.

To ensure the representativeness of the data, a power (by mean of averages, OpenEpi) [15] was calculated for the ultimate embedment strength, comparing the high (mean

https://doi.org/10.52202/069179-0477

= 42.29 MPa, standard deviation = 4.9, sample size = 53, thickness = 20 mm) and low group (mean = 33.61 MPa, standard deviation = 5.4, sample size = 60, thickness = 35 mm) and power of 100 % was achieved.

It is important to highlight here that the Bonferroni analysis pointed out a significant difference (p-value = 0.009) in density for the group of thickness = 30 mm compared to the others (see also Table 1). Therefore, the group shall not be considered for the analysis regarding the thickness influence since it is not representative.

No significant difference was found for the initial foundation modulus, which can also be noted by its distribution presented in Figure 8.

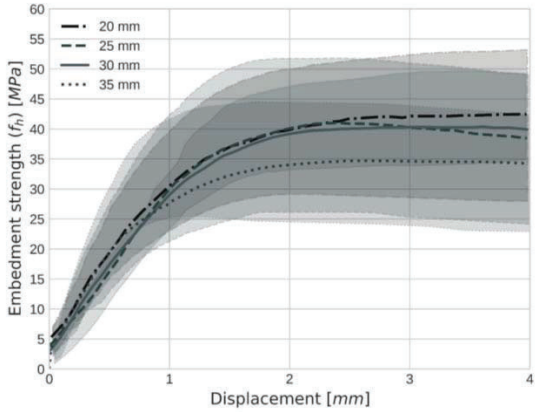

Figure 6: *Mean load-displacement curves for specimens tested according to ASTM D 5764-97a [5] for a dowel of 8 mm*

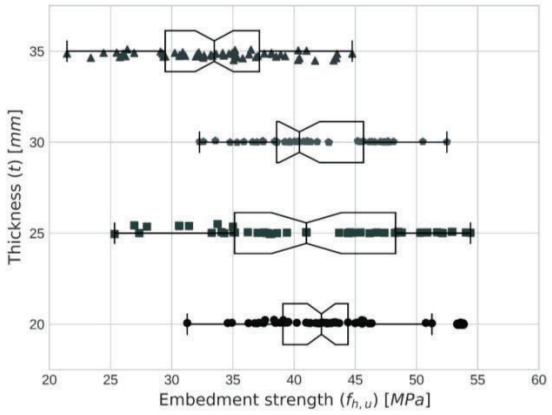

Figure 7: *Embedment strength for different member thicknesses according to ASTM D 5764-97a [5] for a dowel of 8 mm*

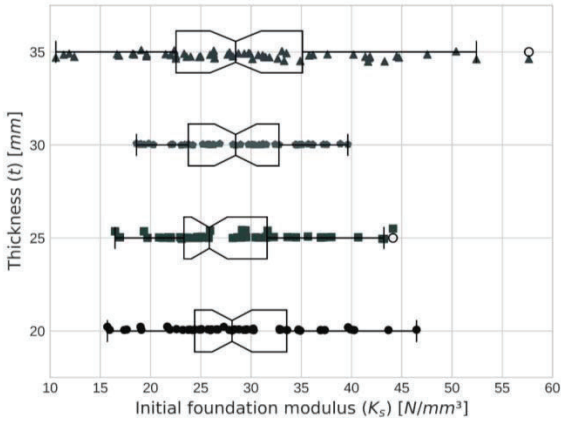

Figure 8: *Initial foundation modulus for different member thickness according to ASTM D 5764-97a [5] for a dowel of 8 mm*

The relationships between density and embedment strength ($f_{h,u}$) is presented in Figure 9.

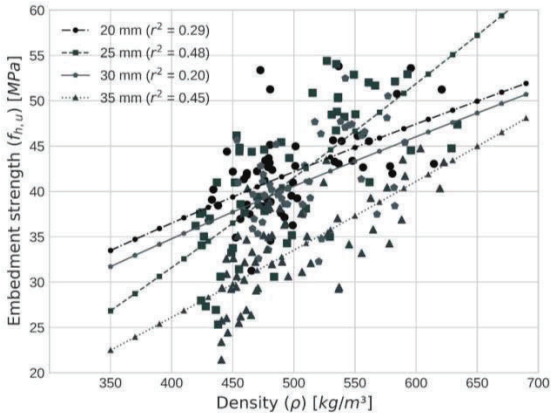

Figure 9: *Scatter plot of density versus embedment strength for specimens tested according to ASTM D 5764-97a [5] for a dowel of 8 mm*

3.2 ASTM D5764-97a vs. EN 383

A significant difference (p-value<0.001) was found, according to the independent t-test, for all the embedment properties retrieved from the load-displacement curves obtained according to ASTM D5764-97a [5] and EN 383 [6] protocols. The statistical test was also conducted to guarantee that there was no statistically significant difference in the densities of each group to avoid bias in the results.

Figure 10 shows the mean-load displacement curves according to both standards. The distribution of the ultimate embedment strength ($f_{h,u}$) and the initial foundation modulus (K_s) is presented in Figures 11 and 12, respectively. The relationships between density and embedment strength ($f_{h,u}$) is presented in Figure 13.

The analysis showed that the $f_{h,u}$ obtained from the ASTM D5764-97a [5] curve is 18.7% bigger than the one obtained from EN 383 [6]. The difference decreases to 9.9% when comparing $f_{h,y}$ from ASTM D5764-97a [5]

https://doi.org/10.52202/069179-0477

with $f_{h,u}$ from EN 383 [6]. In terms of the initial foundation modulus (Ks), the EN 383 protocol yielded a value 39.7% bigger than the one obtained from ASTM D5764-97a [5].

Frankel and Magnière [11] and Van Blokland *et al.* [9] compared the test setup between the investigated standards for Spruce (*Picea abies*) with dowel diameters of 12 mm and 10 mm, respectively, and conclude that the test specimen configuration (half-hole or full-hole), has a relatively small and not statistically significant effect on the embedment strength. Both test configurations followed the loading protocol of EN 383. Nonetheless, Van Blokland *et al.* [9] argue that despite no significant difference being found, embedment strength was around 7% higher for half-hole specimens. The study also found that K_s was 80–180% higher when determined in the half-hole compared to the full-hole test setup, differing from the results found in this study. Santos et al. [7] performed a comparison for Maritime Pine (*Pinus pinaster*) with a dowel diameter of 14 mm by changing both the specimen configuration and the loading protocol. The results showed no significant difference in terms of K_s and $f_{h,u}$. This could indicate the variability of test methods is also dependent on the wood species evaluated and the dowel diameter. An additional comparison was made to infer the influence of the diameter of Scots pine (*Pinus sylvestris*) (see Figure 14) within the scope of EN 383 [6]. Specimens with the same slenderness ratio were considered for the comparison (t/d = 2.5). The largest difference was found for K_s. The specimens with a dowel diameter of 8 mm had a mean initial foundation modulus 42.3% higher than the ones with 12 mm. With respect to the embedment strength, a difference of 17.4% was found.

3.3 INFLUENCE OF TEST SETUP WITHIN EN 383

For the test setup within the scope of EN 383 [6] investigated in this study, no statistically significant difference was found for the embedding properties. The mean displacement curves for both wood species investigated are shown in Figures 15 and 16. This led to the conclusion that once the embedment failure is guaranteed within the experiment, that is, there was no premature splitting or bending of the dowel, the impact of the test setups evaluated is not significant to the results. This was guaranteed by following the recommendations of specimen dimensions of EN 383. A slenderness ratio (t/d) between 2 and 2.5 was adopted for the tests presented.

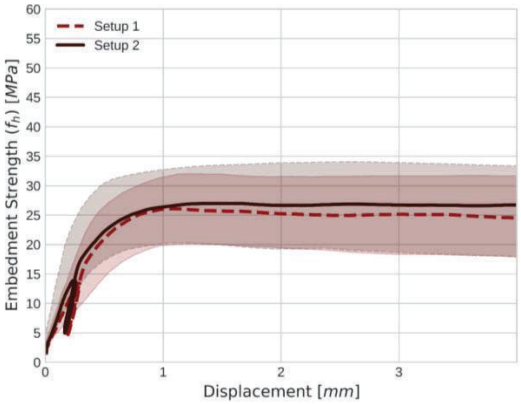

Figure 16: *Mean load-displacement curves for Spruce (Picea abies) according to EN 383 for a dowel of 12 mm in diameter and specimens' thicknesses of 30 mm*

4 CONCLUSIONS

This paper presents an experimental investigation related to testing methods and setup for the timber embedment strength and foundation modulus, two important properties for the connection behaviour. The investigation mainly covered the influence of specimen thickness within the scope of ASTM D5764-97a [5] and the influence of the test protocol in the quantification of the timber embedment according to the grain direction. The latter investigation was conducted by evaluating the embedment strength following both ASTM D5764-97a [5] and EN 383 [6] standards. An additional investigation was also conducted regarding the test setup (load application) of EN 383.

The results showed that the thickness had a significant impact on specimens with 35 mm (4.4d) compared to the ones with 20 mm (2.5d) and 25 mm (3.1d). No difference was found in the initial foundation modulus (K_s). This result points to the need for a deeper investigation regarding the influence of the member thickness on the embedment strength, especially since reference cross-sections of timber elements, commonly used in timber connections, have thicknesses greater than 40 mm. A broader experimental campaign involving other wood species, as well as a robust numerical analysis shall be conducted to confirm the trend found. For this, the half-hole specimen should be used to avoid dowel bending.

The investigation between test protocols resulted in a significant difference for both the embedment strength (yield – $f_{h,y}$ and ultimate – $f_{h,u}$) and the initial foundation modulus (K_s). The results differed from similar investigations found in the literature on different wood species. This could indicate the variability of test methods is also dependent on the wood species evaluated and the dowel diameter.

No significant difference was found in terms of the load application according to the EN 383 [6] standard.

DEVELOPMENT OF COMPREHENSIVE TESTING PROCEDURES FOR HIGH-PERFORMANCE BONDED-IN RODS

Robert Jockwer [1], Pedro Palma [2], Arthur S. Rebouças [3], Alexander Salenikovich [4]

ABSTRACT: Bonded- or glued-in rods are a highly efficient fastening technology. The complexity of the interaction of different materials in the joint (adhesive, rod, and wood) and non-linear stress distribution along the bondline present special challenges for the precise characterisation of the strength and stiffness properties relevant for the design. The existing test standards and protocols specify only the bare minimum for the utilisation of these connections. The following aspects need a more detailed consideration in test specifications: rods in different wood-based products; impact of spacing and end/edge distances; group effects; quality assurance; fatigue; impact of environmental conditions, fire resistance, etc. In the paper, a detailed state-of-the-art regarding testing of bonded-in rods is given and the different aspects with need for further test development are discussed. Proposals are also made on how to better characterize experimentally the properties and behaviour bonded-in rods and on how to fully utilize their potential in design.

KEYWORDS: glued-in rods, bonded-in rods, combined loading, fatigue, group effects, spacing, end/edge distances, RILEM TC TPT

1 INTRODUCTION

Bonded-in or glued-in rods are highly performant fastening technologies, especially when used to transfer axial forces or moments by means of metal or FRP rods into wood members. If properly designed and produced, they can achieve a very high stiffness, load-carrying capacity, fire resistance and be aesthetically pleasing and cost effective. However, due to the complex interaction of the rod, adhesive, and wood, a reliable characterisation of the properties of the bonded-in rods is particularly challenging and consequently, so is the design.

2 STATE OF THE ART

2.1 Development

The development and utilization of bonded-in rods started in the 1970s. Early developments of bonded-in rods can be traced back to the need to introduce high forces into wood members, especially in the direction parallel to the grain [1]-[3], as well as for reinforcements of existing structures, restoration and renovation [4]&[5]. Through the pioneering work of Turkovsky [6]&[7], joints with inclined bonded-in rods have been successfully used in large-span and outdoor timber structures in the USSR and then in Russia since the 1980s [8] (Figure 1). Major advancements in testing and design of bonded-in rods were achieved in the GIROD project [9]&[10]. In recent years, special systems of bonded-in rods have been developed, favouring a ductile failure in the rod to protect the joints form brittle failures [11]&[12]. Otero-Chans et al. [14] divided potential improvements of bonded-in rod systems into four groups: (1) hooped systems, (2) hybrid joints, (3) modified rod shapes and (4) modifications in the shape of the drilled hole (Figure 2).

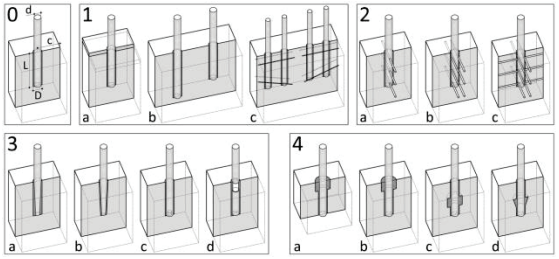

Figure 2: *Potential improvements of bonded-in systems. [14]*

2.2 Structural behaviour of bonded-in rods

Joints with bonded-in rods rely on the interaction between three components – the wood, the rod, and the adhesive – and the performance of the connection depends first and foremost on the adhesive bond between the wood and the rod (Figure 3). Careful planning, design, preparation, execution, and quality control are required to ensure the integrity, resistance, and durability of the bonded-in rod connection during the design working life of the structure.

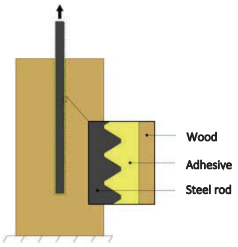

Figure 3: *Glued-in rod composite system.[15]*

The failure of joints with bonded-in rods can occur in the wood substrate, in the rod, in the adhesive, or at the wood-adhesive or rod-adhesive interfaces. For axially loaded bonded-in rods parallel to the grain, the following failure modes [12]-[16] are considered in the most recent draft of prEN 1995-1-1 *Eurocode 5* [17] (Figure 4):

a) tensile failure of the rod
b) compression (buckling) failure of the rod
c) failure of the adhesive within the glue line or in the bondline with the rod and/or timber
d) shear failure of the wood adjacent to the bondline
e) splitting of the wood starting from the bonded-in rods
f) plug shear failure of the wood in a joint with several bonded-in rods
g) net tension failure of the wood et the end of the rod.

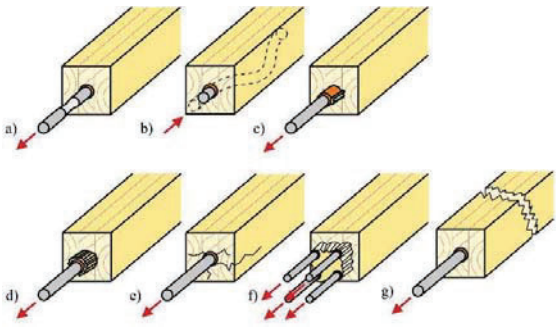

Figure 4: *Failure modes of axially loaded bonded-in rods (based on [16]).*

For the assessment of the load-carrying capacity and the governing failure modes, the different behavior of the joint components at the various locations must be considered. For example, the wood, the adhesive, and the bondline are characterized by large variability in load-carrying capacity and propensity to brittle failure modes. In contrast, mild-steel rods fail through yielding in a ductile manner and their load-carrying capacity is more predictable, especially if the quality of steel is controlled. Therefore, different partial safety factors are considered for the different failure modes in the design. When the yield failure mode governs the design, the bond strength is underutilized, but it is capacity protected (Figure 5).

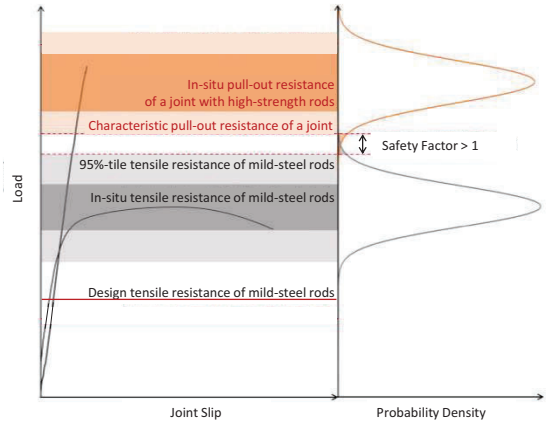

Figure 5: *Graphic illustration of the design philosophy of joints with bonded-in rods.[18]*

2.3 Standards for testing and design

The complex interaction of the different materials in the joint and the non-linear stress distribution along the bondline present special challenges for the precise characterisation of the strength and stiffness properties relevant for the design.

The testing requirements for bond shear strength of bonded-in rods in glued structural timber products are specified in EN 17334 [19]. Except for the Russian design standard [20], it is the first European test standard for bonded-in rods which sets the basis for the declaration of performance and design. In 2022, ICC-ES published Acceptance Criteria for bonded-in rods used as connections in tension and compression [42].

Several national timber design standards and design guides provide guidance for connections with bonded-in rods [21]-[27] with various degrees of detail. The next generation of prEN 1995-1-1 *Eurocode 5* [17], to be published in 2025, will include a chapter on bonded-in rods and will provide general design rules based, amongst other parameters, on the bond strength determined in accordance with EN 17334 [19].

Despite the lack of uniform European or international design guidelines, bonded-in-rods have been successfully applied in a variety of projects across the world. This has allowed further experience to be gained in their use. As a result, various approval documents have been issued for the use of bonded-in rods in timber structures, such as:

https://doi.org/10.52202/069179-0478

- Z-9 1-705 2K-EP-Klebstoff WEVO-Spezialharz [26]
- Z-9.1-896 2K-PUR Klebstoff LOCTITE CR 821 PURBOND [29]
- Z-9 1-778 2K-EP-Klebstoff GSA-Harz [30]
- Z-9.1-791 Studiengemeinschaft Holzleimbau [31]
- Technical Assessment 3/12-716 Societé SIMONIN SAS [32]

Recently, European Technical Assessments (ETA) have also been issued for products from various manufacturers [33]&[34] based on EAD 130006-00-0304 [35].

Based on these approvals, available bonded-in rod solutions can be categorized in two main approaches:

- adhesive-based solutions [29]: adhesive manufacturers have developed and certified special adhesives to produce bonded-in rods for specific customers. In the certification documents, the bond strength is specified without specific consideration of the joint configuration.
- system-based solutions [30]&[32]: other manufacturers have achieved approval and certification of proprietary systems of bonded-in rods, considering joints with particular combinations of rods, wood members, and adhesives.

These two approaches allow enough flexibility and specialisation to address the needs of different customers. Adhesive-based solutions require a higher level of detail in the generalized testing and in the description of design procedures to achieve the same desired level of performance in the application, whereas system-based solutions provide exclusive but potentially optimized configurations and range of applications.

In the specifications of the test procedure, EN 17334 [19] focuses primarily on the determination of the bondline shear strength as part of the description of failure mode c) according to the list in Section 2.2. The selection of the dimensions of the timber specimens and steel rods aims at avoiding failure modes comprising yielding of the steel or splitting of the timber members. This means that only some aspects of the bonded-in rod system are considered.

3 SELECTED CHALLENGES IN BONDED-IN ROD TESTING

The main challenges in testing and evaluation of bonded-in rod connections are related to the impact of the material characteristics, connection geometry, load direction and ambient conditions on the load-deformation behaviour, durability, and failure modes. The following selected challenges will be addressed in this paper:

- impact of the adhesive, wood product and grain orientation,
- quality assurance of the bond,
- behaviour in fire,
- stiffness and deformation capacity, and
- multiple rods

3.1 Impact of the adhesive, wood product and grain orientation

The strength of the adhesive bond is limited by the shear strength of the wood, the shear strength of the adhesive, and the bond between them. The shear strength of epoxy adhesives is in the range of 16 to 20 N/mm^2 [36]. PUR adhesives possess similar strength but are softer and have a lower glass transition temperature [37]. The high strength can only be exploited when rods are used in hardwoods [38]. In softwoods, the adhesive bond strength is generally limited by the shear strength of the wood [39] and the adhesive joint can only be utilized up to a shear strength of about 6 to 8 N/mm^2.

The bond strength depends on the bondline thickness. It is recognized in EN 17334 [19], which calls for evaluation of bondline thickness from 2 to 6 mm. Furthermore, researchers use larger and/or variable glue line thickness in search of improving the overall performance of the joints [14],[40].

In the case of rods bonded-in parallel to the grain and loaded in axial tension, failure occurs due to an irregular breakout cylinder depending on the local strength of the wood. Therefore, an effective bond strength is used in the design, which must be determined for the individual combination of adhesive, wood and size of the rod or reinforcement type according to EN 17334 [19].

The dependence of the bond strength on the bonded length described in EN 17334 [19] was chosen according to DIN EN 1995-1-1/NA:2013 [21]. Aicher and Stapf [39] discuss various other functions for the reduction of the adhesive bond strength as a function of the bonded length and compare them with test results. In a preliminary draft of EN1995-1-1:2004 *Eurocode 5*, a 10% reduction was proposed for rods bonded-in perpendicular to the grain.

The dependency of the bond strength on the bonded length is based primarily on the studies of bonded-in rods parallel to the grain in softwood glulam. It was observed that in joints with rods bonded-in perpendicular to the grain, the bond strength shows a lower dependency on the bonded length, because wood is much softer in this direction. Therefore, the shear stress distribution is assumed to be constant along the bondline, which cannot be said about the stress distribution along the rods bonded-in and loaded parallel to the grain (Figure 6). For this reason, a constant value can be assumed in design of rods bonded-in perpendicular to the grain within certain limits [40]. In addition, since the bondline failure of rods parallel to the grain can be initiated by the exceedance of failure strain of the wood, the bond strength definition in different wood products and wood species should be determined individually as a function of the angle to the grain. Therefore, the ICC-ES AC526 [42] requires tests of bonded-in rods at various angles to the grain.

https://doi.org/10.52202/069179-0478

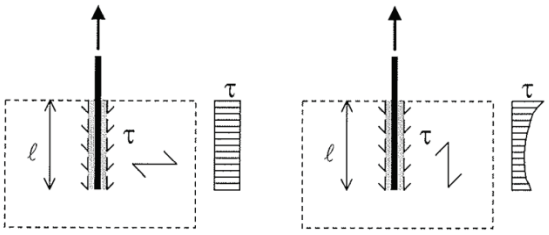

Figure 6: *Approximation of the stress distribution by gluing perpendicular and parallel to the grain direction. [40]*

To determine the bond strength in accordance with EN 17334 [19], the strength class or yield strength of the steel rod is chosen, depending on the rod diameter and the bond length, to achieve the bond or wood failure without rod yielding. Likewise, AC526 [42] requires that every rod diameter is tested at the maximum, minimum and at least one intermediate bond length using high-strength steel rods that have sufficient strength to develop the bond strength. To determine performance parameters of the joints other than the bond strength, the rods used in the tests should be representative of the class of steel intended for the application.

Bonded-in rods in cross-laminated timber (CLT) are permitted according to the next generation of prEN 1995-1-1 *Eurocode 5* [17]. However, Vallée et al. [43] state that the prediction of the load-carrying capacity of bonded-in rods in CLT is more challenging than in glued-laminated timber due to the increased anisotropy arising from the orthogonal arrangement of the layers. Brittle failure modes of the rods with tear-out of wood blocks from the different layers of the CLT were observed in tests in [44]&[45]. The complex brittle failure modes are influenced amongst others by the rod-to-grain angle, the distances to the cross-layers, spacing between the rods, and also include the rolling shear failure in the interface between the layers.

3.2 Quality assurance of the bond

Bonded-in rods are very demanding in terms of execution, as even minor defects and flaws in production can have a decisive impact on the bond performance. Care must therefore be taken to ensure careful and accurate production and quality assurance.

The effects of various production defects on the load-carrying capacity have been studied in detail [46]. It was found that insufficient grouting and voids along the bondline have the greatest influence on reducing the load-carrying capacity of the joint. Other defects include remaining wood chips in the drilled hole or insufficiently degreased threaded rods.

Gonzalez et al. [47] studied the impact of placing 12.7 mm rods of various lengths off-center during fabrication and did not observe any influence on the resistance nor failure modes. While this may be true for the smaller rods and generous edge distance, for rods of larger diameter and bond length and smaller spacing, the deviation of rod axis off-center may become a reason for splitting of the wood around the rod, which was observed by Salenikovich et al. [48] who tested 16 mm rods in glulam and MPP.

Another serious challenge in bonding of joints is the presence of cavities and gaps between laminations in CLT, where the glue may leak and result in starving joints. The gaps not only increase the consumption of the adhesive dramatically, but the starving joints may also not guarantee the full coverage of the adherends and result in defective bondlines.

One challenge relates to the assurance of the correct curing of the adhesives in the connections. Parameters that can have an impact on the curing of the adhesive are, e.g., the ambient and material temperatures during bonding and curing, the correct mixing ratio, and the moisture content of wood. Errors in the estimates of the wood temperature in cold climates may lead to the reduced pot life of the glue and defective bond.

Compliance withdrawal tests that can be used as an indicator for the correct curing of the adhesive in the bondline of bonded-in rods were developed together with the design and execution guidelines for the next generation of prEN 1995-1-1 *Eurocode 5* [17] and should be included in the next revision of EN1382 [49].

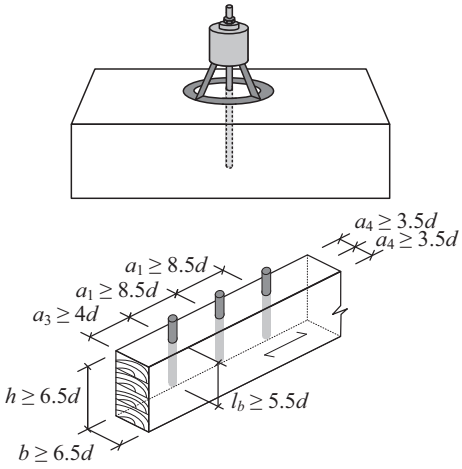

Figure 7: *Example of the compliance withdrawal test arrangement and the specimen geometry*

Such compliance withdrawal test may be carried out in *pull-beam*, *pull-compression,* or *pull-pile foundation* configurations as illustrated in Figure 7. The rods should be bonded in the direction perpendicular to the grain, to avoid splitting of the timber in the vicinity of the bondline. To avoid premature splitting of the wood member, the spacing and end and edge distances should be sufficiently large and exceed the minimum required values in the design regulations. Since the bond shear test is aimed at the bondline failure, the bonded length may be shorter than the minimum values given in the design standards, and a length of $5.5 \cdot d$ can be proposed for softwood. This test procedure is very similar to the quality assurance tests conducted in accordance with GOST R 56710 [20] except that the rods are pushed through (Figure 8).

https://doi.org/10.52202/069179-0478

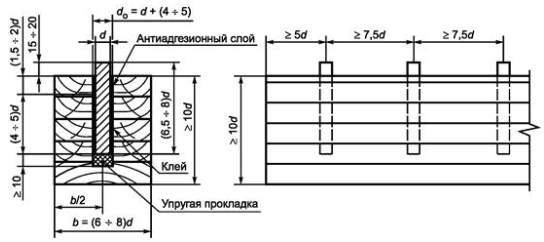

Figure 8: *Control specimens for bonded-in rods. [20]*

The wood material for the test specimens should be representative of the wood product intended for the application. Test pieces made from hardwood species (e.g., beech LVL) are also suitable for the checking of the curing of the adhesive of bonded-in-rods.

To achieve a representative comparison of the adhesive properties and curing in the compliance tests and the actual connections, the fabrication of the test joints shall be performed following the same procedures as for the bonded-in rods in the application. The test pieces should be stored under equal conditions as the bonded-in rods in the application until the full curing before testing.

The testing of the specimens is done as a reference testing, which means that the tested bond strength is benchmarked against a previously determined reference value.

The sampling procedures for compliance and acceptance testing should be in accordance with ISO 2859-1 [50]. A reference value of bond strength should be determined for the specimens stored at least until full curing of the adhesive under reference conditions at 20±2 °C and 65±5% relative humidity.

The bondline strength, corrected for the density, determined during the compliance tests shall be greater than or equal to the corresponding declared value of characteristic bond strength of the adhesive.

3.3 Behaviour in fire

Timber connections with exposed metal fasteners and steel plates are known to conduct heat into the core of the timber cross-section, which leads to increased charring and reduced load-carrying capacity in the connection area [51]-[53]. For connections with dowel-type fasteners, additional protection using panels or wooden plugs can be used to provide some cover to the otherwise exposed ends of the fasteners [54], contributing to increased fire resistance.

Bonded-in rods are inherently embedded in the wood cross-section, which can provide a significant advantage regarding fire resistance. Fire resistance tests on bonded-in rods have been performed with thermal insulation protecting the protruding end of the steel rod [55]-[57] or the other steel parts of the connection [58]. This prevents heat from being conducted from the steel parts into the adhesive, which would severely reduce the fire resistance. The fire resistance of connections with bonded-in rods cannot, therefore, be assessed solely based on the fire resistance of a fully embedded rod. The protection and detailing of the hub or plate connecting the rods to the next member is also a crucial aspect of the fire resistance of these connections [55]. Gaps between the surfaces of connected timber members can have a significant influence in the fire resistance and even small gaps can increase during fire exposure and lead to initially protected steel surfaces becoming exposed [53]. Therefore, an accurate evaluation of the fire resistance of a connection with bonded-in rods can only be made considering the configuration of the entire connection.

Performance criteria for fire resistance testing (maximum deformation or deformation rate) are also not specifically prescribed in EN 1363-1 [59] for structural timber connections, which often leads to different failure criteria being adopted in different studies.

3.4 Stiffness and deformation capacity

Axially loaded bonded-in rods exhibit very high stiffness and slip modulus due to nearly “slip-free” bonding in the joint. Various approvals therefore generally describe connections with bonded-in rods as “rigid”. A high stiffness is often desirable to achieve high efficiency in a moment-resisting connection and to reduce its rotation. However, this assumption might overestimate the stiffness of the joint, especially in the transition between the timber member and connected steel parts. Not only the stiffness of the bonded length of the rod but also the unbonded rod length and the flexibility of connected steel parts need to be considered in the design.

One challenge in determining the slip modulus in tests is the proper arrangement of the measuring equipment to correctly measure the decisive deformation. For example, the free, unbonded length of the rod has a significant share in the total deformation, and the distance between the reference points must be considered in test results.

Stiffness values reported in the literature vary a lot because they are measured differently and on different size, length and number of rods [47],[48]&[60]-[65]. For the rods of 16 mm in diameter, Bouchard et al. [65] and Salenikovich et al. [48] reported the slip moduli between 115 kN/mm and 212 kN/mm per rod. Gonzales et al. [47] and Verdet et al. [64] measured the slip modulus between 60 kN/mm and 110 kN/mm for rods of 12.7 mm and 8 mm in diameter. The latter values are comparable value to that given in the Simonin/Ducret approval [32] of 71 kN/mm. These values are somewhat higher than the slip moduli determined by Blaß and Steige [66] for screwed-in threaded rods, which are the basis for the approach in the most recent draft of prEN 1995-1-1 *Eurocode 5* [17]. To allow for a more effective and competitive use of bonded-in rods, the actual stiffness values of the system need to be determined during the bond strength tests. The placement of slip measuring devices should follow requirements of EN 17334 [19] or AC526 [42]. Characteristics of the bonded-in rod system such as an unbonded length, constriction, or the connection details should be considered in the determination of the real connection stiffness.

https://doi.org/10.52202/069179-0478

3.5 Multiple rods

3.5.1 Situation

During the last 30 years, several studies have been carried out on bonded-in rod connections, mainly focused on the pull-out resistance and on the bond behaviour between the rod and the wood. Most of the literature on the subject was initially focused on investigating the load-slip relationship and defining the failure mechanisms for a single-rod connection.

The few existing design codes with specific guidance for bonded-in rods, such as DIN EN 1995-1-1/NA [21], deal with the definition of the load-carrying capacity of a single rod or provide a simple adjustment to account for the uneven load distribution between the rods [13]. In the most recent draft of prEN 1995-1-1 *Eurocode 5* [17], the chapter on bonded-in rods addresses primarily joints with single rods and is based on bond strength determined in accordance with EN 17334 [19], which is also determined on single rod test specimens.

In practice, bonded-in rods are used in groups and a more detailed knowledge of their structural behaviour is relevant for the research community and designers [67]. That is why AC526 [42] requires testing groups of four rods placed at distances representative of the minimum allowed spacing for the system.

Due to a very high stiffness, bonded-in threaded rods cannot easily ensure redistribution of loads unless the rods start yielding. However, if the yield strength of the rods is higher than the bond strength, then the redistribution may not be possible and an uneven loading in a group of fasteners will lead to a brittle failure of the overloaded rod [65]. That is why the current design philosophy favours the design of joints with bonded-in rods where the yielding of the rods governs.

Unlike single joints, few data are available in the literature for multiple bonded-in rod connections. In general, available studies can be divided into pull-out tests (almost equally loaded tension joint) and moment-resisting connections (unequally loaded joints).

A reduction for the load-carrying capacity due to uneven force distribution is given by Turkovsky [4], based on the USSR standard of 1982. There, the reduction in load-carrying capacity due to uneven load distribution between rods is applied by reducing the load-carrying capacity 10% for two rods and 20% for three rods in a row parallel to the grain. The resistance is further reduced 10% if the bars are arranged in two rows perpendicular to the grain. Buchanan [24] proposed the following reduction of the load-carrying capacity for "closely spaced" rods: the full load-carrying capacity can be used for one or two rods, it must be reduced 10% for three or four rods, and reduced 20% for five or six rods. Based on the above recommendations, in the most recent draft of prEN 1995-1-1 *Eurocode 5* [17], a reduction of 10% is suggested for three to four rods and 20% for five or more rods, unless a uniform load distribution can be assumed. Connections with more than six rods are not recommended without a uniform load distribution.

In moment resisting connections, such as knee joints, with several layers of rods bonded-in parallel to the grain, Buchanan [24] recommended to have staggered bonded lengths by offsetting the rod ends by at least 75 mm to minimize the risk of splitting along the rods and to reduce the stress concentrations at the rod ends (Figure 9). In addition, it is recommended to check the wood fracture at tips of steel rods for the tensile force acting in each layer in such connections [26] (Figure 10).

3.5.2 Multiple rods pull-out tests

Several studies have focused on observing the failure modes, verifying the possibility of achieving ductile failure and evaluating the influence of the main geometric parameters (rod diameter, distance between rods, distance to edges, bonded length) and mechanical properties (yield and ultimate strength of rods) on the structural behaviour of the joints [47]&[68]-[71].

The test setups and procedures used are very similar to that for single rod joints and the loading protocol follows the recommendations given by ISO 6891 [72]. The maximum load, failure mode and displacement at failure are measured. From these tests, the load-carrying capacity of the joint is compared with the pull-out capacity of a single rod and the tensile resistance of the rod, which are usually predicted from analytical formulations. A group reduction factor for connections with multiple rods can be derived from this comparison.

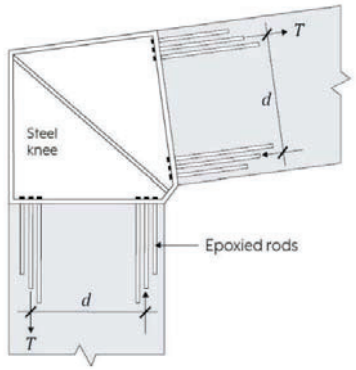

Figure 9: *Staggered rod ends in a knee joint. [26]*

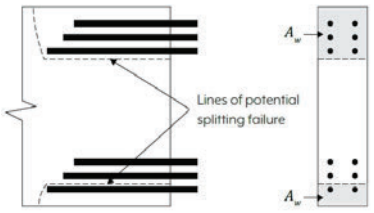

Figure 10: *Wood area for checking wood fracture capacity in a knee joint. [26]*

In many cases, failures occur due to splitting that starts at the end of the wood member and extends along the length of the rod before the onset of yielding. This could be in part due to the difficulty of fabricating connections with multiple rods that are perfectly aligned. Sometimes, there are defects in the bondline along the length of the rods. To mitigate the splitting failures, it is possible to reinforce the

https://doi.org/10.52202/069179-0478

wood member using perpendicular fasteners such as screws or smaller bonded-in rods. In fact, in Russia, the use of bonded-in rods parallel to the grain is not recommended, and transverse reinforcement is required in all connections [13].

In connections with multiple bonded-in rods, it is often aimed at small edge distances to increase the overall efficiency of the connection (i.e., less than $2.5 \cdot d$, which is the minimum distance recommended by most current standards to avoid splitting). When testing the bondline strength according to EN 17334 [19] larger edge and end distances of single rods are used. Gonzalez et al. [47] suggested a minimum edge distance of $3 \cdot d$ to avoid splitting and a minimum spacing of $5 \cdot d$ between rods to prevent splitting. When smaller spacings are used, special measures can be taken to minimize the risk of splitting, such as the use of a not-bonded length towards the end of the timber member. In the current test standard EN 17334 [19], such special measures are not specifically addressed. However, to evaluate the full performance of bonded-in rod system, the bond strength must be tested in combination with the specific measures to reduce the risk of splitting. That is why the not-bonded length and other features may be tested under AC526 [42].

The impact of the rod ductility and redistribution of load was evaluated by Gehri [73] and by Bouchard et al. [65] for connections loaded in axial tension. Larger test series on connections with multiple rods were described by Parida et al. [68], where the influence of low and high steel quality on the failure mode, capacity and ductility were investigated. Steiger et al. [74] stated that the use of "mild steel as well as more bars of smaller diameter are effective measures to increase the ductility of the connection." Especially for connections with several rods where unequal loading in the rods is expected, a high ductility of the joint is required to allow balancing and redistribution of the load.

It can be concluded that not only a single bonded-in rod joint, but the entire connection should be tested and that the system behaviour of the bonded-in rods should be considered. For pull-out tests, it is important to keep an even distribution of stresses across the section so that all rods are equally loaded. This can be achieved using a rigid plate at the end of the rods, fixing them with an extra length so that the rods could deform. However, it is not necessarily representative of the real joint configuration. In general, mild-steel rods are recommended for testing connections with multiple bonded-in rods, as well as in design, to facilitate the yielding and redistribution of loads between rods before other failure modes occur or any imperfections during production of the connection may result in much lower capacity than expected (see Fig.4).

4 PROPOSALS

The complexity of bonded-in rod connections as a system requires further development of tests methods, procedures, and protocols. Some of the most relevant aspects are:

- Rods in different wood-based products. The current European standard test procedures are based on rods bonded parallel to the grain in glued laminated timber or in CLT. The bond strength of rods bonded perpendicular to the grain is assumed to be equivalent. The impact of cross-layers in CLT and veneers in LVL and other wood-based products should be evaluated, especially regarding layer thickness and distribution, edge distances and potential edge intersection with the rod. The literature review revealed the occurrence of undesirable failure modes, including rolling shear of the cross-layers, depending on the specimen configuration.
- Quality assurance of the bond. The quality of the bondline must be verified to ensure the intended performance of the bonded-in rods. Quality assurance testing on representative specimens prepared in parallel to the production of the actual bonded-in rod joints, like it is done in Russia [20], can be a way to verify the correct curing of the adhesive in the bondline under the same environmental conditions and materials. In addition, it would be desirable to perform non-destructive tests to assess the integrity of the bondline after curing (e.g., proof-loading, X-ray scanning).
- Behaviour in fire. The bonded length of the rods is protected by the wood, but different adhesive systems show different sensitivity to high temperatures. The rod end is often exposed and connected to other metallic components that can act as a heat bridge into the connection and bondline. Gaps between connected members also influence the fire performance. The exact configuration of the system and not fully protected rods should be experimentally evaluated.
- Testing groups of rods. Bonded-in rods are most often used in groups, either acting all together with almost equal loading (such as in a tension joint) or with unequal loading (such as in a moment-resisting joint). In both cases, group effects, i.e., reduced load-carrying capacity of the group of rods compared to the sum of the individual rod capacities, may be observed. This aspect should be considered in the testing of the bonded-in rods in a system. Procedures developed in AC526 [42] can be taken as a starting point.
- Rod spacing and improved systems. So far, only tests on single rods with relatively large edge distances have been standardized in Europe for the determination of the bond strength. According to the proposal in the most recent draft of prEN 1995-1-1 *Eurocode 5* [17], the minimum spacing and edge distances must be chosen depending on the bond strength assumed in the design. Hence, to account for a higher bond strength, a larger spacing, a recess (not-bonded length), or any other potential improvements can be required for qualification testing. However, specific spacing requirements for different wood-based products, particularly for hardwoods and LVL, are missing. Procedures developed in AC526 [42] can be taken as a starting point.

https://doi.org/10.52202/069179-0478

- Fatigue behaviour. Bonded-in rods are often applied in conditions prone to fatigue loading. Depending on the configuration, the fatigue strength is typically governed by properties of the rods. However, the fatigue strength of the adhesive bond or wood may also govern. To reliably predict the performance of the connection, the exact configuration of the system should be evaluated.
- Impact of temperature and moisture conditions. The environmental conditions during curing of the adhesive and in the final application have an impact on the performance of the connection. More practical test procedures must be developed to quantify these effects. AC526 [42] may be used as an example.

5 CONCLUSIONS

A review of the state-of-the-art regarding testing of bonded-in rods is given and the different aspects that need for further development of test specifications are discussed.

Proposals are made on how to better characterize the properties and behaviour of groups of bonded-in rods in tests and how to fully utilize their potential in design.

ACKNOWLEDGEMENT

The paper is based on the work of the working group on bonded-in rods in RILEM TC TPT "Tests methods for a reliable characterization of resistance, stiffness and deformation properties of timber joints".

PROTOCOLS AND RESULTS ANALYSIS METHODS FOR CYCLIC TESTS OF TIMBER JOINTS. A DISCUSSION

Meta Kržan[1], Caroline D. Aquino[2], Michael Schweigler[4], Zheng Li[5], Jorge M. Branco[6]

ABSTRACT: Current testing procedures for cyclic loading are quite flexible and the influence of fundamental testing parameters on the obtained load-deformation behaviour is often questioned (number and amplitude of the loading cycles, loading rate, number of specimens, etc.). On the other hand, different methods for data assessment have been used for the definition of stiffness, ductility, strength and stiffness degradation, as well as parameters for analytical and numerical models. However, reliable and well-established assessment methods are required, to support the safe and economic design of timber joints. Fundamental parameters for seismic design, such as ductility or strength degradation, cannot depend on the testing protocol and method for assessment of the data results. In this context, it is important to compare the most representative loading protocols, and assessment methods of the test results, through detailed analysis and discussion. Different types of timber connections, made of distinct materials and tested in different laboratories, must be evaluated. This work will be developed within the RILEM TC TPT, and this paper represents a first contribution to a needed discussion about the testing protocols to evaluate timber connections. In the end, it is expected to present proposals on how to characterize better the properties and behaviour of timber connections under cyclic loading and how to fully utilize their potential in design.

KEYWORDS: Testing protocols, Cyclic loading, Data assessment, Timber connections, RILEM TC TPT

1 INTRODUCTION

The behaviour of timber joints is one of the most important topics in the field of timber structures, and one of the most studied, given their critical role and importance in the local and overall behaviour of timber structures. Due to the brittle nature of wood material, timber elements must be considered elastic, while the nonlinear responses must be concentrated on the joints. The yielding of the metallic dowel-type fasteners can ensure the dissipation of seismic energy together with deformation capacity [1]. As a result, mechanical connections have to be properly designed in order to show adequate low-cyclic fatigue strength, developing plastic deformations with medium-to-high amplitude when subjected to cyclic loads [2]. Given the complexity of their behaviour (anisotropic behaviour of wood, stress concentration around fasteners, variability of mechanical properties, moisture-dependency, size effects), in particular under cyclic loading, research is often based on the experimental evaluation of joints.

Current testing procedures for cyclic loading are quite flexible and the influence of fundamental testing parameters on the obtained load-deformation behaviour is often questioned (number and amplitude of the loading cycles, loading rate, number of specimens, etc.). On the other hand, different methods for data assessment have been used for the definition of stiffness, ductility, strength and stiffness degradation, as well as parameters for analytical and numerical models [3]. Several studies have highlighted the importance of achieving a general consensus within the research community to define a unique cyclic-test procedure and the appropriate definition of yield and ultimate slips to avoid inconsistencies due to high variability in the definition of ductility [3, 4]. Following the initiatives of research and professional community, a technical report ISO/TR 21141 entitled "Timber structures – Timber connections and assemblies – Determination of yield and ultimate characteristics and ductility from test data" was published in 2022 [5] as a result of work and discussions of the ISO/TC 165 technical committee for timber structures. In the document, different methods for determining the yield and ultimate characteristics and ductility of joints and assemblies from test data used in existing standards in Europe, North America and Far East Asia are described and the basic data for unifying the evaluation methods of

parameters by clarifying their similarities and differences is provided.
Meanwhile, a guideline to determine ultimate slip and consequently ductility of timber joints from cyclic tests by considering also strength degradation and impairment is included within an annex to the new Eurocode 8 proposal, namely prEN 1998-1-2:2022, Annex N [6]. However, the relationship between strength degradation and ductility has not been discussed in detail.

2 CYCLIC TEST LOADING PROTOCOLS AND RESULTS ANALYSIS METHODS

The most representative load protocols for cyclic tests are the EN 12512 [7] and ISO 16670 [8]. Equally important, the method used to analyse the test data can differ. Widely used are the analysis methods according to EN 12512, Yasumura and Kawai [9], Kobayashi and Yasumura [10] and the ASTM E2126 [11].

2.1 Cyclic loading protocols

For both EN 12512 and ISO 16670, the loading protocols are defined in dependence on the non-linear response of the connection obtained under monotonic loading, conducted according to EN 26891 [12] and ISO 6891 [13], respectively.
However, according to EN 12512 (and the prEN1998 as well), the imposed cyclic loading in terms of the cyclic displacement schedule (Figure 1) is set based on yield displacement, obtained in monotonic test ($v_{y,M}$), while in ISO 16670, the loading time history is defined based on ultimate displacement ($v_{u,M}$).

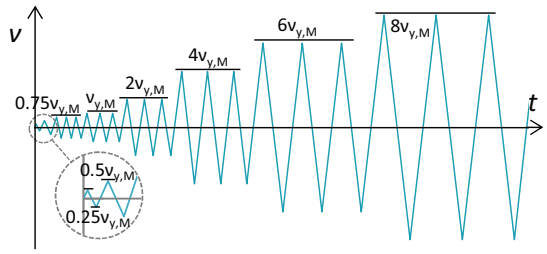

Figure 1: *Loading protocol defined in dependence of yield displacement according to EN 12512 [7].*

The loading protocol in EN 12512 is definite; the first two loading steps applied in one loading cycles (amplitudes 25% and 50% of v_y), are followed by subsequently increased amplitude displacements each with three loading cycles (75%, 100%, 200%, 400%, 600%,… of v_y).
On the other hand, initial loading amplitudes in ISO 16670 up to 10%v_u. (1.25%, 2.5%, 5% and 10% of v_u), are conducted with one loading cycle, but may be omitted or repeated depending on the joint stiffness and testing/measuring equipment. All the subsequent amplitude displacements are loaded in three loading cycles (20%, 40%, 60%,… of v_u).
The ASTM E2126 is more flexible with loading protocols allowing the displacement-controlled loading to be conducted according to: a) Sequential Phased Displacement (SPD) Loading Protocol, which involves displacement cycles grouped in phases at incrementally increasing displacement levels (either sinusoidal or triangular); b) ISO 16670 loading protocol or c) CUREE Basic Loading Protocol, with displacement cycles grouped in phases at incrementally increasing displacement levels and the loading history starting with a series of (six) initiation cycles at small amplitudes (of equal amplitude). Further, each phase of the loading history consists of a primary cycle with amplitude expressed as a fraction (percent) of the reference cycle deformation and subsequent trailing cycles with an amplitude of 75 % of the primary one.
The loading rates also differ according to the standards; the slip rate should according to EN 12512 be constant and may range between 0.02 and 0.2 mm/s, while according to ISO 16670 alternative cyclic displacement schedules – either velocity or frequency based - are allowed with the slip rates between 0.1 and 10 mm/s. Similar is according to ASTM E2126, where the displacement loading rate should be between 1.0 and 63.5 mm/s (standard intended for both lateral resisting systems and shear and hold-down connections) and the cyclic frequency range from 0.2 to 0.5 Hz.
Regarding the loading protocols, Casagrande *et al.* [2] concluded that an increase in the number of cycles leads to greater precision of the results and propose an amendment to the cyclic test protocol given by EN 12512.

2.2 Analysis of the test results

From the lateral force-deformation hysteresis curves various characteristics can be evaluated; besides the performance of the connection in terms of strength and deformation, hysteresis with repeated cycles enables the analysis of strength and stiffness degradation and energy dissipation.
To compare different responses, hysteresis envelope curves are often used. Important parameters, such as elastic and plastic stiffness, yield and ultimate displacement (slip), and ductility are evaluated from hysteresis envelopes by considering agreed criteria for idealisation.

Ductility is defined as the ultimate to yield slip ratio and it therefore highly depends on both yield and ultimate slip definitions.
Ultimate slip v_u is commonly defined as the smallest of failure slip, slip at 20% of strength drop considering 1st Load-Slip Envelope Curve (1st LEC) or absolute slip limit (30 mm in EN 12512).

Yield slip v_y can according to EN 12512 be calculated considering two different procedures. When the 1st LEC presents two well-defined linear parts, the yield slip v_y is determined by the intersection between the two lines

https://doi.org/10.52202/069179-0479

(Method A). When two well-defined linear parts are not observed, ν_y is determined by the intersection of two additional lines (Method B): the first line (denoted as the elastic line), with slope K_α (stiffness), is determined as that drawn through the point on the curve corresponding to 10% of the maximum load F_{max} and the point on the curve corresponding to 40% of F_{max}. This stiffness is in the paper labelled $K_{10\text{-}40}$, in the prEN 1998-1-2 proposal $K_{SLS,v,c}$, but it is also commonly referred to as elastic stiffness and labelled K_e. The second line (denoted as plastic line) is the tangent to the backbone curve having an inclination K_β equal 1/6 inclination of the first line (K_α).

ASTM E2126 [11] and Kobayashi and Yasumura [10] apply the Equivalent Energy Elastic-Plastic (EEEP) method to determine the yield slip ν_y and the ductility (D), through the definition of equivalent bi-linear ideally elastic, ideally plastic curve. In general, to determine such a curve considering the EEEP criterion, two more criteria besides EEEP are needed. While there are not many differences in the definition of ultimate displacement (one criterion), the other criterion may either be assumed/defined effective stiffness and less commonly assumed/defined idealised strength capacity. The first is adopted by Kobayashi and Yasumura, who determine yield slip ν_y through EEEP by assuming K_{ef} and calculating idealised force. The K_{ef} is in their case defined according to Yasumura and Kawai [9] as the point in the curve at the same force, at which the secant line through 10 and 40% F_{max} intersects a tangent line to the curve with an inclination of a secant line through 40 and 90% F_{max}. Similar is proposed in ASTM E2126, where the assumed effective stiffness K_{ef} is defined as stiffness at 40% F_{max}. Some authors use in a similar way the EEEP criterion to define the bi-linear curve considering the effective stiffness determined from EN 12512 (stiffness corresponding to ν_y) and to evaluate ductility more conservatively in comparison to EN 12512 by defining the yield slip as the elastic displacement of the idealised bi-linear curve. The use and comparison of such idealisation are presented in the paper for the second case study.

Within the revision process of Eurocode 8, Casagrande *et al.* [1] proposed a novel methodology, which defines an interaction between the strength degradation and the ductility capacity, offering two major contributions to the field: i) it defines a relationship between the slip amplitude and the impairment of strength from the 1st to 3rd cycle and provides an additional condition for determination of ultimate slip in dependence of strength impairment limit; and, ii) it considers the strength degradation as an additional condition for the determination of ultimate slip of dissipative connections subjected to low-cyclic load testing.

The strength impairment factor φ_{imp} is determined as the ratio of reduction of resistance between the 1st (F_1) and the 3rd (F_3) loading cycle to the resistance obtained at the 1st loading cycle (F_1) for the evaluated amplitude displacement ν_i (Equation (1)).

$$\varphi_{imp}(\nu_i) = \frac{F_1(\nu_i) - F_3(\nu_i)}{F_1(\nu_i)} \quad (1)$$

According to the prEN 1998-1-2, Annex N, the φ_{imp} should be lower than 0.3 and if reached or exceeded, the corresponding deformation should be considered as ultimate deformation.

The strength degradation factor k_{deg} is calculated as the ratio of the resistance obtained in 1st loading cycles (in cyclic tests) to the mean resistance obtained in monotonic tests $F_{max,M}$ (Equation (2)).

$$k_{deg} = \frac{F_1}{F_{max,M}} \quad (2)$$

According to the proposal, the value of k_{deg} should not be smaller than 0.8; if this value is not reached at all, the joint should be considered as non-dissipative, whereas otherwise the deformation at which the defined k_{deg} limit is reached is set as ultimate displacement.
At this point, it can be mentioned that to the authors' knowledge, the reductions of ultimate lateral displacements, apart from those specified also in the current EN 12512 (failure slip, 1st LEC post-peak strength reduction or/and absolute displacement limit) are very rare in the literature for both connections and structural elements. One example is the limitation of ultimate displacement to the intersection of the 1st LEC and the idealised bi-linear curve, obtained with EEEP, in the idealisation of non-linear response of structural masonry walls [14], which is however not used in current practice.

Energy dissipation is another important parameter of non-linear behaviour that is according to EN 12512 evaluated from the tests results in terms of equivalent viscous damping coefficient, ν_{eq}. As opposed to the original definition for its calculation by Jacobsen [15], (Equation (3)), which considers dissipated and input/potential energy (E_D and E_P, respectively) of the whole loading cycle as defined in Figure 2a, EN 12512 considers only half loading cycle (Equation (4)) with E_D and E_P as defined in Figure 2b.

$$\nu_{eq} = \frac{E_D}{4\pi E_P} \quad (3)$$

$$\nu_{eq} = \frac{E_D}{2\pi E_P} \quad (4)$$

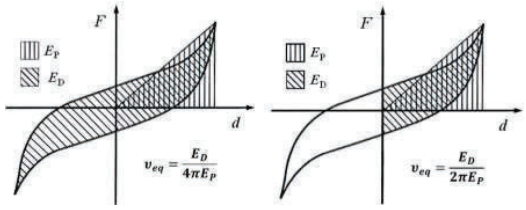

Figure 2: *Equivalent viscous damping according to a. Jacobsen [15], and b. EN 12512 [7].*

https://doi.org/10.52202/069179-0479

3 COMPARISON BETWEEN THE EN 12512 AND ITS PROPOSAL UPDATED FOR ANALYSIS OF RESULTS IN 2019

A first comparison of different methods for the analysis of cyclic test results is presented. In an experimental campaign conducted at the University of Minho (UMinho), a series of angle brackets (AE116) and hold-down (HTT22) connections have been tested under monotonic and cyclic loading. Tension and shear loads were considered while varying the support element (steel and CLT). The loading protocol adopted for the cyclic tests was the one proposed by Casagrande *et al.* [2]. However, two different approaches have been used to analyse the results of the tests. The current version of EN 12512 [7] and a new proposal for this standard presented within the CEN/TC250/SC8/WG3 in 2019 [16], have been used. It is worth mentioning that the definition of the cyclic test protocol was based on yielding displacement quantified based on the method suggested in [16], which is in accordance with ASTM E2126 [11], see Figure 3.

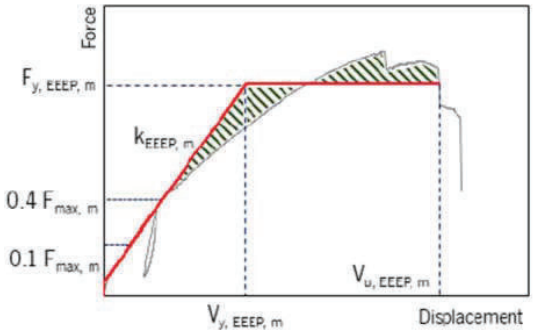

Figure 3: *Analysis of the data from a monotonic test made following EN 26891, as defined by [6] and [14].*

Regarding the degradation factor, which represents a load reduction factor between the 1st Load-Slip Envelope Curve (1st LEC) and 3rd Load-Slip Envelope Curve (3rd LEC), the new proposal [16] does not recommend values less than 0.6, while the current version [7] says nothing about it. The quantification of the different parameters and definition of the bilinear curve is analogous to the monotonic tests, it is being quantified through the 1st Load-Slip Envelope Curve (1st LEC), as can be seen in Figure 4. To define the ultimate displacement, besides those reported for monotonic tests, it can be given by the minimum value of degradation factor (0.6). However, it is important to note that the 3rd Load-Slip Envelope Curve (3rd LEC) can be crucial for the quantification of the ultimate displacement. On the other hand, the strength degradation and the 1st LEC can only be quantified if the total number of cycles is applied to the step.

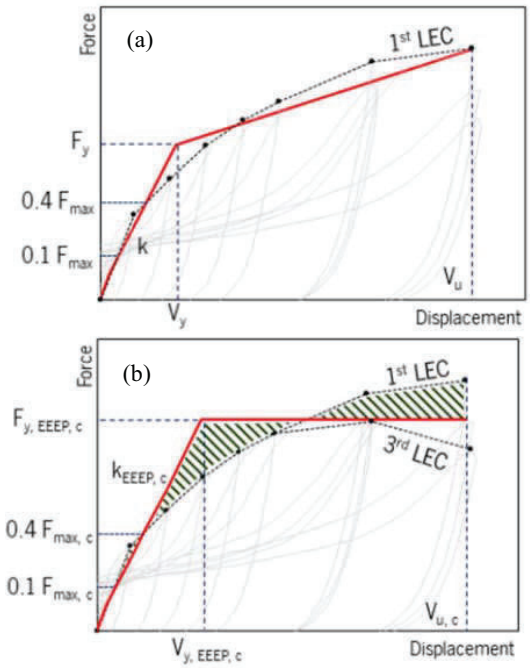

Figure 4: *Brief comparison of the analysis of cyclic tests data between current EN 12515 [7] (a) and the new proposal [14] (b).*

Table 1 summarizes the main results as the average of the three cyclic tests performed for each case studied considering both directions of loading as suggested by [16].

Table 1: *Results of the cyclic tests applying the EN 12512 [7] and the new proposal [16].*

Sample	Method	$K_{10\text{-}40}$ (N/mm)	v_y (mm)	v_{eq} (%)	D
AE116	[7]	6141	3.3	15,6	5,4
Shear	[16]	5392	5.7	3.9	3.3
Steel base	Δ (%)	12.2	70,9	74,8	39,4
AE116	[7]	2749	4.4	20.6	4,9
Shear	[16]	2282	7.7	5.0	2.6
CLT base	Δ (%)	17.0	75.5	75.8	48.2
AE116	[7]	7263	2.6	17.2	8.4
Tension	[16]	5626	6.5	8.7	3,6
Steel base	Δ (%)	22.5	152	49.5	56.7
AE116	[7]	12337	0.6	47.8	7.8
Tension	[16]	6535	2.0	22.5	3.2
CLT base	Δ (%)	47	235	52.8	58.4
HTT22	[7]	8624	2.9	36.5	6.5
Tension	[16]	6456	6.6	19.8	2.9
	Δ (%)	25.1	125	45.8	55.2

The comparison between the methods of analysis come out a difference for all mechanical parameters, where the smallest differences are relative to the elastic stiffness ($K_{10\text{-}40}$). It is possible to see higher values of yielding

https://doi.org/10.52202/069179-0479

displacement (v_y), and, on the other hand, lower values of equivalent viscous damping (v_{eq}), and ductility (D), applying the new proposal discussed within CEN/TC250/SC8/WG3 [16] in comparison to the current EN 12512 [7].

4 COMPARISON BETWEEN THE EN 12512 AND THE prEN 1998-1-2, ANNEX N PROPOSAL

In the second case study, the impact of the analysis method is evaluated for experimental tests conducted according to EN 12512 [7]. The results are analysed according to the referred standard and according to the new proposed prEN 1998-1-2, Annex N[6]. For the comparison, the results of an extensive testing campaign studying the shear behaviour of cement-particle board-to-timber connections by metal staples, conducted at the Slovenian National Building and Civil Engineering Institute (ZAG), have been re-evaluated according to the proposed guideline. The chosen experimental tests are interesting for comparison, because in cyclic tests, large strength degradation was obtained for the connections already before achieving maximum load-bearing capacity (evident from typical backbone envelope hysteresis curves presented in Figure 5, lower). Furthermore, the performance of the studied sheathing-to-timber connections were tested also on the level of structural elements. The connections were used in the construction of light-frame timber shear wall panels (LFTP) whose behaviour under in-plane monotonic and cyclic loading has been experimentally tested as well.

Monotonic and cyclic shear tests were conducted for two variations of boards-to-timber connections with different staple geometry and cement-particle board thickness. They were labelled in dependence of the boards' thickness; B12 for 12-mm and B16 for 16-mm board, respectively, with corresponding staple geometry 1.53 × 11.25 × 45 mm and 2.0 × 11.76 × 50 mm. More specific details on the materials, test specimens and on the test setup of the experimental monotonic and cyclic shear tests of two variations of connections can be found in [17] where the experimental results of cyclic shear tests on LFTP constructed using the tested connections are presented as well.

The test results of connections analysed according to current EN 12512 [7] proved that the connections exhibit large ductility both under monotonic (Figure 5, upper) as well as under cyclic loading (Figure 5, lower). Calculated average ductilities, D, the corresponding yield slip, v_y, the load-bearing capacity, F_{max}, and elastic stiffness, $K_{10\text{-}40}$, are for the conducted tests of connections with monotonic (M) and cyclic (C) loading protocols summarised in Table 2. Furthermore, the table presents ductility calculated by considering EN 12512 and additional EEEP criterion (definition of yield point is equal to elastic displacement v_e of the bilinearly idealised hysteresis curve defined considering equal input energy, see Figure 6), and by considering Kobayashi and Yasumura idealisation criteria [10]. For both tested connections at least three tests were conducted and are considered in statistics for both loading protocols (monotonic and cyclic).

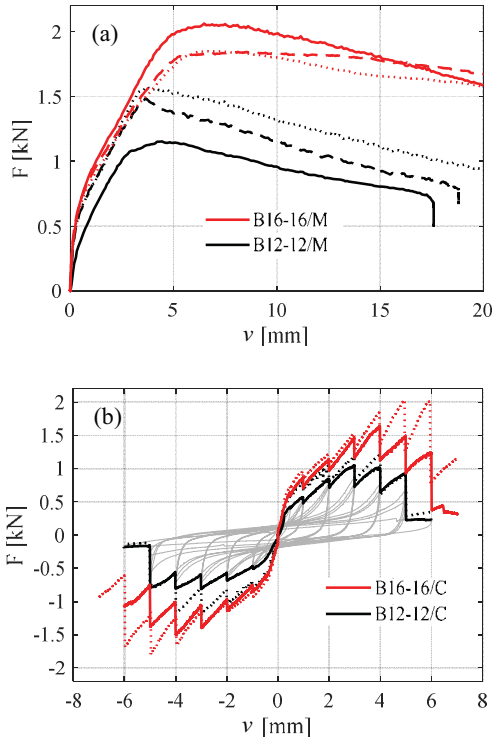

Figure 5: *Lateral load-lateral displacement curves obtained for the two studied sheathing-to-timber connections with staples in monotonic (a) and cyclic ((b), hysteresis backbone envelopes and one full hysteresis curve presented) shear tests.*

Results show that significant differences in ductility are obtained if different yield point definitions are assumed for its calculation. More conservative ductility compared to EN 12512 was obtained considering EN 12512 and additional EEEP criterion. The obtained ductilities in cyclic tests are then lower by 28 and 27% for B12 and B16 connections, respectively. Idealisation by Kobayashi and Yasumura produced even more conservative ductility results, i.e. ductility is in average for 42% and 39% lower than according to EN 12512 for B12 and B16 connections, respectively. Both criteria which consider EEEP are more conservative, since the yielding point for ductility calculation is considered as the yielding point of the idealised bi-linear curve, which is larger than then the yielding point according to EN 12512.

https://doi.org/10.52202/069179-0479

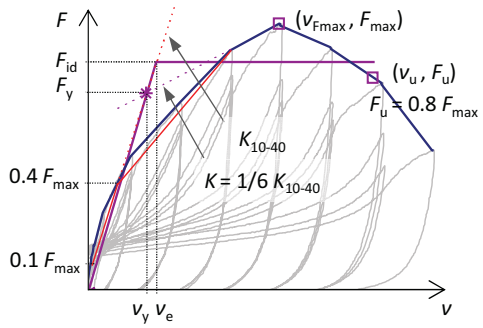

Figure 6: *Idealisation according to EN 12512 and idealisation to bi-linear curve with additional EEEP criterion.*

Furthermore, large differences in average lateral strength were obtained between monotonic and cyclic tests. As evident from the table, the average lateral strengths obtained in the first loading direction of cyclic tests are 14.2 and 17.0% lower than those obtained in monotonic tests for the B12 and B16 connections, respectively. Moreover, the difference in the lateral strength capacities obtained in the two testing directions was not negligible. The strength results are for both connections in the second loading directions lower on average by 12%. The average values of both loading directions are for all the characteristic results too presented in Table 2 (in brackets next to the first loading direction results). For the B16 connection, the average lateral cyclic strength capacity in both directions ($C^{+,-}$) is on average 20% lower than monotonic (M) lateral strength.

While the lateral strength capacity was in the second loading direction evidently smaller, there was however no significant change in ultimate displacements achieved in the two loading directions (that is in case only EN 12512 limit for ultimate displacements, i.e. 20% post-peak maximum lateral strength drop in hysteresis envelope, is considered).

Table 2: *Average results of the monotonic (M) and cyclic tests in first (C) and both loading directions ($C^{+,-}$, in brackets) with evaluated idealised parameters according to EN 12512 [7], EN 12512 with additional EEEP criterion and Kobayashi and Yasumura criteria [10].*

Connection	Loading protocol	No. of tests	$F_{max/staple}$ [kN]	K_{10-40} [kN/mm]	v_y [mm]	v_e [mm]	D	D	D
				EN 12512 [7]	EN 12512 [7]	EN 12512 +EEEP	EN 12512 [7]	EN 12512 +EEEP	Kobayashi and Yasumura [10]
B12	M	3	1.41	1.00	1.09	1.29	9.9	8.2	7.7
	C ($C^{+,-}$)	10	1.21 (1.14)	1.15 (1.10)	0.71 (0.69)	0.94 (0.92)	7.8 (7.8)	5.6 (5.6)	4.54 (4.55)
	Δ (%)		14.2 (19.1)	-15.0 (-10.0)	34.9 (36.7)	27.1 (28.7)	21.2 (21.2)	31.7 (31.7)	69.5 (69.1)
B16	M	3	2.00	0.96	1.25	1.68	18.3	13.2	11.6
	C ($C^{+,-}$)	8	1.66 (1.56)	1.21 (1.20)	0.93 (0.83)	1.21 (1.07)	8.5 (9.7)	6.2 (6.5)	5.20 (5.45)
	Δ (%)		17.0 (20.0)	-26.0 (-25.0)	25.6 (33.6)	28.0 (36.3)	44.1 (36.2)	45.1 (42.5)	123 (113)

The minimum, maximum and average values of ultimate cyclic displacements obtained considering strength impairment limitation equal 0.3, $v_{u,\varphi 30}$, relative to ultimate cyclic displacements, $v_{u,c}$, are presented in Table 3. Similarly, relative comparison of obtained ultimate displacements calculated considering the strength degradation limit equal 20% (k_{deg} = 0.8), $v_{u,kdeg0.8}$, compared to ultimate displacement is presented in Table 4. Since the yield slip v_y is according to prEN 1998-1-2, Annex N the same as according to EN 12512, the presented reductions of ultimate displacements apply for the ductility as well. Nevertheless, the obtained values of ductility corresponding to these reductions are for clarity stated in the tables; ductility calculated according to prEN 1998-1-2 considering both strength impairment and degradation criteria is presented in Table 4 ($^*D$).

With strength impairment limitation equal to 0.3, a significant reduction in ultimate displacements is obtained; $v_{u,\varphi 30}$ range from 0.558 to 0.745 $v_{u,c}$ for B12 and from 0.712 to 0.962 $v_{u,c}$ for B16 connections with average 0.679 and 0.822 $v_{u,c}$, respectively. It should be noted that for B12 connections the strength impairment equal to or higher than 0.3 was achieved prior to maximum strength in 60% of tests, while for B16 connections in 25% of tests. The minimum, maximum and mean strength impairment values obtained at maximum strength displacements in the first loading cycle direction $\varphi_{imp}(v_{Fmax})$, are presented in Table 3.

Table 3: *Minimum, maximum and mean values of strength impairment for maximum strength displacements φ_{imp} (v_{Fmax}), relative values of reduced ultimate displacements $v_{u,\varphi 30}$ and ductility D obtained considering strength impairment.*

Connection		φ_{imp} (d_{Fmax})	$v_{u,\varphi 30}$ / $v_{u,c}$	D = $v_{u,\varphi 30}$ / v_y
B12	Min	0.251	0.558	2.96
	Max	0.419	0.745	8.10
	Mean	0.330	0.679	5.27
	(CV)	(7.9%)	(7.9%)	(26.3%)
B16	Min	0.339	0.712	4.00
	Max	0.233	0.962	16.69
	Mean	0.268	0.822	7.17
	(CV)	(12.9%)	(8.8%)	(55.2%)

https://doi.org/10.52202/069179-0479

The average strength degradations obtained at maximum strength in the first loading directions of cyclic tests were 0.853 and 0.828 for the B12 and B16 connections, respectively, with minimum values 0.680 and 0.653 for the two connections, respectively.

For the particular tests, in 40% of B12 and in 38% of B16 cyclic tests the strength achieved in the first loading direction did not reach 80% of the average connection strength achieved in monotonic tests, $F_{max,M,mean}$, and the connections should according to prEN 1998-1-2 be classified as non-dissipative ("N.D." in Table 4). If the second (negative) loading direction is considered, 60% and 75% of the tested B12 and B16 connections, respectively, do not meet this criterion. It can also be noted that strength degradation at maximum resistance was in most cases higher in the second (negative) loading direction. The average k_{deg} at maximum resistance in negative loading direction were 0.766 and 0.721 for the B12 and B16 connections, respectively, with minimum values as low as 0.577 and 0.634.

The strength degradation criterion is, however, for the tested connections in all cases except for one B16 test, not critical in comparison to the strength impairment criterion in case the strength in cyclic tests indeed reached 80% $F_{max,M,mean}$. For these tests the mean reduced ultimate deformations due to set strength degradation limit, $v_{u,kdeg0.8}$, are 0.965 and 0.920 $v_{u,c}$ for B12 and B16, respectively.

Table 4: *Minimum, maximum and mean relative reductions of ultimate displacements $d_{u,kdeg0.8}$ and resulting ductility D due to strength degradation and final ductility $^{*}D$ according to prEN 1998-1-2, Annex N, obtained from cyclic tests.*

Conn-ection		$v_{u,kdeg0.8}$ / $v_{u,c}$	D = $v_{u,kdeg0.8}/v_y$	$^{*}D$ acc. to prEN8-1-2, Annex N
B12	Min	**0.887	**4.23	**2.96 (N.D.)
	Max	1.00	10.7	6.60

	(CV)	(4.5%)	(27%)	(23.7%)
B16	Min	**0.738	**4.66	**3.99 (N.D.)
	Max	1.00	6.48	5.45
	Mean	**0.935	**5.75	**4.72 (N.D.)
	(CV)	(10.6%)	(11.4%)	(10.2%)

Note: * both $v_{u,\varphi30}$ and $v_{u,kdeg0.8}$ considered
** 6/10 specimens considered (4/10 specimens did not achieve 0.80 $F_{max,M,mean}$)
** 5/8 specimens considered (3/8 specimens did not achieve 0.80 $F_{max,M,mean}$)
Connections should be declared as non-dissipative (N.D.) according to prEN 1998-1-2

Whether it is reasonable to declare the tested connections as non-dissipative, could somewhat be opposed with the results of cyclic tests of LFTPs constructed with the tested connections. For all the tested panels with symmetric board and fastening disposition, ductility higher than 4 was obtained, if more conservative EN 12512 idealisation with additional EEEP criterion was considered (4.82 for panels with B16 connections and 4.14 for panels with B12 connections) and higher than 5 if no EEEP was considered (6.93 and 5.76 for B16 and B12 panels, respectively).

5 SHORT SUMMARY OF MAIN RESULTS AND POINTS FOR DISSCUSSION

The following can be concluded from the conducted and re-evaluated test results:

- The proposed new idealisation considering strength impairment and strength degradation may in some cases significantly reduce the ultimate deformation capacity, and consequently also the ductility.
- For the presented re-evaluated test results of stapled connections, the ultimate slip limitation by strength impairment is more critical than by strength degradation, in case 80% of monotonic strength capacity was at all obtained in cyclic tests; approximately 40% of cyclic tests did for not achieve strength degradation factor equal 0.8.
- The strength degradation limit defined in prEN 1998-1-2 may result in declaring as non-dissipative connections, which exhibit ductile behaviour and enable ductile failure of structural elements.

While the new proposal upgrades the analysis of test results by considering strength impairment and strength degradation criteria, its positive and negative effects should be discussed together with other open questions/issues regarding analysis, some of them being:

- Is considering the results of the second loading direction in case of cyclic shear tests of symmetrical connections relevant; is neglecting them safe? As evident also from the second presented case study, most commonly the strength in the second loading direction is lower than in the first loading direction.
- Should lateral strength obtained in monotonic tests be considered as nominal strength and the characteristic value for design be evaluated from it? It can be seen from the test results that the differences between monotonic and cyclic tests may be quite high. If so, this should be considered in defining the safety factors in the design guidelines.
- What are the results of cyclic (and monotonic) tests intended to be used for? Besides determining resistance, stiffness, and ductility for the design perhaps also for comparisons, modelling, and other applications? If so, should the behaviour be idealised and how and which results should be reported? According to ISO 16670, the testing report should among other present also the tabulated envelope curves

https://doi.org/10.52202/069179-0479

for both loading directions, enabling further test analysis to other parties if needed. In comparison to EN 12512 it is according to ISO 16670 not necessary to report the strength impairment and damping ratios for each loading steps (time consuming and expensive analysis if not automated). On the other hand, it is according to EN 12512 not necessary to report stiffness, e.g. $K_{10\text{-}40}$, though it is necessary to calculate it to obtain the yield slip modulus.

- How should the initial slip, often evident in the curves as part with significantly smaller stiffness, be considered in determining the yield and ultimate slip? Specially in test results, where the loading protocol is not controlled through the deformation measured directly in the joint, but for instance through the actuator, this slip may be quite big. While not eliminating it results in conservative estimations of ductility, it increases absolute values of yield and ultimate displacements potentially limiting also ultimate displacements (if higher than absolute limits, such as 30 mm in the current code).
- Does considering the strength impairment and degradation for determining ultimate displacements indeed produce "better" or more safe results? What are their advantages in comparison to considering other criteria which yield lower ductility, such as the EEEP criterion in Kobayashi and Yasumura or EN 12512, but do not reduce ultimate displacements? Are the over-conservative assumptions on ultimate deformation capacity (and ductility) beneficial for performance-based assessment of structures, which is displacement-based?
- Should the new prEN 1998-1-2, Annex N proposal specify also the minimum number/percent of the tested specimens in group, which can exhibit non-dissipative behaviour in terms of strength degradation, that the connection would/could in general still be considered as ductile (as in the presented second case study)?
- Are the definitions of input and potential energy in dependence of "half cycles" for calculation of equivalent viscous damping optimal? They are in comparison to original definition (set in dependence of the "entire loading cycle") beneficial for shear testing of non-symmetrical connections or testing of the connections in tension and compression. It may however be less convenient for non-symmetrical connections or connections loaded in tension and compression that the "halves" are determined in dependence of deformation (positive and negative slip) and not loading (positive, negative); the ratio of input to dissipated energy can vary significantly in dependence of loading direction and corresponding damage/failure mechanism.

The differences in the loading protocols between different standards, which may influence the behaviour, need to be discussed as well but with considering also other criteria related to tests executions and objectives. Some of these considerations are:

- Regarding the loading rates; the allowed ranges provided in the codes are not the same but are quite large, which is beneficial due to enabling tests execution with various testing and measuring equipment and in acceptable time, but negative in terms of results comparison. The use of EEEP criterion in idealisation of results may be beneficial to reduce the effect of the loading rate, since the influence of loading rate is smaller on the input energy than on the resistance and deformation behaviour (commonly with higher loading rate higher resistances and lower deformation capacities are obtained).
- Regarding the changes of the loading rate within the tests; the possible changes allowed in ISO 16670 enable faster test execution, because for loading cycles with higher displacement amplitudes, higher loading rates can be assigned.
- Regarding the execution of initial slip loading cycles; ISO 16670 is again more flexible by allowing the initial cycles to be omitted and this way enabling the use of wider range of equipment, since inducing loading through very small controlled initial slips according to EN 12512 results in demand for high accuracy controlling and measuring equipment.
- Regarding the definition of amplitude displacements and number of cycle repetitions; issue on how to obtain the proper failure modes of connections under cyclic loading, related to the objectives of the tests, should be addressed; which loading protocol should be used for instance in case of studying the low-cycle fatigue behaviour of the connection or which in case of studying the behaviour under seismic loading.

6 CONCLUSIONS AND OUTLOOK

In the paper, a more detailed state-of-the-art regarding cyclic testing of timber connections is given and the different aspects with need for further test development are discussed. A first comparison of different testing protocols and methods for data assessment is applied for a variety of timber joints. In the case of the experimental campaign performed at UMinho, it was possible to verify large differences between the obtained values by applying two methods for data analysis, namely the current EN 12512 [3] and a proposal discussed within CEN/TC250/SC8/WG3 [14] that has been used as base for Casagrande *et al.* [1]. In this comparison, the smallest difference is relative to the elastic stiffness. Large differences in final results were found also for the second presented case study conducted at ZAG that compares the results of experimental tests analysed according to EN 12512 and the prEN 1998-1-2, Annex N [6]. While

already the strength impairment limitation significantly reduces the ultimate displacements (and consequently ductility), the strength degradation limit set in prEN 1998-1-2 is for the presented experimental campaign in most tests not reached. The connections are therefore according to the new proposal classified as non-dissipative, even though they exhibit significant ductility in cyclic tests of connections as well as in the cyclic test of structural elements.

The need for a unified testing standard for cyclic testing of timber connections and analysis of results is often emphasised within the research community and would be beneficial for the industry as well to enable easier sales and use of products in various markets. Nevertheless, aspiration toward such standards should be accompanied by awareness of all the different purposes such tests are carried out for, the implications of the proposed specific guidelines, as well as of the limitations that laboratories/institutes might have in their implementation.

ACKNOWLEDGEMENT

The paper gives an insight into the ongoing work of the RILEM TC TPT "Tests methods for a reliable characterization of resistance, stiffness and deformation properties of timber joints". The Slovenian Research Agency is acknowledged for financing the second research case study through Research Core Funding No. P2-0273.

World Conference on Timber Engineering Oslo 2023

USAGE OF A BAMBOO HONEYCOMB STRUCTURE (COMBOO) IN TIMBER ARCHITECTURE

Andreas Loth[1], Ralf Förster[2]

ABSTRACT: This paper gives an overview of recent developments of the ecological bamboo based honeycomb like sandwich core material COMBOO and its usage in civil engineering and timber architecture. A brief introduction gives insight into to material bamboo itself and its excellent mechanical properties. The manufacturing process of the COMBOO structure will be described in detail. Previous results from mechanical validation, e.g. 3- and 4 point bending test as well as compression tests will be presented. Main focus of this paper is put on the interesting properties of the bamboo sandwich in acoustics and thermal insulation. The hollow structure with "entrapped" air provides here interesting properties. A good acoustical damping in a frequency range was observed with an artificial and a real COMBOO structure. The results were compared to common acoustic panels. The heat transfer comparison with conventional materials like concrete, double-glazed glass structures (windows) and aerated concrete reveals comparable or better insulation values. This makes the structure suitable for wall and floor elements, acoustic panels, transport boxes and structures in modern transport. Further improvements will be discussed.

KEYWORDS: COMBOO, core material, sandwich construction, insulation, acoustic panels, honeycomb

1 INTRODUCTION

Conventional core materials of sandwich structures mainly consist of polymer foams, metallic foams, aramid honeycomb or balsa wood. The materials are somehow environmental problematic as they consume large amounts of energy during production, were based on mineral oil or grow in monocultures.

A new approach called COMBOO uses honeyCOMB arrangement of bamBOO rings, where the face sheets were covered with glass or natural fibres and a resin. Another type of new material consists of top layers of wood or plywood and a core of bamboo rings, forming a sandwich.

Bamboo itself is a grass with a hollow stem divided by nodes and a hard outer rim. Big advantages lay in the CO_2 storage capabilities of the raw bamboo, the growth rate of up to one meter per day, the height of up to 40 m and its mechanical properties. A tensile strength of up to 370 N / mm^2 and a density between 0.6 and 0.75 g / cm^3 (for comparison: pine 0.45 g / cm^3) were reported. Density distribution across the stem is different to timber. The inner part has a lower density, increasing to the outer area. I can be harvested after just seven years and a reforestation is not necessary. [1]

Bamboo is known in Asia as building material for centuries, while it's nowadays often used for scaffolds, furniture, reinforcements for concrete walls, laminates, laminated beams or chopping boards, where the material is more or less processed.

Bamboo for beams, boards or laminate floor is usually cut in length into smaller stripes, than grinded or milled to receive a rectangular shape, arranged and finally glued together. The price for this procedure is losing the outer regions of the bamboo column with the highest density.

Machining of bamboo requires sharp tools, a coating on hard metals is recommended for milling and sawing. Holes perpendicular to length axis or screws / nails were problematic as the materials tends to split. Splitting of bamboo occurs often during drying. Penetrating the nodes might help. [1]

1.1 PROPERTIES OF COMBOO

Following the COMBOO approach and forming a sandwich structure, excessive machining or processing is not necessary. This saves lots of the overwhelming properties of the natural bamboo. Excellent bending properties, a good compressive strength and a delivery of light through the COMBOO structure if covered with transparent GFRP were interesting features of the new approach (e.g. lower right part of Figure 1).

In addition to the aforementioned properties, density of COMBOO structure through the arrangement of several rings is another main advantage. It is much lower than density of bamboo (wood) itself due to the proportion of wood and air. Density values of 0.2 and 0.25 g / cm^3 were measured.

Mechanical and geometrical properties depends on the chosen bamboo species and the diameter of bamboo, because this determines the ratio between air and material in the core layer. For example Tonkin-bamboo itself reached compression test values of 109 N/mm^2, while other species reach lower values e.g. Moso-bamboo 74 N/mm^2 (when using ring area for calculation). [2], [3], [4]

1.2 IDEA OR APPROACH

The hollow chambers, filled with air, of the COMBOO structure can be used for another topic especially interesting for applications inside a house or factory, the soundproofing of walls.
Acoustic noise in our environment like household, office or at work affect human body. High energetic levels of noise of around 120 dB provide sudden pain and can cause Tinnitus, deafness or sudden hearing loss. But also much lower levels influence wellbeing or concentration especially in resting phase. Sleep disturbances, cardiovascular effects lower productivity at work or school and hearing impairment can occur as long- or short-term effects. [5], [6]
Energy and resource efficiency is a major aim of our time. A closed hollow structure from a natural and renewable source like bamboo could provide a good thermal insulation by the enclosed air. Nearly all bamboo species offer this hollow structure, which might also be also an interesting field of COMBOO usage.
Transferring and extending application opportunities of the new COMBOO structure from mainly mechanical engineering or transportation to civil engineering and architecture is scope of this paper.

2 MATERIALS AND METHODS

The manufacturing of the COMBOO structure itself consists of a few simple steps that can be done without a high level of machinery. For mass production or larger projects, another solution is required.
First, the outer surface of bamboo columns has to be roughened by using sandblasting or grinding. The second step is a cutting process of bamboo rings of equal height. The third step is the arranging of the bamboo rings in a honeycomb pattern in combination with a gluing (wood, plywood or sheet materials) or lamination step (natural or artificial fibres) on both sides, to form a sandwich material.
Surface preparations were found to be a good strategy to improve shear and bending strength of the sandwich, as raw bamboo has an adhesive or coating repellent surface. [2]
In Figure 1, the manufacturing process of COMBOO structure is shown.

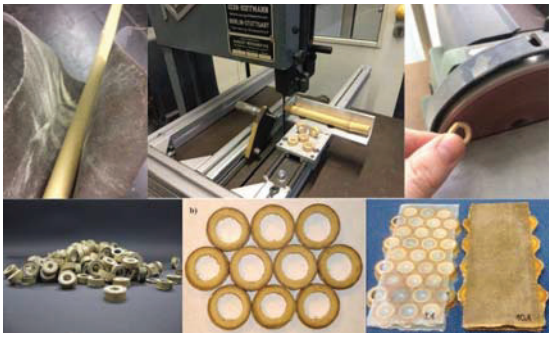

Figure 1: *Manufacturing of COMBOO material (grinding. cutting, deburring, arranging, laminating)*

Besides the flat board like structures, curved COMBOO components were possible too. The type of cover material artificial like fibres or renewable like wood depends on application. Therefore different strategies for connection have to be evaluated.

2.1 INVESTIGATION OF SOUND AND ACOUSTIC BEHAVIOUR

Sound is mainly understood as the spreading of pressure or density fluctuations in “elastic” materials like structures liquids and gases. It can be differed for our application into air-borne and structure-borne noise.
The Sound pressure level is the local pressure deviation from the surrounding or average pressure level. A higher sound pressure refers to a louder incident.
The frequency represents the number of pulsations of the sound per second. The sensitivity of human hearing is adopted to the frequency range of human voice of (250 - 2.000 Hz), but a range between 16 - 16.000 Hz or even higher can be recognized. [9] The range of frequencies interesting for room acoustics is between 100 Hz and 5.000 Hz.
Reverberation time is the period needed for fading of a sound incident to a specified grade. Allowable values depend on application (e.g. office, school or concert hall). It is influenced by sound absorption coefficient α, a value ranging from 0 (total reflection) to 1 (total absorption). Sound absorption coefficient α depends strongly on frequency. Measurement of the coefficient can be done by using an acoustic / reverberation chamber or an impedance / Kundt's tube. [10], [11], [12]
The impedance tube is often used for research and development due to its requirement of much smaller material specimen. It is limited to a sound incident perpendicular to the specimen, whereas a reverberation chamber can be used for a diffuse sound signal direction. In this work a Kundt's tube in single microphone arrangement was used, due to availability at university.

2.2 APPLICATION ACOUSTIC PANELS

The first approach presented here is the usage of the COMBOO structure as an acoustic panel used as absorber. Acoustic panels mounted to walls or ceilings were often used to improve the sound climate in offices, schools, concert halls or factories. A damping of the total amplitude or of certain frequencies or a reduction of the reverberation time can be the aim. Mainly used technical principles to achieve these targets were absorbers, plate transducers or resonators. They often work in a specific frequency range. [7]
Absorbers, often porous, transform the sonic energy into other energy forms mainly heat. Dissipation of energy is a result of friction or contact between air molecules with other air molecules and surrounding structures. Therefore, longer open and narrow pores are required. They often contain either mineral or organic materials. [8]. Porous absorbers can effectively be used for damping in the middle or higher frequency range

https://doi.org/10.52202/069179-0480

Examples for “soft” porous absorbers were typical polymer materials in industry like rebounded foams mainly consisting of PU (polyurethane) and soft foam chopped recombined with a good sound absorption also due to its mass, melamine resin foam wits a low density but many pores, PU or viscoelastic foams. [13], [14]
Wood wool, textile fibre compounds, hemp fibres or moss were porous fibre based sound absorber. They were manufactured by adding cement and water, pressure and heat or a special conservation treatment to be formed. The often provide a wide frequency range for damping. [15], [16], [17]
Sandwich materials i.e. a combination of plates with mainly small holes, a carrier plate and often an acoustic fleece can be found in literature. [18]
Resonator systems were Helmholtz resonators, plate transducers or perforated plate transducers. The working principle is a spring mass design with an optimum working point at their resonance frequency. The mass is often timber, plasterboard or plywood or even air while the spring is an entrapped volume of air. Perforated plate transducers have a regular distributed pattern of holes or slots often combined with porous absorbers for a better absorption range. Common resonator systems can be mainly used at lower frequencies.

2.2.1 Manufacturing and preparation

One suitable way for acoustic measurement is using a Kundt's tube to measure the sound absorption and sound transmission coefficient of small samples with perpendicular sound incidence, as described above. Therefore several conventional materials for acoustic absorption or damping were prepared to compare with the COMBOO structure (ref. Figure 2).

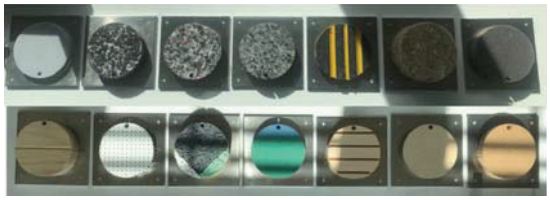

Figure 2: *Materials for acoustic comparison*

They were mainly cut out using a band saw, as can be seen in Figure 3, left side.

Figure 2*: Material preparation (cutting und gluing)*

Bamboo as a natural product is inhomogeneous. For homogeneity and better understanding of the effects, MDF (medium density fibre board) and wood boards with CNC milled holes (15 - 20 mm) were mainly used instead of the more irregular bamboo pattern. Bamboo rings were used for comparison.
The surface of the COMBOO specimen was covered with a 4 mm MDF layer with laser cut holes from 3 - 10 mm (ref. Figure 4). The hollow chamber under the top sheet can be seen as well.

Figure 3: *COMBOO acoustic panel [19] a) top layer b) core material c) bottom layer – left bamboo, right MDF based*

Plain or unmodified materials (aluminium, plywood, MDF, pine (slotted), pine) have been prepared for measurements in Kundt’s tube too, to acquire comparable data of the unmodified surface.
Figure 5 shows prepared COMBOO style structures made of MDF, timber and bamboo.

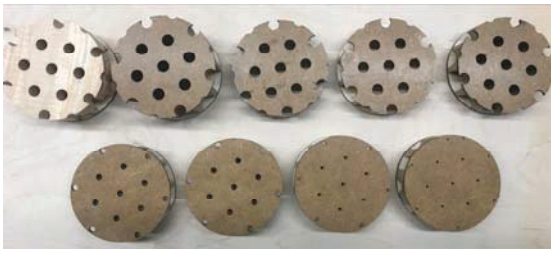

Figure 4*: COMBOO style MDF acoustic panels*

A MDF COMBOO specimen with a hole diameter of 20 mm (inner core region) and 10 mm hole (face sheet) was filled with polymer foam, to combine two absorber principles.
All specimens were mounted to an aluminium sheet, to be fixed at one end of the Kundt's tube. A speaker on the other side generates a signal at different frequencies, here in a range up to 1800 Hz, due to the tubes diameter. A microphone probe, guided through the test specimen acquired the signal, analyzed by an oscilloscope. The test setup is shown in Figure 6 and each test was performed three times.

https://doi.org/10.52202/069179-0480

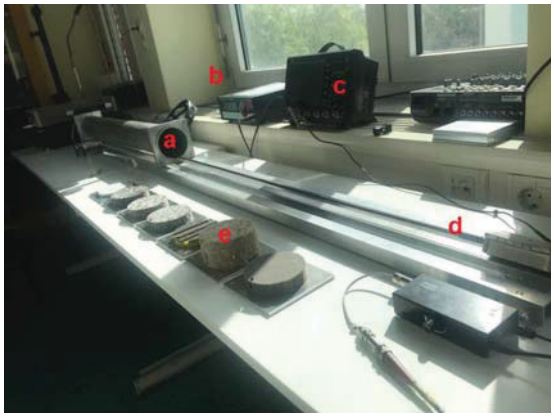

***Figure 5**: Kundt's tube (a) and measurement setup (multimeter (b), oscilloscope (c), microphone probe (d), test specimen (e)*

2.3 INVESTIGATION OF THERMAL INSULATION / THERMAL TRANSFER BEHAVIOUR

Second approach is a comparison of heat transfer through different materials. Therefore five typical materials of civil engineering were chosen, set to identical geometric parameters including thickness. The specimen were the COMBOO structure with a 0.3 mm GFRP layer on both sides, concrete, aerated concrete, styrofoam and a double-glazed window with two 6 mm glass sheets (ref. Figure 7). The dimensions were set to 150 mm x 150 mm x 20 mm. A test chamber (1) according to Figure 7 was created, using a hot air gun (2) to deliver warm air at a temperature of 55 °C. Warm air goes in from left side (in) and leaves the heating area through a smaller hole on the right side (out) to prevent overpressure. Five thermocouples connected to a pc via a precision measurement device (4) (ALMEMO 2890-9- Ahlborn Inc. Germany) were integrated into the chamber to measure the temperature at different positions. The first thermocouple was placed in the heating zone, aside of the direct blast of the hot air pistol. Two thermocouples were located directly above a hole in a bamboo ring and over the covering ring surface (Figure 7, right) of the COMBOO specimen (3). Two thermocouples (T_1, T_2) are behind the rear wall of the test specimen. Additional thermocouples were placed outside for reference. A thermo camera (5) (Optris, Germany) in the front end of the chamber was used to acquire the temperature distribution over the whole surface of the specimen.
Figure 8 shows three different test materials in the heat box. Thermocouples can be seen on specimen surface

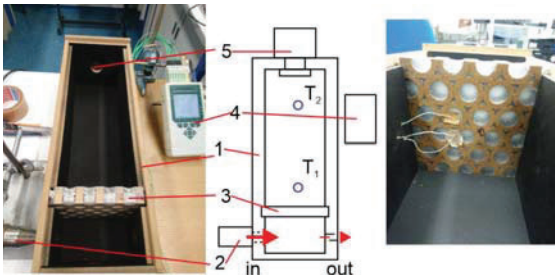

***Figure 6:** Measurement setup and heat box (left / middle), thermocouples on "COMBOO" surface (right)*

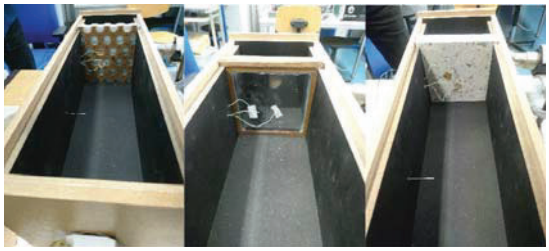

***Figure 7:** Sample structures for thermal measurements*

The hot air gun was activated for at least 60 minutes after the initialization of the measurement devices. According measurement data have been logged. Between the investigations, the whole heat box was cooled down to ambient temperature.

3 RESULTS AND DISCUSSION

3.1 PROPERTIES FOR COMBOO AS MATERIAL FOR ACOUSTIC PANELS

First of all, the sound absorption coefficient was determined for plain or unmodified timber and metal materials. It can be seen (Figure 9) that all materials provide a damping of more than 40 % in the very low (f < 125 Hz) and respectively high frequency (f > 1250 / 1600 Hz) range. Even the aluminium sheet metal shows a damping of more than 20 percent starting at 1250 Hz.

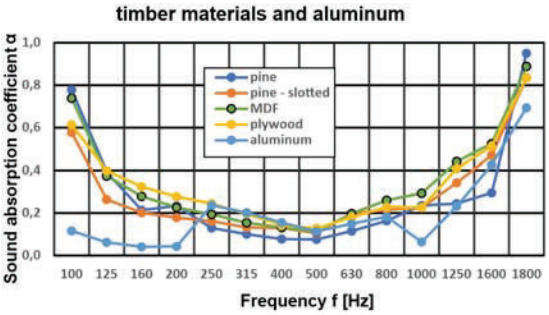

***Figure 8:** Sound absorption coefficient α - unmodified materials*

Further experiments with soft wood like for example Balsa, Paulownia or the inner region of palm wood can be interesting here.
Absorber materials as presented in Figure 10 provide a better damping and hence a higher absorption coefficient.

https://doi.org/10.52202/069179-0480

Especially hemp fibres reach values over 50 %, while wood fibres or wood sandwich material show values comparable to unmodified material. PU is also suitable for damping with a drop in the 500 Hz region.

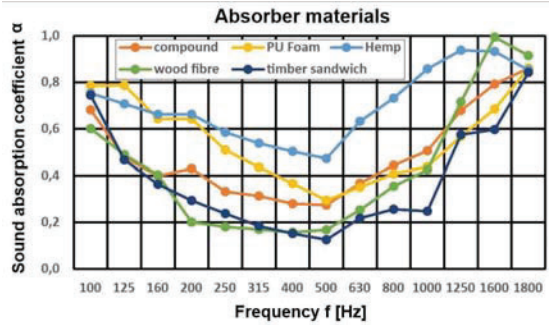

***Figure 9**: Sound absorption coefficient α of absorber materials*

The acoustic composite foams reached these values in the range between 200 Hz and 500 Hz, while the absorption of the fibre materials depends on type of fibre. Special acoustic absorption sandwich materials show similar or slightly different values in a wider range, depending on structure and materials.

The sound absorption coefficient of the COMBOO structures reached α values between 0.2 and 0.56 in a frequency range between 315 Hz – 800 / 1250 Hz, as can be seen in Figure 11. It depends only slightly on inner diameter of the chamber (15 mm – not shown vs. 20 mm) but on the hole diameter of the cover plate. Best damping results have been reached with smallest borehole in the top sheet of 3 mm. Here is a peak at around 500 Hz, providing an extra damping effect. This can be found also at the lower hole diameter of 15 mm, but with slightly lower values.

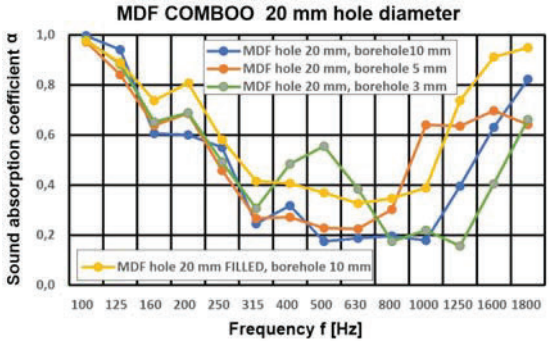

***Figure 10:** Sound absorption coefficient α - MDF COMBOO – hole diameter 20 mm different borehole diameter in top sheet*

Very interesting are the results from combination of COMBOO structure with PU foam (yellow line in Figure 11), where a hole or chamber diameter of 20 mm with a borehole diameter of 10 mm was used. The curve is comparable to the unfilled structure but just shifted upwards by a factor to better absorption.

Hence a combination might be an alternative or an improvement to reach a wider absorption frequency range.

A difference between the artificial COMBOO structures (MDF) and real bamboo could not be found, so the MDF is a suitable substitute for experiments with directly comparable structures.

1.2 INSULATION / THERMAL TRANSFER PROPERTIES OF COMBOO

Several tests have been performed to identify material properties. The logged data were plotted over time and analysed.

A typical set of acquired data is plotted in the next Figure 12, here at the COMBOO structure with GFRP sheets. Immediately after starting the hot air pistol, the temperature increases in the heating zone. After approximately 2 minutes a temperature of above 50 °C is reached, after about 10 minutes the final temperature of 55 °C with light fluctuations.

The temperature directly on the surface of the test specimen is slightly different. Directly on a hole, temperature is 1 K higher then on massive COMBOO structure. The temperature increases from 26 °C to 36 °C and 35 °C respectively. Ambient temperature remains mainly constant at 31 °C but shows fluctuations probably from air movement in the laboratory. The temperature behind the test specimen remains quite constant. Both thermocouple positions (near specimen and in the rear part of the heat box) show finally a nearly similar temperature of 29 °C.

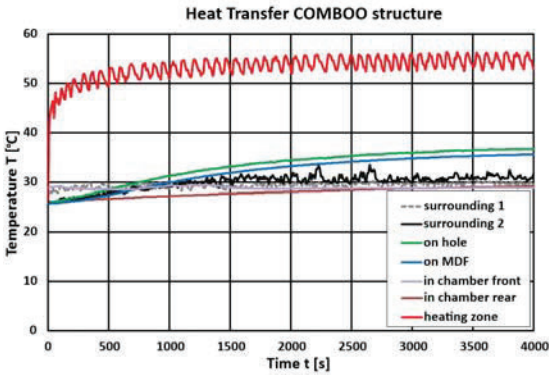

***Figure 11**: Temperature data over time at different locations for testing COMBOO structure in heat box*

Next Figure 13 represents the measured data for all five test specimen. Two temperature values are given for each material. The blue column represents the difference in temperature between the heating zone of the test box at always 55 °C and the average temperature directly on the rear side of the test specimen. Green columns show the temperature difference between the average temperatures (T_1 and T_2) behind the test specimen.

Both columns of the Styrofoam represent the best results, as expected. The difference between heating zone and rear side of the specimen was calculated to 21.05 °C, while

https://doi.org/10.52202/069179-0480

difference between inside and outside of the test box is 2.55 °C.
COMBOO structure showed a lower surface temperature difference (18.85 °C) than the double glazed window (18.4 °C) and much lower value than conventional concrete (13.85 °C). The surface temperature difference of the aerated concrete was 20.5 °C and hence 10 percent better than the COMBOO structures value, which is attributed to the higher mass and the low conduction value, due to encapsulated air at small scale.

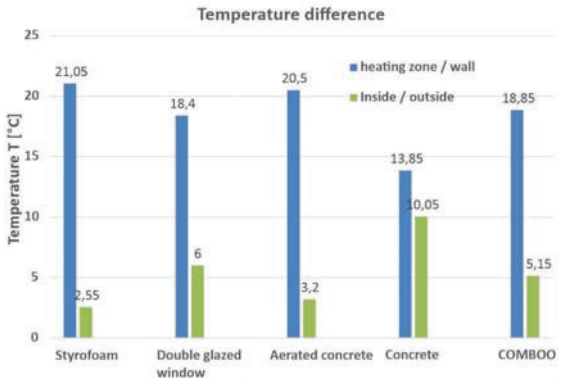

Figure 12: *Temperature difference between: heating zone and rear part of specimen (blue), inside / outside of test box (green)*

A multilayer or multi chamber approach within the COMBOO structure is currently under investigation, also in combination with plywood sheets as top and bottom material. It is assumed that relatively large volume leads to convection inside the chambers and hence a higher temperature exchange. Same problem would occur at the double glazed window with even higher total volume.
Especially the approach with plywood top and bottom sheet and a double layer COMBOO structure would provide a good insulation, a high mechanical stability and a conventional machining / manufacturing of floors and transport boxes.
The infrared camera was used to visualize temperature distribution over the surface area, as thermocouple represent only point measurements. The result is shown in Figure 14, where picture of the COMBOO structure are shown. Time steps are integrated into each single picture. It can be seen, that infrared radiation was detected by thermal camera. First of all temperature distribution is homogeneous in colour over the whole area, while with increasing time, colour of the holes turns to yellow. It can be seen, that temperature rises at the holes. Due to the camera itself, a temperature adaption takes place shifting the colour scale between hottest and coolest points.
In the upper left part of nearly all pictures, a small temperature leak can be seen, as insulation of the rim was disturbed. Camera measurements of the COMBOO structure couldn't be repeated, as a software problem of the old operating system occurred.
Temperature distribution for the other specimen was homogeneous over the whole area during each experiment. The glass surface had to be coated with black dye as reflection disturbed the measurements.

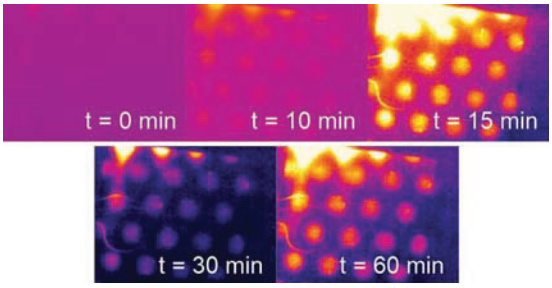

Figure 13: *Pictures of thermos camera at different time steps*

4 SUMMARY AND CONCLUSIONS

This paper described extended research for an alternative sandwich core material made of bamboo. The new material is called COMBOO and it provides not only superior mechanical properties like high compressive and bending strength but also good results in thermal insulation and acoustic damping.
The comparison of sound absorption coefficient in a Kundt's tube of composite foams, fibre materials and COMBOO structures revealed good damping or absorption results in a broad frequency range of the new structure. Different geometrical dependencies have been successfully identified, as the chamber diameter has much lower influence on damping value than the hole diameter in the top sheet. An enhancement of total absorption over the whole frequency range was received when filling the chambers with polymer foam.
Next steps will be an investigation of the effects of chambers depth, a combination of several different hole diameters at one top sheet material and different fillings of the chambers. This might improve damping, also over a wider frequency range.
A visible COMBOO structure (GFRP or polymer sheets) could be very interesting in acoustics if a sound absorption has to be combined with certain requirements of surface stability or stiffness. The specific honeycomb appearance could also be interesting. A fibre filling could provide interesting optical effects.
The other investigation in this paper concerned heat transfer or insulation characteristics of five typical materials for civil engineering. It was found that the heat transfer through a GFRP covered COMBOO board, acquired by the measurement of the surface temperature is lower than through double glazed windows or concrete panels of same thickness and slightly higher than through aerated concrete boards. Best insulation was reached by a styrofoam block.
Next research steps will be the estimation of heat transfer coefficients and improvements of the COMBOO structure. Therefore the thermal analysis of single GFRP sheets might help. The aforesaid multi-layer attempt could reduce possible convection and improve insulation.
In combination with the high compressive strength of the COMBOO structure, utilization as transport container conditioned box or floor material is possible especially if plywood is used as top and bottom sheet.

https://doi.org/10.52202/069179-0480

5 OUTLOOK

In addition to the classic applications of the newly developed COMBOO sandwich material in the area of apartment, house and modular construction, its very interesting properties can also be used for technical applications such as acoustic insulation boards and thermal insulators. This also opens up applications in refrigerated box construction for trucks. A special advantage here is the recyclability of the material, which consists of renewable materials.

BENDING OF CLT BY THE LATTICE HINGE METHOD

Laurane Néron[1]

ABSTRACT: This study provides an overview of ongoing research on cross-laminated timber (CLT) panels bent with the lattice hinge method: a system that has been explored by ArtBuild and Ney & Partners WOW for two temporary structures. First, the parameters that define the lattice hinge cutting process are described and exposed at the scale of CLT panels. Second, the results of a series of experimental tests will be investigated to define the structural behaviour and properties of slotted CLT panels. Finally, the two projects that were built will be presented in terms of architecture and structural details. The first one is a pavilion built for the Libramont Fair in 2019, and the second one, is an ephemeral auditorium that has been set up in the ephemeral Grand Palais in Paris for the International Wooden Construction Forum (Forum Bois Construction) in 2021.

KEYWORDS: CLT, lattice hinge, bending method, CNC manufacturing

1 INTRODUCTION

Traditional methods for wood bending can be classified into four categories:

(1) In-plane cutting of curved piece

The easiest way to obtain a curved piece of wood is to cut it out of a larger raw element. The advantage of this technique is that it is very simple and does not generate internal stresses in the piece of wood. However, it generates large losses of material and is not feasible for large elements and thicknesses. In addition, the wood grain of the curved element is interrupted by the cut-outs and reduces its bearing capacity.

(2) Hot bending

When the moisture content of wood increased it becomes softer and easier to bend. The hot bending process consists of immersing wood in hot water or subjecting it to steam (usually under pressure). Then, it is placed in a bending mould while it dries. Once dry, the wood will keep the curvature that was imposed by the mould. This method requires a lot of time and specific equipment.

(3) Gluing of lamellas

The technique commonly used for glued laminated timber offers the ability to easily create curved beams. The standard lamellas of 40 mm thick have a low rigidity and are easy to bend. The successive gluing of lamellas can be done by a hydraulic press or mould in order to shape the beam with the required curvature.

(4) Notching of wood

The purpose of the notches is to reduce the stiffness of the wooden piece by removing some parts of the material. The advantage of this method is to be reversible because the curvature can be maintained by mechanical fasteners instead of glue. It is commonly used for the realization of musical instruments such as violin and sees its success growing the last few years with the arrival of laser cutters which allow to multiply the number of possible cutting patterns. The lattice hinge method enters in this category.

All these techniques can be applied to solid wood and glulam beams, but it is more complicated for large timber panels such as CLT. Therefore, this study aims to provide a bending technique for CLT panels in order to explore a new architectural typology.

2 LATTICE HINGE : DEFINITION AND PARAMETERS

2.1 DEFINITION

The ‘lattice hinge’ is formed by an array of parallel overlapping cuts in a flat wooden panel. By dividing the panel into a set of thin columns, each column can twist on its own axis and rotate. The length of these so called “torsion legs” drives the overall curvature radius of the panel. The longer the leg, the more flexible the panel. The piece of CLT that links two torsion legs are considered as planar surfaces and have no influence on the overall curvature of the panel.

2.2 GEOMETRICAL PARAMETERS

2.2.1 Panel dimensions

The external dimensions of the CLT panel are determined by its length L, width W and thickness h.

[1] Laurane Néron, Ney and Partners WOW, Belgium, LANE@ney.partners

https://doi.org/10.52202/069179-0481

2.2.2 Lattice hinge pattern dimensions

The cutting pattern of the lattice hinge is defined by the number of torsion legs required across the width n and height N_{div} of the panel, as well as the width b of the legs.

2.2.3 Panel curvature

The bending curvature of the panel is defined by the radius of curvature R. It is also possible to calculate the sag f of the panel once bent, the final reduced width (or chord of the arc C) and the global angle of rotation of the panel φ with the following equations:

$$f = R \cdot \left(1 - \cos\left(\frac{\varphi}{2}\right)\right) \quad (1)$$

$$C = 2 \cdot R \cdot \sin\left(\frac{\varphi}{2}\right) \quad (2)$$

$$\varphi = \frac{W}{R} \quad (3)$$

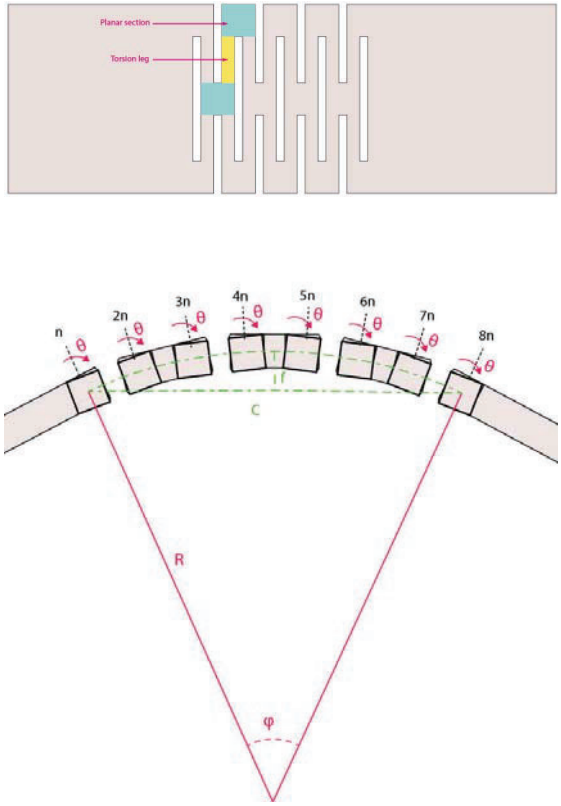

Figure 1: *Geometric parameters of lattice hinge [3] [6]*

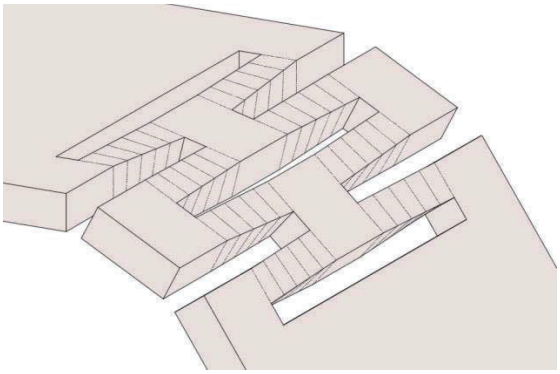

Figure 2: *3D view of twisting mechanism by lattice hinge [3][6]*

2.3 DESIGN OF TORSION LEGS

To bend a CLT panel, each torsion leg rotates around its own axis, with an angle:

$$\theta = \frac{\varphi}{n} \quad (4)$$

The torsion legs are submitted to shear stresses due to a torsion moment. The torsion moment in a square wooden element can be expressed by two formulas [10] - depending on the angle of rotation of the torsion leg (5) or depending on the shear stress (6):

$$T = \frac{G_{eq} \cdot \theta \cdot J}{l} \quad (5)$$

$$T = \tau \cdot \alpha \cdot h \cdot b^2 \quad (6)$$

By combining the two formulas, we can define the expression of the minimal required length for torsion legs in function of the desired curvature and the maximum shear stress allowed $\tau = \tau_{max} = f_{v,d}$:

$$l_{min} = \frac{G_{eq} \cdot \theta \cdot J}{f_{v,d} \cdot \alpha \cdot h \cdot b^2} \quad (7)$$

where:

- G_{eq} is the equivalent shear modulus of a torsion leg that has been defined by a series of tests. The resulting value is given in the table below as well as the standard values for shear modulus of CLT for comparison.

Table 1: *Standard shear modulus value for CLT*

		Design values	
Shear modulus CLT	$G_{0,mean}$	690	N/mm²
Rolling shear modulus CLT	G_R	50	N/mm²
Equivalent shear modulus	G_{eq}	210	N/mm²

- $f_{v,d}$ is the shear resistance capacity of CLT. Bending is applied as a permanent loading, therefore we assume $k_{mod} = 0.6$ and $\gamma_M = 1.25$ for CLT.

$$f_{v,d} = f_{v,k} \times \frac{k_{mod}}{\gamma_M} \quad (8)$$

https://doi.org/10.52202/069179-0481

$$f_{v,d} = 1.68\ N/mm^2$$

- J is the torsional inertia of a rectangular cross-section. As CLT is made of several cross layers of wood, rolling shear probably has an influence on the J value. This interaction will be studied by a series of experimental torsion tests on CLT.

$$J = \beta \cdot h \cdot b^3 \quad (9)$$

– α and β are form coefficients defined with empirical values from the table below.

Table 2: *Form coefficients for torsional inertia [12]*

h/b	1	1,5	2	3	6	10
$\boldsymbol{\alpha}$	0,208	0,231	0,246	0,267	0,299	0,313
$\boldsymbol{\beta}$	0,141	0,196	0,229	0,263	0,299	0,313

2.4 PARAMETRIC MODELLING

All parameters and formulas listed in the previous section have been implemented in a parametric model with Grasshopper/Rhino. The input data are the panel dimensions and the required radius of curvature. The lattice hinge pattern dimensions are given as output and drawn on any given developable surface.

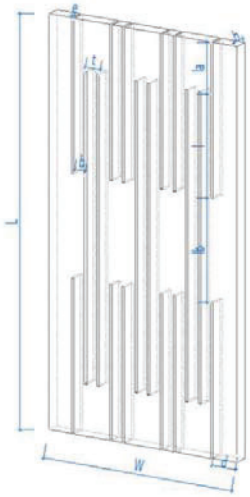

Figure 3: *Axonometric view of slotted CLT panel and dimension parameters*

3 EXPERIMENTAL TESTS

The aim is to define the structural behaviour of a slotted CLT panel for each loading types and directions. A total of 5 different load tests have been realised :

- Torsion test
- Transversal bending test
- Longitudinal bending test
- Axial tension test
- Axial compression test

[5] Ecole Centrale des Arts et Métiers, Brussels, Belgium

The results of those tests helped to quantify the loss of stiffness due to the slots in the CLT panels.
First, the torsion test will be described in order to find the equivalent shear modulus value that is needed to define the length of the torsion legs for the cutting pattern. Then, only transversal bending test is described in this paper as it has the biggest impact on the loss of stiffness for the CLT panel. All test results can be found in [7].

3.1 TORSION TEST

Since torsion tests are rarely performed on wood and the partner laboratory (ECAM[5]) does not have a machine specifically dedicated to torsion tests, an experimental system was designed and implemented on a test bench to allow testing of CLT samples.
A total of 8 samples have been tested in CLT 60 3s:

- 4 samples of 20 mm wide and 800 mm long
- 4 samples of 30 mm wide and 800 mm long

The loading system is composed of a lever arm fixed to the sample by a bolted connection and a rod allowing the placement of weights at the other end. Measures of deflections are taken in the centre and at both supports in order to retrieve the relative rotation angle of the sample. The torsional moment is determined by multiplying the load applied at the end of the lever arm by the distance to the sample.

Figure 4: *Torsion test system*

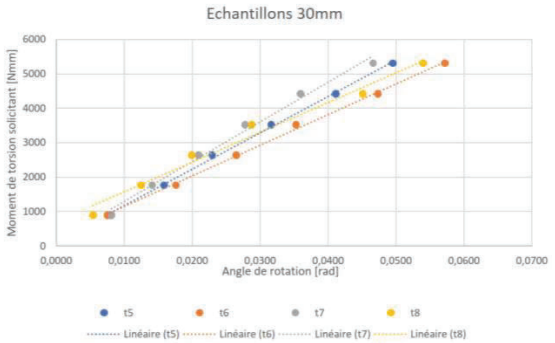

Figure 5: *Rotations* $\boldsymbol{\theta}$ *of the sample in function of the torsional moment* $\boldsymbol{T}$ *applied*

https://doi.org/10.52202/069179-0481

The value of the equivalent shear modulus can be deducted from equation (5), considering that the values J and l are constant for a given cross section. The mean result for all samples is: $G_{eq} = 210\ N/mm^2$.

3.2 TRANSVERSAL BENDING TEST

A 3-point bending test was performed on slotted CLT panel. The loading was done by sand bags.3 samples have been tested in CLT 60 3s with a span of 715 mm.

Figure 6: *Transversal bending test system*

The parameter EI governing the transverse bending stiffness of the panel can be expressed using the deflection formula for a bi-supported beam subjected to point loading as follows:

$$u = \frac{q \cdot L^3}{48 \cdot E \cdot I} \quad \rightarrow \quad EI_{eq} = \frac{q \cdot L^3}{48 \cdot u} \qquad (10)$$

where u = deflection at the centre of the panel, E = modulus of elasticity, I = inertia, q = load and L = span.

Table 3: *Values of deflections for maximum load of 3,125 kNm/m*

Samples	1	2	3	Mean value	CLT (no slot)
u [mm]	33	28	39	33.50	0.32

For CLT, the transversal stiffness is given by the coefficient D_{22} in the stiffness matrix. For a 3-layer CLT panel of 60 mm: $D_{22} = 7{,}733\ kNm^2$. The tests gives a value of $D_{22,eq} = EI_{eq} = 0.071\ kNm^2$. Therefore, the loss of stiffness of a slotted CLT panel compared to a full CLT in transverse direction is about 99%. The panel loses most of its bending capacity, so an external system must be put in place to maintain it in the transverse direction. This was achieved in two different ways for the two projects where curved CLT was used (see section 5).

4 CLT PANEL PROPERTIES FOR NUMERICAL ANALYSIS

Thanks to the test results, we were able to define an equivalent stiffness matrix for a slotted CLT panel. This stiffness matrix is then used in a Finite Element software (SCIA) in order to define a simplified calculation model that is used to check the global behaviour of a structure with slotted CLT panels.

Table 4: *Stiffness matrix for slotted CLT panel*

CLT	60-3s
D11 [MNm]	$2{,}088 \cdot 10^{-1}$
D22 [MNm]	$7{,}100 \cdot 10^{-5}$
D12 [MNm]	0
D33 [MNm]	$6{,}732 \cdot 10^{-3}$
D44 [MN/m]	4,423
D55 [MN/m]	13,800
D66 [MN/m]	480,000
D77 [MN/m]	240,000
D67 [MN/m]	0
D88 [MN/m]	25,969

5 CASE STUDY

5.1 NAUTILE SYLVESTRE

5.1.1 Project background

Commissioned for the 85th edition on the occasion of Demo Forest, an event that follows the Libramont Fair, the wooden pavilion named “Nautile Sylvestre” was conceived by ArtBuild Architects, Saïse Design and Ney & Partners WOW as a totem for forestry and timber trades. It is the first structural use of bent CLT panels.

Figure 7: *General view of the pavilion*

5.1.2 Architectural design

Inspired from the bio-structure of the banana stem, a double revolution staircase gives access to a central elevated platform at 4.5 m above ground level. The upper and lower side of the staircase offer respectively, a point of view and an exhibition gallery. Visitors can wander easily by following the curvature of the walls and crossing the pavilion from one side to the other.

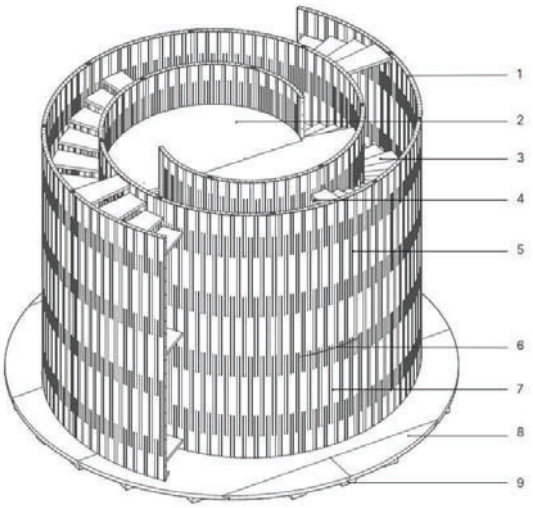

Figure 8: *Axonometric view of the Nautile Sylvestre pavilion – 1. Metal plate at the head of CLT walls assembled with splice joints / 2. Slab with CLT 60 mm assembled by lap joints / 3.Stair steps with CLT 60 mm / 4.Supporting joist for steps / 5.Bent walls with CLT 60 mm / 6. Curved door in metal frame / 7. Invisible locksmithing elements / 8. Base plate with CLT 90 mm / 9. Support wedges 300 x 300 mm*

5.1.3 Connection system of multiple slotted CLT panels

We studied several options to maintain the panels curvature and we retained a combination of three options adapted to each part of the panels. At the base, the panels are inserted into a notch that has been milled in the platform following the spiral geometry. At the top edge, an 8 mm steel plate has been added in order to not only maintain the curvature but also act as protection against rain water. Since the panels are 5.50 m high, we also defined a minimum of two intermediate lateral supports to ensure a constant curvature over the height and serving as supports preventing buckling of the panels. The staircase steps, that are laterally screwed to the CLT walls, are fulfilling this role. The whole structure gains in structural efficiency thanks to the multi-layered shell created by the successive walls of bent CLT-panels connected together : a static diagram that accurately reproduces the functioning of the banana stem.

Figure 9: *Interior view of the staircase*

5.1.4 Mounting process & reuse

For the milling process, a CNC machine was used to make the cuts in the panels. A 10 mm wide saw was chosen over milling to save production time.

Once milled with lattice hinge pattern, the prefabricated panels can be transported flat to the site. This suggests a significant economy in terms of transport costs.

On-site, the panels were curved, erected and assembled by carpentry students in a few days. First, the steel plates were screwed to the top flange and wooden pieces screwed to the bottom flange of the CLT panel to give it the right curvature. Then, the panels were lifted with a mobile crane to move them to their final position. The construction started from the centre and extended symmetrically to the outer edges of the pavilion.

After the fair, the structure was dismantled and the panels returned to their original flat condition. They were stored in a workshop waiting to be reused for the next fair.

https://doi.org/10.52202/069179-0481

Figure 10: *Lifting of curved CLT panel*

5.2 EPHEMERAL AUDITORIUM

5.2.1 Project background

On the occasion of the 10th edition of the “Forum International Bois Construction" in Paris, the ephemeral auditorium stands in the centre of the ephemeral Grand Palais. A total amount of 64 CLT panels are bended and assembled together to create the plenary room for conferences. This temporary structure is easily dismantled and is intended to be reused for other events.

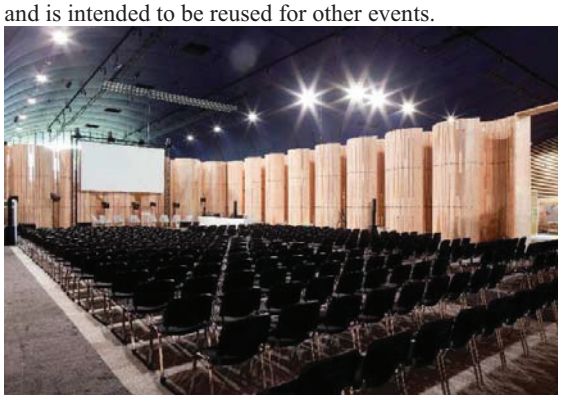

Figure 11: *Interior view of the auditorium*

5.2.2 Architectural design

The auditorium is a rectangular room with seating for 350 people. The perimeter walls cover an area of 29 m x 19 m with a modular construction made of bent CLT panels connected by steel bracings. This wooden curtain provides privacy but it also allows for some subtle transparency. The notches in the wood act as a sound trap and provide an acoustic barrier for the auditorium.

A single panel has a dimension of 2,40 m x 5,25 m and weigh about 300 kg. In order to stand as a stable structure, a minimum of three panels must be connected to each other. This project is made of three different constructive modules : linear walls, doors and angles. They can be inter-connected in many configurations to be able to adapt to the future needs.

The CLT panels are made of Douglas fir wood, a natural durable species. This maximizes the potential for reuse of the structure as it enables it to be used as an outdoor structure (if covered and protected from rain).

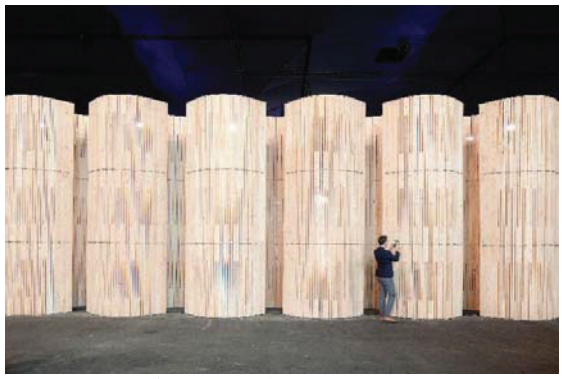

Figure 12: *Wooden curtain of CLT*

5.2.3 Connection system of multiple slotted CLT panels

The curvature of the panels is maintained by a post-tensioning system developed specifically for the project. Custom-made cast iron pieces are inserted into the slots and tensioned by a steel rod at each end. The geometry has been defined according to the curvature of the panel. Holes are integrated on both sides to integrate a steel rod that acts as post-tension to maintain the panel in its curved position.

All these parts can be disassembled to put the panels back flat and facilitate transport.

Figure 13: *Connection detail between curved CLT panels*

6 CONCLUSIONS

Interest in lattice hinge has been revived thanks to the growth of digital tools. This study shows how it has been implemented in CLT panels at a structural scale.

Bending by the lattice hinge method implies that wood is submitted to local torsion. As a multi-layered material, CLT does not behave like solid wood in torsion and the formulas found in the literature to calculate shear stresses due to torsion turned out to be invalid. Therefore, the torsion of CLT has been studied through a series of test to define an equivalent shear modulus that can be used for torsion calculations. Moreover, the global analysis of the projects was performed by using an equivalent stiffness matrix for CLT based on the tests results.

https://doi.org/10.52202/069179-0481

The first application was to create curved bearing walls for a temporary pavilion. In the future, bent CLT panels could be used in buildings for walls or facades. Studies are still on-going to define new developments and potentials for curved CLT panels.

World Conference on Timber Engineering Oslo 2023

STRATOCONCEPTION®, AN ADDITIVE MANUFACTURING PROCESS FOR TIMBER ARCHITECTURE: CHALLENGES AND OPPORTUNITIES

Victor Fréchard[1], Laurent Bléron[2], Julien Meyer[3], Franck Besançon[4], Gilles Duchanois[5]

ABSTRACT: The additive manufacturing has been recently adopted by the construction industry to overcome the existing design limitations and to build large-scale structures. The timber architecture and construction have not yet adopted the additive manufacturing technologies. This paper focuses on the understanding of the use of the Stratoconception® additive manufacturing process for timber architecture and construction by identifying the opportunities it offers and the challenges it presents. First, we outline the Stratoconception® process. Furthermore, we highlight and assess by experiment the opportunities and the challenges of the implementation of this process. We target the complex shape design and the multi-functionalization of the components as important opportunities that can lead the design of new high-value building components for timber architecture. Next, we introduce the potential use cases for the process and emphasize the capacity of the technology to be implemented in the common timber construction practices. The lack for Stratoconception® use in the context and in the dimensions of architecture brings the challenges of scaling-up the process and integrating it into the multicriteria architectural design process which exceed the existing methods and tools. We describe the overriding issue of managing the waste of material caused by the micro-milling phase of the process. The building of a knowledge base of relation between Stratoconception® and timber architecture reveals the need for an adapted and efficient design framework for the process use for timber architecture projects. Thus, we propose and describe a theoretical design framework achieving the integration of the AEC issues into a design process and fostering the development of new efficient building components by guiding the designer towards rational decision making.

KEYWORDS: Timber Architecture, Additive Manufacturing, Stratoconception®, Design for Additive Manufacturing, Computational design

1 INTRODUCTION

1.1 CONTEXT

The adoption of computational design and digital fabrication in architecture, based on Computer Numerical Control (CNC) machining and robotics, fosters a development of an innovative, efficient, and expressive contemporary timber architecture [1]. The formal and structural advances from the digital tools adoption encompass an emergence of new architectural tectonics [2-4], which in the current environmental context are fostering the use of timber [5].

The Additive Manufacturing (AM), comprising a range of processes [6,7], shares the common origin with CNC machining but differs in the ability to produce directly the high level of complexity parts that cannot be achieved by subtractive or formative methodologies. In recent years, we have observed a substantial increase in research topics studying the use of AM methods and their first implementations in the construction industry [8-11] for the large-scale building components and structures by applying the processes based on cementitious materials [12-15], alongside with earth-based [16,17], sand-based [18], polymeric [19], or metal materials [20].

The motivations for the adoption of AM by the construction industry mainly focus on the productivity gains, the reduction of materials waste, the worker availability and safety, or the reduction of the production cost of the complex parts. Also, these motivations correspond to the core challenges of the automation in construction and of digital fabrication adoption. The AM use today is often limited to these core challenges but does not *"reshape the way we think about architectural components"*[21]. According to Labonnote et al. [8], an architectural paradigm shift exploring the inherent potentials of AM is required to improve current construction design approaches. To foster this paradigm shift, the AM constraints must be considered on the early stage of the design, to allow rational decision-making.

Furthermore, the environmental issues require for the use of more sustainable, renewable, and non-petroleum-based materials. Wood could be used in several AM processes [22-24], however the research and technology advances are still needed to meet the requirements of large-scale construction.

https://doi.org/10.52202/069179-0482

This paper reviews the use of Stratoconception® for timber architecture and its integration into the design-to-manufacturing process. First, we define the Stratoconception® process (Section 1.2) and research scope (Section 1.3). Second, we define the experiment context (Section 2). Third, the paper discusses the opportunities of the implementation of this AM process in Architecture, Engineering and Construction (AEC) (Section 3) and summarizes the challenges of its implementation (Section 4) identified during our experiments. The last section outlines the proposal of a framework of architectural design for additive manufacturing (DfAM) by Stratoconception® (Section 5).

1.2 STRATOCONCEPTION®

Stratoconception® belongs to the sheet lamination family of AM processes [6], [25]. It consists in slicing the 3D model of the part by computing into a set of layers called *strata* (Figure 1). Each *stratum* is laid out on a sheet material and is machined on both sides with 2.5 axis rapid micro-milling. Next, the strata are assembled with the relevant techniques. In the production of parts whose dimensions are larger than those of the machines or those of the raw material, the strata decomposition step is added to the process. This process refers to the initial patents [26-27] based on cutting and joining the multiple sheets of material to form the part. The use of multi-axis CNC machining to mill in 2.5 axis the edges of each stratum offers the elimination of the stair-step effect issue due to the sheet lamination process and thus allows to better match the 3D model's shape [28].

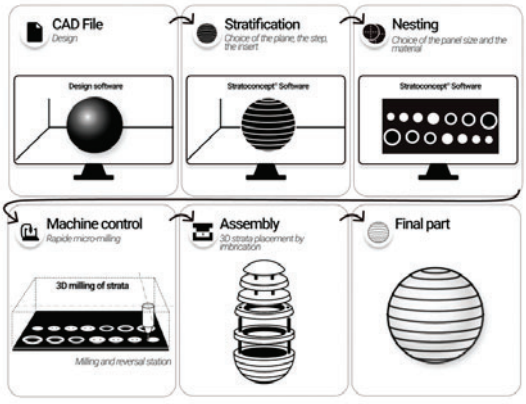

Figure 1: *Scheme of the Stratoconception® process.*

1.3 RESEARCH SCOPE AND ADDED VALUE

The Stratoconception® process application to architecture are currently limited to the scale models and the prototypes, to the formworks for concrete construction, and it is not yet applied to building components. However, the basic technical and material means such as three-axis CNC machining and timber panel materials are commonly used today in timber architecture and construction, thus they create potential opportunities for Stratoconception® process implementation. Despite the lack of the implementation in AEC, we hypothesize that the Stratoconception® process could be beneficial for the construction of complex and expressive large-scale structures or for the production of high-value-adding multifunctional building components.

An identification of the opportunities, of the limitations and the challenges of its implementation in timber architecture and construction is necessary to establish the knowledge base and the design-to-manufacturing framework. This will guide the architects, the engineers and the builders in their work in ways to benefit from the Stratoconception® process. Moreover, this will guide their digital collaboration and the workflow of the design and production of novel timber architecture products and projects.

2 EXPERIMENT DESCRIPTION

Our research is a practice-led research project identifying, emphasizing and analyzing the mechanisms of the use of Stratoconception® design-to-manufacturing process for AEC projects. Thus, our research aims to conduct experiments of Stratoconception® design and manufacturing and to build a knowledge base for the future proposal of a framework of design to additive manufacturing by Stratoconception®.

The experiment had three phases (Figure 2) studying the project *design*, the scale model *prototyping* and the project components *manufacturing*. The phase 1 studies the influence of Stratoconception® use at the early design stage on the final design of the project, by identifying the technical and architectural impact of the design choices, and by collecting the used and exchanged project data. In the phase 1.1, we ran a design experiment with the master program students at the National School of Architecture of Nancy (France). First, the main features of the AM process were introduced. Next, the students worked in teams on freeform architectural projects corresponding to a given program. Stratoconception® was imposed as a constructive system, influencing their design choices. In the phase 1.2, we study the issues of the strata use and influence on the architecture and design with renderings and scale models.

In the phase 2, scale models are used as prototypes to assess the existing digital workflow from design to manufacturing. This highlights the interoperability issues between the architectural CAD software and the Stratoconception® software.

In the phase 3, we design and manufacture the *functional prototypes* to identify the process scale up issues and to analyze the specifics of a building component design (phase 3.1) as well as an entire architecture (phase 3.2). In phase 2 and 3, we updated the inventory of the data exchanged between design and manufacturing.

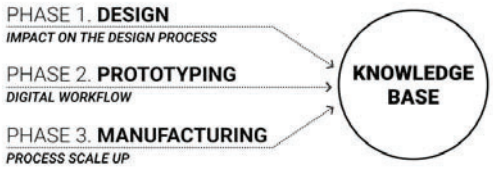

Figure 2: *Scheme of the aim of the experiment phases.*

https://doi.org/10.52202/069179-0482

The results of this experiment are summarized and discussed in Section 3 (opportunities) and Section 4 (challenges).

3 STRATUM AS AN OPPORTUNITY

The architecture development follows an iterative cycle, where the new technologies are developed in response to overcome the existing limits establishing new design paradigms with their own limits [29]. In this context and with its ability to design any shape mathematically [30], AM is a promising new technology to overcome the current limits of timber architecture with the new applications of freeform shapes or multifunctional building components which are today expensive or impossible to produce using the standard fabrication methods. This section overviews the new timber architectural opportunities of the Stratoconception® use.

3.1 NEW DESIGN OPPORTUNITIES

3.1.1 Timber construction existing limitations

The history demonstrates the ability of timber architecture to reinvent itself to develop the optimized building systems allowing to design the freeform shapes. Yet, the limitations still exist in the production of double-curved parts, the management of the envelope-structure relationship in complex shapes, the access to internal geometries or the challenge of achieving three-dimensional timber joints. These limitations are due to the high costs of production of the complex parts, requiring specific and unique approaches; or due to the technical inability to manufacture the three-dimensional parts with exterior and interior geometries on an industrial scale with the current means of timber construction.

3.1.2 Complex shapes: expression and optimization

As AM can mathematically produce any shape [30], it is a relevant solution to fabricate the double-curved geometries of parts. By overcoming the limitations of the standard manufacturing methods, architects can design new shapes for timber architecture and can *"encourage the appearance of new constructive and architectural vocabularies"* [4]. This exploration of new designs encompasses both the purely formal expression and the topology optimization to satisfy technical criteria. Thus, Labonnote et al. describes AM as *"an opportunity for making the link between well-developed, computational-based, optimization and the previously missing physical processes required to reproduce optimized structures"* [8,31]. The optimization usually aims to reduce the material consumption, and it is performed within the functional limits of the part, the material properties, and the constraints of the manufacturing processes. This optimization can also be applied to the thermal, acoustic, or other fluids properties. The recent research on the use of topology optimization in architecture illustrates how AM can enable the production of new complex shapes for the architecture within the limits of its processes [32].

3.1.3 Lightweight and multi-functional parts

The ability to easily access the inside of a part by the designers is, perhaps, AM's most disruptive and relevant contribution to timber construction. Thus, the hollowing out of the parts becomes possible, and it optimizes the amount of material used in the final part. Unlike the other AM processes, Stratoconception® can reduce the weight of the part by designing voids, but it does not allow to optimize the amount of consumed material by the hollowing out material, because the creation of voids during the micro-milling phase generates of as much material waste (see 4.1.2).

Today, timber buildings are composed of the materials layers with different functions such as structural, thermal, acoustic, waterproofing or building systems. The design of the voids allow to integrate a range of such various functions into a single part [7,13]. This can reduce the use of different materials, including the materials with a high environmental impact as well as the amount of assembly operations and it can provide new technical solutions for timber architecture. This may also improve the management and the properties of the envelope-structure relationship for complex structures and produce high-value-adding multifunctional building components.

The section 3.2 emphasizes how these opportunities of AM can be applied to timber construction, using Stratoconception®, by strengthening the envelope-structure relationship of the complex walls or by designing new technical parts.

3.2 APPLICATION EXAMPLES

The phase 1 design experiment proposes a non-exhaustive outline of the fields of structural and non-structural Stratoconception® uses for timber architecture. We present a shell wall project and a three-dimensional mesh joint as two use-cases of Stratoconception® application opportunities.

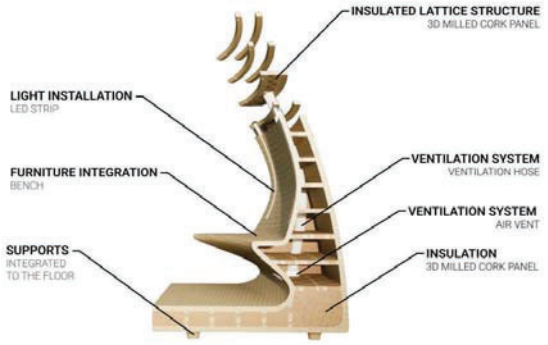

Figure 3: *Proof of concept of a complex multifunctional wall.*

Figure 3 presents a *stratoconceived* shell wall integrating various functions such as structural, thermal, and acoustic insulation, ventilation, electrical systems, and even as the element of furniture (a bench). In the conventional designs of three-dimensional structures these functions are held by different components, systems and materials, which are often assembled with the complex junctions. However, with Stratoconception® these functions may be united in a single component. In such complex double-curved shell wall, the envelope-structure relationship is enhanced. Thus, with the strata, we minimize the amount of the high environmental impact materials and of the

joining operations between the building wall layers. However, we hypothesize that the use of the Stratoconception® process for large-scale structures could have a high impact on the consumption and the wastes of material (see 4.1.2) and thus on the efficiency of the constructive system facing environmental and economic issues. The assessment of the performance of large-scale *stratoconceived* structures is required to validate, or not, the relevance of this particular use of Stratoconception® in AEC projects.

A three-dimensional timber mesh structure type is an elegant and efficient building system. However, it is often built with the metal joints, altering the environmental impact of such type of structure. The Figure 4 presents a timber joint of a three-dimensional timber mesh as an alternative to the metal joints. With Stratoconception®, the timber joint is lightened by hollowing out and it functions as structural element and as lights installation slot. Its use reduces the environmental impact of the project by avoiding the use of metal.

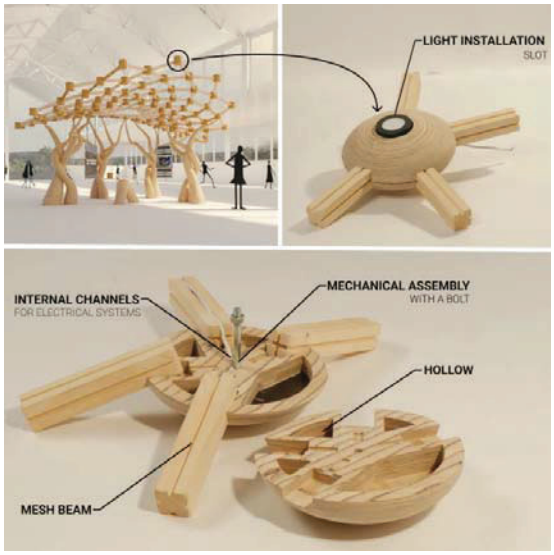

Figure 4: *Prototype of a multifunctional timber mesh node.*

The experiment results indicate other Stratoconception® relevant applications like the technical building parts production and maintenance, the windows and stairs manufacturing, the architectural heritage restoration, the furniture design, the bending mold or even the ornamentation. The further works will portray these identified relevant applications.

3.3 CAPACITY OF IMPLEMENTATION

The attempts of implementation of the automation principles of the manufacturing industry into the construction industry have not yet succeeded, nor have been transferred as a common practice to make a more sustainable impact. According to Wagner et al., *"there is a little doubt that methods of digital automation that aim for a broad impact on the industry will be ultimately judged based on their level of achieved organizational flexibility"* [33] depending on machinery and digital workflows. They identify two relevant success factors of such implementation, which are the economic viability and the architectural discourse which emphasize the opportunities to "*enrich the spatial and cultural qualities of the built environment*" [Ibidem]. We highlighted in the previous sections how the Stratoconception® process provides new opportunities for the timber architecture design.

Stratoconception® uses the basic technical and material means of the timber construction industry such as three-axis CNC machining and timber panel materials. The implementation of the adaptive slicing strategies for the fabrication in the computational design with Stratoconception® allow to machine the strata with the three-axis micro-milling following a digitally generated customizable toolpath.

This means that complex and *stratoconceived* parts can be machined in the same way as the standard parts, thus achieving a high degree of flexibility without additional fabrication costs.

Furthermore, the use of the similar machines in the timber construction companies facilitates the transfer of this new technology to the local construction context and to be used for specific contextualized projects.

However, in order to provide a full flexibility to the Stratoconception® process, the use of the standard technical means must be supported by a relevant digital and physical workflow linking computational design, the CNC milling and the manual construction operations.

3.4 ARCHITECTURAL VALUE

Most architectural projects use the timber panel as the topographic stratum, like in the case of the office and cafe building in Osaka where Kengo Kuma stacks the timber layers (Figure 5). In addition to directing the space and the circulation, the designed shape makes it possible to create a space with the floor, ceiling or walls function also as furniture. This example of the open flight strata emphasizes the layering and confers the apparent lightness of the space. It contrasts with the dense, monolithic strata as if the space was carved out of in a single piece of timber like the National Museum of Qatar Gift Shops where the architect Koichi Takada was inspired by the Dahl Al Misfir, also known as the "Cave of Light" (Figure 5).

Figure 5: *Open layered panels by Kengo Kuma (left) and carved cave by Koichi Takada (right).*

https://doi.org/10.52202/069179-0482

In most cases, timber strata are not used as structure but only as cladding or decoration. In architecture, a "stratum" may offer a design order or a superposition of various layers comprising structural (walls, floors, roofs, floor joists, beams, columns) and finishes (wooden cladding, siding, decorative elements) parts of a building. The stratum is important in the design and construction of a building because it helps to define the overall aesthetic and structural integrity of the building. In timber architecture, multiple strata can create a light and shadow play effect, generate natural textures and patterns, and provide a sense of warmth to the building.

The layering technique, in the case where the stratum remains visible, may prove aesthetic benefits to the design. For example, the lines created by the strata orient and structure the architectural space: high vertical strata generate a perception of monumentality while long horizontal strata give an impression of stability.

Actually, the architecture of strata overcomes the necessity to be thought through such separate elements as walls, floor or roof as is rather a continuous structure that encompasses the space because it creates a seamless integration of the different layers of the building [4]. Each stratum may have different functions and features. From the technical point of view, each stratum can carry different functions, such as structural support, insulation, weather resistance, or aesthetic appeal. The strata are also connected and integrated together in a cohesive system. From the architectural space point of view, the concept of the encompassing space is often used to create an impression of privacy, security, intimacy of the space, and can serve distinct functions for comfort, aesthetic and sustainability of a building.

4 RELEVANT CHALLENGES

In this section, we present the observed from the experiment challenges of the implementation of this process in AEC such as the design and the manufacturing of large-scale structures *stratoconceived*, the material waste management and the lack of the relevant and efficient design framework and methods.

4.1 PROCESS CHALLENGES

4.1.1 The scale-up is not a homothety

The manufacturing of large-scale structures challenges the ability of Stratoconception® process to scale up. The machines and the materials are limited by their dimensions, and the builders are limited by the human physical abilities. These limitations do not allow the scaling-up by a simple homothety applied to the slicing strategies, the fabrication, the assembly and the finishing operations. The phase 3 of the project components manufacturing experiment highlighted that the small building components and the large-scale structures differ significantly in their design-to-manufacturing process because of their size and of their functions.

The production of large-scale structures requires the use of strata decomposition strategies to overcome the limitations of the machines and material size by decomposing each stratum in smaller parts, consequently increasing the number of required assembly operations. The operations of clamping, flipping the panels for machining, assembling the strata and finishing are altered by the large-scale of the project and cannot perform as the small parts manufacturing. Thus, the Stratoconception® use for large-scale projects requires for the specific methods. There is a lack of knowledge about the effects of the project scale on the fabrication and the construction phases of Stratoconception® in AEC industry context, thus further research is required to confirm and precise our observations about these limitations.

4.1.2 Material waste management

Although Stratoconception® is an AM process, it includes a micro-milling phase of removing material to manufacture the designed strata. Therefore, the material waste needs to be analyzed and managed at the design phase to use this process and to satisfy both the economic and environmental performance criteria. For the analysis and the management of the material waste, we outlined the use of the raw material against its products, the strata and the reusable panel offcuts, and its wastes, the wood sawdust and the non-reusable panel offcuts (Figure 5). The material waste is caused by the nesting strategies, to the 3D milling of the strata edges, and to the light-weighting of the part (see 3.1.3).

The scale model prototyping and the project components manufacturing experiment allowed us to measure the material waste (Table 1) from the fabrication of the prototypes and to identify the relevant factors impacting the amount of these wastes in this specific use-case.

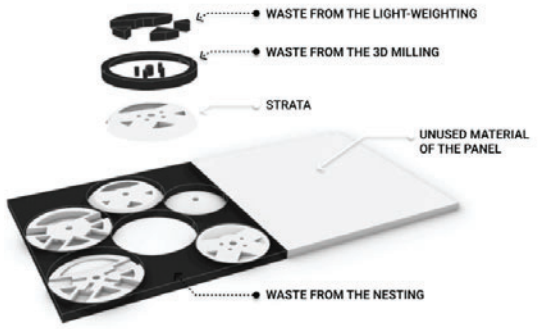

Figure 6: *Material use in the Stratoconception® process. Example of the multifunctional timber mesh joint fabrication (see 3.2).*

Table 1: *Material yield of the multifunctional timber mesh joint fabrication. The results are obtained by the geometric analysis of the nesting presented in figure 5.*

Waste type	Proportion of the material used (%)
Strata	26.13
Total material waste	73.87
Waste from the 3D milling	*31.32*
Waste from the nesting	*34.22*
Waste from the light-weighting	*8.33*

The results highlight that the waste from the 3D milling of the strata is significant when the thickness of the strata is thin in comparison to the thickness of the panel,

requiring for the large facing operations. The thin strata are the result of the implementation of the slicing planes required to guarantee the feasibility of the part and of the use of panels whose thickness does not perfectly fit the size of the part (Figure 6A). In addition, the higher tilt of the strata profile results in higher material waste. Yet, in the fabrication of the large-scale strata, the thickness of the timber panels is limited to their relatively small dimensions in comparison to the final structures. Thus, the profile of the part is highly discretized in strata and reduces the material waste in proportional comparison to the small part composed of strata which share the same order of magnitude with the final part (Figure 6B).

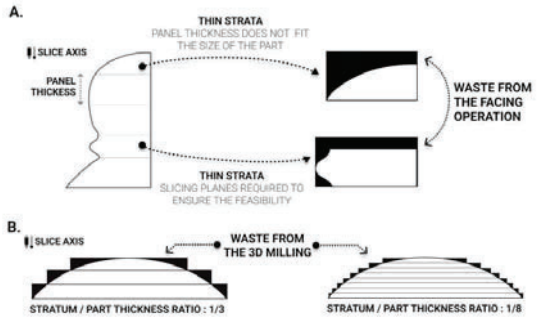

Figure 7: *Factors influencing the wastes from the 3D milling: the facing operations caused by the thin strata (A) and the ratio between the strata thickness and the size of the part (B).*

The waste caused by the nesting of the strata on the panel depends on the nesting algorithm implemented, as well as on the ability of the strata to nest in each other through their geometry (Figure 6). Thus, the minimization of nesting wastes requires for development of specific decomposition and slicing strategies considering the size and the shape of the strata, to enable optimized nesting.
At the present time, there is the lack of analysis tools to measure the material use balance, of evaluation tools to optimize the design choices and, of design strategies and methods based on the material waste management since such management is crucial to provide the economic and ecological efficiency of the use of the Stratoconception® in timber architecture and construction. We identified that a novel design approach is required for the use of Stratoconception® for AEC to manage the material waste. Further work will quantify the material waste balance depending on the size of the parts, for the small building components and the large-scale structures prototypes. The influence of the size of the part on the preponderance of a material waste type will be analyzed in further works.

4.1.3 Timber for Stratoconception® use

The Stratoconception® process uses all available material types in the panel format. The process use for timber construction requires for the structural engineered timber products in panel format such as Cross-Laminated Timber (CLT), Laminated Veneer Lumber (LVL) or Plywood. These are preferred due to the standardized format, the improved dimensional stability and to more homogeneous mechanical and machining properties which facilitate their processing by the CNC machines. However, we must consider that the use of these families of engineered timber products limits the thickness of the strata because of the available timber panel thicknesses, which are small in comparison to the large-scale structures. Thus, the timber panel thickness is a relevant parameter in the manufacturing process for large-scale structures project. This requires for decomposition strategies, the fabrication and the assembly of the large number of elements due to the size limitations. For the small parts, reducing the thickness could minimize the wastes from the 3D milling (see 4.1.2), but also it could complicate the machining and the assembly because of the possible need for thin strata. The use of panels also encompasses the waste materials issues caused by the nesting of the strata on the panels, a lack of diversification of the species used and an environmental impact due to the wood transformation process and the transport, as the transformation plants are rarely local to the projects and the construction firms.
However, timber is not only available as the panel products, thus our research must consider all the products as alternatives that can bring added value to the process. Thus, we hypothesize that the use of Glue Laminated Timber (GLT) can provide an alternative for the fabrication of large-scale strata by avoiding the nesting operation, each stratum corresponding to a single glulam element, and overcoming the dimension limitations of the panels thickness since the GLT products can be thicker. We also hypothesize that the use of the plank timber as an economic and ecological alternative for the manufacturing of small parts although it increases the complexity of the mechanical simulation and of the 3D milling surface quality control for example. Further research is required to explore the use of these alternatives in *stratoconceived* AEC projects.

4.2 DESIGN CHALLENGES

4.2.1 The need of new design approach

The Stratoconception® process follows the design of the part phase, and it begins with a manufacturing preparation phase in which the designer's choices are evaluated from the one prospect of the feasibility. The first experiment phase emphasizes that an AEC project design should be guided by the potentials and by the limitations of the manufacturing process from its early stages. We observe that there is an interdependence between the design and the manufacturing, the design is driven by the manufacturing process and the success of manufacturing depends on the design choices.
Furthermore, the design choices of an AEC project using Stratoconception® also must be assessed and optimized for the architectural, the engineering and the construction requirements for the project success. The slicing design strategies are typical of this phenomenon. They influence the design of all aspects of the project and highlight that the multi-criteria decision-making is required for the design based on the feasibility and performance evaluation. The slicing and the decomposition of the large-scale strata choices influence and are influenced by the visual aspect of the project, the material size and properties, the structural performance, the material yield,

https://doi.org/10.52202/069179-0482

the complexity of the construction and are limited by the fabrication feasibility (Figure 7).
These design criteria are interdependent and may have contradictory purposes. For example, the most efficient slicing direction choices may be contradictory to the intended aesthetic of the project. Similarly, maximizing the structural properties of the part in one direction involves orienting all the strata on the panel in the same direction to respect the wood's grain direction, hence altering the management of the wastes caused by the nesting.

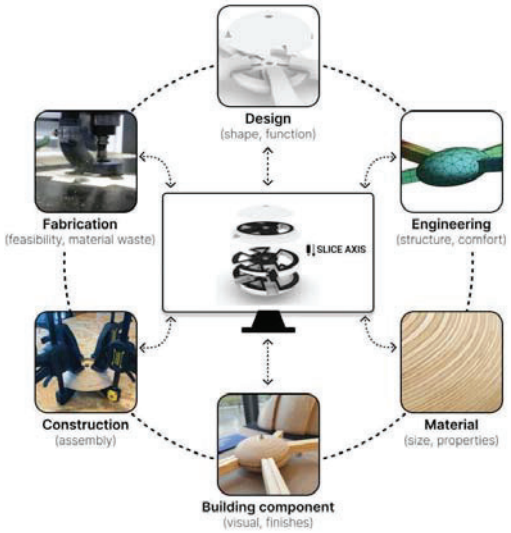

Figure 8: *Scheme of the interdependence of the slice strategies and the AEC project multi-criteria.*

The design experiment with the students has illustrated that the AEC multi-criteria approach of the project, the shape complexity and the functional complexity make the design process unintuitive, and they do not lead to efficient and rational decision-making; nor it is efficient without the implementation of an adapted design environment at the early design stages. The design to manufacturing process becomes a non-linear, dynamic and iterative process with the use of the Stratoconception® process. The level of integration of the AEC issues and the interdependence of design and manufacturing goes beyond the existing construction and Stratoconception® frameworks and design tools then requires for a new customized approach. The increase of a more detailed knowledge of the use of Stratoconception® in AEC projects and the interdependence of the design criteria will help the architects to seize this new manufacturing process and to explore new ways to design and build.

4.2.2 The lack of relevant digital workflow

The customized design to manufacturing approach with Stratoconception® requires for collaboration of the architects, the engineers and the builders. Such collaboration is based on data exchange efficiency which is correlated with the ability to connect different software of each project stakeholder. We have emphasized the lack of relevant design tools for architects and engineers (see 4.2.1). The second experiment phase identifies the lack of interoperability between the design software and the Stratoconception® CAM software.
Two CAM Stratoconception® software tools exist. The first one is StratoPro® CAM software which lacks the tools for evaluation of design choices and has limited exchange from CAD software to the 3D model through an import of the part as the STL file which structures the design-to-manufacturing process as linear with no feedback of the manufacturing preparation to the design (Figure 8). The second software is TopSolid'Strato, an add-in, with the same functionality as StratoPro®, integrated to TopSolid which is a CAD-CAM software used for mechanical engineering. With the development of the add-in of TopSolid the digital information continuum from design to manufacturing with Stratoconception® is supported by the same and only one software. However, this software is not a tool adapted to architectural design. The use of design software adapted to architecture breaks the digital information continuum of the TopSolid'Strato software by the import of the 3D model of the part which, again, prevents the feedback of the manufacturing issues at the design phase whereas we highlight the interdependence between the design and the manufacturing (see 4.2.1). This lack of feedback is not inevitable and the development of the interoperability between TopSolid' and the AEC design software provides an alternative to the existing workflow [34].

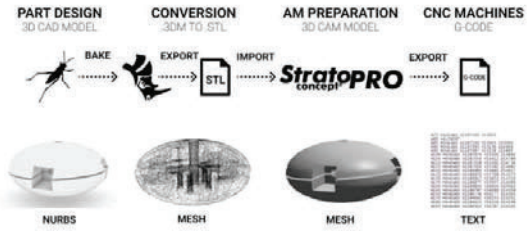

Figure 9: *Linear and non-retroactive digital workflow of the multifunctional timber mesh joint design to manufacturing experiment.*

The experiment confirms that the existing workflow is not continuous (digital data continuity is hindered), inefficient (need for various software tools without clear interoperability) and uninstructive (does not illustrate all the project information and design possibilities, thus hindering the design choices). Despite the interdependence between the design and the manufacturing choices of the Stratoconception® process, the software solutions do not offer an efficient collaboration due to their linear workflow structure, with no feedback on the design, and the lack of multi-criteria evaluation and optimization tools. A new digital workflow must be implemented with the relevant tools for the design and the manufacturing process and with interoperability between all the software for efficient collaboration.

5 PROPOSED DESIGN FRAMEWORK

In section 4, we emphasized the lack of methods and tools integrating the AEC issues, for example the structure or the visual aspect, in the design to manufacturing process

by Stratoconception®. We present in Figure 9 the proposed design framework for the integration of AEC issues into the multicriteria design process. The design framework comprises three phases consistent with the three categories of the Design for Additive Manufacturing research identified by Wiberg et al. [35], thus the "*system*, *part* and *process design"*. It is intended to be flexible to the scale of the designed building component and to the muti-objectives of the project. Three further phases follow the design and include the fabrication of the strata, the construction by assembling the strata and the delivery of the building components. The framework has not yet been fully implemented. It is developed to be independent from a specific software, with a parametric environment which is better adapted to optimize the design choices.

5.1 SYSTEM DESIGN

The *system design* phase aims to identify which project components may be designed and manufactured with Stratoconception® and to define the geometrical and functional boundaries of the design. This phase is led by the opportunities of the Stratoconception® use in timber architecture and construction (see Section 3). The designer relies on the knowledge base of these opportunities to assess whether the use of the AM process adds value to the design or the manufacturing of the component. Next, we establish the specifications of the component which include the geometrical boundaries of the component, its interconnection with the other components of the system and the functionalities that the component must integrate. The multi-functionalization and the shape complexity opportunities provided by the AM use could improve creativity and foster novel designs.

5.2 PART DESIGN

Following the *system design phase*, the *part design phase* leads the designer towards the best design of the previously selected component. The result of this phase is the precise definition of the strata geometry approved for manufacturing.

The phase has three steps: the initial design, the slicing and decomposition of the 3D model, and the assembly of the strata. The initial design is achieved with one of two approaches, either the architect creates the geometry of the component or the architect creates the process generating this geometry in the definition domain stated in the system design using, for example, topological optimization algorithms.

Then, we integrate the slicing and the decomposition of the 3D model at the part design phase before the preparation for manufacturing where it occurs in the existing process. Yet, we have identified that the strata impact the visual aspect of the architecture, if they are visible, and can therefore influence the slicing direction choices. Moreover, the optimal slicing strategies are not always the most intuitive and they depend on the goals defined by designer. Finally, the assembly step creates the final geometry of the strata.

The main contribution of the proposed framework is the coupling of each step of the part design to simulation engines. It satisfies the identified need for assessment of the design choices to lead to efficient and rational decision-making in a flexible and dynamic process. The assessments can be launched at every step of the part design and they adapt to the increase of the level of detail of these steps and to the expectations of the designer. We use four main simulation engines: the fabrication, the construction (the assembly of the strata), the structure and

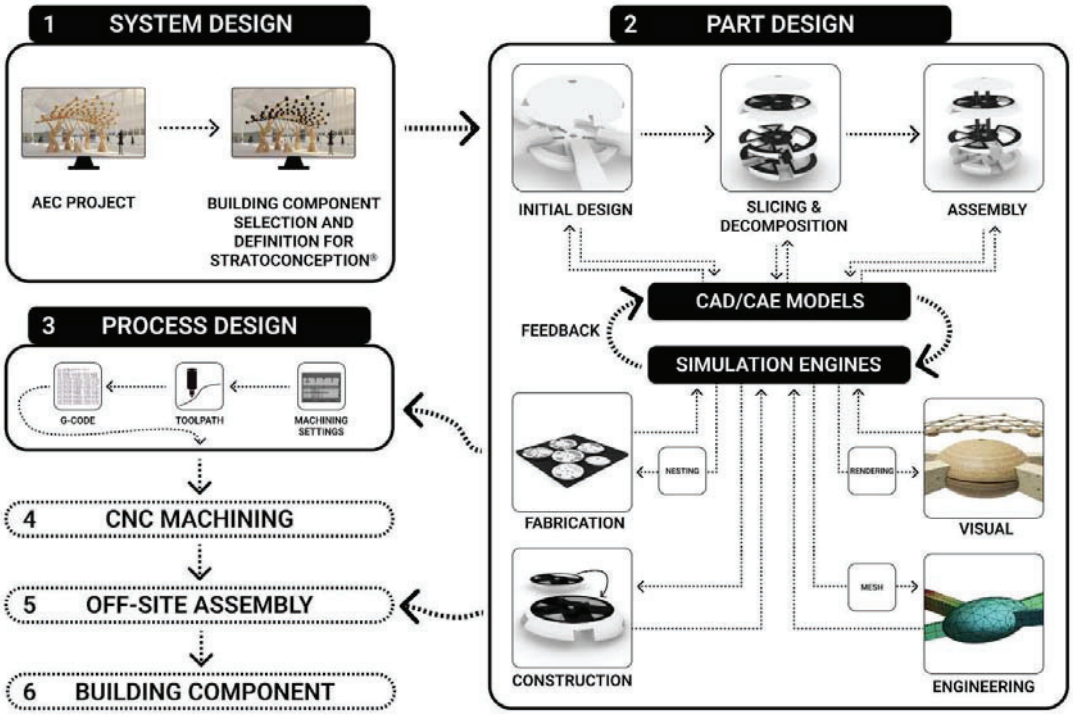

Figure 10: *Proposed design framework comprising the three phases of the system, part and process design.*

https://doi.org/10.52202/069179-0482

the visual aspect of the project if the strata are visible. The fabrication assessment addresses the feasibility and the material yield of the part design. Therefore, the nesting of the strata is integrated into the core design process. Thus, it is a support for optimizing the design choices and it is not confined to a step in the manufacturing preparation process as it is now. Other simulation engines can be developed such as life cycle analysis or time and cost assessment. The simulation engine supports the optimization of the design choices. The optimization objectives may be the minimization of weight of the component, the material waste, the cost, the environmental impact, the structural or the thermal performance. The optimization objective may be one or various.

The integration of the simulation engines into the part design process fosters an integrative approach, involving the strengthening of the relationship of the architect, the engineer and the builder, and goes beyond a design focused solely on architectural concerns or construction feasibility.

5.3 PROCESS DESIGN

Next, the *process design phase* prepares the fabrication of the component and results in the generation of the G-Code that will control the CNC machine. The phase is based on the nesting of the strata approved at the *part design phase*. The steps of this phase are those of the existing process such as the definition of the machining settings and the generation of the toolpath. A contribution to the existing methods and tools of this phase would be to consider the wood anatomy, the species and the wood grain orientation in the definition of the machining settings to improve the surface quality by using adaptative milling.

The design process is followed by the fabrication of the strata, the construction by assembling the strata in the workshop and the delivery of the building components. The assembly of the strata is guided by the assembly documents from the construction simulation engine.

5.4 FURTHER WORK

The implementation of the proposed design framework requires for further work on:

- The summary of the knowledge base of the opportunities and the limitations of the Stratoconception® use in timber AEC, with a detailed study of use-cases, so that architects, engineers and builders can adopt this new technology and identify the building components they can thus design.
- The automation of the non-creative activities of the process and the development of new strategies adapted to the building components, for example, decomposition strategies of the strata minimizing the material wastes.
- The interoperability between different software of the fragmented AEC industry in order to minimize the data waste and the errors caused by the file exchange and to gain efficiency and design integration.
- The development of reliable mechanical, thermal or Life Cycle Assessment (LCA) simulation engines for each step of the part design and go beyond the limits of the conventional tools that lack flexibility for use on non-standard building components.
- The introduction of new materials, such as glue laminated timber, and the adaptation of the operations and practices thus induced in the process to offer an alternative to the use of the timber panel.

Further steps of the research and developments should be conducted to improve step by step the proposed framework.

6 CONCLUSION

As additive manufacturing becomes increasingly implemented in the construction industry, it is important to understand how these new technologies affect the way we design and build timber architecture. By assessing the use of the Stratoconception® process with several experiments, this study established that additive manufacturing could overcome the existing limits of timber architecture to produce new high-value-adding building components. We have addressed a number of key issues and identified the relevant challenges of scaling-up the process and managing the material wastes. We also outlined that *there is a lack of design framework adapted to the multi-criteria decision making required using Stratoconception® in timber architecture and construction*. This paper contributes to the proposal of a framework of timber architectural design for additive manufacturing using the Stratoconception® process in a design-to-manufacturing process. Further research will focus on the implementation and the assessment of the proposed framework.

ACKNOWLEDGEMENT

This research was financially supported by the partnership chair *"Timber architecture and construction: from heritage to digital"* and by the French Ministry of Culture. The authors also acknowledge the students at the National School of Architecture of Nancy for their participation in the pedagogical exercises related to this work.

HYPERBOLIC PARABOLOID SHELLS MADE OF DIAGONAL LAMINATED TIMBER ELEMENTS

Matthias Arnold[1], Philipp Dietsch[2], Stefan Winter[3]

ABSTRACT: This paper deals with the design, calculation, and construction of hyperbolic paraboloid shells made from mass timber elements. Considering the geometrical definition, hyperbolic paraboloid shells can be described as doubly ruled surfaces and can therefore be assembled from twisted rectangular plates.

The membrane theory of the hyperbolic paraboloid shell is derived and compared to previous analytical approaches. A challenge is the realization of the shell using the orthotropic material timber. Therefore, the torsional stiffness of multi-layered mass timber elements is determined by means of analytical and experimental investigations. Taking into account the semi-rigid connection between the layers, resulting in additional shear deformations, nailed and diagonal laminated timber elements are investigated towards the construction of HP-shells.

KEYWORDS: hyperbolic paraboloid shell (HP-shell; hypar), membrane theory, diagonal laminated timber (DLT), nailed laminated timber (NLT), semi-rigid connections, laminate theory, torsional stiffness

1 INTRODUCTION

1.1 BACKGROUND

The application of HP-shells made of timber found its temporary peak around 1970, for example at the exhibition pavilion for the Federal Garden Show in Dortmund, Germany, 1969. For the assembly of the shell, five layers of single laminations were laid on top of each other and fixed by mechanical fasteners, e.g. nails. Timber shells offer many advantages, for example the fast erection, the low weight, and the high quality of the surface. Experiments with timber HP-shells were first carried out at University of Kansas in 1956 [1]. A similar project was realized in Stuttgart in 1963 [2] (Fig. 1).

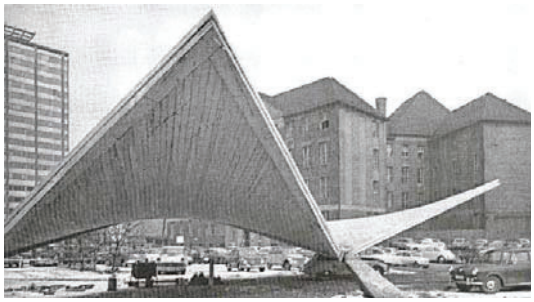

Figure 1: *Experimental timber HP-shell (span l´= 15.0 m) in front of Stuttgart University, 1963* [2]

In general, a hypar can be described mathematically as a translational surface (fictive parabolas in x´ and y´ direction, acting in tension and compression only, Fig. 2) and as doubly ruled surface (straight lines in x or y direction forming rectangular plate elements, acting in in-plane shear only, Fig. 3).

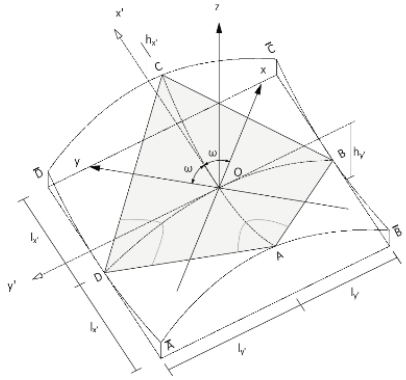

Figure 2: *Hypar described by a translational surface* [3]

The translational surface is given by Eq. (1). By rotating the x' and y' axis by the angle ω, to correspond with the asymptotes of the hyperbola, a new description based on the global x and y axis is introduced—see Eq. (2) [4].

$$z = \frac{h_{x'}}{(l_{x'})} \cdot x'^2 - \frac{h_{y'}}{(l_{y'})} \cdot y'^2 \tag{1}$$

$$z = \frac{4 \cdot sin^2\omega \cdot h_{y'}}{(l_{y'})^2} \cdot x \cdot y \tag{2}$$

$$z = \frac{h_{y'}}{(l_{y'})^2} \cdot 2 \cdot x \cdot y = \frac{h}{ab} \cdot x \cdot y = k \cdot x \cdot y \tag{3}$$

A symmetrical hypar ($h_{y'} = h_{x'}$) over a square plane projection ($2\omega = 90°$) can therefore be described by Eq. (3) using the global x and y axis [5]. Fig. 3 show that

the ruled surface can be assembled from single, twisted rectangular elements.

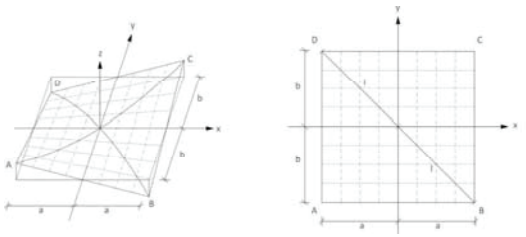

Figure 3: *Hypar described by a ruled surface* [3]

1.2 OBJECTIVE

The objective of the research presented is to create a HP-shell from prefabricated, large-scale NLT or DLT plates and thus to create HP-shells with a high degree of prefabrication. Thereby the elements remain plane during production and get twisted on the construction site, by connecting them to edge beams. In a second construction step, the elements are connected to the adjacent elements, taking the in-plane shear forces n_{xy}.

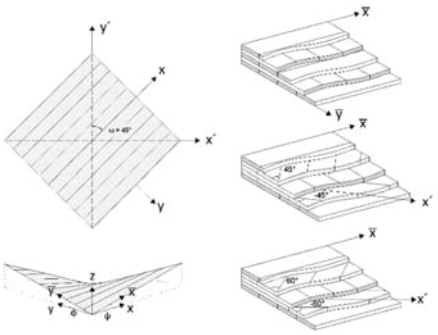

Figure 4: *Exemplary layups of DLT elements according to the geometry of the shell in the plane projection*

Depending on the fictive compression and tension parabolas, the layup of the mass timber elements can be adapted to the principle membrane forces ($n_{x'}$ and $n_{y'}$) by rotating individual layers during production. The resulting multi-layered element is a balanced and symmetric laminate (Fig. 4, right). This means, for each $+\theta$ ply in the laminate there is an equally thick $-\theta$ ply (referred to the symmetry axis). The layers of the laminate are a mirror image about the geometrical midplane.

Within previous research [6; 7] mass timber elements featuring diagonally arranged layers had been defined as DLT. In general, the diagonal layer arrangements of DLT elements lead to an increase of the torsional stiffness compared to conventional CLT elements. This is also due to the high out-of-plane shear stiffnesses S_{xz} and S_{yz} of DLT [8]. In case of the application on HP-shells, the DLT elements should provide a small torsional stiffness in order to not disturb the membrane stress state due to the additional load case of torsion caused by the twisting of the elements. Therefore, a semi-rigid connection of the layers by mechanical fasteners (nails) is introduced.

2 SERIES INVESTIGATED

2.1 LAYUPS

Tab. 1 gives the layup and stacking sequence of the specimens investigated. DLT_n is the designation for nailed DLT. All specimens are made of spruce (see Chapter 2.2). In addition, the number n of specimens investigated is given.

Table 1: *Specimens per Series for the mechanical testing*

series		n	[1)]orientation θ [°]	t [mm]
O1	CLT	4	0°, 90°, 0°, 90°, 0°	100
O2	NLT	4	0°, 90°, 0°, 90°, 0°	105
O3	CLT	2	0°, 90°, 0°	60
O4	NLT	3	0°, 90°, 0°	63

[1)]layer orientation referred to the local $\bar{x}$ axis of the specimens
[2)]DLT specimens with semi-rigidly connected layers using nails

2.2 MATERIAL PROPERTIES

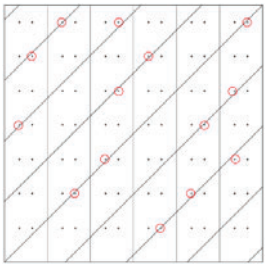
The CLT elements were produced using material properties according to ETA 20/0023 [9]. The DLT elements were produced using according to ETA 16/0055 [10]. Each layer of the CLT has a thickness of $d = 20\ mm$. The laminations are not edge-glued and the board width is $b = 180\ mm$. The modulus of elasticity (MoE) was cross-checked by compression tests according to EN 408 [11] and was $E_{c,0,mean}$ = 10282 MPa (COV 0.56 %). The NLT and DLT_n elements were produced according to ETA 15/0760 [12]. Each layer has a thickness of $d = 21\ mm$. The MoE was determined by four-point bending tests according to EN 408 [11] and was $E_{m,0,mean}$ = 11044 MPa (COV 1.21 %).

At the beginning of the mechanical testing the moisture of each specimen was determined by means of ram in electrodes at a depth of approximate 15 mm. On each specimen 5 measurements were taken. The mean value $u_{mean,15mm}$ of the initial moisture content was 11.2 % (COV 7.6 %). The moisture content u of all specimen was in the range of $12 \pm 2\%$. The mean value of the density at $u = 12\%$ was exemplary determined for series O1 according to EN 384 [13]. The mean value ρ_{mean} was 458 kg/m³ (COV 4.3 %).

2.3 CONSIDERATION OF THE NAILING

The layers of the NLT and DLT_n are connected to the underlying layers with aluminium grooved nails ($t = 2.5\ mm$) [12]. During production, the nailing unit moves over the layers at the same predefined spaces and shoots the single nails into the laminations. Using a Monte-Carlo-Simulation (MC-simulation), the probability of inserting a number m of nails per crossing point of the single laminations is calculated statistically. Nails between the edges of the boards or outside the required minimum edge distance must not be used for the calculation of the stiffness properties of the composites (circled nails in Fig. 5).

https://doi.org/10.52202/069179-0483



MC-simulation:

nails per element: 84
runs: 1000
nails in total: 84000
crossing-points with m nails:
0: 2000 (7.1 %)
1: 2000 (7.1 %)
2: 8000 (28.6 %)
3: 12000 (42.9 %)
4: 4000 (14.7 %)

Figure 5: *Exemplary distribution of nails for joining two layers (crossing angle at 45°) using statistical evaluation*

Determining the statistical distribution of nails per crossing-point, an average effective number of nails per crossing of two layers (1.20 m / 1.20 m) can be calculated (mean value). The result of the simulation is verified by counting the actual nails per layer and crossing-point on the specimens (Fig. 6).

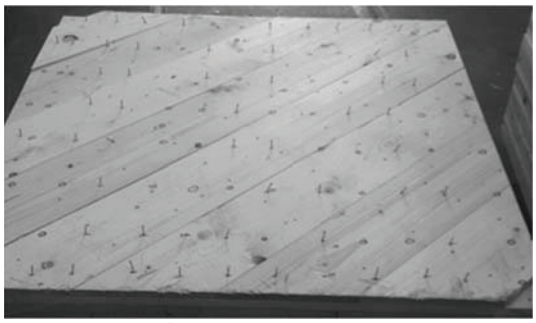


Figure 6: *Exposed nail pattern between two layers, crossing under 45°*

Tab. 2 compares the results of the MC-simulation to the nails counted for two layers crossing under 45°, 60° (30°), and 90°. The number of nails that can be effectively applied per crossing-point are used for the calculation of the stiffness values.

Table 2: *Effective number of nails per crossing of two layers of the NLT and DLT_n specimens*

crossing angle	crossing points with n nails (MC-Simulation) [%]					calculated effective nails (1.20/1.20)	[1]counted effective nails (1.20/1.20)
	m= 0	m= 1	m= 2	m= 3	m= 4		
45°	7,1	7,1	28,6	42,9	14,7	78	80
60°	5,3	0,0	15,8	52,6	26,3	80	80

3 ANALYTICAL INVESTIAGIONS

3.1 STIFFNESS PROPERTIES OF DLT AND NLT

The stiffness properties of multi-layered timber elements can be determined by the stiffness properties of the individual layers i and their interaction as a composite. The laminate theory of orthogonally glued CLT can be taken from several previous publications [14; 15]. Laminates are characterized by their response to mechanical loading, which is associated with a description of the coupling behavior. The matrix notation of the law of elasticity on the plate element consists of submatrices. These refer to the extensional stiffness A, the bending-extension coupling stiffness B, and the bend-twist coupling stiffness D (ABD-relation). Taking into account the transverse shear deformations, which are decoupled from the ABD-relation, a fourth submatrix E has to be introduced [15]. The stiffness parameters can be taken from the ABD-E stiffness matrix. For antisymmetric, balanced laminates, simplifications within the stiffness matrix can be made ($A_{16} = A_{26} = D_{16} = D_{26} = B_{11} = B_{12} = B_{22} = B_{66} = E_{54} = 0$) which leads to the stiffness matrix given by Eq. (4).

$$[Q] = \begin{bmatrix} A_{11} & A_{12} & 0 & 0 & 0 & B_{16} & 0 & 0 \\ A_{21} & A_{22} & 0 & 0 & 0 & B_{26} & 0 & 0 \\ 0 & 0 & A_{66} & B_{61} & B_{62} & 0 & 0 & 0 \\ 0 & 0 & B_{16} & D_{11} & D_{12} & 0 & 0 & 0 \\ 0 & 0 & B_{26} & D_{21} & D_{22} & 0 & 0 & 0 \\ B_{14} & B_{24} & 0 & 0 & 0 & D_{66} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & E_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & E_{44} \end{bmatrix} \quad (4)$$

For CLT and DLT elements, the entries for S_{xz} (E_{44}) and S_{yz} (E_{55}) have to be multiplied by shear-correction factors k_z. A possible calculation of the shear-correction factors in the global x and y direction is based on the Timoshenko Beam Theory [16] according to Eq. (5). The derivation of Eq. (5) is based on the principle of virtual displacements (method of consistent deformations; force method) and the equilibrium between shear and bending stiffnesses over the cross-section [17].

$$\frac{1}{k_z} = \frac{\sum G_{iz} A_i}{\left(\int_{-\frac{t}{2}}^{\frac{t}{2}} E_i(z) z^2 \, dz\right)^2} \cdot \int_{-\frac{t}{2}}^{\frac{t}{2}} \frac{\left(\int_z^{\frac{t}{2}} E_i(z) z \, dz\right)^2}{G_{iz}(z)} dz \quad (5)$$

For NLT and DLT_n on the other hand, the semi-rigid connection of the layers has to be taken into account; the contribution of the layers—especially the transverse layers—on the shear deformations become marginal. Therefore, the laminate theory and shear-strain relation stays no longer valid. DIN EN 1995-1-1/NA [18] provides an analytical method for the calculation of out-of-plane shear stiffness values of semi-rigid connected mass timber elements by Equations (NA.40) and (NA.42). The calculation is based on the *Shear Analogy Method* [19] and considers a constant shear flow over the effective heights (shear area) a (Eq. (6)).

$$\frac{1}{S_{xz/yz}} = \frac{1}{a_{x/y}} \cdot \left[\sum_{i=1}^{n-1} \frac{1}{k_{x,i/y,i}} + \frac{d_1}{2G_{xz/yz}} + \sum_{i=1}^{n-1} \frac{d_i}{G_{xz,i/yz,i}} + \frac{d_n}{2G_{xz/yz}} \right] \quad (6)$$

with
$n = \ number\ of\ layer$ [/]
$a = \ effective\ heigths$ [19]
$G_{xz,\frac{i}{yz},i} = shear\ modulus\ of\ the\ respective\ layer,$
(for layer arranged under 45°, $G_{45} = 370\ MN/m^2$)
$d_i = \ layer\ thickness\ [mm]$]
$k_i = slip\ modulus\ between\ the\ layers\ [N/mm]$

https://doi.org/10.52202/069179-0483

ETA 15/0760 [12] gives an approximate analytical method for the calculation of the out-of-plane shear stiffness values of NLT and DLT_n, taking into account the number of layers n, the effective number of nails per crossing-point m (see Tab. 2) and the initial slip modulus K of the nails. Therefore, the slip modulus k between the layers—see Eq. (6)—is substituted, using Eq. (7).

$$\sum_{i=1}^{n-1} \frac{1}{k_{x,i/y,i}} = \sum_{i=1}^{n-1} \left(\frac{1}{f} \cdot \frac{1}{m \cdot \left(\frac{K}{b_x \cdot b_y} \right)} \right) \tag{7}$$

with
m = *number of nails per crossing point* [/]
K = *initial slip modulus of a single nail* [N/mm]
$b_x = b_y$ = *board width* [mm]
$f = 1{,}25\ for\ m = 4, and\ f = 1{,}5\ for\ m = 2$

3.2 MEMBRANE FORCES OF THE HP-SHELL

3.2.1 Equilibrium conditions and differential equation

Pucher [20] established a method for the calculation of membrane forces in arbitrary shell structures by transferring stress resultants on infinitesimal elements, to their plane projection (Fig. 7). The plane projection is in the state of equilibrium in x and y direction. Fig. 7 shows the geometric relationships $tan\varphi = \partial z/\partial x$ and $tan\psi = \partial z/\partial y$ introducing a third equilibrium in z-direction.

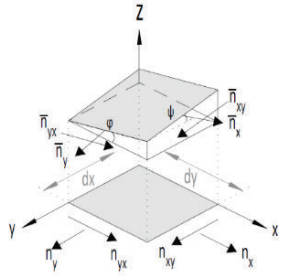

Figure 7: *Transfer of stress resultants to the plane element*

Eq. (8) gives the equilibrium conditions on the plane element.

$$\bar{n}_x = n_x \cdot \frac{cos\varphi}{cos\psi} \;\; ; \;\; \bar{n}_y = n_y \cdot \frac{cos\psi}{cos\varphi} \; ; \quad n_{xy} = \bar{n}_{xy} \;\; ; \;\; n_{yx} = \bar{n}_{yx} \tag{8}$$

The calculation of stress resultants on the infinitesimal shell elements is based on the assumption of the membrane theory for thin shells (transverse shear forces, bending moments, and torsional moments are neglected [21]). This means that the shell is statically determined; Three unknown stress resultants face three equilibrium conditions ($\sum F_x = 0, \sum F_y = 0, \sum F_z = 0$). Hereby, the stress resultants can be calculated without material or kinematic conditions. The derivatives of the equilibrium relations (Eq. (9)) are inserted into the *Airy Stress Function F* (Eq. (10)) to achieve the ordinary differential equation (Eq. (11)) [20].

$$n_x = \frac{\partial^2 F}{\partial y^2} - \int p_x d_x \; ; \quad n_y = \frac{\partial^2 F}{\partial x^2} - \int p_y d_y \; ; \quad n_{xy} = n_{yx} = -\frac{\partial^2 F}{\partial x \partial y} \tag{9}$$

$$F = \frac{\partial^2 F}{\partial y^2}\frac{\partial^2 z}{\partial x^2} - 2\frac{\partial^2 F}{\partial x \partial y}\frac{\partial^2 z}{\partial x dy} + \frac{\partial^2 F}{\partial x^2}\frac{\partial^2 z}{\partial y^2} \tag{10}$$

$$F = -p_z + p_x \frac{\partial z}{\partial x} + p_y \frac{\partial z}{\partial y} + \int p_x d_x \frac{\partial^2 z}{\partial x^2} + \int p_y d_y \frac{\partial^2 z}{\partial y^2} \tag{11}$$

The surface equation $z = k \cdot xy$ (Eq. (3)) is derived according to Eq. (11) to receive the ordinary differential equation of a hyperbolic paraboloid (Eq. (12)) [22]:

$$-2k \cdot \frac{\partial^2 F}{\partial x \partial y} = -p_z + p_x \cdot y \cdot k + p_y \cdot x \cdot k \tag{12}$$

To derive the membrane forces n_x and n_y as well as the in-plane shear forces n_{xy} the equilibrium conditions (Eq. (8)) are solved. A uniform loading p_z leads to in-plane membrane forces n_{xy} only, within the global x-y coordinate system (Eq. (13)).

$$n_{xy} = \frac{-p_z + p_x \cdot y \cdot k + p_y \cdot x \cdot k}{2k} \tag{13}$$

The membrane forces n_{xy} are equivalent to normal forces in the x´-y´ coordinate system. This means that the in-plane shear force n_{xy} can be split into normal forces $n_{x'}$ and $n_{y'}$ (normal forces acting along the fictive compression and tension parabolas of the HP-shell). Therefore, the membrane forces can be calculated on the plane projection of an infinitesimal shell element, taking into account the boundary conditions of the edges. The main boundary conditions are classified into free edges ($n_x = n_{xy} = 0$), linear supported edges (edge beams; $n_x = n_y = 0$ and $n_{xy} \neq 0$) and clamped/ edges ($n_x = n_{xy} \neq 0$) [23].

3.2.2 Simplified calculation method

The basic idea of Parme in 1960 [24] was to describe the load transfer in HP-shells by fictive compression and tension parabolas (Fig. 8). This idea was further developed by Hempel in 1967 [25] and Krauss in 1969 [26].

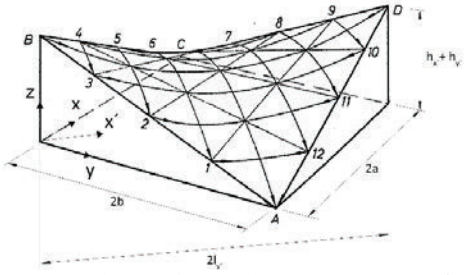

Figure 8: *Distribution of the shell into compression and tension parabolas* [26]

https://doi.org/10.52202/069179-0483

Since the solution of the membrane forces are a function the loading, Parme [24] assumed that a uniform load q_z [kN/m²] on a double symmetric HP-shell over a square projection gets equally distributed between two perpendicular parabolas.

For the boundary condition of linear supported edges ($n_x = n_y = 0 \; and \; n_{xy} \neq 0$) the normal force N—acting along the edge beams—result from the calculation of the horizontal and vertical reactions of the compression and tension parabolas, taking into account load-distribution factors $\chi_{x'/y'}$ (Eq. (14) and (15)) [26].

$$H_{x'/y',\,n} = \chi_{x'/y'} \cdot q_z \cdot \frac{\left(2 \cdot l_{x'/y',n}\right)^2}{8 \cdot h} \tag{14}$$

$$V_{x'/y',\,n} = \chi_{x'/y'} \cdot q_z \cdot \frac{2 \cdot l_{x'/y',n}}{2} \tag{15}$$

$with$

$$\chi_{x'} = \frac{1}{1 + \frac{\sum EA_{y',i}}{\sum EA_{x',i}} \cdot \frac{l_{x'}^4}{l_{y'}^4}} \quad ; \quad \chi_{y'} = 1 - \chi_{x'}$$

If the distribution of the axial rigidity is the same in x´ and y´ directions ($\chi_{x'} = \chi_{y'} = ½$)—which is the case for the chosen series (Tab.1)—the shear force n_{xy} equals the resultant R of the horizontal reactions of the fictive compression and tension parabolas (Fig. 9).

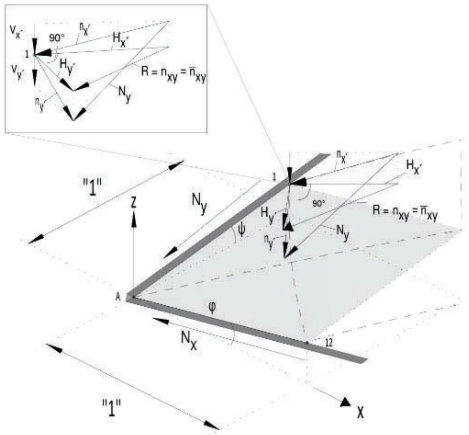

Figure 9: *Resulting forces in the HP-shell and in the edge beams under a uniformly distributed load p*

The geometric relationship of Fig. 9 can also be proven mathematically by comparing n_{xy}—calculated from $n_{x'}$ and $n_{y'}$ according to Pythagoras' Theorem—with n_{xy} according to the membrane theory under a uniform surface load q_z.

4 EXPERIMENTAL INVESTIGATIONS

4.1 TEST SETUP

After analytical investigations of the torsional stiffness properties, NLT, CLT, and DLT specimens featuring layups according to Tab. 1 with a side length $a = 1200\ mm$ are twisted in biaxial bending tests. The aim is to determine the torsional stiffness properties of the various specimens from the deformation of the elements under an external point-load, in order to make statements on the additional out-of-plane load case of torsion at the assembly of HP-shells. Parts of the results of the mechanical testing on CLT and DLT were already published within [7] and [8]. Fig. 10 shows the test setup of the biaxial bending test.

The point-load, directed vertically downwards, is applied to the free corner of the specimens by a hydraulic cylinder. The load-application point as well as the supports are realized by steel plates ($120/120/12\ mm$). They each are articulated and offset inwards by 100 mm from the free edges of the specimens. No reinforcement for compression perpendicular to the grain stresses in form of self-tapping screws is applied.

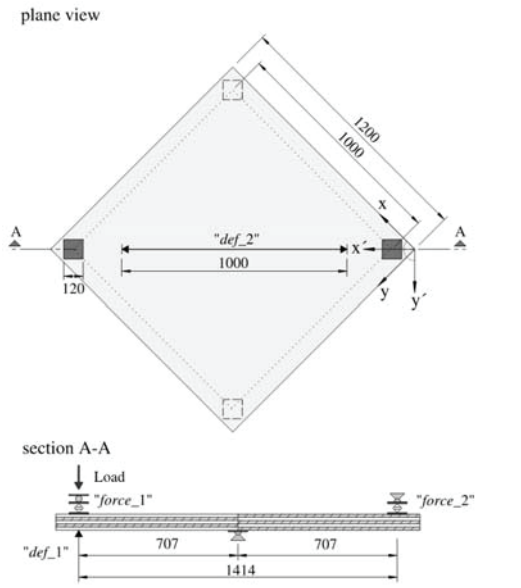

Figure 104: *Biaxial bending tests to determine the torsional stiffness of CLT, DLT, and NLT specimens*

The applied loading "$force_1$" (point-load F) as well as at the reaction force on the opposite support "$force_2$" are measured by force transducers. Deflection "def_1" (deflection w in z direction) is measured using a rope extensometer which is attached at the opposite side of the load-introduction point at the bottom of the test specimens. In addition, the change in the curvature κ_{xy} is measured determining the arc length "def_2" over 1000

mm by means of a second rope extensometer on the upper side of the specimens. The mechanical testing is carried out deformation-controlled. This means that each test specimen is loaded until a unit-deflection w (def_1) of $100\ mm$ (geometrical limit imposed by geometry of load-introduction) or failure. All specimens are loaded with a constant feed rate of about $0.30\ mm/s$. The corresponding forces F ("$force_1$" = "$force_2$") are measured as a function of the time.

4.2 TEST RESULTS AND COMPARISON TO AN ANALYTICAL APPROACH

Fig. 11 exemplary gives the load-deflection diagrams for the NLT and DLT_n series. Load-deflection diagrams for the CLT and DLT series can be taken from [7].

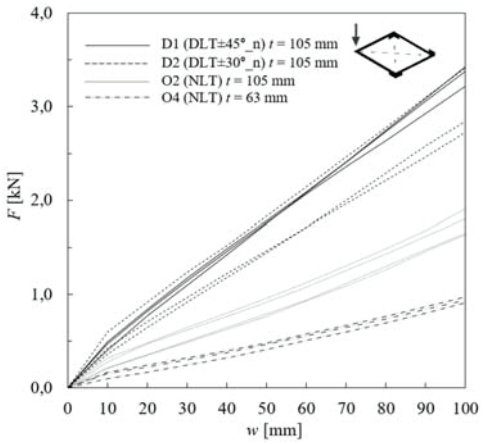

Figure 11: *Load-deflection diagrams of the NLT and DLT_n specimens under biaxial bending*

The load-deformation curves show a kink when overcoming the static friction force in the joint between the board layers ($F_{st,fr} < 0.2F_{w_{100}}$). The torsional stiffness for each specimen is calculated within the linear elastic range $0.2F_{max}$ $(0.2F_{w_{100}})$ and $0.4F_{max}$ $\left(0.4F_{w_{100}}\right)$ using linear regression. The torsional stiffness values determined experimentally are effective torsional stiffness values $B_{xy,eff,exp.}$ since the transversal shear deformations are included in the total deformation w measured by the rope extensometer [7]. For all specimens that did not reach a failure load, the corresponding load F_{w100} to reach the unit deformation of $100\ mm$ is used instead of F_{max} to determine the effective torsional stiffness. The evaluation is based on the force method (Eq. (16)) and carried out using Eq. (17) [7, 27].

$$w = \int \frac{m_{xy} \cdot \widetilde{m_{xy}}}{2 \cdot B_{xy}} \cdot dx = \int \frac{F \cdot a \cdot \bar{1} \cdot a}{2 \cdot B_{xy}} \cdot dx \tag{16}$$

$$B_{xy,eff,exp} = \frac{F \cdot a^2}{2w} = \frac{(0.4F_{max} - 0.2F_{max}) \cdot a^2}{2\left(w_{0.4F_{max}} - w_{0.2F_{max}}\right)} = \frac{1}{2} \cdot m \cdot a^2 \tag{17}$$

In order to compare the results of the numerical models with analytical solutions, out-of-plane shear deformations have to be taken into account within the analytical derivation of stiffness values. These values are referred being "effective" stiffness values and depend on the loading and equivalent static system. For thick plates and shells, taking into account out-of-plane shear deformations is mandatory (Reissner-Mindlin plate theory). Within this investigations, no comparable thick series ($t \geq 200\ mm$) was investigated. Nevertheless, the analytical approach shall be described in the following, because for NLT the semi-rigid connection—and therefore the low out-of-plane shear stiffness—has to be taken into account also for comparable thin layups:

Analytically, effective torsional stiffnesses ($B_{xy,eff}$) can be determined using the method of consistent deformations (force method) on equivalent static systems. Fig. 12 shows the extended girder grid model. Here, in addition to torsional stiffness, shear and bending stiffnesses are assigned to the girders (dx/dy).

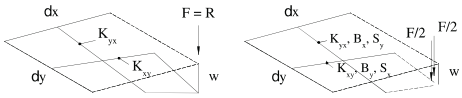

Figure 12: *Girder grid model of an infinitesimal element taking into account bending and shear deformations* [7]

Following the girder grid model in Fig. 12, the following energy theorem results (Eq. 11):

$$w\delta_{ij} = \int_0^1 \frac{\delta m_{xy} \cdot m_{xy}}{2K_{xy}} dx + \int_0^1 \frac{\delta m_x \cdot m_x}{B_y} dx + \int_0^1 \frac{\delta m_y \cdot m_y}{B_x} dy + \int_0^1 \frac{\delta V_x \cdot V_x}{S_{xz}} dx + \int_0^1 \frac{\delta V_y \cdot V_y}{S_{yz}} dy \tag{11}$$

The bending and torsional stiffnesses $B_x, B_y,$ and B_{xy} refer to the entries ($D_{11}, D_{22}, and\ D_{66}$) of the ABD-E Matrix (Eq. (4)). For CLT and DLT, the shear stiffnesses S_{xz} and S_{yz} can be taken from the entries E_{55} and E_{44}, multiplied by k_z (Eq. (5)). For NLT and DLT_n, S_{xz} and S_{yz} should be determined according to Eq. (6). Based on Eq. (11) the equilibrium of Eq. (12) applies to the total deformation w of the element, taking into account the transverse shear deformations.

$$\frac{F \cdot dx \cdot dy}{B_{xy,eff}} = \frac{F \cdot dx \cdot \bar{1} \cdot dy}{2D_{66}} + \frac{1}{3}\frac{\frac{F}{2} \cdot dx \cdot \bar{1} \cdot dx}{D_{22}} + \frac{1}{3}\frac{1 \cdot F/2 \cdot dy \cdot \bar{1} \cdot dy}{D_{11}} + \frac{F/2 \cdot \bar{1}}{E_{55}} + \frac{F/2 \cdot \bar{1}}{E_{44}} \tag{12}$$

From this, effective torsional stiffness values are analytically calculated according to Eq. (13).

$$\frac{1}{|B_{xy,eff}|} = \frac{1}{|B_{xy}|} + \frac{1}{6 \cdot |B_x|} + \frac{1}{6 \cdot |B_y|} + \frac{1}{2 \cdot |S_{xz}| \cdot dx} + \frac{1}{2 \cdot |S_{yz}| \cdot dx} \tag{13}$$

https://doi.org/10.52202/069179-0483

Tab. 3 gives the results of the evaluation of the effective torsional stiffnesses from the experimental investigations ($B_{xy,eff,exp.}$) compared to the analytical approaches ($B_{xy,eff}$ and B_{xy}) for each series investigated. For the determination of the analytical solutions, material parameters according to [9; 10; 12] and the effective number of nails according to Tab. 2 are used (see Chapter 2). In this paper the Poisson's ratios according to Halász and Scheer [28] ($\nu_{xy} = 0.380$; $\nu_{zx} = 0.018$) have been chosen for the calculation of the stiffness matrix. However, when calculating the stiffness properties of CLT and DLT, the chosen values for the Poisson's ratio have no decisive influence.

[1)] values without consideration of transverse shear deformations of the layers
[2)]values without consideration of the semi-rigid connection between the layers and without consideration of transverse shear deformations

Compared to the five-layered CLT series O1 with an overall thickness of $t = 100\ mm$, the effective torsional stiffness $B_{xy,eff,exp}$ of DLT±45 series D3 is increased by 28.4 %, for DLT±30 series D4 by 21.9 % (mean values). Following the results of the mechanical testing, a considerable ratio of stiffness increase can be determined for DLT_n series with a layer thickness of $21\ mm$ and semi-rigid connected layers, compared to the orthogonal layered NLT series. Compared to the NLT series O2, the effective torsional stiffness of DLT±45_n series D1 can be increased by 76,9 %, for DLT±30_n series D2 by 69.2 % (mean values). The torsional stiffness of the 3-layered orthogonal CLT series O3 is smaller by a factor of 4.94 compared to the 5-layered orthogonal series O1. The DLT_n (series D1 and D2) consisting of five layers can be compared to the NLT consisting of five layers under 0° and 90° respectively (O2). By rotating the laminations of the 2nd and the 4th layer by ±45 (D1), an increase in torsional stiffness of 90.5 % can be achieved compared to the NLT with five laminations under orthogonal orientation (series O2). By rotating the laminations of the 2nd and the 4th layer by ±60° (series D2), an increase in torsional stiffness of 70.6 % can be achieved compared to series O2 (see Fig. 13).

For the glued CLT and DLT series, the pure torsional stiffness values of (B_{xy}) represent the experimental results better than the analytical values of $B_{xy,eff}$—albeit not significant. This is not surprising, since the application limits/criteria of the calculation theories according to *Kirchhoff-Love* (B_{xy}) and *Reissner-Mindlin* ($B_{xy,eff}$) retain their validity for the rigid DLT and CLT series. To further underline this, additional test results on the torsional stiffness of CLT and DLT from previous studies on DLT [7] are given in Tab. 4. The O5 and D5 series have the same stacking sequence as the O1 and D3 series, but this time with a layer thickness of 40 mm and thus a total thickness of 200 mm, instead of 100 mm.

Table 4: *Exemplary additional investigations on the torsional stiffness of the series with t = 200 mm* [7]

[1)]values without consideration of transverse shear deformations of the layers

Without taking the transverse shear deformations into account, the torsional stiffness values B_{xy} fail to represent the experimental values on the thick plate elements. The influence of the out-of-plane shear stiffness and therefore the transversal shear deformation of the 40 mm thick layers are much more pronounced, compared to the series with 20 mm layers. The effective torsional stiffness values $B_{xy,eff}$ on the other hand nearly hit the experimental investigations and confirm the analytical solutions.

When comparing the experimentally determined effective torsional stiffnesses $B_{xy,eff,exp}$ of NLT and DLT_n with the torsional stiffnesses previously derived analytically, it becomes clear that the derived approach for considering transversal shear deformations (Eq. (13)) in combination with Eq. (6) and Eq. (7) leads to satisfactory values for the effective torsional stiffness properties $B_{xy,eff}$. As previously described, values B_{xy}—neglecting both, the out-of-plane shear deformations of the layers and the semi-rigid connection between the layers—are inappropriate to represent the actual/effective torsional stiffness of NLT and DLT_n. The analytical values for $B_{xy,eff}$, on the other hand, can represent the relatively negligible torsional stiffness of the nailed specimens.

5 EXAMPLE OF APPLICATION— DOUBLE SYMMETRIC HP-SHELL

In the following a reference HP-shell from twisted DLT elements is exemplary constructed and calculated. The double symmetric hyperbolic paraboloid to be planned over a square projection has the dimensions $l_x = l_y = 5.30\,m$ and $h_{x'} = h_{y'} = 2.00\,m$; $h = 4.0\,m$. In the context of application-optimized mass timber elements DLT±45°_n elements are used for the construction of the load-bearing structure (ref. to D1 series). The elements remain plane during production and get twisted on site by connecting them to edge beams. Each DLT_n element has a length of about 10.60 m and therefore a width of 1.0 m (without consideration of distortions acc. to Eq. (8)). The plate is loaded with a constant surface load of p = 3.6 kN/m² composed by the self weight (lower right, Fig. 13) and snow (upper right side, Fig. 13).

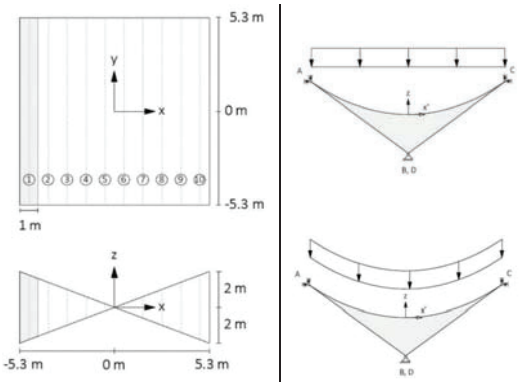

Figure 13: *Ground plan and side view of the HP-shell, divided in sections, representing the DLT elements* [3]

The uniform surface load p_z= 3.6 kN/m² leads to in-plane membrane forces n_{xy} in the shell. Therefore, the connections between the elements have to be dimensioned mainly for in-plane shear forces. The connections are fitted on site after twisting the elements by screwing, or dowelling the longitudinal element edges.

The analytical solutions (membrane theory and simplified approaches) according to Chapter 3.2 show in-plane shear forces only (n_{xy} = 25.28 kN/m). In order to evaluate the calculation methods, girder grid models are chosen as well as finite element method (FEM) models using the software Dlubal RFEM 5.23 (Quadrangle tool or RF Laminate tool) by inserting the previously calculated *ABD-E* stiffness matrix (Fig. 14).

Figure 14: *FEM shell model created with Dlubal RFEM* [3]

Fig. 15 shows the distribution of shear forces n_{xy} .

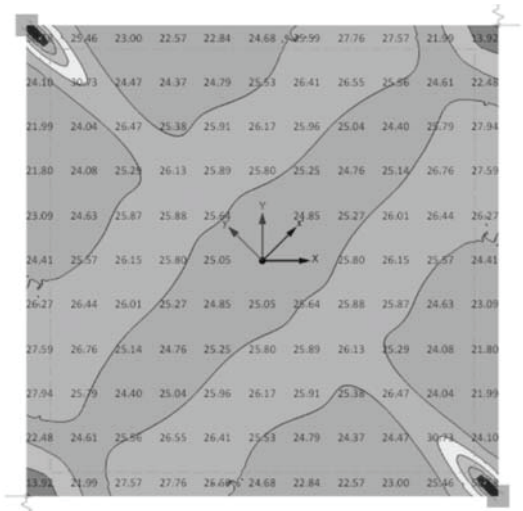

Figure 15: *Shear forces n_{xy} acting in the calculated with Dlubal RFEM* [3]

The shear forces converge to the solution of the membrane theory (n_{xy} = 25.28 kN/m). Bending moments m_x and m_y vanish (extreme values according to the FEM model: $m_x = 0.30\ kNm/m$). With respect to the segmentation and assembly of the shell small torsional moments will occur due to the twisting of the elements on site. These moments should be considered by an additional load case within the model. The torsional stiffness of the elements of D1 series is 0.023 MNm²/m (see Tab. 3). The torsional moment M_T acting within the elements due to the selected element geometry ($w/l = 1.06m/10.6m$) and hights h of the shell is 0.78 kNm—calcualted by Eq. (16). For glued DLT series D3, M_T would appear to be 7.08 kNm. The moment M_T is easily taken by the edge beams (exemplary $w/l = 2 \cdot 0.26m/0.20m$) connected (bolted) to the shell, beyond and above of the edges (Fig. 16).

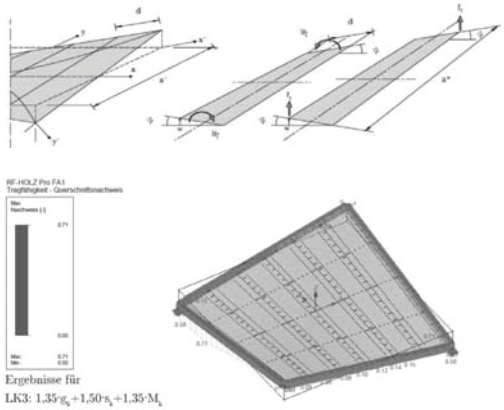

Figure 16: *Torsional moments by twisting the elements (upper sketch) and verification of the load bearing capacity of the beams in the ULS* [30]

https://doi.org/10.52202/069179-0483

As described previously in Chapter 3.2.2, the normal forces acting along the fictive compression and tension parabolas can be calculated by varius simplified methods. For the given example the 4th or 2nd layer of the chosen DLT follows these parabolas providing a high axial rigidity (extensional stiffness) in x´and y´direction. By using these simplified methods, the normal forces within the edge-beams can be estimated without FEM models (Fig. 17).

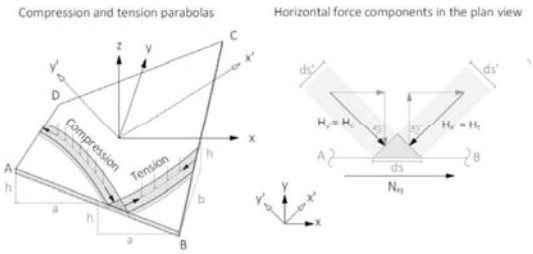

Figure 17: *Disassembling of the stress resultants acting on the edge beam according to Parme* [3; 24]

As in the entire shell, no bending moments act on the edge beams under the given load—besides the small torsional moments from the twisting of the elements. The surface load results in normal forces N, which are the product of the shear force n_{xy}, multiplied by the length of the edge beams. For the chosen example the normal foces N_x and N_y at the support apper to be 286,4 kN each and are taken by steel connectors and concrete supports.

6 CONCLUSIONS

This paper deals with both, results from the fild of structural analysis and timber engineering, leading to the HP-shell. The HP shell is an architecturally sophisticated, wide-span timber structure that can also be used to roof industrial buildings (Fig. 18). With its structural and architectural relevance, the HP-shell may be brought back into the focus of planners.

Figure 18*: Roof structure of the "Silhouette Corset Factory, Market Drayton" made form symmetric timber HP-shells* [31]

In addition, the basics of the plate theories according to Kirchhoff-Love and Reissner-Mindlin multi-layered mass timber elements under biaxial bending are applied. This leads to an analytical approach for the determination of the stiffness properties of DLT—with and without consideration of the transverse shear deformations. In addition an analytical approach for the consideration of semi-rigid connected layers of NLT and DLT_n is derived. Extensive series of mechanical experiments are carried out and serve to verify the analytical solutions. At the same time, the test data forms the basis for the calculation and construction of HP-shells using FEM and girder grid models.

Regardless the findings on the sophisticated HP shell structure, the enormous potential of diagonal layer arrangements within mass timber elements becomes obvious. DLT achieves significantly improved torsional properties with the same amount of material. The main outcomes achieved of the experimental investigations are as follows:

- The increase in the effective torsional stiffness of DLT_n elements compared to the NLT elements is undeniable. Compared to the five-layered NLT series with an overall thickness of 105 mm, the effective torsional stiffness $B_{xy,eff}$ of DLT±45_n elements is increased 76.9 % on average. For DLT±30° with t = 100 mm the increase is 69.2 % on average.
- The increase in the effective torsional stiffness of five-layered DLT elements compared to CLT elements with a thickness of 100 mm is 33 % on average for DLT±45°. For DLT±30° with t = 100 mm the increase is 24 % on average.

The investigations show that the torsional stiffness of DLT elements is significantly higher compared to CLT elements. The outcomes of this research render DTL ideal for plates under biaxial bending and concentrated loading, as required for point-supports [32] and promotes a more efficient use of mass timber elements.

ACKNOWLEDGEMENT

The NLT and DLT_n specimens were provided free of charge by Massiv-Holz-Mauer Entwicklungs GmbH. Thank you, Mr. Rainer König. The CLT specimens were produced by Pfeifer Timber GmbH. Thank you Mr. Bernd Gusinde. The DLT specimens were produced by Holzbau Unterrainer GmbH. Thank you, Mr. Leonhard Unterrainer and Dr. Roland Maderebner. The research was carried out within the research project InnoCrossLam and has received support within ERA-NET Cofund ForestValue by FNR (Federal Ministry of Food and Agriculture, Germany) and funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N° 773324.

MASS TIMBER PANELIZED WORKFORCE HOUSING IN OREGON, U.S.

Judith Sheine[1], Mark Fretz[2], Simone O'Halloran[3], Mikhail Gershfeld[4], Jason Stenson[5]

ABSTRACT: Mass timber panel production came to the United States after developments in Europe and Canada; the first domestic structural cross-laminated timber (CLT) panels were manufactured by DR Johnson Wood Innovations in Riddle, Oregon in 2015. With its history of timber product manufacture, the state has embraced this new material for its potential for economic development and environmental stewardship and Oregon has become the epicentre of mass timber development in the U.S. As in many places in the U.S., Oregon has a critical shortage of affordable housing and it has been challenging to find paths for mass timber to enter this market where light-wood-frame construction is dominant. In 2018, Freres Engineered Wood, working with the TallWood Design Institute, a collaboration between the University of Oregon and Oregon State University, developed a new product: mass plywood panels (MPP). This product provides a possibility for constructing single-family houses economically with mass timber using thin panels derived from small diameter logs. This paper describes the research leading to a pilot project utilizing MPP for workforce housing in Milwaukie, Oregon.

KEY WORDS: Mass Timber, Affordable Housing, Oregon

1 INTRODUCTION

Mass timber panel production came to the United States, after developments in Europe and Canada; the first domestic structural cross-laminated timber (CLT) panels were manufactured by DR Johnson Wood Innovations in Riddle, Oregon in 2015. With its history of timber product manufacture, the state has embraced this new material for its potential for economic development and environmental stewardship and Oregon has become the epicentre of mass timber manufacture, design, research, testing and construction in the U.S.

While timber production has been central to Oregon's economy since its founding, timber production has fallen significantly over the past 50 years, due to environmental regulations restricting timber harvest, and job losses have been severe due to the reduced production and to automation in the industry [1]. Combined with changes in tax laws that have led to further losses of income, rural counties in Oregon have suffered significant economic declines which have exacerbated tensions between environmentalists and those in the timber industries and communities [2]. However, with climate change leading to worsening drought conditions in the American West and years of forest management policies restricting harvest, coupled with the promotion of fire suppression, devasting wildfires have served as an impetus for change [3]. Because mass timber utilizes small diameter logs that can be harvested from forest restoration projects that reduce wildfire risks, environmental groups and the timber industries have been able to find common ground in advocating for changes in forest management policies that allow for additional selective harvesting. Mass timber manufacture provides economic benefits by creating well-paid high tech jobs manufacturing mass timber panels and environmental benefits by utilizing forest restoration products and by substituting a bio-based carbon sequestering material for steel and concrete [4].

Because the state recognizes these benefits, the Oregon Legislature provides funding for the TallWood Design Institute, (TDI) a collaboration of the University of Oregon's (UO) College of Design and Oregon State University's (OSU) Colleges of Forestry and Engineering. TDI's mission is to promote economic development and environmental stewardship by advancing engineered timber products through research, testing, outreach and education. TDI has been critical in providing research and testing for DR Johnson Wood Innovations to produce their CLT panels and worked closely with Freres Engineered Wood in Lyons, Oregon, to develop a new mass timber product, mass plywood panels (MPP).

At the University of Oregon, we have engaged in design research projects demonstrating the feasibility of using mass timber products in a variety of building applications.

https://doi.org/10.52202/069179-0484

However, demonstrating that mass timber can provide affordable and energy efficient housing at single-family scale has been an elusive goal. With the development of MPP, we saw an opportunity to use thin, very strong panels that could be fabricated with digital workflows to make affordable single-family houses, adding social equity to mass timber as an additional benefit for Oregon.

2 BACKGROUND

As in much of the U.S., Oregon has a critical shortage of housing that is affordable. Lack of housing inventory and spiraling home prices have reached a crisis point in both rural and urban communities; over the next 20 years, Oregon will need about 584,000 new homes [5]. It has been challenging to find paths for mass timber to enter this market where the dominant construction method for up to five stories of a structure is light-wood-frame; since CLT uses comparably more wood fibre it can be more costly. However, MPP is 20% stronger than CLT and allows the use of thin panels (51-76 mm) derived from small diameter logs (as small as 127 mm) [6], providing a new possible path for a sustainable mass timber product to be used in residential construction [7].

To address the housing shortage, the Oregon Legislature passed House Bill 2001 in June 2019; it requires cities with a population over 10,000 to eliminate single-family zoning and allow two or more units on sites that were previously zoned for only single-family houses. In the metropolitan area around Portland, the largest population centre in the state, the law has allowed cities and counties to permit quadplexes and groups of small units ("cottage clusters") in areas previously zoned for single-family housing. This law was meant to promote the creation of more housing units and to reduce their cost by increasing land use intensity on sites formerly zoned for only a single house.

The City of Milwaukie, just outside Portland, took a proactive approach to respond to these new requirements and commissioned a planning study of the impacts of this required land use change with recommendations for the new standards [8]. These included updating their existing "cottage cluster" code to stimulate development of these groups of small freestanding houses arranged around a communal open space, and also allowing for groups of attached houses, known as "middle housing," all on single-family lots with bicycle storage, open space and tree canopy standards, and associated reduced parking requirements.

3 UNIVERSITY OF OREGON DESIGN RESEARCH STUDIO

At the University of Oregon, Professor Judith Sheine taught a design studio in winter 2020 focused on creating modular mass timber housing for a single-family double lot in Milwaukie that was part of the cottage cluster feasibility study. The studio followed the land use and massing guidelines recommended in that study and focused on using volumetric modules of MPP, producing some compelling designs that were presented to the Milwaukie planning staff, who found the visualizations of these zoning proposals useful for their development of their new land use regulations. These regulations evolved over the next two years, and were finally adopted by the City of Milwaukie in June, 2022, allowing for cottage clusters and middle housing on a single lot.

Figure 1: *MPP Modular Housing, Milwaukie, Oregon; University of Oregon Student project by Flynn Casey*

4 PROJECT

Following the studio project, UO faculty Sheine and Mark Fretz and structural consultant Mikhail Gershfeld, started a collaboration to design a small, energy efficient house constructed with MPP panels that would result in publicly available documents for application in cottage clusters, or stand-alone units, affordable to households with 80-100% of the area median income, which includes middle class households for whom housing in Oregon has become unaffordable. Swinerton Builders, a construction firm with significant expertise in mass timber, joined the team and provided critical practical advice on cost and construction efficiency. At their urging, the design team decided to embrace panelised prefabrication of the modular units, to avoid the transportation challenges of the volumetric modular model and to produce a design that could be built by small construction firms on a variety of sites with panels that could be prefabricated in a small warehouse facility or in a large factory.

The design team partnered with an affordable housing developer, HomeWork Development, that was interested in using these units for a pilot project in Milwaukie, on the lot that was the site for the 2020 design studio and some nearby lots. A large healthcare provider, Providence Health, which was eager to provide affordable, healthy housing for their workforce in Milwaukie, decided to invest in the project and contribute two small conjoining lots; however, due to the economic conditions following the Covid-19 pandemic, Providence was unable to follow through on this commitment and the pilot project was scaled down to two lots. The design team explored a variety of site configurations over the two-year period that the new Milwaukie zoning ordinance was being

https://doi.org/10.52202/069179-0484

developed and, once the ordinance was adopted, found that the most efficient site utilization resulted in cottage clusters of free-standing units, with 11 units on one site (Figures 2, 3) and 15 units on the second one, for a total of 26 units. While originally the designers had planned for both two-and three-bedroom prototypes, the developer advocated for one repeatable two-bedroom unit for maximum site utilization and potential cost efficiencies.

Figure 2: *MPP Panelized Housing, Milwaukie, Oregon; rendering by Simone O'Halloran*

4.1 THE OREGON MASS TIMBER COALITION

Following devasting wildfires in September 2020 in Oregon, which burned 4,452 square kilometres and destroyed over 4,000 houses, many of them manufactured houses occupied by low-income households, several Oregon state agencies started holding (virtual) discussions about how to address reduction of wildfire danger and the creation of affordable and more resilient housing. Business Oregon (BO), the state's economic development agency, the Department of Land Conservation and Development (DLCD), the Oregon Department of Forestry (ODF) and the Port of Portland (Port) joined with TDI, which included UO and OSU, to strategize about creating mass timber housing at a large scale, housing that would be far more resilient than the manufactured houses built with light-wood-frame to minimal standards that had burned in the wildfires and that would provide economic and environmental co-benefits by expanding the mass timber market.

These discussions evolved into the Oregon Mass Timber Coalition (OMTC) that applied in October 2021 to the U.S. Economic Development Administration's (EDA) Build Back Better Regional Challenge (BBBRC) to address economic development, environmental sustainability and social equity with investments in research and development and infrastructure that would drive a new industry. The OMTC proposed a group of projects that spanned the mass timber housing supply chain, from forest restoration and mass timber manufacturing (ODF and OSU) to updated land use legislation (DLCD) to MPP panelised prefabricated housing development (UO) to infrastructure for a mass timber housing factory at an industrial site in Portland (Port), along with new research facilities for testing mass timber assemblies for acoustic and fire resistance ratings at UO and OSU, respectively, and workforce development in forest restoration, mass timber manufacture, and housing construction (Port, ODF, OSU, DLCD). The OMTC was one of 60 regional coalitons (out of 529 applicants) to receive Phase 1 funding ($500,000) and one of 21 coalitions to receive finalist funding: $41.4 million; Business Oregon supplied an additional almost $6 million in required matching funds for UO and OSU. Out of this funding, $2 million was awarded to UO for developing and building prototypes of the MPP panelised housing, to determine the most efficient construction methods and the labour and material costs. This work will be undertaken over the next several years, 2023-2025.

In order to continue to develop the design of the MPP housing unit for prototype construction, funding was supplied by TDI and by the developer, HomeWork, with funding from two U.S. Forest Service Wood Innovation Grants for design development and an Energy Trust of Oregon Fellowship for energy efficiency analysis, and funding from the EDA BBBRC Phase 1 award.

4.2 UNIT DESIGN

Mass timber panels are a prefabricated building material as either small lumber or veneer elements are glued together and pressed into large panels, beams and columns in a factory, as opposed to framing a wall on site as is done with light-wood-frame construction. These panels can be manufactured to order and can be digitally pre-cut and routed to achieve panels with door and window cut outs to be quickly assembled on site. Additionally, vapor barriers, insulation and cladding can be pre-applied off-site, to simplify construction in the field. While even more efficiencies can be achieved with assembling a volumetric module in a factory [9], it is more efficient to ship flat panels which may not require special permits (and costs) for oversized truck loads. In the case of our pilot project, while the panels can be prefabricated in a factory, the mass timber housing factory is still at least several years from existence in Oregon, and the panels can also be fabricated in a smaller warehouse setting with existing facilities.

In order to allow the MPP construction to compete in cost with light-wood-frame, it was necessary to work with the panel sizes that Freres Engineered Wood manufactures and to minimize waste. The length of the basic unit footprint was established as half of the maximum panel length Freres produces, or 7.3 m (total maximum panel length of 14.6 m), and the width was based on a combination of the panel widths in the Freres catalogue, or about 4.9 m. As noted above, the units are identical two-bedroom units; in order to fit a maximum number of units on each site, the units are two-stories (about 6.5 m at the top of the gable roof).

For this project, only stand alone and duplex units were considered, due to higher fire ratings required by triplex and quadplex units, which would have added additional wood fibre or the inclusion of gypsum board to achieve

the required fire resistance. The design team wanted to avoid the use of gypsum board, with its high carbon footprint. And, in order to maximize the number of units allowed within the new Milwaukie zoning code, the units are stand alone in cottage clusters, which did not require any on-site parking (Figures 2, 3).

The units have living spaces on the ground floor and two bedrooms on the upper floor. The upper floor bathroom is stacked over the half bath and kitchen, with one plumbing wall applied as a chase over the MPP panel, in order to separate it from the exterior solid wall panel. Apart from the plumbing walls, all interior surfaces are MPP, eliminating the need for finishes (Figure 4).

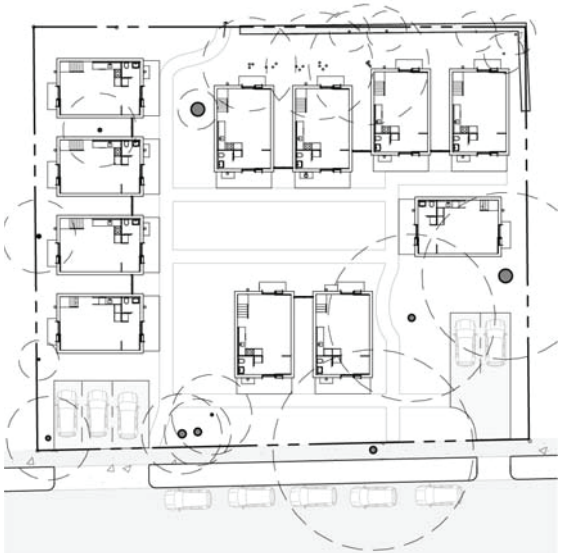

Figure 3: *MPP Panelised Housing, Cottage Cluster, Site 1, Milwaukie, Oregon*

Within the cottage clusters, units are set 1.8 meters apart (a code requirement), leaving the front and back elevations as the best locations for windows. These were aligned on the upper and lower floors to allow sufficient solid panels to support the roof. To allow more light into the units, skylights were added, and a space was opened to below adjacent to the stairs, allowing light to penetrate to the lower floor. A translucent polycarbonate material is used in strategic locations to allow more light to penetrate the unit. (Figures 4, 5, 6).

4.3 STRUCTURAL DESIGN

The use of MPP panels, 51 and 76 mm, would reduce the use of wood fibre but does not currently meet the code requirements of SDPWS 2021 [10]. Comprehensive testing of MPP to assess the global and local stability performance of thinner shear walls resisting both gravity and lateral loads is not currently available.

Based on Frerres MPP design guidelines, it was determined that a minimum of 76 mm panels would be required for the roof, floor and exterior wall construction assemblies. The use of 51 mm panels placed horizontally for the exterior walls that are not supporting roof or floor loads, and thus non-bearing, was explored. This design would require the addition of posts, would complicate the construction process and could be significantly below approved lateral system requirements. Thus, 76 mm panels were considered a more effective solution for all exterior walls. All non-bearing interior walls remained at 51 mm (Figures 7, 8).

Also, hybrid construction (MPP + light-wood-frame) vs. an entirely panelized system was considered. While hybrid construction would reduce wood fibre use, it would impact prefabrication potential and efficient constructability and thus overall cost.

The panelised system selected requires beams at two locations; a ridge beam, 76 mm MPP, at the intersection

of the roof panels and a wide MPP floor beam, to break the floor span sufficiently to allow the use of a 76 mm floor panel. The wide beam (flat use) was chosen to minimize its intrusion into the ground floor space, keeping it as open as possible (Figures 7, 8). MPP ledgers are used to support the floor and roof MPP panels and also help to create spaces for electrical routing, lighting and window shading.

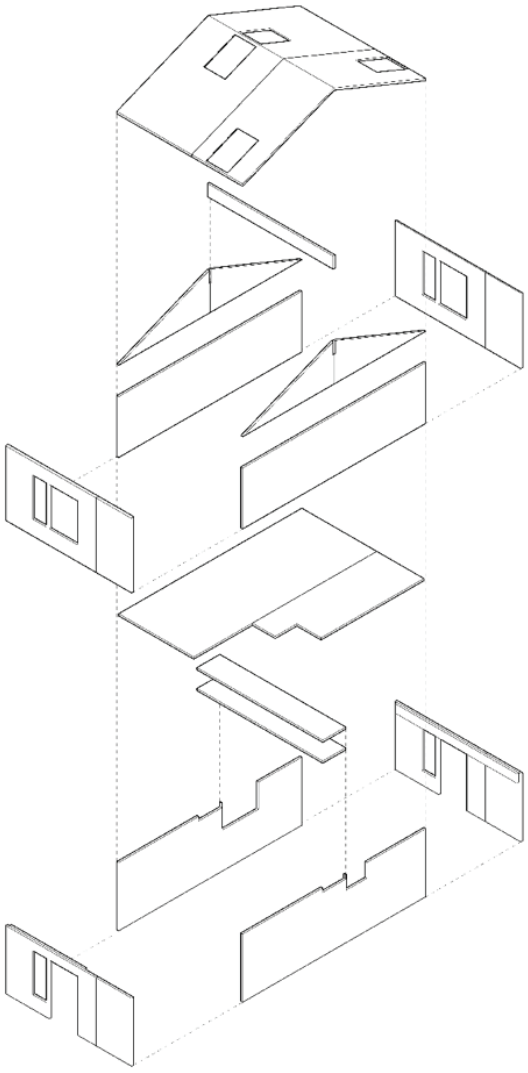

Figure 7: *MPP Panelised Housing, Assembly*

4.4 MATERIAL EFFICIENCY

An additional consideration was minimizing waste in the usage of the panels. Trials with panel layouts eventually allowed a realization of around 95% utilization for 51 mm material (Figure 9) and around 90% utilization for 76 mm material (Figure 10). The overall wood fibre volume for the house, which includes structure, partitions, doors and casework, is approximately 19.9 m^3. To eliminate the

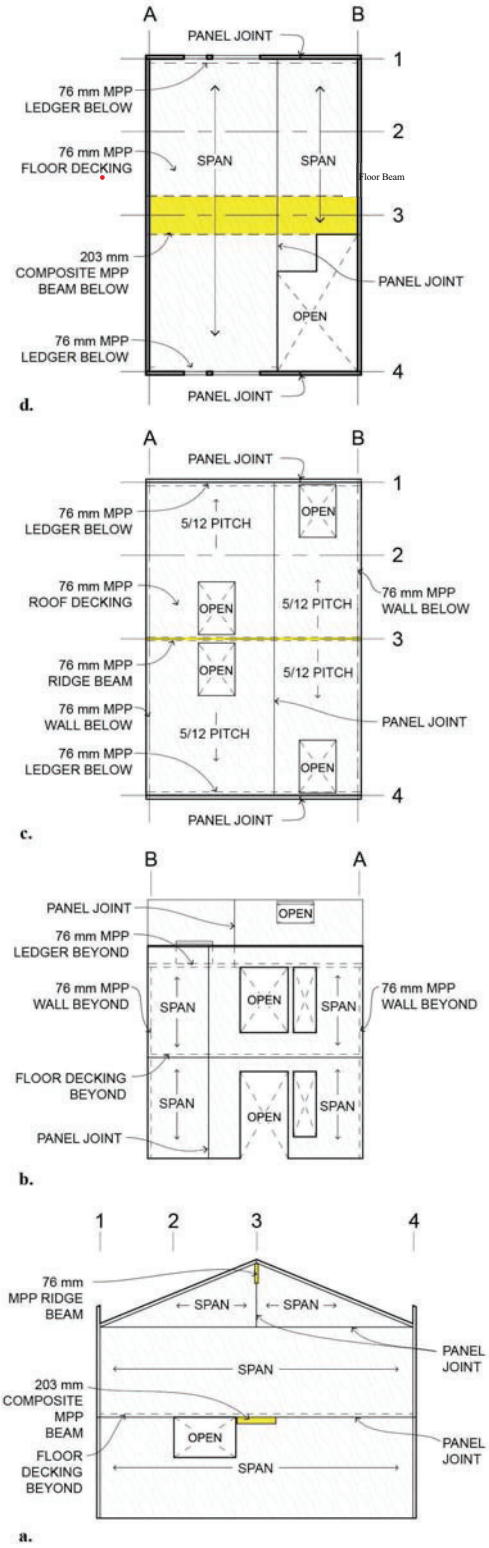

Figure 8: *MPP Panelised Housing, Framing. a. Side Wall Framing Elevation; b. Front Wall Framing Elevation; c. Upper Floor Framing Plan; d. Roof Framing Plan*

https://doi.org/10.52202/069179-0484

expense of transporting oversized loads, panels that are no more than about 2.4 meters wide were used.

One issue to be resolved in the first, iterative prototype is whether window and door openings for the front and back walls of the unit will be cut out of the panels, or assembled through a series of straight cuts that are infilled with rectangular panels above and beneath those openings. The latter method would result in an approximate 5% increase in material use efficiency due to not having the leftover fibre from the cut-outs, but would also increase the number of parts to handle from 25 to 41. Therefore, a higher fibre utilization could be offset by higher labour. Also the cost of routing the openings using a CNC versus cutting them with a handheld electric panel saw using a prefabricated jig will be compared.

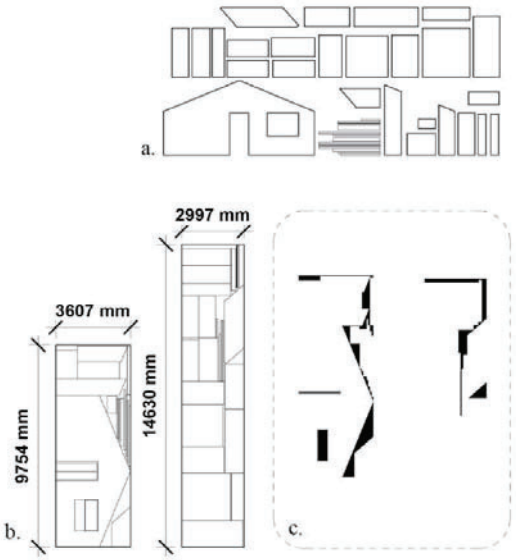

Figure 9: *MPP Panelised Housing, 51 mm Material Efficiency. a. Panels for Project; b. Panels Arrainged on Standard-Size Billets for Material Efficiency; c. Unused MPP Material.*

4.5 ENERGY EFFICIENCY

The goal of the study funded by Energy Trust of Oregon was to meet net zero energy goals while reducing the cost of these standards in construction in the residential sector, a primary barrier to deploying net zero ready construction at scale without substantial subsidy. The use of MPP to create a higher performing thermal envelope was explored by the design team. With MPP, the envelope is more monolithic than light-wood-frame construction, with fewer joints for air infiltration, and outboard insulation that wraps the entire structure with fewer thermal bridges. Furthermore, the MPP itself has insulative properties. The panelized wall assemblies facilitate a novel window integration (Figure 11) that seeks to increase the energy performance and esthetics of low cost off-the-shelf windows, employing a twin-wall polycarbonate shade and

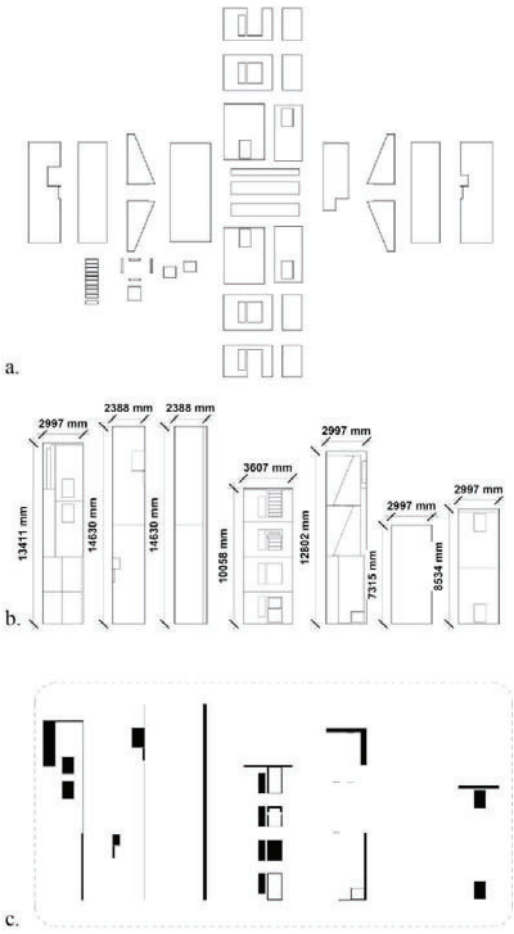

Figure 10: *MPP Panelised Housing, 76 mm Material Efficiency. a. Panels for Project; b. Panels Arrainged on Standard-Size Billets for Material Efficiency; c. Unused MPP Material.*

deep inset for solar shading while maintaining simplicity to reduce construction costs. Moreover, as the new MPP units can be arranged in dense courtyard clusters they create opportunities where the units could share thermal energy through district heating/cooling strategies and charging of a high-mass ground floor slab and shared peer-to-peer solar photovoltaic energy, thus simultaneously preserving existing tree canopy while balancing loads across the site and larger energy grid. The buildings themselves will serve as thermal storage, with the concrete slab and the high-performing thermal envelope facilitating proactive strategies for optimizing when and how energy is consumed on site.

This study included:

1. An energy model of a prototypical MPP panelized single-family house with concrete slab-on-grade, and an all-electric monobloc heat pump system configured either individually for each unit or as a district strategy.

https://doi.org/10.52202/069179-0484

2. A physical mockup of a higher-performance low cost window that includes infiltration testing (Figure 12) and thermal imaging (Figure 13).

4.5.1 Energy Model

The energy analysis was based on a combination of Honeybee 1.4.0 (via Grasshopper and Rhinoceros 7) and OpenStudio 3.3.0, both of which rely on EnergyPlus 9.6.0 for the annual energy calculations. The MPP model geometry was based on the most recent design documents, while the model performance is reflective of the U.S. Department of Energy (DOE) Zero Energy Ready Homes (ZERH) standard. The model is currently set with a packaged air-to-air heat pump system as baseline. The team is exploring system options, including an air-to-water district heat pump and hot water strategy to serve multiple units. Targeting the ZERH standard for the basis of design, the simulated preliminary results show an EUI of 52.7 kWh/ m^2 with the majority of energy consumption attributed to heating and interior equipment. Additional selection and testing of low cost windows will be performed in future prototyping, in order to meet the prescriptive requirements of the ZERH standard

The design of each housing unit is configured for hydronic heating, cooling and coupled domestic hot water. Units can be coupled with a district heating loop that supplies domestic hot water all year using a dedicated heat exchanger and additional space heat to the floor slab during heating and shoulder seasons. During the cooling season, natural ventilation will provide the primary cooling with supplemental cooling provided by centralized heat pumps that are staged to deliver chilled water via a cooling loop and floor slab hydronics valved to switch from heating to cooling. For both space heating and cooling seasons, the slab and centralized thermal storage tanks can be either heated or chilled at night to take advantage of off-peak electrical rates from the grid. This design is intended to not only reduce unit energy use but provide overall operational affordability, load sharing and resilience since the centralized heat pumps can be operated by site microgrid photovoltaics during a grid outage.

In the case of a single unit configuration, the district heating and cooling loops can be substituted by an air-to-water heat pump and a small heat exchanger for domestic hot water.

Primary cooling will be provided by cross-ventilation and stack ventilation using operable skylights. Supplemental cooling will be provided by a chilled slab using an air-to-water heat pump coupled to a hydronic cooling loop.

4.5.2 Physical Mockup

While the MPP can create a tight thermal envelope, the performance of the windows is critical to overall energy efficiency. The team explored an alternate to costly triple-pane windows by employing a double-pane window coupled with a sliding shutter of twinwall polycarbonate, which would provide additional thermal insulation while allowing some light into the interior (versus a solid panel). The upper track for the shutter additionally conceals LED strip uplighting. The space between the lower track and the floor allows for a service chase running the width of the window wall to be used for electrical and other services without any penetrations or chases occurring through the MPP exterior wall panel.

An assembly detail prototyped with the mock-up had the window frame sit within the thickness of the MPP panel, including 51mm of MPP (R-value of 2.50) covering the window frame when viewed from the interior. The intent was to have the MPP serve as structure, finish material and frame insulation; thus, requiring no additional trim work or finish treatment (Figures 11, 12, 13).

The relatively thick outboard insulation with rainscreen and cladding at the exterior allows the window plane to be recessed providing some inherent exterior shading. A sheet metal window surround including a vertical mullion between the two windows adds some depth and improves shading performance while acting as window trim. The sheet metal work proved a complex process between model, fabrication, and installation. A number of interface issues will be able to be refined and improved based on mocking up this façade integrated element. Alternate materials (e.g., fiberglass, plate steel, wood) may also be pursued for constructability, cost, thermal and durability considerations.

The tolerance for a CNC-cut window opening was much tighter than that of a conventional light-wood-framed rough opening, where a process of shimming and squaring a window during installation requires extra space in the site-built structure. The precision fabrication possible on the CNC allowed for the rough opening in the MPP to be less than 2 mm larger than the window itself on each side, whereas window manufacturers require rough openings for conventional construction to be anywhere from 13 mm to 25 mm larger on each side. The tighter tolerance meant that the window was square as soon as it was placed in the opening and air sealing was more precise.

One benefit to panelized wall construction using MPP is a significant reduction in the possible locations for air infiltration to occur. With fasteners not penetrating the surface, potential infiltration locations are limited to panel-to-panel joints and panel penetrations like window openings. Furthermore, electrical outlets located on exterior walls are all surface mounted on the interior, thereby reducing the need to pay particular attention to outlet air sealing.

For performance testing, an enclosure was constructed and air sealed to the interior side of the mock-up for use of a blower door fan and instrumentation to positively pressurize the interior of the wall assembly. Smoke was introduced to the pressurized interior side of the mock-up at 30 Pascals and ramped to 62 Pascals while the exterior

https://doi.org/10.52202/069179-0484

was visually inspected for smoke leakage. Window penetrations were sealed with a liquid applied membrane (Soprema Sopraseal Liquid Flashing, SKU: A508). Minimal smoke leakage was observed around the window; the team plans to explore further sealing steps in the larger prototypes.

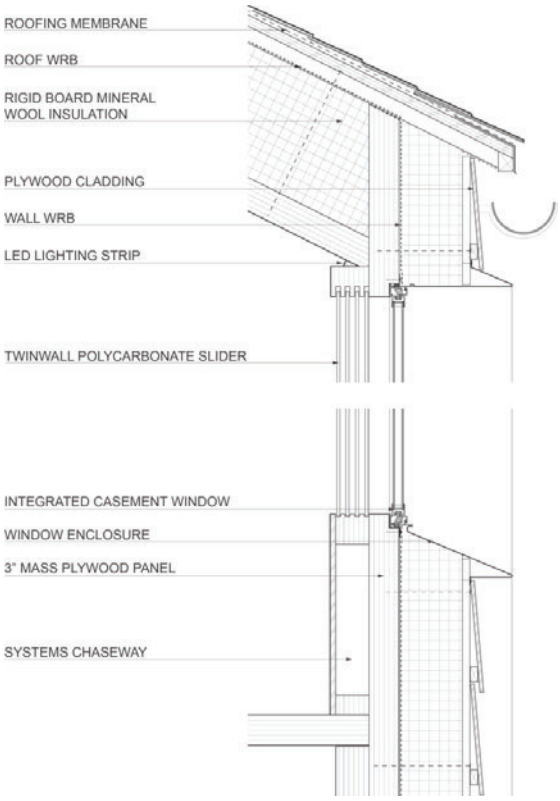

Figure 11: *Detail of window mockup showing wall and roof assemblies*

4.6 PROTOTYPES

The EDA BBRC award with BO match will allow the team to test and refine the design and construction methods of the MPP unit. The first prototype will be constructed in TDI's A. A. "Red" Emmerson Advanced Wood Prodcuts Lab, using the strong floor and wall to conduct structural tests of the MPP building envelope, which will be required by building departments in local jurisdictions in order for permits to be issued. This prototype will also entail fabrication of the MPP panels with insulation and cladding, iterative assembly and evaluation of details, including window assembly, panel connections, and electrical, mechanical, and plumbing systems integration. Following the documentation and disassembly of the first prototype, a contractor will be employed to fabricate and construct a second prototype in the Emmerson Lab's exterior yard. This will test construction means and methods, including evaluation of shipping efficiency and field assembly, and include documentation of costing of materials and labor. The team will test the performance of the design, including

Figure 12: *Window mockup*

Figure 13: *Window Mockup Thermal Performancem, False Color Infrared Image*

confirmation of energy modeling by measuring envelope infiltration, and acoustic testing, followed by documentation and disassembly. Documentation will include data collection and fabrication- and construction-

https://doi.org/10.52202/069179-0484

ready documents, including digital files. Prototyping is scheduled to begin in June 2023.

5 CONCLUSIONS

The success of this project depends on the efficient utilization of the MPP panels, including digital fabrication workflows, reduction in finish materials, the capacity to offset small cost increases above light-wood-frame with more efficient energy performance, and their affordability to the workforce market (those earning 80-100% of the area median income). The preliminary costing model indicates that this is achievable, but the prototyping of the project will be able to provide proof of concept for the open-source documents that will be available for construction on multiple sites in Oregon.

ACKNOWLEDGEMENT

The authors wish to acknowledge the contributions of Swinerton Builders and the support of the TallWood Design Institute for this work. Funding was also provided by HomeWork Development and Shortstack LLC via subaward from two U.S. Forest Service Wood Innovation Grants, "Milwaukie Courtyard Housing Project," Grant # 22DG11062765744, and "Shortstack Housing Mass Timber Platform to Develop Prototype Replicable Affordable Housing," Grant #21DG11062765738, and a fellowship from the Energy Trust of Oregon, Contract #3431. Additional funding was provided by a subaward from the Port from the EDA BBBRC Phase 1, "Build Back Better with Mass Timber," Grant #ED22HDQ3070069. The prototyping is funded by the EDA BBBRC "Mass Timber Prefabricated Panels for Affordable Housing Prototypes," Grant # 07-79-07906, and by Business Oregon's University Innovation Research Fund, Contract # C2022840.

UTILIZING LOW-VALUE WOOD SPECIES FROM FOREST RESTORATION PROJECTS IN LOCAL CLT MANUFACTURE AND DESIGN

Payton Narancic[1]

ABSTRACT: Years of wildfire suppression and ever-extending periods of drought are fanning the flames of catastrophic wildfires at an unnatural scale. The west coast of the United States has suffered the brunt of these negative impacts as wildfire seasons are becoming increasingly worse every year. The abundance of small-diameter trees and dry fuel accumulating in forests is reinforcing the need for better forest management practices as human activity in the last century has proven to be detrimental to the global climate. The goal of this research is to examine the relationship between collaborative forest restoration and local mass timber production to showcase the use of mass timber as a means to improve wildfire resilience and push the United States toward developing its mass timber industry at a local scale. The use of low-value species, harvested from forest restoration projects, in mass timber panels can create a symbiotic relationship between forestry, architecture, and the respective local economy. This project addresses the utilization of low-value species (Ponderosa pine) from forest restoration projects in the Sierra Nevada forests of California to manufacture mass timber locally that, in return, can provide the material for public lands facilities as demonstration projects in parks affected by wildfires.

KEYWORDS: CLT, Ponderosa pine, wildfire management, forest restoration, public lands facilities

1 INTRODUCTION

Forest management policies in the western United States are worsening the effects of climate change and, thus, causing forests to suffer. Years of wildfire suppression due to human intervention has caused forests to become increasingly vulnerable to unnatural fire behaviour [1, 2] Although forest restoration projects, including thinning efforts, are effective at creating forest resiliency, these efforts are often expensive ventures and harvest low-value wood species that are used for low-yield profit products such as biofuel and paper pulp; this results in immense expenditure losses that government agencies are typically burdened with. Mass timber products offer an alternative for lower-grade species as they can be engineered to enhance the wood's structural capabilities. Unfortunately, the production of mass timber, such as CLT (cross laminated timber) panels, can require significant investment in expensive equipment in an industry that is still developing in the United States. For this reason, mass timber production has been largely unattainable for small-scale production. All of these intersecting issues lead to the primary research question: how can forest restoration and thinning, used to reinforce wildfire resilience in forests, create local benefits by using mass timber production generated from associated local forest restoration endeavours? Addressing this question can expand the narrative of the possibilities of mass timber production in the United States while also tackling the issue of wildfire vulnerability in forests.

1.1 WILDFIRE THREATS TO PUBLIC LANDS

Public lands, such as national and state parks, in the western U.S. are facing increased wildfire activity driven by severe drought and an abundance of small diameter trees and dry fuel. The KNP complex fire in Sequoia National Park decimated an estimated 3-5% of California's giant sequoias and, in the past two years, 20% of all sequoias have been lost due to fire activity [3]. In addition to ecosystem devastation, the built environment is also severely affected. In August of 2020, Big Basin Redwoods State Park, the oldest state park in California, suffered catastrophic losses as a result of the CZU complex fire; nearly all of the park's facilities were destroyed leaving only charred remains of the park's historic structures. Lassen Volcanic National Park fell victim to the 2021 Dixie Fire, the second largest wildfire in California history, which not only devastated significant acreage in the park, but also laid ruins to the nearby communities of Greenville, Warner Valley, Canyon Dam, and Indian Falls, amongst others; wildfire threats are not isolated on public forest lands, but also the communities that surround and exist within them. As climate change continues to worsen wildfire seasons, we can expect to witness more and more environmental destruction, both natural and built. For these reasons, this

[1] Payton Narancic, University of Oregon, School of Architecture and Environment, USA, pcn@uoregon.edu

https://doi.org/10.52202/069179-0485

project explores the designs of typical public forest lands facilities to address the replacement of these structures that are in the most vulnerable wildfire regions.

1.2 FOREST RESTORATION AND MASS TIMBER

Wildfire and forest management are complex issues that are becoming increasingly urgent to address due to catastrophic fire behaviour. With each fire season becoming increasingly worse on the U.S. west coast, creative solutions involving collaborative measures are beginning to unfold [4]. Forest restoration collaboration projects are currently underway such as the A to Z Forest Restoration Project in Colville, Washington. This project is a collaboration between Vaagen Timbers and the US Forest Service that focuses on allocating harvesting from restorative operations to Vaagen Timbers in order to offset the costs that the US Forest Service would typically be responsible for funding [5]. In return, Vaagen is able to utilize the harvested timber to create mass timber products and sell them for a profit. However, not many projects like this exist. Additionally, a small number of companies are beginning to venture into small-scale mass timber production such as Stoltze Timber in Montana and Timber Age Systems in Colorado. Timber Age Systems (TAS) is producing CLT made of Ponderosa pine, a species that has generally been deemed as low value for construction uses. The company is the first CLT producer in the U.S. Southwest and is capitalizing on the need for healthier forests and more sustainable construction materials [6]. The Sierra Institute for Community and Environment in Taylorsville, California is also developing small-scale, local mass timber production in tandem with their forest restoration projects which often result in harvesting lower-value species of timber [7]. The intersection between forest management and mass timber production has the potential to create a synergetic relationship that addresses multiple issues at once: the need for forest thinning and a sustainable mass timber market in the United States.

2 APPROACH

This project is a demonstration of the use of small-scale, Ponderosa pine CLT that can be harvested from forest restoration projects in the Sierra Nevada mountains of California and used to replace public forest lands structures that were destroyed in wildfires. The intent of this design demonstration is to show a variety of typical park buildings that cover a range of spans, sizes, and levels of complexity as well as to exhibit the unique relationship between forestry and architecture. The designs of these buildings reflect the redefining of park architecture in the U.S. to demonstrate a more contemporary approach, versus a more conventional rustic one, that celebrates the use of modern technologies and natural materials. The use of timber from forest restoration-harvests also provides the opportunity for local mass timber production. The basis of this design project makes use of TAS's production processes, structural data, and 152cm x 305cm Ponderosa pine CLT panels.

2.1 TIMBER AGE SYSTEMS PONDEROSA PINE CLT

TAS utilizes Ponderosa pine harvested from forest restoration projects to produce vacuum-pressed CLT panels that are 152cm x 305cm and 76mm or 127 mm thick for 3-ply and 5-ply panels respectively; the company has invested approximately 1.2 million USD total into their operations and functions under a vertically integrated system from log hauling and milling to kiln drying and pressing. The panels they are currently producing have been accepted for local building department permitted use and have undergone evaluation from a local university engineering department, with validation by an external engineering peer review, to demonstrate that they meet the requirements of IBC 2018; TAS is currently seeking ANSI PRG 320 certification for their CLT panels. This project demonstrates the design opportunities for the use of forest-restoration-harvested Ponderosa pine CLT panels manufactured using this vacuum press process by showing their design application in a series of typical public lands' facilities, which are more typically constructed of light wood frame and/or heavy (sawn) timber. The central question regarding the application of these CLT panels is the following: What are the implications of the Ponderosa pine CLT panel sizes and structural characteristics (e.g., what is the best way to address connections and openings for windows and doors, and long span conditions)?

2.2 PUBLIC LANDS BUILDINGS

Public lands are home to various types of buildings that serve a multitude of purposes. After an in-depth evaluation of the types of buildings found in public lands, the following building types were chosen as a representative sample of typical scales, spans, and details that could be applied to not only the building types they represent, but also other park facilities of a similar nature: a visitor center, information center, restrooms, cabin, and entrance fee station.

3 DESIGN DEMONSTRATION

In the proposed designs, both dimensional lumber and heavy timber sourced from Ponderosa pine are used in tandem with the Ponderosa pine CLT to achieve larger roof spans; the intention is to maximize the use of forest restoration-harvested Ponderosa pine and maintain its connection to the local communities that will manufacture these products. However, the dimensional lumber and heavy timber are not limited to strictly Ponderosa pine; other species harvested from forest restoration projects that are structurally appropriate can also be used. Glulams were intentionally not chosen for additional structural members to avoid sourcing that may not be local and employs a different technology. Strategies for windows, doors, and other details were also developed. With structural engineering guidance from Professor of Civil Engineering Mikhail Gershfeld of California State Polytechnic University, Pomona, it was determined that no more than two panels should be stacked vertically

https://doi.org/10.52202/069179-0485

without additional structural support to avoid buckling at the horizontal splines.

3.1 DETAILS FOR PANEL APPLICATION AND WILDFIRE RESILIENCE

Systems for typical details were developed as standards for the application of Ponderosa pine CLT panels and wildfire resilience strategies. The wall assembly in Figure 1 maximizes the use of bio-based materials such as CLT, wood fibre insulation, wood furring, and wood siding. Ideally, all of the wood-based products can be sourced from forest restoration-harvested timber including species that are not Ponderosa pine. This idea reinforces local sourcing, manufacturing, and maximum wood utilization. Fire resilience is also a critical aspect of these structures. Although the intent is to maximize the use of low-value wood from forest restoration projects, metal siding can also be used in place of wood siding to increase fire resilience. Other fire resilience strategies include minimal roof overhangs, metal roofing, mass panel wall construction, and fire-resistant insulation. Eaveless roofs prevent flames and embers from catching underneath overhangs, which can cause the entire building to combust. The CLT wall and roof panels also create a continuous envelope that are intended to improve thermal performance and mitigate fire spread. Similar to CLT panels, wood fibre insulation carbonizes when exposed to fire which helps to insulate the rest of the assembly from fire spread [8]. Wood fibre insulation treated with borate provides fire protection [8]; however, mineral wool insulation can also be used for increased fire resistance.

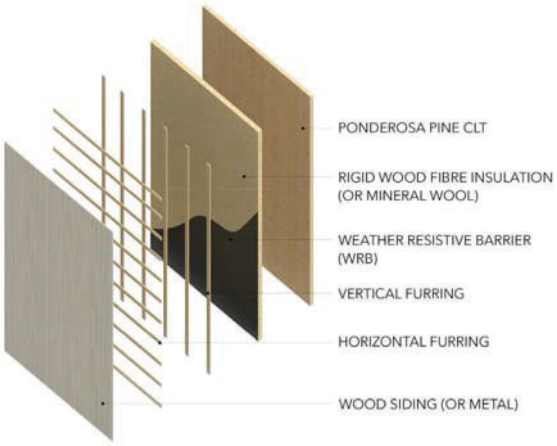

Figure 1: *Typical wall assembly*

Strategies for window and door openings were also developed. Although openings can be cut directly out of a panel, best practice is to avoid cut out openings due to the panels' small size and to minimize waste. Where appropriate, windows should fit between panels as illustrated in Figure 2. Additionally, windows that are carried to the underside of a CLT roof can use the roof panel itself as a header. This approach also prevents waste from panel off-cuts. Small skylight openings should not be cut from the centre of the panel, but rather at the ends of a panel to maintain structural properties. It is important to note, however, that these strategies may not be appropriate for every building. Openings are dependent on a building's program and may require other configurations.

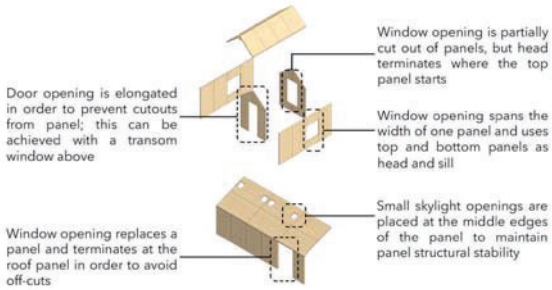

Figure 2: *Strategies for panel openings*

Because these structures could be located in a variety of landscapes, two different foundation systems were developed to accommodate possible site constraints. A concrete foundation with a concrete floor, as shown in Figure 3, would be an appropriate application in larger scale buildings, restrooms, and any building requiring a permanent foundation with few site challenges.

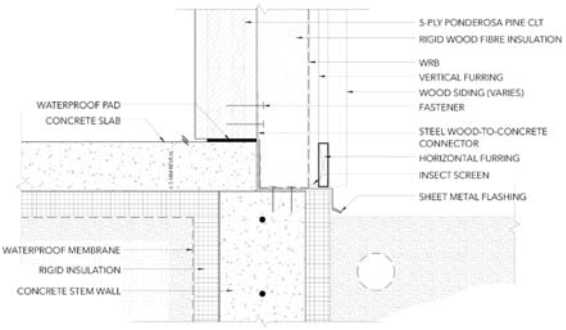

Figure 3: *Concrete foundation with concrete floor detail*

A pier foundation, as seen in Figure 4, would be appropriate for buildings in difficult terrain; the pier system enables the building to be lifted above grade and placed where necessary on its respective topography, which may be appropriate for cabins.

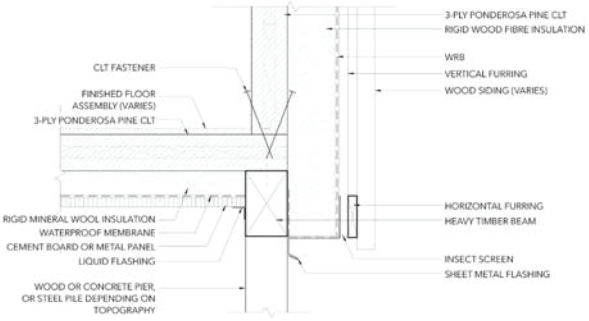

Figure 4: *Pier foundation with CLT floor detail*

https://doi.org/10.52202/069179-0485

3.2 VISITOR CENTER

Figure 5: *Visitor centre rendering*

The visitor centre is intended to accommodate different site variations by dividing the program into three separate buildings: an exhibit area, gift shop, and cafe. Restroom facilities for guests are a separate building type that can be placed near the visitor centre. Each building is connected to the others through a breezeway that can either be open air or enclosed depending on the climate.

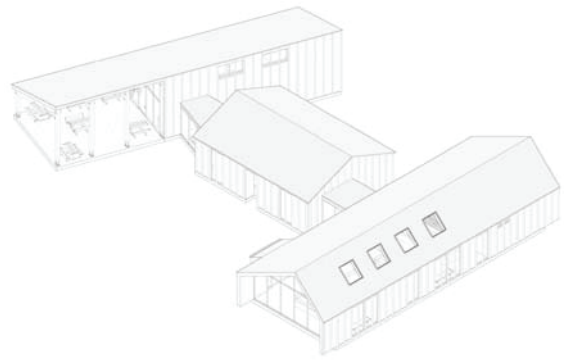

Figure 6: *Axonometric of visitor centre*

Figure 7: *Floor plan of visitor centre*

Due to roof span structural demands, the buildings have Ponderosa pine beams. The gable roofs of the exhibit area and gift shop require beams and steel collar ties, while the shed roof of the cafe requires beams with knee braces. These building types can also host different programmatic functions depending on the needs of the park; for example, the cafe can also be used as park ranger headquarters. In brief, the intent of this programmatic composition is to allow for the most amount of flexibility with straightforward construction solutions. Five-ply CLT is used for the walls and roofs of these structures and light-wood-frame is used for walls that require plumbing for toilets and sinks.

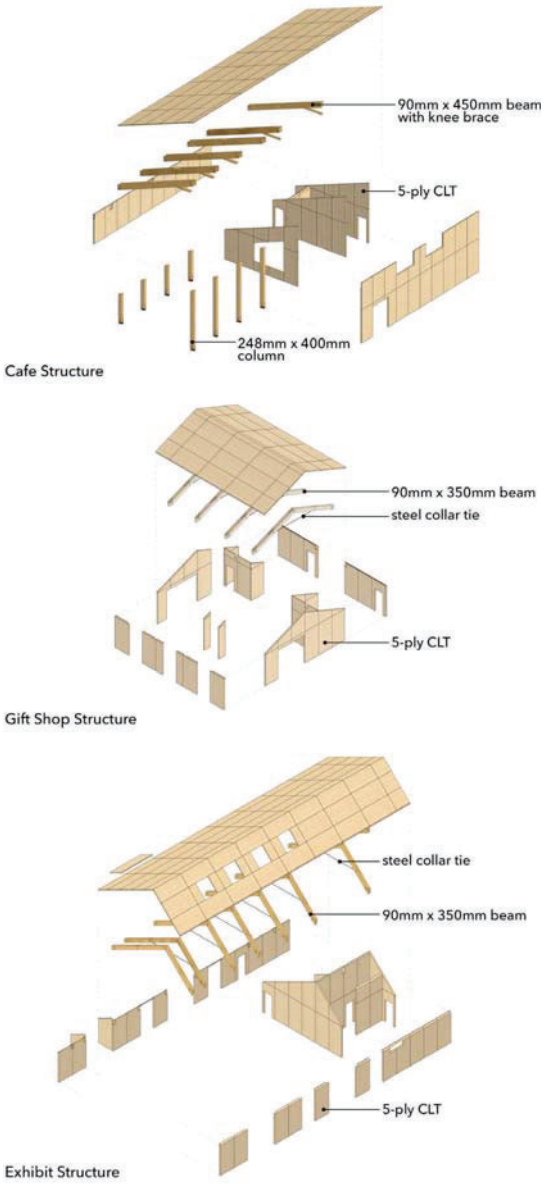

Figure 8: *Visitor centre structure*

https://doi.org/10.52202/069179-0485

3.3 INFORMATION CENTER

Figure 9: *Information centre rendering*

The information centre is intended to be used near park entrances and/or operate as a ranger station. The program features an information desk for guests, restrooms, and an office for park staff.

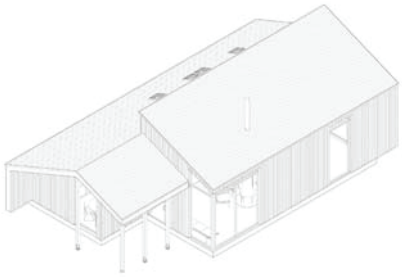

Figure 10: *Axonometric of information centre*

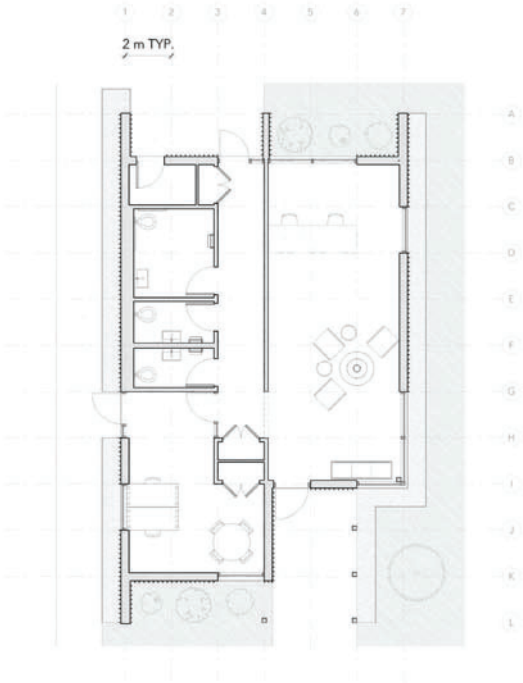

Figure 11: *Floor plan of information centre*

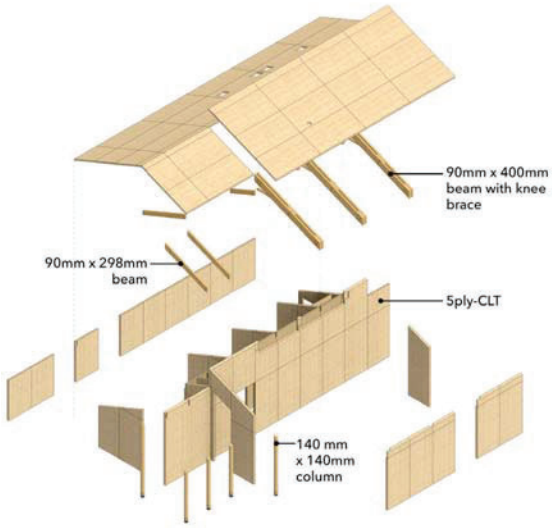

Figure 12: *Information centre structure*

Due to the building's small footprint, simple beam systems are used to span the roof with knee braces where necessary. Five-ply CLT is used for the walls and roof of this building and light-wood-frame is employed for walls that require plumbing for toilets and sinks.

3.4 RESTROOM FACILITIES

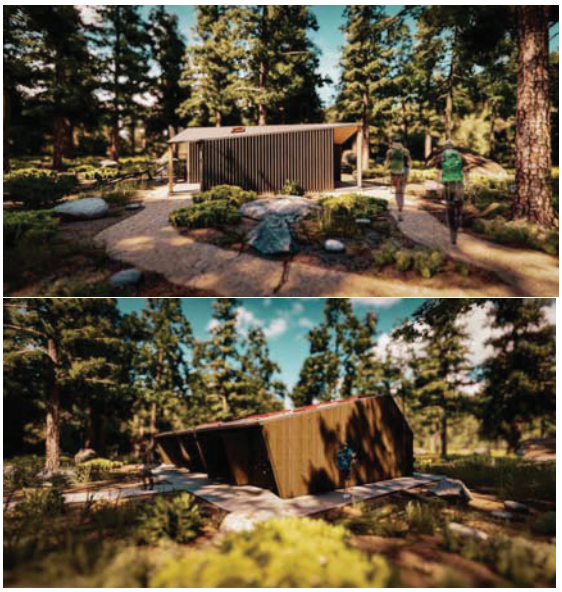

Figure 13: *Restroom renderings*

This building type consists of two different designs: small restroom structures intended to be scattered throughout a park and larger restroom facilities for busier parts of a park and its campgrounds. The small restroom facility is constructed with 3-ply CLT and utilizes a Ponderosa pine column where the roof cantilevers. The program consists of two private accessible stalls and a small utility closet. The larger restrooms are comprised of a flexible program

https://doi.org/10.52202/069179-0485

that allow it to be adapted to different needs of a park. For example, showers can be added to the building to accommodate a campground and stalls can be added to the floor plan as needed. This facility is also constructed of 3-ply CLT and does not require additional structural members to support its roof. Light-wood-frame is used for walls that require plumbing for toilets and sinks. Due to the nature of this building type, the roof and wall assemblies do not need to be insulated and the building does not need to be conditioned which significantly simplifies construction.

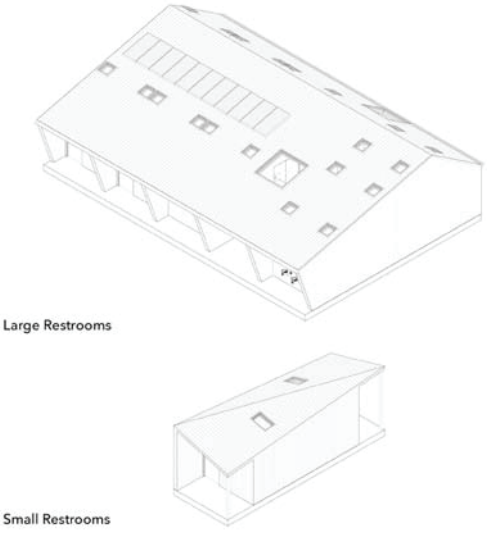

Figure 14: *Axonometric of restrooms*

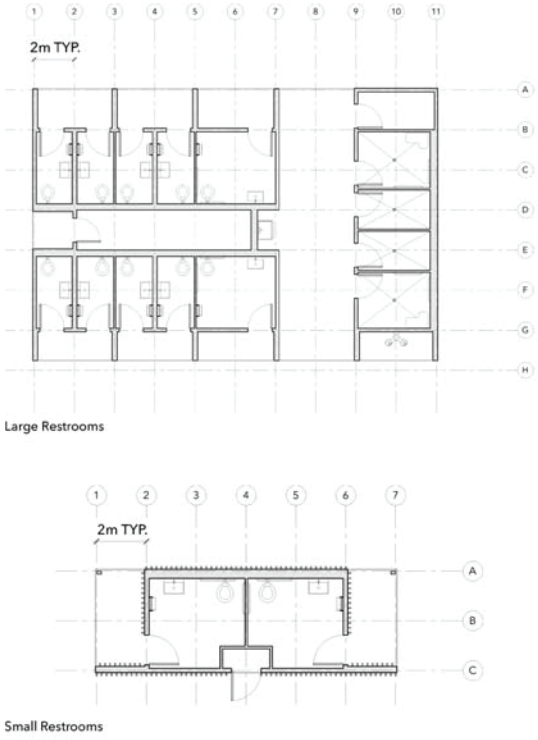

Figure 15: *Floor plan of restrooms*

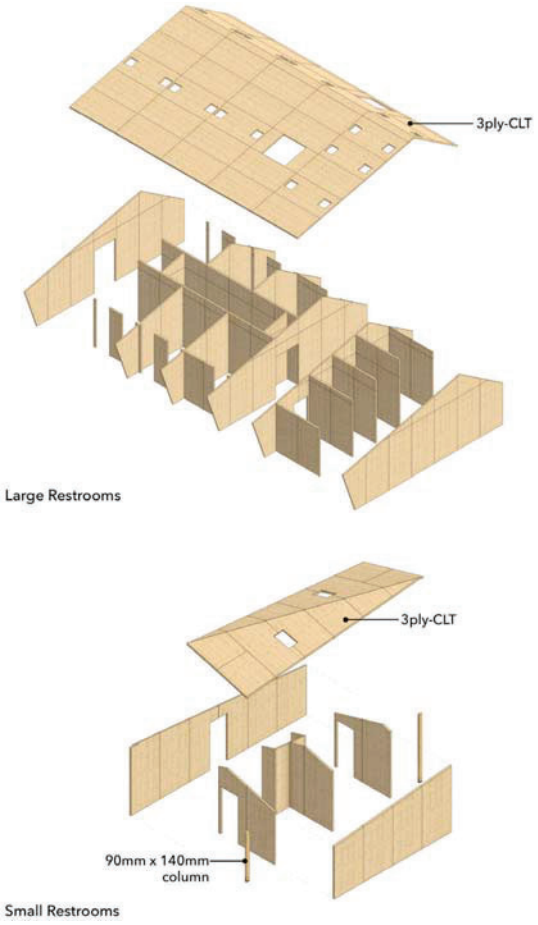

Figure 16: *Restrooms structure*

3.5 CABIN

Figure 17: *Cabin rendering*

The program for this building type is a one-bedroom space with designated sleeping, lounging, and eating areas. This structure requires 3-ply CLT, a ridge beam, steel collar ties, and a column to support the roof cantilever. The cabin is intended to be placed in nearly any condition and can be supported on a simple pier or pile system.

https://doi.org/10.52202/069179-0485

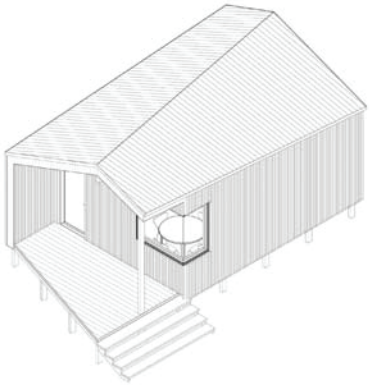

Figure 18: *Axonometric of cabin*

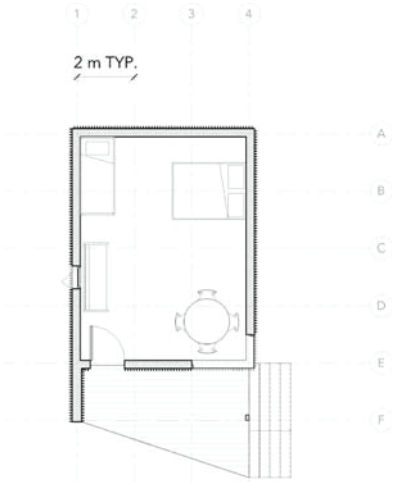

Figure 19: *Floor plan of cabin*

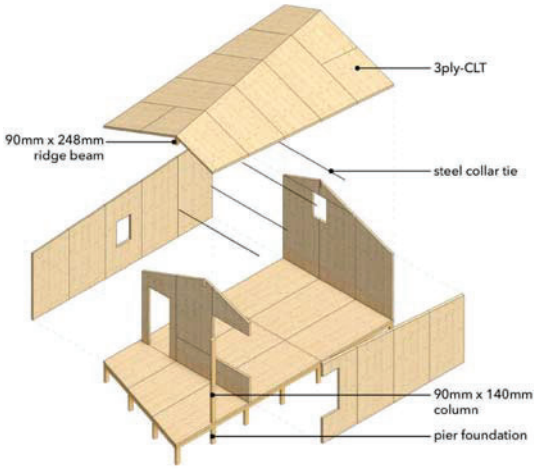

Figure 20: *Cabin structure*

3.6 ENTRANCE FEE STATION

Figure 21: *Entrance fee station rendering*

This small-scale building has a simple structure. Due to its small loads, the roof can be spanned using only 3-ply CLT and a ridge beam at the roof. This program features adequate space for 2-3 park employees and drive-up windows for incoming guests.

Figure 22: *Axonometric of entrance fee station*

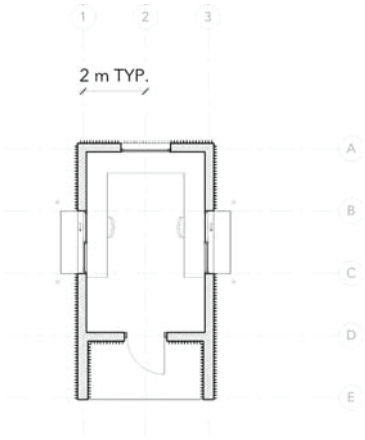

Figure 23: *Floor plan of entrance fee station*

https://doi.org/10.52202/069179-0485

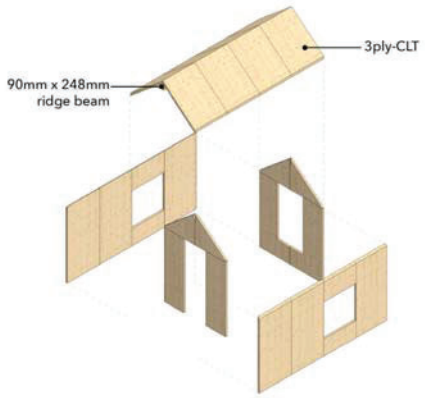

Figure 24: *Entrance fee station structure*

4 CONCLUSIONS

Although the structural properties of Ponderosa pine are less robust than some other wood species such as Douglas fir, Ponderosa pine CLT panels can be an effective structural system with proper detailing and an understanding of small mass timber panels. Unlike most CLT panels on the market, 152cm x 305cm Ponderosa pine panels require integrating other structural systems to carry longer roof spans. These secondary structural systems can also be sourced from Ponderosa pine, but may not necessarily be Ponderosa pine or from forest restoration projects; heavy timber and dimensional lumber can either be sourced from a productive site, other low-value species, or can be recovered from past burn sites; it is important to note that Ponderosa pine can reach a diameter of 66cm in 30 years and diameters of 76cm to 127cm are not uncommon for the species [9]. These CLT panels also have significant height restrictions; because they are only 3 meters tall, panels need to be stacked vertically to achiever taller wall heights. However, it is advisable not to stack more than two panels to maintain structural wall stability. Furthermore, compared to conventional light-wood-frame and heavy timber buildings typically found in public lands, the Ponderosa pine CLT allowed for greater design flexibility in terms of architectural expression. Because the structures do not require conventional wood framing, the panels can be prefabricated to create expressive forms that can be rapidly assembled. CLT also provides opportunities for faster construction time, less construction waste, off-site pre-assembly, and less on-site labour when compared to other construction types. In conclusion, the exercise of designing public lands facilities from small-scale, low-value species mass timber panels sourced from forest restoration proved to be a viable construction type for replacing buildings in wildfire vulnerable areas.

In addition, this project addresses only one timber species and one CLT manufacturing process. There is much more research that can be done on alternative low-value species mass timber products from varying regions across the U.S. and Canada as well as on a variety of manufacturing processes (dowel-laminated timber, interlocking timber, etc.) that can make up an array of different mass timber products for local applications in the future. White fir, for example, is a low-value species that only has preliminary structural data, but could potentially be used in a similar application to Ponderosa pine in CLT. There are several recently completed and planned low-value species testing projects undertaken at the TallWood Design Institute and Oregon State University on Oregon-harvested Ponderosa pine in collaboration with Vaagen Timbers, and, additionally, California white fir and Alaskan spruce using a more capital-intensive process with a large timber press; there is growing interest in the structural and commercial possibilities for these materials, along with the increasing local, less-capital intensive efforts as noted above [10–12]. Furthermore, continued development of construction details and the application of these panels to other building types, such as housing and multi-story structures, is a potential area of study. Much more work in this area should be coming in the near future and this project should become part of the growing efforts to create a sustainable mass timber industry in the U.S. supporting forest restoration efforts.

ACKNOWLEDGMENTS

This research is supported by the University of Oregon as part of the Master of Science degree, Mass Timber Design focus area. Thank you to my graduate committee members Mark Fretz, Mariapaola Riggio, and Judith Sheine, among others from the School of Architecture & Environment at the University of Oregon and the College of Forestry at Oregon State University, for your guidance and support. Thank you to Professor Mikhail Gershfeld from California State Polytechnic University, Pomona for offering structural engineering expertise and advice for this project. And lastly, thank you to Timber Age Systems for supporting my work and providing me with the necessary data to make this project possible.

AMAZONIAN MASS TIMBER IN THE NEW CIPEM'S HEADQUARTERS – MATO GROSSO, BRAZIL

Roberto Lecomte[1], Sheila Beatriz[2]

ABSTRACT: The Mato Grosso Timber Production and Export Industries Center (CIPEM) is the union of eight forest-based employers' unions, whose purpose is to organize and strengthen the sector. It encourages the productivity and conscious consumption of wood and its forest-based products regarding the current legislation and in a sustainable basis. Cipem is at vanguard of sustainable forest management in Brazil and there is a huge potential of exploiting medium and low density amazonian species that are ignored by the market. Its new headquarters was designed by using mass timber made of Amazonian wood. The partnership between Cipem and mass timber brazilian manufactors will allow all the required certification for those species' behavior aiming to produce CLT and glulam components. The design of the building had as premisses the fast assembling of the timber structures based on its constructive rationalization, the maximum exposure of the variability of the amazonian species managed by Cipem and the search for an architectural language and contemporary design. Huge poles with 10m heigh and coming from the Amazonian forest will be highlighted in the building, aiming to show the amazing transformation from this raw material into a contemporary constructive material.

KEYWORDS: Wood, Amazonian Wood, Mass Timber, Timber Structures, Contemporary Design

1 INTRODUCTION

CIPEM is the entity that represents the forestry sector in the state of Mato Grosso and its objective is to organize and strengthen this sector. The entity promotes the productivity and conscious consumption of wood and forest based products in a sustainable way, in accordance with current legislation and in harmony with the environment. Within this philosophy and with the aim of promoting the use of Amazonian wood in the construction sector, the design of its new headqurters was developed with mass timber solutions that highlight the material. This article presents the design of this building.

2 METHODOLOGY

The project of the Cipem's new headquarters was developed from the following premises:

- use of lesser-known species added to efficient timber structures to promote the quality of native essences;
- definition of constructive solutions based on mass timber components made of Amazonian woods;
- use of several Amazonian wood species managed by CIPEM in different uses in the building;
- highlight colour, texture, and workability of this raw material.

3 DESCRIPTION OF THE PROJECT

The design of the building was conceived with two main areas of interest, a 3 stories central area were administrative and technical staff will be installed, and an auditorium linked to a central hall that connects all areas of the building. Figure 1 shows its ground floor plan, and a section of the building can be viewed in Figure 2.

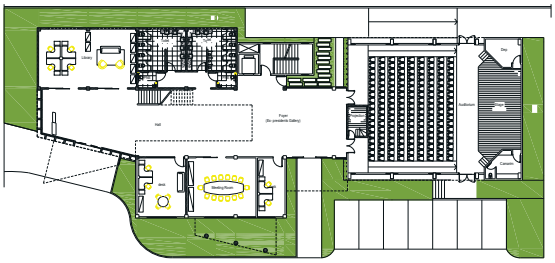

Figure 1: Ground floor plan

Figure 2: Section

[1] Roberto Lecomte, Casacerta Architecture Design & Building, Brasília, Brasil, roberto.lecomte@gmail.com

[2] Sheila Beatriz, Casacerta Architecture Design & Building, Brasília, Brasil, sheilatriz@hotmail.com

https://doi.org/10.52202/069179-0486

The fist and second pavement of the building are illustrated in Figures 3 and 4 highlighting several levels of the timber structures. Figure 5 shows a cross section of the building.

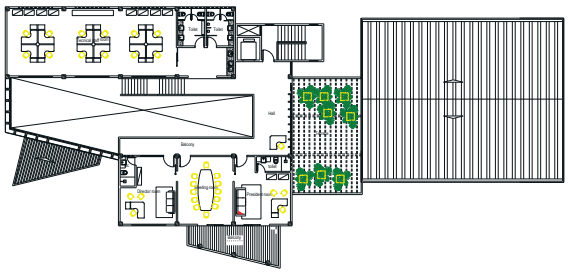

Figure 3: *First pavement*

Figure 4: *Second pavement*

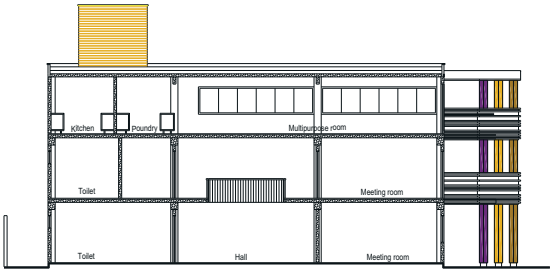

Figure 5: *Cross section of the building*

Wood species were selected according to CIPEM's priorities related to market strategies and aiming to promote lesser-known essences. Also, their physical and mechanical properties were considered taking in account their specific use in the proposed timber structures.

Low density species like Cedrinho (*Erisma uncinatum*), Amescla (*Trattinnickia burseraefolia*) and Marupá (*Simarouba amara*) were selected for glulam and CLT. Secondary structures, flooring and finishings will be made with Tauari (*Couratari sp.*), Roxinho (*Peltogyne sp.*), Cumaru (*Dipterix sp.*), Muiracatiara (*Astronium lecointei*) and Orelha de Macaco (*Enterolobium contortisiliquum*). Figure 5 illustrates those selected Amazonian woods.

Wood came from different exploitation regions and this diversity represents the eight forest-based employers' unions that are organized by CIPEM.

Figure 5: *Selected Amazonian woods*

4 BUILDING PROCESS

The use of amazonian wood in the buildings starts with applied research related to the physical and mechanical behavior of these species. For example, glulam can be manufactured using both softwood and hardwood and can use a variety of different types of timber.

https://doi.org/10.52202/069179-0486

CLT has many applications in the building as it is used for walls, floors, and roofs. CLT and glulam products are significantly lighter the traditional building materials, so foundations were designed to support smaller load and therefore use less material.

The building structural system was based on a glulam post and beam structure with CLT slabs, walls, and ceiling. Post and beam construction utilizes large, widely spaced wood to provide structural support to the building, allowing the desirable freedom in developing both interior and exterior space of the building, as showed in Figures 6 and 7.

Figure 6: *Post and beam MLC consumption is about 80 m3*

Figure 7: *CLT slabs and walls' consumption is 330 m3*

CLT and glulam will be fully fabricated before transportation to site. It will enable quicker construction times compared to other materials, and cost savings.

The construction will start with the execution of foundations and concrete core. Concrete core aids the building's structural stability and provides access and escape via lifts and stairs, regarding fire code requirements. Figure 8 shows an image of the building highlighting mass timber and concrete core.

Figure 8: *Aerial 3D image of the CIPEM's new headquarters*

Amazonian wood will be used to create delicate and warm spaces inside the building. Research has demonstrated that like the way indoor plants can help ease stress, using indoor natural wood surfaces can also improve physiological health.

Figures 9 and 10 illustrates the central area of the building where mass timber solutions made of Amazonian wood are exposed.

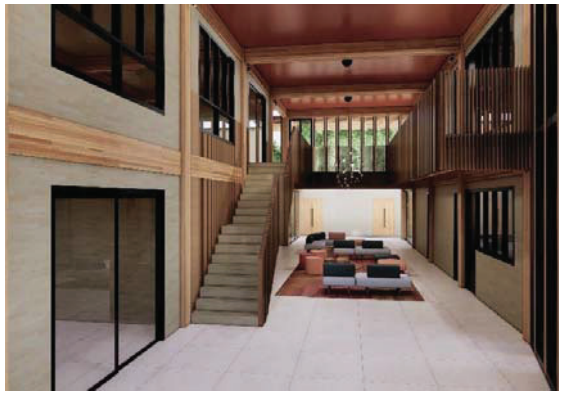

Figure 9: *Internal view of the central hall of the building*

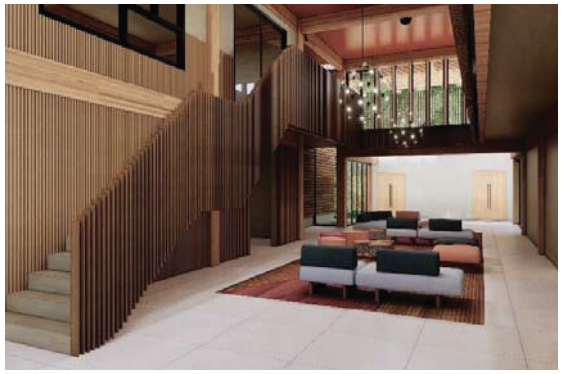

Figure 10: *Internal view*

https://doi.org/10.52202/069179-0486

Aesthetics reasons and the warmth given using wood are key elements of the auditorium, and room acoustics are improved. As showed in Figures 11 and 12, the presence of wood gives a contemporary design and instantly adds a natural light to the interior.

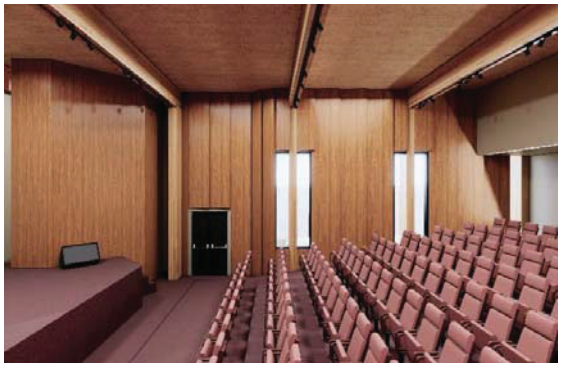

Figure 11: *Internal view of the auditorium*

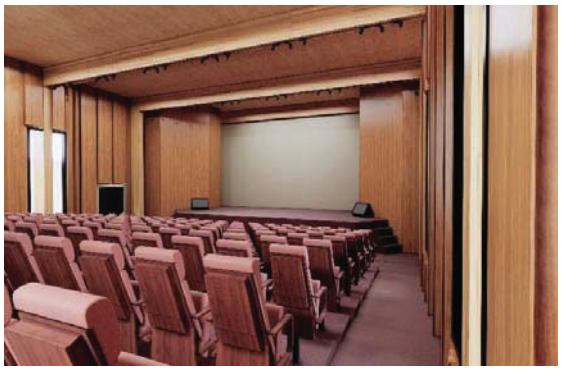

Figure 12: *Internal view*

Wooden cladding made of Amazonian species will give durability, colour options and easy-maintenance to the facades of CIPEM"s new headquarters. They are not structural elements and form a protective layer on the building.

They are more than just decorative elements and help in aiding sound insulation. Wooden cladding can be easily recycled, renewed, or painted over to provide a whole new look. Figures 13, 14 and 15 illustrates the use of Amazonian wood cladding in the facades of the building.

Figure 13: *Wood cladding in the main entrance of the building*

Figure 14: *Main entrance*

Figure 15: *External wood cladding in the auditorium*

Huge poles with 10m heigh and coming from the Amazonian Forest will be highlighted in the building, aiming to show the amazing transformation from this raw material into a contemporary building material.

High density species like Roxinho (*Peltogyne sp.*), Cumaru (*Dipterix sp.*) and Orelha de Macaco (*Enterolobium contortisiliquum*) will be placed in the facade. Figure 16 shows the presence of Amazonian timber poles in the building.

https://doi.org/10.52202/069179-0486

Figure 16: *Amazonian timber poles in the façade*

Thermoacoustic roof will be installed in the building and external pergolas will act as green roofs with many benefits in terms of sustainability because the vegetation will convert CO2 into oxygen and filters particulate matter from the air.

The pergolas will provide shade, remove heat from the air and reduce temperatures of the roof surface and surrounding air. They can also contribute to moderate the heat island effect specially in a city with hot climate. The building is in Cuiabá, the capital of Mato Grosso State. Figure 17 shows an aerial view of the building highlighting the presence of the pergolas.

Figure 17: *Aerial view showing the pergolas*

5 CONCLUSIONS

The experience of designing CIPEM's new headquarters with mass timber made of Amazonian wood confirms the several possibilities of building with this raw material, aiming to create an unique Mato Grosso's native wood showcase.

The use of mass timber in our country is increasing in a remarkable rate, and due to its huge market Amazonian timber has strategic role in this field. The reduction in the assembling time that is typical of the prefabricated structures is added to the aesthetics given by the presence of wood, making it very competitive against other building materials.

Some advantages of using glulam and CLT structures like prefabrication of large components at the factory and short assembly times at the construction site will be highlighted to improve timber construction techniques in Brazil's central region.

The use of Amazonian timber structures is evidence of the flexibility of this sustainable and locally sourced material. It should be pointed out the importance of demystifying the use of timber structures as "non-ecological" in our country, because wood is the only choice for a renewable and sustainable building material and wood materials are desirable for their strength, durability, beauty, and cost-effective construction.

ACKNOWLEDGEMENT

The authors thank CIPEM for the support in all stages of the conception of the building, as well as in the presentation of this article.

INTEGRATING TIMBER PANEL ELEMENTS INTO HISTORIC CHINESE TIMBER-FRAMED HOUSES TO ENHANCE MULTIPLE BUILDING PERFORMANCES

Harrison Huang[1], Kapulanbayi Ailaitijiang[2], Hui Zhan[3]

ABSTRACT: The traditional timber-framed house has a several thousand-year-long history in China, and it is an important part of Chinese architectural culture. Despite their high historic value, these buildings have limitations in comparison with today's standards, especially in terms of indoor comfort. This study explores the potential of integrating modular timber panel elements (TPE) into historic Chinese timber-framed houses to enhance multiple building performance, i.e., thermal-acoustic insulation for a comfortable indoor environment and better noise reduction. Comprehensive analyses are carried out on the application of TPEs for the building envelope, including exterior walls, roofs, floors, doors, and windows, to demonstrate the feasibility of using these techniques and to quantify the improvement of building performance. This study innovatively contributes to healthy and energy-efficient living conditions by revitalizing historic Chinese timber-framed houses.

KEYWORDS: Timber panel element, Historic Chinese timber-framed house, Building performance enhancement, Prefabrication potential, Thermal-acoustic insulation

1. INTRODUCTION

Timber framing has been a traditional building method for constructing framed structures in many regions of the world for millennia [1]. China is one of the earliest countries to adopt wooden structures. Timber buildings are the protagonist of ancient Chinese architecture, representing an important part of Chinese traditional culture [2]. A fundamental achievement of Chinese timber architecture is the load-bearing timber frame, a network of interlocking wooden supports forming the skeleton of a building. This is considered China's major contribution to architectural technology worldwide [3]. Although these historic timber-framed houses have such a high historic value, these buildings have largely failed to meet people's modern living standards due to the increase in living requirements [4]. This is because some functions of the building envelope are inadequate, such as thermal and sound insulation and fire prevention. Therefore, these historic buildings need to be transformed for modern use. According to international experience in renovating traditional timber-framed buildings, many methods have been used to improve indoor comfort, structural stability, fire protection, and other building performance [5]. Among them, the use of timber panel elements (TPEs) can not only improve building performance but also help reduce costs. Therefore, TPEs have become increasingly popular in the European building industry in recent years [6]. It is worth mentioning that no scientific research results related to using TPEs in Chinese timber-famed houses have been found after a literature review. There is no concrete evidence to verify whether TPEs suit these specific building types. Therefore, this paper explores the integration of TPEs into Chinese historic timber buildings and simulates and analyses to what extent TPEs enhance building performance.

2. ANALYSIS AND METHODS

2.1 BACKGROUND ANALYSIS

Chinese timber buildings can be categorized into three types in terms of structural forms, namely, *Chuandou* (column and tie construction), *Tailiang* (post and lintel construction), and *Jinggan* (log cabin construction). Although the two former types are both timber-framed structures, *Chuandou* consumes less timber and is more structurally stable than *Tailiang*. Therefore, the vast majority of traditional ordinary residential buildings were built as *Chuandou*. Their exterior walls define the building enclosure but may not be load-bearing elements [3]. The enclosure system is relatively independent of the main structure.

According to the "shearing layers" concept, first conceived by architect Frank Duffy and later developed by Steward Brand in his book *How Buildings Learn: What Happens After They're Built* [7], there are 6 layers of a building: site, structure, skin, service, space plan, and stuff. Based on this 6S theory, TPEs can be applied to structure, skin, and service. However, a TPE has the most potential as a skin layer in relation to improving the performance of Chinese historic timber-framed buildings.

[1] Harrison Huang, College of Civil Engineering and Architecture & Balance Architecture Research Center, Zhejiang University, Hangzhou, China, harrison@zju.edu.cn
[2] Kapulanbayi Ailaitijiang, College of Civil Engineering and Architecture & Architectural Design and Research Institute, Zhejiang University, Hangzhou, China, Qaplanbay@zju.edu.cn
[3] Hui Zhan, Design & Research Institute of Shanghai Jiaotong University, Shanghai, China, 1796427208@qq.com

https://doi.org/10.52202/069179-0487

As mentioned above, the enclosure system is often independent of the load-bearing structure system, so the skin can be renewed and replaced during the entire life cycle of a building. For the application of TPEs, the envelope elements in *Chuandou* houses, including exterior walls, roofs, foundations, floors, windows, and doors, need to be first analyzed (Figure 1).

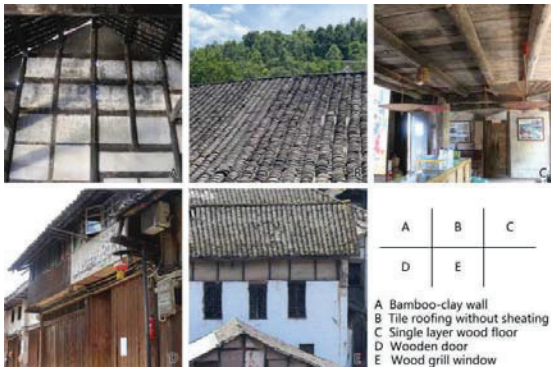

Figure 1: *Envelope system of a historic Chuandou house*

2.1.1 Exterior walls

The exterior walls take up the largest proportion of the envelope system, and their thermal performance also directly affects the building's indoor comfort. Wall infill materials are mainly clay, stone, and brick, among which clay has the longest history and widest prevalence [8]. Compared with walls made of other materials, clay walls are more economical and durable and have better performance in terms of fire prevention, sound insulation, and heat preservation. Despite the advantages of clay walls, there are also many difficulties in evaluating wall performance. The wall thickness and composition vary greatly in different places according to the local climate and natural environment. The wall is usually made of a mixture of several local materials, such as clay, straw, and bamboo, and it is difficult to check the thermal or acoustic standard values, and it is necessary to measure the relevant indicators for every single case.

2.1.2 Roofs

The roofs in a building envelope should not only prevent the intrusion of rain and snow but also offer good insulation. For the vast majority of *Chuandou* buildings, the double-pitch roof is the most common form. Taking houses in southern China, for example, tile roofing without sheathing is very common because of its simple structure, convenient construction, and economical applicability [9]. However, the thermal and sound insulation performances of the roofing are abnormally poor and do not meet the thermal and sound insulation requirements of today's building codes.

2.1.3 Foundations and floors

The foundation not only bears all the loads transmitted from the superstructure but also prevents moisture from penetrating. There are many types of foundations for historic *Chuandou* buildings, such as raw soil, composite soil, slate, and mortar [10]. Among them, composite ground has a wider range of applications because of its better thermal properties and stability. For floors, wooden planks are often laid directly on top of beams. This is a simple and common method, but the sound insulation performance is seriously poor.

2.1.4 Door and windows

Regardless of the types of exterior walls, the typical doors of traditional houses are made of single-layer wooden boards. As far as the material is concerned, wooden doors have good thermal performance, but the boards are vulnerable to deformation, and gaps can appear between the boards. If not properly maintained, the airtightness will be extremely poor, especially between the door leaves, threshold, and walls, where large gaps are located. Similar problems occur in windows, as the materials used are the same as in doors. Since most windows are used solely for lighting and ventilation, there is no consideration for airtightness or sound insulation at all [10].

2.2 DATA MODELING

Integrating TPEs into a *Chuandou* building has the potential to improve building performance. To determine the thermal and sound insulation performance enhancement, this study proposed possible TPE applications and compared the performance of building envelope elements with the original state. The size and number of panel elements are directly related to the size and spacing of the columns and ties in the building.

In this study, typical *Chuandou* houses in the Sichuan Basin in south-western China are used as modelling prototypes. The experimental design was carried out based on the research results of Huang's study [11] and the personal survey of the authors in the ancient village of Fubao in Sichuan Province. The foundation of the building model is set as 5×8 m, and the height is 7.5 metres. The first floor is 3.5 metres high, and the attic floor is 2–4 metres (Figure 2) [11]. According to local construction methods, the double-pitch roof is covered by the most common tile roofs 25 mm thick. The exterior wall is set to 50 mm thick with bamboo-clay infills, and the foundation material is set as 150 mm thick and mixed with lime, sand, and clay. Because the historic wooden doors and windows are made of a single-layer wooden board, they are uniformly set as 20 mm thick pine boards in the model. Based on the research and calculation of local buildings and the references of papers in related fields [10] and the comparison with the building code *Design Standard for Energy Efficiency of Rural Residential Buildings (GB/T 50824-2013)* [12], the following data have been obtained (Table 1).

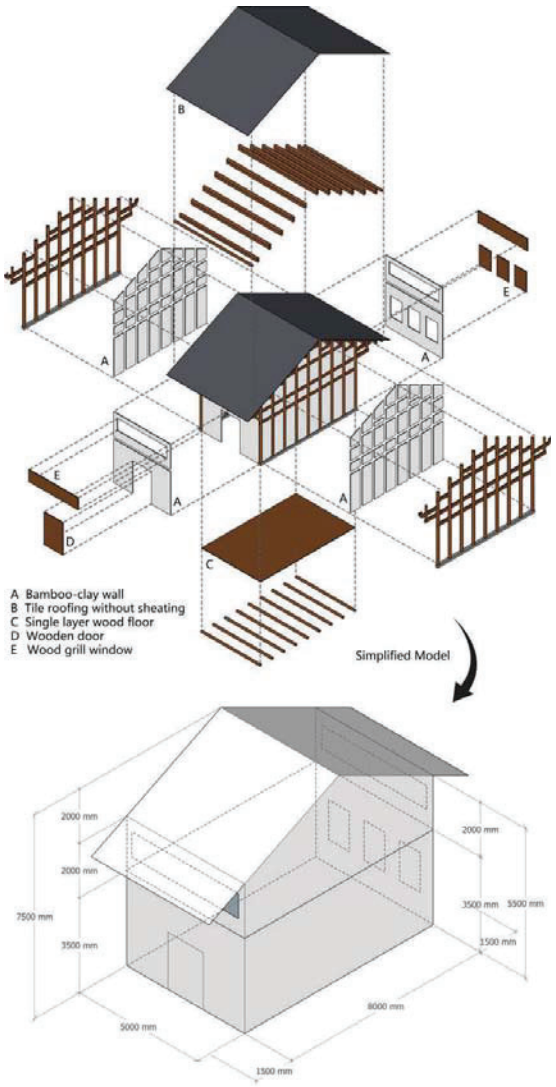

Figure 2: *Simplified model from a historic Chuandou house*

Table 1: *Thermal performance of the building envelope*

Envelope elements	Thermal Resistance/R (m²·K/W)	Standard Requirement/R (m²·K/W)	Comment
Walls	0.29	0.52	○
Roof	0.18	1.10	○
Ground	0.22	-	-
Floors	0.216	-	-
Doors	0.14	0.18	○
Windows	0.14	0.16	○

○Unqualified - Inapplicable

In addition, the computational model in this study is set to a location in Fubao in south-eastern Sichuan Province. Based on the thermal analysis of this building model by Ecotect Software, the following results can be drawn. It illustrates the energy gain/loss for a year from 1 January to 31 December (Table 2, Figure 3). The process of conduction through the building envelope loses the maximal heat by approximately 91.6%. Heat gains that disrupt comfort in summer months are approximately 26.2% because of conduction. Passive solar radiation gains that affect the architecture of the building are approximately 48.9% over a year. According to the data, the heat lost in the form of conduction through the building envelope accounts for the vast majority.

Table 2: *Heat gains for the original model*

Category	Losses		Gains	
	Heat (Wh)	Proportion (%)	Heat (Wh)	Proportion (%)
Fabric (Conduction)	727,886	91.6	359,426	26.2
Sol-Air	0	0	670,837	48.9
Solar	0	0	45,271	3.3
Ventilation	58,008	7.3	42,528	3.1
Internal	0	0	237,331	17.3
Inter-Zonal	8,741	1.1	17,834	1.2
Total	794,635	100	1,373,227	100

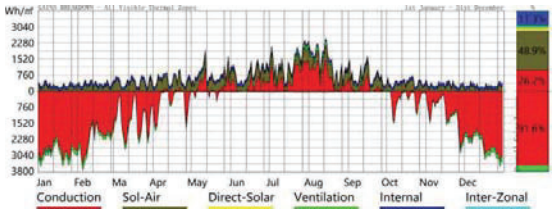

Figure 3: *Thermal performance of the original model*

A temperature analysis of the hottest and coldest days in the year was conducted, from which the related analysis results can be observed in Figure 4. The green and orange lines indicate the hourly internal temperature change of the ground and attic floors of the original model, respectively. The blue line indicates the outdoor temperature change. The differences between indoor and outdoor temperatures are very small, which indicates that the thermal insulation performance of the building envelope is weak.

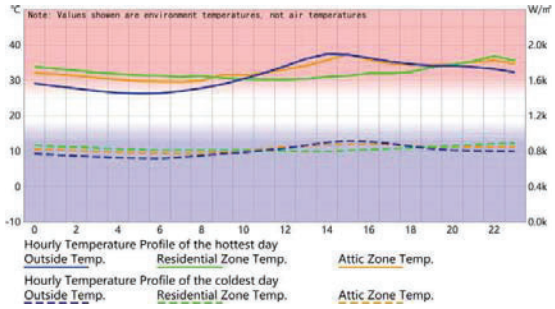

Figure 4: *Hourly temperature change on the hottest and coldest day in a year*

Figure 5 indicates that much more heat is lost or gained through the building envelope than through ventilation. On the hottest day, the conducting heat gain of the building envelope can reach 9,000 W or more. The situation in winter is even worse, and the conducting heat loss can reach 12,000 W.

https://doi.org/10.52202/069179-0487

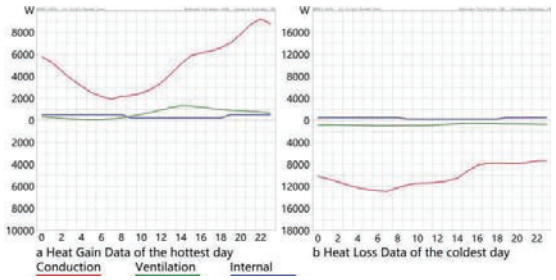

Figure 5: *Heat gain and loss on the hottest and coldest days in a year*

According to the thermal analysis above, the building envelope is the key factor in improving the building's thermal performance.

In addition to the bad thermal performance, the sound insulation is also poor. This problem is closely related to the structure, materials, and constructional characteristics. The roof has no sound insulation measures because of the clay tiles directly on the rafters, so the falling sound of rainwater can be noisily heard inside, especially on the attic floor. The low density and poor airtightness of bamboo–clay walls and wooden board walls are the main causes of poor sound insulation performance. The plank floor laid directly on the wooden beams has poor resistance against walking noises concentrated at 20–200 Hz. When walking, there is also noise from the mutual squeezing of the wooden boards caused by slight deformation. Doors and windows are also problematic for sound insulation. According to field research and a literature analysis, the standardized sound pressure level differences of enclosure structural components such as walls and floors are all no more than 30 dB. According to the requirements in the relevant specifications (*Technical Standard for Infills or Partitions with Timber Framework GB/T 50361-2018*[13] and *Code for Design of Sound Insulation of Civil Buildings GB 50118-2010*[14]), the acoustic environment is not qualified.

3. INTEGRATING A TPE INTO A BUILDING ENVELOPE

3.1 DESIGN OF TPE COMPONENTS

Prefabricated timber panels are elements that are produced in a factory and can be well-insulated, fireproof, waterproof, or soundproof. Their dimensions can vary according to the structural system and the material used. Various performances that provide energy conservation or efficiency can be realized in a prefabricated TPE that improves the living quality of the indoor environment by providing visual, thermal, and acoustic comfort [15]. The thermal and sound insulation performance are examined using Ecotect and INSUL after construction designs are implemented to integrate the TPE into the building envelope parts of the *Chuandou* house.

3.1.1 Exterior walls

TPEs have the potential to be applied in infill compartments in the exterior walls of the *Chuandou* house (Figure 6). The TPE infill wall is composed of a 10 mm plaster board, 15 mm gypsum fibre board, 90×45 mm timber studs, mineral wool, vapour barrier, and 15 mm gypsum fibre board from outside to inside. This allows for calculating the heat transfer coefficient and thermal resistance of this wall scheme according to the thermal parameter table of building materials in *Thermal design code for civil buildings (GB/T 50176-2016)* [17]. The calculation indicates that the U value (thermal transmittance) of the wall is 0.42 W/(m²·K), and the R-value (thermal resistance) is 2.35 m²·K/W, meeting the related requirements in the same design standard [12]. The sound insulation performance of the wall was simulated in INSUL, and the following data were obtained (Figure 7). The air-weighted sound insulation R_w of the wall is 53 dB, the traffic noise spectrum correction C_{tr} is -6 dB, and the R_w+C_{tr} value is 47 dB, which meet the relevant requirements in the *Code for Design of Sound Insulation of Civil Buildings (GB 50118-2010)* [14].

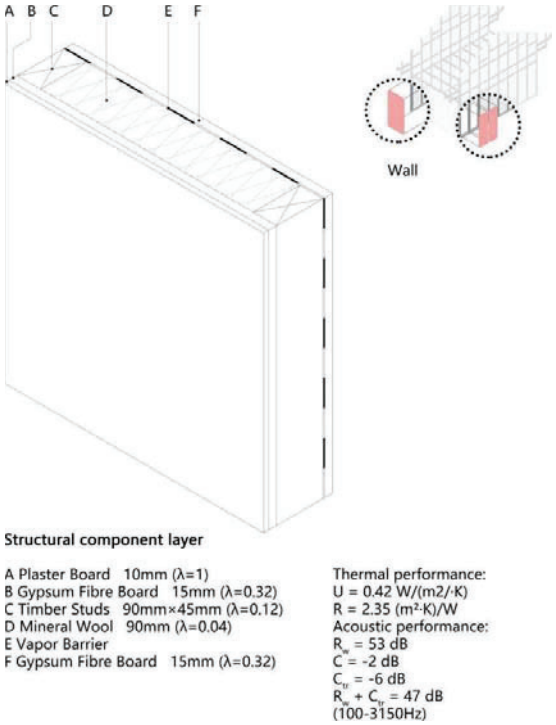

Figure 6: *Construction of the TPE infill wall*

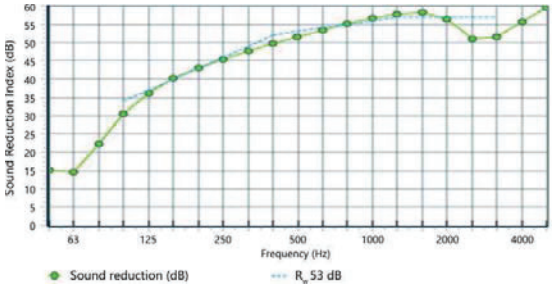

Figure 7: *Sound insulation simulation of the TPE infill wall*

3.1.2 Roof

There is the possibility of introducing a TPE into a traditional double-sloping roof as an intermediate layer

between purlins and tiles. Figure 8 shows the construction design of the TPE roof layers, which consist of 80 mm thick wood battens, a waterproof membrane, 12 mm OSB, 90×45 mm timber studs, mineral wool, a vapour barrier, 15 mm OSB and 15 mm gypsum fibreboard from outside to inside. It is calculated that the U value of the roof is 0.41 W/(m²·K), and the R-value is 2.46 m²·K/W, meeting the relevant requirements in *GB/T 50824-2013*[12]. The sound insulation performance of the roof was also simulated in INSUL, and the following data were obtained (Figure 9). The L_{iA} value (floor impact sound level) of the roof is 45 dB, which meets the relevant requirements in *GB 50118-2010* [14].

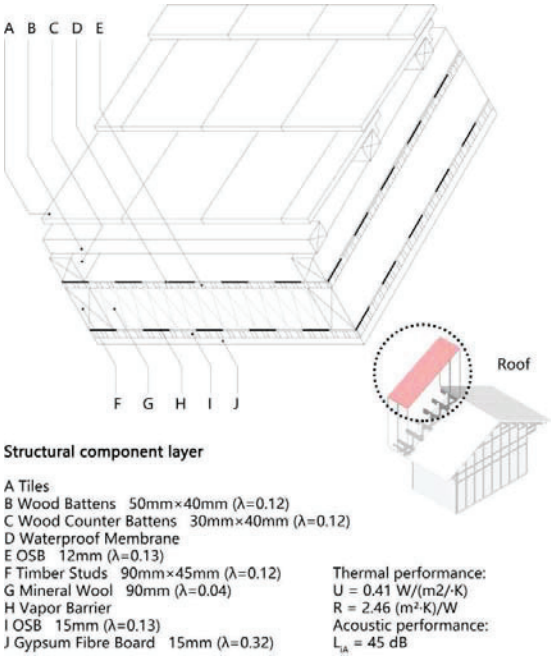

Figure 8: *Construction of the TPE roof*

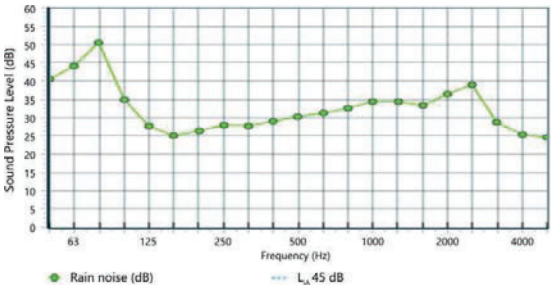

Figure 9: *Sound insulation simulation of the TPE roof*

3.1.3 Floors

It is possible to apply the TPE on top of the floor beams. Figure 10 shows the construction design of the TPE floor layers, which is composed of 12 mm OSB, 90×45 mm timber studs, mineral wool, 15 mm OSB, and 12 mm gypsum fibreboard from upside to downside. It is calculated that the U value of the floor is 0.40 W/(m²·K), and the R-value is 2.50 m²·K/W. The sound insulation performance of the floor was simulated in INSUL, and the following data were obtained (Figure 11). The $L_{n,w}$ value (weighted normalized impact sound pressure level) of the roof is 68 dB, which meets the relevant requirements in *GB 50118-2010* [14].

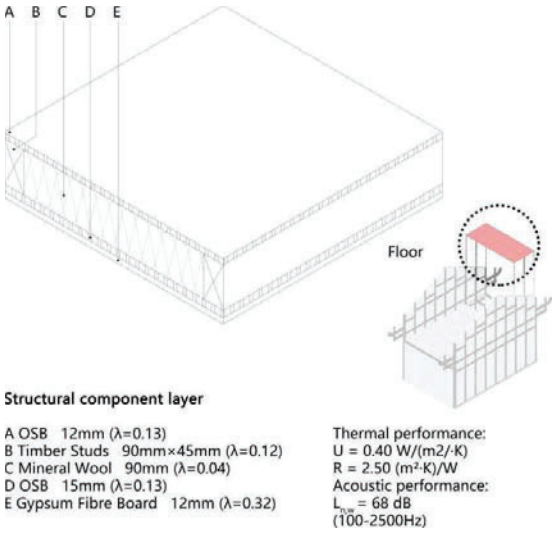

Figure 10: *Construction of the TPE floor*

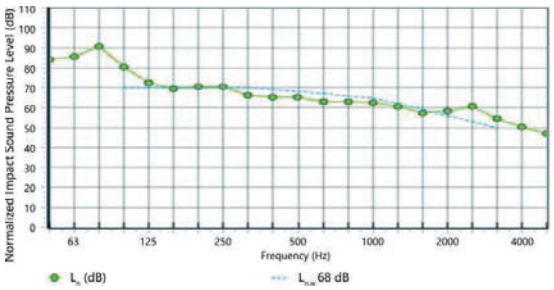

Figure 11: *Sound insulation simulation of the TPE floor*

3.1.4 Door and windows

Traditional doors and windows can also be transformed into TPEs, optimizing the physical properties. The doors are constructed of double wooden panels sandwiching a 20 mm particle board, while the windows are constructed of double glazing sandwiching a 15 mm air layer (Figure 12). It is calculated that the U values of the doors and windows are 0.95 W/(m²·K) and 1.5 W/(m²·K), and the R values are 1.06 m²·K/W and 0.67 m²·K/W, respectively, meeting the relevant requirements in *GB/T 50824-2013*[12]. The sound insulation performance of the doors and windows are simulated in INSUL, and the following data were obtained (Figure 13). The R_w-value of the doors is 36 dB, the pink spectrum correction C is -2 dB, and the R_w+C value is 34 dB. The R_w-value of the windows is 36 dB, the traffic noise spectrum correction C_{tr} is -5 dB, and the R_w+C_{tr} value is 31 dB. Both meet the relevant requirements in *GB 50118-2010* [14].

https://doi.org/10.52202/069179-0487

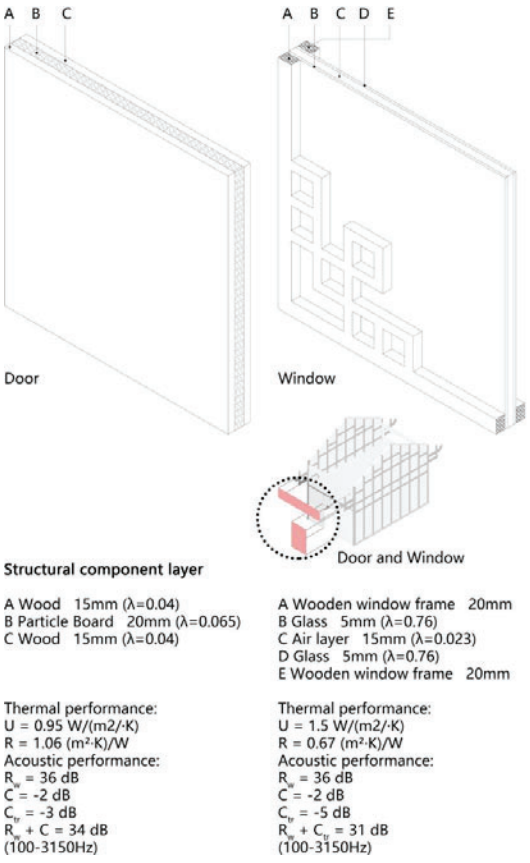

Figure 12: *Construction of the TPE door and window*

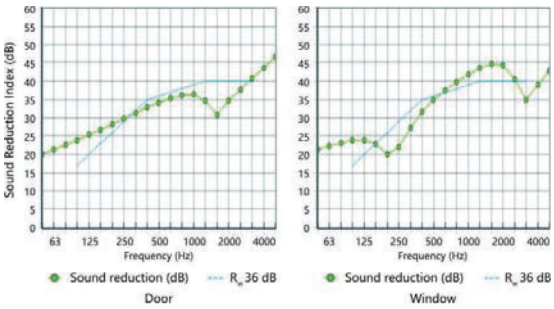

Figure 13: *Sound insulation simulation of the TPE door and window*

3.2 BUILDING PERFORMANCE ENHANCEMENT

Table 3 and Table 4 show the thermal and sound insulation performances of each envelope component. It can be seen from the data that the thermal and sound insulation performance of the building enclosure layer has been significantly improved after using TPEs, all of which have filled the relevant national specifications and standards *(GB/T 50824-2013* [12]*, GB/T 50361-2018* [13]*, GB 50118-2010* [1]*)*.

Table 3: *Thermal performance of TPEs*

Envelope structure parts	Original Thermal Resistance/ R (m²·K/W)	TPE Thermal Resistance/ R (m²·K/W)	Increased ratio	Comment
Walls	0.29	2.35	810.34%	●
Roof	0.37	2.46	664.86%	●
Floor	0.216	2.50	1157.41 %	-
Door	0.14	1.06	757.14%	●
Windows	0.14	0.67	478.57%	●

● Requirement filled - Inapplicable

Table 4: *Acoustic performance of TPEs*

Envelope structure parts	Original Sound Insulation	TPE Sound Insulation (dB)	Standard Requirement (dB)	Comment
Walls		R_w+C_{tr}=47	$R_w+C_{tr}\geq45$	●
Roof		L_{iA}=45	$L_{iA}\geq40$	●
Floor	＜30 dB	$L_{n,w}$=68	$L_{n,w}$＜70	●
Door		R_w+C=34	R_w+C≥30	●
Windows		R_w+C_{tr}=31	$R_w+C_{tr}\geq30$	●

● Requirement filled

On the basis of the original architectural model, the wall was designed as a 130 mm thick TPE wall, the roof part was replaced with a 212 mm TPE roof, a 129 mm TPE floor was added, and a 50 mm thick soundproof door and 65 mm thick windows were added. In this study, the above structures were brought into the original model, thermal analysis was carried out in Ecotect to obtain new simulation data, a comparison between the original data and the optimized data was carried out, and finally, a conclusion was drawn.

By applying all the designed TPE envelope components in the presented building model, it can be seen that the amount and ratio of heat loss or gain through the building envelope in the whole year are significantly reduced after using TPEs. Especially in summer, heat conduction through the building envelope is nearly ten times lower than before, with original values of 359,426 Wh to 37,593 Wh (Table 2, Table 5, Figure 14). The fabric heat loss is reduced to 93,597 Wh from 727,886 Wh. Passive solar radiation gains that affect the architecture of the building are also reduced to 52,092 Wh from 670,837 Wh. This is a reduction of almost 13 times. In addition, the total heat loss and gain of the building throughout the year have been significantly reduced, and the proportion of the building envelope in heat transfer has also been decreased. This shows that the thermal insulation performance of the TPE is very superior.

Table 5: *Heat loss and gains after installing TPEs*

Category	Losses		Gains	
	Heat (Wh)	Proportion (%)	Heat (Wh)	Proportion (%)
Fabric (Conduction)	93,597	56.1	37,593	10.2
Sol-Air	0	0	52,092	14
Solar	0	0	32,433	8.8
Ventilation	59,729	35.8	36,119	9.8
Internal	0	0	198,653	53.9
Inter-Zonal	13,347	8.1	12,162	3.3
Total	166,673	100	369,052	100

https://doi.org/10.52202/069179-0487

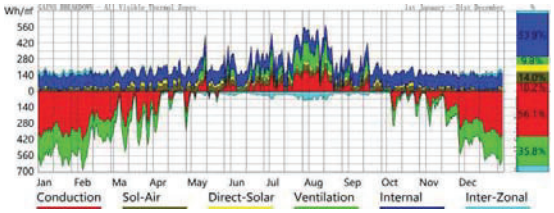

Figure 14: *Thermal performance for the model using TPE*

Figure 15 shows that the temperature difference between the outside and the inside of the building has widened by using TPEs. Especially on the coldest day of the year, the indoors are always warmer than the outside the whole day long, and the temperature difference is more than 5 ℃. However, the indoor temperature on the hottest day of the year is kept at approximately 35 ℃, which is 2 to 3 ℃ warmer than before. This may have something to do with the abated natural ventilation in the building due to the improved airtightness.

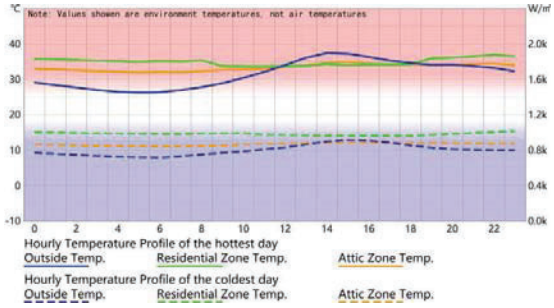

Figure 15: *Hourly temperature change of the hottest and coldest day in the year after using TPEs*

Figure 5 and Figure 16 show that the maximum heat gain on the hottest day is reduced from 9,000 W to 1,200 W, and the maximum heat loss on the coldest day is also reduced from 13,000 W to 1,600 W after using TPEs. The heat lost or gained by the building through heat conduction is approximately 7-8 times less than the original value.

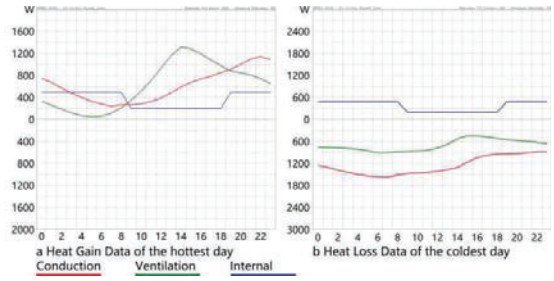

Figure 16: *Heat loss and gain on the hottest and coldest days in the year after using TPEs*

Figure 17 shows the yearly total hours by temperature in the simulation. The time for indoor temperature within the comfort band between 18 ℃ and 26 ℃ lasts 3,968 hours and takes up 45.3% of a year without using TPEs. After using TPEs, the comfort time increased to 4,573 hours and accounted for 52.2% of the total hours for the year, with a 6.9% increase. From this comparison, it can be concluded that the thermal comfort of the historic *Chuandou* house has been improved in general through the application of TPEs.

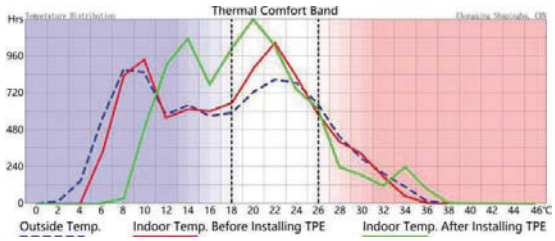

Figure 17: *Comparison of total hours by temperature*

4. DISCUSSION

Through this study, it can be seen that the use of TPEs plays a significant role in improving the performance of historic Chinese timber-framed buildings. TPEs, which integrate the functions of enclosure, heat preservation, and sound insulation, can effectively improve living comfort. The proposed solutions consist of cladding the building envelope with a new skin based on prefabricated timber panels, improving the thermal and acoustic performance and architectural quality. The use of preassembled timber-based components and external installation reduces construction costs and time and embodied energy, which is a sustainable approach from social, economic, and environmental viewpoints.

However, this approach of this study also shows limitations. Only two performance, thermal and acoustic insulation, have been simulated and compared. Other performance, such as fire resistance and moisture-proofing, are ignored in the analysis.

In the simulation, the thermal insulation of the building in winter has been significantly improved, but the indoor temperature in summer is surprisingly higher than without TPEs. The factor leading to this result may be that the airtightness of the building has improved, so the natural ventilation for heat dissipation is also reduced. In fact, for houses in southwestern China, which are very warm in summer, the natural ventilation of the building should also be considered.

This study only designed the details of the TPE components themselves, but the details for the interface and connection between TPEs and the main building structure are not considered. Therefore, cold bridges may occur in practice and differ greatly from the experimental results. In addition, the weight of the TPE components was not taken into account, which in fact has something to do with structural safety.

5. CONCLUSION

China's historic timber construction technology used to be extensively spread and advanced, but new developments in modern timber construction in Europe and North America has progressed forwards in many aspects. With the promulgation and implementation of China's national standard *Technical Standards for Prefabricated Wooden Structures* and the new version of *Standard for Design of Timber Structures (GB 50005-2017)* [17] and the

https://doi.org/10.52202/069179-0487

promotion of national policies to encourage the development of prefabricated buildings, China's timber construction industry is experiencing steady growth.

This paper has gone through the design of building envelope components, integrating TPE prefabricated components into historic Chinese buildings, and obtained experimental results by software simulations. The results show the potential effectiveness of TPEs in improving building performance and demonstrate their application feasibility. However, these simulations still need practical verification, which will be a further research direction in the future. Moreover, this paper can provide a reference for the research and development of the modern adaptability of historic Chinese timber architecture.

ACKNOWLEDGEMENT

This research was funded by the Start-up Foundation for the Hundred-Talent Program, Zhejiang University, and a project grant from the Centre for Balance Architecture of Zhejiang University.

ARCHITECTURAL POTENTIAL OF NEW WOODEN MATERIALS & TECHNOLOGIES

Ramona Schwertfeger[1], Markus Lager[2], Studio LAGERSCHWERTFEGER

oo

ABSTRACT: In this text, we like to showcase some of our more ambitious projects: The first high-rise in timber construction in Germany, our project SKAIO received the so-called DGBN certificate in gold, a proof of air quality, and a DGBN-Diamond award. In addition, it exemplifies our approach to design for disassembly—all materials can be clearly separated. SHAA, a university and office building we currently design in timber construction, advances some of the findings we gained in a recently finished university building: here, we develop a building frame at once simple and able to accommodate pipes and cables. In office areas, glued laminated timber slabs [Brettstapeldecken] span the timber frame, in corridor areas cross laminated timber elements span in two directions, so that we can dispense with bearers to incorporate wiring and plumbing. Another project of ours, NXT, is an attempt to design quite an ordinary office building. By that we mean a focus on comfort and flexibility for third party users. We devise a flat slab with integrated bearers. The timber–concrete composite slab spans from beam to the façade.

KEYWORDS: LAGERSCHWERTFEGER, Berlin, Germany, Timber architecture, housing, education

1 Introduction

Between 2012 and 2021, the architecture practice Kaden+Lager, the former office of Markus Lager, realized a large number of hybrid-timber construction projects in the so-called building classifications four and five, comprising all buildings higher than seven meters. Berlin's building code allows for such constructions since 22 March, 2018. Previously, architects had to have such constructions approved as departures from the norm and through individual exceptions, which required huge efforts both in terms of time and money. Meanwhile, four of sixteen state building codes in Germany allow for the use of timber constructions in said building classifications. In addition, since mid-2021, the federal states integrated what is called Musterholzbaurichtlinie MHolzBauRL (Construction Guideline for Timber Construction) into their administrative regulations on technical building codes. This regulation basically controls the use of timber in building classifications four and five, respectively, and it allows for superstructures already used in buildings between 2012 to 2021.

While this new guideline for timber constructions has been developed and introduced, an increasing number and size of realized structures helps to technically advance applied timber constructions: referring back to already existing structures makes the design and construction of new ones much easier. We can now simplify superstructures, for instance, by reducing individual layers in their buildup. And not least do we have to use materials according to their nature. Between 2012 and 2021, errors occurred during the planning and execution phases, both in our own practice and more generally. Statistically, an increasing number of timber-constructions will inevitably lead to an increase in water and fire damage. As a consequence, we need to take stock of our projects to date and the concomitant regulations they entailed. It is not a question of lowering our protection goals or of unconditionally reducing complexity; rather, timber constructions must become more robust. There is, for instance, still a lack of solutions for both temporary and permanent waterproofing of construction sites and bathrooms. Another example is the integration of building technology mainly in prefabricated wall and ceiling elements. This article aims to trace the above-mentioned developments through the lens of our own projects. In addition, this article offers an outlook on current tasks that are constantly changing.

2 SKAIO

SKAIO is Germany's first wooden high-rise and—at the time of its opening—the country's tallest wooden building. Measuring 34m in height, its timber-frame construction is to large extents prefabricated, comprised of supporting structures made of laminated timber, and wooden slabs which rest on steel ring beams that resonate to the slim design of the construction. The project is part of the recently developed residential quarter Neckarbogen, an urban district in Heilbronn. The residential block features ten storeys and offers 60 apartments, 40% of which are subsidized by the state.

The internal layout has been adapted to reflect the new urban realities, in which the nuclear family no longer represents the sole point of reference. SKAIO instead offers apartment types which are usually hard to come by in a contemporary city: 56 smaller studios and one-bedroom apartments. These individual units, however,

[1] Dipl. Ing. Architektin AK Berlin Ramona Schwertfeger, head and owner of LAGERSCHWERTFEGER
[2] Dipl. Ing. Architekt AK Berlin Markus Lager, head and owner of LAGERSCHWERTFEGER

https://doi.org/10.52202/069179-0488

can be easily combined to accommodate future changes in use. In addition, four shared apartments are dedicated to socially disadvantaged members of society, run by two of Heilbronn's social welfare organizations.

Above an underground car park, the ground floor features commercial spaces, common spaces—laundry room, communal kitchen—and ample bicycle parking. Common laundry rooms in Germany tend to be rare and save valuable surface area in each apartment. A central core made of reinforced concrete contains the safety-stairwell and an elevator, which allows for barrier-free access to all apartments. While the primary structure in the basement, ground floor, and first floor are made of reinforced concrete, all other load-bearing components are made of timber or wood-steel hybrids.

The studios start, in floor space, at 40 square meters; the largest flats offer 90 square meters. Every apartment has its own loggia, floor to ceiling windows to provide for a maximum amount of daylight, and energy-efficient underfloor heating. The roof has a common garden terrace, partly furnished, partly green, with produce gardens and stunning views across the city.

During the so-called Bundesgartenschau 2019, a biennial federal horticulture show held in Germany, SKAIO marked the entrance to the show, constituting one of three landmarks in the vicinity.

2.1 Structural Contribution

SKAIO's ceiling and wall structure can be dismantled into its individual parts, that is, all materials can be separated by type. What is more, all superstructures are dry to guarantee a fast and clean construction process. Floor slabs are smoke-proof, a property we achieved by using so-called panel bundles in conjunction with a continuous layer of Fermacell above the impact sound insulation. That part of the primary timber construction facing the apartments we did not cover with plasterboard, something the MHolzBauRL (the guideline for timber construction) commonly asks for. The underside of the 26cm thick cross-laminated timber ceiling remains visible. On top of this ceiling panel, we installed lighting and sprinklers which are then brought down through drill holes. A wall of 12cm thick cross-laminated timber panels on the inside closes of the living space. The degree of prefabrication of walls is quite common in many other timber constructions. Prefabrication of the ceilings, however, is limited to the joinery of the cross-laminated timber elements.
The dry floor construction can only be made in situ, as the high-pressure water mist firefighting system has to be installed first throughout all apartments and in the safety stairwell. Even though it is possible to use a dry construction method that does not impede construction progress with drying time or require the use of chemicals to accelerate any drying, the complexity of this method is rather high. SKAIO's shell received a total of around 26,400m2 of panel materials, which is equivalent to the size of almost four soccer fields, an amount that adds to the complexity of the construction site. In comparison, prefabricating the ceiling panels with dry construction in the workshop might have been significantly less complex. However, the installation of the sprinkler system in particular would not have been possible with prefabrication.

Figure 3: *view SKAIO: aluminiumfacade, skeleton construction, columns on public ground*

3 TzW, Hamburg

In 2015, Kaden+Lager won a competition for "Baakenhafen, Baufeld 89," with the design of a residential building in hybrid-timber construction eight stories high. The building group inhabiting this structure consists of 29 parties and is made up of families, couples, singles—younger as well as older residents. Our aim was to build privately-owned, affordable housing with a high standard of living in Hamburg's HafenCity, by virtue of sustainable, ecological, climate-friendly construction methods. Completed in 2022, the apartment building is located alongside the Elbe River on the west side of a new urban block offering direct vistas onto the famous philharmonic. Towards the river, the block is open, providing light and air to its courtyard. All apartments face westward towards the city, and east towards the courtyard, providing excellent conditions for light and ventilation. Through participatory workshops we developed individual apartments according to the specific needs of each user.

Thanks to the building's robust primary structure, we could ensure cost security in construction, as well as a high degree of flexibility for potential conversions in the future over the entire life cycle of the building, while also providing a great variety of individual floor plans. Two staircases—each one of them leading to two apartments on every floor—provide access to the building. Three cross walls run unbroken through the entire building, dividing it longitudinally into four units which then get stacked on top of each other, and which contain the individual apartments. Easily adaptable, lightweight walls respond to the specific needs of each party. The curtain wall features rear ventilation and consists of light, large-format ceramic elements. Two different window formats as well as balconies and loggias, offset floor by floor, subdivide the facade and give rhythm to it. The floor-to-ceiling windows and French doors provide very good natural lighting for the apartments while at the same time offering views onto Hamburg's harbor. The inhabitants can use the roof terrace collectively as a communal area and playground. The rest of the roof area is green and serves for rain retention, cooling, and to increase biodiversity. The building received the HafenCity Gold eco-label.

3.1 Structural Contribution

The building is constructed as a solid timber structure. For reasons of flood protection, we devised the two-story dwelling mound as well as the stairwells and fire walls as a solid construction in reinforced concrete to ensure both bracing and emergency exits with economic means. All other structural elements, ceilings, cross walls, exterior walls and balconies are made of cross laminated timber. Here, too, we exclusively employed certified timber and took into account that this building might have to be dismantled at one point, which is also why it contains no harmful substances. The interior atmosphere is characterized by an interplay of natural wood surfaces, reinforced concrete, and neutral wall surfaces. During the construction phase, the TzW suffered from significant water damage due to water entering through leaking, temporary balcony sealing. Defective or incorrectly installed sanitary objects bring about further water ingress. The resulting damage prompted us to scrutinize the so-called DIN 18534-2 (a building norm addressing construction waterproofing), and to publish a solution better suited than the existing two-layer sealing.

4 UWH

The private university Witten/Herdecke in the southern Ruhr area is committed to teaching its students issues of culture and morality, as well as exposure to nature and production processes. Such concerns are fundamental to the relationship between people. Perhaps as a reaction to this, many students wanted to get involved in the design of a new central building, and in developing ideas about the arrangement of rooms and the materials used. The university opted for a timber construction able to bind carbon dioxide, thus contributing to the decarbonization of our planet.

The structure has many diverging tasks to fulfil at the same time: as a link between already existing, different buildings on campus, it also acts as an independent center that contains the library which spreads out across two floors. It also houses seminar rooms and work spaces. Rooms are used simultaneously or consecutively for different purposes. One can find silence and concentration side by side with lively discussions and teamwork. Many different parties require short paths out of different areas while in other parts of the building ask for much less circulation.

To make all this possible, we as architects subdivided the building into a square grid to keep the volume compact on one hand, while on the other to allow for individual rooms to contract or expand. Whether different functions remain separate or conjoin, things remain straight and simple.

Whereas to the south the building folds into the slope and adjacent park, towards the north it creates a new public square. The new building frames one side of a wide rectangle, while the large lecture and conference hall as well as a café open up towards the square. From here we catch a glimpse of the wide spiral staircase behind the main entrance, leading students and teachers into the first floor. This staircase is part of what we call ”aorta,” a central circulation area which not only opens up parts of the building, but which also offers niches to study and suites for discussion.

Materials can be experienced on the facade as well as inside: The open structure, walls and ceilings are made of wood, and large windows let in plenty of daylight. Towards the park, parts of the volume recede and thus create roof terraces. Of course, there is a bus stop directly in front of the campus, and those who come by bike can store it in the covered bicycle garage. Clear components for a climate-friendly future.

***Figure 5** – campus at UWH*

4.1.1 Structural Contribution

We applied the above-mentioned grid throughout the entire building. This allows for an efficient use of cross-laminated timber: within the grid, three fields in a row exactly match the length that can be easily manufactured and delivered to the construction site. From the onset, the manufacturer is involved in the process, which simplifies the planning in terms of optimisation and efficiency. Ecological balance sheets reflect both transportation and the CO2 emissions associated with it, which in turn drive of the cost of construction.

In a university building the units are larger than in a residential building. In the case of the University of Witten/Herdecke with a gross floor area of 6,880m2 there are a total of 14 units each up to 550m2 in size (compared to SKAIO with a GFA of 5,685m2 and 63 units). In general, the number of users per unit and in absolute terms is significantly higher in university or commercial buildings than in residential buildings of the classifications four and five. The large number of users is usually met with more powerful building technology. While the university’s own residential projects mostly manage without mechanical ventilation, this is impossible to maintain in lecture and seminar spaces as they are commonly used today. Here, the air is conditioned accordingly. However, the new UWH building features mechanical ventilation only in those rooms whose number of users does not allow for natural ventilation by means of simply opening windows. In office spaces without mechanical ventilation, we installed simple ceiling fans to lower the inhabitant’s sensitivity to temperature by around 2 degrees Celsius. In doing so, there is no need to further cool the building, a condition which helps significantly reduce the use of energy-intensive technologies.

https://doi.org/10.52202/069179-0488

We designed the building as a simple timber frame structure. The posts connect with double tie joints to the beams of the ceiling, which is made of cross-laminated timber, spanning across three fields of the grid (which equals 13.95m/3 x 4.65m). The exterior walls are made of timber panels, in part of solid timber construction, and clad with an untreated larch wood facade, which features rear ventilation.

A column-free structure for the lecture hall spans across 15m, on top of which there are two floors with office space. Here, one can detect the truss system directing the loads of the office spaces on the ground floor to the outside, thus making posts unnecessary. UWH's design has been subject to repeated changes. To be sure, both the organizing grid and our construction method demonstrate a sufficient degree of flexibility to respond to changing requirements. It became apparent, however, that we could not consider the construction alone, without creating enough space for the HVAC and electrical installations.

5 SHAA

The university campus of Aalen, a city located in the eastern part of the German state Baden-Württemberg, is continuously expanding, and in the course of this expansion the Steinbeis Stiftung für Wirtschaftsförderung (foundation for economic development) wants to create an office building, the so-called SHAA, on the campus Burren. Exposed to an adjacent state road, the so-called Bundesstraße 29, the building serves as a landmark, thus completing the height development sloping down from the east Unclear to me and offering its future users distant views over the Ostalb. The office building, consisting of a three-story wing and a seven-story tower, is built in wood; only the two cores and the basement are made of reinforced concrete. Due to its construction method and delicate wooden facade design, the building blends into its vernacular neighborhood as much as into the overall layout of the campus Burren. While the lower floors will be open to the public—here the university will primarily accommodate lecture halls and spaces for leaning—the upper floors will house exclusive office spaces.

***Figure** 7 – view from campus on 7-storey timber construction and larch-façade with changing fins*

5.1 Structural Contribution

The SHAA project, too, is designed as a timber-frame construction. Based on the experience we gained from realizing the UWH project, this structure required that all HLS/E (in principal HVAC and electricity) ducts can be installed everywhere without having to cross or go below beams. Thus, we created a post and lintel structure with double tie joints Correct? based on a grid of 5,20 m. In office areas, glued laminated timber slabs span the timber frame across one unit of the grid. In corridor areas cross laminated timber elements span in two directions so that we can dispense with bearers to incorporate wiring and plumbing. As these elements structurally engage in two axes, here we can avoid the use of double tie joints and building technology can run through the entire structure without crossing any beams. One layer of beams spans two lecture halls, located on the first and second floors,

https://doi.org/10.52202/069179-0488

the gaps of which we used to accommodate building technology which runs between individual beams.

***Figure 8** – HLS / E + pipes integrated in construction*

For the facade, we used prefabricated elements made of preaged larch that is treated with grey pigment. Below ground, geothermal probes extract soil heat for heating and cooling the building.

6 NXT

The first out of nine buildings of the NXT Airport Collaboration Village grouped around the village green is an office building we havedevised since 2021. Its presence and appearance point the way towards the future, as a harbinger for the village still under construction near Berlin's airport BER. Welcoming first users, this structure is a place for physical and virtual networking as it creates a vital environment to foster cooperation, creativity and growth.
A wooden frame used as a balcony and placed in front of the main facade Correct? welcomes the arriving users. Inside, the scheme offers contemporary office spaces, highly flexible and geared towards co-working. Public areas include a café and a multifunctional space connected to the central foyer located on the first floor, as well as outdoor spaces.

6.1 Structural Contribution

The design of NXT aims at commercial clients. Here our goal was to achieve the same level of comfort in the planning and operating phases one is used to from conventional construction. Due to high levels of vibration in the ground, we used timber-concrete composite slabs that are supported by glued-laminated timber posts and so-called delta beams, that is, composite beams of steel and concrete. This construction is akin to a flat ceiling and offers maximum flexibility with regard to the installation of building technology and potential changes to all non-load-bearing interior walls during the building's future use.

7 Silos - An Outlook

We currently develop a project on our own initiative. Instead of demolishing existing silos—as is proposed in the correlating master plan—we seek to preserve and repurpose this structure. Thus, we create residential and commercial spaces as we use the remaining volume of industrial buildings to store energy and potentially implement an indoor farm.
So far, we can share the following observations: The existing structures already cover the spatial requirements as laid out in the master plan. Furthermore, additional floor space can and should be created. By not demolishing the existing silos and doing without new structures we can save almost 70% of gray energy, evidence of which we provide by virtue of CO2 and life cycle assessment. Those building parts not dedicated to living and working can store electricity from renewable sources, which in turn can supply 18,000 households per day with power. We propose different options for energy storage and exchange these ideas with Flensburg's municipal utilities.

https://doi.org/10.52202/069179-0488

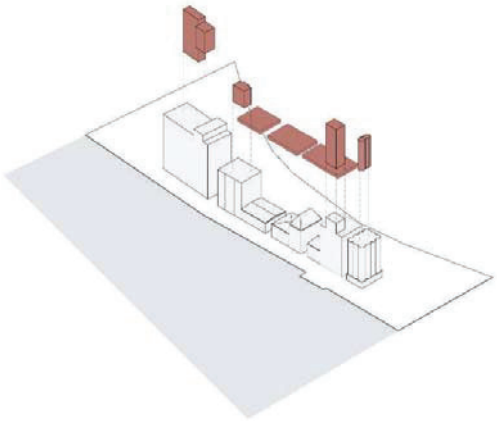

Figure 10 *– potenzial battery volume in Silos*

7.1 Structural Contribution

Here, the aim is to convert existing structures with as little effort as possible. To this end, we provide prefabricated wooden panels and solid wood elements that can be easily attached to the existing buildings and that already contain all necessary installations, so as to simplify the production processes on site.

8 Conclusion

During the time of this work, the design of timber constructions in particular has continued to develop gradually towards greater comfort and more simplicity. Above all, interdisciplinary planning processes from the beginning turn out to be essential and veryproductive. In order to keep the currently rising numbers of projects in timber constructions free of damage, we require proper planning solutions as much as manual dexterity in prefabrication and on the construction site.

SPECIAL SIZED TIMBER POLES AS MAIN STRUCTURAL MATERIAL IN TWO SPORTS GYMS AND A WINERY – BRAZIL

Roberto Lecomte[1], Sheila Beatriz[2]

ABSTRACT: Brazil has a long tradition of building with concrete. Although our country possesses the largest tropical forest of the planet, timber structures aren't the first choice for designers and builders. The urgency of develop low-carbon solutions to built environment is the key element of promoting the only construction system sequestering carbon and engineered to be “energy positive”, and this raw material is wood. In central Brazil, due to its geographic location, there are suppliers for both hardwood from the Amazon region and softwood from the southern. Starting from the experience of several timber structures executed in this region, it was proposed the use of pressure treated eucalyptus poles as the main structural material in two sports gyms and a winery, also using sawed hardwood as secondary structure. The structural system of the gyms is composed of porticos and the size of the rounded pieces reaches 24m long. A spatial structure was proposed to the winery according to contemporary design. The remarkable aesthetics given by the natural appeal of timber along with its sustainable aspects became powerful marketing tools to the enterprises.

KEYWORDS: Timber Structures, Low-carbon Solutions, Eucalyptus Poles, Structural System.

1 INTRODUCTION

Although timber structures are yet undervalued as building solutions in Brazil, new demands coming from the urgency of develop low-carbon solutions are indicating that wood products are strategic to the planet.
Starting from the experience of several timber structures executed in central Brazil, it was proposed the use of pressure treated eucalyptus poles as the main structural material in two sports gyms and a winery. This article shows the design and construction of these buildings.

2 METHODOLOGY

The projects of the buildings were developed from the following premises:
• structural modulation that optimizes the dimensions of the porticos and the size of the eucalyptus poles;
• intensive use of continuous members to the whole structures looking for simplify construction;
• standardization of bolted joints and carvings aiming to rationalize its assembling system;
• timber structures designed with base fixity and a consequent reduction in bracing elements;
• use of Amazonian sawed wood as secondary structure.

3 DESCRIPTION OF THE PROJECTS

As the main structural material of the related buildings, wooden poles are ecological materials that comes from reforestation and need much less energy for their production, and that production does not involve non-renewable components.
The wooden posts are much lighter than the concrete posts, reducing the cost of transportation. In addition, the handling of these poles is very simple, as it does not require the use of special equipment. It is also important at the time of installation, which is much easier to do.

3.1 UNIQUE GYM EXPANSION

Unique Gym is a remarkable building made of eucalyptus timber poles and since 2005 stands out as one of the most original gyms in our city as showed in Figures 1 and 2.

Figure 1: *External image of the Unique Gym*

[1] Roberto Lecomte, Casacerta Architecture Design & Building, Brasília, Brasil, roberto.lecomte@gmail.com

[2] Sheila Beatriz, Casacerta Architecture Design & Building, Brasília, Brasil, sheilatriz@hotmail.com

https://doi.org/10.52202/069179-0489

Figure 2: *Internal view of the wooden building*

The covering of the building's expansion is a mix between ceramic tiles and thermoacoustic covering according to the plan is showed in Figure 3.

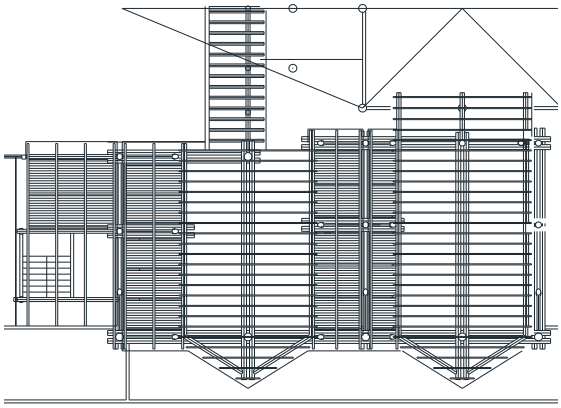

Figure 3: *Plan of the covering showing timber pieces*

The design of the expansion of the original Unique Gym was conceived considering its location over an existing concrete slab area. Due to this special location its structural system was designed by using 12m long beams, aiming to reach special sized pillars installed outside the slab area as illustrated in Figures 4, 5, 6, 7 and 8.

Figure 4: *Assembling of the timber structure over the existing concrete slab*

Figure 5: *Assembling of the timber structure*

Figure 6: *Assembling of the covering timber structure highlighting the 12m long beams*

Figure 7*: Execution of the covering*

Figure 8: *Internal view showing the original building and the expansion of the gym*

Besides providing both vertical and horizontal structural support to the gym's expansion, the presence of timber pole's structural system reveals its outstanding aesthetics that links the to the original building and highlight wood as the main building element of the sports complex. Figures 9, 10 and 11 shows images of the buildings.

Figure 9: *External view of the buildings*

Figure 10: *External view of the buildings*

Figure 11: *External view of the finished wooden pole structure*

3.2 NEW UNIQUE GYM

The design of the new Unique Gym was defined according to timber structural solutions experienced in the original building. Eucalyptus timber poles of special sizes allows larger spans and heights resulting in a 3 times bigger building then the original. Figures 12, 13, 14, 15 and 16 shows the plan and a scale model of this building.

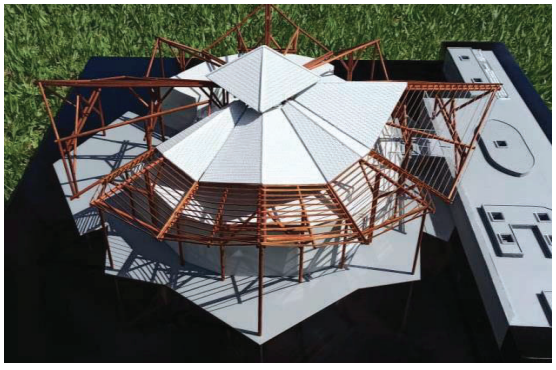

Figure 12: *Scale model of Unique new building*

Figure 13: *External view of the model*

Figure 14: *Internal view of the model*

Figure 15: *Internal view of the model*

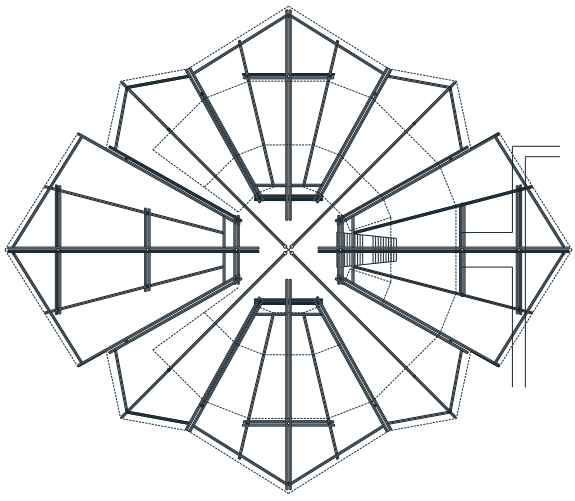

Figure 16: *Plan of the new Unique Gym*

https://doi.org/10.52202/069179-0489

3.3 WINERY

The building consists in a massive reinforced concrete block where's the winery central core, sheltered by a wood cantilever umbrella cover that defines a terrace with panoramic view of the vineyards. Figures 17 and 18 shows a covering plan and a section of the building.

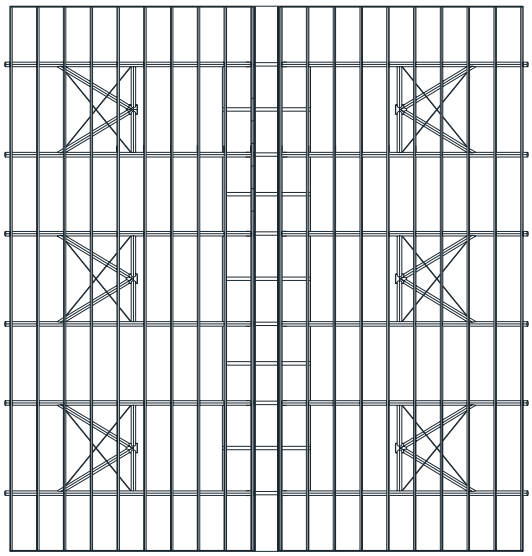

Figure 17: *Plan of the covering of the winery*

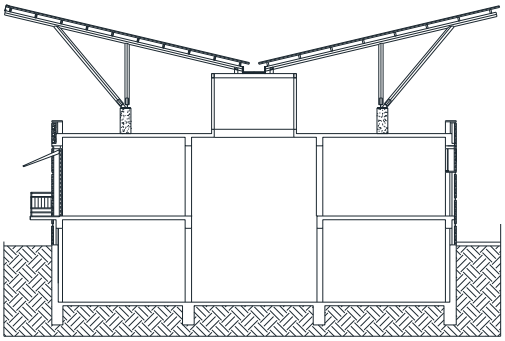

Figure 18: *Cross section of the building*

In this building timber poles are typically utilised to provide support for gravity loads and resistance against lateral forces. But the natural appeal of timber ensures that its role is not purely structural however, and it enables the design conception to take full advantages of beautiful outlooks as it can be viewed in this winery.
Due to its larger sizes such as 12m long beams, poles where spaced further apart than is usual, creating a more spacious building interior, that allowed greater interior design flexibility to the terrace.

Figures 19, 20, 21 and 22 illustrates the designed pole frame and its base plated connections and steel bracing sets. Columns were designed from the outset as columns with pinned bases. A grid of sawed hardwood was used to install the thermos acoustic metallic covering.

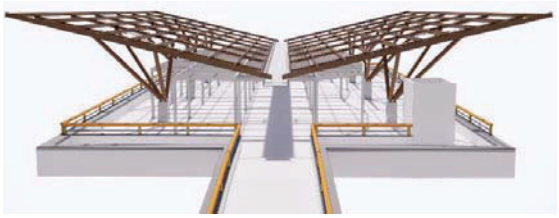

Figure 19: *3D image of the timber structure of the winery*

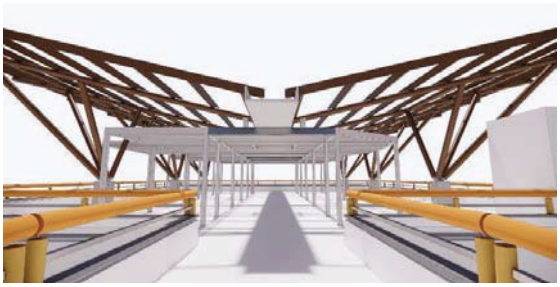

Figure 20: *External 3D image of the terrace*

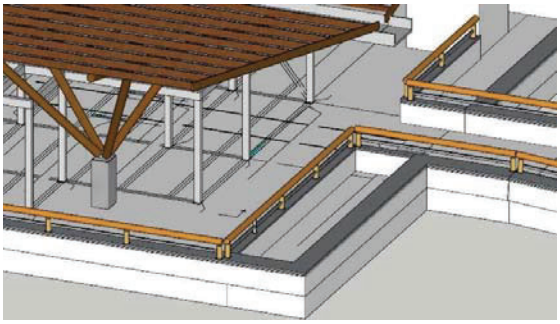

Figure 21: *3D image of the terrace*

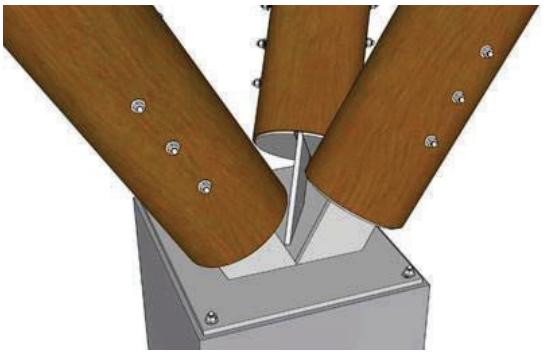

Figure 22: *Base plated connections detail*

Pole frame construction was extremely adaptable to architectural expression as showed in Figures 23,24, 25, 26, 27, 28 and 29.

Figure 23: *External view of the spatial structure of the winery*

Figure 24: *External view of the pole frame*

Figure 25: *Internal view of the pole frame*

Figure 26: *External view*

Figure 27: *Panoramic view of the terrace*

Figure 28: *External view of the winery*

Figure 29: *External view*

4 CONCLUSIONS

The experience of designing timber structures with special sized eucalyptus poles confirms the several possibilities of building with this raw material.

https://doi.org/10.52202/069179-0489

The excellent balance between its weight and resistance results in lighter components that can be more easily transported and assembled.

Finally, it should be pointed out the aesthetics benefits that come from the presence of the timber structures in the buildings, once complementing architectural designs and promoting low-carbon solutions.

MODULAR CONSTRUCTION WITH LOW-GRADE HARDWOOD CROSS-LAMINATED TIMBER

Edward Becker [1]

ABSTRACT: In this paper the author evaluates the results of a design-build project that employed the use of prefabricated, modular construction with cross-laminated timber (CLT) panels custom-developed from local, low-grade hardwood (Yellow Poplar, Liriodendron tulipifera). The American Institute of Architects award-winning project is the first permanent building in the United States to be granted a building permit for, and complete construction with, hardwood CLT. The paper presents and evaluates the attainment of each of the following research objectives in the design-build process and includes a review of the mechanical and structural testing underpinning panel performance. The project's research objectives included: (1) the development of locally-sourced, pressed, and utilized hardwood CLT that mechanically outperforms commercially available softwood CLT; (2) the development of low-carbon project logistics that allowed for all design and construction steps – from wood harvesting to CLT layup and utilization – to occur within a 3-hour driving radius of the project site; and (3) the development of prefabricated, modular construction workflows for the project's structural, exterior-exposed hardwood CLT. The 10-meter-tall hardwood CLT project was completed, passed all inspections, and opened to the public in 2021.

KEYWORDS: Hardwood cross-laminated timber, Modular timber construction, Local-species CLT development

1 INTRODUCTION

1.1 PROJECT BACKGROUND

The following paper presents the material development process of Yellow Poplar (Liriodendron tulipifera) hardwood cross-laminated timber (HCLT) and a built structure resulting from the HCLT's application in the public realm. The author focuses specifically on the development and testing of the HCLT product as it relates to the modular construction methods employed for the construction of the built structure, the New River Train Observation Tower in Radford, Virginia. The handicap-accessible train viewing tower is the first permanent building in the United States to be granted a building permit for, and complete construction with, hardwood CLT.

The author of this paper was approached in Fall 2017 by a colleague at Virginia Tech to help co-lead a new design-build project funded by the nearby City of Radford, Virginia. The city sought to build a train observation tower to provide public, handicap access to views over the New River and a historic railway line adjacent to the city's history museum. Over the following two-and-a-half-year period, the author and Professor Kay Edge led the development of full-size, 5 foot by 10 foot, structural, exterior exposed HCLT panels created from locally-sourced, low-grade Yellow Poplar. The panels were subsequently assembled off-site into two prefabricated modules joined by a heavy timber base frame, transported to the site, and attached by crane to a steel and helical pile substructure. The project was completed in 2021. The project has won local, state, national, and international design awards.

1.2 COURSE ORGANIZATION

1.2.1 Course Types

Upon the launch of the design project for the New River Train Observation Tower in Spring 2018, the two faculty leaders co-taught a graduate-level design studio, as well as co-taught a seminar course that paired students from the Department of Sustainable Biomaterials at Virginia Tech with graduate architecture students.

Figure 1: *View from railroad of completed tower*

Faculty from Wood Science, Timber Engineering, and Forestry were also involved in joint teaching sessions. The multi-disciplinary teams presented numerous design schemes to the City of Radford and received feedback. Over the forthcoming semesters, students across the

[1]Edward Becker, Virginia Tech, United States, egb@vt.edu

https://doi.org/10.52202/069179-0490

undergraduate and graduate curriculum were engaged in various aspects of the project. Third-year undergraduate students developed façade studies while graduate design-build students designed technical details for construction, for example. The faculty led the design development project phase and a graduate student assumed project and construction management responsibilities, as well as late-stage project design work for his M.Arch thesis project.

1.2.2 Concept and Schematic Design

The project site is located adjacent to Norfolk Southern rail lines, an industrial tar storage site, and an industrial access road. The site descends from the road level approximately 16 feet to the base of the structure, and subsequently another 20-25 feet to the rail lines. The students began conceptual design with the idea that the building should showcase the structural potential of softwood cross-laminated timber (CLT), as well as its warm aesthetic, by exposing the material on the interior and exterior of the structure. Following numerous design iterations over a multi-month period, the students created a design whereby the difficult site conditions could be managed through off-site prefabrication of timber modules. Two modules were to be constructed with CLT and were each approximately ten by fifteen by ten feet. The modules were to be placed atop both a steel (Module A) and concrete (Module B) substructure per site conditions. The modules were then designed to be bisected by a pedestrian bridge such that the bridge would serve as a structural datum tying the entire building together while also helping to minimize pendulum vibrations from foot traffic. Module A was designed to be 18 feet above grade and closest to the railroad tracks while Module B was designed to be two feet above grade and closest to the access road (see Figure 2). Both modules were to be built entirely of CLT. To reduce the potential for structural degradation over time, Module A was adapted such that it would be primarily supported by a heavy timber frame atop a steel, hollow tube substructure. If damage were to occur over time to the CLT, a new module could easily be installed to replace it.

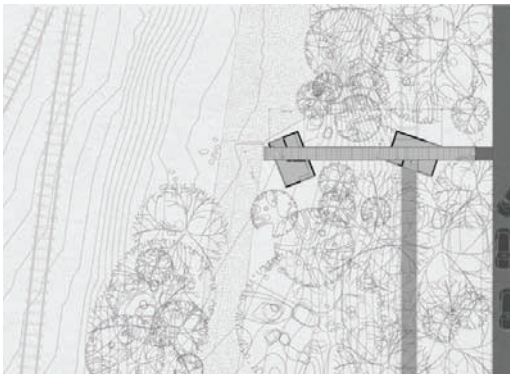

Figure 2: *Site Plan*

As the team moved closer to construction, it became apparent that softwood CLT would not be available regionally as wait times for production and delivery were significant. Additionally, CLT sourced from Canada, Europe, or the Pacific Northwest of the Unites States had such a high carbon cost for transport that it did not meet the sustainability goals of the design.

1.3 YELLOW POPLAR CLT DEVELOPMENT

1.3.1 Lab Testing Background

Due to the lack of softwood CLT availability, the project team consulted with faculty from the Department of Sustainable Biomaterials at Virginia Tech who had been intimately engaged with hardwood CLT research during prior years using locally-sourced Yellow or Tulip Poplar. Sustainable Biomaterial faculty had worked with the product at a lab-sample size and had not yet produced full size panels. A decision was made by the project team to develop full-size panels and apply them to the project based upon the lab-scale testing that the Sustainable Biomaterial faculty had undertaken. Their knowledge of the product was well developed. By 2018, Virginia Tech timber researchers in coordination with West Virginia University had published more articles on hardwood CLT than any other university unit globally for both Beech and Yellow Poplar based products. Their work focused specifically on the mechanical properties and yield analysis of Yellow Poplar CLT [1]. Even with that research background, when the author first began working on hardwood CLT with the Sustainable Biomaterial faculty, including Dr. Daniel Hindman and Dr. Henry Quesada, testing had only recently been completed at West Virginia University regarding Yellow Poplar CLT delamination and other key mechanical properties.

1.3.2 Mechanical and Structural Literature

Dr. Omar Espinoza and Dr. Urs Buehlmann have written about the "technical and economic feasibility" of hardwood CLT in the United States. They provide an overview of current applications of HCLT, including projects by Hasslacher Norica, Waugh Thistleton, and IDK [2]. Additional projects by Alison Brooks Architects and DRMM in the UK, in association with the American Hardwood Export Council (AHEC), have increased public attention on hardwood cross-laminated timber (HCLT) products. The Journal of Contemporary Wood Engineering article "The Quality Assurance of Tulipwood Cross Laminated Timber (CLT) for Multi-Ply" directly addresses AHEC's work with American hardwood in a British context [3]. Other recent research had been completed on the mechanical and structural performance of Yellow Poplar CLTs before the Virginia Tech project team attempted the production of a full-scale panel [4, 5].

Mechanical and structural testing by Dr. Daniel Hindman was key to the project team's product development work. The report "Mechanical Performance of Yellow-Poplar Cross Laminated Timber" (2015) by Milad Mohamadzadeh and Dr. Hindman was particularly useful as the purpose of the research was to "evaluate mechanical performance of yellow-poplar CLT as an alternative for standard CLT made of softwood species" [6].

https://doi.org/10.52202/069179-0490

Mohamadzadeh and Hindman tested "mechanical properties such as bending strength and stiffness as well as bond line shear strength and face delamination of three layered yellow-poplar CLT" to determine the product's feasibility for structural engineering applications [7]. They concluded that the "bending stiffness, bending strength and interlaminar shear capacity were significantly greater than specified values for Grades V1 and V2 in PRG 320" per ANSI/APA guidelines in 2012 [8]. Bending strength, bondline shear strength, face delamination, wood failure, and interlaminar shear capacity were deemed appropriate for HCLT structural applications, while the authors recommended further long-span testing and noted that relatively high glue failure was likely the result of the HCLT's uniquely high shear strength per the wood type, Yellow Poplar [9].

Notably, AHEC's "Tulipwood CLT Properties and Manufacturing Requirements" document, published September 2019, was created after the Virginia Tech project team had already settled on a product development path using Dr. Hindman's aforementioned research. AHEC's document, produced in coordination with the Centre for Offsite Construction + Innovative Structures at Edinburgh Napier University, the Construction Scotland Innovation Centre, and others, provides a thorough overview of the key considerations of Yellow Poplar CLT including sourcing, fabrication, and application. From procurement, pre-processing of lamellae, assembly, and post-processing, AHEC's document focuses on the production process in the UK in coordination with European Standard (EN) regulations. For the Radford project, many of the same production steps were followed. The manual would have been used by the project team if it would have been available at the appropriate time.

2 RESEARCH OBJECTIVES

2.1 DEVELOPMENT OF LOCALLY-SOURCED HCLT

Due to the availability of Yellow Poplar CLT manufacturing knowledge and the logistical difficulty to access softwood CLT, the project team chose to develop our own HCLT product using locally-sourced, low-grade wood. The project was an attempt to illustrate the economic potential for an overlooked and underutilized forest resource, low-grade Yellow Poplar, and also an opportunity to showcase the upcycling potential of under-valued local resources. The Virginia Tech team partnered with the Southern Virginia Higher Education Center (SVHEC) to produce the panels on the same equipment where the lab-sample panels had earlier been produced for structural testing. SVHEC's manufacturing facility was the only facility within a 300-mile radius of Virginia Tech's campus capable of pressing full-size HCLT panels. The facility had modified an industrial plywood press such that it was capable of achieving the required pressure to press the HCLT. Wood was sourced from multiple regional sawmills and refined on site at SVHEC. The boards were planed and aligned before gluing and pressing. After pressing, the rough-edge panels were cut on an industrial CNC. Unlike the Scottish production process for Multi-Ply's HCLT panels as outlined in the AHEC manufacturing document, SVHEC used a hydraulic press rather than a vacuum press.

Figure 3: *Advantage EP-950A glue application by student during assembly.*

While the panels looked factory finished after manufacture, the project team noticed 1/16" or less hairline gaps at the panel edges between lamellae. At the time, the project team assumed that there may have been a glue distribution error or a lack of hydraulic press pressure within two-inches of the panel edge. The latter was determined to be the issue and this gap later led to minor delamination of the product in south-facing, vertical applications. The HCLT panels were noticeably heavier and denser in comparison to a softwood CLT panel made of Southern Yellow Pine or Spruce-Pine-Fir. As such, project team needed to develop our own internal workflows to handle the panel finishing and assembly for panels with such unique properties, as well as work with our project engineer to make sure that the heavy panels were suitable for the modular construction methods that we planned to use per the difficult project site.

2.2 LOW-CARBON PROJECT LOGISTICS

Through the project partnership with the SVHEC, the project team was able to source local materials, use a locally-upcycled press, assemble panels within a 15-mile radius of the project site, and efficiently deliver and construct the tower. This highly-localized process can be compared to the primary alternative which would have entailed shipping panels hundreds or even thousands of miles to the project site while local, low-grade Yellow Poplar resources remained unused. The SVHEC manufacturing facility is housed in a former tobacco warehouse that was adaptively reused, thereby also lowering tangential carbon emissions compared to a workflow that used facilities with high-embodied carbon. In fact, the SVHEC facility will be prioritized for future projects simply because it aligns with the low-carbon, circular economy mission of the project and supports the

https://doi.org/10.52202/069179-0490

overarching goal of lowering carbon emissions holistically across the entire project ecosystem. The bullet points below list the 'project strategies' (PS) that saved operational and embodied carbon versus the 'typical alternative' (TA) to the relevant issue as shown below:

Radford Train Tower Carbon-Smart Strategies
PS1: Upcycling of tracked, local, low-grade timber
TA: Variable; Non-specific material approach
PS2: Layup conducted in low-embodied carbon facility
TA: Support of high embodied carbon facilities via use
PS3: High-efficiency, low waste, offsite assembly
TA: Low-efficiency, high waste, on site assembly
PS4: Design for replacement and disassembly
TA: Disassembled and discarded after useful life

Despite the successes of a highly localized material sourcing, upcycling, shipping, assembly, and delivery process, the project's carbon ecosystem could have been improved via the following 'strategies' (S):

S1: All-wood structure with replaceable foundations
S2: Use of hardwood-nail or dowel-laminated timber
S3: Use of a carbon-tracking digital management system
S4: Holistic use of renewable energy (saws, delivery vehicles, computers, etc.)

Underpinning all of the carbon strategies in the project is the modular approach to construction. If the project were site built, the project team estimates that even with all the realized and unrealized carbon-saving strategies aforementioned effectively implemented, the project would still be carbon positive simply due to the inefficiency of on-site construction. Tangential carbon emitting sources such as finishing materials (e.g., EDPM, adhesives, waxes, etc.) plus the inefficiency of labor (e.g., additional food costs, wear on vehicles from excessive trips to the site, etc) would offset the carbon saved for a project of this scale.

The project effectively accomplished multiple key carbon-reducing strategies, but there are also improvements that can be made. Through offsite manufacturing and descriptive material-IDs affiliated with each building product used, the entire construction process could be tracked and carbon inefficiencies reduced – see restado.de and Concular, as well as Madaster digital carbon management systems [10,11].

2.3 MODULAR CONSTRUCTION WORKFLOWS

2.3.1 Panel Preparation

Following the arrival of the HCLT panels at Virginia Tech's Research and Demonstration Facilty (RDF), each panel underwent a three-step process: (1) hard wax was applied to lamellae end grain; (2) pilot holes were drilled for the forthcoming 12" timber screws; and (3) certain panel faces were treated with a base coat of linseed-oil-pine-tar mix. As some panel end grain would be concealed by other panel faces after assembly, the end grain of exposed lamellae was treated in advance. The project team was concerned about water absorption through the end grain if the panel was immersed in standing water after construction on site. Pilot holes were drilled into each panel in a staggered manner so as to avoid the timber screws splitting the wood when installed. The pilot holes were drilled multiple inches away from the panel's edge and in a manner that would allow them to align with the adjacent lamella, as opposed to a glue joint.

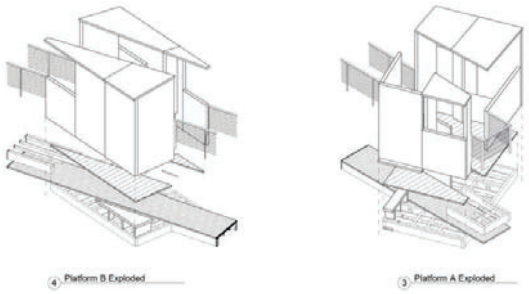

Figure 4: *Structural drawing of Module A*

Drawing upon the history of Virginia as a tar-producing state and the aesthetic and smell of the adjacent railroad tracks, the project team chose pine tar as the protective coating for the exterior of the HCLT. A 50% pine tar and 50% linseed oil mix was used to maximize the tar's penetration into the wood grain for maximum protection. Both the linseed oil and pine tar are natural products. The linseed oil significantly slowed the drying time of the pine tar application, but allowed for a deep grain penetration. The pine-tar-linseed-oil mix took approximately one week to dry per coat. The base coat was applied at the RDF facility and quickly soaked into the HCLT, forming a dark low-mess coating. Subsequent onsite applications were significantly slower to dry and were generally more messy to apply.

Figure 5: *Module A and B bisected by bridge*

2.3.2 Modular Construction

The modular assembly of HCLT panels occurred at RDF following panel preparation. The base of Module A was designed as a heavy timber structure for the following reasons: (1) a concern that the HCLT should not be the

primary substructure due to its exposure to the elements and potential to delaminate over time; (2) the structural need to support cantilevering elements of the module off the hollow-core steel substructure; and (3) the ease of structural attachment that heavy timber provided over a more thin, panelized timber product. The module assembly team was primarily composed of two people, a forklift operator and a labourer whose primary role was to stabilize the panel in place, fine tune its location with a rubber hammer, and screw the HCLT panel in place via the pilot holes. The HCLT was exceptionally heavy due to its density and therefore special consideration in regard to the forklift movement and driving surface needed to be considered. Due to the HCLT's eventual exposure to the elements, all timber screws were coated with liquid wax before being driven into the pilot holes. The project team took this unusual step to avoid water being sucked into each screw hole due to capillary action, thus leading to wood rot. By impregnating each hole with liquid wax, the project team sought to keep the screw holes free of water. A staggered screw placement allowed the HCLT panels to have an enhanced moment resistance when attached to the thick heavy timber beams. Each screw was determined by the engineer to carry 200 pounds of load and the screws were spaced approximately every twelve inches across the HCLT-to-HCLT and HCLT-to-timber joints.

Figure 6: *Wax application by student during assembly*

2.4 TRANSPORTATION AND ON-SITE LOGISTICS

Each timber module weighed in excess of 2,000 pounds. Module A was assembled offsite at RDF and transported via an industrial forklift and low-boy trailer to the construction site. Module B was partially assembled offsite before being transported to the site flat packed and assembled on site. It was determined that Module A was structurally robust enough for full prefabrication, transport, and crane assembly due to its 90-degree corner joints and HCLT interior columns. Module B was less rigid and prefabrication was determined to be detrimental to the assembly process.

Figure 5: *Industrial forklift transporting Module A*

3 POST-CONSTRUCTION VISUAL INSPECTION

3.1 OVERVIEW

The New River Train Observation Tower opened to the public in 2021. The author conducted a limited visual inspection in February 2023 to assess potential deterioration of exterior exposed HCLT, as well as any general aesthetic changes due to sunlight, freeze-thaw cycles, and insects. The project's modular design allows for the replacement of HCLT components. As such, regular visual inspections should be conducted to determine if any exterior-exposed HCLT elements need to be repaired or replaced. This visual inspection did not address the current structural condition of the tower as its primary objective was to denote the aesthetic changes that have taken place since construction completion.

3.2 DISCOLORATION

Despite the HCLT modules being protected with a pine-tar-linseed-oil finish on one face and a clear ASTM-D4446-rated sealant on the other, some discoloration of the wood product and finishes has occurred. The discoloration that has occurred is not unexpected for UV-exposed surfaces. The sharp black pine-tar-linseed-oil treatment has dulled to a dark gray or soft matte black finish. Multiple coats of the mixture were originally applied to exterior-facing elevations of the HCLT product and the treated surfaces held their color for the first year. It is recommended that the wood surfaces be re-coated every two years in the project's maintenance manual and it seems unlikely that such a re-coat has occurred. The faces coated with a clear wood sealer have maintained their warm, natural wood color, minus a slight dulling of the color from a soft brown to a warm gray or tan.

3.3 DELAMINATION

Perhaps the most serious visual change in the project observed during the visual inspection was the partial delamination of the outermost lamellae on south-facing HCLT panels wherein the outmost layer of lamellae is oriented vertically. Per prior text, the project team was concerned during the manufacturing process that the

https://doi.org/10.52202/069179-0490

custom-engineered press was not able to achieve the proper pressure on the outer two inches of each 5 foot by 10-foot panel. The project team hypothesizes that south facing HCLT panels receive a greater thermal load than other panels in the module and therefor the improper pressing process has led to micro delamination or cracking. The cracking has then allowed water to infiltrate and through freeze thaw cycles and has exacerbated the delamination. An alternate hypothesis is that the panels were already deaminating in a minor way when installed. Freeze-thaw cycles have therfore simply exacerbated cracks that were already present during manufacture. While the delaminating lamellae only have a maximum separation of .25 inches or less, maintenance will need to be performed before any additional separation occurs. The HCLT modules were prefabricated such that panels were oriented vertically as a means to align the strongest axis of the product with the highest tensile forces resulting from module transportation, each panel needing to be strong enough to support its own self-weight. Thus, the vertical panel orientation is better than a horizontal panel orientation at channelling rainwater away from the exterior seams of the lamellae, but there is still significant water exposure for the panel.

3.4 INSECTS

The author did not observe any modifications to the panels' physical integrity due to insect activity. The author was concerned about termite damage to the exterior exposed HCLT panels, but no evidence was present of any insect activity.

4 CONCLUSIONS

Through the achievement of the project's research objectives, the author and project partners were able to establish workflows for future projects that seek to utilize Yellow Poplar cross-laminated timber for modular, offsite construction. The built project illustrates the architectural and structural potentials for HCLT use in modular assembly workflows and confirms certain architectural and spatial potentials for the product, notably its free-span potential at a relatively thin cross-sectional thickness. Certain project decisions, including the use of a laminated product for an exterior application were justified due to the experimental nature of the structure and use of the structure as a prototype. However, the application of the HCLT product in a long-term or permanent use case wherein it is exposed to water, and thus freeze-thaw cycles, is not recommended, even with high-performance surface treatments. This follows common guidance on the use of structural, engineered wood products in exposed settings. The procedural decision to pre-drill pilot holes in the HCLT for wood screws to prevent cracking, as well as to impregnate the holes with a liquid wax, has proven to be a workable approach as confirmed by the two-year visual inspection. Lastly, but perhaps most importantly, the author recommends a highly-controlled fabrication/pressing process for any HCLT product that is produced in smaller factory setting less accustomed to industrial CLT standards and workflows. The production process can use AHEC's manufacturing requirements document as a guide. Quality control during a distributed manufacturing process is difficult to achieve, but necessary to ensure product quality and safety.

Figure 7: *Yellow Poplar CLT panels before surface treatment*

ACKNOWLEDGEMENT

The author wishes to acknowledge the seminal Yellow Poplar research by Dr. Daniel Hindman and Dr. Henry Quesada that underpinned the Radford design-build project, as well as the USDA's Wood Innovations program for early-stage research funding for HCLT development and testing. Additionally, key project partners including Walder Foundation Products, Henard Metal and Fabrication, the City of Radford, and Virginia Tech donors were key to the project's completion. The author would like to thank Professor Kay Edge, Robert Riggs, and Kirt Hilker for their project efforts.

MASS TIMBER, SMALL FORMAT: OPEN SOURCE FURNITURE PROTOTYPING FROM MASS TIMBER SCRAPS

Cory Olsen[1], Linda Zimmer[2]

ABSTRACT: In assessing current mass timber manufacturing practices, the project team has identified an opportunity to generate well-designed human-scale furniture pieces from commonly occurring small sized offcuts in the factory setting. Typically destined for biomass/cogen or even the landfill relative to local environmental legislation, the possibility of upcycling these scraps by creating furniture instead preserves more embodied energy and sequestered carbon, and may generate additional profit as a value-add offering for mass timber manufacturers.

Through partnerships with the Tallwood Design Institute/Emmerson Lab of Oregon State University as well as DR Johnson Wood Innovations in Riddle, Oregon, the research team has produced both digital as well as built prototypes to test production viability and market interest. With an eye towards open source file sharing, the long term goal is to provide designs to interested mass timber manufacturers in order to reduce unnecessary material inefficiencies in the mass timber production cycle. One of the built prototypes has already gained considerable traction and was showcased at WantedDesign's LaunchPad as part of ICFF (International Contemporary Furniture Fair) NYC in May 2022.

KEYWORDS: Upcycling, Furniture, Offcuts, Value-Add, Open Source

1 INTRODUCTION

By way of a hypothesis from individuals not intricately involved in the mass timber industry, the research team speculates that mass timber manufacturers must inevitably generate an assortment of scraps as panels are sized and architectural fenestration is accommodated [1]. In speaking with industry experts we discovered this to hold true and found that from lack of alternative, current practices relegate this material to indeterminate long term storage, chipping, incineration, or landfill. We propose that an opportunity exists to translate some portion of this remaindered material into useful, well designed furniture pieces and preserve the embodied energy contained in the mass timber product.

2 INDUSTRY INTERVIEWS

To date the research team has interfaced primarily with three entities for interviews on material, production, and life cycle: the Tallwood Design Institute of Oregon State University, Freres Lumber in Lyons, Oregon and DR Johnson Wood Innovations in Riddle, Oregon. These represent two key profiles in the mass timber ecosystem: a research lab and two manufacturers- one of mass plywood and the other of CLT.

2.1 TALLWOOD DESIGN INSTITUTE

TDI hosts a variety of mass timber research projects across various scales in its Emmerson Lab, from small CLT sample chunks for mold and mildew testing to multi-story structural assemblies on a seismic table. The materials used in these mockups and tests have little to no application after they have served their initial research intent. In speaking with then-Technical Manager Jörn Dettmer we found that most material would be relegated to the landfill as local environmental codes limited opportunities for incineration due to the adhesives present across the various materials in the lab (CLT, MPP) [2]. As part of the lab's research posture, they have a suite of fabrication tools available including a small format CLT press, an Italian Biesse CNC panel cutting machine, and a track mounted KUKA industrial robotic arm with a positioning table.

2.2 FRERES ENGINEERED WOOD

Freres is a central Oregon plywood producer that expanded their facilities to become a domestic producer of mass plywood panels in 2017. Speaking with their design and engineering team gave the research team key insights into their (proprietary) target efficiency goals for each architectural project regarding percentages in panel efficiency. Additionally, we were provided an informative disclosure of how they currently address

[1] Cory Olsen, Department of Interior Architecture, University of Oregon, United States, coryo@uoregon.edu
[2] Linda Zimmer, Department of Interior Architecture, University of Oregon, United States, lzimmer@uoregon.edu

https://doi.org/10.52202/069179-0491

scraps- thin panel clean-ups are collected and periodically taken to their offsite facility for cogen electricity production, while larger scraps are piled and covered in their yard for long term storage, Figures 1,2. The larger pieces are occasionally informally sold to local DIY-minded fabricators but there are no recurring outlets for the large scraps to be repurposed at the moment.

***Figure 1**: Thinner and small scale scraps of MPP suitable for chipping and cogen collected at Freres' Cedar Mill facility.*

***Figure 2**: MPP saved scraps, of a scale and dimension suitable to furniture reuse but irregular and impractical for building applications.*

Freres utilizes a German made Weinnman 5-axis CNC to size and cut their panels.

2.3 DR JOHNSON WOOD INNOVATIONS

Following an industry presentation of our research hypothesis, Levi Huffman of DR Johnson Wood Innovations reached out to the research team. He confirms that DRJ has been looking for ways to utilize scraps generated in their CLT production line [3]. Equally interesting, we were informed that some panel waste is necessary in their production to maximize press efficiency when transitioning between orders by gluing multiple 3 or 5-ply panels simultaneously even if the additional panel width exceeds project spec. In our eyes, this material is prime grounds for furniture forms that can take advantage of CLT spanning abilities, such as elongated benches for public lobbies and school projects.

DR Johnson utilizes a German Hundegger CNC panel cutter.

3 DESIGN THINKING

3.1 MATERIAL PROPERTIES

To design viable furniture proposals, the research team first assessed the material properties of CLT and MPP. Key considerations throughout the design process have been material visual scale, volumetric weight, standard thicknesses, and sound joinery detailing. Material consistency, particularly in CLT, is understandably variable and designs have sought flexibility in accommodating surface gaps, voids from wanes, and a minimization of slivered remnants from certain cut angles and depths. As CLT is not edge glued there is a certain risk that some acute cuts may result in unadhered geometries. Mass plywood is available in an array of thicknesses beginning at 2" up to 24" in one inch increments, while CLT is assembled in odd number plys, most commonly in 3-ply which is approximately 4" or 105mm. While mass ply can be considered more-or-less uniform for designing joinery, the scale of the alternating laminations in CLT requires that grain direction and board orientation be thoughtfully considered.

3.2 MANUFACTURERS TOOLING

Our designs operate under a basic assumption that mass timber manufacturers will have tooling on hand to create cuts in panels for overall sizing, craft bevels/miters, and cut out openings (either via plunge saw or router milling heads). The OSU Emmerson lab additionally has a KUKA robotic arm which has been utilized for prototyping but may exceed a baseline manufacturing ability expectation.

Our interviews with mass timber manufacturers regarding their tooling abilities and strategies was very illuminating. While our proposal for utilizing scraps was widely well met, a variety of potential obstacles presented including:

- A CNC bottleneck in current existing production slows jobs and additional machine time for

https://doi.org/10.52202/069179-0491

furniture components would have to be well justified. Minimizing tool changes and optimizing for fast cutting operations would alleviate- routing a profile takes considerably longer than rip cuts with a circular blade, for example.

- Small scale objects present an operational challenge relative to the CNC panel cutter setups. Panels are supported by spaced bucks with sacrificial cutting layers, but small components could potentially occur between supports. An object cut free could pose an operational risk if it were to bind with a cutter head if unsupported. As a result, machine operators will sometimes prefer to "dust" smaller areas to avoid captured objects and tabbed elements that could bind in the CNC
- For torsional integrity during installation, some panels will ship with openings still tabbed in place, effectively removing the scrap from the factory and placing it at the jobsite where it may be more challenging to recapture.

3.3 PRECEDENT

As mass timber panels are a relatively new building material, there are understandably few direct precedents for mass timber furniture. One notable collection is the Pipedreams set of residential scale pieces by Douglas & Company based in Cape Town [4]. Their pieces utilize reclaim material from an architectural project and manifest as a daybed, bench, and stool.

The mass of our potential pieces led us also to various precedents of other wooden construction, with significant relevance towards laminated plywood constructions and milled solid timber pieces. Similar in form to the Squall is Nadaaa's Bob Sidetable, constructed from a billet of laminated plywood pieces and milled [5]. Bernard Cache and Patrick Beauce's Objectile outputs are another CNC produced form of laminated and formed plywood construction [6]. The studio furniture of the late Wendell Castle reveals a more intuitive approach to a stereotomic carving of wooden mass [7]. And recently the works of Gareth Neal such as his Hack Chair and Of Cuts series emerge from a starting point of mass [8].

4 PROTOTYPING

4.1 DIGITAL MODELS

The research team initially develops digital proposals to explore aesthetic quality, scale, material relationships, and joinery. These models are created as 3D digital forms in Rhino, which allows for volumetric file sharing through a variety of file extension types (OBJ, STL, DXF, SAT, etc). This flexibility allows reasonably easy interface with a variety of CAM software that may be used across the mass timber manufacturing spectrum. Beyond a proof of concept in generating prototypes, our goal is that panel manufacturers can incorporate these component cuts into their active production lines as an open-source design sharing model and fabrication opportunity.

Through the use of rendering software such as VRay, materials are accurately mapped to test the visual character of each piece, Figures 3,4. Renderings also enable a discussion with manufacturers in regards to parts orientation and grain direction, again particularly relevant when considering CLT and joinery, Figure 4,5.

***Figure 3**: Mesa Bench visualization*

***Figure 4**: Facet Table visualization*

***Figure 5**: Facet Parts illustration for visual communication to saw operators*

4.2 TDI EMMERSON LAB : SQUALL STOOL

Capitalizing on the availability of the Emmerson lab KUKA robotic arm, an initial prototype was produced that leveraged the tools spatial flexibility to create a complex undulating surface, Figure 6. Named the Squall Stool, see: Figure 7, the piece consists of a stack lamination of four pieces of 3-ply CLT milled to a compound flowing

surface. The design is parametric in nature, such that every stool produced can easily incorporate formal variations for each to be unique within a family of serial difference. The Squall was recently shared with an international audience at the 2022 ICFF as part of WantedDesign's LaunchPad prototypes feature.

***Figure 6**: KUKA robotic arm milling Squall prototype*

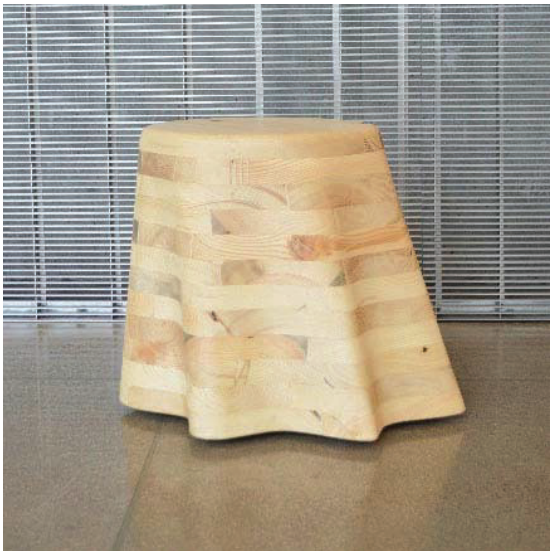

***Figure 7**: Squall Stool*

The Squall took approximately 7 hours to mill on the KUKA as an initial prototype run. While a considerable amount of time, in the lab setting the machine is rarely occupied and this form is a capitalization of its abilities and components, including the positioning table for milling pieces in the round. With further experience, refinement and optimization the milling time could be reasonably expected to reduce.

The stool sits on 5 rotational casters for ease of movement. The recesses for the casters were machined by hand while the team was iterating through options, though these also offer an opportunity to leverage the KUKA while the piece is being fabricated.

As a furniture piece the Squall provides an ergonomic seating height at 16.5" suitable for table height work and casual use, figure 8. It can easily serve a secondary role as a side table as well. Aesthetically the smooth surface provides a novel visual to the CLT where the 90 degree alternating laminations blend smoothly from edge grain to end grain. Each milled blank will reveal a different grain pattern and coloration adding to the uniqueness of the serial family.

***Figure 8**: Squall in use*

https://doi.org/10.52202/069179-0491

4.3 TDI EMMERSON LAB : THE "SUITCASE"

Following the success of the Squall, an additional prototype the "Suitcase" has been produced with the assistance of the TDI labs, Figures 9, 10, 11. Recognizing that the utilization of the KUKA may exceed industry capabilities, the design team shifted our focus to the panel CNC. The "Suitcase" as it is currently codenamed represents a culmination of our learning since embarking on our mass timber furniture research. The design consists of four bevelled CLT strips that are assembled together into a single mass. The component widths are sized to take advantage of linear narrow scraps, such as those common in the DRJ production when they are pressing multiple panel specs in job transitions. The components are cut with a vertical or bevel rip cut, utilizing the circular blade of TDI's Biesse CNC machine. The length of the suitcase can be anything from a single seat to the full length of a mass timber panel. From an efficiency standpoint, longer lengths negate concerns about pieces being unsupported by the saw bucks. Each rip cut takes from seconds to minutes, adding a minimal amount of machining time to any job. The small single seat Suitcase was assembled using Domino XL joinery and adhesive, while a larger prototype has been assembled using CLT wood screws. On reflection, using wood screws has benefits of allowing lighter individual parts to be transported and assembled on site quickly with tools that will already be in use. Parts could be delivered pre-sanded and prefinished or completed on location.

After lamination, a simple bent steel backrest is bolted on along with a linear dimensional lumber lumbar support, maintaining the SPF materiality of the CLT itself. Similar to the Squall, the individual Suitcase rests on four recessed casters to allow an ease of movement despite the overall weight of the piece. For longer runs of the Suitcase a fixed foot strategy would be utilized to make it into a stationary monumental installation.

***Figure 9**: Suitcase parts at TDI fresh from the Biesse Saw*

***Figure 11**: Suitcase in use. Bevel angle allows for natural footrest and backrest placement.*

https://doi.org/10.52202/069179-0491

4.4 DR JOHNSON

In partnership with DRJ, files have been shared so that they may pursue factory produced prototypes. These are generated in between panel production runs at the discretion and availability of the saw operators. One design has been produced in multiple, the Torii Bench as shown in Figure 12. Additional pieces are available in their queue and will be produced as their fabrication schedules allow. This includes designs from a family of related forms named the Capsule Collection, see Figure 13.

Figure 12: *Torii Bench cut and assembled by employees at DR Johnson's Riddle, OR location.*

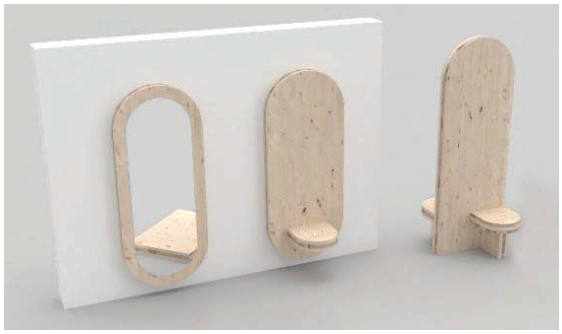

Figure 13: *Capsule Collection showing wall mounted mirror, seat, and freestanding 'Tete a Tete' chair sharing a common pill shape feature geometry.*

5 FUTURE-CASTING

5.1 DESIGN FOR DECONSTRUCTION/DISASSEMBLY

One of the leading arguments for the environmental benefit and sustainability of mass timber architecture is its ability to sequester carbon [9]. While most mass timber structures are too recent to be facing replacement those days will inevitably come. The tectonic nature of mass timber assembly can lend to an organized disassembly enabling building elements to be recaptured and reused [10]. Ideally architectural panels could be recycled into new architecture but this would require a considerable amount of planning, anticipation and execution. The research team proposes that a highly flexible secondary application for recaptured mass timber would be furniture scale objects. Oddly shaped, unique, or damaged panels could be reasonably easy to optimize through parts nesting, with the majority of the sequestration volume left intact.

6 CONCLUSIONS

Scraps and offcuts are known to occur in mass timber production though current means of utilizing these are limited. Furniture design prototypes have been produced as a means to upcycle and preserve the embodied energy of these materials, and the research team hopes to involve more interested manufacturers to reduce waste stream volumes while providing functional, aesthetically pleasing furnishings to projects. Further, as mass timber constructions reach their end of life, the potential for reuse increases with avenues such as furniture and products.

CARPENTER AND ROBOT: HOW TO BENEFIT FROM THE KNOWLEDGE OF CRAFTSMEN AND THE STRENGTH OF ROBOTS

Wolfgang Schwarzmann[1]

ABSTRACT: In this research project, the working process of carpenters using a CNC joinery robot was observed, documented and evaluated on the basis of a small building, the *'Werkraum Häuschen'*. Designed as a building made of traditional timber joints, the entire construction was produced on a modern CNC joinery system. Under aspects such as the utilization of mono materials, simplified disassembly and reuse, as well as the need for later deconstructability, the wooden knots proved to be functional and resilient. According to interviews with the craftsmen, not only the skills of experienced carpenters but also the advantages of a modern CNC-joinery machine contributed significantly to the success of the project.

KEYWORDS: CNC robot, craft, carpenter, tradition, human-machine interaction,

1 INTRODUCTION

The profession of carpenters has always been in a constant process of change parallel to our society [1,2]. While in former times purely manual work was significantly changed by the emergence of metal tools, steam power and later on electricity, today, a major driver in this process of change is computer-controlled joinery robots [3]. By opening up new applications, these machines offer additional possibilities from the construction and design perspective. While a lot of research projects start from a process optimisation perspective when considering new digital tools [4,5,9], the focus of this paper is on the merged potential of the craftsmen's knowledge and the opportunities offered by joinery machines. As described by Nonaka and Takeuchi, craft professions involve profound tacit knowledge [6], and therefore it is highly relevant to not only conduct research on new applications but also on the context of knowledge generation and manufacturing processes from a craftsman's perspective. In the context of this research, tacit knowledge and the associated perception of the craftsman is explored and discussed in relation to the contemporary technological developments of a cnc-joinery robot.

1.1 NEW SKILLS UNDER AN OLD LABEL:

With a history of more than 7,000 years, the craft of carpentry can look back on a long and dynamic history [1]. Besides the historical evolutionary stages related to steam engines and the introduction of electricity, digitalisation in the craft of carpenters can be considered as a further, fundamental moment of transformation [3]. While craftsmen once had to prepare raw tree trunks themselves, nowadays they can access an almost infinite range of electrically powered and digitally controlled tools. Today, modern joinery robots and corresponding CAD systems mean that much of the work that once had to be done by hand is now done by digitally controlled machines. Apart from these technological changes, wood has remained central as a building material over all that time. A rather similar situation can also be observed in the job description. Although the work of the craftsmen has changed fundamentally, we still refer to them as carpenters today.

This changing field of work for carpenters was already examined in connection with their working process [7], their tradition, and the role of the technologies involved [8]. In this paper, we examine the task of the craftsmen and how they experience their work alongside the joinery robot.

1.2 A MOBILE STRUCTURE MADE OF WOOD

As part of the exhibition Constructive Alps 2021, the *'Werkraum Häuschen'* was built at the *Werkraum Bregenzerwald* in Andelsbuch in autumn/winter 2021. The region of the Bregenzerwald in Vorarlberg, Austria, is known for its timber construction culture and its high regard for craftsmanship. A debate concerning modern manufacturing methods and traditional craft culture is particularly exciting in this region.

The *'Werkraum Häuschen'* (Figure 1) is a small, mobile building, constructed from solid wood. The intersections and corner joints were resolved as pure wood-wood joints. Fully erected, it measures 5.50m x 2.80m x 4.36m (l/d/h). The locally harvested, sawn and dried wood (within a radius of 18km) was processed on a joinery robot. The connections were designed and manufactured as dovetail joints, mortise-and-tenon joints or similar. In the manufacturing process, great care was taken to use traditional, i.e., once commonly used, timber connections, whereby these connections were now fabricated by a joinery robot. All parts were manufactured on a state-of-the-art joinery machine, a Hundegger 'Robot-Drive'

https://doi.org/10.52202/069179-0492

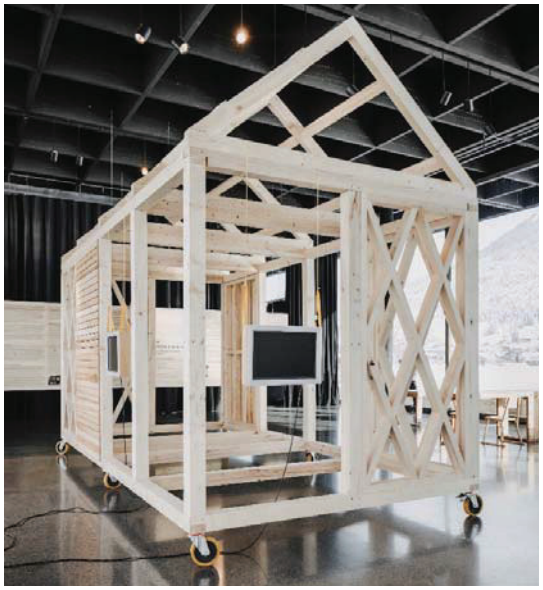

Figure 1: *The 'Werkraum Häuschen' a modular wooden construction kit, after completion, ready for the upcoming contributions of the craftsmen*

1.3 THE WORKING PROCESS AS FIELD OF RESEARCH

As an essential part of the qualitative research work, the construction process was documented with photos, video and audio, and then transcribed. In just one day, the structure was assembled and erected by 3 craftsmen (1 craftsman and 2 trainees) as well as the author himself (Figure 2).

Figure 2: *A carpenter assembling the wooden frame. The complicated connections in the frame are still visible.*

After approximately 3-4 weeks, all the craftsmen that had worked on the project were invited to participate in interviews. They were asked about the manufacturing process, sharing their insights concerning the challenges but also the positive qualities related to the robotically manufactured construction components. The interviews were supported by drawings of the construction as well as a time-lapse video of the construction process and photos of the assembly. It was intended to spotlight the assembly process once again. In addition to the 3 assembling craftsmen, the two CAD draftsmen responsible for the working plans but also for programming the joinery robot were interviewed. This wide range of audio and video material formed the basis of this research work.

1.4 A JOINT DESIGN AND PLANNING PROCESS:

Based on an initial meeting with a team of curators and carpenters, a simple CAD sketch was developed. This sketch already illustrated the requirements for the finished project without detailing the timber construction.

The basic principles of the concept sketch were:

- **Simple load-bearing structure:** the geometry of the building is formed by a simple load-bearing system made of wood. Similar to a shelf, the supporting structure is intended to form the framework for the contents.
- **Modularity:** Modules will be inserted into this supporting structure by the craftsmen. The individual wall, floor and ceiling modules should be insertable at any desired position.
- **Mobility:** The finished building should be just large enough to be transportable by truck. This building should be able to function in a variety of places. Wheels on the underside allow an uncomplicated positioning of the building.
- **Circularity and deconstructability:** All solutions for the project should be developed under the aspects of circularity and deconstructability. If possible, hybrid materials like glued beams or plywood should be avoided. The individual modules should be reusable for other purposes later.

2 METHODS

Based on these principles, several workshops and discussions were organised with the carpenters. Step by step, the craftsmen worked out the individual details. In the process, attention was paid to ensuring that the experience, the expert knowledge, and ideas of the carpenters could be implemented as effectively as possible while relying on the 4 basic principles.
The resulting sketches and CAD drawings, as well as notes from discussions were recorded and integrated as data for the project. Over the duration of approx. 8 weeks, a design was developed that could then be manufactured on a CNC joinery system (Figure 3).

https://doi.org/10.52202/069179-0492

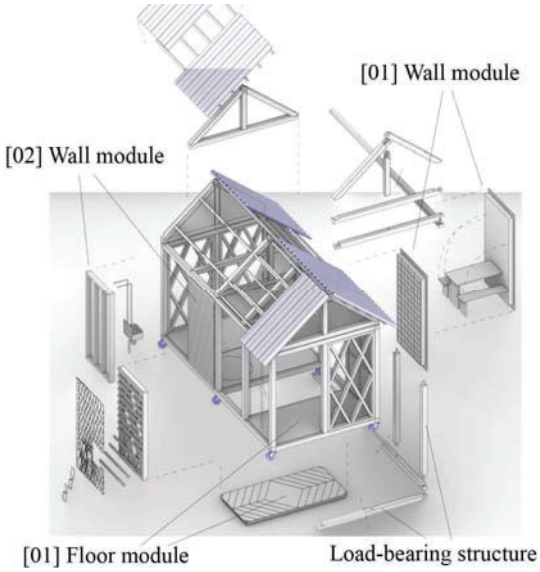

Figure 3: *Modular, dismountable and transportable; the small house was designed to work in different application scenarios.*

2.1 MANUFACTURING OF COMPONENTS AND CONSTRUCTION:

All parts of the supporting structure (columns, bottom plate, roof structure etc.) were manufactured on a 'Hundegger' joinery machine. The previously discussed construction details like dovetail, tenon, groove etc. were adapted and translated by an experienced carpenter to the technical possibilities of the machine. In order to be able to use mono materials and deconstructable connections, all the corner joints were designed as pure wood-wood connections. As a result, it was possible to omit further steel parts from the load-bearing structure. The stability of the construction was made possible by interlocking rhombic lattices that were installed as frames at each corner. At some points, the construction was stabilised with screws for safety and transportation reasons. The 6 wheels were also fixed with 4 screws each. The spruce wood was harvested in the region (12km distance) and stored and dried directly in the carpentry workshop (0km). A young carpenter operated the joinery robot and selected the raw wooden beams for their quality, as not all wooden logs offered the same properties in terms of straightness and stability. The finished beams were then delivered to the *Werkraum Bregenzerwald* (6km distance).
In a joint work process (1 carpenter, 2 trainees and the author) it was possible to erect the construction within one day. None of the carpenters who erected the structure at the *Werkraum Bregenzerwald* had been involved in the planning process before. This decision was intentional, as it meant that it was the first time for them that they came into contact with the project. This division between the planning and the construction process was made intentionally. Due to this separation, the craftsmen's comments during the construction were particularly interesting. They had to rethink the construction plans, the building parts and the construction process and develop their own approach to the project.

Figure 4: *The assembly of the wooden construction was completed within one day by 4 people.*

2.2 DEBRIEFING WITH CRAFTSMEN:

About 3 weeks after the completion of the construction, the craftsmen were interviewed in a semi-open interview to discuss and share their perspectives on the project. The interviews were supported by a video (duration 2:25 min.) showing the construction process of the building and by a selection of pictures illustrating the fabrication process (approx. 20 photos). The persons were interviewed in small groups and divided into 3 main work themes: (1) CAD and workshop drawing; (2) programming and application of the joinery robot ; (3) assembly and erection of the construction. The individual craftsmen were asked about their role as craftsmen in the process, how they used their expertise, and what the work process with a joinery robot meant to them.

Referring to the following research question, the collected data were transcribed, coded and analysed accordingly:

What are the perceptions of timber construction experts in the work process with a joinery robot in the development of alternative timber joint details.

3 RESULTS

Considering the collected data and the question defined above, 3 main phenomena could be observed:

3.1 THE RIGHT TOOL, AT THE RIGHT TIME:

One main observation was that the craftspeople always had to decide which tool would provide a good and correct solution at the right time. This situational problem-solving competence can be seen as a key component in the success of the project and ultimately as a crucial skill of their

https://doi.org/10.52202/069179-0492

profession. Whether the tool selected was an electrically powered circular saw, a manually guided plane or a digitally controlled joinery robot was of secondary importance to the craftsmen. For example, it could be observed that although the joinery robot is capable of producing complex solutions quickly and efficiently, the interviews revealed that the correct positioning of an appropriate timber joint was based on the expertise and experience of the CAD draftsman.

Figure 5: *Angled and sloping tenons are not a time-consuming challenge for the machine. However, most tenons still had to be cleaned by hand to ensure smooth assembly later.*

With his knowledge as a carpenter and a CAD draughtsman, this expert had previously designed the building in his head and simultaneously step by step on the computer. Thanks to his experience as a craftsman, he was able to imagine the subsequent assembly process in working-stages and thus could optimise it correspondingly. The joinery robot was then able to perform the job in a comparably short time. For the craftsmen, this computer-controlled production of the components was a significant reduction in their workload. However, as they explained in the interviews, the robot did not do anything that they could not have done themselves in a more manual process.

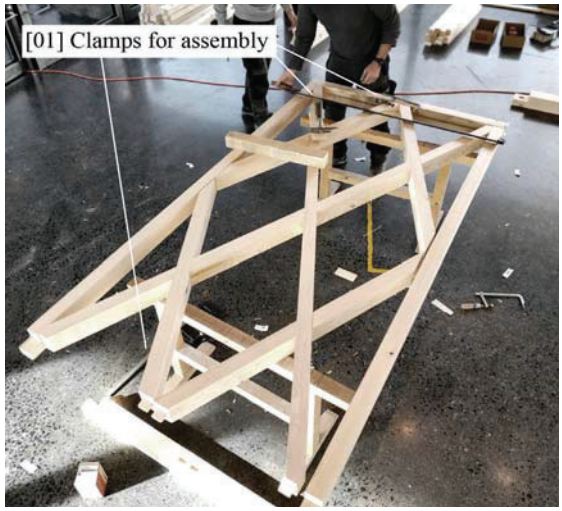

Figure 6: *At the right time, in the right place; the skilled application of screw clamps is crucial when it comes to precise assembly. The CNC robot is quick and accurate, but the assembly of the parts is still demanding.*

3.2 EARLY COMMUNICATION IN THE PROJECT PLANNING

Several rounds of talks were held with the project participants before the first CAD drawings for the joinery robot were produced. These preliminary discussions about statics, structure, construction, and design clarified and fixed fundamental details at an early stage. This preliminary coordination between the project participants demanded knowledge and experience from everyone involved. Problems that occurred later during assembly can be related to late involvement in the project or an inadequate flow of information. For example, a timber beam was installed in the wrong place during assembly. Except for 3 small boreholes, the column also fitted in the other place. Interestingly, the craftsmen already realised this irregularity during assembly and mentioned that the joinery robot must have made a mistake. Afterwards, they simply drilled some additional holes by hand. It was only at the end of the project that it turned out that two columns had been mixed up. This situation might have been avoidable with more accurate coordination, simpler drawings and a correspondingly more intuitive labelling. However, it was also impressive to see how the craftsmen solved the apparent machine error in just a few moments and then continued with the process.

https://doi.org/10.52202/069179-0492

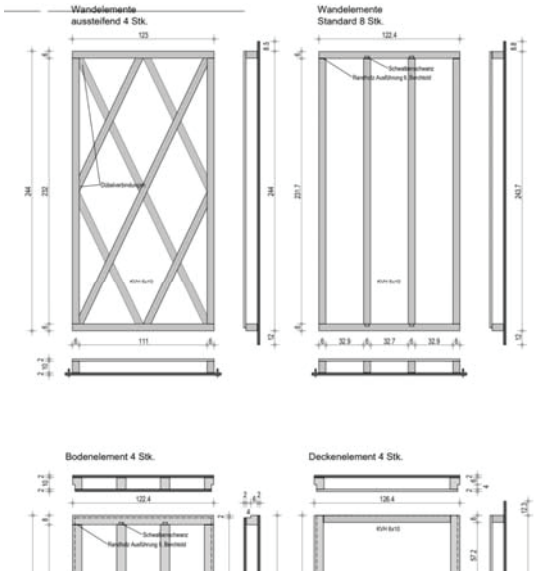

Figure 7: *Sketches, construction drawings, 3D plans; and in-between, there were meetings and discussions. The early and intensive exchange between all the project participants contributed significantly to the success of the project.*

3.3 MAN AND MACHINE COMPLEMENT EACH OTHER

As all the project participants mentioned, the craftsmen would have been able to produce the *'Werkraum Häuschen'* even without a joinery robot. The complexity of the project and the wooden details in the process are time-consuming in most cases, but in terms of production geometry they are not exceptionally complex. The project has shown the importance of the carpenter's expertise, both on the computer and in assembly. In addition to these cognitive skills, it was also the strength, speed and precision of the joinery robot that provided space for the valuable human resources. Because of the mechanical manufacturing, tenons traditionally designed as angular were realised in a round shape. Therefore, there was an adjustment of the timber construction geometry in favour of the machine production. Unfortunately, this geometrical solution could not be applied to all details. Since a joinery robot is not able to produce sharp-edged inner corners (Figure 8; '*[01] Remaining piece'*), the craftsmen had to rework them with a chisel and hammer and with an oscillation tool (Figure 9).

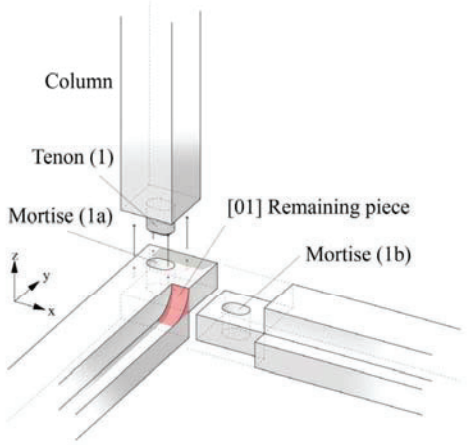

Figure 8: *Due to the technical limitations of the CNC joinery machine, the red corner had to be reworked by hand.*

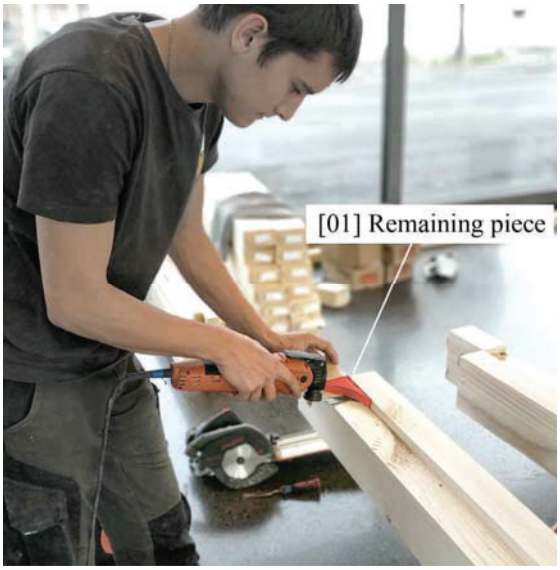

Figure 9: *During assembly, the remaining piece was removed by hand with an oscillating tool.*

In this case, it would not have been possible to simply modify the geometry, as in the case of the tenons. The joint work process, i.e., rapid production on a joinery robot and completion by experienced craftsmen, proved to be an effective and favourable solution in this case.

4 DISCUSSION AND CONCLUSION

In this paper, the question was asked how carpenters perceive their work in relation to a joinery robot in an exploratory construction process, the *"Werkraum Häuschen"*.

Where do the carpenters see their human skills as a key strength, and what kind of work can be performed efficiently and effectively by a joinery robot? As the results illustrate, the carpenters' expertise in the areas of assembly and construction is essential, regardless of

https://doi.org/10.52202/069179-0492

whether they are working with a hand-held circular saw or a joinery robot. This knowledge is central in the project discussion, the creation of the CAD plans, and the production on the joinery robot as well as the subsequent assembly.

While in this case a purely manual production of the construction would have been too time-consuming and therefore too expensive, the joinery robot was able to produce the laborious timber joint details quickly and efficiently. Furthermore, the joinery machine can be seen as a physical extension of human capabilities. Traditional timber joints could be interpreted and translated in a new context, where the strengths and expertise of the craftsmen were shown to be a key competence. The joinery robot and the corresponding software package can simplify and speed up work processes, but the underlying skills of the people operating the machine remain a key resource in this process.

With regard to future developments in timber construction, the question can be asked how the profession of carpenters will continue to change, what role their knowledge and experience will have in the process, and where new necessities will arise.

5 OUTLOOK AND LIMITATIONS:

As the project review has shown, there are certainly further, more detailed options to be explored in the project. Due to the very tight schedule of the project, new wooden beams were used. Retrospectively, the use of already used wooden beams from, for example, a demolished building would have been a significant enrichment to the findings. Furthermore, a consequent expansion of the wooden joints would be conceivable. In a next step, it would be conceivable to replace the screws used with wooden solutions such as wooden nails or similar. Another point worth exploring would be to optimise the geometry in order to further benefit from the potential of the joinery machine. Due to the limited time available, the focus was placed on the joint working process of developing and implementing pure timber joints and the subsequent assembly process.

ACKNOWLEDGEMENT

This research project was funded by the Research Promotion Fund of the University of Liechtenstein (FFF). New insights were gained as part of the project *'Digitale Meister'* (Digital Masters). Furthermore, we would like to thank the craftspeople and the *Werkraum Bregenzerwald* for supporting this project.

A BIM-BASED MODULE DESIGN METHODOLOGY FOR THE ROOF PLANNING OF MODERNIZED KOREAN TRADITIONAL WOODEN BUILDINGS

Dongwook Kim[1], BongHee Jeon[2*], Gee Heon Kim[3]

ABSTRACT: This study proposes a design methodology for modernized Korean traditional wooden buildings, *modernized-Hanok*, with a roof-*Kan* module based on parametric design. In the *modernized-Hanok*, the subordinate relationship between the body and roof structures has been diminished. Therefore, the purpose of the design methodology is to provide a tool that allows designers to plan the roof-frame structures unconstrained by plane shapes using Autodesk's Revit. Once the user determines the desired roof type, purlin number, module size, and reference dimensions, the parameters of families in the module interact with each other with functional formulas. As a result, the roof-frame module is automatically placed at the designated position with the appropriate roof shape. This module-based methodology provides users with a high degree of freedom in design.

KEYWORDS: Korean traditional wooden buildings, Roof-frame, Module design, *Modernized-Hanok,* BIM

1 INTRODUCTION

The *Hanok,* a Korean traditional timber-frame structure created by assembling elements, is one of the most challenging architectural types in terms of design, modeling and construction due to its atypical morphological characteristics. Recently, to overcome the difficulties of planning and constructing *Hanok* and to promote its market expansion, R&D projects for modernizing *Hanok* have been actively pursued, with efforts to create an environment that allows for more convenient design and modeling while securing structural and construction performance [1, 2].

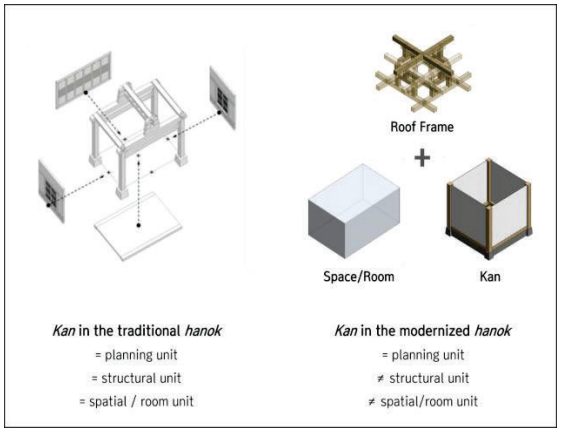

Figure 1: *Concept diagram of Traditional Korean House(Left) & Modernized-Hanok(Right)*

The research of design and modeling methodologies laid the groundwork for the *modernized-Hanok* and securing the structure and construction performance. The precedent *Hanok* BIM design methodologies are as follows. First is the member-unit design methodology, in which the modeling data is completed by stacking members [3]. Second is the joint-unit design methodology, in which the joinery is constructed by assembling members and placing the modeling data [4, 5]. The third is the integrated *Kan* unit design methodology, in which a *Kan* is an integrated unit of the shape of each member and joinery and surface elements such as floors and wall libraries [6]. The limitation of these methodologies is that they focus on the modeling process rather than the design process; therefore, they deteriorate the ability to respond to design change with a low degree of freedom.

In contrast to the precedent methodologies, the research team proposed a 'module-based design methodology' as a solution to the fragmented modeling-based design process. With the 'module-based design methodology' presented, the research team recently developed a '*Hanok* BIM Design Support Program' that allows the users, including both experts and non-experts to approach the *Hanok* design process in a more user-friendly way and contribute to the revitalization of the *Hanok* industry with the support of the Ministry of Land, Transport, and Maritime Affairs of the Korean Government.

The overall design process of the '*Hanok* BIM Design Support Program' is carried out through the arrangement of the modules. Meanwhile, the simple repetitive arrangement tasks, which do not correspond to the

[1] Dongwook Kim, Seoul National University, Republic of Korea, kdwooks@gmail.com
[2*] Contact Author: BongHee Jeon, Dept. of Architecture and Architectural Engineering · Institute of Construction and Environmental Engineering · Institute of Engineering Research, Seoul National University, Republic of Korea, jeonpark@snu.ac.kr
[3] Gee Heon Kim, Seoul National University, Republic of Korea, aiden.gkim92@gmail.com

https://doi.org/10.52202/069179-0493

designer's substantive design tasks, fall within the scope of automation. For example, the beginning of the design process provides an environment in which modules could be used to derive various plans using the spatial module. Then, the roof frame module is placed on the rectangular grid system of the building, completed with the spatial module, and an independent roof structure is created with members such as purlins and beams. Finally, in the latter part of the design, the details could be designed reasonably by replacing the already determined modules with members, and roof tiles are placed on each reference point of the planned roof frame.

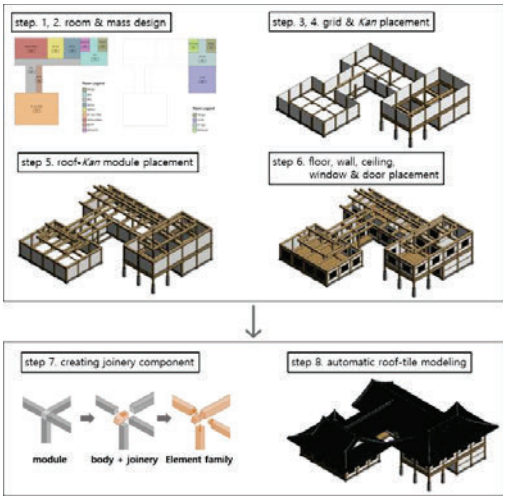

Figure 2: *Design process of the 'Hanok BIM Design Support Program'*

This paper specifically concerns the methodology of the roof frame design step of the '*Hanok* BIM Design Program' that the research team developed and proposed. One of the limitations of planning traditional *Hanok* is that the *Kan,* a bay unit, contains all of the body and roof structures and space in one unit. However, in the *modernized-Hanok*, the subordinate relationship between the body and roof structures has been diminished due to improved structural performance, such as horizontal expansion in the direction of the beam without columns. As a result, the modern *Kan* is no longer a composite unit of the body and roof structures. Therefore, isolating the roof structure from the body structure in the design process on the premises became crucial.

Hence, the research team approached the roof as an independent structure and proposed a module-based methodology to devise a roof-*Kan* module that allows designers to plan the most complicated 3D atypical curved roof-frame structure unconstrained by the body structure. This roof-*Kan* module was developed by extracting data from traditional *Hanok* and implemented using Autodesk Revit, a widely used BIM tool, to approach the design process in a more user-friendly way and contributes to the revitalization of the *Hanok* industry. The '*Hanok* BIM Design Support Program' was completed as a Revit's Plug-in, and released to the public through 'Autodesk's BIM guidebook' and the department of Architecture and Architectural Engineering, Seoul National University.

2 MODERNIZED-HANOK DESIGN, MODELING AND ROOF-KAN MODULE

2.1 HANOK MODELING METHODOLOGY AND ROOF-FRAME PLAN

The design methodology of what the library unit is composed of in precedent research can be classified into individual component units (M1), joint units combined by Skeleton-Assembly (M2), and integrated modules that are unitized by both the body and the roof (M3), depending on the unit type and level of detail (LOD) in *Hanok* design, modeling methodology, and planning [8]. As mentioned above, the roof and body are unbinding independent structures in *modernized-Hanok* and can be planned separately.

The roof planning methodology's strength comes from the ability of establishing various planning unit libraries. Additionally, the amount of libraries necessary is inversely proportional to the level of detail (LOD). Therefore, many libraries are required in cases where the *Family in Family* concept is weakly applied, such as in M1 and M2, while M3 requires a smaller number of libraries. On the other hand, the relationship equation within the unit is proportional to the number of families within the planning unit. In other words, while the relationship equation is defined at the level of component size for M1, it extends to the scope of detail design, such as connections for M2, and M3 has the possibility of parametric design based on the relationship between components.

Therefore, regarding roof planning, M1 effectively represents the details of the roof's shape as various components are differentiated and detailed. On the other hand, the unit planning elements of M3 are advantageous for organizing each part's shape, size, and composition, as multiple components are interconnected.

Table 1: *Classification of precedent Roof frame structure Design Methodology*

Metho-dology	M1	M2	M3
Library Unit	Member	Skeleton-Assembly Joinery	Kan
LOD	5	2 → 5	5
Relation with Design Process	Low	High	Low
Relation with Body part	Low	Medium	Equal

https://doi.org/10.52202/069179-0493

Possibility of Parametric Design in Unit	Low	Medium	High
Link with Other Units	Very High	Medium	Low
Difficulty	Difficult	Medium	Easy

The *modernized-Hanok*'s roof structure is mediated by the body structure but can create an independent shape. In particular, since the structure of the *Jungdori* (middle purlin) and the *Jongdori* (top purlin) is separate from the body structure, related lower components can be planned independently. In other words, since the pre-defined information is associated with the *Jusimdori* (column-raw purlin), the *Daedulbo* (main beam*)* connected to the body, the horizontal range of the roof part can be adjusted through these components, and the lower pieces are linked as independent relational functions. Therefore, the information that needs to be input to create the shape, height, and curve of the roof is the roof type, the position of a *Jungdori* and a *Jongdori*, and the relational function information that can adjust the lower components. Once the input of information about the wooden structure is completed, the roof tiles can be generated, and the position of the tiles can be determined with the *Seokkarae* (rafters) and the *Gaepan* (shingle) based on the reference points of the purlins. However, information related to the definition of the outermost coordinates of the roof, eaves extension, *Buyeon* (double rafters*)*, the curves of the rafters (hipped and hipped-gabled roof), location of the gable (hipped-gabled roof), length of purlin extension (gabled roof) must be defined independently.

Table 2: *Classification of Roof-element's Information by Process*

Type of Information	Subject	By Para-meter	By User
Pre-defined Information	Geometry of Jusimdori & Daedulbo	-	
Information to define	Roof type		●
	Geometry of Jongdori		●
	Geometry of Jungdori & Jongbo		●
	Geometry of Seokkarae	●	
	Geometry of Gaepan	●	
Information to be defined	Extruding of Eaves		●
	Installation of Buyeon		●
	Ang-gok & Anheorigok (Paljak or Woojingak)		●
	Location of Hapgak (Paljak)		●
	Length of Bbaelmok (Matbae)		●
	Composition of Hoecheom		●

2.2 DEFINING THE ROOF-KAN COMBINED MODULE

The design and modeling of *Modernized-Hanok* differ from traditional *Hanok* in that it can plan the body and roof in a loose relationship. Therefore, the planning stages of the body and roof can be done independently, and using modules that meet the objectives of each step is highly effective in the early stages of design. In other words, the main focus of roof planning is to define the shape and scale of the roof. The conditions that modules should have are as follows.

2.2.1 COMPONENTS OF INDIVIDUAL MODULE

To plan the roof part of *Modernized-Hanok*, the roof-*Kan* combined module should be considered from two significant aspects. First, it should follow the principles of traditional wooden architecture for roof construction while simultaneously accommodating the wide spans in the beam direction. In other words, it should reflect the planning logic of the body part but should not be entirely dependent on the structural logic of the body by forming an independent roof structure. Therefore, it should be possible to independently implement the morphological characteristics of the roof, such as *Matbae* (gabled), *Paljak* (hipped-and-gabled), *Woojingak* (hipped), and linked to the planar system.

Firstly, it is necessary to define the scope of the components included in the roof-*Kan* module. In *Modernized-Hanok*, the roof is composed of four main layers, including the roof tile surface, the *Boto* (roof-filling soil) and the *Jeoksim* (roof-filling wood) layer, the *Seokkarae* and *Gaepan* layer and the purlin and related substructures, which are components of the roof-*Kan* combined module. However, since the *Jusimdori* and the *Daedulbo* located at the boundary of the building must be modified according to the orientation of the building's facade, it is reasonable to include them in the roof plan to minimize errors. On this premise, the components in the vertical range of the roof-*Kan* module consist of the *Jusimdori*, *Daedulbo, Jungdori*, *Jongbo*, D*ongjaju* (short-column on beam*)* and *Daegong* (truss post). The horizontal range is one *Kan* unit of the body in the purlin direction and the entire *Kan* unit in the beam direction, and this is repeated within each *Chae,* a building unit, to implement the roof for each house.

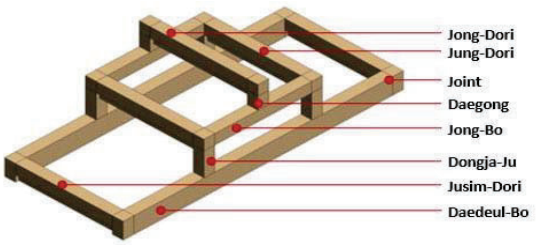

Figure 3: *Roof-Kan Assembly Module Basic Type*

https://doi.org/10.52202/069179-0493

2.2.2 TYPES OF THE ROOF-KAN COMBINED MODULE

The *Modernized-Hanok*'s roof frame is consisting the edge-*Kan*, which defines the shape and scale of the roof, and the middle-*Kan*, which defines only the scale. This research suggests that the proposed roof-*Kan* module should also reflect this characteristic of *Modernized-Hanok* and be operated in a dualized module.

The vertical position of the roof parts can be divided into three levels based on the purlin members to determine the roof scale. First, the *Jusimdori* and the *Daedulbo* are placed at the lower level of *Jusimdori*. The *Jungdori* and the *Jongbo* should be placed at the *Jungdori level* and the *Jongdori* at the *Jongdori* level. Additionally, the *Dongjaju* and *Daegong* are placed at each level, and a purlin connecting member is created in the outer direction of the beam to correspond to the cornered houses.

The middle-*Kan* is composed of only the substructures mentioned above, but the edge-*Kan* requires additional substructures that can determine the shape of the roof. The starting position of *Jongdori* and *Jungdori* determines the shape of the edge-*Kan*. And the *Jongdori, Jungdori*, and *Jusimdori* touch the surface parallel to the outer edge of the edge-*Kan* in the *Matbae* roof. At the same time, the *Jungdori* is on the linear of 45 degrees to the direction of the *Jusimdori*, and the *Jongdori* is on the vertical plane in *Paljak* roof. In the case of the *Woojingak* roof, it creates the roof surface by allowing the starting points of the *Jungdori* and *Jongdori* to touch the linear that is 45 degrees to the direction of the *Jusimdori*. Therefore, the edge-*Kan*, the types of roof are determined by the existence of the *Chunyeo* (angle rafters) located on a straight line in the 45-degree direction, and the starting coordinate of the *Jongdori* again defines the *Paljak* and *Woojingak*. In addition, each roof requires different substructures to form its shape, with *Matbae* requiring extended purlins, while *Paljak* and *Woojingak* need *Chunyeo, Waegidori (*outer purlin*)*, and *Chungryang (additional beam on purlin direction)*. Therefore, the module must secure the required substructures to create desired roof shape [9].

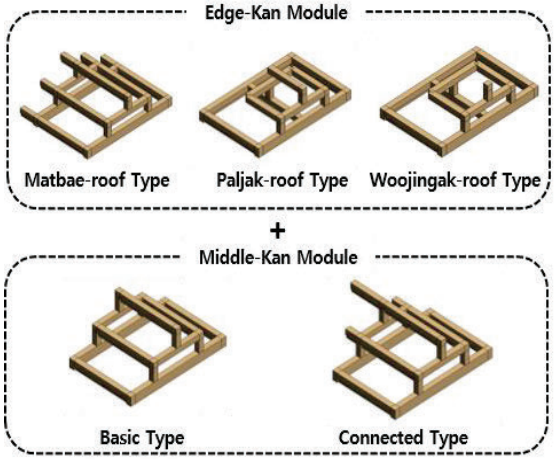

Figure 4: *Type of Roof-Kan Assembly Module*

3 IMPLEMENTAION OF ROOF-KAN COMBINED MODULE

3.1 ROOF SHAPE DETERMINATION FORMULA

A correlated function is a logic that can implement changes in each target by controlling the common factors among multiple targets. Revit's parameters consist of the parameter's name, the parameter's value, and the formula between parameters, and they work by connection with the target element.

The parameters work in two ways. The first is to link the parameter's value to the target element. For example, when modeling a rectangular shape, values for length, width, and height are defined simultaneously during the modeling process. By creating a parameter and linking it to the length, width, and height of the target element, the length value of the parameter can be linked to the length value of the target absence, allowing for changes in the shape of the target element through the parameter.

The second method involves linking each parameter through a formula. For example, "Height = Length/12" is a simple function that defines the dependent parameter "Height" as the value of the independent parameter "Length" divided by 12. If the parameters "Height" and "Length" are linked to the height and length of the target element, adjusting the parameter value for "Length" can adapt not only the length but also the height. The defined formula expression serves as the algorithmic basis for enabling continuous changes to the target element and reflecting the actual construction or modeling principle. In addition to arithmetic operations, conditional statements such as "if" can also be used to define the value through the formula for when conditions are met. For example, Users can reconfigure most simple functions, such as the visibility of the target element or specifying its material. Therefore, complex shapes can be easily created by adjusting a few independent parameters by defining dependent parameters with various formula expressions.

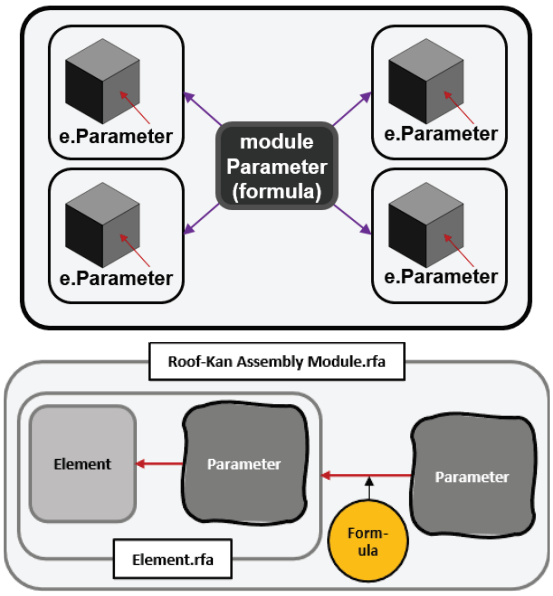

Figure 5: *Concept diagram of Parameter and Formula*

https://doi.org/10.52202/069179-0493

The roof-*Kan* combined module proposed in this study comprises multiple parameters and families within a single family, and their correlation allows the creation of each roof shape.
The edge and middle *Kan* modules can implement five and three-purlin structures and connect the roof type and the *Kan*. The operation of parameters is defined as an essential element of each direction's length, material, and component name within the module family, while the parameters specified within the module family are again defined as a formula of the parameters defined in the module.
For example, creating a *Matbae* roof with a three-purlin structure can be replaced with the logic of defining two independent parameters, one with the roof shape (Name) as *Matbae* (Value) and the other with the number of purlins (Name) as three (Value) in the edge-*Kan* module. Once the value of "*Matbae* roof with a three-purlin structure" is created, the value shapes the defined roof through the formulas previously specified for each component. Also, each roof shape is differentiated by the presence and position of each component; therefore, the roof-*Kan* combined module is created with type parameters [10].

3.2 LAYOUT LOGIC FOR ROOF-KAN COMBINED MODULE

The initial layout of the module begins by defining the main facade of the building based on the number of the body module in perpendicular and horizontal directions, which is already placed in the previous steps. For the roof-*Kan* module to be placed on the top of the body module, the building must be hypothetically divided into an independent l-shaped building, *Chae*. A main and subordinate *Chae* is distinct by a change in the number of *Kan* in the vertical direction of the main facade.

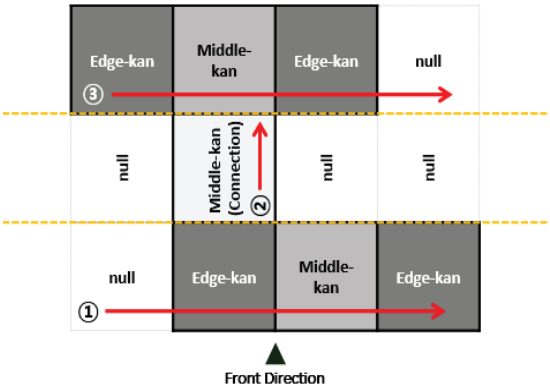

Figure 6: *Arrangement process of Roof-Kan Assembly module*

Once the buildings are separate, the roof frame module is placed from the lower-left *Kan* of each *Chae,* where the coordinate is set to 0, 0. The module first decides whether it is an edge-*Kan* module or a middle-*Kan* module based on the existence of the adjacent module, then it is placed from left to right accordingly in the independent *Chae*. The rest of the independent *Chae* repeats the same process to complete the placement of all roof frame modules.

The rules for placing the roof-module combinations in each *Chae* are further divided based on the number of *Kan* in the front facade. If the building has three or more *Kan*, the initial module will be an edge-*Kan* with a defined roof shape while hiding the *Daedulbo* and *Jongbo*. And the module type of the second *Kan* is determined according to the existence of a *Kan* to the right.
For the first middle-*Kan* module of the second *Kan*, all the parts of the *Jusimdori* level are generated, while the *Dadulbo* and *Jongbo* on the left are hidden for the rest of the middle-*Kan* module. Finally, the right edge-*Kan* of the *Chae* is placed while hiding the *Dadulbo* and *Jongbo* on the left to complete the placement of the module. This process minimizes the error in the quantity data and ensures there are no overlapping elements once the entire roof-*Kan* module is placed.
Only the edge-*Kan* module is placed in the building with two *Kan* in the front facade. The first module generates all the *Daedulbo* at the *Jusimdori* level, while the second module hides the left *Daedulbo* and *Jongbo*. In the case of a building with only one *Kan in the* front facade, only one module is placed.

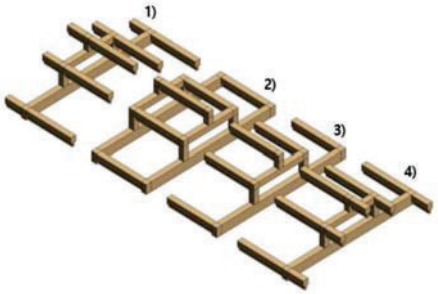

Figure 7: *Arrangement Process of Edge-Kan and Middle-Kan Module*

A middle-*Kan* module is generated to create the connecting edge in the corner of the house where two or more *Chaes* meet vertically. The additional elements must be created outside of the module range in this process.
The current module placement has each *Chae* as an independent state; therefore, the *Chaes* must be connected with purlins. The connection process of *Chaes* is followed. First, a main *Chae* and a subordinate *Chae* are determined, then the subordinate *Chae*'s middle-*Kan* module generates the connecting purlins. Once the connecting purlins are created, the cornered house is completed, adjusting the height of purlins according to the hierarchy of the *Chae*. The *Matbae* roof requires the purlin extension that goes beyond the boundary of the roof-*Kan* module. However, the edge-*Kan* module that determines the roof's shape is always placed at the beginning and end of the *Chae*, and the purlin extension is created outside the *Chae*, so it does not affect the adjacent *Kan*. Therefore, the purlin extension for the *Matbae* roof is made outside the boundary of the roof-*Kan* module using the same logic as the middle-*Kan*'s connecting purlin creation.
On the other hand, for the *Woojingak* roof, the *Chunyeo* extends to the *Jongdori*, which means the *Jongdori*, *Daegong*, and *Jongbo* need to move inside the *Chae*. This means it can affect the adjacent *Kan*, but this is

https://doi.org/10.52202/069179-0493

resolved by separating the constraints of the *Daedul-bo* and *Jongbo*.

3.3 COMPLETION OF ROOF PLANNING AND MODELING

The roof planning process takes place after the completion of the body plane planning, with the lower *Jusimdori* level fixed, where the body and roof intersect. Therefore, the user can independently define the roof type, scale, purlin structure, and the rafters' curve. During the roof-*Kan* module placement, the program automatically identifies the designated plan below and creates the user-interface presenting the pre-view of the floor plan and the section for the user to decide which floor or *Chae* to work on.

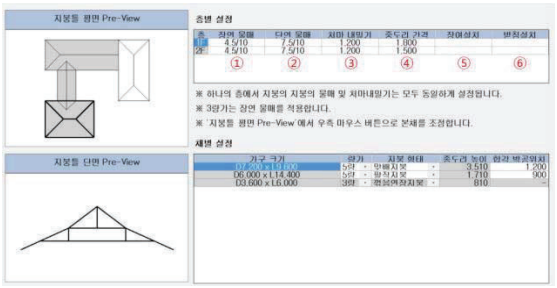

Figure 8: *Pre-view of roof planning UI*

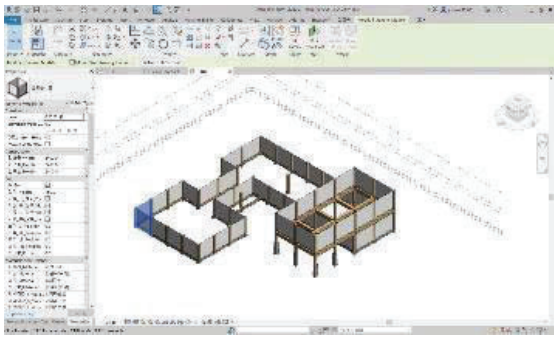
On the 'floor' part of the UI, the users can type-in the desired values of the angle of rafters, overhang depth, and purlin spacing and etc. However, the range of these values is pre-set based on the analysis of existing *Hanok* to prevent users from creating an impractical roof. On the other hand, users can determine the roof type, the purlin structure, and the location of the bargeboard on the '*Chae*' part of the UI. This process allows users to determine the roof type of each *Chae* independently while suggesting the appropriate purlin structure according to the scale of the body structure. The purpose of this program is to reflect the principles of the *Hanok* construction while promoting efficient modeling.



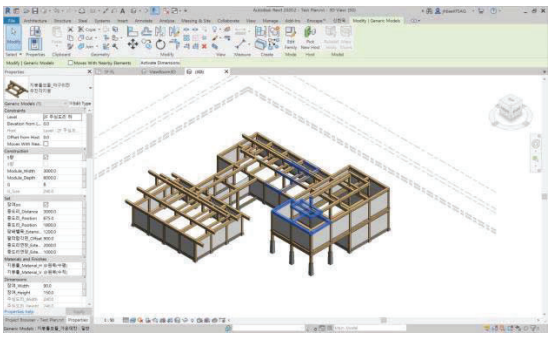


Figure 9: *Before and after the roof-Kan module placement*

4 CONCLUSIONS

It is crucial to solve the difficulties of *Hanok* design for the growth of the Modern *Hanok* industry. The roof of *Hanok*, in particular, requires a curved roof with a combination of various wooden structures, which is the biggest obstacle in the design process of *Hanok*. Therefore, this study regarded the roof frame as an independent structure, breaking out of a general notion that the roof frame is a subordinate structure of the body, and proposed a roof-*Kan* combined module.

The significances of this research are as follows. First, it defines criteria for separating the body and roof parts by focusing on the module-based design methodology. In addition, it distinguishes information that has already been determined in the preceding stage, information that is automatically generated through it, and information that needs to be redefined by the user and aims to improve design efficiency by accumulating data.

Secondly, it provides a basis for constructing a cornered roof efficiently. Considering the timing of placing the roof-module combinations, the modules were divided into middle-*Kan* and edge-*Kan*, and an effective methodology for placing the modules between *Chae* and between adjacent *Chae* was proposed.

This study is part of developing a Modernized *Hanok* design tool that can be easily used by non-experts who are not familiar with *Hanok* architecture. This tool is expected to provide a better *Hanok* design environment by accumulating information from the plane, elevation, and cross-section plane of the building to the details of each member.

STEPS TOWARDS A UNIVERSAL SCHEME FOR PARAMETRIC DETAILING OF COMPOUND TIMBER STRUCTURES

John Haddal Mork[1], Sveinung Ørjan Nesheim[2]

ABSTRACT: The paper presents potential steps towards a universal scheme for parametrically detailing compound timber structures. Two fundamental concepts are presented: Firstly, a method of combining manual 2D-detailing with parametric modelling, and a secondly concept of simplifying parametric detailing by splitting the detailing process into two. Achievable implications of the scheme are illustrated through a surface-based FEA model of a timber-building. The paper ends by discussing further development steps toward a universal parametric detailing scheme.

KEYWORDS: Parametric detailing, Information models, parametric method development, FEA

1 INTRODUCTION

1.1 BACKGROUND

The Norwegian timber sector is immature, and the industrial potential is underexploited. The market impact associated with an increased degree of completion for timber-based building elements is considerable[1], but the digital infrastructure required for cost- and resource efficient processes are currently fragmented. The digital transformation is suffering from lack of standards for interoperability and from various levels of maturity at the various stakeholders in the value chain. Increased digitalisation has the potential to manufacture cost- and resource effective products faster and with a higher degree of completion. For the timber industry increased digitization has the potential for unlocking a significant production volume of prefabricated elements with a high degree of completion, and therefore to act as an important contribution for the industry to meet climate goals. Parametric modelling has become an increasingly important method in this context and can increase efficiency in both planning, manufacturing, and construction phase. However, the tool is often limited to be applied by specialists, and building a parametric model is a time-consuming process. At worst the expense of developing a parametric model absorbs the profit of increased efficiency in other parts of the process.

Reindeer [2]is a tool that aims to reduce time demanded to prepare a parametric model and to simplify the process of detailing timber structures. However, the tool is limited to 1D-elements, and is not applicable for compound structures such as complete walls and slabs. A main challenge is the number of joint types that occurs in compound structures. Between modules, and between individual components. Hereby, the authors have identified a demand of a further improved scheme for parametric detailing.

1.2 OBJECTIVES

The paper presents potential steps towards a universal scheme for parametrically detailing compound timber structures. The scheme is built around a generic data model, and the output is hence applicable for both architects, engineers, manufacturers, and other stakeholders. Both 1D-elements (beams, columns, etc.) and 2D-elements (CLT, plywood etc.) are included.

In the present study the methodology is implemented in a framework to increase material efficiency, where the structural analysis is used as a vehicle for demonstrating the flexibility and applicability of the method. The case structure is a modular load-bearing building system purposed for multi-storied wooden buildings. The modules are principally standardized, but not fixed in size. Although the case is a building system for tall structures, the methodology has a high re-use value and is working across building systems and makes parametric design available to stakeholders who are not parametric experts.

2 FLIPPING THE MATRIX

The more logically consistent a building system is, the more reasonable the use of a parametric model. A geometric output can largely vary in shape if it is within the same logic. Simplified, one can say that the modular building system consists of four building elements: exterior walls, interior walls, slabs, and roofs. Thus, an intuitive approach is to develop four corresponding parametric modules. However, when taking into account the various the connections between the building elements, the complexity drastically increases while an intuitively clear logic is heavily disrupted by deviations.

The phenomenon is illustrated in Figure 1. Elements that are topologically similar, are coloured similarly. While one wall element is only connected to its parallel vertical and horizontal wall neighbours (grey-green), other walls are corners, connected to the roof, the ground, a slab or

[1] John Haddal Mork, Rallar AS, Norway, john@rallararkitekter.com
[2] Sveinung Ørjan Nesheim, SINTEF Community, Norway, Sveinung.nesheim@sintef.no

https://doi.org/10.52202/069179-0494

other combinations. In conclusion: If basing parametric modules on its building element type, the result is a dirty logic scattered by challenging topological variations. This challenge makes the foundation for the flipped matrix and the proposed scheme.

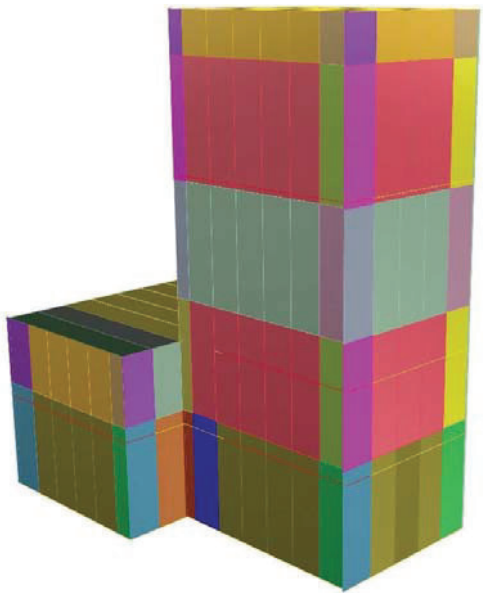

Figure 1: *Each color reprents topologically similar elements. Since the elements are connected in various ways, the amount of element types*

3 THE PROPOSED CONSEPT

The proposed concept has two main features. Firstly, the concept proposes a two-step detailing method that drastically reduces the complexity and deviations as described above. Secondly, a method of combining parametric modelling and manual detailing is introduced.

3.1 Two step detailing process

The proposed detailing concept flips the matrix. Instead of developing parametric modules based on its main building components, the proposal is to develop a two-step detailing system that firstly takes care of the individual joints between the building elements and secondly detailing the module itself.

This concept allows the single-responsibility principle(SRP) known from programming. A parametric module is now either a vertical connection between main building components or geometric population and detailing internally in a module.

The first detailing step determines the axis, orientations and boundary of the components directly related to the module joints. Knowing the boundary of the module, the internal components can be generated. The second detailing step determines how components within the module interacts, and hereby also determines the length of the components preliminary generated in step one.

The output of the scheme is a light, yet detailed representation of a structure, applicable for multi-scalar modelling[3]. This concept makes it very suitable as a feature in a building design and engineering framework, and the output of the parametric model may easily be adapted to support various design and analysis strategies.

3.2 MANUAL DETAILING

The Single-responsibility detailing principle not only simplifies the parametric model, but also enables the potential of combining parametric modelling and manual detailing. If a joint type in a structure has multiple variations within the same logic, e.g. wall corners with varying angle, a parametric joint can be powerful. However, in many cases, a detail is fixed and scattered in a structure. For such cases, developing a parametric detail is excessive – a manually drawn, fixed 2D-detail is less time-demanding.

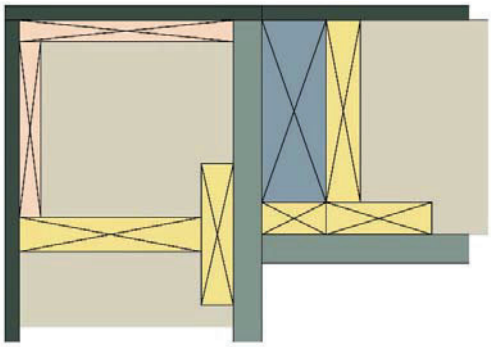

Figure 2: Manually drawn detail

However, an arbitrary 2D-detail is not directly readable by an algorithm. Figure 2 displays a manually modelled corner detail. Further, modern digital fabrication requires fully detailed 3D-models. Hence, it has been developed a rule-set for drawing 2D-details manually and a method for turning the detail into a parametric detail stored in the algorithm. The rules are as following:

1) Any component in the detail requires a parent. The parent is the element the component belongs to in the prefab-phase. In additions, some components might belong to the joint itself. Hence, in a joint where two elements connects, a component is connected to elem0, elem1 or joint. Further, any component requires designated material properties/functional names/purposes. See Figure 3

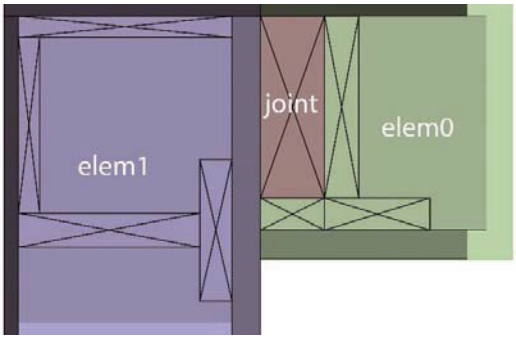

Figure 3: Parent elements

2) The joint requires a local plane. As seen later in the article, the origin of the local plane corresponds to the axis of the joint created from the element's reference surfaces. The X-axis is of the plane is parallel to elem0. See Figure 4

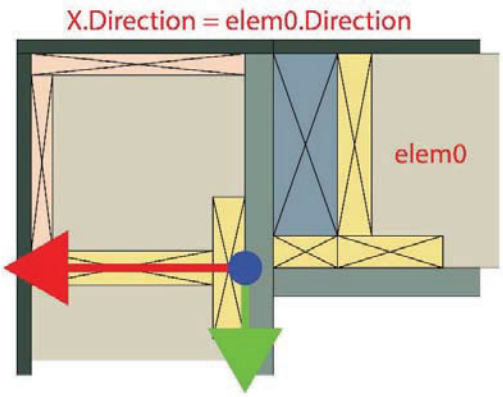

Figure 4: Local Plane

3) A component in the joint has either a defined cross-section within the boundary of the joint, or the cross-section is extend to another joint in the assembly. This is solved by two types of shapes: Closed cross sections are drawn as closed polygons, extended cross-sections are drawn as open U-shapes. See Figure 5

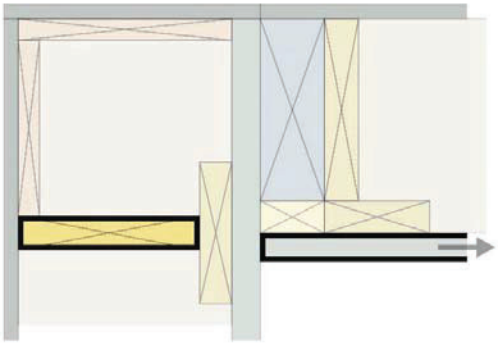

Figure 5: Closed and open cross-sections

Applying the three previous rules, an algorithm can turn the manually drawn joint into a lightweight information model. The joint is wrapped in a block anchored by the local plane. On a superior level, metadata can be connected to the joint it-self. Further, components are described as alpha-numerical enhanced local planes [4],positioned relatively to the main local plane. See Figure 6. Further, Figure 7 renders the data stored in the component's local plane. This is data extracted from the manual drawing, and is the data required to regenerate a physical component.

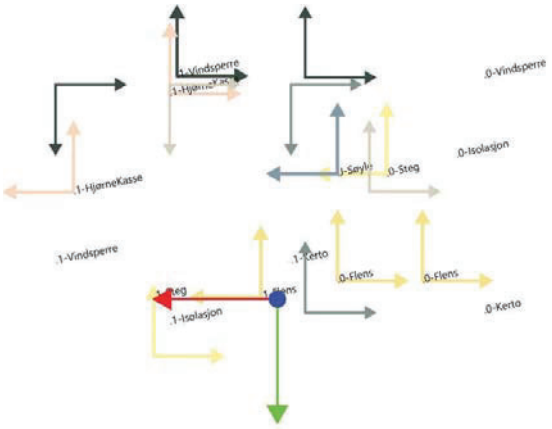

Figure 6: Lightweight joint description

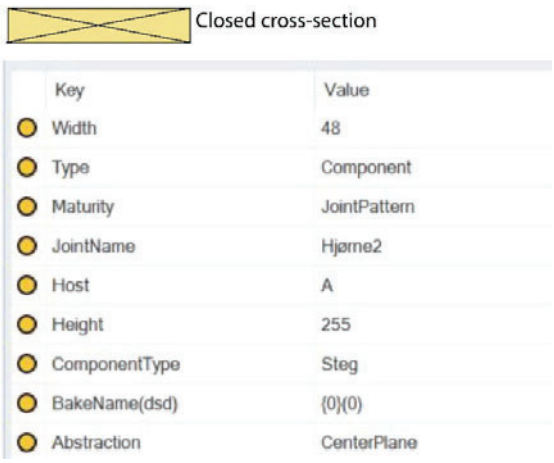

Figure 7: Component enhanced with alphanumerical data

The collection of planes is a simple representation of components in a detail, and contains information about cross-section width, length, element host and detail ID. These 2D-details are oriented to its linear joints, and the detail's components are generated in the assembly.

4 THE SCHEME STEP BY STEP

The proposed scheme consists of individual algorithms that step by step matures a geometric information model from a simplified reference model represented by surfaces and curves to a fully detailed structure. The steps relates

https://doi.org/10.52202/069179-0494

to a conventional parametric process and allows manual interactions between each step.

4.1 Normalizing input geometry and register basic geometric properties

For such workflow, the geometric input can vary. In some cases, a manually modelled geometry can be suitable, for other cases the geometry can be parametrically generated. Regardless, the geometry needs to be scheme-based, applicable for extracting precise geometry. The first step consists of cleaning the geometry, normalizing surface-vectors, and not least analysing the geometry and register its basic geometric properties. With help of a defined assembly vector, and the geometry itself, properties such as orientation, determination if the wall is exterior or interior, levels and an initial ID is set.

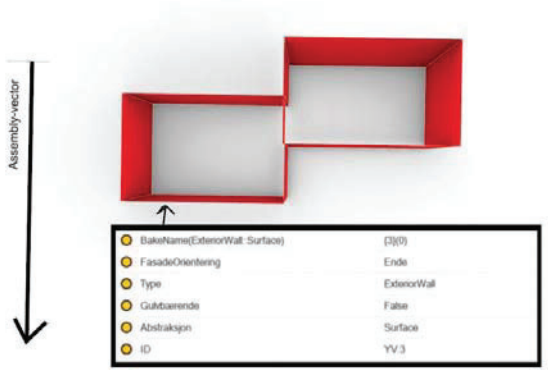

Figure 8 The geometry itself and the assembly-vector are the basis for basic for registering basic geometry properties

4.2 Dividing geometry into building elements

Most building systems divides its structure into elements. The case structure's logic divides the floors and walls into transportable widths and manufacturable heights. Hence the walls and floors are divided into sub-surfaces, inheriting its properties from its parent wall/floor, but adding information about its related axises and its levels.

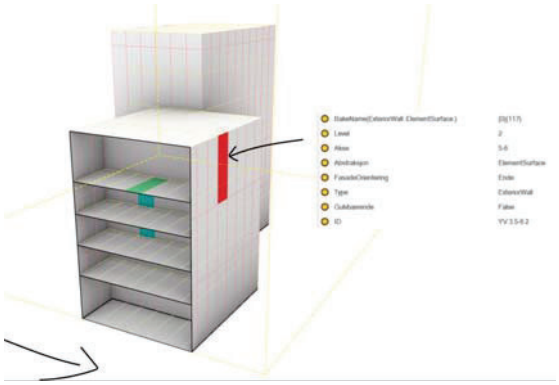

Figure 9. The element is part of its parent wall named YV3, is between axis 5 and 6 and is the third element vertically (2). Hence its ID becomes YV.3.5-6.2

4.3 Register all joints (linear joints) and store geometric properties

Now having all elements generated, the algorithm identifies all joints in the assembly. In this case, linear joints between the elements are the most relevant joints. The algorithm individually searches for joints between exterior or interior walls, between exterior and interior walls, and not least intersection internally between floors and in relation to its walls. The joint itself, is initially just a line and its local plane, but the registered properties and geometric orientation of the joint's walls/floors, and its internal relation, determines what type of joint it is. Following are a few examples:

- A joint between two north-facing walls at the same level, determines that the joint is a horizontal connection between parallel walls.
- A joint between two nort-facing walls, at different levels, becomes a vertical connection of parallel walls.
- A north facing wall and an east facing wall becomes a specific type of corner, and with help of the assembly axis, the joint also consist information about the assembly order of its elements.

Figure 10 A joint and its properties

4.4 Categorize joint type instances in the building and map matched joint types

Various joints are modelled according to the description in chapter 2. See Figure 12. Each joint type has multiple geometric requirements for a joint type instance to be applicable. This step analyse all joint instances in the structure and map its suitable joint type. This by orienting the described joint type local plane, to its joint instance local plane.

When the algorithm has finished this stage, all joints are populated with a joint detail represented as a series of property enhanced planes. Further, components in the joints can be extruded according to the length of its joint. Figure 13 displays a corner joint being extruded, while Figure 14 shows the structure being fully populated by the first detailing stage.

https://doi.org/10.52202/069179-0494

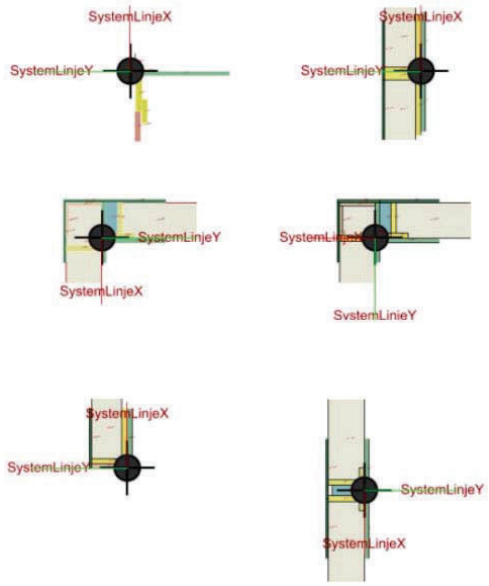

Figure 11 Joint types

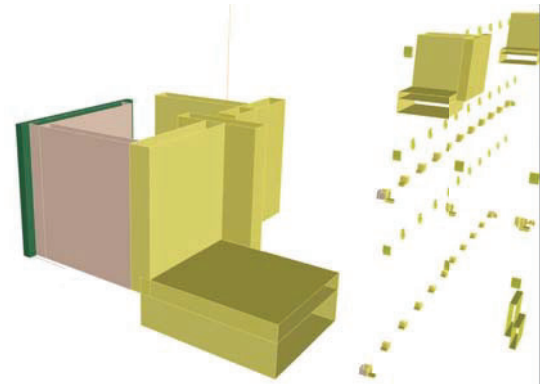

Figure 12 A corner joint being extruded

Figure 13: The structure partially populated

4.5 The second detailing stage

Now, the first detailing stage has determined the relationship between the main elements, and the next stage of populating the element itself, is simplified. This due to not needing to take neighbouring elements into account. Figure 15 shows a fully populated model

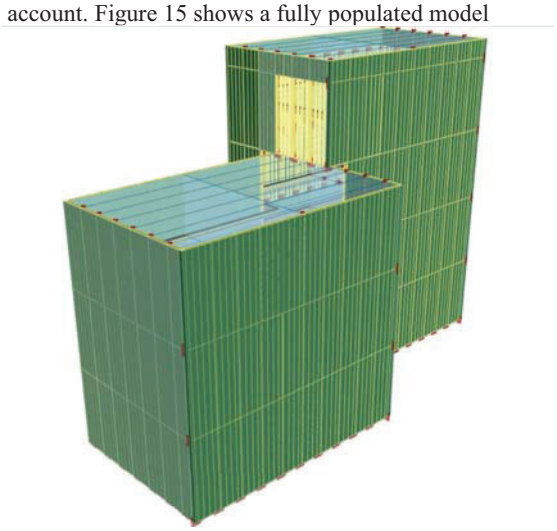

Figure 14 Fully populated model

4.6 Detail component connectons

By the last stage the model is fully populated, but not fully detailed. The last stage, not yet developed in this project, is to detail the connection between the components: the components in the described joints, and the joints made by the components internally in the elements. This procedure can be similar to the steps described in in chapter 4.3-4.4, but in this case, the joint is not a line, but a point in the intersection between two or more components..

https://doi.org/10.52202/069179-0494

4.7 Geometric representation

The above steps displays the components as boxes, but the geometry is still multi-scalar and can be rendered in different ways. By representing the parametric description of the compound timber structure as a surface with associated data, the benefit of object-oriented programming may readily be exploited. In the present project this yielded an efficient method of geometrical representation of the structure. Here additional information such as material model, cost, and embedded carbon emissions may be organized around the surfaces, rather than as a conventional method where this data is organized in logical functions.

The method of parametric description of compound timber structures was advancing in joint development of an element-based building system suitable for high-rise timber buildings. This building system is inherently parametric and modular and comprises solutions for loadbearing exterior and partition walls, flooring system and roof. The building system is based on continuous system planes and system axes from where the parametric rules defining the geometry is referenced, and where loads and linear connections are introduced. This design philosophy allows for a flexible positioning and distribution of both shear connectors and joints between modules. The principle of continuous system planes and system axes is beneficial for a parametric geometric representation, though not required for the scheme for parametric detailing as presented herein.

5 USE CASE

5.1 Methodology to minimise material use

One apparent outcome of the geometric representation is the establishment of an efficient computational finite-element representation of the structure. As a vehicle to demonstrate the potential outcome, a structure generated using this scheme was transformed into a surface-based finite-element model. Due to the object-oriented architecture of the parametric scheme, the base feature of the members associated with a given surface could be defined as beam, shell or solid. For the building system used in the present work, the members have a thickness to length ratio typically less than 0.25 and with transverse shear less important, shell elements are suitable for the numerical model. In Figure 16 a detail of the numerical representation is shown.

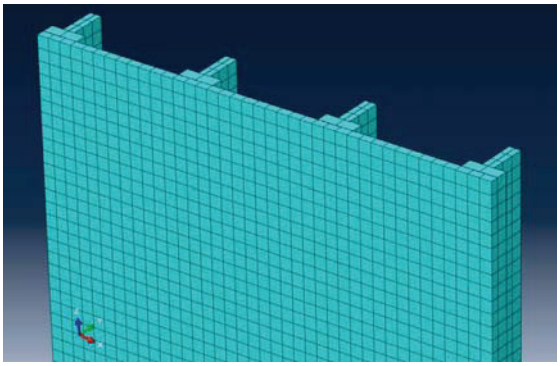

Figure 15: Shell elements with rendered thickness

The methodology permits any information associated with the surfaces to be accessed for a member. In this way the material properties, the associated connection lines of a surface, thickness, and orientation to mention some, are all accessible. Similarly, the properties of the associated connection lines are returned to obtain information about boundary conditions. Principally this enable any property that is stored and associated with a surface to be accessed, making the methodology very powerful and flexible.

This setup allows for easy automation of various tasks. The establishment of a live link between the parametric model and the FEA may be used in an optimization workflow to increase the material efficiency. Here the optimization of the structure may be done with respect to material volume, material cost or embedded CO2 to mention some. The constraints of the optimization is governed by the design code.

The advantages with letting the associated thickness of the shell be a variable parameter in an optimization algorithm may easily be exploited and may offer an efficient computational methodology to minimize material use. Results from finite-element analysis and material minimization of the complete building system referenced in the present work will be published in due time.

5.2 A Twin-transition Tool

The achievable implications of the scheme were assessed during the work of modelling and assessing the structural response of a high-rise timber building employing the building system briefly explained above. In industry 4.0, efficient and practical solutions for digitalisation is crucial. The present work has identified several achievable implications related to digitalisation, and that the methodology may offer an efficient expansion of the toolbox for digital transition of the construction sector.

As described in section 3.1 the scheme is a two-step detailing process, starting with the manual two-dimensional details of the joints of the building system. Due to this the possible implications of the method may be much larger than originally envisioned. Because of the two-dimensional details, the scheme may be used in the mapping of existing built works where only two-dimensional drawings exist. This may aid to digitalize

existing built works subject to renovation or extension, and therefore also an expansion of the toolbox for twin-transition.

The methodology is suitable for scalability and may be an additional and valuable tool in the work to build digital twins both for new and existing built works as well as for documentation.

6 DISCUSSION

The paper discusses potential steps towards a universal scheme applied when detailing parametrically. Creating an possibility for inputting manually drawn details into a complex algorithm is seen as promising concept. A key benefit is that the concept democratizes the use of a parametric model – further, time is saved if joint type variations are limited.
The two-step detailing process is seen as promising candidate to ensure single responsibility details, reducing the amount of joint types required. However, more investigation is required. Finally, a potential further development, is to turn the two-step detailing process into a generic, nested parametric detailing process, allowing infinite levels of parametric details within a parametric details.

MOISTURE PREDICTION OF TIMBER FOR DURABILITY APPLICATIONS USING DATA-DRIVEN MODELLING

Seyyed Hasan Hosseini[1], Jonas Niklewski[2], Philip Bester van Niekerk[3]

ABSTRACT: Durability and service life assessment is a major challenge for the design and use of timber in outdoor weather exposed environments. Rate of deterioration by fungal decay is closely linked to variations in wood moisture content. The objective of the present paper is to test and evaluate different data-driven models based on the multilinear regression (MLR) and artificial neural network (ANN) approach. Moisture content was predicted at the surface and core of a rain-exposed wooden element in the context of durability and service life assessment. Synthetic data stemming from a numerical model were used to fit time-series weather variables, including different combinations of time-lagged daily precipitation, relative humidity, and temperature, to temporal variations of daily average wood moisture content. Based on a set of statistical and qualitative analyses, using the weather variables lagged by 0 – 11 days as input variables for 11 mm depth moisture prediction, ANN showed the highest accuracy and least sensitivity to its initial setups, and could significantly outperform the MLR with the same input variables. The resulting models for surface and core moisture prediction were then tested against two different datasets consisting of measured data from wood specimens subjected to outdoor exposure.

1 INTRODUCTION

Service life assessment is a major concern for timber in weather exposed environments. The problem largely stems from the natural deterioration caused by fungal decay, a mechanism that is exacerbated by poor moisture management and suboptimal use of materials. Recent efforts to systemise service life assessment of timber have resulted in various performance-based design guidelines for European conditions. The guideline in [1] is based on a dose-response relationship where the rate of fungal decay is expressed as a function of wood moisture content and temperature. Therefore, dose-response models enable service life assessment based on wood moisture content and temperature [2].

Wood moisture content is a measure of the material microclimate and one of the main vectors for biotic deterioration by fungal decay. In general, the moisture variation of wood depends on various factors such as local weather, the wooden element's distance to ground, and detailing. Brischke et al. [3] categorize these influences as 'indirect', since they are primarily linked to service life via their effect on moisture content. For modelling purposes, moisture content can either be obtained by measurement [4] or modelling [5,6].

Using a modelling approach, the wood moisture content is estimated based on these indirect factors and in a subsequent step, used with dose-response models to predict service life. Figure 1 shows how indirect variables (weather) can be used via numerical modelling to estimate direct variables (moisture content), which can then be used via empirical damage functions to model wood decay. The limit state defines the acceptable response in terms of material deterioration and the service life is defined as the period until the limit state is reached.

Numerical modelling of moisture transport in wood is an integral part of several branches of wood technology. Common applications include the migration of free water from green lumber during drying [7] and moisture gradients of sheltered structural timber during service [8]. These models transfer poorly to predictions of service life where the wood surface is subject to cycles of wetting and drying and the main region of interest lies above cell wall saturation. The simple numerical model developed in [6] was made specifically for use with dose-response models and integration with performance-based service life design.

The integration of numerical moisture modelling in service life prediction led to improved accuracy, but simultaneously introduced a dependency on commercial software and increased the computational time. These

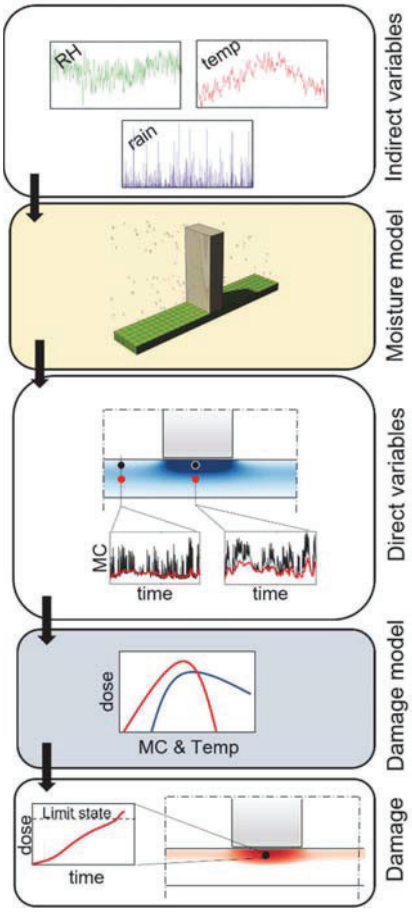

Figure 1: *Framework to predict moisture content and damage from environmental variables.*

downsides limit the practicality of numerical modelling. Alternatively, data-driven (DD) models that are considerably less computationally expensive than numerical models can easily be integrated into digital design tools for applications of service life prediction.

This paper explores new DD approaches for moisture content prediction of rain-exposed wood. The aim is to develop an efficient alternative to existing numerical models for moisture content prediction, with minimal loss in accuracy. For this purpose, synthetic data obtained from the numerical model in [9] were used for model development. A set of DD models based on the multiple linear regression (MLR) and artificial neural network (ANN) approaches, under various settings and input variable assumptions, were developed and evaluated via statistical and qualitative methods. The models are then tested against two different data sets based on real measurements.

2 METHOD

2.1 Data

2.1.1 Synthetic data for model development

Each data set (synthetic or measured) includes time-series of the moisture content at a specific depth from the wood surface (response/output variable) and relative humidity, precipitation, and temperature (predictor/input variables). A model was first fitted and verified against a set of synthetic data obtained from a one-dimensional numerical model for moisture transport in Norway spruce (*Picea abies*) wood [3]. The model geometry was modelled as 22 mm, reflecting the thickness, and transport properties reflecting moisture flux perpendicular to the grain direction. More details regarding the dataset can be found in [10], where the same data was used to map the decay hazard in a variety of different climates.

2.1.2 Measured data for testing

Two different datasets were used for testing the model against real measurements of varying moisture content. Both datasets consisted of measurements of moisture content obtained for Norway spruce boards in outdoor conditions, with weather data recorded in parallel. Moisture content was measured by resistance-type moisture sensors using insulated electrodes in both cases. Important to note is that the valid range of resistance-type measurements is (generally) below the point of cell wall saturation.

The first data set came from [11] and spanned a period of about 2.5 years. Measurements of moisture content were obtained from horizontal boards with a thickness of 22 mm. The top face was exposed to precipitation while the bottom face was considered sheltered and end-grain surfaces were sealed by silicone-based adhesive. Measurements were obtained at a depth of 11 mm from the top face, i.e., at half of the board's thickness. The geometry and exposure setup of the dataset were consistent with the numerical simulations used for DD modelling.

The second dataset came from [12] and spanned a period of about two years. Measurements of moisture content were obtained from inclined (45º) boards with a thickness of 20 mm. The test included specimens with both planed and pre-weathered top faces. Here, only the measurements obtained from pre-weathered samples were used. All short sides as well as the back face of the boards were sealed by silicone-adhesive, leaving only the top face exposed to the ambient weather. Surface moisture content was monitored every 5 minutes. After 18 months of exposure, the test setup was sheltered from precipitation, but remained outdoors for an additional 6 months. The specimens were similar to the geometry used for producing the synthetic data, but it should be noted that the specimen thickness was 2 mm less, the backside was sealed, and the boards were inclined. However, the small discrepancy in thickness nor the sealed bottom face were expected to have a significant influence on the surface moisture content of the exposed face.

https://doi.org/10.52202/069179-0495

2.2 MODELLING

The study includes several approaches for DD moisture prediction of rain-exposed wood, preliminary based on MLR and ANN approaches with various assumptions of input variables. The simplest MLR model can be defined as:

$$u_t = \beta_0 + \beta_1 \times RH_t + \beta_2 \times T_t + \beta_3 \times p_t \qquad (1)$$

where t is the index of time, and β_0, β_1, β_2, and β_3 are constants relating the relative humidity RH, temperature T, and precipitation p to the moisture content u at a given depth of a horizontal wood specimen (e.g., 11 mm). The reference values for u were outputs of a numerical model developed based on an average year of exposure for different climate data of about 550 sites across Europe [10]. More complex MLR could be achieved by relating u_t to RH, T, and p from t, t-1, t-2, …, t-L where L is a maximum time lag to consider potential contributions from previous time steps. The constants, as expected from eq. 1 (β_0, …, $\beta_{(L+1)\times 3}$), were obtained using the conventional least square method for a set of known u (synthetic data by numerical model). A suitable range of L was primarily estimated by cross-correlation analysis, which evaluates linear relationship between u and time-lagged versions of p, T, and RH. Then, L was fixed after evaluating the performance of ANN with multiple options from the estimated range, to take the non-linear relationships into account. These analyses were done for the 11 mm depth moisture content, but the resultant L was assumed valid for shallower depths too.

While the input variables used for MLR and ANN could be the same, the way they were related to moisture content was different. The equations used for ANN, are usually better described using an architecture resembling the neural network of a human brain, as exemplified in Figure 2.

For the example of Figure 2, each black node on the input layer includes a data vector corresponding to an average daily value of an input variable (e.g., RH). Then, each red neuron on the first hidden layer (HL) multiplied the input variables by a corresponding scalar weight w and added a scalar bias b to the sum of all weighted input variables. Finally, a transfer function (f) was applied to give a value n to the neuron. Thus, the mathematical expression for a neuron on the first HL (h=1) can be written as:

$$n_{j,h=1} = f\left(\sum_{i=1}^{4}(X_i \times w_{i,j,h=1}) + b_{j,h=1}\right) \qquad (2)$$

where j is the index of neuron (j=1, ..., 5 for h=1). Generally, a neuron on the second HL considers the results of the neurons on the first HL as input variables, and so forth for the next HL and output layer. To calibrate the parameters of ANN (w and b), an iterative optimization problem was solved to minimize the mean squared error (MSE) between the estimated and reference moisture u. The process starts with random initial parameters (variable between -1 and 1, similar range as the normalized input variables), which were changed at multiple iterations until a minimum MSE was achieved.

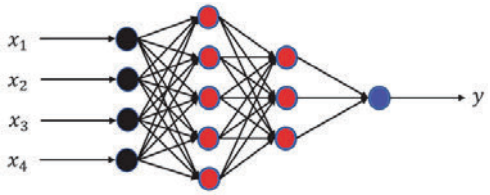

Figure 2: *A feedforward ANN architecture, connecting input variables X1-X4 to output variable y through two hidden layers (HLs) with five and three neurons (red) between input layer (black) and output layer (blue).*

Then, f had a mathematical form, making MSE differentiable with respect to the parameters w and b. In this study, $f(n)=n$ for the output layer, and $f(n)=(\exp(2\times n)-1) / (\exp(2\times n)+1)$ for the HLs as a conventional method. The suitable ANN architecture is usually a trial-and-error problem, and this study used up to two HLs and 4–20 neurons per HL.

Conventional ANNs are usually prone to overfitting due to the use of many parameters (i.e., perfect fit to the calibration data, but noisy for new data). To prevent this, a stopping rule was defined based on a part of the data (validation portion) separate to the data used for direct calibration of the ANN (training portion). This study used a so-called, "maximum validation fail (MVF)" criterion, which monitors validation MSE at the iterations. This criterion stops modelling when the MSE in the validation dataset increases for 10 consecutive iterations regardless of possible improvement in training for additional iterations. As a result, the parameterization is fixed based on the iteration that resulted in minimum validation dataset MSE (rather than training dataset MSE). The length of the study's dataset was near two hundred thousand, i.e., number of sites × (365 – L) days, due to the use of time-lagged inputs, which was quite long compared to the number of ANN parameters. So, overfitting could be less problematic. However, the MVF criterion was still useful to address the possible issue of ANN converging at a local minimum. To clarify, it is favourable to stop an ANN parameterization based on the MVF criterion and repeat it with new random initial parameters that are likely to end at a new final parameterization and exit the local minima. Finally, the ANN with minimum validation MSE among all repeats was selected. Alternatively, a hybrid of outputs from a few top ranked ANNs by validation MSE could be used, which was shown useful for generalization of the ANN outputs for other DD problems (see e.g. [13]).

As said at the beginning of this section, different models were developed based on various assumptions of input variables. These assumptions were different in, firstly, the number of lags used to consider effects of previous weather conditions, and secondly, the definition and number of principle components of the time-lagged input variables used based on the PCA method [14]. Thus, while L increased the number of input variables, PCA was a method to combine and reduce them. Thus, 12 different input variable combinations were defined as follows.

- **Direct_inputs**, where all the time-lagged versions of the three weather variables (lags 0, 1, …, *L* days) were directly used (without any reduction via PCA). So, in total, there were 3×(*L*+1) input variables.
- **All_PCA5**, **All_PCA6**, **All_PCA7**, **All_PCA8**, and **All_PCA9**, where all variables in **Direct_inputs** were reduced, in total, to 5, 6, 7, 8, and 9 variables, respectively, via PCA.
- **Lags_PCA3**, **Lags_PCA4**, **Lags_PCA5**, and **Lags_PCA6**, where, for each of the three weather variables, the *L*+1 time lagged versions were reduced to 3, 4, 5, and 6 variables; so, in total, there were 9 (=3×3), 12 (=3×4), 15 (=3×5), and 18 (=3×6) input variables, respectively.
- **Variables_PCA1**, and **Variables_PCA2**, where, for each of 0, 1, …, *L* lags, the three weather variables were reduced to 1, and 2 variables; so, in total, there were (*L*+1), and (*L*+1)×2 input variables, respectively.

The developed ANNs based on the above combinations of input variables were evaluated for a verification portion (Figure 3), separated entirely from the training and validation portions, using the modelling performance criteria Nash-Sutcliffe Efficiency (NSE) that is:

$$NSE = 1 - \sum \frac{(\hat{u}_i - u_i)^2}{(u_i - \mu)^2} \qquad (3)$$

where, $\hat{u}$ and u stand for estimated and reference moisture content, μ is average of u, and i denotes the index of the verification data. NSE can be reformulated as NSE=A–B–C; where $A=2\times\frac{\hat{\sigma}}{\sigma}\times\rho$, $B=(\frac{\hat{\sigma}}{\sigma})^2$, $C=(\frac{\hat{\mu}-\mu}{\sigma})^2$, $\hat{\mu}$ and $\hat{\sigma}$ are mean and standard deviation of $\hat{u}$, ρ is correlation coefficient (perfect linear relationship between $\hat{u}$ and u is ρ=1, while the lack of linear correlation is ρ=0), and σ is standard deviation of u. Hence, NSE is different from the coefficient of determination ($R^2=\rho^2$), in that it includes additional elements considering the biases in estimates of variance (in B) and mean (in C), along with ρ (in A) to describe the modelling performance. The perfect accuracy is NSE=1 while NSE<0 is a condition worse than the use of μ as a simple estimator. NSE is widely used as an independently interpretable performance index of DD predictive modelling relying on weather data in various fields (e.g., [15,16]).

It is noted that, for a fair distribution of variable moisture data, in all portions in Figure 3, the Scheffer climate index, SCI, as described in [17], was calculated for the studied sites to classify them into 40 classes, with a frequency of 13 to 14 sites per SCI class, equivalent to 0–2.5, 2.5–5, …, 95–97.5, 97.5–100 percentiles of SCI as shown in Figure 4. Then, from each class, one site was randomly selected for "verification", another for "validation", and the remaining 11-12 for "train".

3 RESULTS AND DISCUSSION

3.1 Model performance against synthetic data

To predict daily wood moisture content via ANN and MLR, *L* was defined first. Based on the cross-correlation analysis in Figure 5, among all weather variables, the highest correlation (ρ~0.55) was observed for *RH* at *L*=2; meaning that u had the highest linear relationship to relative humidity of two days earlier. For *RH*, ρ remains above 0.4 for up to *L*=10 and gradually decreases with further increases of *L*. Negative ρ for *T* indicates reverse changes of u and temperature. Among the variables, the absolute value of ρ dropped the fastest (slowest) for precipitation (temperature) from the max ρ at *L*=2 to the more stabilized ρ at higher *L*. Generally, a suitable range of options for *L* was estimated not to exceed 6 – 13 days, when ρ stabilized for different variables. Therefore, the development of ANNs using the 12 input variable combinations (as defined in section 2.2) was repeated for each choice of *L* between 6 – 13. The NSE of the ANNs are summarized in Figure 6a (for *L*=6–9) and Figure 6b (for *L*=10–13).

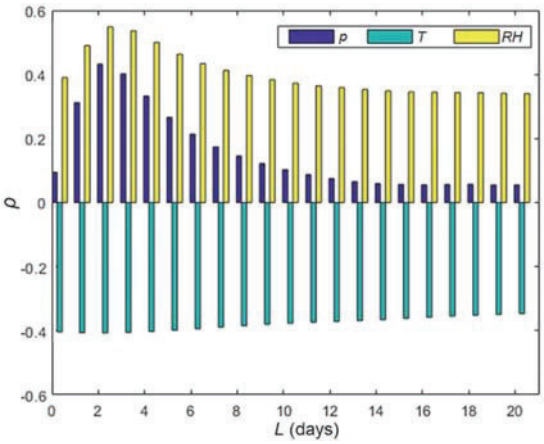

Figure 5: *Cross-correlation between 11 mm depth synthetic moisture content and three weather variables lagged by 0 – 20 days.*

https://doi.org/10.52202/069179-0495

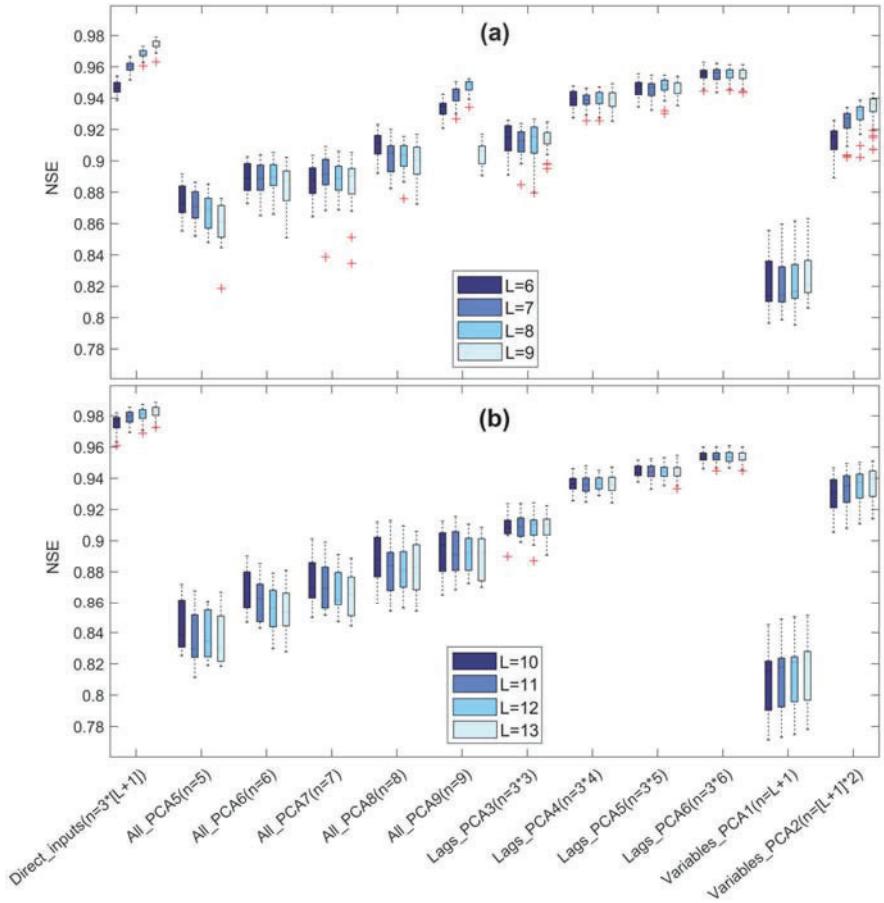

Figure 6: *Boxplots representing the range of NSE obtained from up to 25 repeats of ANNs developed for 11-mm depth moisture content modelling using time-lagged input variable combinations. On the horizontal axis,* n *gives the total number of input variables based on (a) L=6–9 days and (b) L=10–13 days. Red plus markers show outliers.*

The type of delayed response seen in Figure 5 and discussed in the previous paragraph is typical for moisture transport phenomenon. The delay primarily depends on the transport properties and depth. The increase in moisture content stemming specifically from lagged precipitation tends to decrease with decreasing distance to the rain-exposed surface. Therefore, less lags could be used for predicting the response at 1 mm (e.g., compared to 11 mm) depth. As mentioned earlier, the lags were, however, not varied between the two depths.

In Figure 6, for every input variable combination (e.g., Direct_inputs), eight boxplots are presented, corresponding to different choices of *L*. Each boxplot shows the range of obtained NSE for the repeats, where the bottom and top of each box corresponds to the first and third quartiles (q_1 and q_3, respectively), and the line within the box depicts the median NSE. The whiskers extend to the most extreme NSE, with outliers shown by the '+' marker. Outliers were greater than $q_3+w\times(q_3-q_1)$ or less than $q_1-w\times(q_3-q_1)$, where w was 2.7×(standard deviation of NSE). All the outliers in Figure 6 are located below the boxes (least NSE), which could mean that the outliers belonged to the repeats where ANN was trapped within the local minima of MSE.

As a result, while higher NSE is favourable, smaller intervals between the q_3 and q_1 (i.e., shorter boxes), show less sensitivity of modelling to the employed ANN architecture and initial random parameters in repeats. The shortest boxes were primarily observed for the ANN models using Direct_inputs, and Lags_PCAx (when x=6, 5, or 4). However, Direct_inputs resulted in the highest NSE that increased with increases of *L*, e.g., from 6 to 9 days (Figure 6a). Further increases of *L*, e.g., from 10 or 11 to 13 days (Figure 6b), did not result in a significant NSE increase for Direct_inputs. Lags_PCAx generally showed sensitivity to x rather than *L*.

Thus, the accuracy of predictions using input variable combinations of the form Lags_PCAx was mainly controlled by the adopted number of principal components, e.g., see the jumps in NSE values from Lags_PCA3 to Lags_PCA4 (Figure 6).

In view of the above, Direct_inputs and *L*=10 or 11 days seem to be enough for accurate prediction of the synthetic wood moisture content with a minimum sensitivity to ANN architecture and initial random parameters. Using such a combination for input variables, ANN could significantly outperform MLR. For example, by *L*=10, the

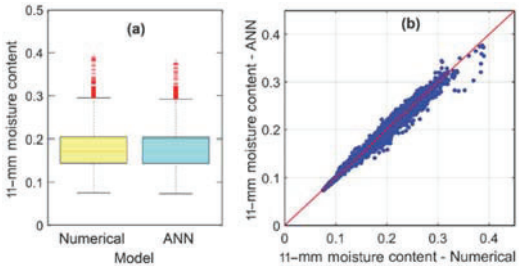

Figure 7: *Comparison of synthetic vs modelled (ANN) 11-mm moisture data in box plot (a) and scatter plot (b)*

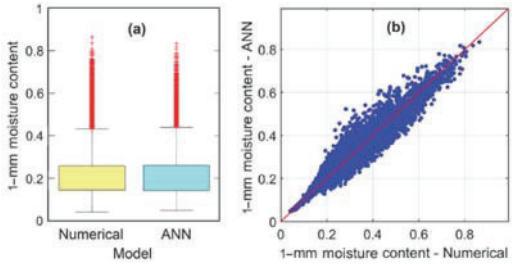

Figure 8*: Comparison of synthetic vs modelled (ANN) 1-mm moisture data in box plot (a) and scatter plot (b).*

corresponding NSE for MLR was 0.86, so 10% smaller than the least (outlier) NSE shown in Figure 6b for ANN under Direct_inputs and L=10 (0.96). Also, for an arbitrary ANN (not the best) with the same inputs, mean absolute error in verification of ANN was three times smaller than that of MLR (0.004 vs 0.013).

So far, the evaluations are based on the statistical performance criteria of the DD moisture content prediction at 11-mm depth. Figures 7 and 8 help to visually examine the predicted moisture content by ANN versus the synthetic moisture content by numerical model (as reference) at 11- and 1-mm depth, respectively. The box plots (Figures 7a and 8a) compare the synthetic and modelled data variability while the scatter plots (Figures 7b and 8b) compare the exact data points with the 45-degree line equivalent to the best fit for verification. Based on Figure 7a, except for a few top outliers ("+" markers), the elements of the boxplots for ANN and synthetic data match together, which is supported by the scatter plot (Figure 7b) showing a generally good agreement between ANN and synthetic data except for a few data points of synthetic values above 0.3 that are underestimated by ANN. Similarly favourable results can be observed for 1-mm moisture prediction in Figure 8. However, as seen in Figure 8b, the extreme data points (e.g., synthetic data below 0.2 and above 0.6) do not show significant over- or underestimations by ANN, and the highest discrepancies were observed for data points between 0.2 and 0.4.

Further evaluations of the moisture content predictions by the selected ANNs are described below by comparing the modelling outputs with the experimental measurements.

3.2 Model performance against measured data

Figure 9 shows the predicted daily average moisture content with measured data. Qualitatively, the model captures the seasonal variation, the timing of the peaks and the width of the peaks at the surface with reasonable accuracy. It should be emphasized that, due to measurement limitations, the amplitude of the rain-induced peaks cannot be compared. The final months of the measurement confirm that the model performs well in the absence of precipitation.

The comparison at a depth of 11 mm indicates that the model, at least initially, overestimates the rain-induced peaks, but is able to reproduce the seasonal variation quite well. The limitation regarding the valid moisture range is less problematic in the core of the sample, since the moisture content generally remains within the valid measurement range.

The vertical shaded lines indicate periods of time when one or several weather variables were missing. It can be noted that every instance of missing inputs results in a gap in the output equal to the window of missing data plus an additional 11 days (considering the required lagged inputs for DD modelling). So, the size of these gaps is consistent with L. To reduce the impact of missing data, smaller gaps

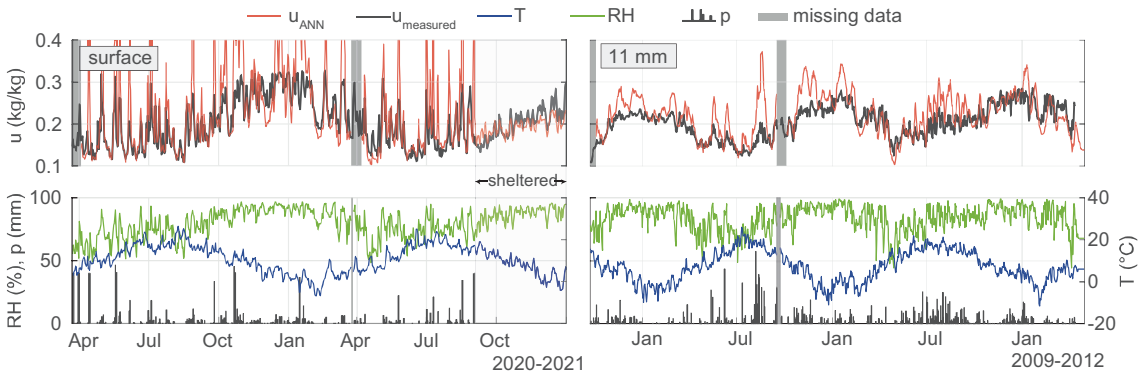

Figure 9: *ANN model compared against measured data (top row) from two different experiments where the moisture content was measured at different depths (surface and 11 mm) together with weather data over the respective periods (bottom row). Shaded vertical lines indicate periods when at least one weather variable is missing.*

https://doi.org/10.52202/069179-0495

can be filled by interpolation of weather prior to the estimations by modelling. Relative humidity and temperature can be interpolated linearly with reasonably low errors since the variation between adjacent days is usually small. Instances of missing precipitation can be substituted by zeros or data from near locations. A single missing rain event will then introduce an unknown degree of uncertainty in the following 11 days of predicted moisture content (if L=11 days) due to the usually high variability of spacetime precipitation. The related error will generally be significant a few days after the missing rain event, and will decrease as the weight of the lagged inputs decrease.

Figure 10 shows the relative time spent above a certain moisture content near the surface. Accordingly, the minimum and maximum measured daily average moisture content are approximately 10% and 32%, respectively, whereas the corresponding modelled values are 10% and >35%. The modelled time spent above a certain threshold remains accurate up until a threshold of u=23%, after which the modelled values increasingly exceed the measurements. As noted in section 2.1.2, this discrepancy can be mainly explained by the nature of the resistance-type measurements. Unless carefully calibrated (see e.g. [18]), measurements based on this technique tend to underestimate the moisture content in the over-hygroscopic moisture range. Consequently, model accuracy cannot be evaluated in the over-hygroscopic region and predicted values should be interpreted and used with caution. The discrepancy already at 23% moisture content is likely related to aggregation of the measurements to daily averages. To clarify, while measurements are relatively accurate up to around 25% moisture content, a daily average of 23% can include sub-daily measurements exceeding 25%. This limitation can be dealt with in durability applications by interpreting any values exceeding 25% as being favourable for fungal decay, and/or by adapting the decay model by reducing the critical moisture-threshold [2].

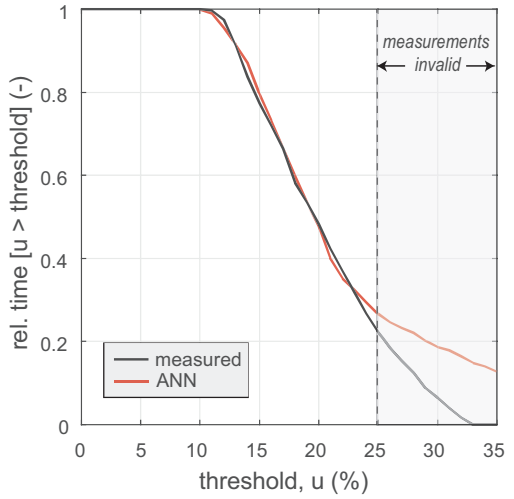

Figure 10: *Measured and modelled relative time spent above a certain moisture content-threshold near the surface.*

4 CONCLUSIONS

Data-driven models can be used to predict moisture content of rain-exposed wood. Contrary to numerical models, data-driven models are efficient and deployable and can thus be integrated into existing digital performance-based service life design frameworks for wood. This will potentially lead to improved and accessible service life prediction of wood.

Using simulated data for model fitting is not ideal, as any errors stemming from the numerical model are transferred to the DD model. In addition, the range of wood species for which the numerical model is valid is limited. On the other hand, when fitting a model to measured data, any uncertainties and limitations (such as the valid measurement range) of the system are instead transferred to the model.

In future work, the model will be used to map decay risk based on data sets with high spatial resolution (on different scales) and longer timespans (multiple years), where numerical models are too computationally expensive.

HYGRO-THERMAL EXPERIMENTAL ANALYSIS OF A FLAT ROOF STRUCTURE INTEGRATING A VARIABLE VAPOR-DIFFUSIVITY MEMBRANE

Riccardo Pinotti[1], Paola Brugnara[2], Stefano Avesani[3]

ABSTRACT: The work presented hereby aims at verifying the hygro-thermal performances of a non-ventilated timber frame flat roof structure integrating a variable vapor-diffusivity membrane. In particular, the objective is to verify the drying up process of the specimen after a humidity storage phase. These two phases have been determined referring to the typical conditions occurring in a European continental winter period (when, usually, humidity coming from indoor environments is stored by the structure) and a summer period (when, typically, the structure has should dry up). Hence, considering the specific use of variable vapor-diffusivity membrane, the main objective is to verify whether a drying process is allowed towards the indoor environment. An experimental test on a specimen has been performed in a double climatic chamber and the results have been used in order to validate an hygrothermal model. The model allowed then to study the structure's hygrothermal behaviour in different climatic conditions, showing promising outcomes related to the use of a variable vapor-diffusivity membrane in such envelope component.

KEYWORDS: Dynamic hygro-thermal behaviour, Modelling and simulation, Membrane and timber-based construction

1 INTRODUCTION

Vapor membranes are used to manage vapor transfer through the building structures.

It is well-known that excessive humidity levels within the building envelope may cause relevant damages to structures and materials, affecting both structural and physical performances (e.g., decreasing thermal conductivity) [1] [2] [3]

Typically, in continental climates, vapor-retarder or barriers membranes are used to prevent high level of moisture to reach the outer layers of the envelope in order to avoid condensation issues during the cold season.

Nowadays, the use of variable vapor-diffusivity membrane in the building sector is growing [4]. These membranes can vary their vapor permeability properties depending on the humidity of the environment in which they are embedded. In particular, they reach high vapor permeability when surrounded by high humidity levels and vice versa.

However, it is not a common approach to use this kind of membranes in roof structures since, in order to avoid condensation issues in the outer layer of the structure during cold season, vapor barriers or retarders are usually installed on the inner side of the structure. Actually, this approach does not consider eventual criticalities occurring on the building site while installing these membranes, since the posing procedure may cause dangerous leakages for vapor within the structure. Small damages, scratches and imperfections during the laying of those membranes may be the cause of potentially critical one-way vapor leakages through the envelope, in particular if timber based. The variable vapor-diffusivity membrane can potentially solve this issue, behaving as a vapor retarder within typical indoor relative humidity ranges, while becoming more vapor-open when surrounded by higher humidity values.

Hence, in this study, an alternative solution to the application of vapor retarders or barriers has been investigated, namely adopting an innovative variable vapor-diffusivity membrane. Such membrane has the capability of varying its permeability to vapor, behaving as a vapor open layer when embedded in high moisture conditions hence, allowing a higher flexibility in the application procedure, ensuring a drying potential to the structure containing high humidity levels. A detailed dynamic model of the construction has been setup, supported by experimental tests and a set of simulations has been run to calculate the whole construction hygro-thermal performance under different climates, aiming at validating the use of such innovative layer.

2 METHODOLOGY

To access the performances of the proposed solution, a typical timber frame roof structure integrating a variable vapor-diffusivity membrane has been tested in a controlled environment and a numerical model performed in Delphin 6 has been calibrated with test results. The

https://doi.org/10.52202/069179-0496

model has been run for 10-years-long hygro-thermal simulations in different climatic conditions.
The following steps have been followed in order to set up the analyses:

1. Assembling of the prototype – the prototype has been assembled at EURAC Research laboratories, in order to allow an easy installation of the hygrothermal sensors within the material layers.
2. Pre-conditioning – the different layers, still not completely assembled, have been kept in a climatic chamber at high relative humidity level (~80%) and constant temperature for 3 days. This procedure ensured that the humidity content of the specimen would have been high enough at the beginning of the dynamic test, having reached an hygrothermal balance with the surrounding environment, and could have highlighted the drying process during in the following testing phases.
3. Dynamic test – after the pre-conditioning, the prototype has been completely assembled and installed within the testing facility (i.e., the Multifunctional Façade Lab, namely a double climatic chamber at EURAC Research laboratories). Here, dynamic test has lasted 15 days. Temperature and relative humidity of a continental summer weather condition have been replicated on the outer side of the specimen (one of the two chambers of the Multifunctional Façade Lab) in order to verify the drying potential towards a constant-condition inner side of the prototype (facing the other chamber of the testing facility).
4. Model calibration and extended simulations – measuring realistic dynamic hygrometric behaviours within building materials would require very long timespans, in the range of seasonal climatic variations, and this is of course not feasible to be performed in a laboratory on large scale specimens. Therefore, it has been decided to use the results from the tests to calibrate and validate a numerical model using Delphin 6. The model allowed to evaluate the hygrothermal behaviour of the structure in an extended timespan and in different climate conditions.

2.1 EXPERIMENTAL SET-UP

The tested prototype has an area of 1.44 m² (1.2m x 1.2m). The layer and material properties within the structure are described in Table 1.

Table 1: *Structure layers and material properties*

Layer (inside to outside)	Thickness	Density	Heat Capacity	Conductivity	Vapor Permeability
	[mm]	[kg/m³]	[J/kgK]	[W/mK]	Sd[m]; μ[-]
Gypsum fibre Board	12.5	744	1384	0.21	μ =4
Variable Vapour Diffusivity Membrane	*	*	*	*	Sd_variable = 0.15 ÷ 5
Mineral Wool Insulation	240	110	1030	0.036	μ = 3.5
OSB Panel	20	530	1880	0.1	μ = 280
Self-Adhesive Bituminous Membrane	*	*	*	*	Sd= 200
Self-adhesive Slate Bituminous Membrane	*	*	*	*	Sd= 280

** Delphin is not requiring this parameter for simulations*

The above-mentioned values have also been used in the simulation model. Anyway, for some of the materials, detailed data sheets were not available. For these specific cases, assumptions have been made using typical values for similar products. These values have been considered as main parameters to be calibrated in order to match model and test results.
The test has been performed in double climatic chamber and in order to monitor the hygrothermal conditions within the specimen, it has been equipped with 8 Amphenol T9602 sensors, measuring temperature (-20÷70°C ± 0.3°C) and relative humidity (0÷100% ± 2%). In Figure 1, Figure 2 and Figure 3, sensors' position within the prototype is represented.
Sensors 1,2 and 3 are placed between the OSB partner and insulation layer, being embedded in this last.
Sensors 4,5 and 6 are placed between the vapor variable diffusivity membrane and the insulation; hence, they are not in contact with the gypsum-fibre board.
Sensors 7 and 8 are positioned between two insulation layers, approximately in middle of the specimen thickness.

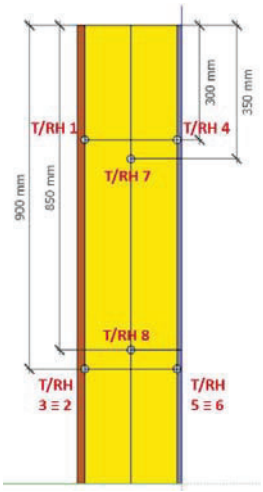

Figure 3: *Sensor positioning scheme, vertical section*

2.2 DYNAMIC TEST

Once the pre-conditioning phase, used to load the specimen of vapor, has been concluded (3 days at 80% relative humidity), the dynamic test started. Hence, operative conditions typical of a summer continental European climate have been reproduced within the facility.

In particular, in order to determine the external temperature and relative humidity conditions to be applied during the test, a typical climatic year related to Munich (Germany) has been used the weather file has been made available by the World Meteorological Organization (https://public.wmo.int/en) and downloaded by the Energy Plus website (https://energyplus.net/weather). From this reference hourly data, 4 summer days (middle of June) have been extrapolated and used to build the temperature and relative humidity curves to be reproduced by the testing facility's chamber representing the outdoor environment.

Concerning the conditions set on the indoor side, where humidity is free floating between 30% and 60%, temperature has been set to 20°C. A scheme of the test setting in shown in Figure 4, while a picture of the specimen installed in the Multifunctional Façade Lab is in Figure 5.

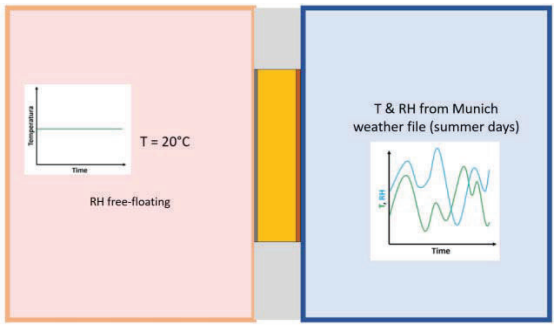

Figure 4: *Schematic view of the test setting within Multifunctional Facade Lab; the specimen is between indoor and outdoor conditions created in the chambers*

Figure 5: *Prototype installed in the testing facility*

Dynamic tests took about 17 days. In Figure 6 and Figure 7, the graphs are showing the monitored boundary conditions in the chambers during the test.

https://doi.org/10.52202/069179-0496

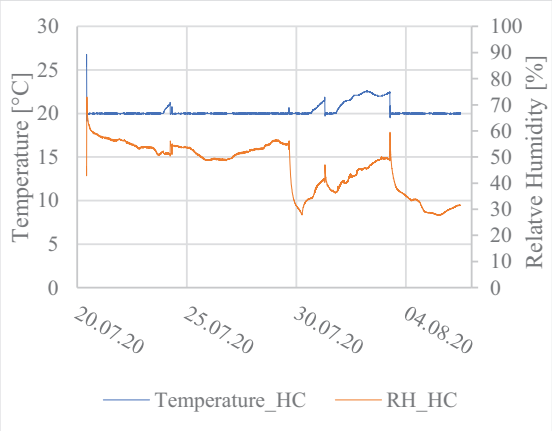

Figure 7: *Temperature and Relative Humidity conditions on the Outdoor side of the specimen during the test. "_HC" stand for "Hot Chamber", referring to the facility chamber reproducing the indoor environment*

2.3 MODEL CALIBRATION

After about two weeks of dynamic test, the data acquired by the sensors within the specimen have been used to calibrate a bi-dimensional hygro-thermal model, developed with the software Delphin 6. Hence, the model aimed at reproducing faithfully the testing conditions, also taking into account the gravity effect on vapor transfer dynamics, due to the vertical position of the prototype.

In Figure 8, a schematic representation of the bi-dimensional prototype geometry modelled is shown. The initial values for material properties used by the model are reported in Table 1.

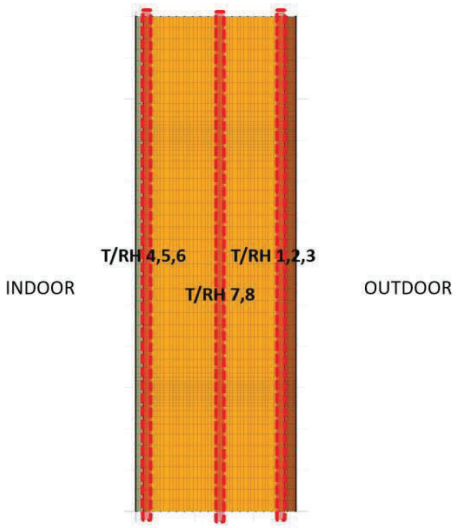

Figure 8: *Geometrical model used in Delphin 6; it is possible to notice the calculation mesh and the layers (marked in red) where the model outputs have been evaluated*

Figure 8 is also showing (in red) the layers in which temperature and relative humidity outputs from the model has been taken, as averaged value of the selected nodes within the mesh.

As a consequence of this, temperature (T) and relative humidity (RH) measured by sensors T/RH 1, 2 and 3 will be compared respectively with model outputs called T123 and RH123; values from sensors T/RH 4,5 and 6 will be compared with output T456 and RH456; values from sensors T/RH 7 and 8 will be compared with output T78 and RH78.

In the following graphs (from Figure 9 to Figure 14), calibration process' results are shown. In these graphs, it is possible to notice the comparison between monitored data and results from the model in the specific layer.

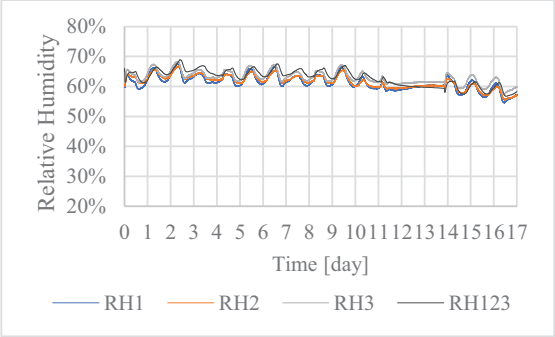

Figure 9: *Comparison between RH 1, 2 and 3 from tests with model results RH123*

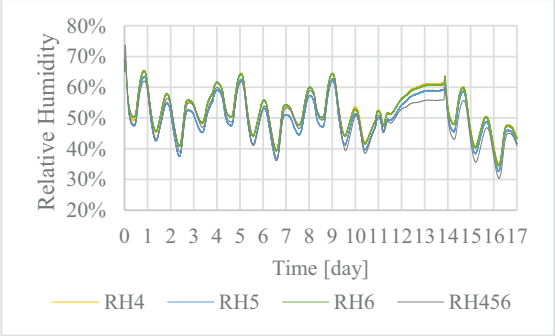

Figure 10: *Comparison between RH 4, 5 and 6 from tests with model results RH456*

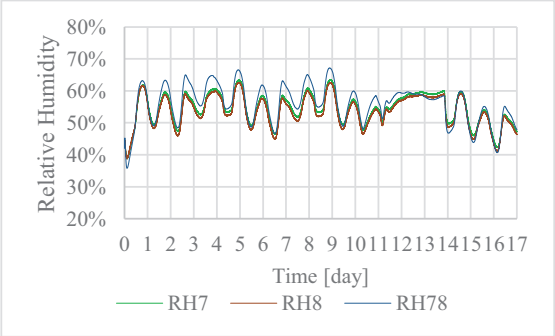

https://doi.org/10.52202/069179-0496

Figure 11: *Comparison between RH 7 and 8 from tests with model results RH78*

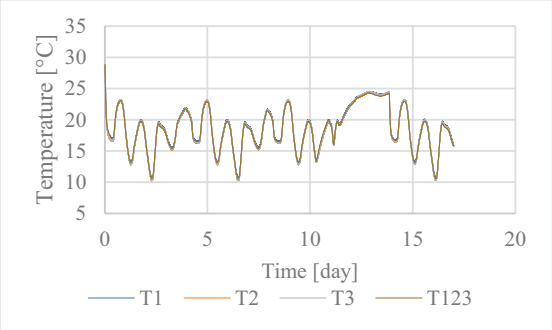

Figure 12: *Comparison between T 1, 2 and 3 from tests with model results T123*

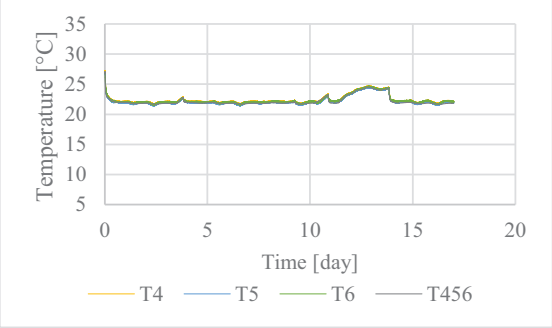

Figure 13: *Comparison between T 4, 5 and 6 from tests with model results T456*

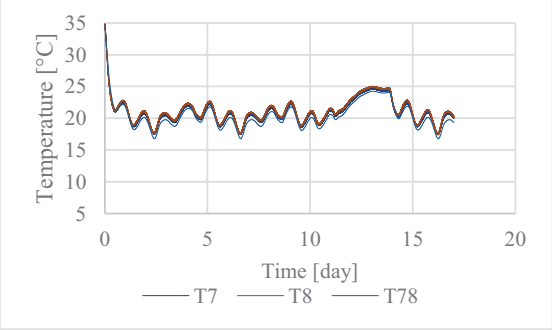

Figure 14: *Comparison between T 7 and 8 from tests with model results T78*

In the following Table 2 and Table 3, the Mean Absolute Error (MAE) and the Root Mean Square Error (RMSE) between model output and the average value of the sensors within the same layer are reported.

Table 2: *MAE and RMSE for relative humidity values*

	RH 123	RH 456	RH 78
MAE	0.014	0.019	0.023
RMSE	0.017	0.024	0.027

Table 3: *MAE and RMSE for temperature values*

	T 123	T 456	T 78
MAE	0.14	0.15	0.56
RMSE	0.17	0.18	0.60

To calibrate the model which brought to the above-mentioned results, it has been necessary to slightly modify the materials' properties within the software, applying some small variations on the values taken from the datasheets. Calibrated material properties used in the model are shown in Table 4. In particular, some change in the vapor permeability of the insulation layer has been applied. Nevertheless, this variation is acceptable, especially considering the high-compression and high-humidity levels of the material within the specimen. Some other variations of the vapor permeability of material have been adopted, but always within ranges reported on their technical sheets. Table 4 shows the material properties used in the calibrated model.

Table 4: *Material properties used after calibration process; for those values which have been modified respect to the initial one, this last is shown between brackets.*

Layer	Thickness	Density	Heat capacity	Conductivity	Vapor permeability
	[mm]	[kg/m³]	[J/kgK]	[W/mK]	Sd: [m]; μ:[ ]
Gypsum fibre Board	12.5	744	1384 (n.d.)	0.21	μ =4
Variable Vapour Diffusivity Membrane	*	*	*	*	Sd_variabile = 0.15 - 6
Mineral Wool Insulation	240	110	1030	0.036	μ = 3.5 (1)
OSB Panel	20	530	1880 (n.d.)	0.1	μ = 280 (90 – 150)
Self-Adhesive Bituminous Membrane	*	*	*	*	Sd=200
Self-adhesive Slate Bituminous Membrane	*	*	*	*	Sd=280

** Delphin is not requiring this parameter for simulations*

3 EXTENDED ANALYSIS IN DIFFERENT CLIMATES

Once performed the model calibration, it has been used to extend the hygrothermal study in different climatic conditions for 10-years-long simulations. The objective is to verify the effective drying potential of the structure in the summer period after and eventual humidity storage during the coldest season. Furthermore, a simulation set up (namely "Condition 2") verified a slightly different stratigraphy, also considering an additional insulation layer and a gypsum fibre board in the inner layers.

Being the simulation referred to a roof structure, the model has been set in horizontal direction, taking into account the gravity effect on moisture transport. This allowed to verify the real hygrothermal behaviour of the roof structure.
Table 5 is reporting the configurations used for extended hygrothermal analyses.

Table 5: *Boundary conditions for extended analyses*

Condition	Model stratigraphy	Internal condition T and RH	External condition T and RH
Condition 1	Stratigraphy calibrated with test results (**Errore. L'origine riferimento non è stata trovata.**)	WTA adaptive indoor climate model[1] implemented in software Delphin6.0	Yearly weather file Central Europe[2] Munich
Condition 2	Stratigraphy calibrated with test results (**Errore. L'origine riferimento non è stata trovata.**) + 5 cm insulation + gypsum fibre board	WTA adaptive indoor climate model[1] implemented in software Delphin6.0	Yearly weather file Central Europe[2] Munich
Condition 3	Stratigraphy calibrated with test results (**Errore. L'origine riferimento non è stata trovata.**)	WTA adaptive indoor climate model[1] implemented in software Delphin6.0	Yearly weather file hot and humid conditions[2] Brisbane
Condition 4	Stratigraphy calibrated with test results (**Errore. L'origine riferimento non è stata trovata.**)	WTA adaptive indoor climate model[1] implemented in software Delphin6.0	Yearly weather file hot and humid conditions[2] Abu Dhabi

[1] *WTA Adaptive Indoor Climate Model provided from DIN EN 15026; it allows to determine indoor temperature and relative humidity conditions in relation to the outdoor ones*
[2] *Outdoor climatic data to run the simulations have been provided by the World Meteorological Organization and taken on the Energy Plus website (https://energyplus.net/weather)*

Here below, for the modelled configurations, the trends for integral humidity content within the stratigraphy and the relative humidity value in the layer between insulation and OSB board (RH123) are reported. It may be noticed from Figure 15, Figure 16, Figure 17 and Figure 18 related to Condition 1, 2, 3 and 4 that the humidity content during the 10-years-long simulation is periodically increasing in winter seasons while dries during summer periods. It is important to highlight that humidity content peaks are growing in the first simulated years (around 3) and then they are constant for the rest of the simulation. Furthermore, these peaks are not even reaching critical relative humidity leading to over-hygroscopic content (95%). Indeed, higher relative humidity values within the structure, reached in Condition 1 simulation, are around 87%.

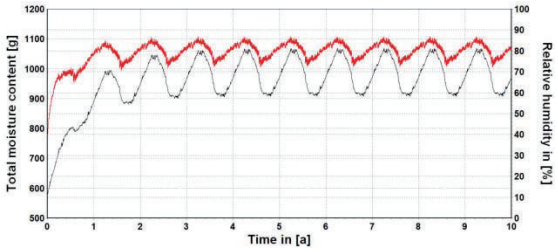

Figure 15: *Condition 1 Munich (Germany) - humidity content trend (black curve) and relative humidity at interface insulation-OSB (red curve)*

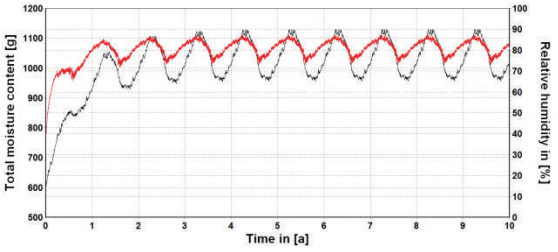

Figure 16: *Condition 2 Munich (Germany) - humidity content trend (black curve) and relative humidity at interface insulation-OSB (red curve)*

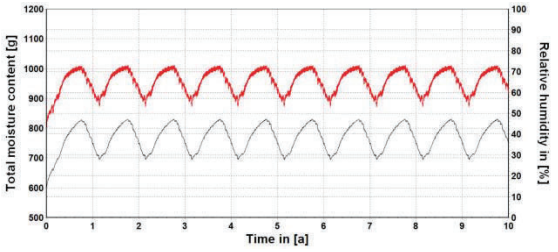

Figure 17: *Condition 3 Brisbane (Australia) - humidity content trend (black curve) and relative humidity at interface insulation-OSB (red curve)*

https://doi.org/10.52202/069179-0496

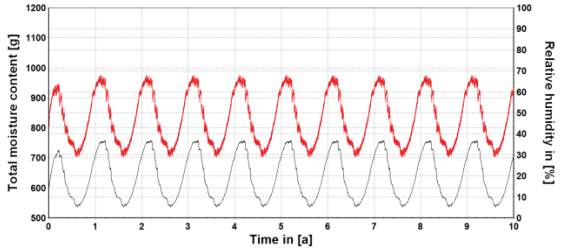

Figure 18: *Condition 3 Abu Dhabi (United Arab Emirates) - humidity content trend (black curve) and relative humidity at interface insulation-OSB (red curve)*

In Figure 19, the comparison of internal moisture content in Condition 1 (Munich climatic condition) with and without variable vapor diffusivity membrane is shown. It can be noticed that the moisture content is clearly higher in the condition without the membrane and, furthermore, this configuration is leading to cyclical creation (up to ~150 g) of over-hygroscopic content (Figure 20).
Despite the condensate dries every year, this condition is potentially dangerous for the envelope due to a possible mould-growth phenomenon or deterioration of materials.

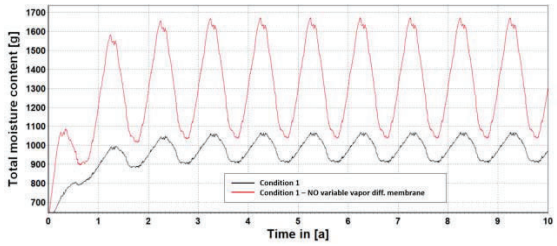

Figure 19: *Condition 1 - moisture content with (black curve) and without (red curve) variable vapor diffusivity membrane*

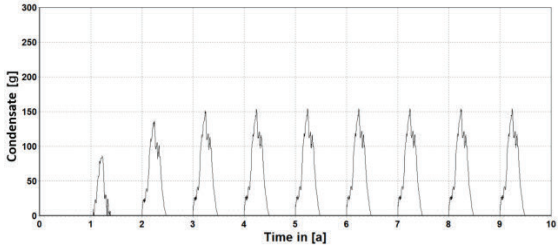

Figure 20: *Condensate in Condition 1 without variable vapor diffusivity membrane*

4 CONCLUSION

The methodology described allowed to successfully verify the hygro-thermal behaviour of a flat roof structure integrating a variable vapor diffusivity membrane.
After having performed 15-days-long experimental tests with dynamic boundary conditions across the specimen, temperature and relative humidity monitored values have been used to calibrate a numerical model developed with the software Delphin 6.
Once a detailed level of precision of the model was reached, it has been used to extend the analyses to 10-years-long period, evaluating the behaviour of the flat roof stratigraphy in different climatic conditions.
In all the simulated cases, the stratigraphy has not presented critical issues related to condensate formation, suggesting that the use of the variable vapor diffusivity membrane is effective to prevent from excessive moisture storage within the structure, allowing its drying during the warmer season.
As demonstrated by the simulation in Central European weather condition, without using the variable vapor diffusivity membrane, its presence is crucial to avoid periodical condensation events in the outer layers of the envelope during winter conditions.
The methodology applied to the specific stratigraphy analysed in this paper may be successfully replicated for developing further analyses, varying the application context and, hence, boundary conditions of the evaluated envelope structure.

DEVELOPING SLIMMER TIMBER WINDOW FRAME.

Katarzyna Ostapska[1], Tore Myrland Jensen[2], Lars Gullbreken[3], Petra Ruther[4],

ABSTRACT: Demand for the ever-increasing performance of windows when it comes to the thermal insulation properties requires, among other things, designing thinner timber frames. Structural strength and dimensional stability of wood under changing climate condition is of the key importance. In this paper the experimental and numerical investigation of the mechanical behaviour of the typical wooden window frame is presented. Based on the results, a new, slimmer timber window frame is designed and evaluated numerically. Large material savings and thermal insulation gains can be achieved with retaining required structural strength by use of optimized frames. The new frame design requires however proper design of hinge connection, protection against moisture accumulation and sufficient wood laminating for dimensional stability when exposed to varying climate conditions.

KEYWORDS: slim window timber frames, DIC, FEA, timber-to-steel screw connection

1 INTRODUCTION

Timber is the most popular material used for window framing. Its combination of high structural strength, good thermal isolation properties, and low carbon footprint makes it a natural choice for frame structures with crucial insulation functions. The further advantage of wood over plastic, aluminum and steel frames is its low energy demanding production and processing, renewability, and carbon storage qualities. To verify the design of the window, the thermal transmittance is commonly evaluated, e.g., with the formula shown in Equation (1) below:

$$U_w = \frac{U_{cg}A_g + \sum U_f A_f + \sum U_{eg}A_e}{A_t} \quad (1)$$

where U- thermal transmittance, *A*- area measured in window plane, indexes: c-central, e-edge, f-frame, g-glass, t-total. The total thermal transmittance is thus dependent, among others, on the area of the frame in relation to the total area of the window in its plane. Reducing the area of the frame, not only decreases thermal transmittance but also increases glazing area that allows for energy gains due to irradiance [2], [3].

2 METHODS

2.1 EXPERIMENT DESIGN AND PROCEDURE

To establish current window frame capacity, the static loading test was performed on the 90-degree opened window frame with point force located at the top frame corner as shown in Figure 2.1. Such load case is important in case of exceptional load during fire emergency and evacuation. The estimated ultimate failure capacity based on the preliminary numerical simulation and analytical estimation was 1.5-2 kN and the load was applied discretely with 0.2 kN intervals by adding weight.

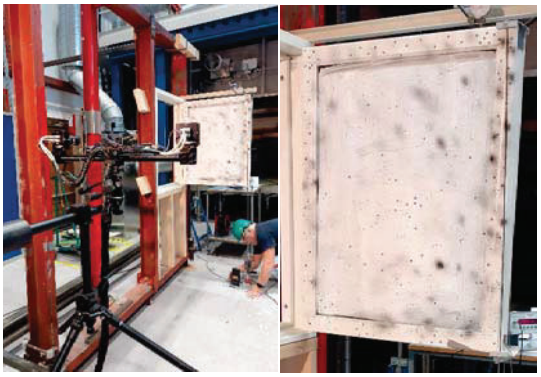

Figure 2.2: *Window frame and glazing painted for optical deformation tracking (left), image from the laboratory set-up.*

Deformations were measured optically on the whole window frame plane using commercial system of digital image correlation (DIC), ARAMIS, see Figure 2.2. Two cameras were used at a fixed distance and angle to produce the 3D displacement field that was required due to substantial out-of-plane deformation of the window during loading procedure.

2.2 NUMERICAL MODEL

The numerical mechanical model was built in the commercial software ABAQUS, where the internal stresses in wood were simulated with the use of finite element method (FEM) [1]. The geometry was based on the cross- section drawings of the original window design obtained from the producer (Røros Dører og Vinduer AS) and are shown together with subsequently modified frame sections in the Figure 2.3. The thinner frames dimensions are reduced across the thickness as the depth remains 117 mm. The thinnest frame design has wood volume reduced by 36%. This leads to the glass area increase by around 22% with the same external typical window dimensions of 1000x700mm.

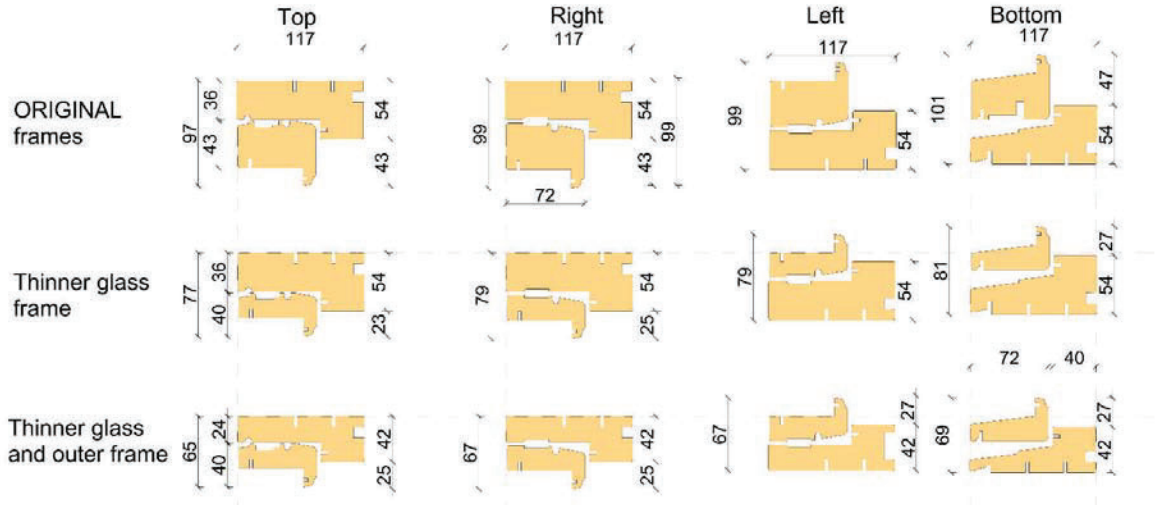

Figure 2.3. Cross section of the four frame parts for original (first row of drawings) and slim geometry after redesign (second and third raw).

Orthotropic elasticity was applied for wood material model, see Table 2.1, ideal elastic-plastic behaviour was assumed for steel hinged connection and elastic isotropic material model was used for glass (E = 50 GPa, ν=0.18).

Table 2.1*. Engineering constants for wood lamellas.*

Wood material properties [GPa]								
E_L	E_T	E_R	ν_{LR}	ν_{LT}	ν_{RT}	G_{LR}	G_{LT}	G_{RT}
10	0.6	0.6	0.5	0.5	0.8	0.6	0.6	0.06

The fixed steel-wood connection was used instead of screws for simplification in the preliminary model (model A). Screws were added to the model (model B) to

https://doi.org/10.52202/069179-0497

investigate the influence of their location and spacing on the force distribution in the hinge plate and timber. Screws were modelled with smooth shanks an assumed tied to the surrounding wood on the shank perimeter, see screw and hinge CAD geometry in Fig. 2.4.

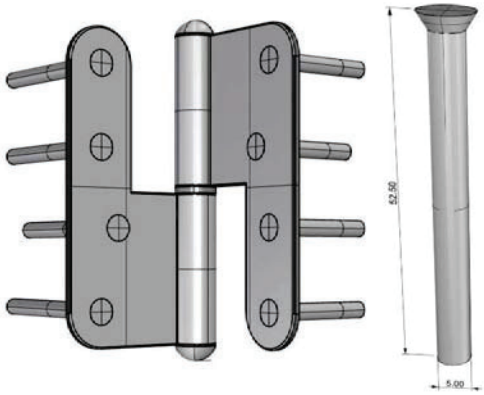

Figure 2.4: Hinge and screw model geometry.

Boundary conditions applied on the window encasing both in experiment and numerical analysis are depicted in Figure 2.5.

Finite element mesh was generated, see Figure 2.5 and 3.4, with continuous 3D solid elements. The two-layer glazing part was fixed to the timber frame part at the edges.

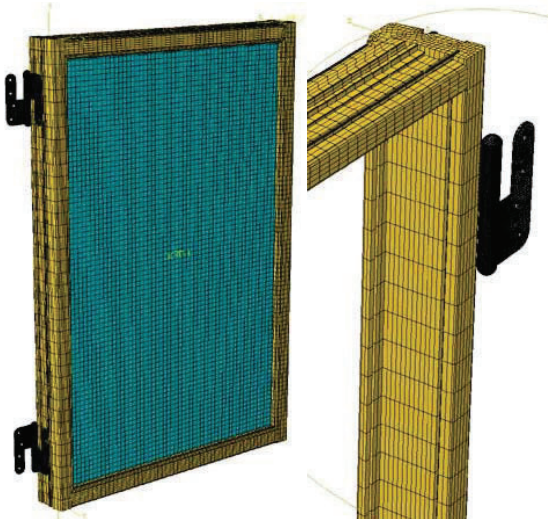

Figure 2.5: FE model geometry and mesh of the whole slim window with hinges (left) and timber frame corner detail (right).

3 RESULTS

3.1 DEFORMATIONS

The maximum measured total deformation corresponding to the maximum applied force of 1.6kN in the test was around 28 mm. The deformation is occurring in the hinge plates and the inner bolt undergoes localized bending and plastic hinge is formed.

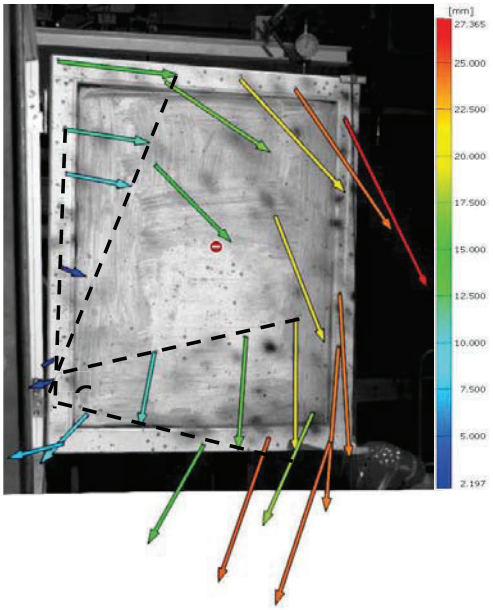

Figure 3.1: Deformations measured with DIC at 1.7kN load.

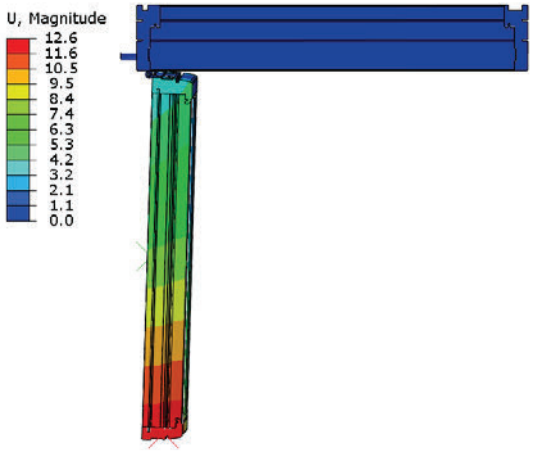
The window internal frame with glazing is rotating in plane initially as a whole, performing as a stiff shear plane component with slight in-plane shear deformations, see Figure 3.1. From the deformation field analysis, the centre of rotation is located in the vicinity of the bottom hinge. The frame is slender enough though and small out-of-plane force components caused by eccentricity of loading and boundary conditions (hinge fixings) lead to out-of-plane bending mode immediately. At this stage, large shear forces are transferred to the screw shank which leads to collapse of the frame element with glass.
Deformation modes obtained in the numerical analysis show similar behaviour and are depicted in the Figure 3.2.



https://doi.org/10.52202/069179-0497

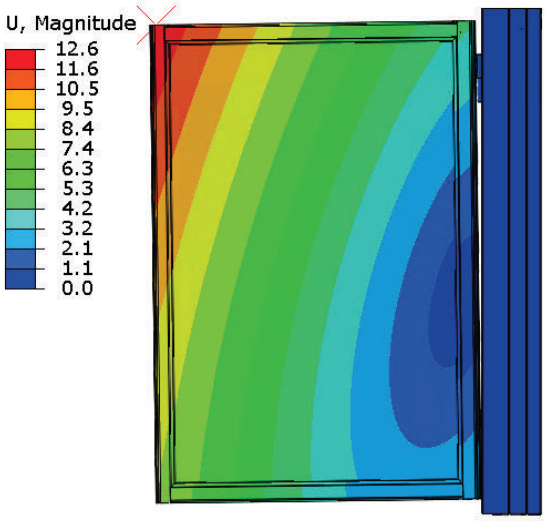


Figure 3.2: Deformation of the window in the numerical analysis from top and side view.

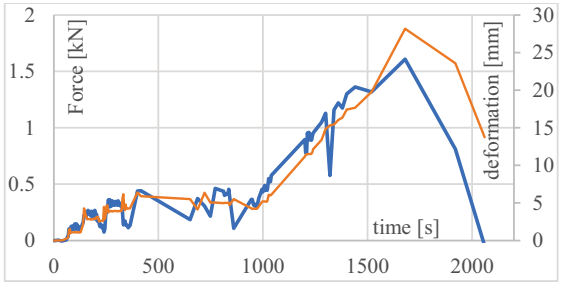

Figure 3.3: *Force (blue), load program (blue dashed) on the window frame and corresponding maximum deformation (red).*

3.2 STRESSES AND FAILURE MODE

3.2.1 STRESSES IN THE HINGE

Numerical simulation indicates the damage first occurs in the top plastic hinge, Figure 3.4, where the inner bolt starts to bend and steel plate bends because of resulting eccentricity. Based on that failure mechanism the window capacity was estimated at 1.5-2kN. Global stresses in timber frame sections are not exceeding the strength limits at the point of hinge connection failure.

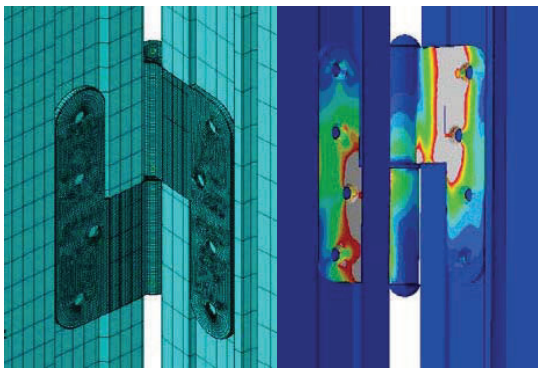

Figure 3.4: FE model of steel hinge connector (left) and stress distribution under 2kN Force (right). Gray colour areas indicate von Mises stress exceeding 250MPa.

3.2.2 STRESSES IN THE TIMBER FRAME

Timber frame is mostly not utilized in the performed test. Stresses in wood are exceeded only locally around the screw shanks, where critical concentrations start to occur as soon as 0.5kN load is reached.

Another stress concentration zone develops around the frame corners when the in-plane shear deformations and out-of-plane rotation starts. Rolling shear stresses and perpendicular to grain compression and tension in the corner of the bottom beam of the frame with glass are shown in figures 3.5 and 3.6. The presence of those stresses is a result of the twisting deformation in the glass-frame element occurring due to the eccentric and asymmetrical load.

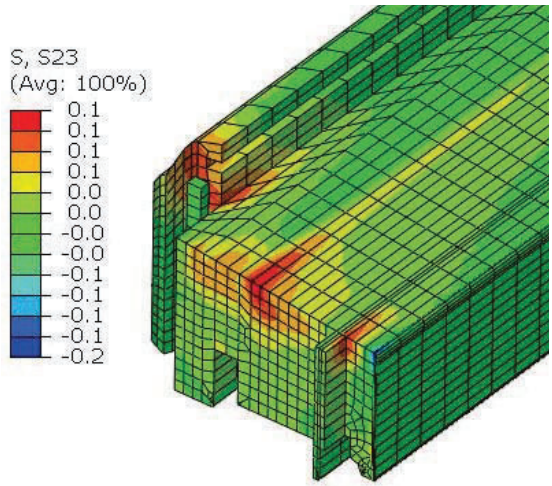

Figure 3.5: Rolling shear stresses in the end of the bottom beam of the window frame with glass at load of 1.6kN.

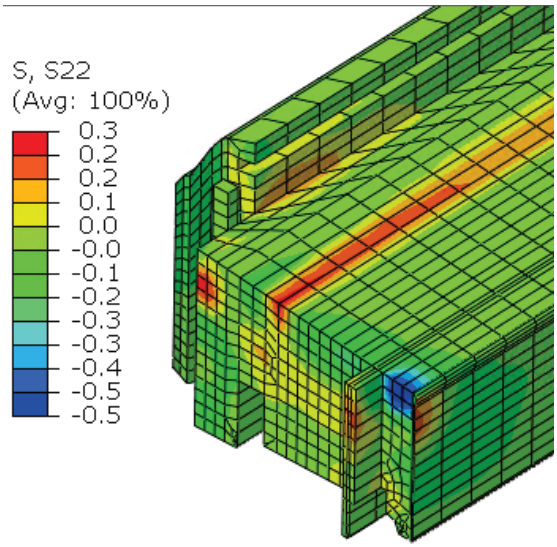

Figure 3.6: Perpendicular to grain stresses at the end of the bottom beam of the window glass frame at the load of 1.6kN.

https://doi.org/10.52202/069179-0497

3.2.3 STRESSES IN THE HINGE SCREWS AND IN WOOD AROUND THE SCREWS

Ultimate failure occurs in wood in shear around screws in the top hinge in the glass frame, see Figure 3.4.
The screws are not uniformly loaded since the plate of the connector is bended, and screw placement is not symmetrical. Forces in the screws from 1 to 4 were evaluated with the numerical model and their values are presented over the load history in Figures 3.8 and 3.9.
Screws are loaded both axially as intended and bended and pressed into the wood perpendicularly to the grain. This transverse force distribution is shown in the Figure 3.8. The top screw is subjected to the half of the total transverse force transferred from the glass frame through the hinge. The bottom screw shares only 8% of the transverse load. Axial forces in the screws are shown in the Figure 3.9. Screw number 3, the second from the top, is subject to the axial withdrawal, while remaining screws no 1, 2, and 4 (see Figure 3.7 left) are axially pressed into the timber.

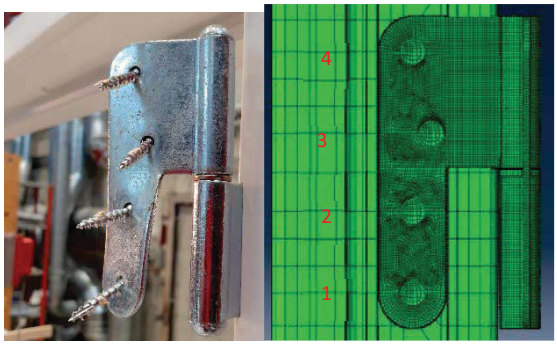

Figure 3.7: Screws in hinge after failure (left) and the numerical model with mesh and screw numbers (right).
The negative force (compression) transferred via screws 4,2, and 1 is in equilibrium with the positive (tension) force transferred by screw no 3. The screws do not cooperate in axial resistance to withdrawal, but are counteracting the hinge plate bending.

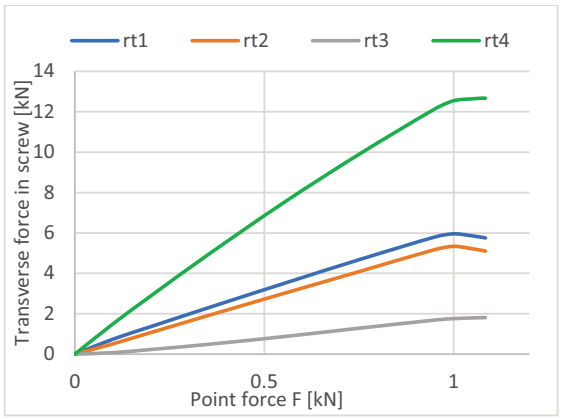

Figure 3.8: Distribution of transverse forces in the screws through loading history.

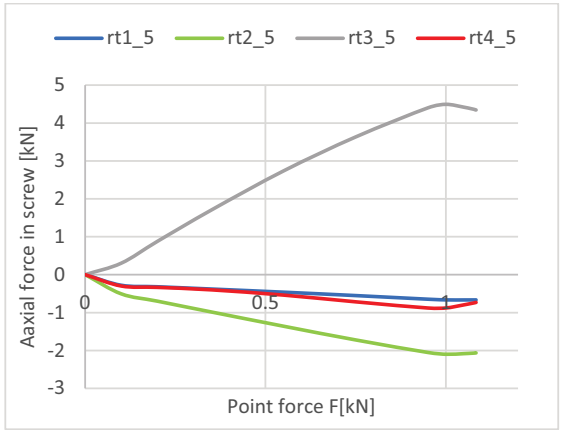

Figure 3.9: Deformation of the window in the numerical analysis from top and side view.

3.3 EXPERIMENTAL AND NUMERICAL RESULTS: COMPARISON

Window frame test shows plastic deformation in the top hinge and ultimate failure of wood around the screws in combined shear and perpendicular to grain tension at ca 1.6kN force, see Figure 3.7 to the left. The block shear failure in screws leads to sudden glass-frame collapse. The ductile deformation and onset of damage in wood-screw area can be visible much earlier, at around 0.6kN force (see both numerical and experimental force-displacement curves in Figure 3.10) and at around 1kN for the thinner frame according to the simulation.
The numerical analysis leads to good prediction of initial damage mechanism that can be set as the capacity limit for window frame in the considered load scenario.
The difference in the apparent stiffness can be mainly subjected to the different eccentricity of the initial set-up and force position in relation to the gravity centre of the glass-frame. The apparent stiffness is considerably higher for the thin frame that has 4 layer glass pack compared to the original 3-layer glass pack in the thick frame or the 3-layer glass pack thin frame model.

https://doi.org/10.52202/069179-0497

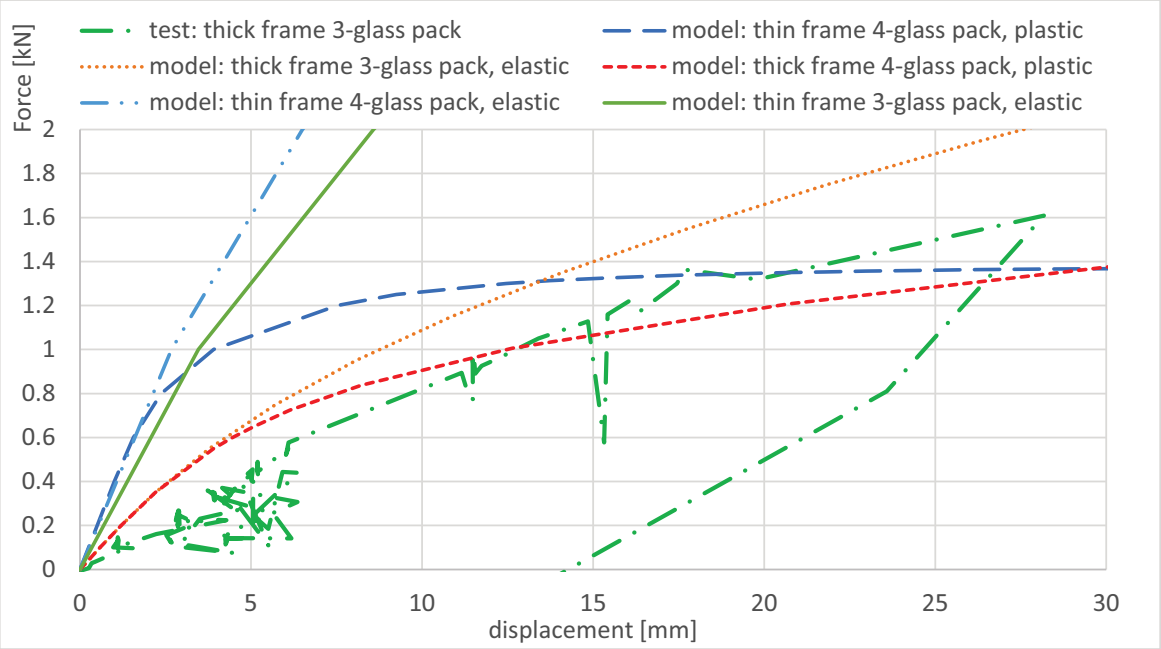

Figure 3.10: Force- displacement curves from the test and from the numerical model simulations for different settings.

4 DISCUSSION

Based on the validation via experiments, the numerical model of the thick frame with 3-layer glass pack was further developed into variants with the slim frame design and 3 and 4-glass packs. The new, slimmer design of the frame is subject to more impact from the localized failure around the screws due to the decreased dimensions so the detail study of the screw around the stresses was performed. The simulation shows that force distribution in screws is not as intended in the considered design case and leads to only one screw being effectively transferring withdrawal loads. The new shape of the hinge plate and optimized placement of the screws could improve the design. The analysis focuses on static strength and does not consider moisture variation that can introduce stresses and dimensional changes. Those dimensional changes due to moisture fluctuations would further increase the stresses localized in the frame corners that are more vulnerable due to the decreased area of the gluing.

During the development of the slimmer frame design, the need for rethinking the connection arose. The localized screwed in connection causes damage in slim frame to occur in wood shear failure (at 1-1.2kN according to the simulation) before hinge plasticisation. Better distribution of the stresses via use of linear hinge or a clamp should be considered in future investigations.

5 CONCLUSIONS

Current wood window frame thickness can be decreased from the structural point of view to improve thermal properties, increase glazing area, and save raw wood material and costs. The dimensional stability of the window over cycling moisture load is more critical than the static strength. The glass pack is found to be the main stiffness source for the frame. Screw configuration in the commonly used hinge is not transferring forces optimally and uniformly and can be optimized or redesigned.

OUTDOOR PANELS FROM NORWAY SPRUCE – THE EFFECT OF COATING COLOUR ON THE TEMPERATURE

Sebastian Svensson Meulmann[1], Åsa Rydell Blom[2], Michael Dorn[3]

ABSTRACT: Wood used outdoors is often surface treated with a paint to protect the wood from moisture and deterioration. If coated with a dark colour, the albedo value is lowered. A lower surface albedo generates greater amounts of energy absorption and makes the surface, and subsequently the wood, warmer and dryer. This study was carried out to increase knowledge of how different coating colours impact the temperature of the underlaying wood, and the effect this has on the moisture content (MC). The study was performed by exposing panels of Norway spruce [*Picea abies* (L.) H. Karst.] painted with three different colours (white, red, and black) to natural sunlight over a month during summer. Each panel fitted with a dry-bulb humidity sensor inside. The results showed a greater variation in calculated equilibrium moisture content (EMC) in the darker panels, since the temperature reached higher levels than the white panels when exposed to sunlight. The maximum recorded temperature was around 50 °C for the dark panels while the maximum for white was around 40 °C. Furthermore, it was shown that the temperature inside the panel reaches its maximum around the same time as the outside air, while the maximum values for EMC were recorded approximately 8-9 hours apart between the panels and the outside air.

KEY WORDS: Coated wood, Coating colour, Moisture content, Natural exposure

1 INTRODUCTION

Wood is a bio-based material which decomposes under unfavourable conditions. When used as a façade material, the wood is exposed to water in the form of precipitation which increases the moisture content in the wood. After long exposure, in situations where the wood cannot dry out, it can lead to discolouration or rot by wood-decay fungi. Both cause a decrease of the service life of the façade. To be able to fully implement wood as a construction material, research within the field is necessary.

Wood used for facades is often surface treated with a coating to protect it from moisture. This coating can have different colours which are affected differently through their surface albedo. The surface albedo causes dark surfaces to reflect less solar radiation than light surfaces, in turn making them warmer than a light surface subjected to the same amount of solar radiation [1]. This means that a façade panel coated with light paint should also be less warm than one painted with a darker paint.

All NCS-colours provide a number regarding the blackness, chromaticness, and hue. Since the blackness and chromaticness of the colour should be the factors theoretically most important regarding the effect of albedo, these will be studied closer in this study. The risk for fungal development and decay is closely related to the temperature [2-4]. A greater variation in temperature also leads to a greater variation of the equilibrium moisture content (EMC) in the wood [5]. Relative humidity is the factor that affects EMC the most [6]. The EMC is the point where the moisture content in a material is constant, and will not change as long as the RH and the temperature around is also constant [7]. A façade panel with different colours should in theory reach the same temperature during night-time without sunlight, causing darker panels to be subjected to a greater variation in temperature during a 24-hour span.

The increase in temperature of darker coloured paints has also been shown to create a more rapid moisture diffusion [8]. A greater variation in moisture content causes cracks in the wood as well as the paint layer at an earlier stage than for a constant MC [9,10]. Sources suggest that the risk for cracks in the wood occurs already when the EMC of the surrounding environment and the MC of the wood deviate with 2%, the risk increases the higher the difference [11].

Only few studies that investigate the effect of a specific coating colour on the moisture content and the temperature in a material have been carried out. Furthermore, most of the studies carried out measure the moisture content in the material either by weighing the entire test piece [8,12-15] or with electrical resistance [13,16].

This work aims to study the temperature and calculated EMC just below the coating. By collecting the data for the given exposure, it will increase the understanding of how

moisture and temperature in the wood fluxes under similar conditions. As this in turn is related to both microbial activity and crack formation, this will increase the understanding of the most suitable coating colour for a given situation, with regards to moisture and temperature related issues.

2 MATERIALS AND METHOD

A total of nine test pieces (panels) were made of Norway spruce [*P. Abies* (L.) H. Karst.], with dimensions 300x105x45 mm. The panels consisted of two boards of 22 mm thickness glued together with a silicone adhesive, creating a single panel with a thickness of 45 mm (Figure 1). The panel behind was added to prevent moisture from entering from the backside of the panel as the adhesive film between the two parts creates a vapor barrier (Figure 1).

A waterborne alkyd primer was used before applying the top coating according to the instructions from the manufacturer (Becker). All panels were top coated with waterborne acrylic paint in the three different colours: white (NCS S 0502-Y50R), red (NCS S 5040-Y80R) and black (NCS S 9000-N). Three panels were coated with each colour. By using the NCS atlas [17], the luminous reflectance factor (LRF) can be found. This value is based on both the blackness and chromaticness of the colour to represent the percentage of reflection of the colour when shone with a light. The values for white (NCS S 0502-Y50R) and black (NCS S 9000-N) were given as 87% and 4.0% respectively. The value for red (NCS S 5040-Y80R) was interpolated to be approximately 8.5%. These values were then used when studying the temperature increase found in the samples during sunlight.

Each of the nine panels were equipped with a dry-bulb relative humidity sensor (Sensirion SHT35-DIS-F), which also measured temperature. The sensors were placed within a pre-drilled hole and fixed 8 mm from the coated surface (Figure 1). The holes were then sealed with silicone to prevent moisture from entering from the back of the panel. The sensors were connected to a data acquisition system that logs the parameters in 5 min intervals and their respective time stamps to a .txt-file, see [18] for a general description of the system.

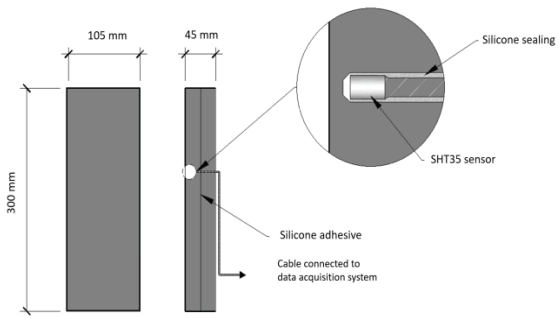

Figure 1: *Dimensions of the panels and placement of sensor*

The panels were placed outdoors in Växjö, Sweden, on a rack facing south, with an angle of 45° to the ground. Apart from the sensors in the boards, a separate sensor was placed freely without direct sunlight, which measured temperature and RH in the surrounding air.

The measured values for temperature and relative humidity were used to calculate the EMC using Equation 1 by Simpson [19]. The EMC indicates the MC once it has been stabilized and not the actual MC at a given time.

$$EMC(\%) = \frac{1800}{W}\left(\frac{K\,h}{1-K\,h} + \frac{(K_1\,K\,h + 2\,K_1\,K_2\,K^2\,h^2)}{(1+K_1\,K\,h + K_1\,K_2\,K^2h^2)}\right) \quad (1)$$

Where:

h = relative humidity in decimal form

$W = 349 + 1.29\,T + 0.0135\,T^2$

$K = 0.805 + 0.000736T - 0.00000273\,T^2$

$K_1 = 6.27 + 0.00938\,T - 0.000303\,T^2$

$K_2 = 1.91 + 0.0407\,T - 0.000293\,T^2$

T = temperature in °Celsius

The density of the panels was measured after the exposure by the simple displacement method. The mean value of the oven-dry density was 495.6 kg/m^3 (Table 1).

Table 1: *Saturated density and oven-dry density in the samples*

Sample	Saturated density (kg/m^3)		Oven-dry density (kg/m^3)	
	Mean	Std. deviation	Mean	Std. deviation
White	716.3	35.1	501.5	31.1
Red	743.4	11.8	505.5	15.3
Black	721.9	17.8	479.7	5.2
Overall	727.2	29.0	495.6	21.2

3 RESULTS AND ANALYSIS

The following weather data is collected from observations in Växjö, Sweden, by the Swedish Meteorology and Hydrological Institute (SMHI) during the month of July 2021 [20]. The total precipitation was 98 mm distributed over 16 days, where each day must have at least 0.1 mm of precipitation to be included. A total of 243 hours of sunlight was recorded, which is slightly higher than the average of 234 hours. The total global radiation during the month was 162.6 kWh/m^2.

All data presented is calculated as a mean value between all three panels of the same colour, the maximum and minimum values are therefore not extreme values for the individual panels but a calculated mean of all panels of the same colour at a given time. The only exceptions to this are found in Figure 6, where the values are instead shown individually for all samples.

3.1 TEMPERATURE ANALYSIS

The measured temperature for all values recorded during the month of July can be seen in Table 2.

https://doi.org/10.52202/069179-0498

Table 2: *Internal temperature for the different coating colours and the outside air during the entire month of July*

Sample	Temperature (°C)			
	Mean	Max	Min	Std. deviation
White	21.3	41.0	11.0	6.3
Red	23.3	49.7	11.0	8.5
Black	23.6	51.3	11.0	8.9
Outdoor	21.0	37.8	11.5	5.2

The results in Table 3 are based on measured values between 6:00 AM-6:00 PM from the whole measurement period. This interval lies safely between the average times of sunrise-sundown during July in Sweden. The table contains the mean, maximum, minimum, and standard deviation of temperature during all days of the month.

Table 3: *Internal temperature for the different coating colours and the outside air during the entire month of July between 6:00 AM-6:00 PM*

Sample	Temperature (°C)			
	Mean	Max	Min	Std. deviation
White	24.9	41.0	12.5	6.2
Red	28.7	49.7	12.9	8.4
Black	29.3	51.3	12.9	8.7
Outdoor	23.9	37.8	13.2	5.0

The table clearly shows the influence of the coating colour on the mean temperature during the month. The differences become even more pronounced when only studying values during a single day (Table 4).

Table 4: *Internal temperature for the different coating colours and the outside air during a single day between 6:00 AM – 6:00 PM*

Sample	Temperature (°C)			
	Mean	Max	Min	Std. deviation
White	25.2	32.8	15.9	5.2
Red	29.8	41.2	16.3	8.0
Black	30.5	42.4	16.3	8.4
Outdoor	23.8	29.9	17.1	4.0

3.2 EMC ANALYSIS

The calculated values of EMC considering all values of RH and temperature recorded during the month of July can be seen in Table 5. The calculated EMC of the surrounding air is included as a reference.

Table 5: *Calculated values of EMC presented for the different colours and the outside air during the entire month*

Sample	EMC (%)			
	Mean	Max	Min	Std. deviation
White	13.9	20.3	11.6	1.5
Red	11.8	26.5	8.4	3.4
Black	11.4	24.5	8.2	3.0
Outdoor	15.9	29.0	5.5	6.6

The results presented in Table 6 contain calculated values of EMC based on values measured between 6:00 AM-6:00 PM from the whole measurement period of July 1 until July 31.

Table 6: *Calculated values of EMC presented for the different colours and the outside air*

Sample	EMC (%)			
	Mean	Max	Min	Std. deviation
White	14.8	20.3	11.8	1.6
Red	13.7	26.5	8.6	3.9
Black	13.2	24.5	8.4	3.4
Outdoor	13.0	29.0	5.5	5.9

The standard deviation is much lower for the white panels than the red and black. Just like for the temperature, the differences are even more apparent when only studying the variation during a single day (Table 7).

Table 7: *Calculated values of EMC for the different coating colours day-time hours of a single day*

Sample	EMC (%)			
	Mean	Max	Min	Std. deviation
White	15.5	18.4	13.0	1.8
Red	16.4	24.6	10.4	5.1
Black	16.2	23.4	10.3	4.5
Outdoor	15.6	29.0	7.6	7.7

The variation in calculated EMC during every single day can be seen in Figure 2, where the y-axis values are the differences in maximum- and minimum EMC calculated from the values extracted during 24-hours for all days of the month.

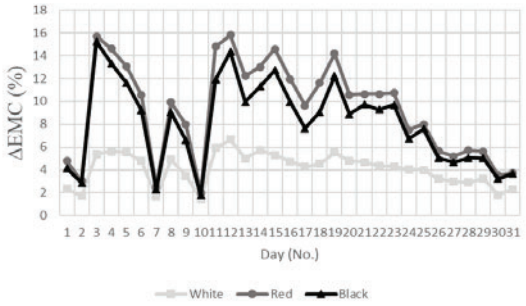

Figure 2: *Maximum daily absolute difference in EMC within the panels for all days of the month of July*

3.3 TEMPERATURE AND EMC IN THE PANELS COMPARED TO OUTSIDE AIR

The temperature in the panels fluctuates in phase with the outside air (Figure 3) while the EMC fluctuates counter-phase (Figure 4). The figures display a typical distribution during a single day with a clear influence of solar radiation.

https://doi.org/10.52202/069179-0498

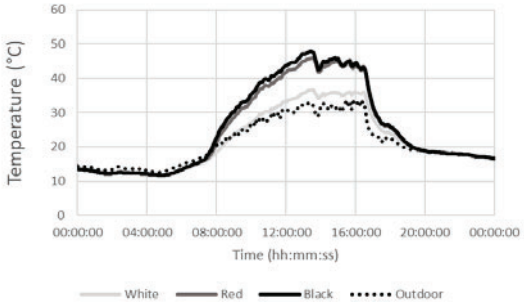

Figure 3: *Temperature distribution in the panels and outside air during 24 hours*

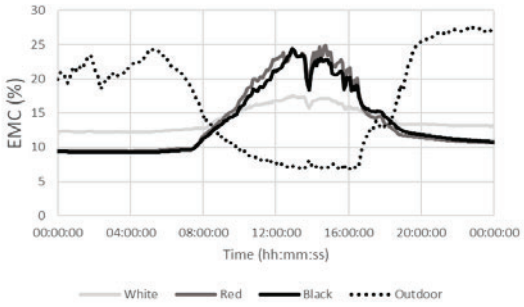

Figure 4: *Distribution of EMC in the panels and outside air during 24 hours*

The difference in time for the panels and outside air to reach its daily peak during the day is presented in Table 8. The results are presented as the average absolute difference between the time stamps at which the daily maximum was recorded for the outside air and within the panels, respectively. The darker panels reach their peak temperatures earlier than the white panels, while the peak temperatures in the outside air were generally recorded later in the day. The EMC shows barely any difference between the different coating colours.

Table 8: *Absolute difference in time of peak values between samples and outside air*

Sample	Difference to outside air (hours)	
	Temperature	EMC
White	0.52	8.60
Red	0.80	8.65
Black	0.90	8.62

The peaks in EMC in the ambient air predominately appeared close to midnight (the coldest period of the day), while the EMC peaks in the panels appeared during the early afternoon (the warmest period of the day). All peak values in temperature within the panels and in the outside air are shown in Figure 5.

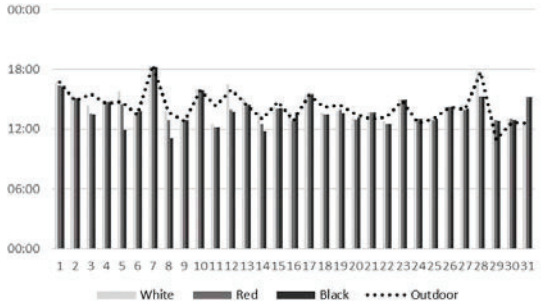

Figure 5: *The time of day when the maximum temperature was recorded in the panels and in the outside air*

3.4 THE INFLUENCE OF COATING LRF ON THE MAXIMUM TEMPERATURE

To isolate the albedo effect, the temperature differences in the panels compared to the outside air temperature at the same time were studied (Figure 6). The figure shows temperature difference when the difference between the outside air temperature and panel temperature was the greatest.

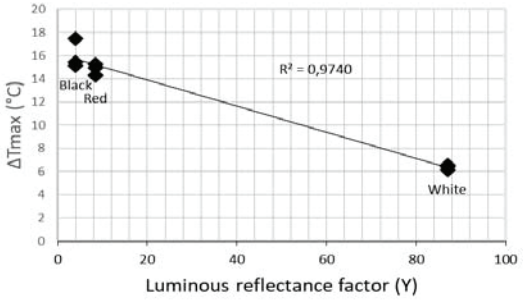

Figure 6: *Maximum temperature difference between the panels and outside air recorded during the month in dependence of the LRF*

The results show a greater variation in maximum temperature in the red and black samples than in the white samples. The LRF naturally has a negative correlation with the temperature increase in the panel compared to the ambient temperature during sunlight.

3.5 THE INFLUENCE OF TEMPERATURE ON THE EMC

Temperature is used to calculate the EMC, albeit weighed less than the RH.

The correlation was best explained with an exponential function for all samples, where T is defined between the minimum and maximum temperature recorded. See Table 9 for the equations used and the R^2-value related to the equations.

https://doi.org/10.52202/069179-0498

Table 9: *Data fit equation for the EMC depending on the temperature and their R^2-values*

Sample	Equation	R^2
White	$EMC(\%) = 10.483e^{0.0130T}$	0.60
Red	$EMC(\%) = 6.2917e^{0.0256T}$	0.80
Black	$EMC(\%) = 6.4383e^{0.0231T}$	0.81

Where:
EMC = The equilibrium moisture content (%)
T = temperature in °Celsius

The equation for the white samples is close to being linear within the defined range. The maximum value for EMC and temperature within the samples were predominantly recorded less than an hour apart.
The average time between reading of the maximum temperature and maximum EMC for the respective coating colours were, 57 minutes for white, 35 minutes for red, and 29 minutes for black.

4 DISCUSSION

With the temperature being measured within the board, it is likely that the difference in temperature at the surface could be even more pronounced. The temperature measured 8 mm behind the coating could vary between 16.3-42.4 °C in just 12 hours, as seen in the black panels (Table 4). The temperature at the surface is likely even higher than the recorded values.
Despite having a much lower blackness value than the black samples, the red samples reached temperatures very close to the black ones. This is likely due to the two colours having similar luminous reflectance factors (LRF), and therefore absorbing similar levels of sun light. This indicates that the chromaticness is also an important aspect regarding the increase in temperature of the panel. The black panels could reach temperatures which were more than 17 °C higher than the outside air at the same time, while the red samples were around 15 °C warmer than the outside air at most. Assuming that the back of the panel was closer to the temperature of the ambient air, this could generate significant temperature and hence moisture gradients within the panel. This could generate strains and, subsequently, cracking in the panels.
The results also showed a clear difference in calculated EMC between the samples of different coating colours. However, the EMC is not sufficient in determining the actual moisture content at a given moment in time. It is however useful when analysing the mean values over an entire month, as this is likely close to the actual mean moisture content. Therefore, the variations in EMC over a single day should be treated as indicators of possible variations, rather than actual variation. The variations in EMC in the darker panels could be close to the fibre saturation point and below levels of industrial drying during the same day, which is likely not possible for the actual moisture content. However, the increase in temperature is likely enough to create greater variations in MC in panels of darker colours than light colours, although to an unknown degree. A greater variation in EMC for the darker panels was calculated for all days during the month, not only those with high solar radiation. Surprisingly, the red panels achieved a greater average EMC than the dark panels, even though the LRF was lower, and lower average temperatures were recorded inside the panel.
It is also possible that the high temperatures achieved on the surface of the darker panels are enough to temporarily stop the mould growth, as temperatures around 40 °C can have a negative effect on growth [21].
The correlation between temperature and EMC within the panel is not surprising as an increase in temperature leads to an increase in vapor pressure.
The temperature within the panels and in the outside air fluctuated closely in-phase, while the EMC was affected by the slow water transition between the surrounding and inner relative humidity. The different correlations between EMC and temperature in the different coating colours could be explained by a faster spike in RH due to higher temperatures. The variations in relative humidity were greater in the outside air than in all the panels, while the variation in temperature was greater in the panels than in the outside air.
The white panels never reached the same maximum EMC as the red and black panels. This could have been caused by an increase in water evaporation due to higher temperatures within the darker panels and similar levels of water content. The water would then be concentrated around the area where the relative humidity was measured. However, this is only a hypothesis and should be studied further to increase understanding.
Analysing the minimum values of temperature showed that the minimum daily temperature in the panels never deviated with more than 0.2 °C between the different coating colours. This indicates that high solar absorption in non-reflective colours during the day does not affect the minimum temperature during the full 24 hours of a day. The minimum daily temperature in the panels were on average approximately 0.6 °C colder than the minimum in the outside air.
A similar study [13] also tested moisture conditions and temperature within samples of different colours. It was concluded that the lighter samples kept higher and more constant levels of moisture content than those of darker colour due to a lower absorption of sunlight. This corresponds well with the results acquired in this study. It should however be noted that the authors in [15] measured the MC by use of mass variation and electrical resistance, compared to the use of sensors in this study.

5 CONCLUSIONS

Using darker colours of paint increases both the fluctuation in temperature and moisture content within the panel over the course of a day. The temperature 8 mm below the surface decreased along with the reflectance factor of the colour. This suggests that both the blackness and the chromaticness of the colour are important regarding the solar absorption of a panel, and that the solar absorption of low-reflectance coatings can generate much higher temperatures inside the wood than the ambient temperature.

https://doi.org/10.52202/069179-0498

The temperature within panels of white coating is close to the outside temperature and barely deviates from the outdoor temperature when considering the monthly average. The calculated mean EMC in the red and black samples were similar, even though the mean temperature was slightly higher in the black samples. To further validate the results, the authors recommend testing common coating colours which have an LRF between the white and red colours used in this test. Furthermore, these values of both temperature and EMC are only applicable for the given geographical location and time of year. Also, the differences between the panels could be different at a different location of exposure. Comparing the results found in this study to a different location and/or time of year would aid in increasing the knowledge of how coating colours affect the wood.

Although this study shows some clear results and trends, the low number of samples decreases validity and further studies should be carried out with a greater sample size. Furthermore, weighing the samples during the exposure to measure the actual moisture content within the panels at a given time could enhance the value of the measurements. Efforts to further understand the temperature and moisture gradients, e.g., by using multiple sensors at different depths, could be helpful when assessing the risk for crack formation within panels of different coating colours.

HYGROTHERMAL PERFORMANCE OF NATURE-BASED INSULATION MATERIALS INTEGRATED IN TIMBER-BASED WALL-SYSTEMS

Dimitrios Kraniotis [1], Samee Ullah[2], Stine Lønbro Bertelsen[3]

ABSTRACT:

This study is part of the European research and innovation project Build in Wood and has investigated the hygrothermal performance of nature-based insulation materials in two timber-based wall systems: i) stud wall and ii) externally insulated cross-laminated timber (CLT). Six nature-based insulation materials were selected for the analyses. The analyses conducted have focused on optimization of exterior wall configurations to avoid moisture-related problems, i.e. interstitial condensation and mould growth, in the wall constructions under various climates in Europe. For this purpose, three European locations representing respective geographical parts of Europe and corresponding climate zones, were selected as input for the simulations: Oslo (Northern Europe), Paris (Central Europe), and Barcelona (South Europe), while different exterior and interior claddings were considered. A commercial 1D hygrothermal software, i.e. WUFI Pro 1D, was used for the computation of the hygrothermal performance of the wall systems, while the add-on software WUFI Bio has been further employed for the detailed evaluation of the risk for biodegradation. In total 684 numerical simulations were conducted. The results show the various insulating materials behave differently when integrated in timber-based system. Generally speaking, both wall systems, i.e. stud wall and CLT, function similarly in Oslo, while in Barcelona the CLT was systems show better performance. The climate of Paris is critical for most of the wall configurations. Furthermore, the existence of ventilated air cavity back from the exterior cladding has a positive effect on all assembly configurations, while the high water vapour diffusion resistance of the exterior cladding might be determinant, in a negative way, for the moisture problems in nature-based insulating materials.

1 INTRODUCTION

The European Commission aims at the decarbonization of building sector by 2050, starting the drastic reduction of greenhouse gas emissions (GHG) in the coming years; as of 2030, all new buildings must be zero-emission, while all new public buildings must be zero-emission already as of 2027 [1]. Given that energy efficiency in buildings has been on focus the last decades, the interest has been switched to life-cycle stages before as well as after operation. In particular, the extraction, production and manufacturing of building materials are stages with remarkably high embodied GHG emissions, therefore there is an increasing demand for building materials with low carbon footprint, such as structural timber and nature-based insulating materials, e.g. [2]. Wood-based wall systems have several advantages, such as low carbon footprint, moisture buffering effect etc., while they show durability against mould growth upon proper design [3]. Commercial wood-based insulation materials, e.g. wood fibreboard and wood woolboard, have also gained ground in building applications. In addition, other nature-based building materials such as hemp, cellulose, flax etc. have started getting integrated in building systems, usually as insulation materials. Generally speaking, material selection is a complex equation that considers various parameters, material properties, GHG emissions, availability, cost etc. In particular for insulation materials, durability is an important aspect, so that they can function adequately during operation stage, without increasing the need for replacement, which would have negative consequences for the total GHG emissions. In this study, the hygrothermal performance of innovative nature-based insulation materials integrated in timber-based wall systems is investigated and the risk for moisture damages and degradation is identified.

2 MATERIAL AND METHODS

2.1 Wall systems and assemblies

Two different exterior wall systems have been employed for the analyses: 1) stud wall and 2) externally insulated cross-laminated timber (CLT) (Fig.1). A short literature review of nature-based insulation materials gave an indication on various insulation types used in the

https://doi.org/10.52202/069179-0499

European market. According to [4], there are six different types of nature-based insulation materials: sheep's wool, hemp fibre, flax fibre, wood fibreboard, cellulose, and wood woolboard. In total 22 different products of the six different types of nature-based insulation were identified. One product of each of the six types has been selected for the analyses in this study. The six chosen insulation products are hemp fibre, sheep's wool, flax fibre, wood fibreboard, cellulose and wood woolboard.

Figure 1: *Overview of the two wall systems and the corresponding assemblies.*

2.2 Coupled heat and moisture transport (HAM)

A major challenge for all nature-based building materials is their potential vulnerability to moisture. A commercial 1D hygrothermal software i.e., WUFI® Pro 1D [5], has been used for the computation of the hygrothermal performance of the wall systems, with focus on the risk for interstitial condensation. WUFI® Pro is a dynamic simulation tool that accounts for the coupled heat and moisture transport across building components, including latent heat of sorption and heat and moisture storage in building materials, as mentioned by Karagiozis *et al.* [6]. In particular, WUFI® Pro 1D computes the variation of moisture content in each material/layer of building component, while it can provide additionally detailed information about temperature and relative humidity in numerous cross sections of the component and consequently provide the risk of condensation.

By integrating the results of WUFI Pro into an another (add-on) software of WUFI® family, called WUFI® Bio [7], the risk of mould growth and biodegradation can be classified. The latter is the most crucial parameter for the evaluation of nature-based insulation materials. WUFI Bio provides the mould growth coverage in building materials, expressed in mm. In addition, it includes an empirical model which has been developed by Viitanen [8] and computes the so-called mould index (MI). This index takes values from 0 to 6 and reflects the risk of biodegradation of building materials (Table 1).

Table 1. *Description of mould index (MI) according to Viitanen model [7, 8].*

Mould index	
0:	No growth
1:	Some growth visible under microscope
2:	Moderate growth visible under microscope, coverage more than 10%
3:	Some growth detected visually, thin hyphae found under microscope
4:	Visual coverage more than 10%
5:	Coverage more than 50%
6:	Tight coverage, 100%

For the classification, the 'signal light' is employed by the software (Table 2); the green light shows low or no risk for biodegradation, the yellow light reflects moderate risk and additional control may be needed and the red light reveals high risk for biodegradation and therefore the construction is considered as not acceptable. In this study, three different cross sections of the insulation layer have been checked; exterior, middle, and interior cross section. For each of these cross sections, the bio-hygrothermal analysis has been conducted and the respective results, in terms of 'signal light' are provided, in three positions: i) outer part of insulation, ii) middle part of insulation and iii) inner part of insulation.

Table 2.1. *'Signal-light' classification in WUFI Bio, reflecting the three different evaluations, i.e. green: acceptable, yellow: acceptable under conditions, red: not acceptable [7].*

		Surfaces inside constructions without direct contact to indoor air
	Mould growth (g_m): Mould-Index (MI): Assessment:	< 176 mm/year ≤ 2 Usually acceptable.
	Mould growth (g_m): Mould-Index (MI): Assessment:	176 < g_m ≤ 239 mm/year 2 < MI ≤ 3 Additional criteria or investigations are needed for assessing acceptability.
	Mould growth (g_m): Mould-Index (MI): Assessment:	> 239 mm/year > 3 Usually not acceptable.

2.3 Exterior and interior climate

To investigate the impact of the exterior climate three European locations representing respective geographical parts of Europe and corresponding climate zones, were selected as input for the simulations: Oslo (Northern Europe), Paris (Central Europe), and Barcelona

(Southern Europe). The climate characteristics for each location are shown in Table 3.

Table 3. *Climate characteristics of the chosen locations for the numerical simulations – Oslo, Paris and Barcelona [5].*

	Oslo	Paris	Barcelona
Mean air temperature [°C]	6.8	10.9	16.3
Max. air temperature [°C]	29.3	36.3	34.3
Min. air temperature [°C]	-14.8	-8.9	-1.0
Mean air relative humidity [%]	73.1	80.6	66.8
Max. air relative humidity [%]	100.0	100.0	99.0
Min. air relative humidity [%]	15.0	19.0	13.0
Mean wind speed [m/s]	2.7	2.6	4.1
Normal rain [mm/year]	604.7	817.4	513.3
Counter radiation [kW/m^2*year]	2 641.4	2 851.5	not available
Mean cloud index [-]	0.67	0.67	not available

For the interior climate, the European standard EN ISO 13788 was used [9]. In particular, the indoor air temperature was assumed constant at 20°C, a humidity class of 3 has been considered. This class, among the five available (1-5), reflects better the moisture production in residential buildings, which is the majority of existing building stock in Europe. while the initial relative humidity across the wall systems have been set at 50%, which reflects dry state of the building materials. All the cases have been solved for 10 years period.

2.4 Thermal transmittance (U-value) of assemblies

The national building regulations in the three selected countries Norway, France and Spain, have set different requirements regarding the thermal transmittance in exterior walls. The chosen U-values for the wall systems in the three locations are: Oslo, 0.18 W/m^{2}K; Paris, 0.23 W/m^{2}K; Barcelona, 0.35 W/m^{2}K.

2.5 Categorization of hygrothermal numerical simulations

The hygrothermal numerical simulations were organised in 'Groups' for better overview:

- Group A – Wall systems with wooden panel (picea abies) as exterior cladding and gypsum board (standard density, ρ = 720 kg/m^3) as interior cladding. The CLT case has been additionally studied exposed, without the gypsum board as interior cladding.
- Group B – Wall systems with wooden panel as exterior cladding and two different interior panels: a) gypsum board of high density (ρ = 1 153 kg/m^3) and b) a plywood panel. The latter has been used only in the stud-wall system but not in combination with the CLT cases.
- Group C – Wall systems with various panels (two different types of cement-based board and wooden panel with fire retardant) as exterior cladding and gypsum board (standard density) as interior cladding. In particular, three boards were employed: a) a cement-based board with low density, ρ = 1 150 kg/m^3 b) a cement-based board with high density, ρ = 1 650 kg/m^3, and c) a solid wooden panel with fire retardant.

All the abovementioned cases have been computed having considered both limited-ventilated air cavity back from the exterior cladding and fully ventilated air cavity. In total, around 600 simulations have been performed.

3 RESULTS

3.1 Group A – Wall systems with wooden panel as exterior cladding and gypsum board (standard density) as interior cladding

3.1.1 Oslo

In stud wall systems (Fig. 2), all insulation materials have shown no remarkable moisture problems when used in a stud wall system with a wooden panel as exterior cladding and a gypsum board of standard density, i.e. ρ = 720 kg/m3. The materials that have showed the best performance, regardless the orientation nor the natural convection in air cavity, has been the wood woolboard followed by the flax fibre and cellulose (the last two have shown some minor issues at the edges of the insulation layer).

In contrast, the materials that have shown some issues, but only in the worst orientation and when assuming limited natural convection (ACH = 1h-1) are:

i) the sheep's wool and hemp fibre, which have shown risk for mould growth during a few weeks in summer, when the reverse of moisture transport occurs due to increase of partial air pres-sure outdoors. This is a common problem in Scandinavian exterior wall systems due to the presence of vapor retarder on the inner side of insulation layer, which causes temporal (sea-sonal) blockage of water vapor when the moisture transport is reversed.
ii) the wood fibreboard that shows risk of condensation on the cold side of insulation layer when the wall is exposed to the orientation with most wind and driving rain.

These materials have shown no moisture problems in all other wall orientations. Furthermore, when the air cavity back from the exterior cladding is fully ventilated by natural convection, no moisture problem has been identified (Fig. 3).

In CLT wall systems (Fig. 2 and 3), similarly to the stud wall, the wood woolboard and the flax fibre has shown the best performance, i.e. no moisture problems regardless the level of ventilation in the air cavity and the use (or not) of gypsum board on the interior side of the CLT. All the other four insulation products, i.e. sheep's wool, hemp fibre, wood fibreboard and

https://doi.org/10.52202/069179-0499

cellulose, require that the air cavity is ventilated by natural convection to avoid showing condensation problems and mould growth in a few years after the use of the building.

Figure 2: *Risk of mould growth in the insulation layer in Group A wall systems in Oslo, when the air cavity is limited ventilated.*

Figure 3: *Risk of mould growth in the insulation layer in Group A wall systems in Oslo, when the air cavity is well ventilated.*

3.1.2 Paris

In case of Paris (Fig. 4 and 5), natural convection back from the exterior cladding is essential in order to avoid moisture damages in the insulation layer. This has been observed both in stud wall systems as well as in the CLT walls without gypsum board on the interior side. When the CLT is covered by gypsum board, the results are considered generally as not acceptable for all the six materials, regardless the level of natural convection in the air cavity.

The only insulation material that has shown a moderate hygrothermal performance in stud wall system when there is limited natural convection in the air cavity, it's the wood woolboard. However, even this material has shown moisture problems in the worst orientation (West for Paris) when integrated in a stud wall system, while when used in CLT wall systems, the moisture diffusion resistance of interior cladding contributes positively.

For all other insulation products, ventilation in air cavity by natural convection contributes drastically to avoid biodegradation in stud wall systems, while in CLT walls there is the additional prerequisite of low water vapor diffusion resistance on the interior surface (no gypsum board).

Figure 4: *Risk of mould growth in the insulation layer in Group A wall systems in Paris, when the air cavity is limited ventilated.*

Figure 5: *Risk of mould growth in the insulation layer in Group A wall systems in Paris, when the air cavity is well ventilated.*

3.1.3 Barcelona

The wood woolboard has been the only insulation material showing no moisture problems regardless the type of wall system and the level of natural convection in the air cavity (Fig. 6). The source of problems for the other five insulation materials when used in the stud wall system is the presence of water vapor tight layer at the interior side of insulation, e.g. vapor retarder, vapor-tight

https://doi.org/10.52202/069179-0499

interior cladding. This because in hot and humid climates, such as Barcelona's, the moisture flow is expected to take place from outdoors to indoors for the longest part of the year (in contrast to colder climates like Oslo). A solution is to use a vapor retarder at the exterior side of the insulation layer in order to block the moisture transport from outdoors. It should be mentioned that this issue remains in the stud wall systems even when the air cavity is considered as fully ventilated (Fig. 7).

Figure 6: *Risk of mould growth in the insulation layer in Group A wall systems in Barcelona, when the air cavity is limited ventilated.*

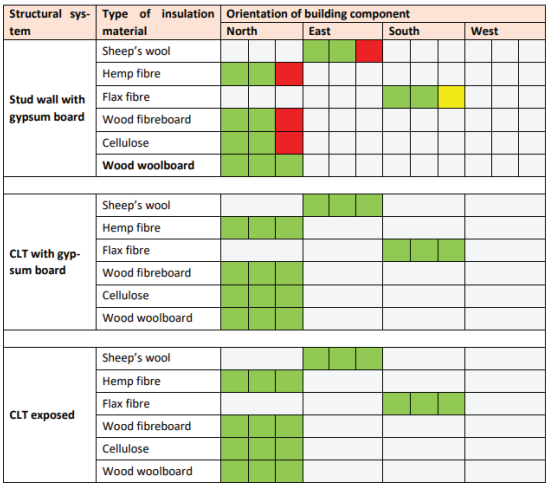

Figure 7: *Risk of mould growth in the insulation layer in Group A wall systems in Paris, when the air cavity is well ventilated.*

However, when the insulation materials are used in CLT walls, the hygrothermal performance becomes better. In particular, sheep's wool, flax fibre and wood woolboard show no moisture damages regard-less any other requirement. The other three materials, i.e. hemp fibre, wood fibreboard and cellulose, have shown biodegradation on their exterior parts when the air cavity is limited ventilated. By ensuring natural convection in the air cavity the risk of interstitial condensation will be drastically decreased both in stud wall and in particular in CLT wall systems, where no insulation material would show moisture problem.

3.2 Group B – Wall systems with wooden panel as exterior cladding and various panels (gypsum board of high density and 3-ply cross-laminated timber panel) as interior cladding

3.2.1 Oslo

The change of type of gypsum board, i.e. higher density, in the stud wall systems in Oslo (Fig. 8 and 9) hasn't showed any impact on the hygrothermal performance of the insulation materials. The findings are identical with the ones in the Group A, where the wood woolboard, the flax fibre and cellulose have showed the best performance. In contrast, the other three materials, i.e. sheep's wool, hemp fibre and wood fibreboard have shown moisture problems, either on the interior part of insulation layer (sheep's wool and hemp fibre) or at the exterior part of insulation layer (wood fibreboard). These problems disappear when the air cavity back from the exterior cladding is fully ventilated by natural convection (Fig. 9).

However, in particular for hemp fibre and wood fibreboard the already problematic hygrothermal performance in the stud wall systems becomes slightly worse when the plywood has been used as interior cladding. The change of interior cladding hasn't affected the other four materials. It is worth to mention that even in this case, i.e. 3-ply cross-laminated as interior cladding, all insulation materials have shown no moisture problems when the air cavity back from the exterior cladding is fully ventilated.

Figure 8: *Risk of mould growth in the insulation layer in Group B wall systems in Oslo, when the air cavity is limited ventilated.*

In the CLT wall systems (only the gypsum board has been considered as alternative here), only the wood woolboard has shown no biodegradation. The flax fibre has also shown good performance but there are some moisture problems on the outer part of the insulation

https://doi.org/10.52202/069179-0499

layer. All the other four materials have shown unacceptable hygrothermal performance. The natural convection in the air cavity would reduce drastically the risk for biodegradation and make all CLT wall systems acceptable.

Figure 9: *Risk of mould growth in the insulation layer in Group B wall systems in Oslo, when the air cavity is well ventilated.*

3.2.2 Paris

The change of type of gypsum board, i.e. higher density, in the stud wall systems in Paris (Fig. 10 and 11) hasn't showed any remarkable impact on the hygrothermal performance of the insulation materials. The wood woolboard is the only insulation material with acceptable performance, while all other materials have shown high risk of biodegradation. The use of the plywood as interior panel has made the performance even worse, even for the wood woolboard which in this case cannot be considered as acceptable. Similar situation in the CLT wall systems where all insulation materials have shown high risk for biodegradation.

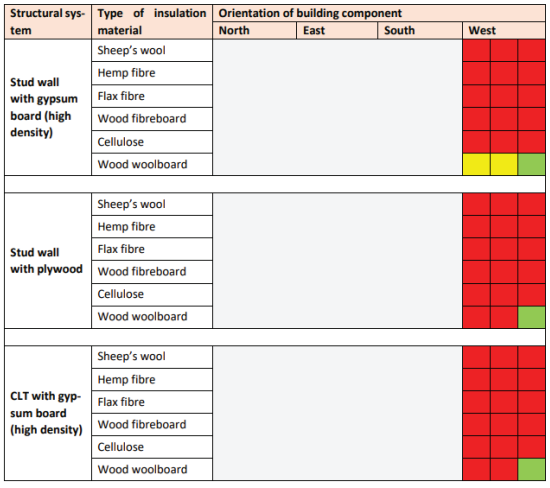

Figure 10: *Risk of mould growth in the insulation layer in Group B wall systems in Paris, when the air cavity is limited ventilated.*

All these results refer to the case of limited natural convection in the air cavity back from the exterior cladding (Fig. 10). The increase of air exchanges in the cavity will affect positively all the insulation materials, both in the stud wall and CLT systems resulting in acceptable hygrothermal performance (no risk for biodegradation) for all of them (Fig. 11).

Figure 11: *Risk of mould growth in the insulation layer in Group B wall systems in Paris, when the air cavity is well ventilated.*

3.2.3 Barcelona

In the stud wall systems in Barcelona (Fig. 12 and 13), the use of higher density gypsum board (with additional higher water vapor diffusion resistance) have shown higher risk for biodegradation compared to the respective Group A cases (gypsum board of standard density). This is rather expected because, as analysed in Group A above, the moisture transport by diffusion takes place towards indoors for the largest part of the year and therefore an increase in water vapor diffusion resistance at the inner part of the insulation layer would result in higher degree of vapor blockage and consequently higher mould growth. The only insulation material that has not been affected by the change of the type of the gypsum board and has shown as good hygrothermal performance as with the gypsum board of standard density (Group A) is the wood woolboard.

The use of plywood as interior cladding in the stud wall systems hasn't changed the overall picture; the wood woolboard has shown acceptable hygrothermal performance, while all other five materials have shown risk for biodegradation, either in parts of the insulation layer, i.e. in sheep's wool, wood fibreboard and cellulose, or throughout the entire layer, i.e. in hemp and flax fibre.

Remarkable but expected, the consideration of fully ventilated by natural convection air cavity back from the exterior cladding (Fig. 13) has only partly contributed positively in the cases of stud walls in Barcelona, in contrast for example to Paris. In particular, the inner parts of the insulation layers have still shown moisture problems due to the predominant water vapor flow to indoors.

https://doi.org/10.52202/069179-0499

Figure 12: *Risk of mould growth in the insulation layer in Group B wall systems in Barcelona, when the air cavity is limited ventilated.*

Figure 13: *Risk of mould growth in the insulation layer in Group B wall systems in Barcelona, when the air cavity is well ventilated.*

In Barcelona, the CLT wall systems have generally shown better hygrothermal performance than the stud walls. Even when the ventilation in the air cavity is limited, only three insulation materials have shown moisture problems: hemp fibre, wood fibreboard and cellulose. These problems appear only at the outer part of the insulation layer. The other three materials, i.e. sheep's wool, flax fibre and wood woolboard, have shown no risk for biodegradation when integrated in CLT wall systems. Last but not least, by ensuring fully ventilated air cavity the risk for biodegradation vanishes even for the hemp fibre, wood fibreboard and cellulose and all insulation materials can be considered as acceptable.

3.3 Group C – Wall systems with various panels (two different types of cement-based board and wooden panel with fire retardant) as exterior cladding and gypsum board (standard density) as interior cladding

3.3.1. Oslo

All insulation materials have shown poor overall hygrothermal performance when integrated into stud wall systems, regardless the type of exterior cladding. However, when the air cavity is fully ventilated by natural convection, flax fibre primarily followed by sheep's wool and hemp fibre have shown acceptable performance, when the exterior cladding is the wooden panel with the fire retardant. No wall configuration with cement board as exterior cladding can be considered as acceptable.

The CLT wall systems have shown similar moisture problems as the stud walls. When the cement board (either type, i.e. density) is used as exterior cladding, all insulation materials have shown high risk for biodegradation. When the air cavity is fully ventilated and the wooden panel with fire retardant is used as exterior cladding, the sheep's wool, the hemp fibre and the flax fibre have shown good hygrothermal performance, with minor moisture issues on the cold side of insulation. No wall configuration with cement board as exterior cladding can be considered as acceptable.

Figure 14: *Risk of mould growth in the insulation layer in Group C wall systems in Oslo, when the air cavity is limited ventilated.*

https://doi.org/10.52202/069179-0499

Figure 15: *Risk of mould growth in the insulation layer in Group C wall systems in Oslo, when the air cavity is well ventilated.*

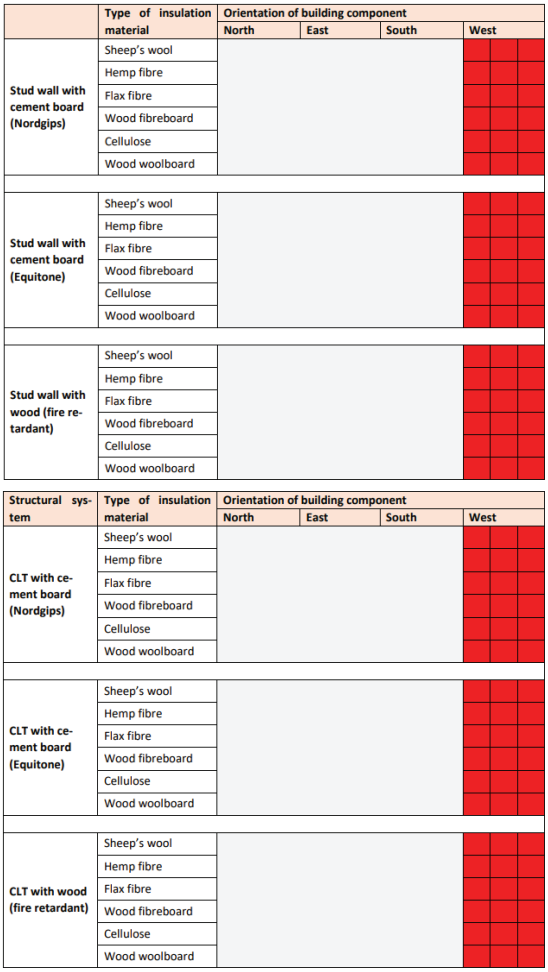

Figure 16: *Risk of mould growth in the insulation layer in Group C wall systems in Paris, when the air cavity is limited ventilated.*

3.3.2 Paris

In Paris, none of the wall configurations can be considered as acceptable, neither stud walls nor CLT walls. All the insulation materials have shown high risk of biodegradation, which can lead to the conclusion the cement board and the wooden panel with fire retardant (with a very high water vapor resistance) are not optimal choices foe getting combined with the specific nature-based insulation materials. The degree of natural convection in these case hasn't had any (positive) impact on the results.

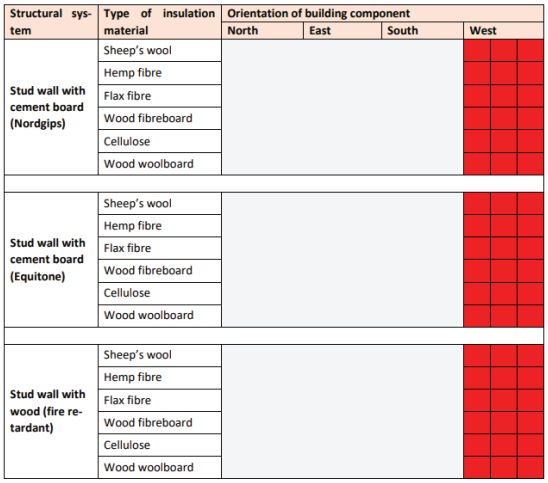

Figure 17: *Risk of mould growth in the insulation layer in Group C wall systems in Paris, when the air cavity is well ventilated.*

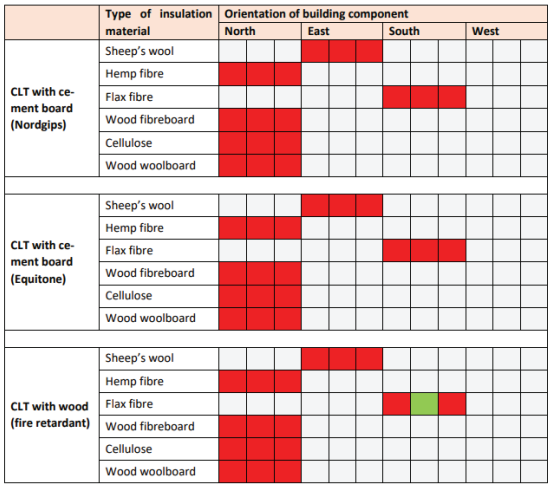

Figure 18: *Risk of mould growth in the insulation layer in Group C wall systems in Barcelona, when the air cavity is limited ventilated.*

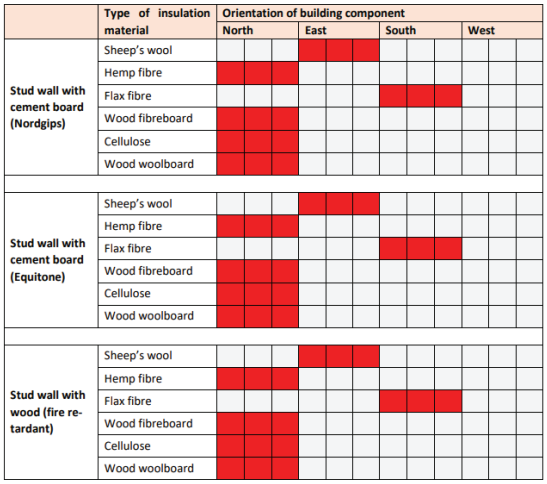
3.3.3 Barcelona

In Barcelona, none of the insulation material have shown acceptable hygrothermal performance when integrated into stud wall systems, regardless the type of exterior cladding, i.e. cement board or wooden panel with fire retardant. The impact of natural convection in the air cavity is negligible.The CLT wall systems have shown better hygrothermal performance, but only when the wooden panel has been used as exterior cladding and the air cavity is considered as fully ventilated. In this case, the flax fibre and the wood woolboard have shown no risk for biodegradation, while the sheep's wool have shown some local moisture problems at the inner side of the insulation layer. All cases with cement board as exterior cladding cannot be considered as acceptable.



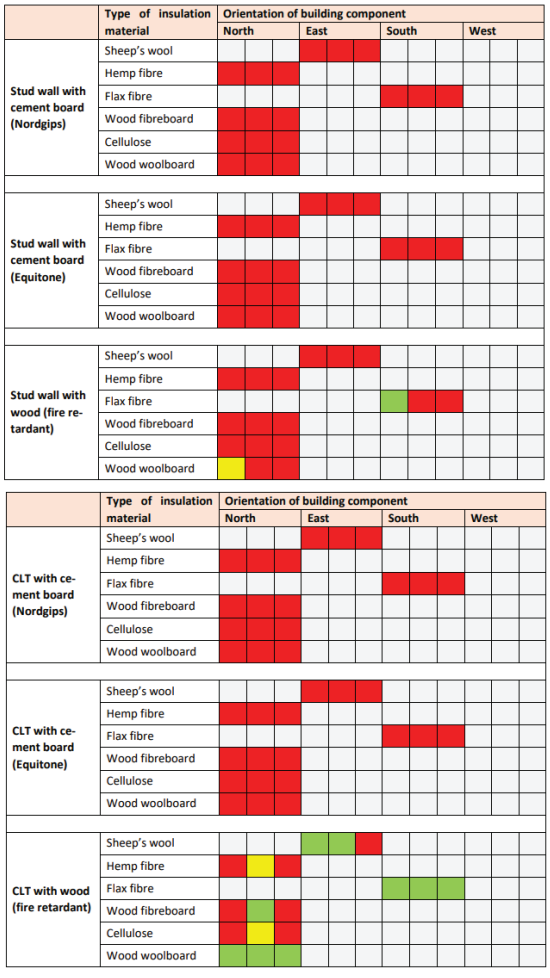


Figure 19: *Risk of mould growth in the insulation layer in Group C wall systems in Barcelona, when the air cavity is well ventilated.*

https://doi.org/10.52202/069179-0499

4 CONCLUSIONS

The following points summarize the most important findings from the hygrothermal analyses:

- Wood woolboard has shown good hygrothermal performance when integrated in different timber-based wall systems in different climates.
- Flax fibre, followed by sheep's wool and hemp fibre can also be considered as acceptable in some cases.
- Natural convection in the air cavity back from the exterior cladding contributes to drastic reduction of the moisture problems in most of the cases.
- Cement-based board should be avoided in wall systems with nature-based materials.
- Paris has a challenging climate for nature-based insulation materials.
- In Barcelona, CLT wall systems have shown less moisture problems than stud walls.

5 AKNOWLEGDEMENTS

This study has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 862820.

TIMBER CLADDING DISCOLOURATION IN TROPICAL MONSOON CLIMATES

Shinya Okuda[1], Laurent Corpataux[2], Kua Harn Wei[3]

ABSTRACT: This paper addresses the factors affecting timber facade discolouration in tropical monsoon climates. We measure the colour change of timber cladding in the northern (N), eastern (E), southern (S) and western (W) orientations in relation to the prevailing wind directions through a year-long field test. The objective is to find a way to guide the timber cladding discolouration in a more controlled manner. The background aim of this research is to reduce the existing negative preconception of timber resulting from the visual discomfort of uneven timber colour change, which contrasts with the established industrial aesthetic norms. The following tectonic configurations were tested: i. Red balau (*Shorea collina*) timber cladding in horizontal and vertical orientations and ii. Norway spruce (*Picea abies*) and red jabon (*Anthocephalus macrophyllus*) cross-laminated timber walls overlayed with ultraviolet-filtered glazing. The discolouration was measured using a Konica Minolta handheld spectrophotometer CM-2600d, and the results were assessed in the colour space of CIE *L* a* b**. The average discolouration (ΔE*) was the largest in the S- and W-side vertically oriented boards (ΔE* = 17.0-18.4) and the smallest in the N-side horizontally orientated boards (ΔE* = 10.2). The horizontally oriented boards exhibited lower and more uneven discolouration than the vertically oriented boards. The prevailing S and SSW wind direction on-site may have concentrated the driving rainwater on the S and W facades, resulting in faster and more even colour changes on the vertical boards.

1 INTRODUCTION

1.1 TIMBER AS INDUSTRIAL MATERIAL

While wood was the most prevalent building material before the nineteenth century, since the Industrial Revolution, we have relied on steel and concrete as the major building materials for the construction of our cities [1]. Wood's decline was furthered by the emergence of modern architectural styles that promoted the use of mass-produced industrialised components, often to achieve a universal aesthetic. Wood, with its ever-changing appearance resulting from chemical and physical degradation, was deemed unsuitable in the era of industrialisation.

The recent development of new composite wood products and timber construction technologies, along with amendments to building codes, has allowed timber construction to finally resurge in the late twentieth century [1].

Most buildings today are erected using hybrid construction techniques that utilise a combination of different materials for technical, functional or aesthetic reasons. When building with wood, non-combustible elements made of steel or concrete are frequently incorporated to enhance characteristics such as structural capacity, fire resistance and acoustic performance.

As a natural material, various properties of wood continue to change even after it has been harvested, sawn, dried, converted into building products and incorporated into structures. UV radiation gradually affect exposed wood, and the associated visible degradation of surfaces can be polemic topic. While some cultures may accept and appreciate the look of weathered and worn wood, it is not always the case when more permanent industrial aesthetics is preferred. The use of timber as a building material is increasing in urban environments, where the majority is made of industrial materials, such as concrete and steel, finding ways to incorporate ephemeral timber aesthetics with the established norm of industrial aesthetics is important and influence to the popularity of timber construction in the future [1].

1.2 PUBLIC PERCEPTION OF MASS-ENGINEERED TIMBER IN SINGAPORE

In Singapore, the Building & Construction Authority (BCA) is pushing the use of mass-engineered timber (MET) due to the increasing need for smarter, greener and higher-quality building structures. This positions MET as a valuable solution for heightened productivity and sustainability in construction. According to a survey by Low et al. [2], professionals in the Singapore construction industry recognise MET's normative and rational merits, including the enhancement of biophilic aesthetics, a decreased carbon footprint, shorter construction time and the reduction of on-site waste. However, cultural and cognitive barriers have been identified as the key factors preventing the adoption of MET in Singapore, including a lack of knowledge and expertise in MET, a shortage of commercial opportunity and challenging raw material acquisitions from overseas, in addition to the higher costs associated with importing MET. These challenges have resulted in the limited adoption of this technology, and few projects in Singapore using MET have been constructed to date. Interestingly, the 'enhanced beauty of buildings' is listed

[1] Shinya Okuda, National University of Singapore, Singapore, akiso@nus.edu.sg
[2] Laurent Corpataux, laurent1corpataux@gmail.com
[3] Kua Harn Wei, National University of Singapore, Singapore, bdgkuahw@nus.edu.sg

https://doi.org/10.52202/069179-0501

among the top drivers of MET adoption, which implies greater concern for the visual quality of MET projects. Therefore, understanding the key factors that cause changes in the colour of timber in tropical monsoon climates and ways to predict it in a controlled manner may help to promote the long-term adaptation of MET buildings in Singapore.

2 LITERATURE REVIEW

2.1 TIMBER DISCOLOURATION

Biodegradation, weathering and ageing can deteriorate wood as a natural material [3]. Wood discolouration is a complex phenomenon, mainly affected by heat, light, physiological and biochemical reactions and microorganism attacks [4].

The colour change manifests in a range from a reddish yellow to a dark brown tone depending on the intensity and duration of the radiation. The red tones in wood are often attributed to extractives within the wood, while the yellow tones are mainly dictated by the photochemistry of the wood, especially in relation to lignin [4].

2.1.1 Weathering

Hill et al. [5] explain that weathering is a combination of biotic and abiotic degradation mechanisms acting on the wood's surface. Prolonged exposure to ultraviolet (UV) light degrades the lignin in wood, which is an organic polymer responsible for binding the cellulose fibres together. The decomposed lignin is soluble in water and may therefore be dissolved and washed out by driving rain, leaving behind the white cellulose fibres [1].

The degradation of lignin produces fragments that act as nutrients for mould and fungi, leading to increased crack formations in the exposed wood. As weathering progresses, the bleached surface region of the wood develops a grey colour as the wood is colonised by mould and staining fungi (e.g., *Aureobasidium pullulans* and *Sclerophoma pithyophila*).

The length of time that the wood is wet is a significant factor in determining the likelihood that mould or stains will develop, and surfaces that dry rapidly because of prevailing winds are much less likely to show mould growth [5]. The completely weathered grey layer is only a few tenths of a millimetre thick, and, within two millimetres from the surface, the wood itself is not affected any further. The effect of weathering on strength properties is very limited [6].

2.1.2 Ageing

Matsuo et al. [3] explain that ageing proceeds slowly in wood through a combination of omnipresent oxygen and water. The ageing and subsequent change in wood colour begin at the time of tree harvesting. Colour properties are in direct relation to ageing (the lightness of the wood decreases, and the hue becomes slightly redder). The colour change during natural ageing could be explained as a mild thermal oxidation process. In other words, heat treatment could accelerate the wood's change in colour that occurs during ageing.

It is generally accepted that colour changes increase as the temperature increases. Heat can directly alter the colour by causing hydrolysis and the oxidation of the wood's components. As timber dries, extractives accumulate on the surface and oxidise, manifesting as a brown colour. According to White and Dietenberger [4], the darkening of wood due to heat is caused by the thermal degradation of hemicelluloses and lignin. Tolvaj et al. [7] studied the effects of steam on softwood's change in colour, which showed a slow but continuous increase in redness at 70°C and a linear correlation between lightness and colour hue at all steaming times and temperatures.

3 RESEARCH METHODOLOGY

The National University of Singapore (NUS) and City Developments Limited's (CDL) Tropical Technology (T^2) lab (Figure 1) was set up at the end of 2018 at NUS in Singapore to investigate the influence of aspects of tropical climates, such as sun, wind and humidity, on photovoltaic panels, green façades and natural ventilation and the behaviour of MET under tropical climate conditions. The MET façade field test was conducted for one year, from January to December 2019, at the T^2 lab, which was naturally ventilated with no casting shadows from the surroundings throughout the testing period.

Figure 1: *Tropical MET architectonics study set up at NUS-CDL T^2 Lab (Nov. 2018)*

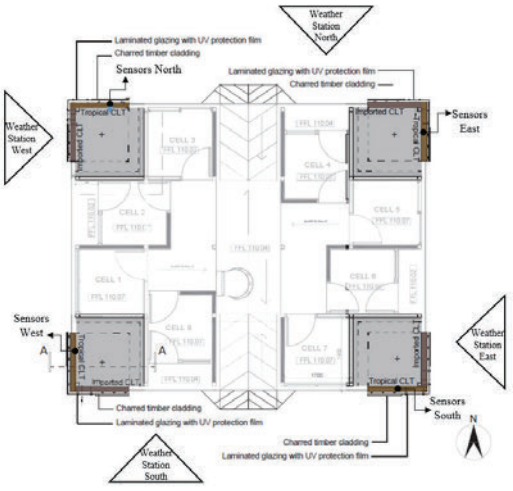

Figure 2: *The locations of the sensors and weather stations*

3.1 FIELD TEST

The four facades of the NUS-CDL T^2 lab are perfectly aligned to the north, east, south and west (N, E, S and W) orientations (Figure 2). The four test corners consisted of

NUS custom-made tropical cross-laminated timber (CLT) walls made of red jabon (*Anthocephalus macrophyllus*), a fast-growing tropical plant [8], in a side-by-side comparison with Norway spruce *(Picea abies)* CLT imported from Europe, which has been the local standard since 2012 due to Singapore's Eurocode compliance. Each CLT panel was 2.4 m in height and 1.4 m in width with 150 mm thickness and was clad with three façade configurations: horizontally (H) and vertically (V) oriented red balau (*Shorea collina*) timber cladding and UV-filtered grazing (Figure 3).

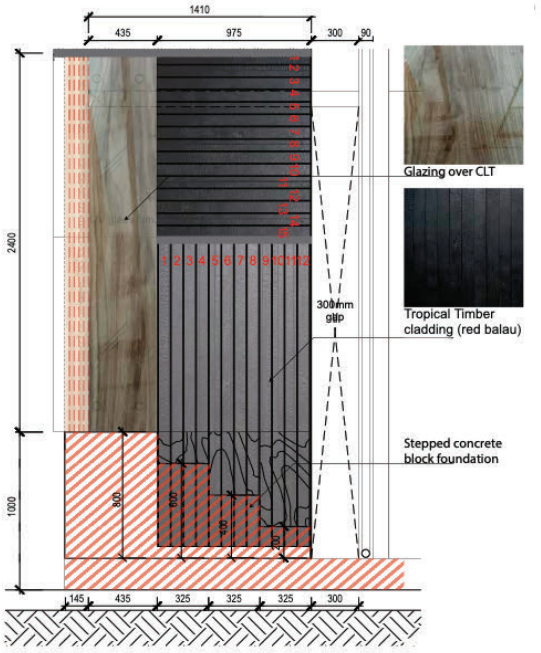

Figure 3: *An illustration of the typical CLT wall configuration at the T² lab.*

3.2 THE SELECTION OF TIMBER SPECIES FOR CLADDING

Untreated red balau (*Shorea collina*) was selected for timber cladding tests, which is classified as moderately durable for fungal and termite attacks according to BS EN350:2016. Red balau is also commonly used for outdoor decking and cladding in Singapore.

3.3 CIE-L*a*b* ANALYSES

In accordance with BS EN ISO 11664-4:2011, the change of colour coordinates (ΔL*, Δa* and Δb*) were calculated as the difference between the value of the control samples and the value of the tested specimen. We measured the average of two control samples for 200 timber boards across the four orientations.

The measurements were recorded using a Spectrophotometer CM-2600d (Konica Minolta), which was set to measure the samples' L*, a* and b*colour coordinates, where L* is lightness from 0 (black) to 100 (white), a* is chromaticity coordinate + (red) or − (green), and b* is chromaticity coordinate + (yellow) or − (blue). From the relative colour changes, ΔL*, Δa* and Δb* (i.e. changes between the weathered and control samples), the total colour difference, ΔE*, was calculated by equation (1) [9] to compare the individual colour shades.

$$\Delta E* = \sqrt{\Delta L*2 + \Delta a*2 + \Delta b*2} \quad (1)$$

There were noticeable natural colour differences among the timber specimens at the beginning of the tests (Figure 4, left). To minimise the influence of the natural colour variations, each board was measured at three points (left, middle and right for the H-oriented boards and top, middle and bottom for the V-oriented boards) to determine the average ΔE* for each timber board (Figure 4 Right).

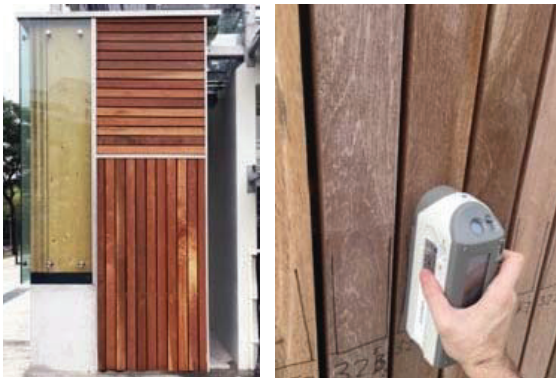

Figure 4 Left: *Newly installed tropical timber cladding (red balau). There were noticeable natural colour differences among the timber boards. (W side, Oct. 2018)* ***Right:*** *Colour measurement with handheld spectrophotometer (Konica Minolta CM-2600d). Each board was measured at three points to determine the average ΔE* for each timber board.*

3.4 UV-FILTERED GLAZING

Cross-laminated timber is only to be used for service classes 1 and 2 (BS EN 1995-1-1:2004+A2:2014), which means it is not possible to use it for service class 3: direct exposure to the weather (NA to SS EN 1995-1-1:2018). The UV-filtered glazing overlaying CLT walls could be considered as service class 2, which makes untreated timber visible through the glazing (Figure 4, left).

To effectively cut the UV exposure, 3M Prestige Window Film PR70 (Visible light transmitted: 69%/UV rejected: 99.9%/Infrared rejected: 97%/Total solar energy rejected: 50%) was applied inside the glazing. A point-fixing method was used to fix the glazing on both the NUS custom-made tropical CLT and the spruce CLT.

Wong et al. [10] simulated the surface temperature profile of a double-glazed wall in the context of Singapore. The external surface temperature of a double-glazed facade could become very high if heat absorption glass is used. But the mechanism of heat extraction, either by stack effect or mechanical fans, in the double-glazed cavity can maintain a lower internal surface temperature, thus minimising solar heat transfer to the internal spaces. As in the case of the fourth-floor east orientation, with the external surface of the inner layer glazed wall with no ventilation as the worst scenario, the most probable temperature is around 37–38°C. To

https://doi.org/10.52202/069179-0501

generate sufficient natural ventilation by stack effect in the façade cavity, we kept the bottom part and the vertical gaps between the two glazing panels open.

4 RESULT AND DISCUSSION

4.1 LEACHING EXTRACTIVES

Figure 5: *Brown stains on the concrete foundation were observed during the first few months after the installation. They were likely deposited by leached extractives from the red balau timber (red dotted circle, October 2018)*

The installation of timber cladding specimens was completed in October 2018. Temporary brown stains on the concrete foundation were observed for the first few months, which were likely deposited by leached extractives from the red balau façade. Those stains were later washed away by natural rainfall.

For the first two months between October and December 2018, the rapid discolouration (ΔE*) between the averages of the two control samples and the 200 specimens was recorded (ΔE* = 6.5–8.7, Figure 5, 7). There were noticeable natural colour differences among the 200 specimens initially (Figure 4, left), which might make the difference in the colour change (ΔE*) in the orientations less clear. After two months' exposure, the natural variations in colour among the specimens seemed to be relatively moderate. Therefore, we excluded those first two months (ΔE*) in the colour change analysis (Figure 7).

4.2 COLOUR DIFFERENCES IN ORIENTATION

The average colour coordinate of the two controlled samples was recorded as (L*: 48.24, a*:11.58, b*: 19.50) prior to the testing. The colour measurement of the 200 specimens in the NWSE orientations was recorded at two-month intervals between December 2018 and December 2019 for one year. The colour change field test result is shown in Figure 7.

The decrease in the lightness of the specimens was recorded for all samples. After the testing period, the overall colour change, ΔE^*, was the largest in the S- and W-side V-aligned cladding (ΔE^* = 17.0–18.4), which was classified as a different colour according to the colour change assessment guidelines (Figure 6). The smallest ΔE^* was the N-side H-aligned cladding (ΔE^* = 10.2), which was classified as a distinct colour change according to the same assessment guidelines.

ΔE^*	Description
$\Delta E^* < 0.2$	Invisible changes
$0.2 < \Delta E^* < 2$	Small changes
$2 < \Delta E^* < 3$	Colour changes visible by high quality filter
$3 < \Delta E^* < 6$	Colour changes visible by medium quality filter
$6 < \Delta E^* < 12$	Distinct colour changes
$\Delta E^* > 12$	A different colour

Figure 6: *Assessment guidelines for colour change* [11]

It is generally observed that the overall colour change (ΔE*) on the S and W sides increased faster than on the E and N sides, except for the E-side V-aligned boards, where the ΔE* increased as fast as the S and W sides. The colour change (ΔE*) differences in orientations generally grew wider over the testing period (Figure 7).

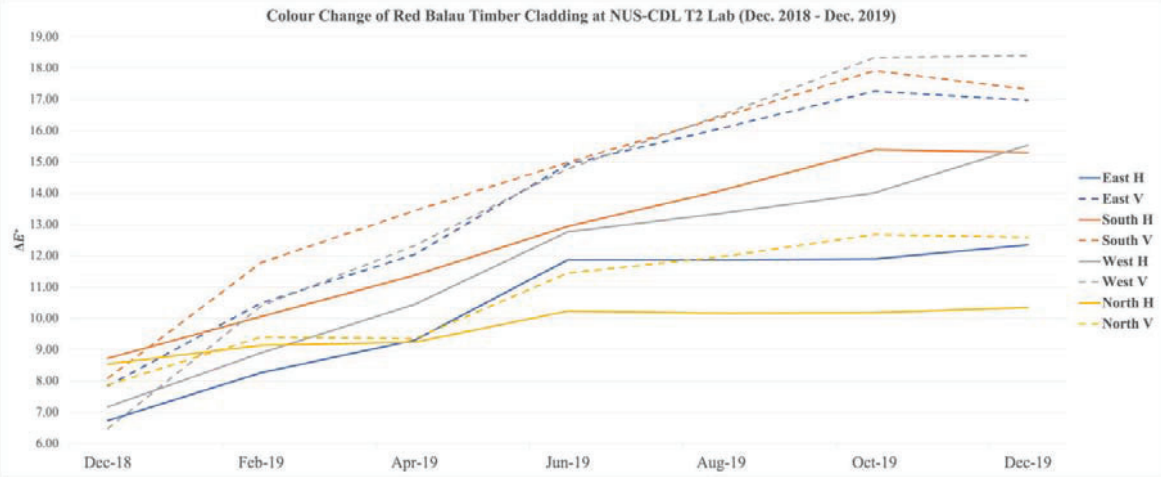

Figure 7: *Discolouration of the red balau V- and H-aligned cladding in NWSE orientations.*

https://doi.org/10.52202/069179-0501

4.3 HORIZONTAL/VERTICAL CLADDING

It was observed that the H-aligned boards exhibited lower overall discolouration (ΔE*) values than the V-aligned boards. Except for the first measurement in December 2018, when the initial natural colour variations among the specimens were still prevalent, all the other measurements exhibited lower ΔE* in the H-aligned boards than the V-aligned boards. Generally, the gaps in ΔE* between the H- and V-aligned boards continuously increased, except for the last measurement in December 2019 (Table 1).

Table 1: *The discolouration (ΔE*) comparison between H and V-aligned red balau timber cladding in the NWSE orientations. Except for the first measurement in December 2018, all other measurements exhibited higher ΔE* for the V-aligned boards than the H-aligned boards (Ref. red underlined figures).*

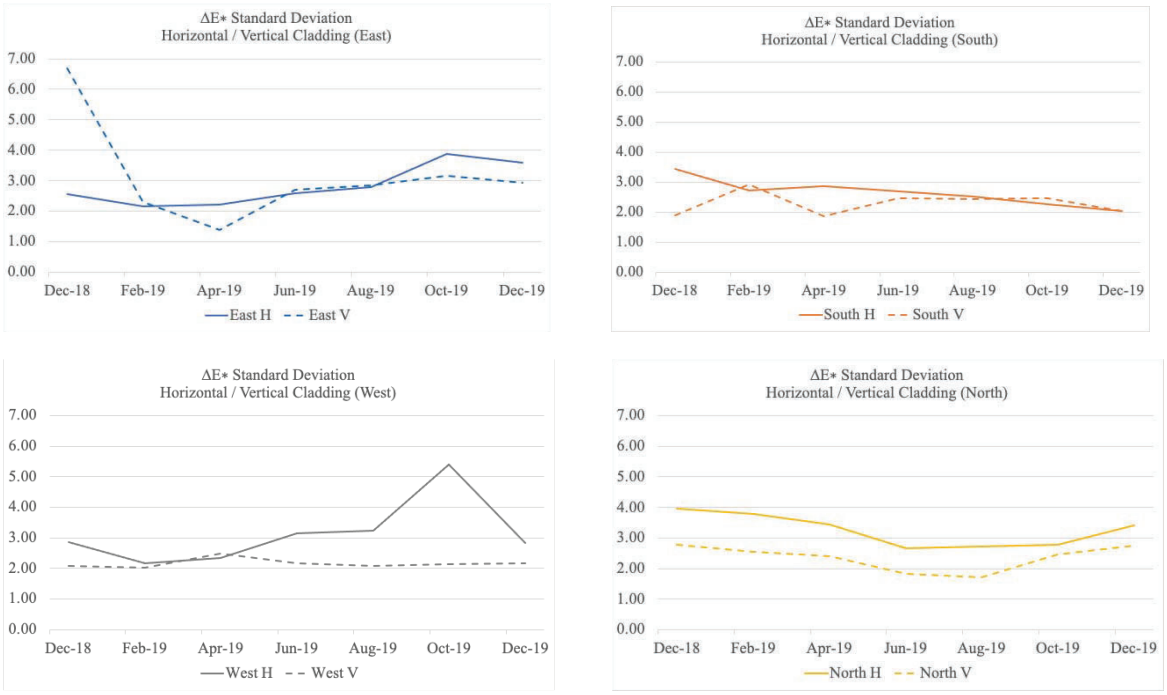

Figure 8: *ΔE* standard deviation among all H-aligned and V-aligned boards in each orientation (**Upper Left:** E, **Upper Right:** S, **Lower Left:** W, **Lower Right:** N.)*

https://doi.org/10.52202/069179-0501

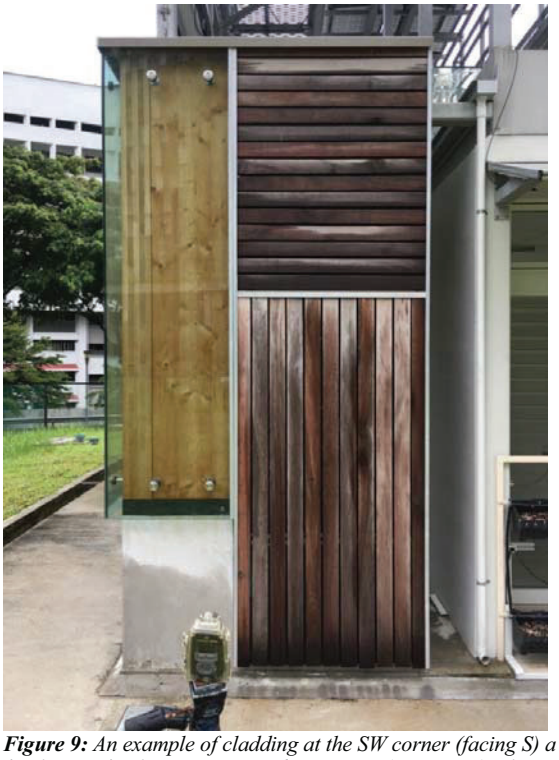

Figure 9: *An example of cladding at the SW corner (facing S) a few hours after heavy monsoon driving rain (Nov. 2019). The H-aligned cladding was mostly still wet, while the V-aligned cladding dehydrated relatively quickly.*

The ΔE* standard deviation among all H- and V-aligned boards in each orientation was computed to understand the degree of even discolouration. While it was generally observed that the discolouration (ΔE*) standard deviation became smaller in the S orientation, there were two exceptions: the E-side V-aligned boards at the beginning of the testing period and the W-side H-aligned boards in October 2019.

The former was due to the initial natural colour variations among the specimens, as the ΔE* standard deviation for the V-aligned boards in all orientations stabilised after six months.

The latter helps us to understand the cause of the late ΔE* standard deviation spike in the H-aligned boards, which fluctuated more than the V-aligned boards throughout the testing period. As UV-degraded lignin is washed away by rainwater, the fluctuated discolouration (ΔE*) standard deviation might be caused by water-flow patterns over the H- and V-aligned boards.

Figure 9 illustrates an example of the S facade a few hours after the heavy monsoon driving rain. While the H-aligned boards retained their wet surfaces for a longer period, the V-aligned boards exhibited a relatively quicker drying process, which implies that the driving rain ran smoothly along the direction of the wood grains. In contrast, the water flow direction was not aligned with the direction of the wood grains in the H-aligned boards, resulting in wet surfaces for relatively prolonged periods.

4.4 MONSOON WIND AND RAIN SHOWERS IN THE TROPICS

In the tropical monsoon climate, much of the rain is heavy and accompanied by monsoon wind. Timber weathering is caused by UV decomposing the lignin, which is soluble in water and may therefore be dissolved and washed out by driving rain [1]. Therefore, the prevailing wind direction is an important factor influencing timber weathering in the tropical monsoon climate.

Two monsoon seasons and two inter-monsoon periods define Singapore's local climate. The two monsoon seasons are the southwest monsoon season (June to September, south-easterly to southerly winds) and the northeast monsoon season (December to early March, northerly to north-easterly winds), while the two inter-monsoon periods take place from late March to May and from October to November with light breezes. Rainfall is plentiful in Singapore, with an average of 167 rainy days per year. The long-term mean annual rainfall from 1981 to 2010 was 2165.9 mm [12], which is approximately three times higher than the mean annual precipitation in Germany from 1991 to 2020 (728.9 mm) [13], for example.

According to the annual wind rose for 1981–2010 in Singapore [12], the two prevailing wind directions are NNE and S. However, the Figure 7 discolouration analysis indicated that the highest discolouration occurred in the S and W orientations, while the N orientation recorded the lowest level of discolouration.

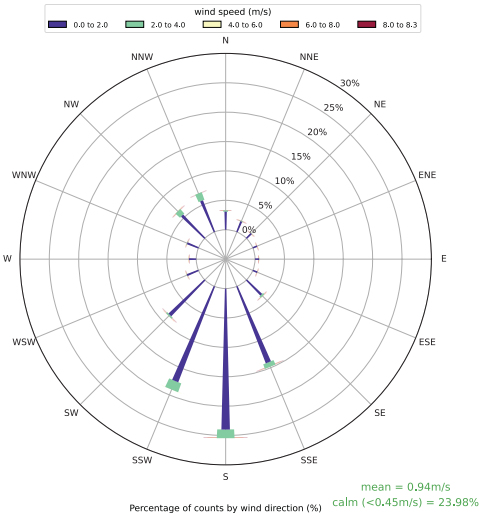

Figure 10: *Annual wind rose based on the measurement at the NUS-CDL T2 lab, January to December 2019*

We further analysed the wind data recorded at the rooftop level of the NUS-CDL T^2 lab. The 2019 annual wind rose at the T^2 lab (Figure 10) indicates the clear S and SSW dominant wind directions, which deviate from the prevailing monsoon wind direction. Therefore, the higher and faster discolouration in the S and W orientations might be a result of heavy monsoon driving rain by the locally dominant S and SSW wind at the T^2 lab site.

However, we are not certain of the cause of the deviated dominant wind direction at the T^2 lab site. The T^2 lab site was surrounded by high-rise residential buildings, which are typical in Singapore's high-density urban environment. This might be the cause of the varied wind directions at the rooftop level of the low-rise T^2 lab. This may indicate that local wind measurements are important for estimating the weathering effects in Singapore's high-density urban environment.

4.5 RAIN SPLASH WATER

The growth of decay-producing fungi only occurs if wood is continuously saturated with water in the presence of oxygen and its moisture content remains above 20% over prolonged periods. Construction details that either keep building components dry or help them to dry quickly will reduce the likelihood of infestation by wood-destroying fungi and insects. Best practices include raising wooden facades high enough above adjacent horizontal surfaces to prevent damage caused by splashing water [1].

According to the DIN 68800, the distance between the underside of exposed timber members or construction elements and the ground (or surrounding surface) must be at least 30 cm to prevent exposure to splash water. This distance can be reduced to 15 cm if additional technical measures, such as a gravel bed in front of the timber cladding, are taken to reduce the impact of splashing [14].

The greying of damp wood is generally due to the presence of stain fungi (*Aureobasidium pullulans*). The hyphae of these fungi are pigmented, and they tend to refract visible light; accordingly, the timber surface appears grey. Refraction varies depending on the surface moisture content, and weathered timber is always darkest when wet [15].

At the NUS-CDL T^2 lab, where there is no shade from the surroundings, generally strong splashes at the ground level were observed when tropical monsoon driving rain directly hit the concrete ground surface. We intentionally narrowed the gaps between the bottom end of the timber cladding to the ground level to 20 cm to observe how high the splash water could wet the timber façade with the tropical monsoon driving rain.

Figure 11 illustrates an example of timber cladding on the S side several hours after heavy monsoon driving rainfall. Generally, we observed that the wall base became wet and darker up to 40 cm in height in the S and W orientations. The tendency was less obvious in the N and E façades. If we were not mitigating the splash water through additional technical measures, it would probably have been better to raise the bottom end of the timber cladding at least 40 cm from the ground level to protect the timber façade from constant wetting, especially for the façade facing prevailing wind directions in the tropical monsoon climate.

Further investigation is needed to develop guidelines; however, the 30 cm guideline in the temperate climate is not sufficient in the tropical monsoon climate.

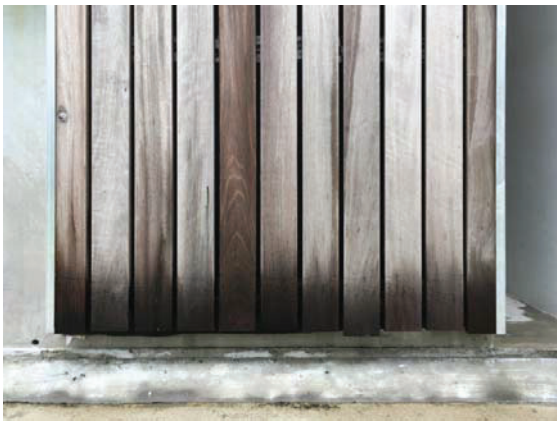

Figure 11: *An example of a wet timber cladding base several hours after heavy monsoon driving rainfall (November 2019) – generally, the bottom of the S and W façades became wet and grew darker because of the splash water up to 400 mm above ground level.*

4.6 UV-FILTERED GLAZING

The UV-filtered glazing overlayed CLT walls made of Norway spruce (*Picea abies*) and red jabon (*Anthocephalus macrophyllus*) to protect them from weathering and make them visible from the outside. As the UV-filtered glazing was point-fixed over the CLT walls, the colour change measurement via handheld spectrometer was restricted. Instead, the general discolouration observation was made visually after 28 months of exposure as a reference.

Figure 12: *Examples of colour changes after 28 months exposure behind UV-filtered glazing (April 2021).* ***Left:*** *Norway spruce (Picea abies),* ***Right:*** *Red jabon (Anthocephalus macrophyllus).*

As the UV-filtered glazing effectively protected the CLT walls from monsoon driving rain, there were no signs of grey colour weathering observed for both the Norway spruce and red jabon. However, noticeable colour changes were still observed, especially for the Norway spruce, which changed to a darker reddish colour over time, while the red jabon's change in colour was less obvious. There were also noticeable cracks on both the Norway spruce and red jabon CLT walls (Figure 12). The visually noticeable dark reddish colour changes of the Norway spruce and the moderate reddish colour of

https://doi.org/10.52202/069179-0501

the red jabon seemed to be a part of the ageing process, which is considered as a slow thermal oxidation [3]. It is generally observed that heat can directly alter the colour by causing hydrolysis and the oxidation of wood components. As timber dries, extractives accumulate on the surface, where they oxidise to a brown colour. The effect is usually short-lived, as rainwater will remove the extractives, although it can persist where the timber is protected [15]. It is also generally accepted that colour changes increase as the temperature increases. Long-term exposure to heated double facade cavities in hot and humid climates probably accelerates the ageing process. This phenomenon requires further investigation.

Figure 13 *Examples of overall timber cladding discolouration after 28 months exposure (April 2021).* ***Left:*** *N side,* ***Right:*** *S side. The S-side facade exhibits mostly darker colours, while the N-side facade exhibits more moderate and uneven colour changes.*

5 CONCLUSIONS

Timber weathering is caused by UV decomposing the lignin, which is washed out by the driving rain. In tropical monsoon climates, much of the rainfall is heavy and accompanied by monsoon wind. The mean annual rainfall in Singapore is approximately three times higher than in Germany. Therefore, the prevailing wind direction is one of the important factors influencing timber weathering and discolouration in tropical monsoon climates.

The overall colour change (ΔE^*) was the largest in the S- and W-side V-aligned cladding ($\Delta E^* = 17.0–18.4$), and the smallest ΔE^* was the N-side H-aligned cladding ($\Delta E^* = 10.2$). The dominant wind directions at the T^2 lab were S and SSW; therefore, monsoon driving rain seems to be the main cause. However, in Singapore's high-density urban environment, the prevailing wind direction in microclimates may differ from the prevailing monsoon wind direction. Therefore, on-site wind measurement is essential to estimating future weathering.

The general observation was made that the H-aligned boards exhibited lower overall discolouration (ΔE^*) than the V-aligned boards. The ΔE^* standard deviation for the H-aligned boards was generally higher than the V-aligned boards throughout the testing period. After a 28-month period, the V-aligned boards exhibited a relatively homogeneous facade outlook, while the H-aligned boards still exhibited uneven weathering (Figure 13).

Despite the UV-filtered glazing, the natural colour changes still occurred for the CLT walls, which seemed to be caused by a mild thermal oxidation process. The effect of prolonged exposure to the heated double-grazing cavity requires further investigation.

The discolouration of timber elements is unavoidable; however, if the discolouration could manifest more evenly, it could still resonate with the dominating industrial aesthetics. The field test demonstrated that vertical cladding constantly exhibited a lower ΔE^* standard deviation than horizontal cladding, which means that relatively even weathering can be expected. Overall, this is still an initial attempt to control the discolouration of timber facades in tropical monsoon climates. We must investigate with further variations in tectonics and more tactile strategies to control and blend in ephemeral timber aesthetics with the industrial aesthetic norms. We hope this may eventually ease the negative public preconception of timber and contribute to the adaptation of MET buildings in tropical monsoon climates.

ACKNOWLEDGEMENT

The NUS-CDL T^2 lab, Department of Architecture, College of Design and Engineering, National University of Singapore is financially supported by City Developments Limited, which aims to test various advanced building technologies related to the tropics, such as Building-integrated photovoltaics, green façades, natural ventilation and climate-responsive building design strategies. The CLT-filed test was funded by the MNDRF Innovative Mass Timber Construction Systems for High-density Urban Environment in the Tropics project (BCA RID 94.18.2.1).

CREEP TESTING OF A TIMBER LATTICE FRAME USING IMAGE RECOGNITION

Nicolas Giron[1], Hideyuki Nasu[2]

ABSTRACT: A one year creep testing for an architectural project was conducted for a 8650mm span timber lattice frame. In parallel of the standard measurement with dial gauges, three cameras were set and 400 pictures were taken on a regular base for the full year. To process the picture data, an image recognition program was used. The displacement of each node of the lattice frame was extracted and the central deflection of the frame was evaluated. The deflection measured by dial gauge and the one estimated by image recognition were compared and a very good accordance was observed. In addition to the central deflection, deformation and stress of each member of the lattice frame can be estimated, allowing to understand the global and the detailed behaviour of the frame. Applications of the proposed method are presented.

KEYWORDS: Creep testing, Image recognition, Structural analysis

1 INTRODUCTION

As timber is a viscoelastic material, creep amplification, which refers to amplification of elastic deflection over time, is an important factor to consider when designing a timber structure. For a single structural element, the range of the amplification is well documented for various periods of time and types of loading [1]. However, for a composite structure like the lattice frame presented below, accurately evaluating the expected amplification is difficult due to factors such as connections and the mix of loading types. For non-conventional types of structure with long-term deflection that may be critical, creep testing is frequently undertaken.

While creep testing a large structure is costly and time-consuming, generally only a few measurement devices are used, mainly to estimate the central deflection, leading to an understanding of the global behaviour of the structure but not the behaviour of each element.

In 2018, a creep testing using standard measurement devices was conducted for a full year. At that time, it was expected that in image recognition algorithms would be improved and become a powerful tool to enhance the results of such a testing. Therefore, distinctive marks, hereafter templates, were placed on the node of the lattice frame in anticipation of future research.

This article proposes a method using image recognition to estimate the creep amplification factor, along with other meaningful structural characteristics. Without installing any recording devices like dial gauges or strain gauges, the complete behaviour of a structure can be recorded using pictures taken by a standard camera (in this study, NIKON COOLPIX W300 with 16.05 million effective pixels and a 1/2.3" CMOS image sensor)) and then analysed using an image recognition program.

The central deflection estimated through this proposed method shows good agreement with the measurement of the dial gauge. Additionally, the displacement and rotation of all the nodes, and the evolution of the length of each element of the lattice frame were estimated. While there are issues with accuracy and points to be improved, the authors believe that promising results were obtained, even if the testing that was planned for standard measurement method with no particular attention given to the proposed method.

A roof composed of frames similar to the tested lattice frame has been in service since four years in an elementary school in Japan (Figure 1), and to this day, the structural behaviour of the frames is within the design range.

2 CREEP TESTING SETUP AND RESULTS

2.1 TESTED FRAME OUTLINE

A lattice frame system composed of superimposed dimension lumber (38x140 SPF) and laminated veneer lumber (LVL) gussets was tested. Lumbers are arranged on a grid with horizontal spans of 910mm and vertical spans of 400mm. The frame includes horizontal, vertical and diagonal elements. The frame consists of three layers with one vertical lumber in the centre between two horizontal or diagonal lumbers, giving the frame a total thickness of 114mm. When lumbers from more than two directions meet at one point, 38mm thick LVL gussets are inserted, as shown in Figure 2. The lumbers are connected using wood screws as a double shear connection. The screw length is 110mm with a thread length of 40mm, and the screw material is carbon steel wire for cold heading and cold forging (SWCH) respecting JIS G3507-2 regulation. Ruspert anti-corrosion treatment is applied.
The lattice frame spans over 8.645m with a rise of 2m and a minimal depth of 400mm. Further details can be found in [2].

2.2 TESTING SETUP

Two frames were placed side by side in a hangar and connected at roof level by plywood. They were loaded with steel rebar for an entire year. Each frame was equipped with 3 dial gauges, as in Figure 3. In addition to the dial gauges, four cameras were placed (Cameras 1, 2, 3: NIKON COOLPIX W300, Camera 4: NIKON Keymission 170 (wide angle)). At each node of the frame, a template was placed (Figure 6) to facilitate the image recognition process. The frames were loaded using a total of 900 pieces of steel rebar, resulting in a total load of total load of 53kN, including the self-weight of the frames and the additional elements used to connect them. The total load corresponds to twice the expected long-term dead load considered in the design.
The testing began on August 27th, 2018, and ended one year later. The dial gauge data were collected every 10 minutes. During the first hour, pictures were taken every 10 minutes. Afterwards, picture were taken every hour until the next day, every 3 hours until the third day, every 6 hours until the fourth day, every 12 hours until the fifth day. Then, pictures were taken once a day during the first month and twice a week until the end of the testing for Cameras 1 to 3. For Camera 4, pictures were taken twice a week for 3 months.

2.3 RESULTS

The initial elastic deflection is approximately 17.82mm. The maximum deflections recorded after 1, 6 and 12 months are respectively 22.81mm (1.28 times), 27.29mm (1.53 times) and 33.08mm (1.86 times), respectively. The power law creep equation is used to evaluate the creep amplification coefficient at 50 years. The approximation of the power law equation parameters with the data recorded during one year yielded a 50-years deflection about 49mm and a creep amplification factor of 2.8. The results are presented in Figure 5.

https://doi.org/10.52202/069179-0502

3 IMAGE RECOGNITION PROCEDURE

3.1 METHODOLOGY

The proposed method has been applied to the pictures from Camera 2 and Camera 3. The pictures from Camera 4 have large distortions due to the wide-angle lens and were not analysed this time. However, with an appropriate algorithm and some calibrations, it is possible to restore the true angles and geometry, allowing for the processing of the pictures in the same way.

The data are processed with a Python program using the OpenCV library for image recognition. The "matchTemplate" function is used, and results are calculated based on the normalized correlation coefficient. This function assigns a score between 0 and 1 to each pixel of the picture based on the resemblance between a given template and the corresponding picture area. For a single node, many matches are returned, and therefore, a filtering procedure is required to assign a unique coordinate to a node, as shown in Figure 7. The procedure is as follows:

In the first step, the images from Camera 2 and Camera 3 are combined to form a picture of the whole frame. The four marks of the overlapping area are used to determine the differences in scale and angular rotation of the two pictures, along with the coordinates where the images can be stitched. The two pictures are accordingly rotated, scaled and stitched, as shown in Figure 8.

In the second step, two areas of the pictures that are likely to be unchanged during the test process are chosen. Using the image recognition of the first step, all the pictures are scaled, rotated, resized and aligned to a common base with the same origin and axis from a reference picture, as shown in Figure 9. This allows the location of the marks in each picture to be compared, and the location variations correspond to the displacement of the frame.

In the third step, each node of the first picture is copied and rotated from -2.00 to 2.00 degrees with 0.01 degree intervals. The resulting images are saved as new templates for the next step, as shown in Figure 10.

In the fourth and last step, the original template is used to locate all the nodes. Then each node is compared with its dedicated template from -2.00~2.00 degrees from the first picture, and the template with the best matching is assumed to be the variation of the angle since the beginning of the testing. This process is detailed in the next section. In addition to the node marks, the three anchors of the frame to the ground are also located. Data is stored in an Excel sheet with coordinates and rotation angle of each node and the date of the picture. Also, the original pictures are edited with the located nodes, their number, and rotation angle, as shown in Figure 11.

The data is then available to be processed for structural analysis. The length of a known element is used to calibrate the pixel size, allowing the coordinates of each node to be calculated in millimetres.

3.2 ROTATION ANGLE

To identify the variations in the rotation angle of a mark, the mark is compared to templates of various angles and the best match is chosen. Initially, a common template was planned for all the nodes, but during the evaluation process, issues arose.

Testing was conducted with digital data and real pictures with various backgrounds using the layout and rotation angles in Figure 12. Accurate results were obtained for digital data, but for real pictures, noise from the background and picture distortion had a significant impact, as seen in Figure 13. To reduce the noise, two options were considered: making the template as small as possible to remove the background and keep only the mark, or using a different template for each node to include the background into the identification process. The latter option was chosen because reducing the mark of the creep testing which is already small (55x55 pixels), would also reduce the minimum resolution available, while using a local template would allow for a larger template size 135x135 pixels that includes the background, improving resolution. Additionally, when limited to a located area, the impact of image distortion in the templates and pictures is approximately the same, mitigating its impact on the identification process.

For the digital testing, the results showed a continuous distribution with an error of +/- 0.02 degree for a 150x150 template, as shown in Figure 14. For the full scale creep testing, a resolution of around 2x0.02x150/55 = 0.11 degrees is expected. However, with real pictures, the results included some noise, making it difficult to determine whether the best result is due to noise or is the true maximum. Results are expected to have a continuous bell shape distribution, and therefore, are approximated with a curve obtained with Savitzky-Golay filter, as in shown Figure 15.

4 STRUCTURAL ANALYSIS

4.1 FRAME DISPLACEMENT

By estimating the location of each node, it is possible to create a digital twin of the frame, as shown in Figure 16. This enables measurements of the displacement in both vertical and horizontal directions of each node of the frame at a given time, in comparison of the vertical displacement of the three dial gauges.

The central deflection is plotted in Figure 17, which shows good agreement between the measured data and the estimated data obtained using image recognition.

During the creep testing, the hangar experienced large variations in temperature, causing the steel beam connecting the two extremities to dilate and inducing undesirable vertical displacement in the gauge measurement. Fortunately, the temperature of the room was also recorded along with the gauge displacement, and the results were adjusted accordingly. However, the proposed method eliminates the dependence to temperature, making the measurement more stable.

4.2 MEMBER STRESS

By knowing the horizontal and vertical coordinates and the angle of rotation of each node at each step, it is possible to calculate the displacement and the rotation of each extremity of the member composing the lattice frame. Assuming that all the displacements occur in the 2D plane and using an initial Young's modulus, it is possible to apply the stiffness matrix and to calculate the axial force, shear force and bending moment of all the members. However, the current testing setup does not account for the displacement at the connection, and the results for vertical and diagonal members may differ significantly from reality. Additionally, the accuracy of angle measurement is questionable at this stage of research, so only the axial stress is calculated. Nevertheless, theoretically, it is possible to obtain all stresses of a member with this method with Equation (1) below:

$$\begin{bmatrix} a_N & 0 & 0 & -a_N & 0 & 0 \\ 0 & 12a_M & 6La_M & 0 & -12a_M & 6La_M \\ 0 & 6La_M & 4L^2a_M & 0 & -6La_M & 2L^2a_M \\ -a_N & 0 & 0 & a_N & 0 & 0 \\ 0 & -12a_M & -6La_M & 0 & 12a_M & -6La_M \\ 0 & 6La_M & 2L^2a_M & 0 & -6La_M & 4L^2a_M \end{bmatrix} \begin{Bmatrix} u_1 \\ v_1 \\ \theta_1 \\ u_2 \\ v_2 \\ \theta_2 \end{Bmatrix} = \begin{Bmatrix} N_1 \\ Q_1 \\ M_1 \\ N_2 \\ Q_2 \\ M_2 \end{Bmatrix}, \quad a_N = \frac{EA}{L}, \quad a_M = \frac{EI}{L^3} \tag{1}$$

where L = member length, A = cross-sectional area, I = cross-sectional second moment of inertia, E = Young's modulus, u = axial displacement, v = transversal displacement, θ = the rotation angle, N = axial force, Q = shear force and M = bending moment for both extremities.

An example of results is shown in Figure 18 with a comparison to the computational model. The stress direction, i.e., tension or compression, shows rather good agreement. As for the intensity, good results are obtained for the centre and top part; however, close to the connection to the ground, result improvements are required. The main cause seems to be the picture distortion.

4.3 MEMBER CREEP

The overall creep of the frame is estimated with the central deflection. But not all the members of the frame participate equally to the creep amplification, and in the case of countermeasures to reduce the creep are required, knowing the members that suffer the most from creep can be very efficient. Indeed, by increasing the cross-section of such a member, it is possible to reduce the stress intensity and therefore to creep impact on the structure, allowing a cost-efficient design.

In Figure 19, the evolution of the length of several members from 30 minutes after the beginning of the testing to its end is shown. As an example, according to the recorded data, reinforcement of the member section between nodes 0-1 seems to be the best option to reduce the overall displacement, as this member has the largest change in length during the testing span.

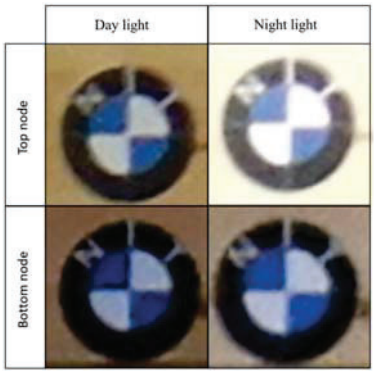

Figure 20: Comparison of 2 nodes during day and night time

5 LIMITATIONS AND IMPROVEMENT POINTS

5.1 TESTING SETUP

The testing setup was designed for standard creep testing and therefore was not optimized for the proposed method. For future developments, the following points should be revised.

5.1.1 Camera

The camera should be fixed on a weighted tripod to improve its stability. The camera should be actioned remotely to avoid any changes in distance or orientation relative to the frame and to avoid any blurring.

5.1.2 Environment

The lighting environment should be controlled to improve the continuity within a picture (space) and between the pictures (time), to reduce the disparities, as shown in Figure 20. Also, the camera should be set to manual to maintain the same aperture for all the pictures. The aperture should be around 8-12 to control lens aberration. A fixed low ISO is recommended to reduce the sensor noise.

5.1.3 Layout

The overlapping area of the cameras should be extended to improve the quality of the picture stitching. When better accuracy is required, the resolution and/or the number of cameras should be increased. In this testing, the resolution was about 70mm/55pixel or 1.3mm/pixel.

5.1.4 Additional marking

Distinctive marks should be added at anchor points and close to them on the ground to create fix points. In this setup, the anchor points were connected by a steel beam, so the effect of the horizontal thrust and corresponding horizontal displacement was neglected. For structure with significant horizontal sliding, independent fix points are required.

5.1.5 References

To obtain precise results, a reference, such as a lead wire, should be added to set the vertical axis. Also a reference should be added to calculate the pixel/millimetre ratio to calibrate the lengths.

5.1.6 Template

A larger template should be used to calculate the rotation angle. With a 55x55 template, only rotation about 1 (= arctan (1/55)) degree should be measurable. However, with the proposed image recognition procedure, subtle colour variations of the pixels are included, and a better resolution around 0.1 degree is obtained. The colours of the template should be selected to offer good contrast with timber or other testing material, and surrounding environment.

https://doi.org/10.52202/069179-0502

5.2 MULTILAYER STRUCTURE

The considered frame was composed of three layers. The marks were set only on the exterior layer, and therefore the displacement at the connection level due to the deformation of wood screws was not measurable. By adding additional marks close to the connection on the vertical member, as shown in Figure 21, the relative displacement between horizontal and vertical member at the connection can be estimated.

5.3 PROGRAMM

5.3.1 Step one and two: stitching and aligning

For the first step of the procedure, the picture stitching can be improved with the "SIFT" (Scale-Invariant Feature Transform) function from the OpenCV library. It locates key points on the both pictures and then compare them looking for similarities. It was tested for the available pictures of this test. However, the overlapping area was too small, with too large distortion and change in perspective, as shown in Figure 22. As a result, it was not possible to successfully apply it.

If enough trustable key points could be identified, the RANSAC (RANdom SAmple Consensus) algorithm could be applied to find a transformation (homography) that deforms continuously the first picture so that all its key points match those of the second picture.

This transformation process can also be applied to the second step to align and scale the pictures. However, only key points independent of the frame, i.e. which coordinates does not change over time, should be selected.

5.3.2 Step four: location and rotation

In the current procedure, the coordinates of the template mark are given in pixel, limiting the available precision. To improve this step, after the mark is located, a colour decomposition could be done to isolate the mark and identify its centre.

In this particular case of the presented testing, the mark is composed of blue, white and black. But, due to the lighting environment, white is sometimes considered as grey, and the blue/black mix is assimilated to violet in certain cases. Therefore, those two colours are also included in the allowed colour set for the mark isolation process. On the contrary, the wood colour is close to the yellow and red, and therefore, those two colours should be removed. The mark is obtained by adding the elements from the allowed colour set and subtracting the yellow and the red. A thresholding process is used to obtain a binary representation of the picture with the pixels of the mark in white and the other pixels in black, as shown in Figure 23. Then the "findContours" function from the OpenCV library is applied to identify the mark outer shape and estimate its centre with better precision. The mark is approximated by an ellipse, so that the length difference of the major and minor axis and their rotation angle can also be used to reduce distortion.

In addition, this method can also be used to locate accurately the straight lines of the mark and identify directly its rotation angle. The procedure should be faster, but resolution is likely to be worsen. An appropriate choice is needed according to the application.

5.3.3 Distortion

In the end, the most important improvement should be to add an algorithm to reduce or cancel the distortion from the lens and perspective, so that the proportions, parallel lines, and perpendicular lines are preserved.

Calibration of the camera using chessboard could be done along with other calibration depending on the layout of the testing setup.

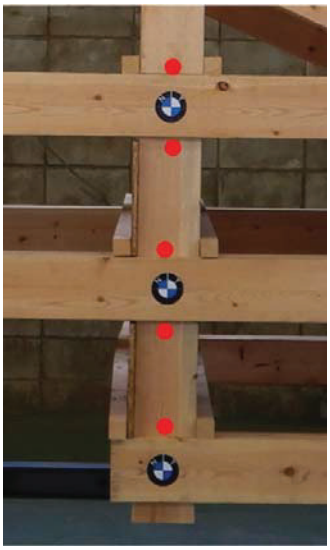

Figure 21: Example of additional marks to estimate inner layer displacement. Rotation is not required, therefore simple mark is enough.

Figure 22: Key points comparison for left and right picture

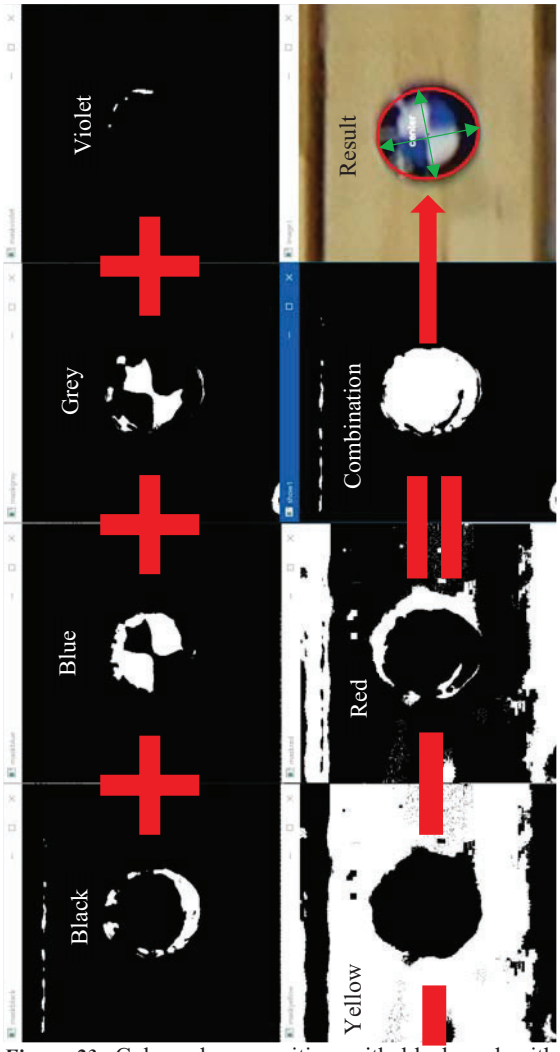

Figure 23: Colour decomposition with black and with thresholding followed by a combination to isolate the mark contour and identify its centre

6 CONCLUSIONS

In conclusion, the proposed method of using image processing and analysis techniques for measuring the deformation of timber structures has shown promising results.

However, there are limitations and improvement points that need to be addressed to increase the accuracy and reliability of the method. These include optimizing the testing setup, improving the stitching and aligning of the images, and reducing distortion from the lens and perspective. By addressing these issues, the proposed method has the potential to provide a cost-effective, non-destructive and precise means of measuring the deformation, stress of timber structures among other, which can have important applications in the field of civil engineering and architecture.

Further research and development in this area can lead to more accurate and efficient methods for monitoring the structural integrity of timber buildings and bridges, ultimately contributing to safer and more sustainable infrastructure.

World Conference on Timber Engineering Oslo 2023

A MOISTURE MANAGEMENT STRATEGY FOR CLT USING SENSOR TECHNOLOGY TO CREATE A ROBUST NORWEGIAN SCHOOL

Laura Vestergaard Kellgren[1], Astrid Charlotte Seeberg [2], David Hagle[3], John Øvregård[4], Jeppe Rasmussen [5]

ABSTRACT:

To monitor the use of cross-laminated timber (CLT) and how it is affected by moisture in the construction phase, Woodsense has incorporated sensor technology in the moisture management strategy and construction of the Sophie Radich school in Lillestrøm. The use of sensor technology supports several aims of the BREEAM-NOR manual, which seeks to increase the use of sustainable building materials and improve robustness to moisture damages. With a preventive approach in moisture management in the construction phase, it is possible to reduce resource waste, as damages can be found earlier in the process and before the building is put into use. After having used sensors on the Sophie Radich project, increased moisture levels were detected. The preventive approach made it possible to correct the cause of moisture increase, avoiding further damage to the construction while illustrating the advantages of sensor technology.

KEYWORDS: CLT, moisture management, sensor technology, sustainable building materials, BREEAM-NOR,

1 INTRODUCTION

More sustainable construction calls for solutions that reduce resource consumption and CO_2 emissions through an increased use of sustainable building materials such as timber. This is also emphasized in the new BREEAM-NOR manual V.60 [1] in issue MAT 01 – *sustainable material choices – LCA and climate gas calculation*s where points are given for using sustainable materials with low carbon emission. Although timber is a more climate friendly material than conventional structural materials such as concrete and steel, there are concerns with using it in construction due to challenges associated with moisture protection and management.

Some of the main barriers preventing the use of timber as a building material is the risk of moisture damage and as a result, a waste of resources. To document the moisture management of the Sophie Radich project - a Norwegian school constructed with cross laminated timber (CLT) - an intelligent sensor solution by Woodsense has been incorporated into the project. Through constant monitoring and automatic alarms, the sensors assist in carrying out an effective moisture content strategy with documentation of correct moisture management throughout the entire construction process.

The sensors are effectively used to, for example, document that there is no excessive moisture in the elements, and share said data between construction actors in the project. Additionally, the sensors contribute to the reduction of resource waste and a responsible use of building materials. This complies with the aim of issue MAT 05 *Robust and climate adapted buildings.* By preventively monitoring the growth of mold, the sensors also promote a healthy indoor climate to benefit the health and well-being of the building's users.

1.1 MOISTURE DAMAGES

Moisture is the leading cause of damage in construction, accounting for 71% of all damages from a study of 175 defect cases [2]. Of these damages, 69% occur within the first five years of a new construction project. In addition to causing damage, changes in wood moisture content can also impact the load bearing capacity and the tightening power of fastenings and screws, as studies show a reduction of WMC of 3-4% around threaded rods can lead to critical stresses leading to moisture induced cracks [3].

https://doi.org/10.52202/069179-0503

The study between 2017-2020 shows that unventilated compact roofs and terraces (on concrete floors) are the most common building component exposed to damages mainly caused by precipitation. The study shows that around 80% of the defects on terraces are linked to penetration of precipitation, where leakages in the roof membrane and insufficient connections around terrace doors are recurring reasons for defects.
As climate changes cause more and more intense rainfall in short periods. Even with well designed building details and well done craftsmanship the risk of mistakes will always be applicable.
Measuring water content in building components before closing is well known. Disadvantage is that if small mistakes are done, the small mistakes can cause major damages. Sensor technology used during construction phase can discover the small mistakes before causing major damages.

1.2 MONITORING FOR CRUCIAL AREAS

Norwegian building regulations (Plan og bygningsloven and Byggteknisk forskrift) are familiar with timber constructions. Product and building components must be dry enough when installing and sealing that there is no risk of fungus, decomposition of organic materials or increased degassing.

Drying material takes time, especially components applied to one-sided drying, like sills in timber constructions. The moisture content must be measured in order to document that the required moisture content is met.

Pre-accepted moisture content to avoid fungal growth on timber is 20 weight percentage moisture. Building components with a low capacity for drying out the moisture content must be lower than 15 weight percentage moisture before closing the building component.

Risk strategies prepared according to MAT 05 *Robust and climate adapted buildings* should identify and propose risk reducing measures for parts of the building that are exposed for degradation as a result of the current and future climate. The risk strategy should also uncover risks of moisture damages caused by build in moisture during the construction phase.

The design phase should choose building materials and structural principles that are common. Roof constructions and access for maintenance are essential.
Norwegian Standard NS 3514:2020 *Moisture safe construction - Planning and execution* is meant to be a tool for the construction industry to prevent moisture-related incidents during the construction phase and create awareness about moisture-proof construction [4]. The standard shows guidelines and procedures related to moisture safe construction and reference to NS 3512 *Measurement of moisture in timber structures* [5].

1.3 DETAILS EXPOSED TO MOISTURE DAMAGES

Some construction principles can be risky to build. The figure below shows building details that above mentioned studies show that are exposed to moisture damages.

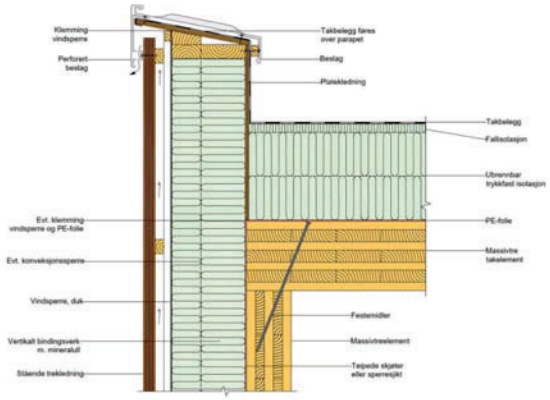

***Figure 1**: Principal detail parapet at unventilated compact roof and CLT-Element [6]*

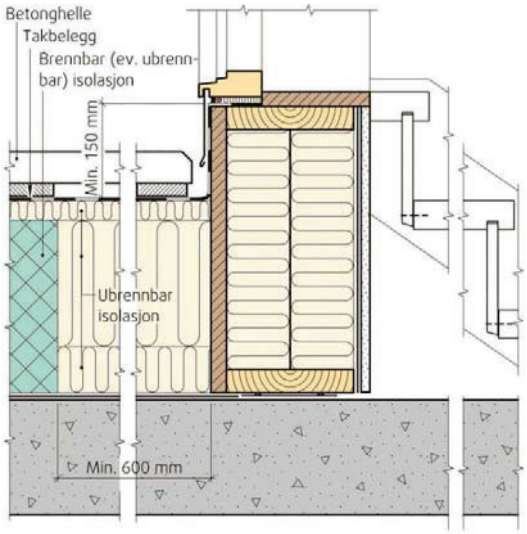

***Figure 2:** [7] Terrace door to unventilated compact roof.*

Overlight windows are often placed during the roofing. The construction on the inside is open and affected by large amounts of building moisture from for example concrete work and straightening of floors.

https://doi.org/10.52202/069179-0503

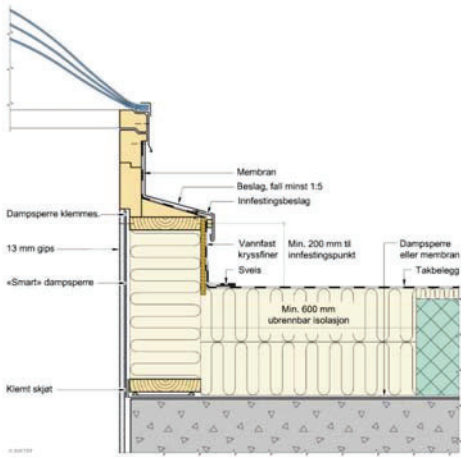

***Figure 3**: [8] Overlight in unventilated compact roof.*

These are examples of building components that are well known details and common to build and still risky for moisture damages.

2. SOPHIE RADICH PROJECT AND MOISTURE MANAGEMENT STRATEGY

Sophie Radich ungdomsskole in Lillestrøm is a Secondary school with a total area of approximately 130000 m2 and space for 720 students. The project has been developed in collaboration with contractor Kruse Smith and Lillestrøm municipality. Arkitema is involved as architect and landscape architect. The building is a CLT construction and has a very high environmental ambition with a blue-green focus. The school has a distinctive footprint shaped like a four-leaf clover. With a strong focus on the surrounding nature, students will experience an interaction between the indoor and outdoor environment.

Timber has been chosen as part of the main construction for the entire building, primarily from an environmental point of view. However, the choice is also based on the theory that the use of wood has a positive impact on physical and mental health [9]. Findings from another study regarding the use of wood in buildings show a significant decrease of systolic and diastolic blood pressure [10]. This is, in addition to an aesthetic consideration, the reason for choosing visible wood in the building's interior.

2.1 THE MOISTURE MANAGEMENT STRATEGY

The Norwegian climate posed a challenge during the construction process, as rain, moisture, ice formation and snow can cause major problems.
Using a tent during construction was considered, but this would mean additional costs which is a disadvantage compared to traditional construction methods. It was therefore decided not to cover the building during the construction period. It was expected that repair of any damage would be less than the cost of a tent / superstructure. Unfortunately, the autumn of 2021 was particularly rainy and windy, and there was some concern related to moisture, especially on the roof. An agreement was therefore made with Woodsense, to uncover any leaks and moisture problems.

3. USE OF SENSOR TECHNOLOGY TO AVOID DAMAGES CAUSED BY MOISTURE

When working with timber in construction, one of the main issues is related to moisture damage. The sensor solution by Woodsense seeks to address that issue by measuring wood moisture, temperature and humidity, and comparing the data with local weather data. By analysing the collected data, it is possible to detect leaks and conditions that can lead to mould and rotting of the wood. Through constant monitoring, moisture damage can be prevented, thus reducing resource waste. The embodied CO2 emissions associated with a moderate defect in terms of disposing of materials and replacing with new materials amounts to 572.32 Total GWP [kg CO2eq] equivalent to 2% of the entire buildings embodied carbon emissions [3].

***Figure 4**: Sensor that monitors wood moisture content, temperature and humidity from Woodsense.*

This strategy complies with the aim of issue MAT 05 *Robust and climate adapted buildings* which focuses on the reduction of the need to repair or replace damaged materials. It can also be part of the risk analysis which is needed to get the score in part 2 of MAT 05 – *Protect exposed parts of building against damage.*

https://doi.org/10.52202/069179-0503

Figure 5: *Blueprint from the 3rd floor. Sensor placement on this floor in wet rooms close to the concrete floor to detect leakages, on the balcony under a pavilion to ensure water doesn't get in and under a window to test window is tight during construction,*

Figure 6: *Sensor under window. © Kruse Smith*

The digital platform of the sensors has integrated the so-called mould curves, derived from mathematical models from research in the field. These are used, among other things, to visualise the environment of a given sensor and determine the risk of mould growth. By preventively monitoring the growth of mould, the sensors promote a healthy indoor climate to benefit the health and well-being of the building's users.

Sensors were placed on various locations in the main construction to monitor particularly exposed areas, detect critical moisture levels before damage could occur and document moisture management throughout the construction.

3.1 IMPORTANT DATA TO MEASURE CRITICAL FOR A HEALTHY BUILDING

According to *Sintef Byggforskserien 421.132 Fukt i bygninger. Teorigrunnlag.* To avoid moisture damage and other moisture-related problems during construction a critical moisture level is used as a limit to determine whether a material is dry enough to proceed in the construction process. Critical moisture level is usually given with the designation RH. Absolute moisture content is usually used for wood materials (Wood Moisture Content).
When RH in the surroundings is more than 80% and temperature above 0°C in some time, risk of mold growth can appear. Spruce and pine will have a WMC around 16-18%, when the RH in the surroundings are around 80%.
With well documented design phases and procedures to prevent moisture related damages there will always be some risks of moisture damages.
Due to tight schedules and time between planning and execution, drying of materials can be challenging.
Sintef byggforskserien 474.533 Uttørking og forebygging av byggfukt a sill as example for drying is made. For a sill 25 mm with natural one-sided drying from 28 to 18 weight percentage moisture in a building with 20°C and RH 60%. The drying time is estimated to be 21 days.

Developers have expressed their satisfaction when working with the sensors and digital platform, due to the ability to constantly monitor the moisture level. This leads to a higher sense of control with the moisture content of the construction materials.

4. CONTINUOUS ANALYSIS OF INCOMING DATA TO DETECT DAMAGES

4.1 WMC LEVELS IN DIFFERENT CONSTRUCTION PHASES

There are general thresholds of WMC values that are accepted in timber structures. These values vary based on whether the timber structures are exposed during construction or if they are enclosed and the building is in its maintenance period. Also, what measurements that are critical depends on the season and the local climate.

4.2 DURING CONSTRUCTION

The WMC can vary a lot during construction if the building is exposed to rain. Experts suggest that pools of water gets removed daily and that CLT shouldn't be above 20% for extended periods of time.
Many vendors of CLT put requirements for CLT to be enclosed at WMC levels below 12% to ensure no moisture is built in.

4.3 MAINTENANCE

In areas with high relative humidity, such as bathrooms and kitchens, the WMC of CLT elements should be kept below 20%. In other interior spaces with moderate humidity, such as living rooms and bedrooms, the WMC of CLT elements should be kept below 18%. In exterior wall and roof elements, the WMC should be kept below 16% to minimise the risk of decay due to exposure to the elements.

It is important to note that the WMC of timber can vary based on the ambient humidity and temperature conditions. In general, the WMC of timber will increase in humid environments and decrease in dry environments. This means that the WMC of timber may be higher in the summer months when relative humidity is typically higher, and lower in the winter months when relative humidity is typically lower.

Hence it is necessary to use an alarm system that takes into account all these parameters before it is possible to detect damages automatically without human supervision.

4.4 ANOMALY ALGORITHMS FOR DAMAGE DETECTION

Anomaly algorithms with multiple parameters have proven efficient to detect outliers in general data, but haven't been used before to detect damages in timber.

Anomaly algorithms work by forecasting a predicted value based on multiple parameters. On the Sophie Radich school Wood Moisture Content, Relative

https://doi.org/10.52202/069179-0503

Humidity, Temperature and local weather data were taken into account.

Table 1: *Ongoing measurements every 4 hours*

Measurement	**Location**
Wood Moisture Content (WMC)	In 20mm depth
Relative Humidity (RH)	From sensor at timber surface
Temperature	From sensor at timber surface
Precipitation, snow, outdoor humidity & outdoor temperature	From local weather station integrated into platform

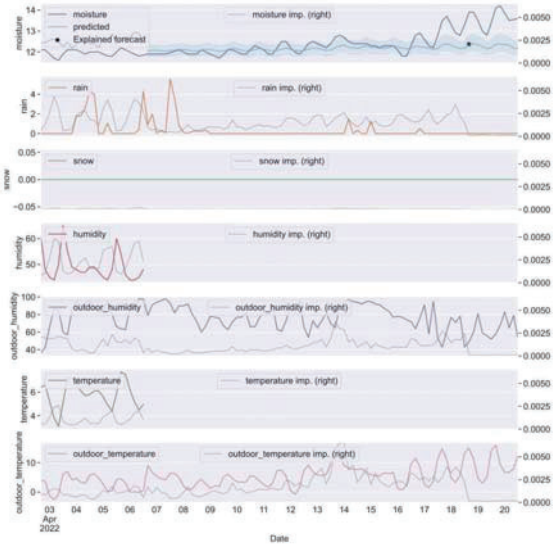

Figure 7: *Predicted value and the importance of supporting parameters in the prediction of that value.*

This result, when also taking into account the placement of the sensor, gives a strong indication when a sensor hits critical levels.

According to data from Woodsense, the WMC of CLT in roofs is the highest with a median value of 13.6 over an entire year, followed by slabs at 11.8 and external walls with 11.4.

4.5 TYPES OF ALARMS

In one of the selected areas, sensors were placed towards the edge of the roof, under rooflights, and on different facades to monitor the difference in north-, south-, east-, or west-facing facades. Additionally, a sensor was placed on a cornice to monitor the cover towards the edge. Here, the sensor found a mistake made by the roofer, as the covering had not been completed. This had resulted in water entering the construction and moisture levels rising to more than 30 %.

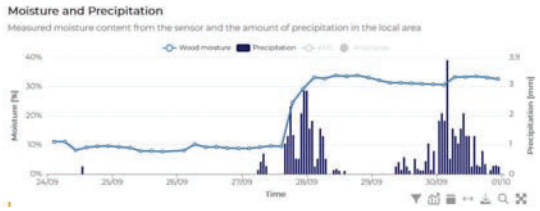

Figure 8*: Showing a rapid increase in WMC immediately after heavy precipitation.*

Had the sensor not detected the damage in the cornice, it could have led to a substantially more expensive repair, as the moisture could have been trapped in the construction for several months, potentially causing mould to establish. The same happened on a balcony where a temporary cover had been installed to protect the balcony from water damage. A sensor was installed beneath to monitor if the cover was efficient, but after just weeks of installation was the first water ingress found. This led to an immediate action to remove the water, dry the timber and improve the cover.
This exemplifies the advantages of sensor-based technology, as it is possible to capture situations such as these immediately.

Another sensor also detected a rise in wood moisture content, but a slower one over a 3 day period with ongoing rain. It is only normal to expect such an increase in WMC in the bottom of a facade element during construction when the building hasn't been enclosed, hence this did not trigger an alarm, but only led to a notification to the contractor.

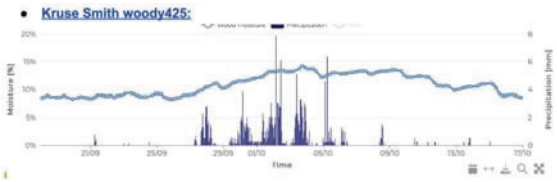

Figure 9**:** Showing the incremental moistening of a CLT slab due to continuous rain and increase in humidity, but not a leakage.

5. CONCLUSIONS

Using the sensor solution, several increases in moisture level were detected, which could have developed into more extensive moisture damage. The critical moisture levels found by the sensors exemplifies the advantages of sensor technology, as it is possible to immediately identify situations that can be damaging to the construction. Furthermore, developers and other participants of the project expressed their satisfaction with the product due to a higher sense of moisture control. Going forward, several sensors will remain on the roof to ensure that the green roof laid on top lasts as expected, and that the drains likewise work as intended.

https://doi.org/10.52202/069179-0503

Sensor technology can be used in most of the different building components. And the use of sensor technology should be more common in the future. To reduce the number of damages on terraces and similar components.

Further research can be done to investigate how different coating on the interior side of CLT, for example fire painting, affect the moisture storage in wood-based materials and the indoor climate. This can be done by using Woodsense sensor technology.

PRINTED SENSORS FOR MONITORING WOOD MOISTURE CONTENT INSIDE TIMBER BUILDING ELEMENTS

Boris Forsthuber[1], Michael Truskaller[2], Irene Spitaler[3], Pavel Kulha[4], Maximilian Scherf[5], Gabriel Partl[6], Albert Rössler[7], Gerhard Engelbrecht[8], Gerhard Grüll[9]

ABSTRACT: Moisture accumulation in wood constructions can lead to severe damage and premature construction failure. This is especially problematic for covered areas such as wet rooms (e.g. cross laminated timber (CLT) ceilings and covered dry walls), where moisture accumulation can occur without being noticed for a long time. The current paper describes the development and application of novel printed moisture sensors, that can be integrated directly into wooden construction elements, such as CLT or Glulam. This allows continuous *in-situ* monitoring of wood moisture content. A special wood primer was developed for the inkjet-printing process that is required to obtain high printing resolution and efficiency. The optimal sensor geometry on wood for highest measurement sensitivity was found by systematic variation of geometric details of the sensors and measuring conductance and impedance during a climate trial. The relative humidity was gradually increased while keeping the temperature constant within the chamber. After each step of moisture increase, impedance, phase angle and deduced variables at different voltages, currents and frequencies were measured. Furthermore, a proprietary measurement system was used. With the novel printed moisture sensors, it was possible to reliably monitor accumulation of moisture within CLT elements.

KEYWORDS: printed moisture sensor, moisture sensing, timber building, impedance measurements, capacitive moisture measurements

1 INTRODUCTION

Moisture accumulation can have severe consequences in wooden constructions. Short periods with higher moisture contents can be considered unproblematical, since wood destroying fungi need a wood moisture content at or above fiber saturation point (FSP) over longer time periods to grow. On the other hand, if the time of wetness is limited, the durability of the construction is usually not negatively affected [1]. It is therefore crucial to detect moisture entry into the construction as quickly as possible. According to Ott & Aondio [2], the design details of buildings play an important role here. For example, water penetration into a cross laminated timber ceiling is detected much later than on a beam ceiling. If drying of the wooden elements is restricted, moisture accumulation will enable fungal growth, leading to severe damage and premature construction failure. This is especially problematic for areas that are at least partially covered, such as CLT elements in wet rooms behind a dry wall.

Moisture accumulation can occur without detection for many years. When finally detected, costly renovation is inevitable. For that purpose, standards such as the ÖNORM B 2320 [3] require either at least two layers of bituminous sheeting with 8 mm thickness or an inspection port. Both can be avoided, if a moisture monitoring system is installed.

Several methods for measuring wood moisture content are available. While the gravimetric method gives by far the most accurate results, moisture monitoring on wood constructions is not possible as it is a destructive method. According to Dietsch et al. [4] requirements of a moisture monitoring system are as follows:

- The measurements must be taken without damaging the structure or taking samples
- The accuracy of the method should be consistent
- The system must be mountable on the structure itself
- Digital logging of the measurement results on different spots must be possible

- The timber moisture content should be measured and recorded in equal time intervals (e.g. one hour)

Generally, wood moisture content strongly affects the electrical properties of wood below the fibre saturation point [5]. Extractives which are not soluble in water are expected to decrease conductivity while the opposite is true for water soluble extractives [5,6].

The electrical resistance method fulfils all the requirements of a moisture monitoring system and is therefore available in many commercial systems [4]. However, electrodes must be placed inside the wood and is therefore destructive to a certain extent. Furthermore, the moisture measurements are locally restricted, as the moisture content is measured just between the two electrodes.

Aside from electrical resistance, capacitive moisture measurements of wood are also possible. Additionally, they do not need electrodes inside the wood and are therefore completely non-destructive. Measurements are taking place on the surface and an average wood moisture content near the surface (<35 mm) is measured [4]. Capacitive moisture measurements use the property that the dielectric constant of the wet wood increases with increasing moisture content, as the permittivity of water is higher than that of dry wood [7]. Since the relative permittivity of water ($\varepsilon_r \sim 80$) is many times higher than oven dry wood ($\varepsilon_r \sim 1.4$-4), capacitive techniques are well-suited for moisture measurements [7, 9]. Grain orientation is known to affect the dielectric properties of wood, where the complex dielectric constants are 20% to 50% higher in longitudinal direction compared to the direction perpendicular to the grain [7]. The dielectric constant of wood increases with increasing wood density [9]. Additionally, the dialectical properties of wood are affected by temperature and AC frequency [5, 10]. The higher the AC frequency of the measurement signal, the lower the dielectric constant [10]. However, it has to be noted, that the lower practical limit for most electrical meters is of the order of 6-8% and the highest limit is about 25% to 30% [11]. A low-cost capacitance sensor for wood moisture content was developed by Korkua and Sakphrom [12].

Another electrical method i.a. for wood moisture content is the measurement of the electrical impedance (Z). The impedance can be represented as a complex quantity with the resistance as real part and the (capacitive and inductive) reactance as imaginary part [6]. Since the impedance can be measured at several frequencies, this method is often described in the literature as electrical impedance spectroscopy (EIS) [6]. Impedance measurement was successfully used for evaluating the moisture content of sugi logs to monitor the drying process [13]. EIS was also used to determine wood decay [14].

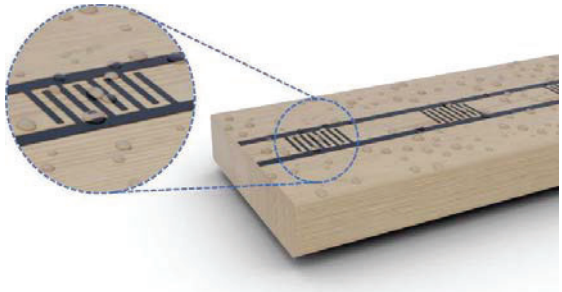

Figure 1: *Schematic of moisture sensors printed onto wood.*

The aim of the current study was the development of novel printed moisture sensors on wood. These sensors would allow *in-situ* monitoring of the moisture dynamics within construction elements such as CLT during use. In contrast to the resistance method, the printed sensors allow extensive area moisture monitoring, using an interdigitated electrode design (Figure 1). In terms of printing technology, digital inkjet printing offers many advantages over other printing techniques such as high throughput and flexibility of the printing pattern. Alternatively, screen printing was also investigated as a possible printing technique. In each case, carbon-based inks were used in order to not impose a problem for the recycling process after use of the construction elements.

2 MATERIAL AND METHODS

2.1 MATERIALS

For all printing trials, wood blocks measuring 150 mm x 75 x mm x 20 mm from Norway Spruce (*Picea abies, L.*), free from knots and with growth ring orientation of 5-45° (quarter-sawn) were used. All samples were planed and conditioned for at least one month in a climate room at 23°C and 50% RH to constant weight. Equilibrium wood moisture content was therefore at app. 9%.

For the inkjet printing process, a carbon-based Sicrys™ RI-6DM-3 ink with low viscosity (~3-5 cP) was used. For the dispensing and screen printing trials, a carbon-based Ink SE1502 from ACI materials with high viscosity was used. Screen printing was conducted using a commercial screen with mesh size 90T.

Two wood primers as pre-treatment for inkjet printing were investigated. The first primer was based on a highly viscous UV-curable putty "UV putty" for roller application. This variant was used with or without intermediate sanding. The second primer was based on a waterborne acrylic wood coating.

Wood primers were applied either by roller application (UV putty) or by spraying (water-borne coating). No primer was used for screen printing.

https://doi.org/10.52202/069179-0504

2.2 METHODS

For preliminary trials to obtain an optimal printing pattern, a dispensing printing process was used. The dispensing device was developed by Profactor GmbH and essentially consist of a motorized maneuverable platform with a controllable syringe head.
Inkjet printing was performed using a Süss LP50 printer with a KM512 print head from Konika Minolta. The cartridge temperature and the nozzle temperature were kept at room temperature.
Screen printing was performed manually without primer. Sintering for all samples was done at 120°C for 30 min in an oven.
Climate chamber tests were performed in a climate chamber SK40420 of Simtech (AT). The climates and corresponding equilibrium wood moisture contents are shown in Table 1. Each climate was kept constant, until the wood samples reached equilibrium. This was usually the case after 3 weeks. The samples were weighed at regular intervals, until the difference in mass was below a 0.3 g threshold, which was considered stable. After the end of the climate chamber tests, the samples were measured and weighted.

Table 1: *Climate settings and corresponding equilibrium wood moisture content (EMC) during the climate chamber test.*

Relative Humidity	Temperature	Corresponding EMC
50%	23°C	~9 %
71%	23°C	~13%
85%	23°C	~18%
93%	23°C	~22%
98%	23°C	~25%

Impedance and phase angle at different voltages, currents and frequencies were measured during the climate chamber test with an LCR measurement bridge, HM8118 from Rohde&Schwarz. For estimating the optimal printing pattern for maximizing sensitivity of the printed moisture sensors towards moisture uptake, a base pattern of interdigitated electrodes was varied systematically. The width, length and number of the strips were varied and regressed against the actual wood moisture content during the climate test. For the main tests, the optimized geometry was used and only the thickness of the ink-layer and the growth ring orientation were varied. Three samples for each variant were used.

3 RESULTS AND DISCUSSION

3.1 DEVELOPMENT OF INKJET-PRINTING PROCESS ON WOOD

For inkjet printing, inks with very low viscosity are required. Consequently, direct inkjet-printing on wood is not optimal, as a lot of ink is soaked into the wood. This significantly reduces efficiency, as the ink inside the wood hardly improves conductivity. Furthermore, the printing resolution is affected, as the ink gets transported, preferentially along the fibre direction, thus blurring the printing pattern. Therefore, several primers were investigated as suitable pre-treatment for the subsequent inkjet printing. Some of the pre-treatments were air drying while other systems were UV-curing.

Microscopic analysis revealed that the UV-primer with and without intermediate sanding led to interdiffusion of carbon ink particles into the coating which was reducing the conductivity (Figure 2). Better results were achieved with a water-borne primer where no visible interdiffusion occurred.

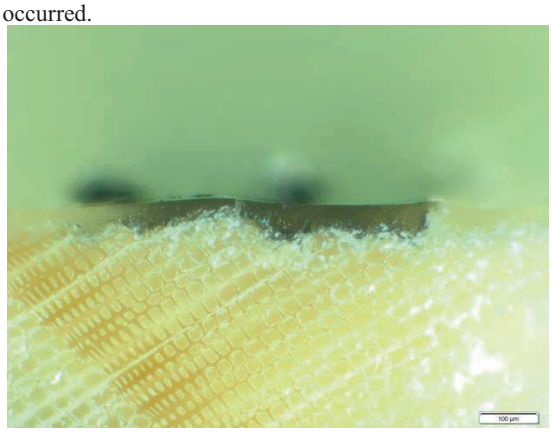

Figure 2: *Result of inkjet printing process on wood with UV-putty as primer; interdiffusion of ink into the coating. Cross section of spruce wood with clear primer and black printing under the microscope.*

The final results of the inkjet printing process, using the water-borne primer, revealed an interdigitated sensor pattern with very high resolution and sharp edges (Figure 3). The main advantage of the inkjet-printing process compared to other printing technologies is its high versatility and adaptivity. Hence, the printing pattern can be adjusted almost instantly and could be fine-tuned for optimal printing on the substrate almost in real-time. The downside of the inkjet process is the need for a primer, which inhibits direct contact between wood and printed sensors. This would be a major drawback for resistive sensors but not for capacitive sensors, as the primer can be seen as just another dielectric layer.

Figure 3: *Result of Inkjet printing process on wood with water-borne acrylic primer*

An alternative method used in this study is screen printing. Due to the higher viscosity of the screen printing ink, there is no need for a primer. This has the main advantage that the ink is in direct contact with the wood substrate, thus being able to measure the moisture directly without any layer in between. The printing quality of the printed electrodes is lower than those printed via inkjet (Figure 4), but still suitable for this purpose. The sharpness of the edges depends on the meshsize of the screen. Finer meshes (e.g. 90T or even 120T with 50µm/45µm mesh opening) allows printing of much finer details. However, the thickness of the ink-layers gets reduced, thus limiting the bulk conductivity. Nevertheless, the conductivity of the prints with meshsize 90T was still good enough for the intended purpose while the printing quality was high.

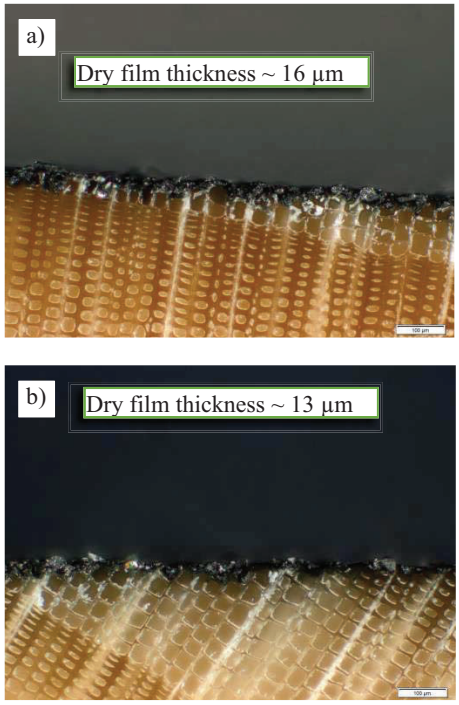

Figure 4: *Influence of screen printing meshsize on the dry film thickness of ink on wood; a) meshsize 43T; b) meshsize 90T.*

All inks needed sintering at elevated temperatures (120°C for 30 mins). Thus, wood moisture content had to be low (around 9%) before sintering to avoid cracking during the process. A systematic variation of the sintering times and temperatures revealed higher conductivity with higher sintering temperatures. Lower temperatures (100°C) for longer periods did not lead to the same conductivity.

3.2 OPTIMIZATION OF SENSOR GEOMETRY

The optimal sensor geometry for measuring the moisture content of wood was determined by a systematic variation of the sensor pattern from a base pattern of interdigitated electrodes. In this test, the number of electrode fingers, the distance between the fingers but also the thickness of the electrode fingers itself were varied systematically. During a test in the climate chamber, the response in terms of impedance and phase angle with increasing wood moisture content was measured.

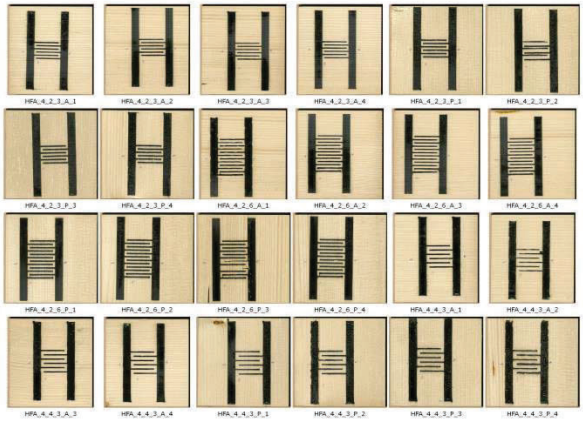

Figure 5: *Result of inkjet printing process on wood with UV-putty as primer; interdiffusion of ink into the coating. Cross section of spruce wood with clear primer and black printing under the microscope.*

The highest correlation of the measured impedance and phase angle to the actual wood moisture content was achieved with the pattern shown in Figure 6). The results revealed that the best correlation of the measured impedance with the increasing wood moisture content was with the highest sensor surface area and with the greatest number of interdigit probes.

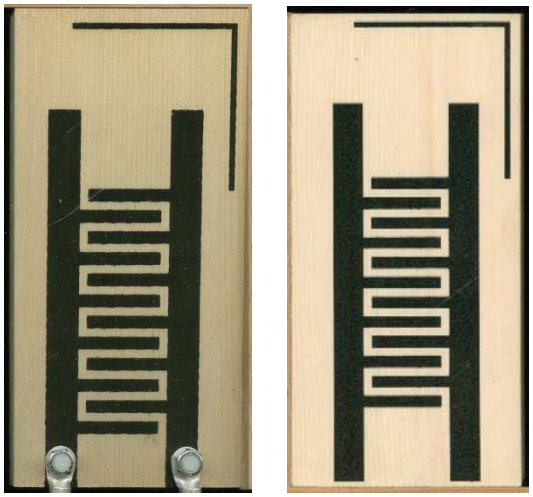

Figure 6: *Left: Screen printed moisture sensor: Right inkjet-printed moisture sensor. The optimal pattern was obtained from measurements during a climate test.*

https://doi.org/10.52202/069179-0504

3.3 CORRELATION BETWEEN ELECTRICAL SIGNALS AND WOOD MOISTURE CONTENT

For determining the relationship between the measured impedance and phase angle as well as derived values (e.g. capacity) with the wood moisture content, samples with the optimized sensor geometry were again subjected to tests in a climate chamber. Again, the moisture content within the chamber was increased gradually, until the equilibrium wood moisture content was reached. During this trial, the impedance and phase angle of the printed sensors were measured with different AC frequencies.

It was observed that the phase angle was frequency dependent and lower phase angles were seen with higher frequencies (Figure 7). This indicates lower capacitive reactance with lower frequencies compared to higher frequencies. This was expected, as the capacitive reactance decreases with increasing frequency and with increasing capacitance.

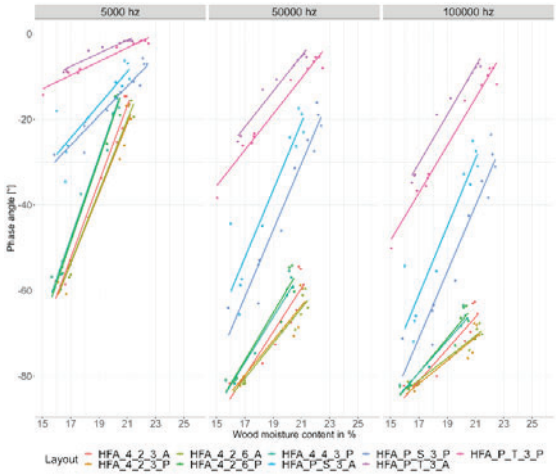

Figure 7: Phase angle vs. wood moisture content at different AC frequencies during a climate chamber test

In Figure 8, the impedance as function of the wood moisture content at different AC frequencies is shown. Generally, a strong correlation of the measured impedance with the wood moisture content was observed. Again, a clear influence of the measurement frequency was seen. The results revealed the highest regression coefficient/steepest slopes of the regression line with lower frequencies, e.g. 5000 Hz.

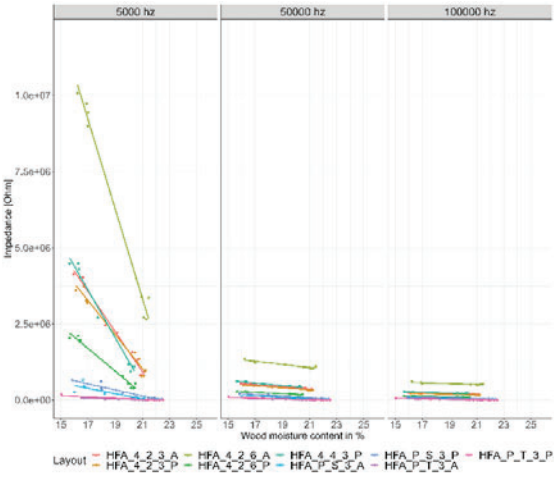

Figure 8: Impedance vs. wood moisture content at different frequencies during a climate chamber test

In figure 9, the influence of the voltage on the impedance for different wood moisture contents is shown. It is evident that the voltage does not seem to have a significant effect on the measurement result. Hence, the voltage was kept the same in later trials.

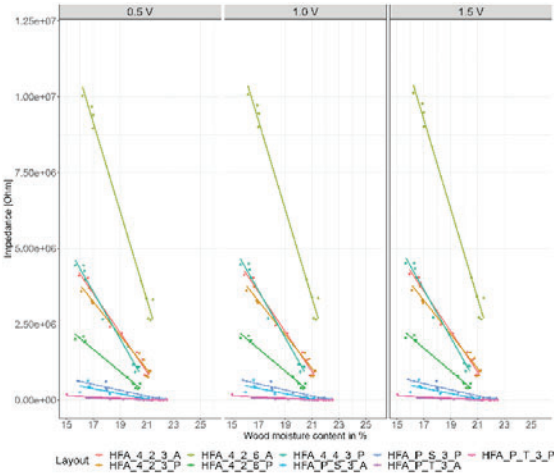

Figure 9 Impedance at different voltage levels vs. wood moisture content during a climate chamber test

The results reveal that the measured impedance at a frequency of 5000 Hz and a voltage of 1 V predicts the wood moisture content, with $R^2 = 0.94$, $F(1, 1155) = 2.03*10^4$, $p < 2.2*10^{-16}$.

It can be stated that the wood moisture can be monitored accurately with the printed moisture sensors. Since all the criteria mentioned by Dietsch et al. [4] for moisture monitoring systems are met, the developed method is highly suitable for monitoring the wood moisture content in timber constructions.

https://doi.org/10.52202/069179-0504

4 CONCLUSIONS

Two printing methods for conductive paths on wood were developed. Inkjet printing gave better printing quality but required a waterborne acrylic primer to achieve the desired printing quality. Screen printing was possible without primer and is therefore in direct contact with the wood surface.

The optimal printing pattern with highest sensitivity towards moisture accumulation during a climate chamber test was found. From the AC frequencies measured in these tests, a frequency of 5000 Hz showed the highest regression coefficients for predicting wood moisture content. As all requirements of a moisture monitoring systems are met, the developed method based on printed moisture sensors is highly suitable for monitoring the wood moisture content in timber constructions.

ACKNOWLEDGEMENT

The results presented in this paper are part of the research project ‘‘Mindwood’’. Financial support by the Austrian Research Promotion Agency (FFG) as well as companies and associations of the wood and coating industries is gratefully acknowledged.

MOISTURE AND TIGHTNESS MONITORING WITH DIFFERENT MEASURING SYSTEMS AND METHODS - EXAMPLE APARTMENT BUILDING

Anton Kraler[1], Andreas Pomaroli[2]

ABSTRACT: Moisture monitoring is becoming an increasingly relevant technique to ensure that buildings remain in good quality. Building with wood, whether it is for family homes or mid-rise buildings, is more popular than ever. Rising prices, high-quality requirements and calls for swift construction completion are impacting contemporary modern architecture. These changes are far-reaching: after all, simple, straight structures offer enormous advantages in terms of systemisation, prefabrication and the mounting of buildings. Consequently, there has been a visible change from sloping roofs to flat roofs. In addition, even storey levels offer further advantages: compliance with distance regulations to neighbouring properties is facilitated. These areas can partly be used as terraces, gardens, and also for the installation of building service equipment (heat pumps, ventilation equipment, etc.). Concerning moisture issues, natural building materials must be handled with great care in order to ensure the durability of a building structure. Despite great craftsmanship in the construction of buildings, unforeseeable problems due to moisture penetration occur time and again. To counter such issues, a range of moisture and tightness monitoring systems have come onto the market in recent years. How do they work, which system is best suited for which monitoring purpose? Which dangers arise from installing additional structures? With the support of the Province of South Tyrol/Italy and the company Ligna Construct for this research project, it can be shown how important monitoring systems can be. The measurement results of the three installed monitoring systems show that already in the construction phase, but also in the later use phase, a high degree of safety is given with regard to moisture penetration and water ingress.

KEYWORDS: Moisture monitoring, area sensors, point sensors, wood moisture measurement, timber construction, flat roof, terraces

1 INTRODUCTION

Research institutions and companies have been working on the topic of moisture and tightness monitoring for years. The aim is to bring systems to the market for monitoring moisture and tightness in the sealing and insulation level, in addition to material moisture in order to increase moisture protection in wood buildings. In this research work, three quality-assuring active monitoring systems are presented, with which moisture-prone building components can be monitored. Components at risk of moisture penetration are e.g. roof and terrace sealings, insulation layers in warm roofs as well as the supporting wooden structures located under the sealing levels. Furthermore, measurement monitoring of water-bearing installations in floor and wall constructions is an important aspect. Active measurement monitoring involves monitoring with automated evaluation and alarming systems in case a defined threshold value is exceeded. Questions that arise in the context of leakage and material moisture monitoring are: How do active moisture monitoring systems work? Which systems are best suited for which monitoring tasks? Which risks arise from installing measuring systems? In order to provide answers to these and other questions, three active monitoring measurement systems were used in an apartment building. This research project, with a two-year time frame, was developed in cooperation with the timber construction company Ligna Construct from St. Pankraz in South Tyrol/Italy and with the financial support from the Province of Bolzano/Italy. The official research project ended in September 2022. The monitoring by means of the three measuring systems will be continued for the time being in order to obtain long-term data about the moisture behaviour in the specified areas.

2 PROJECT DESCRIPTION

The apartment building is a newly constructed three-storey building with five residential units, a garage in the basement and an adjacent existing single-storey building with a green roof. The two upper floors and parts of the floor slab on the ground floor were built in cross-laminated timber. Due to the multiple levels (flat roof, terraces, balcony, etc.) as well as changing materials (reinforced concrete, cross laminated timber, bitumen sheeting and plastic waterproofing) and the exposed location, this building is particularly well suited for

[1] Anton Kraler, University of Innsbruck – Unit for Timber Engineering, Austria, anton.kraler@uibk.ac.at
[2] Andreas Pomaroli, University of Innsbruck – Unit for Timber Engineering, Austria, andreas.pomaroli@uibk.ac.at

https://doi.org/10.52202/069179-0505

investigations of this kind. Planning and investigations began in September 2020.

Figure 1: *Investigated Apartment Building*

The first step is to determine which and how many measuring systems are to be used in and on the building. When determining the number of systems, special attention is paid to monitoring those areas of the building where there is a higher risk of moisture or water ingress. The number and types of measuring systems used are to be installed in such a way that leakage and moisture monitoring is provided for all flat or slightly sloping external surfaces such as roofs, terraces and greened areas. Furthermore, it is important that the measurement results of the installed monitoring systems can be compared with each other. The aim has been to obtain as many results and findings as possible for future timber buildings. In consultation with the timber construction company Ligna Construct, the following three moisture monitoring systems were used:

- Measurement of wood moisture content
- Measurement with area sensors
- Measurement with point sensors

Before installing the moisture and leakage monitoring systems, detailed installation plans are drawn up for all three measuring systems. They are discussed with the project partner on site and checked for completeness. All three measuring systems are equipped with a remote monitoring modem so that monitoring and reading data are accessible at any time.

2.1 MEASUREMENT OF WOOD MOISTURE CONTENT

The electrical resistance measuring method of the company Scanntronik Mugrauer GmbH is used to monitor wood moisture. Electrodes in the shape of stainless-steel screws of different lengths are mounted to measure the wood moisture distribution. The screw shaft is insulated with a shrink sleeve so that the moisture is only measured at the tip of the screw. This makes it possible to measure the wood moisture specifically at different depths of the wood. The distance between the electrodes is 30 mm. The measuring electrodes are connected to the material moisture meter with shielded coaxial cable, which may have a maximum length of 15 metres. Up to eight measuring points can be monitored with one device and, depending on the pre-setting, forwarded to a data logger and stored every second, minute or hour. Furthermore, it is possible to record the temperature (e.g. wood, air) and the relative humidity via a data logger in combination with a sensor unit. The measured values stored with the data logger can be received by e-mail. If there is a power connection to the measuring systems the data can be accessed via telephone. Otherwise a specified time interval is set and the data are sent via email. The output value of the wood moisture is provided in percent or in ohm. In addition, the temperature in the wood and the relative humidity in the interior of the building were recorded.

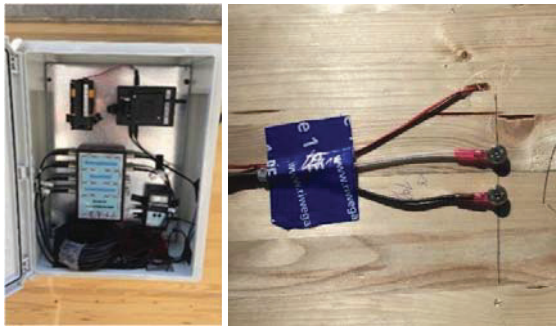

Figure 2: *The wood moisture measurement equipment, left data storage, transmission modem, right moisture sensors (below) and temperature sensor (above)*

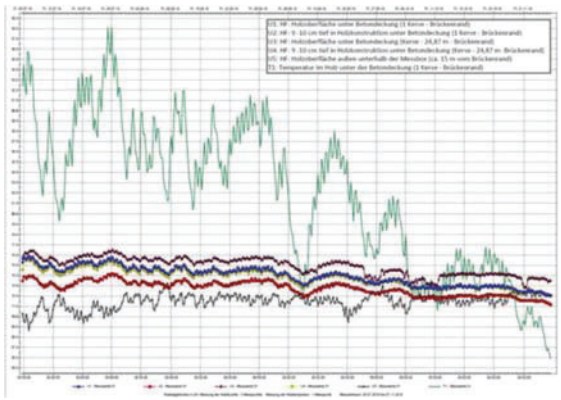

Figure 3: *Wood moisture data*

2.2 MEASUREMENT WITH AREA SENSORS

The Optidry® Monitoring System (OMS) is an active building monitoring and warning system for the early detection of hidden water damage. The area sensors are installed on the diffusion-inhibiting or vapour-blocking (warm roof) level as the flat roof covering is attached. Before installing the area sensors, the roof is divided into different zones (edges, main area, risky spots). Installation is straight forward and it depends on the waterproofing membrane used (bitumen, plastic, raw ceiling), whether the area sensors need to be glued or nailed. Up to eight

https://doi.org/10.52202/069179-0505

independent monitoring areas (area sensor units) can be connected via a bus system and the data saved in a control centre. If the specified upper humidity limit, gauged in digits, is exceeded, an alarm is triggered by the central unit and forwarded to the customer. The current moisture status at the sealing level can be accessed and evaluated directly on a smartphone, tablet or PC using the OMS Inspector app. Water ingress can thus be detected at an early stage and localised. In addition to flat roofs and terraces, the system is also used in wet rooms from service class W3. The Optidry Monitoring System can be integrated into smart-home systems or into the building technology equipment.

Figure 4: *Area sensor measurement*

The belt or area sensors are approx. 5 cm wide fabric strips containing two stainless steel wires. The moisture content in digits is determined via the resistance between the two wires.

Figure 5: *Area sensor measurement*

2.3 MEASUREMENT WITH POINT SENSORS

The system used, the RPM ROOF PROTECTOR, is a simple and efficient device to immediately detect moisture in roof structures and to take timely action. Indicators evenly laid out over the roof surface measure the moisture and temperature. This allows gaining insight into the moisture condition of a roof package (insulation package). The measuring system can be applied to all commercially available roof layers (waterproofing, insulation, etc.). The system also fulfils the additional measure required in ÖNORM B 3691 for the monitoring of flat roofs of use category 3. The recorded measurement data are stored on a central server of RPM Gebäude Monitoring GmbH and can be retrieved permanently and at any time via a web browser. The measuring sensor is located in the warm roof structure just above the sealing membrane (vapour barrier). In addition to measuring the humidity, which is indicated in digits, the temperature is also measured in the area of the vapour barrier and on the outside at the surface of the roof structure. The sensor is usually installed after the top waterproofing layer has been laid. The insulation material in the warm roof structure is drilled out with a so-called box drill, which has the same diameter as the point sensor, and the fully insulated point sensor is inserted there. The system used is battery-powered and is therefore self-sufficient and can be used wherever there is a radio contact for data transmission. The system measures the humidity and temperature in the insulation level and also on the sealing level of the raw ceiling.

Figure 6: *Point sensor measurement*

Figure 7: *Point sensor measurement*

3 INSTALLATION OF THE MEASURING SYSTEMS

The measuring systems are installed on three levels of the apartment building: on the flat roof (humidity measurement, area sensors, point sensor), on the first floor (area sensors) and on the ground floor (area sensors, point sensor). Area sensors are also installed in the six bathrooms. In this paper, however, only the measurement systems in the outdoor area are dealt with.

3.1 MEASURING SENSORS ON THE FLAT ROOF

Figures 8, 9 and 10 show the floor plan of the flat roof with the arrangement of the measuring circuits and measuring points. To provide a better overview, the related systems and measuring areas are shown individually in the floor plans.

https://doi.org/10.52202/069179-0505

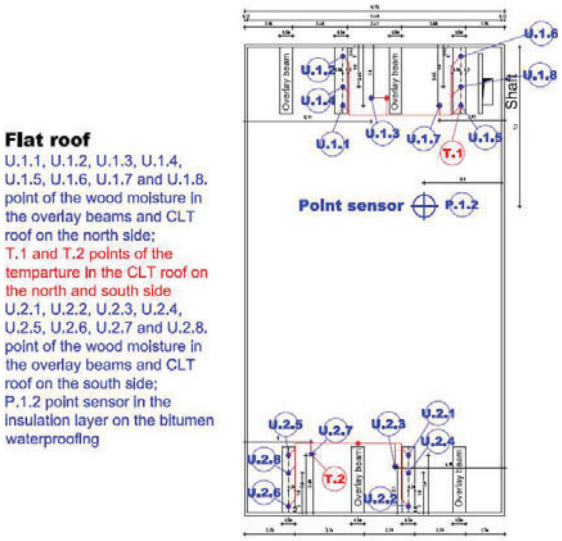

Figure 8: *One point sensor and 16 measuring points of the wood moisture and temperature measurement.*

The first flat roof plan shows the measuring points for the wood moisture measurement, of which eight measuring points each (label U) were installed on the south and north sides of the roof. The two temperature sensors used are marked T in red. The point sensor is also shown on this flat roof plan. The position was placed slightly outside the centre of the roof surface, in the north-east area. The reason is that the roof slopes to the east (water drainage) and an installation shaft penetrates the roof in the northeast. Thus, this area is considered to be the most vulnerable in terms of possible leaks.

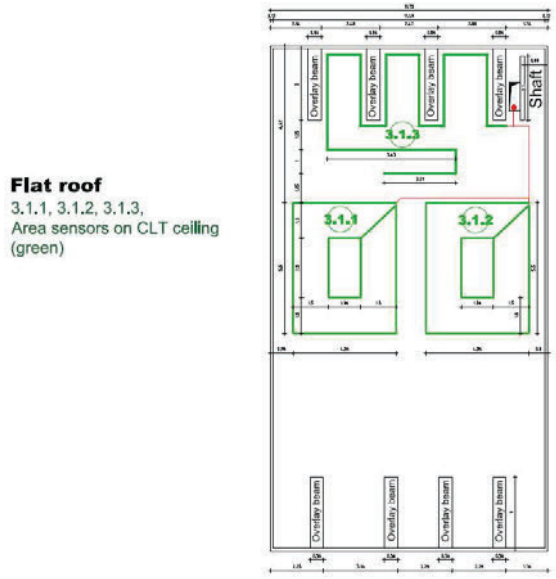

Figure 9: *Three area sensors on the solid wooden roof*

This flat roof plan shows three measuring circuits with area sensors mounted directly on the solid wooden roof. This arrangement was chosen because the deflection is greatest in the central area of the roof surface, i.e. in the event of water ingress, this area is likely to be the first to suffer moisture penetration. The measuring circuit on the north side was laid close to the statically required overlay beams. These beams have only a small amount of insulation on the above surface, i.e. the risk of condensation at low outside temperatures below the waterproofing layer is very high. Therefore, it should be monitored whether this minimal insulation also impacts the moisture situation on the surface of the supporting structure (cross-laminated timber) screwed to the overlays.

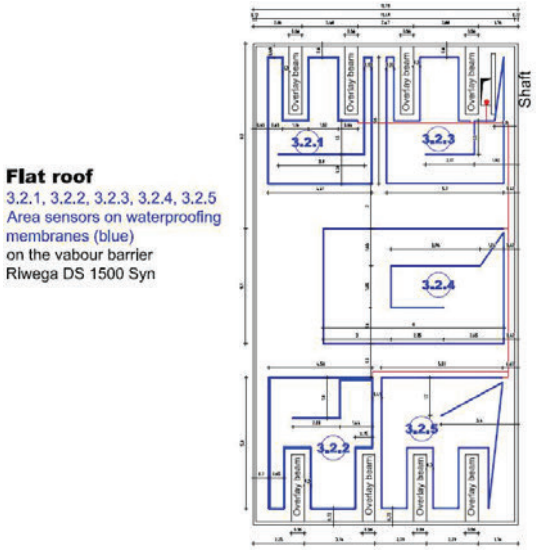

Figure 10: *Five area sensors on the waterproofing membranes*

This flat roof plan shows five measuring circuits with area sensors on the first sealing level (vapour barrier). The arrangement was chosen due to the roof pitch (towards the east) and to be able to monitor the entire roof surface for moisture.

3.2 MEASUREMENT SENSORS ON THE 1st FLOOR

On the 1st floor, area sensors were installed on the terraces and in the sanitation facilities. Three measuring circuits were attached to a bitumen seal on the terrace (west side) above the living space below. Further measuring circuits (shown in green) were installed in the three sanitation rooms directly on the raw ceiling made of cross-laminated timber. On the north side there is a roof-covered terrace with a passageway below. The measuring circuit was attached to the bitumen seal. This spot is interesting, because the temperature differences in this part of the building are significantly lower and due to the north-facing orientation little solar radiation can be expected in

https://doi.org/10.52202/069179-0505

the winter months. The investigation aim at this floor level is also to monitor the overall humidity and tightness. Furthermore, the monitoring should also provide information about the influence of the different thermal conditions.

Figure 11: *First floor - area sensors on bitumen (blue) - sanitation areas sensors on solid wood (green)*

3.3 MEASUREMENT SENSORS ON THE GROUND FLOOR

On the ground floor, the three sanitation rooms were also equipped with area sensors. The sensors were mounted on a reinforced concrete ceiling in the two bathrooms on the north side and on a cross-laminated timber ceiling in the bathroom on the south side. The area sensors in the outdoor area were arranged in such a way that they again enable extensive monitoring of the main building. The measuring circuits 1.2.2, 1.2.3 and 1.2.4 are mounted on the first bitumen sealing layer. Measuring circuits 1.2.2 and 1.2.4 are located above a roof-covered entrance and on a cantilevered balcony. In measuring circuit 1.2.3, the area sensors are partly installed above the living area and partly in the cantilevered area of the storey ceiling. The raw ceiling of these three measuring circuits is made of cross laminated timber. Measuring circuit 1.1.1 was laid directly on the reinforced concrete ceiling. The underground car park is located below this measuring circuit. Measuring circuit 1.2.1 was laid on a plastic membrane (vapour barrier) on the existing single-storey building. Originally, inside this building there was a swimming pool. At the time the measurement sensors were specified, it had not yet been decided whether the swimming pool would be put back into operation or whether it would be used as a fitness room. In addition to the flat roof sensor, another point sensor was installed on the west side of the newly built warm roof on the west side of the single-storey existing building. The position was chosen because this area of the green roof surface is usually without sun in winter due to the terrain formation.

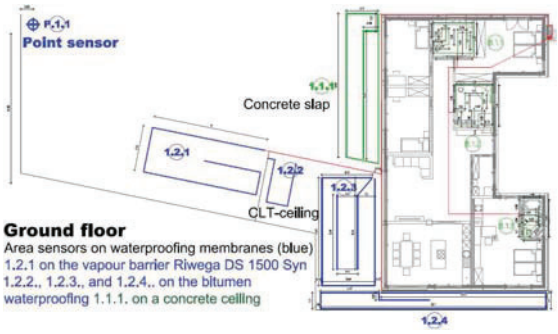

Figure 12: *Ground floor - area sensors on waterproofing membranes (blue) - on the raw ceilings (reinforced concrete; green), point sensor - single-storey existing building*

4 RESULTS FROM MOISTURE AND TIGHTNESS MONITORING

The diagrams and measurement results show an overview of the measurement process up until January 2023. It should be mentioned that due to the lockdowns that occurred during the investigation period, construction completion and therefore the commissioning of the measurement systems and the moving-in was delayed by approximately one year. From September 2021 to January 2022, there was partly no data transmission because the internet connection at the location of the building was inadequate and the installation of the fibre optic cables was delayed by several months. Therefore, there are no consistent area sensor measurement results for this period. The winter of 2022 to 2023 was the first season the premises were lived in. Thus, no meaningful results are yet available regarding the moisture behaviour in the sanitation rooms, on the roof and on the terraces. This means that it is not yet possible to answer the question whether in addition to the mere tightness monitoring of the waterproofing membranes, the habitation and use of the rooms, because of differing temperatures and relative humidity values, has an effect on the moisture conditions in the areas monitored.
The recordings to date show clear differences in humidity between summer and winter. The following diagrams give an overview of the measurement period and feature special conditions.

4.1 MATERIAL MOISTURE MEASUREMENT

The measurement diagram from the south side of the flat roof (Fig. 13) shows the wood moisture content of the eight measurement points (U 2.1 - U 2.8) as well as the temperature curve in the wood (T 2.1) and in the living room area of the first floor (T 2.3) where the data logger is located. The Y-axis of the diagram shows the temperature and wood moisture and the X-axis depicts the time progression. All other diagrams have the same

structure. The measuring system was put into operation on 08 April 2021. The measurement data in the diagram show the course of the wood moisture from the time of commissioning until 31January 2023. The course of the wood moisture lies in the normal range between approx. 8% and 15%. The differences in the wood moisture content can be explained by the different depths of the inserted measuring electrodes. At measuring point U 2.6, a steady increase in the wood moisture content of up to 15% can be seen from May 2021 to the beginning of October 2021, before it drops again in the winter months. At low temperatures, it is noticeable that the measuring system repeatedly experiences disturbances in data storage, as can be seen at measuring point U 2.7 from mid-December 2021 to mid-February 2022. The measured values have a high fluctuation range due to the temperature changes. It is also noticeable that in the winter months the temperature in the cross-laminated timber drops below 10°C, i.e. into the dew point range, despite the external insulation.

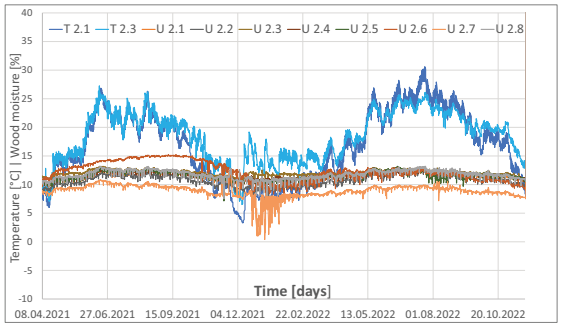

Figure 13: *Flat roof (south side) - wood moisture measurement U 2.1 - U 2.8; temperature in cross laminated timber - T 2.1; temperature interior 1st floor - T 2.3;*

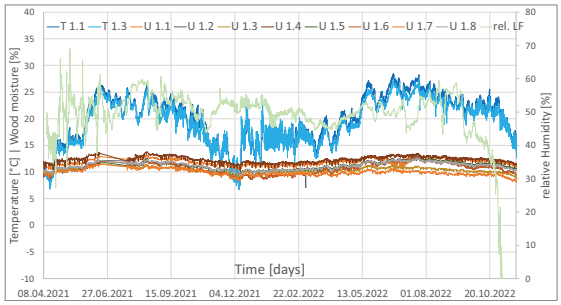

Figure 14: *Flat roof (north side) - wood moisture measurement U 1.1 - U 1.8; temperature in cross laminated timber - T 1.1; temperature and relative humidity in interior 1st floor - T 1.3 and relative humidity;*

The measurement period on the north side of the flat roof is the same as described for the south side (Fig.14). The wood moisture content is very even and inconspicuous over the entire measurement period. It can be seen, however, that the wood moisture content decreases somewhat over the course of time shown (April 2021 to November 2022). This also corresponds in principle to the behaviour of wood: The material becomes drier when professionally installed under the typical living room climate of 22°C and approx. 40 % relative humidity in the heated and occupied interior. In contrast to the south side, to check the indoor climate, the relative humidity in the interior of the 1st floor is also measured at this measuring station. In the period from 16-06-2021 to 15-08-2021, there was an interruption in the measurement recordings, because a cable was unintentionally detached from this measuring device during construction work.

4.2 AREA SENSORS

Not all area sensors on the flat roof, on the 1st floor and on the ground floor could be installed and commissioned at the same time due to the construction progress. This explains why for some measuring circuits the basic voltage is 120 digits. During commissioning, a steep increase in humidity can be seen in some cases, as in the case of measuring circuit 1.2.1 in Fig. 17. In each of the three diagrams (Fig. 15-17) it can be seen that there is one or more measuring circuits at each monitored floor level where there is already a high moisture content at the sealing level from the start. The reason for this is that water ingress occurred during the installation of the roof superstructures due to rain and snowfall and therefore the specified limit range of 11500 digits (laid on waterproofing membranes) was exceeded in some cases. Furthermore, it should be mentioned that there was no network connection from mid-September 2021 to the end of January 2022 and therefore no online access was available. However, it can be seen that the moisture content in the building components became significantly lower over the winter months. In spring, from around mid-March 2022, the moisture content on the waterproofing membranes (vapour barriers) begins to rise again. However, the increase is significantly lower than in the first year of monitoring in 2021. In the autumn months from September 2022 onwards, a clear reduction in moisture on the waterproofing layer is again evident. With the increase in outdoor temperatures, the moisture content on the sealing levels also increases in February 2023. In the coming months and years, monitoring will show which level the moisture content will adjust to over the course of the year (summer, winter). The measuring circuit 1.2.1 in Fig. 17 should be mentioned separately, as it shows a moisture behaviour that is not yet comprehensible. From about April 2022, there is a strong increase in humidity to about 10000 digits. This remains almost constant until the beginning of November 2022, after which the moisture content of this measuring circuit drops to approx. 1000 digits within 2.5 months. Measuring circuit 1.2.1 will therefore be monitored in particular over the next few months to find out whether the increase in humidity is possibly related to leaks in the upper sealing level. If the strong moisture fluctuations continue, the sealing level in the area of this measuring circuit will be opened, dried and resealed

https://doi.org/10.52202/069179-0505

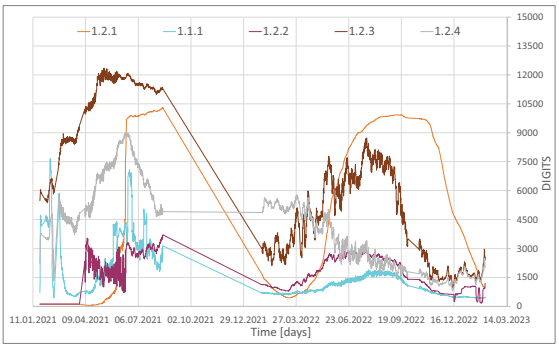

Figure 17: *Ground floor - area sensors 1.1.1 mounted on reinforced concrete ceiling; 1.2.1 - 1.2.3 mounted on bitumen sheeting; 1.2.4 mounted on plastic sheeting - vapour barrier*

4.3 POINT SENSORS

The point sensor on flat roof 1.2 (Fig. 18) is installed near measuring circuit 3.2.3 (area sensor). In the area of this measuring circuit, moisture penetration occurred when sealing the top sealing level. The increased moisture content is also indicated by the point sensor. At the end of January 2022, however, a very rapid drop in moisture occurred within a few days. This means that there must have been a strong drying process within this short time in the insulation level and on the sealing level. If we look at the moisture curve one year later, in February 2023, there is again a sudden sharp drop in moisture. This time, however, it is already in November. In December 2022, there is a brief intensive rise followed by a sharp drop in the measurement curve. The moisture behaviour in the insulation level is difficult to interpret using the point sensor as the measurement period is still relatively short. Questions as to how these very rapid increases in humidity and drying phases can occur still need to be investigated in detail. For point sensor 1.1 (on the green roof of the single-storey existing building), no changes in moisture or conspicuous moisture occurrences can be detected in the first year of monitoring. From June 2022 to mid-October 2022, there is a slight increase in moisture of up to 20 digits. Compared to the area sensors, the limit value for liquid water for the point sensors is 80 digits. Therefore, the value of 20 digits is considered a dry component. However, the reason for this slight increase in moisture has yet to be determined. One reason could be that the measuring device is subject to fluctuations. Otherwise, no other abnormalities can be detected in the insulation level of the green roof.

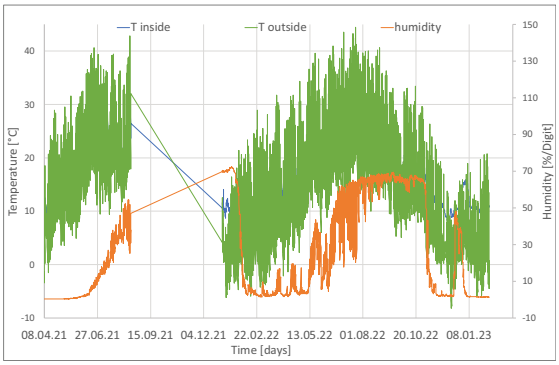

Figure 18: *Point sensor 1.2. on the flat roof*

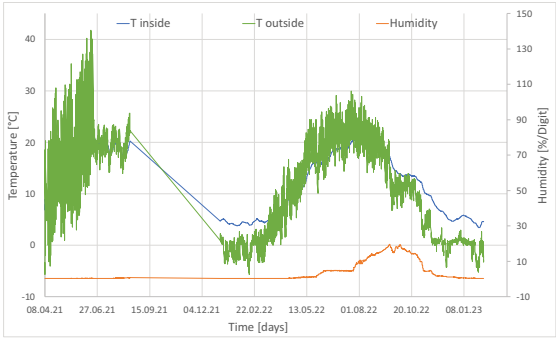

Figure 19: *Point sensor 1.1 on the green roof surface of the existing single-storey building*

5 CONCLUSIONS

The research results so far are as follows: The planning, installation and commissioning of the measuring systems

could be carried out without difficulties. Immediately after commissioning the measurement technology, leakages at the sealing levels could be detected and immediately repaired. Therefore, the positive effect of moisture and tightness monitoring systems was already evident during the construction phase. The interpretation and comparison of the measured values is still somewhat complex due to the different scaling units (percent, digits) of the measuring devices. Depending on the system or materials used (waterproofing, wood, concrete, etc.), the scaling of the measured values also changes.

The wood moisture is expressed in percentage points, the limit value, which must not be exceeded, is at a maximum of 20% wood moisture. Higher values lead to insect and fungal attack and thus to the destruction of the supporting wooden structure.

The moisture content of area and point sensors is displayed in digits. However, in different orders of magnitude. For the point sensors, the measuring range is between 0 and 150 digits. This measuring range is also known for determining the moisture on concrete surfaces. The limit value that should not be exceeded is approx. 80 digits. If the values are higher, there is increased moisture in the building material.

With the surface sensors, the measuring range is higher by a factor of 100. A distinction must be made here as to whether the sensors are installed on the raw material (wood, reinforced concrete) or on a sealing membrane (bitumen, plastic sealing). The measuring range starts at 120 digits and goes up to 15000 digits. The limit value with regard to increased moisture status is 11500 digits for waterproofing membranes and 3500 digits for installation on the raw material. The lower value for the raw material can be explained by the fact that the material can already absorb moisture and therefore a low moisture content, measured on the surface, is already sufficient to have increased building material moisture in the component. This is not the case with waterproofing membranes, as the material cannot absorb moisture.

Therefore, the use and installation of moisture and leakage monitoring systems requires precise documentation and recording of the measuring results and on which materials the measuring sensors are laid or installed in order to be able to carry out a professionally viable moisture assessment.

Of the five residential units in the apartment building, the first flat on the ground floor was occupied in autumn 2021. The remaining four flats were occupied in spring 2022. These four flats are rental flats or holiday homes. This means that they are not occupied throughout the entire year. At the time of the evaluation, the building has only been occupied for approximately one year. More precise interpretations and statements about the measurement results are usually only possible after three to five years of monitoring. Therefore, the monitoring will be continued in the coming years.

Based on the state of the investigation so far, the following can be stated:

- The planning, installation and commissioning of the measurement systems was simple and straight forward.
- Shortly after commissioning the area sensors, leakages in the sealing due to increased moisture could be detected. The quick repair of the defects in the sealing prevented future moisture damage.
- The interpretation of the measured values is still somewhat challenging due to the different scaling of the measuring devices and scarce empirical values. In addition, the limit values (area sensors) change when used on different materials. Therefore, accurate and complete documentation is essential during planning, installation and monitoring.
- At the beginning of the monitoring, the moisture values for some measuring circuits (area sensors) were in the limit range during the summer months resulting from increased component moisture. Therefore, it is not clear whether the moisture content is reduced or evened out over the year or whether the top sealing level should be opened in order to start drying measures.
- Due to the fact that the entire building has only been occupied for one year, results from the sanitary areas as well as the measuring circuits on the flat roof, which were laid on the cross laminated timber elements, are still missing as to what effects this has on the moisture content in the solid wood elements.
- The results so far show that, especially for the area and point sensors, several years of recordings and experience are needed in order to better assess the aforementioned challenges regarding to the evaluation of the results.

ACKNOWLEDGEMENT

This research project is financially supported by funds from the Province of South Tyrol for Consulting and Service Innovation and by the timber construction company Ligna Construct.

We would like to thank them for their willingness to support this project. For the timber construction sector, this is another important contribution to the quality and durability of timber buildings.

World Conference on Timber Engineering Oslo 2023

A PROMISING APPROACH OF LINEAR TIMBER STRUCTURAL HEALTH MONITORING

Johannes Koch[1], Martin Ganß[2], Martin Kästner[3], Antje Simon[4]

ABSTRACT: Structural monitoring of timber bridges includes the moisture monitoring as well as strain and crack monitoring of critical parts, especially when considering new construction methods. Currently, single-point sensors are used for moisture monitoring on timber bridges. However, the parts of the structural components which are not being measured may be moist. The lack of monitoring can result in wet areas not being detected. This could result in major damage, e.g. due to fungal decay. A higher degree of protection can be achieved with linear or area sensors. The same applies for strain monitoring using electrical strain gauges. The possibility of monitoring larger areas using new measurement methods like distributed fibre-optical sensors and technologies may help to promote new construction methods and structural health monitoring (SHM) of timber bridges.
This paper presents a literature survey of moisture monitoring and fibre optical measurement techniques, own studies on moisture monitoring on timber bridges and the strain analysis in mechanical load tests on timber-concrete composite beams. Finally, an overview of the combination of moisture monitoring and fibre-optical measurement techniques is given.

KEYWORDS: structural health monitoring, fibre-optical sensors, FBG, distributed sensing, moisture monitoring

1 INTRODUCTION

A high timber moisture content is a problem for timber bridges as well as it is for any timber structure. This is associated with a high risk of insect infestation and infestation by wood-destroying fungi. Wood moisture contents of more than 20 mass-% over a longer period of time are considered as a potential problem.[1, 2].
Bridges must be regularly inspected in Germany [3]. However, this only offers a limited possibility to monitor the long-term development of the timber moisture content of a bridge. Therefore, monitoring concepts can help to ensure that the timber moisture content is kept within acceptable limits. If timber moisture levels higher than 20 mass-% are measured, it is possible to detect and remedy the problem before major economic damage occurs. For this purpose, new sensors, measurement methods and technologies are required that allow reliable monitoring of the structures.
High-performance fibre-optical measurement techniques allow accurate and distributed or closely spaced linear measurements of strain and temperature changes in large structures such as bridges. If it were possible to use distributed fibre-optical sensors to measure the timber moisture content in addition to strain and temperature changes, it would be a major step forward in structural health monitoring (SHM) of timber bridges.
On the one hand in this paper, the different measuring methods for determining the timber moisture content are presented. It is explained which measurement methods are used in practice and which current developments are known. On the other hand, fibre-optical measurement methods and the usage of these methods for strain and temperature measuring of structures are described. Finally, an outline of the combination of these two methods and new concepts is presented.

2 TIMBER MOISTURE MONITORING

2.1 OPPORTUNITIES OF TIMBER MOISTURE MEASUREMENT

Different methods are available to determine the timber moisture content. An overview is provided in Table 1, according to [4].
The direct measurement of the timber moisture content is possible in two ways. The first possibility is the measurement of the mass of water of a material sample by using the kiln-dry method or the distillation/extraction method. The kiln-dry method is standardised in Germany [5]. It is necessary to take a sample from the building

[1] Johannes Koch, University of Applied Sciences Erfurt, Germany, johannes.koch@fh-erfurt.de

[3] Martin Kästner, Bauhaus-University Weimar, Germany, martin.kaestner@uni-weimar.de
[4] Antje Simon, University of Applied Sciences Erfurt, Germany, antje.simon@fh-erfurt.de

https://doi.org/10.52202/069179-0506

components. Temperatures above the boiling point or solvents are used to extract the water from the sample. The moisture content is calculated by dividing the mass of the water by the mass of the dry sample. These methods are destructive but very accurate and therefore used as reference measurement methods.
The other possibility is the measurement of physical or chemical properties which correlate with the moisture content. Several methods are available, see Table 1. For these methods the dependency on moisture content of the electrical resistance (electrical resistance method), the dielectrical constant (dielectrical method), the energy absorption (microwave method), the braking process of neutrons (radiometrical method), the reflection of light waves (spectrometrical method) and the colour reaction of chemicals (chemical method) is used.

Table 1: *Timber moisture measurement methods*

Method	Measured parameters
Kiln-dry method	Direct measurement of the mass of water in the timber
Distillation/extraction method	
Electrical resistance method	Measurement of physical or chemical properties which correlate with the timber moisture content
Dielectrical method	
Microwave method	
Radiometrical method	
Spectrometrical method	
Chemical method	
Sorption method	Measurement of the relative humidity and air temperature close to a timber surface which correlate with the timber moisture content

An indirect way to determine the timber moisture content is the sorption method, which uses the hygroscopicity of the wood. For this method, a borehole is made in a structural timber component, into which a climate sensor is inserted and sealed off from the outside. The climate sensor is then positioned in an enclosed air volume that constantly changes its humidity due to the timber moisture of the walls of the borehole. The relative humidity and air temperature is measured and then converted into the material humidity.

2.2 MOISTURE MONITORING OF TIMBER BRIDGES IN PRACTICE

Not all of the methods described above are appropriate for monitoring timber structures. Only methods used for monitoring purposes are discussed below.
Timber moisture monitoring is often carried out using the electrical resistance measuring method. This method is standardised for sawn timber in DIN EN 13183-2 [6]. The measurement method is based on the correlation between electrical resistance and timber moisture content. The electrical resistance increases as the timber moisture content decreases. In particular, the type of wood has a considerable influence on the electrical resistance to be determined. Therefore, wood species-specific calibration curves must be used to determine the wood moisture content when using this method. Timber temperature has also a relevant influence on the electrical resistance. Therefore, a temperature compensation is necessary.

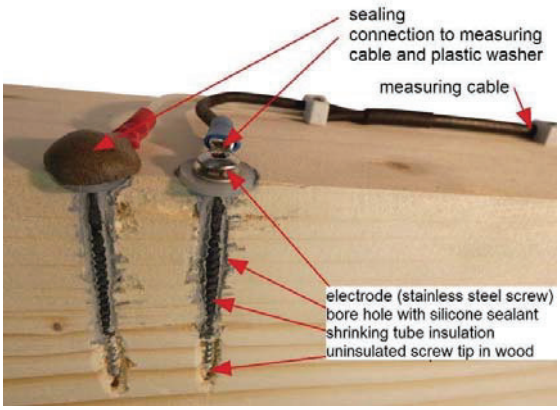

Figure 1: *Model of electrodes in a test specimen*

In a monitoring programme at the University of Applied Sciences Erfurt the following measurement setup was used [7], [8]: Stainless steel screws were used as electrodes, inserted into a pre-drilled hole and insulated with shrinking tube to the specified measurement depth. The exposed part of the thread was screwed into the wood without pre-drilling and the holes were sealed with silicone to prevent water and air ingress. Plastic washers and insulating putty were used to decouple the screw heads from the wood to prevent creepage currents on the wood surface (see Figure 1). The measuring equipment used was from the company Scanntronik Mugrauer GmbH. A similar measurement setup has been used in several other studies [9, 10, 11].
The sorption method has been used in a monitoring programme on several bridges in Norway [12]. Sensors were placed at different depths in the cross section of the main components of the bridges. The boreholes were sealed from the outside. The sensors measure air temperature and relative humidity in a small cavity. The moisture content was initially calculated using Simpson's equation for equilibrium moisture content [13]. However, a more accurate equation was found.

2.3 CURRENT DEVELOPMENTS

New sensors are currently being developed by several institutions. At the Bern University of Applied Sciences, a single-point sensor has been developed that also uses the sorption method. The advantages are the low costs and wireless data transmission of each sensor. This simplifies the application of this system. A gateway close to the sensors can transmit data to a server or send alerts to mobile phones [14].
Another approach is the usage of Radio Frequency Identification (RFID)-tags. An RFID-tag is a small device that uses radio waves to receive, store, and transmit data

https://doi.org/10.52202/069179-0506

to a reader. The capacitive measurement method is used. The water in the wood affects an RFID-tag antenna and causes its impedance to deviate from its intended design value. This effect becomes stronger as the moisture content of the surrounding medium increases. Therefore, it is possible to determine the moisture content. Tags are available which get their energy by electromagnetic transmission from the reader. Wires and an energy supply are not necessary, only a reader is required. The tags can be applied to the surface or inserted into the timber components. The disadvantages of this method are its low level of accuracy and the fact that it is a single-point sensor, as it is the case with many other techniques described before [14, 15, 16].

Single point sensor measurements only give information about the moisture content at the measurement points. It is not possible to detect potentially high moisture levels next to the measurement points. This disadvantage of single-point measurement is overcome by linear or area sensors. Such sensors are currently being developed as described in the following.

In [17] the development of a 'sensor lamella' is described, which can be used as a linear or area sensor. The measurement principle is based on the determination of the specific resistance of the wood volume between two plate electrodes. The system is suitable in the range of 10 mass-% to 20 mass-% but not for the detection of locally increased moisture content above the critical value of 20 mass-%.

Kühne et al. [18] describe linear sensors using dielectric measurement techniques such as Time Domain Reflectometry (TDR) and Damping and Phase Shift in the Alternating Voltage Field of Electrical Conductors (DPW). They allow local estimation of wood moisture, but require calibration for each application.

Research at the University of Applied Sciences Eberswalde is taking a different approach. In his dissertation [19], Winkler describes the use of piezoresistive wood adhesives. In [20] it was already shown that it is in principle possible to use such electrically conductive adhesives for timber moisture detection. In addition, strain can also be determined. It is therefore a technology that can be used in many ways to analyse timber structures. The measured resistance depends on the load, temperature change, moisture and the associated swelling and shrinking of the material. The task at hand is therefore to distinguish between the causes of this 'sum signal'.

Although commercially available linear and area moisture sensors are used to monitor bridges, they are used in particular for flat roofs. However, these sensors are not used to measure the timber moisture content, but only as a continuous check on the integrity of the waterproofing layer. These systems usually include a leak detection option. However, as the timber moisture content is not measured, these systems are not included in the following discussion.

3 THE USE OF A FIBRE-OPTICAL MEASUREMENT METHOD FOR THE ANALYSIS OF TIMBER STRUCTURES

3.1 FIBRE-OPTICAL MEASUREMENT METHODS

3.1.1 Principles

Fibre-optical sensors and measurement methods provide another approach for the analysis of timber structures. In principle, the sensor technology is based on passing a light wave through the core of an optical fibre and measuring the reflected and/or the transmitted light wave properties. External influences such as temperature changes and mechanical strains in the direction of the fibres cause them to stretch or compress and affect the light properties. This method may also be suitable for determining the timber moisture content i.e., by measurement of hygric strains of the timber or analysis of the relative humidity of the air close to wood using a fibre-optical sensor with humidity sensitive coating.

Fibre-optical sensors are divided into single-point, semi-distributed and distributed sensors. Single-point measurement systems and sensors are not part of the present discussion.

3.1.2 Fibre Bragg Grating (FBG) Sensors (semi-distributed measurement)

Very thin fibre-optical sensors, such as fibre Bragg grating sensors (FBGS), allow the measurement of changes caused by temperature and mechanical strain. Due to their insensitivity to electromagnetic interference, corrosion resistance and long-term stability, FBGS are widely used for structural monitoring in various applications [21], [22].

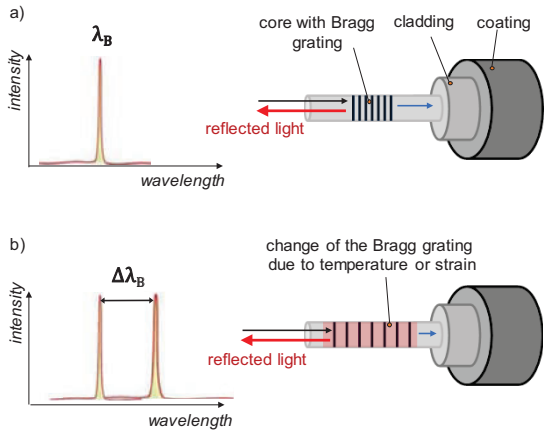

Figure 2: *Schematic representation of the principle of fibre Bragg grating sensors (a) FBGS with the reflected light spectra (wavelength at the maximum of the peak is the Bragg wavelength λ_B) and (b) shift of the Bragg wavelength ($\Delta\lambda_B$) due to changes in temperature and/or mechanical strain*

FBGS are light guiding optical fibres with zones where the refractive index in the fibre core is periodically modulated. The zones with modified optical properties are

called Bragg gratings [23]. When broadband light is passed through the fibre Bragg grating, a wavelength-selective reflection of the light occurs as schematically shown in Figure 2. The light is reflected at the Bragg wavelength λ_B [23].

If temperature or mechanical strain is applied to the fibre Bragg grating along the fibre axis, the Bragg wavelength is shifted to lower or higher wavelengths depending on the situation. The Bragg wavelength shift is given by Equation (1) below:

$$\frac{\Delta\lambda_B}{\lambda_B} = (\alpha + \xi) \cdot \Delta T + (1 - \rho e) \cdot \varepsilon \qquad (1)$$

with $\Delta\lambda_B$ = change in the Bragg wavelength, ρe = photoelastic constant, α = thermoelastic coefficient, ξ = thermo-optic coefficient, ΔT = change in temperature and ε = strain.

For more information on the relationship between the change in optical properties with temperature and strain see [23]. The Bragg wavelength shift depends on both temperature and mechanical strain. For strain measurements at constant temperature, the peak shift of the Bragg wavelength is typically converted into a measurement of strain along the axis of the optical fibre. If the temperature is not constant, temperature effects must be separated from mechanical strain effects using temperature compensation techniques. For strain measurements, the FBGS are normally attached to the surfaces of the structure of interest using structural adhesives. It has been shown that FBGS can also be used as embedded sensors in laminated composite structures [24] as well as in adhesive layers of structural joints [25]. Embedded FBGS can therefore provide detailed information on strain or temperature at different points in a structure [26].

3.1.3 Distributed Fibre Sensing

In recent years, distributed measuring fibre-optical systems have also become established. These measurement techniques use the light scattered back from 'defects' and inhomogeneities in the optical glass fibre itself. The optical fibres contain a characteristic reflection signal whose defined changes under the influence of temperature and mechanical force are analysed to determine temperature and strain. Special interferometer measurement techniques and defined tunable laser light sources are used to evaluate the light scattered back into the fibre.

Optical frequency domain reflectometry, which uses frequency analysis to evaluate the Rayleigh components in the backscattered light, is well established for applications requiring high spatial resolution in the millimetre range over the entire fibre. The measurement systems consist of a tunable narrow-band laser and a Mach-Zehnder interferometer, with one arm used as a sensor and the other as a reference. By using special analysis techniques and algorithms strains and/or temperatures can thus be continuously recorded over the entire optical fibre (over a length of up to 100 m) with high spatial resolution in the lower millimetre range. Usual optical fibres and optical fibre cables can be used for this measurement technique [27].

Other measurement techniques are used to analyse the Raman and Brillouin components in the backscattered light. These techniques can measure over distances of tens of kilometres, but their spatial resolution is limited [27].

A new technique of interest for spatially resolved strain monitoring is the combination of FBG technology and frequency domain reflectometry. By inscribing a large number of low reflective Bragg gratings of the same output wavelength into the fibre, a better backscatter signal is obtained. Strains of up to 30,000 µm/m can be measured with spatial resolution along a fibre length using frequency domain reflectometry [28].

3.2 EXPERIMENTAL STUDIES USING FIBRE-OPTICAL MEASUREMENT METHODS

3.2.1 Strain Measurement along the Joint of Adhesively Bonded Timber-Concrete Composite Beams for Bridge Construction

A research project [29] carried out at the Bauhaus-University Weimar included component tests on timber-concrete composite beams. The subject of the research project was the investigation of new types of composite joint configurations for timber-concrete composite road bridges with continuous bond between the concrete deck slab and the main timber girders. One of the composite variants investigated was the adhesive connection of the components using tolerance-compensating polymer mortar with mineral fillers. Together with the Materials Research and Testing Institute at the Bauhaus-University Weimar, a fibre-optical measurement system was used in two bending tests (beams HBV-11 and HBV-12), which allowed a nearly continuous measurement of the strains over the entire length of the adhesive joint. Detailed information on the investigated composite system and the results concerning deformation, load-bearing and failure behaviour of the components are documented in [29, 30, 31]. An overview of the fibre-optical measurements of the strains is given below. Further information can be found in [32].

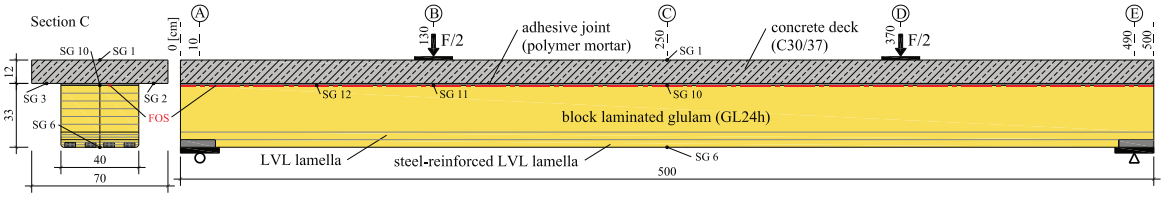

Figure 3: *Specimen dimensions of the four-point bending tests with fibre-optical strain measurement along the adhesive joint of the timber-concrete composite beams HBV-11 and HBV-12*

https://doi.org/10.52202/069179-0506

General information on the test specimens and boundary conditions are given in Figure 3. To prevent sudden failure of the wood, the glulam beams were reinforced with both tensile and shear reinforcements. Details can be found in [30]. The adhesive was applied to the full surface on top of the glulam beam over its whole length. The average thickness of the adhesive joint was approximately 13 mm (± 3 mm). The optical sensor fibre was previously applied over a length of 5 m in the area of the composite joint on the timber surface (see FOS in Figure 3) and, in the case of the HBV-12 beam, also in the bending tension zone. Strains along the sensor fibre were already measured using an optical frequency domain reflectometer during the production of the adhesive joint and during the short-term bending test. The global and local deflections were measured according to the relevant standard [33], as well as the relative displacement between timber and concrete components using inductive displacement transducers at different points on the composite beam. In addition, local measurement of longitudinal strains was carried out using electrical strain gauges in the following areas of the composite beam (see Figure 3):

- in the middle of the composite beam at the top and bottom surface of the concrete deck slab (SG 1, SG 2 and SG 3)
- in the middle of the composite beam at the top and bottom surface of the block laminated glulam (SG 10 and SG 6)
- in axis B at the top surface of the block laminated glulam (SG 11)
- in the middle between axis A and B at the top surface of the block laminated glulam (SG 12)

In the four-point bending tests the load was applied displacement controlled in four consecutive load cycles (see Figure 5) until failure at the end of the fourth cycle. Strain changes were detected along the whole length of the fibres during the production of the adhesive joint. Events such as loading due to the application of the concrete deck and strain reduction due to the hardening of the polymer mortar (reaction and cooling shrinkage) were identified.

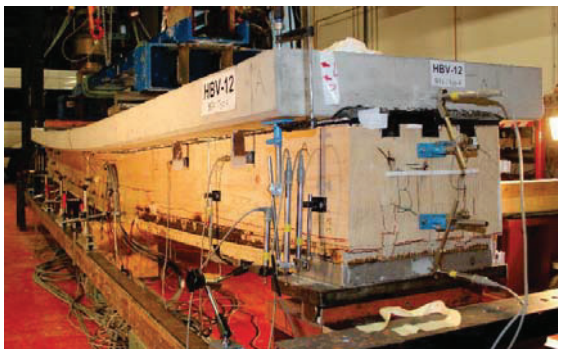

Figure 4: *Deformed timber-concrete composite beam HBV-12 at the end of the bending test; cracks in the LVL and in the glulam are marked in red*

Figure 4 shows the significantly deformed HBV-12 test specimen. Figure 5 shows the strain distribution determined by fibre-optical sensing in the adhesive layer along the whole specimen for five load levels. Using the optical frequency domain reflectometer, strains between -400 and +700 µm/m were determined up to final bending tensile failure at t = 2442 seconds. The maximum load was 1221 kN.

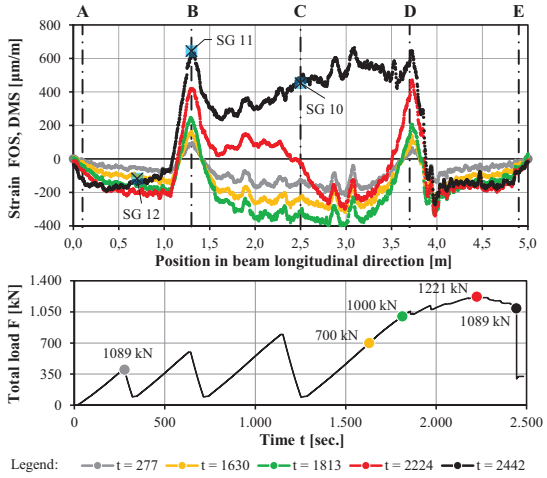

Figure 5: *Strain distribution along the fibre-optical sensor within the adhesive joint of the timber-concrete composite beam HBV-12 for five specific test times (above) and associated load levels (below)*

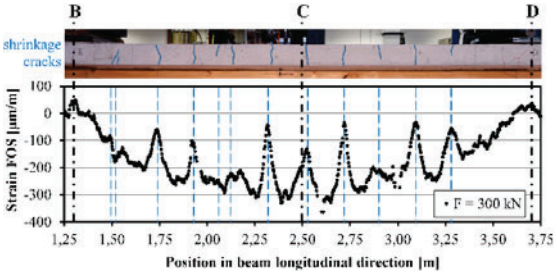

Figure 6: *Correlation between the location of shrinkage cracks within the concrete slab and local peaks in the strain distribution measured with the fibre-optical sensor along the adhesive joint of timber-concrete composite beam HBV-11*

The results of the strain measurements using strain gauges on the one hand and the fibre-optical measurement method on the other showed a high level of correlation (see Figure 5, for t = 2442 seconds). Due to the stiffness of the rigid-bonded timber-concrete composite beam, the sensor fibre is largely within the bending compression area of the undamaged test specimen (negative strains). Local influences, such as the concentrated load application in axes B and D, can be seen as peaks in the strain distribution. Below the load application points, local tensile strains of more than 600 µm/m were measured within the adhesive joint. The location of previously detected shrinkage cracks in the concrete slab correlates with the location of smaller strain peaks along the sensor fibre (see Figure 6). The theoretically

continuous force transmission is locally interrupted by the existing crack structure, which is clearly demonstrated by the measurement results.
The results of the studies presented here show that it is possible to measure strain values in the adhesive joint over the whole length with a high spatial resolution by using distributed fibre-optical sensors. If the data is correctly analysed and interpreted, it can be used to gain a lot of information. This allows the detection of local events as well as influencing factors from the production process and during the service life.

3.2.2 Optical Fibre Sensors for Strain Monitoring on Bridges

Fibre-optical sensor solutions have sporadically been used for the strain monitoring of bridges. In particular, fibre-optical displacement transducers and FBG sensors have successfully been used to monitor some bridges. In 2016, Roßteutscher et al. showed in the research project 'i.bridge' [34] that the deflection and vibration of a concrete bridge in need of repair can be measured using a fibre-optical measurement system based on optical frequency domain reflectometry and Rayleigh backscattering. Optical fibres were applied to the concrete surface, vehicle overpasses were analysed and correlated with sensor data [34]. Distribution measuring sensor systems based on Brillioun scattering have also been used [35, 36]. With this measurement technique, spatially resolved sensor data can be recorded at a distance of approximately 0.50 m. In the investigations by Wosniok et al. [37], the fibre-optical sensors were applied to the surface of the concrete structure of a bridge in Amsterdam. Static loads were induced by controlled truck overpasses, which were detected by the fibre-optical sensors with a spatial resolution of 0.20 m. The temperature compensation was done using unloaded areas of the sensor fibres [37].

3.3 CONCEPTS OF TIMBER MOISTURE MEASUREMENT USING FIBRE-OPTICAL SENSORS

3.3.1 Using the Sorption Method

As shown above, fibre-optical measurement methods are in principle very powerful technologies. They are particularly well-suited to monitoring long structures such as bridges. So far, the technology described has been used to measure strain and temperature in this field of application. It would be a major step forward in structural health monitoring if these methods could be used to measure the timber moisture content. There are different suitable possibilities.
One option is the combination of the sorption method and the fibre-optical measurement method. A humidity-sensitive fibre-optical sensor is required to calculate the timber moisture content from the relative humidity and temperature of a small cavity in the wood. The FBG technology is suitable to make this possible. The cavity could be a notch. The usage of a perforated stainless-steel capillary around the fibre might also be an option.
Normally FBGS are used to measure both temperature and longitudinal strain. To make the FBG sensitive to the relative humidity of the surrounding air a hygroscopic coating of this part of the fibre is necessary. Polyimide [38, 39] or ORMOCER® (organically modified ceramics) [40] are suitable coating materials. The coating induces strains in the FBG structure by hygroscopic expansion if the relative humidity is changing as given by Equation (2) below:

$$\varepsilon_{RH} = \beta \cdot \Delta\mathrm{RH} \tag{2}$$

with ε_{RH} = hygroscopic strain, β = humidity-induced expansion coefficient and ΔRH = change in relative humidity.
The strain ε in Equation (1) could be replaced with the hygroscopic strain ε_{RH}. The result is given in Equation (3) below:

$$\frac{\Delta\lambda_B}{\lambda_B} = (\alpha + \xi) \cdot \Delta T + (1 - \rho e) \cdot \beta \cdot \Delta\mathrm{RH} \tag{3}$$

This is only applicable if the fibre is not bonded to the wood and thus mechanical strain is excluded. To separate temperature and relative humidity temperature compensation techniques are necessary, e. g. an additionally temperature sensor close to the humidity sensor. Other techniques enable the separation within a single FBGS [40].
In [41] the development of a fibre-optical sensor is described that is suitable for measuring hygric induced strain, temperature and relative humidity. It is a combination of three FBGs. The humidity sensitive part is a commercially available polyimide coated FBG [42]. The timber moisture content was calculated according to [43]. The sensitivity of the sensor was customised and the temperature influence was compensated. Therefore, this measuring method seems to be a good alternative to established methods.

3.3.2 Using the Hygroscopic Strain of Wood

The other option is to use the hygric induced strain of the wood itself to determine the moisture content. The challenge in this case is to separate the measured signal into its component parts as there are:

- mechanical induced strains
- thermal induced strains
- hygric induced strains

The measured strain combines all of them in a 'sum signal'. This is described in Equation (4) below:

$$\frac{\Delta\lambda_B}{\lambda_B} = (\alpha + \xi) \cdot \Delta T + (1 - \rho e) \cdot (\beta \cdot \Delta\mathrm{RH} + \varepsilon) \tag{4}$$

Using an additional fibre that is unloaded or unloaded parts of the same fibre offer the separation of the thermal induced strain.
The separation between mechanical and hygric induced strain is more difficult. A concept must be developed for the separation taking into account the following aspects:

- strain direction and maximum strain value (swelling and shrinking is much different between grain direction and perpendicular to grain; and also different between radial and tangential wood anatomic direction),
- influence of wood defects like knots, cracks etc.,

https://doi.org/10.52202/069179-0506

- prevention of swelling and shrinking due to connected components like concrete slabs or perpendicular arranged timber layers.

One option is the definition of a 'sensor lamella'. As part of the research project 'HBVSens' concepts of the described measurement method will be tested in TCC structures.

4 CONCLUSIONS

Structural health monitoring can help to detect potential damage of timber bridges at an early stage and thus to prevent major economic damage. As presented, semi-distributed and distributed fibre-optical sensor methods are good solutions for strain sensing including temperature measurement. At present, the moisture monitoring is often carried out using single-point sensors. The disadvantages associated with this can be overcome by using fibre-optical sensing not only for strain and temperature, but also for moisture. On the one hand, this is possible by combining the sorption method with the use of FGBS. On the other hand, the hygric induced strain of the wood itself could be used to measure the moisture content. Both proposals require further investigations.

ACKNOWLEDGEMENT

Thanks go to the Fachagentur Nachwachsende Rohstoffe e.V. (FNR) and to the Federal Ministry of Food and Agriculture (BMEL) of Germany for funding the ongoing research project 'HBVSens' (FNR-project no.: 2221HV097) and the already completed FNR-project no. 22000612 [29] under the direction of Prof. Dr.-Ing. Karl Rautenstrauch. Thanks are also owed to the sponsors of the completed research project 'Protected Timber Bridges (ProTimB)': Federal Ministry of Education and Research of Germany, the companies of the Qualitätsgemeinschaft Holzbrückenbau e. V. (Schaffitzel Holzindustrie GmbH + Co. KG, Schmees & Lühn Holz- und Stahlingenieurbau GmbH, Grossmann Bau GmbH) and Setzpfandt Beratende Ingenieure GmbH & Co. KG.

FEDERATED USE OF HYGROTHERMAL MONITORING DATA IN MASS TIMBER BUILDINGS: OPPORTUNITIES AND CHALLENGES

Mariapaola Riggio[1], Jan Vcelak[2], Pekka Kaitaniemi[3], Andre R. Barbosa[4], Niki Hrovatin[5], Anna Sandak[6], Jakub Sandak[7], Michael Mrissa[8], Miklos Kresz[9], Anssi Yli-Jyrä[10], Ritva Toivonen[11], Laura Alakukku[10]

ABSTRACT: Several structural health monitoring projects have recently emerged to document the hygrothermal behaviour of mass timber buildings during both construction and service. Understanding moisture conditions on site can significantly impact the construction efficiency of mass timber structures. It is also essential to comprehend the effectiveness of moisture control strategies and construction practices in different climates to streamline project delivery and prevent long-term durability issues. This paper describes the first period of hygrothermal monitoring of three mass timber buildings in three different climate zones, outlining potential approaches for enhancing and integrating data, which can leverage the increasing availability of data from various monitoring projects.

KEYWORDS: moisture monitoring, mass timber, construction phase

1 INTRODUCTION

Faced with timber products and construction systems that are growing in scale and spreading to new climate zones, the mass timber building community increasingly needs information to understand the impacts of environmental exposure during a building's entire life cycle and the efficacy of existing moisture management practices. Several monitoring studies have provided insights on wetting, drying and durability performance of wall and floor assemblies in varying exposure conditions (for instance [1-7]), and have also highlighted the potential benefits of developing more unified monitoring methods and data-driven approaches to moisture management. Oregon State University, InnoRenew CoE, the University of Primorska and the University of Helsinki have established a research alliance to share information on mass timber buildings performance. The alliance will utilize monitoring data from three mass-timber projects, Peavy Forest Science Center (PFSC) in Oregon, USA, InnoRenew CoE in Slovenia, and the Hyytiälä Forestry Field Station in Finland. A federated use of data from the three monitoring projects presents an opportunity to provide valuable insights into the hygrothermal behaviour of mass timber buildings, enabling a comprehensive understanding of moisture levels in CLT panels during construction and in service, while taking into account specific building systems, construction processes, water management strategies and climate zones. However, data integration can be challenging due to differences in data collection methods, equipment, and techniques, as well as variations in the number and types of monitored locations and measurement periods. These differences can result in variations in accuracy, resolution, and quality of the data obtained. In addition, data ingestion and processing techniques can also significantly impact data integration, such as the way data is formatted, organized, and stored, affecting its usability and compatibility with other data sources. Variations in data processing techniques, including algorithms used for data cleaning, filtering, and normalization, can also impact data integration. This paper outlines the methodology used in the development of the three monitoring projects and provides examples of

the challenges and opportunities that arise when using hygrothermal monitoring data from different mass timber buildings.

2 METHODOLOGY

2.1 SCOPING THE MONITORING PROGRAMS

The first crucial step in planning a monitoring program is to clearly define the project's objectives and the phenomena of interest. Next, the required measurands and data collection and management approach should be defined, taking into consideration factors such as budget and building constraints.

The PFSC is a three-story building completed in Corvallis, Oregon in 2019. The location has a Mediterranean/dry-summer subtropical climate with mean annual precipitation of 1295.4 mm and temperatures ranging from 2°C to 30°C over the course of the year. The building's gravity load-bearing system comprises glulam beams and columns, cross-laminated timber (CLT)-concrete composite floors, and a mass ply panel (MPP) roof. The lateral force resisting system features self-centering, post-tensioned CLT shear walls. The construction of the timber structure began in winter 2017 and was planned in three sequential spatial zones to minimize exposure to the weather. To protect against moisture during construction, a vapor permeable coating was applied in the shop to exposed end grains, such as panel edges, connections, and cut-outs, as well as to the faces of glulam members and visible CLT panels. Additionally, temporary tarps were placed on the upper edges of the CLT wall panels to prevent water from entering through any discontinuities (Figure 1).

Figure 1: *Zone 1 of the PFSC, Corvallis, Oregon, during construction (up), detail of temporary moisture protection during transportation and erection (bottom)*

The objectives of the hygrothermal monitoring plan during construction of the PFSC were manyfold: a) to provide benchmark data on the wetting/drying behaviour of domestically produced Douglas Fir CLT exposed to the rainy Pacific Northwest climate, b) to evaluate the effectiveness of localised moisture exclusion measures in reducing moisture uptake in CLT and glulam members and, consequently, mold risk; c) to provide indications on proper dry-out schedules to avoid build-in moisture that minimize checking and uncontrolled building movement. Additional MC, RH and T sensors were installed to evaluate conditions in service [8] and correlate hygrothermal behaviour and long-term performance of structural systems (such as, for instance, effects of mechano-sorptive creep and moisture induced movement on tension losses in post-tensioned shear walls [9]).

InnoRenew CoE's building is located in a Mediterranean seaside climate in Izola, Slovenia, with 1313 mm mean annual precipitation and temperatures ranging from 1.7°C to 28.9°C over the course of the year. It is a 4-story 8194m^2 building with a concrete podium and three timber stories featuring CLT panels and glulam. The building was completed in February 2022. No extraordinary measures against rainwater were taken during construction, and the building was exposed to outdoor conditions until the roof was installed. CLT panels were not equipped with protection membranes. However, in-plane panel-to-panel floor connections were sealed using surface-applied tapes to avoid water penetration between the panels (Figure 2).

The main objectives of the hygrothermal monitoring plan of the InnoRenew CoE building mostly target the service life of the building, after commissioning. Specifically, internal MC sensors were installed for early detection of leakages in wet room areas. MC, RH and T sensors in the envelope measure conditions in air-gaps or breathable materials.

Figure 2: *InnoRenew CoE's building, Izola, Slovenia, during construction (up), detail of the CLT floors (bottom*

https://doi.org/10.52202/069179-0507

Figure 3: *The main building of Hyytiälä Forestry Field Station after removal of construction shelter. Six groups of MC sensors are indicated with black text.*

The four new mass timber buildings at the Hyytiälä Forestry Field Station, Finland, are located in the boreal climate zone with 711.0 mm and mean monthly temperature extremes ranging from -10.3°C to 21.8°C. Construction started in spring 2021 and completion is scheduled in autumn 2023. The buildings have 1-2 stories with CLT walls and exterior wood cladding. Wooden pedestrian bridges and platforms connect the facilities. One week prior to the transportation of CLT elements to the construction site in early November 2021, a construction shelter was fully installed over the building. The top of the shelter was opened periodically until the roof construction was completed, at which point the tent was fully removed in late January 2022. To cover the window openings temporarily, plastic sheeting was used until the windows were installed in the first week of February (Figure 3). Measurements are taken from the interior CLT wall element located adjacent to the lower floor fenestration on the northwest side of the building.

Overall, the objective of wood moisture content measurements in the new Hyytiälä Forestry Field Station is to ensure the long-term health and safety of the building's structure by providing a reliable system for monitoring and maintaining the moisture levels of the CLT elements. In addition, data collected during the construction period enables monitoring the success of practices for protecting the elements from moisture during transportation, storage, and construction.

2.2 DATA COLLECTION

Sensor installation in the PFSC was conducted in two stages. During the initial construction phase, 19 permanent resistance-based MC sensors (SMT-PMM) were installed in the timber framing. These sensors were placed in the first erected CLT shear wall panels and a floor, which were deemed representative of areas in the building that could be affected by prolonged exposure to precipitation. Subsequently, 111 additional MC sensors were installed in locations where in-service wetting was a concern or where structural behaviour was being monitored. During the first monitoring period, in addition to continuous MC measurements, discontinuous MC readings were made using a resistance handheld meter (Delmhorst 18-ES), both in locations contiguous to those continuously monitored and in comparable locations but with different exposure conditions. Internal temperatures in the CLT wall panels were measured in specific locations to have accurate corrections of MC readings in internal CLT laminations. Air humidity (RH) and temperature (T) sensors were integrated in the local data acquisition systems. Weather data was collected by a nearby weather station [10]. Additional RH and T gauges were installed during the second phase.

One of the sampling criteria in the project was to include redundant sensors to account for potential malfunctions and data losses.

In the InnoRenew CoE's building, eleven (11) resistance-based MC sensors (MoistureGuard MHT sensors) were installed during construction, in 2020, but measurements started in April 2022 after the power and Ethernet networks were fully functional and the building was commissioned. One MC sensor was installed on each side of the building, on the external lower part of the exterior CLT walls. Seven additional MC sensors were placed in high-risk interior areas of the CLT structure to monitor water damage during normal building operations (toilets, bathrooms, and kitchens). Fifty-one (51) sensors for relative humidity (RH) and temperature (T) were installed in the building envelope to measure conditions within air gaps or breathable materials. (MoistureGuard HT sensors). During construction, measurements were taken manually on a weekly basis at 289 floor locations. Two types of moisture meters were used: a pin-type resistance meter (Humimeter WLW) to measure moisture content (MC) at a depth of 2.5cm, and a pinless capacitance moisture meter (Humimeter M20). Each location was labelled with a unique ID number, and manual measurements were continued until MC values reached 21% or lower, and there was no risk of additional wetting. Thermal imaging was used as a secondary, screening method [11] to identify possible wet spots in the interiors [12]. Data from two nearby weather stations were also used for data correction and post-processing.

In the Hyytiälä Forestry Field Station, continuous wood MC measurements were initiated already at the CLT plant, where 4 groups of 4 or 3 Wiiste WM1-WAN resistance-based wood moisture meter sensors (Wiiste Oy) with different measurement depths were pre-installed in CLT panels in November 2021. The panels were delivered on site in 5 days and erected in 9 days, hence the measurements also cover the short periods of storage and transportation. Additional 9 groups with 4 sensors were mounted in exterior CLT panels at the construction site in winter 2022 to cover a representative sample of microsites with potentially differing environmental conditions. Each group of four sensors in the 240 mm thick exterior CLT panels covers measurement depths from 13 mm to 218 mm at 5 to 50 mm intervals. The single group of three sensors in the 180 mm thick interior panel covers depths from 8 mm to 148 mm at 10 to 30 mm intervals. Weather data are constantly monitored near the building by both the Finnish Meteorological Institute and the University of Helsinki.

It is important to note that while some data collection occurred during transportation, the majority of the sensor installation was conducted after the wall elements were in place. This is because installing sensors during transportation or early construction phases requires an elevated level of coordination and significantly increases the risk of physical damage to the sensors.

2.3 DATA INGESTION

Table 1 shows measurement range, resolution and listed accuracy of the MC sensors used in the three buildings, as well as sample time intervals used in each monitoring project. Specifications of the hand-held meters used in the PFSC and InnoRenew buildings are also included in the table.

Table 1: *Sensor specifications in the three projects*

Project / sensor	measurement range	resolution	accuracy	sample interval
PFSC / PMM	8–30%	0.1%	+/-1%	1st phase: 1 minute - averaged hourly 2nd phase: 60 minutes
PFSC / Delmhorst 18-ES	5–60%	0.1%	Not available	1st phase: varying
InnoRenew / Humimeter WLW	7-150%	0.1%	+/-1%	1st phase: 1 week
InnoRenew / Humimeter M20	2-30 %	0.1%	Not available	1st phase: 1 week
InnoRenew / MHT	7–28%	0.1%	+/-1%	2nd phase: 15 minutes
Hyytiälä / WM1WAN	6–30%	0.1%	+/−1%	60 minutes

The data from the permanently installed MC sensors in PFSC is periodically transmitted to a local data acquisition unit, where it is stored and wirelessly transmitted to a dedicated computer equipped with a receiver. Finally, the data is synchronised with a cloud database for further analysis and storage.

In addition to the commercially available solution, the collected data is transmitted to a local, custom server, where data from other sensors/suppliers is also collected [13].

The MC sensors permanently installed in the InnoRenew CoE building are equipped with a digital RS485 wire interface and are powered by the same cable. The cable connects the sensors to EDGAR ethernet gateways, which are powered over ethernet and connected to the building's LAN. As a result, each sensor is accessible from any computer or system on the building's network. A dedicated PC runs a LabVIEW code developed by the research team which stores the data a local database for further analysis. To supplement the data collected from the sensors, precipitation data (daily sum in mm/day) is collected from the nearby official Slovenian Environmental Agency weather station in Strunjan (located 3km away). Additionally, temperature and relative humidity data are retrieved from the weather station in Portorož, which is situated 9 km away.

At Hyytiälä, the MC sensors are also equipped with sensors that measure ambient humidity and air temperature at the sensor positions on the faces of the CLT elements. The MC data collected from the construction site are transmitted periodically to a cloud database via a commercial LoRaWAN network, which is supported by a local repeater to improve the signal quality. To monitor the weather conditions at the site, open data collected by the Finnish Meteorological Institute is used, which is obtained from a weather station located 200 meters away from the building site.

2.4 DATA CONVERSION AND TEMPERATURE CORRECTION

Raw resistance ohmic values from MC sensors is converted to moisture content using equations designed for specific wooden species; published correction factors for Douglas Fir were used for the PFSC data, and for spruce and pine in the other two projects [14].

Temperature compensation is also applied to the data collected [14-16], using either temperature data from the closest thermistor depths (in some locations in PFSC [10]), air temperature measured in correspondence of each MC sensor (Hyytiälä), or air temperature values from nearby sensors (in some monitored locations in PFSC and in the InnoRenew's building).

The conversion of data and temperature correction are typically offered as post-processing features in dedicated hygrothermal monitoring platforms (e.g., SMT-Analytics). Alternatively, these functionalities can be implemented directly in sensors or developed through custom code.

2.5 DATA ENHANCEMENT

To facilitate automated data processing, unifying the data formats from various sources is the initial step. Moreover, it is essential to ensure the quality of the data is assessed and validated before integrating it into a larger dataset.

Hygrothermal data enhancement can be performed with several objectives in mind. These include: a) data cleaning by removing outliers, applying a moving average, performing wavelet packet analysis, and correcting for environmental effects; b) data enriching and correlation by calculating the equilibrium moisture content (EMC) from temperature and RH data using the Hailwood and Horrobin equation [14].

This section provides examples of data enhancement for the studied projects.

https://doi.org/10.52202/069179-0507

2.5.1 Reconstruction of missing data

Data monitoring infrastructures are not always fully dependable and data loss during communication is common. Wireless data transmission, such as the LoRaWAN network used in the Hyytiälä forest station monitoring project, is susceptible to various effects that can cause data loss, including signal attenuation in building structures, adaptive spreading factor and transmitting power, interference from other devices, changing transmission conditions, infrastructure outages, and cable interruptions.

To date, wired communication technologies are more reliable than wireless communication technologies. However, during construction works, cable connections and the entire power infrastructure may become less reliable, which can result in outages, and consequently data loss. Table 2 shows percentage of monitoring data loss for the three projects.

To obtain a complete time-series dataset that can be processed by advanced algorithms, such as mold growth models, missing data must be reconstructed using one of the standard methods, such as using the last previous valid data or using linear, cubic, or other interpolation techniques (see, for instance, [17]). Other methods for reconstructing structural health monitoring data, include machine learning and model-based estimation techniques [18-21].

Table 2: *Data loss observed in the three projects.*

Sensor ID & Type / Project	Communication type	Transmission period	Observed data loss
WM1 WAN 33874 / Hyytiälä	wireless LoRa	1 hour	11,2%
WM1 WAN 33875 / Hyytiälä	wireless LoRa	1 hour	8.9%
WM1 WAN 33876 / Hyytiälä	wireless LoRa	1 hour	16,4%
MHT03 + EDGAR converter / InnoRenew	wired RS485+Ethernet	15 min	17.7%
PMM562 / PFSC	Analogue (sensor->DAQ)+ wireless (DAQ -> cloud)	1hour	7.9%

Figure 4 shows an example of MC data reconstruction performed for the data in the Innorenew building using the last valid data in the set.

2.5.2 Data validity check

Temperature and RH measurements are typically assumed to be accurate within the specifications of the sensors used. As a standard practice, the average values of temperature and RH data from multiple sensors are compared to ensure the reliability of the measurements. However, obtaining accurate wood moisture measurements can be challenging due to numerous factors that can affect electric resistance measurements. These factors include the loss of contact between the electrode and the wood, which can lead to erroneous readings of very low moisture levels. Resistance-type meters are also commonly known to become less accurate beyond the fibre saturation point (FSP), as the presence of free water in the wood cell can affect resistance readings. Therefore, all out-of-range data should be filtered from the dataset. Loss of battery capacity can also be a phase during which the data can become corrupted. A simple moving average is often applied for cleaning MC data [6, 8]. When using moving averages in different projects, consistency in the used period is important. In some cases, statistical processing has been implemented to remove unreliable data. In [9-13], wavelet packet analysis was utilized to apply a standardized statistical filtering approach to data collected from various types of sensors. Figure 5 shows trimming of erroneous MC data measured by one of the WM1 WAN sensors in the Hyytiälä's building. Note that it was found that approximately 7% of the data were invalid because they fell outside of the sensor's measuring range. Removal of out-of-range data allowed to observe wood MC changes more accurately within the hygroscopic range.

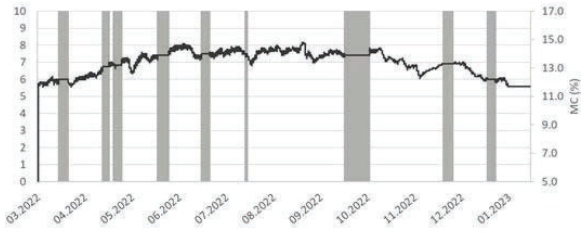

Figure 4. *MC data loss (grey bars) & reconstruction (MC measurement, InnoRenew).*

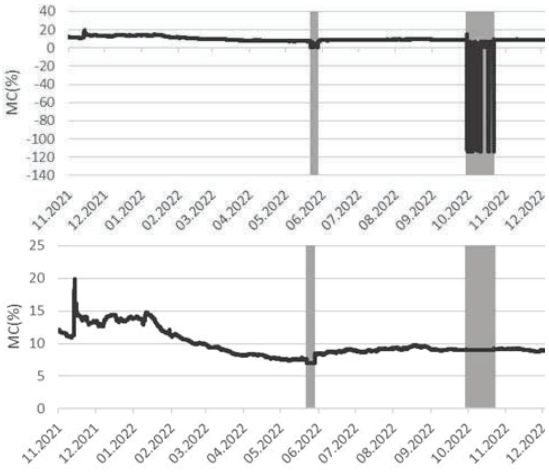

Figure 5. *Data validity check and trim (MC measurement, Hyytiälä) before correction (top), after correction (bottom).*

2.6 DATA ANALYSIS AND VISUALIZATION

This section presents examples of hygrothermal and climate data plotted against construction events, and predicted mold growth curves. The objective is to utilize visualization to facilitate a comprehensive understanding of the data and enable better-informed decision-making. The graphs in Figures 6 and 7 display moisture content (MC) data in CLT walls of the buildings in Corvallis and Hyytiälä, respectively, along with meso-climate data such as air relative humidity and temperature at the wall location, and macro-climate data (i.e., precipitation) recorded at the weather station locations. The unprocessed MC data can aid in identifying patterns in the behaviour of the material during construction, although it may exhibit unrealistic spikes during rainy periods and abrupt drops during lower humidity periods due to direct sensor exposure to precipitation. In addition to the measurements, the graphs in Figures 6 and 7 show the mold growth index calculated using meso-climate data. The Mould index (M-index) is computed utilizing the VTT model [22]. The model considers periods of mold decline, which are influenced by the duration of unfavourable environmental conditions, specifically when the RH falls below a certain threshold.

Vertical lines on the graphs depict certain construction key dates. Figure 6 refers to the first six months of construction of the PFSC in Corvallis. Throughout this period, the monitored location was continuously exposed to outdoor conditions. The plotted MC data correspond to measurements taken in the fourth ply of the CLT panel, from south to north, at the upper part of the tendon shaft of the shear wall. During the monitoring period, the location was subject to wetting, resulting in moisture content (MC) increases exceeding 24%. Subsequently, a slow drying process occurred, bringing the MC to around 18% after 5 months. The M-index, which was calculated using the air temperature and relative humidity (RH) data collected near the installed sensor, indicates a slight risk of mold growth.

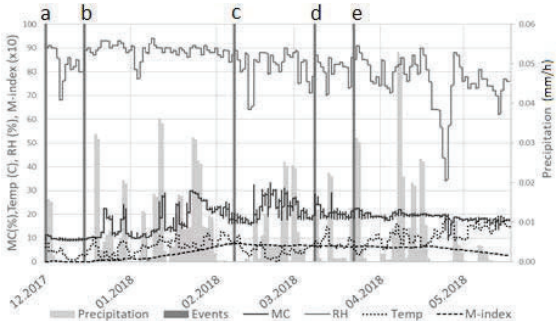

Figure 6. *Corvallis. MC, RH, Temperature, precipitation data, M-index. Vertical lines: (a) installation of sensors in the shear wall; (b) installation of the 1st floor, which partially sheltered the north side of the wall; (c) completion of the roof framing and (d) weather protection, with the exclusion of the stairwell where the monitored shear wall was located; and (e) temporary construction suspension.*

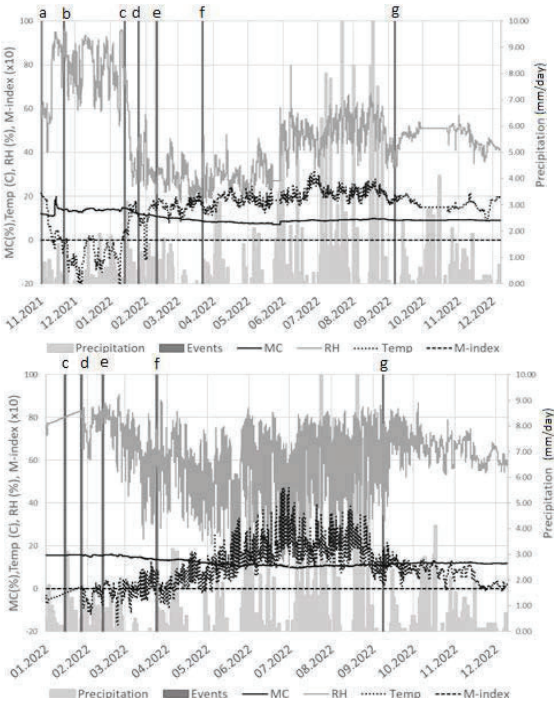

Figure 7. *Hyytiälä. MC, RH, Temperature, Precipitation data, M-index. Vertical lines: (a) installation of the sensors at the CLT facility, (b) wall erection complete, (c) removal of the temporary canopy, (d) installation of windows, (e) indoor heating started, (f) enclosure complete, (g) floor heating turned on.*

Figure 7 depicts the MC readings in two CLT wall locations in Hyytiälä covering a period from transportation to building decommissioning. In all the time the panels were protected from direct exposure to water. The data in Hyytiälä show that, despite some periods of heavier rain in summer, MC values in the panels remained stable and RH did not reach levels of concerns for the development of mold. This is supported

https://doi.org/10.52202/069179-0507

by the calculated M-index. The data also indicates that turning on the heating caused a rapid increase in temperature and a decrease in humidity, which led to a reduction in the wood MC and stabilization at 10%.
A third example, in Figure 8, shows discontinuous MC hand-held readings taken on a CLT floor panel in the building in Izola. The measurements were taken at different depths and positions close to an in-plane floor connection and the average of these readings is presented in the plot. The figure also includes climate data, key construction dates, and the calculated M-index.
As it can be observed, a spike in the MC corresponding to a period of heavy rainfall, which began in December 2020. During this time, the building's structure was complete, but the roofing assembly had not yet been finished, resulting in leaks and wetting of the floor connection details.
The plot also illustrates the increase in the M-index curve calculated from the RH values estimated using the inverse sorption equation based on the MC values [23], as no RH sensors were installed in that location at the time.

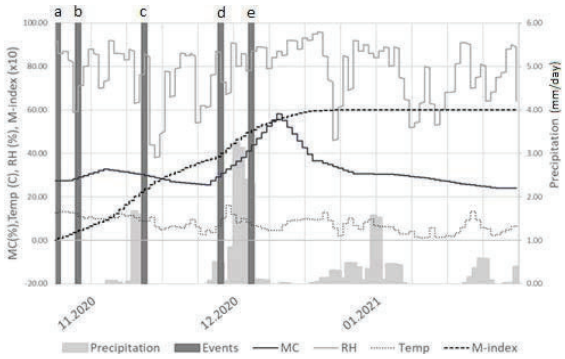

Figure 8. *Izola. MC, RH (estimated), Temperature, precipitation data, M-index. Vertical lines: (a) erection of the CLT floors (b) timber structure complete, (c) window installation complete, (d-e) period of heavy rainfalls and reported leaks.*

2.7 CONTINUING RESEARCH ON A UNIFIED FRAMEWORK FOR DATA EXCHANGE, INTEGRATION AND ANALYSIS

The examples presented in this paper underscore the significance of implementing a data integration framework that can effectively oversee the complexities of merging data from various monitoring projects, while also guaranteeing a smooth and precise integration process.
Such a framework can also provide tools for data analysis, knowledge extraction, and recommendation generation.
Our previous work [24] described a unified framework based on the concept of avatars [25], which are decentralized computing agents that use Web languages and protocols to create a virtual representation of entities such as buildings, building elements, and sensors. This avatar-based framework has been compared to state-of-the-art Structural Health Monitoring (SHM) solutions and offers a promising approach to data exchange, integration, and analysis.
In this approach, each entity in the framework is represented as an avatar, which is a software that operates on a device connected to a physical object. Avatars compute essential information about their corresponding physical objects locally and can share, integrate, and analyse data with nearby avatars. For example, an avatar installed on a building can combine its data with that from an avatar on a meteorological station for moisture monitoring. By elevating the avatar concept to represent individual buildings, the framework overcomes interoperability issues, enables the sharing of information and knowledge among buildings, and promotes the widespread adoption of SHM systems and data exchange.

3 DATA-CORROBORATED ON-SITE OBSERVATIONS

The areas of concern for moisture ingress were primarily observed at edges, gaps, and connection points. Despite the presence of local measures to protect against moisture, such as taping at the floor joints and using end grain sealant at panel cuts, extended exposure to precipitation and limited ventilation in these areas can result in water retention and create conditions that can lead to mold growth. Although using a temporary canopy was successful in preventing the structure Hyytiälä from becoming wet, this practice is not widely accepted in many countries. Therefore, it is important to consider alternative measures to prevent moisture accumulation in vulnerable areas. This can be achieved by locally deflecting water, implementing effective drainage systems, and promoting drying prior to enclosing the mass timber elements in less breathable assemblies.
The detection of checking in the CLT panels in Hyytiälä, developed during a period of significant temperature increase, indicates the need for not only monitoring excessive wetting during construction but also controlling the drying process once the building is enclosed and during its initial period of use. Hygrothermal monitoring data can aid in the creation of effective drying protocols on site to address these concerns.

4 CONCLUSIONS

This paper showcases three hygrothermal monitoring projects in mass timber buildings and emphasizes some factors in a project implementation that impact the quality of data and subsequent opportunities for data integration within a single project and among multiple projects. This paper also explores various methods for improving data quality and introduces a new integrated framework for data management and integration to facilitate the collective use of hygrothermal monitoring data across multiple mass timber projects. Certain data enhancement techniques were particularly applicable to utilizing data in predictive models, particularly for assessing the risk of mold growth.

https://doi.org/10.52202/069179-0507

The hygrothermal data was presented in a format that promotes more comprehensive comprehension of relevant phenomena and facilitates informed decision-making. Hygrothermal data was utilized in conjunction with visual inspection to identify areas of concern, highlighting the potential to improve wetting and drying control in mass timber panel construction through more effective use of data. Effective use of data across multiple projects requires intention and planning during the initial stages of a hygrothermal project. Nonetheless, it offers significant potential to advance our understanding of the behaviour of mass timber buildings over their lifespan, thereby supporting this growing industry.

5 ACKNOWLEDGEMENTS

The authors gratefully acknowledge the U.S. Department of Agriculture's Agricultural Research Service (USDA ARS) for funding the Oregon State University's projects (Agreements No. 58–0202-5–001 and No.58–0204-9–165); the European Commission for funding the InnoRenew CoE project (Grant Agreement #739574) under the Horizon2020 Widespread-Teaming program and the Republic of Slovenia (Investment funding of the Republic of Slovenia and the European Regional Development Fund). TOWARDS DESIGN FLEXIBILITY AND FREEDOM IN MULTI-STOREY TIMBER CONSTRUCTION: ARCHITECTURAL APPLICATIONS OF A NOVEL, ADAPTIVE HOLLOW SLAB BUILDING SYSTEM

Hana Svatoš-Ražnjević[1], Anna Krtschil[2], Luis Orozco[3], Gregor Neubauer[4], Jan Knippers[5], Achim Menges[6]

ABSTRACT: This paper discusses the architectural design potentials of a novel hollow timber slab building system for flexible and adaptive multi-storey timber building typologies. Current timber building systems are defined by their standardized nature, which limits most structures to unidirectional, rigid grids and limits designs to rectilinear layouts. At the same time, recent developments in computational design and digital fabrication open new possibilities to overcome these limitations. In this paper we present four building design applications of a new multi-directional slab building system that allows for a greater level of spatial flexibility and adaptability with free column placement and a tuned network of internal shear webs. These examples expand on previous work through the co-development of building design, skin, building system, and building service integration strategies for a long lifespan and changeable building program. The design applications illustrate open, reprogrammable floor plates that can support three different program states: office, residential, and mixed-use. Furthermore, the novel conceptual approaches to building service integration and the resulting slabs are compared to approaches more common in mass timber construction. Finally, we contextualize the study with related developments and discuss how computational and integrated design thinking could lead to a greater level of design freedom in timber construction and an increased applicability to more complex site conditions than in conventional mass timber construction.

KEYWORDS: multi-storey timber buildings, flexibility, adaptability, multi-directional timber slab, digital design

1 INTRODUCTION

Since the early 2000's, there has been an increase in worldwide construction of multi-storey timber projects [1]–[3]. This is in part due to environmental issues [4], the urbanization and densification of cities [5], [6], and material and building system developments [7], as well as to policy changes that allow taller timber buildings [8]. Although current projections show is a global demand for more building area [9], there is ongoing stagnation in the building industry [10], [11]. Additionally, there is a contradictory situation in which usable buildings are being prematurely demolished when they are considered to no longer be valuable [12]. Adaptable buildings are increasingly important in the face of changing economic incentives, rising material costs that make reuse more economically viable, and climate change [13].

Housing in some Asian countries has always had a shorter life expectancy than in the West, with an average demolition age of about 30 years versus 50-70 [14]. However, studies have shown that in some European countries the average demolition age is between 30 and 60 regardless of the building's program [15]. Furthermore, future demolitions will include buildings constructed only fifty years ago due to current methods of renovation and changing energy performance requirements [16]. In addition, changes in building layers are not made due to elements being obsolete but mostly due to external factors, such as economic or business-models [17]. This may be not only due to buildings being difficult to adapt, but also not designed for longevity or to accommodate future needs.

Timber is suitable for tackling challenges related to stagnation in the building industry because it is a digital material that is easily machinable and highly suitable for prefabrication [8], [18]. It also has a good stiffness to weight ratio [19], making it relatively lightweight for

transportation, and can address challenges related to decarbonization thanks to its great potential for carbon storage [20]–[23]. While timber construction allows for relatively easy building component and process modification compared to concrete and steel, its flexibility is limited by shorter spans and limited architectural typologies [3].

1.1 FLEXIBILITY IN ARCHITECTURE

In literature, the terms adaptability and flexibility have multiple definitions and characteristics attached to them, often with overlapping meanings, such as expandability, polyvalence, or partitionability [24]–[27]. Perhaps the most widely accepted concept is that of separating, or shearing, building layers by their rate of change [17], [28]–[30], because the "longevity of buildings is often determined by how well they can absorb new services technology" [31]. The authors distinguish between two terms: (i) design for flexibility, which refers to the manipulation of design factors that affect the building's adaptability to change [32], and (ii) process flexibility, or flexible planning, which can refer to the ability of a (design) process or a system to adjust to and accommodate change and disruption [33], [34]. Both of these are needed for adaptable buildings and building systems [13].

1.1.1 Approaches to flexible design

There have been many approaches to flexible design throughout history, including, recently, Open Building projects [35]. In general, flexibility has been achieved through the use of an open area as a universal floor plan that can be subdivided into spaces based on need [17]. Therefore, homogeneous spaces and a "generality" of space [36] define the modern concept of flexibility, as opposed to heterogeneous spaces, which exhibit a more diverse range of spatial qualities. Conversely, interchanging and removing components is important for building use conversion [29], [37] as can be seen in projects such as the Multifunk building, whose networks of services and shafts to handle transformation, or the CiWoCo building, which separates service layers and partition walls from the structure [38].

1.1.2 State of the Art flexible projects in timber

While there are many concrete projects with large open floorplates, there are still relatively few flexible projects in timber construction. One of the more flexible projects is Patch 22 in Netherlands, a mass-timber frame project with 9m spans. Its general layout is enabled by a Slimline floor, a concrete slab that rests on timber beams with integrated steel profiles that provide cavities for installations in the raised floor [39]. This floor enables the residents to swap technical systems themselves [40]. Together with hollow floors, no vertical structure in the apartment interiors, a central service core, a tall stories and a high floor load, this produces a flexible and durable design. Another proposal for flexibility in timber construction is the Kiubo construction system, where prefabricated timber modules can be inserted into a concrete skeleton structure [41]. They can be swapped or connected to extend or change the interior requirements. While modular construction is developed at an industrial level, research is also being conducted on future-oriented timber buildings. The project "Convertible wood hybrid for differentiated expansion stages" tested a seven-storey timber frame structure for the use of parking, living, and working [42]. The design aimed for a neutrality of use and utilized recyclable materials at the building, assembly, and material levels. This was achieved through load bearing and window elements that could be reused or had reversible connections, enabling the non-destructive dismantling of components. It had a grid of 5.4m x 7.9m in the beam direction.

1.2 FLEXIBLE TIMBER DESIGN CHALLENGES

Engineered wood products, such as CLT have enabled increased structural performance and new heights of construction. At the same time, studies show that multi-storey timber construction has so far been limited to grid-based and mostly orthogonal and rectangular designs [3], [43]. Although timber construction offers the advantages of automation and prefabrication in terms of speed and cost-effectiveness, current wood building systems are defined by their modular and standardized nature. Even though elements of almost unlimited size and shape can be fabricated out of engineered wood, transport and assembly requirements greatly limit the complexity and scale of these systems and the resulting buildings. This is also partly due to the lack of suitable load transferring connections in timber [44]. In contrast, conventional reinforced concrete or steel structures allow can have larger spans and be more adaptable to site constraints or design intent. Therefore, timber building systems with spans competitive to concrete construction are mostly post-and-beam structures with a comparatively greater structural depth. Beams and girders impact the placement of partition walls, reducing options for interior partitioning and compromising the building's adaptability for future changes of use and therefore its life span.

Timber construction faces additional challenges in terms of flammability and acoustics. Building service integration is therefore often problematic, as services and any openings must be pre-planned and prefabricated.

1.2.1 Building services in mass-timber construction

In mass-timber frame structures, services are most often hung below beneath slabs or integrated between beams to increase flexibility and because they are easier to place and access. Services can also be placed above the structure either as an accessible layer, such as in a raised access floor, or as a permanently embedded layer of the structure, in conduits that run through the concrete topping of the slab. In exposed timber post-and-beam structures, services can be even more integrated, and run through and between structural elements, either through cut outs in timber beams, by staggering the heights of the

beams, or by providing gaps in the structure, such as indents in the assembly of the structural elements. Table 1 shows how these service integration strategies, which can have different impacts on accessibility and freedom of placement of services, can be layered, embedded, or integrated into the building system.

Table 1: *Common horizontal building service integration strategies in post-and-beam mass-timber construction and type of integration based on accessibility.*

Service location	Integration type
Below structure	Layered
Above structure	Layered / Embedded
Through structure	Layered / Integrated

The structural system can inform or inhibit the way the building service systems appear and perform [45]. While the direction of beams can inform service paths, the structural grid can also intersect with MEP (mechanical, electrical, plumbing) paths, resulting in non-systematic overlaps. Additionally, current MEP systems, such as air ducting, are ill-suited to frequent changes of fit outs to adapt to new program or tenant requirements. Finally, the rectangular geometries and 90-degree corners of existing ductwork and mechanical systems are optimized for manufacturing and not for efficient air movement or distribution [46].
To allow timber construction to break free from current limitations and for its architectural possibilities to be competitive with concrete and steel construction, it is necessary to innovate on multiple levels, from design to fabrication processes, including service integration.

1.3 AIM AND SCOPE

This work investigates novel possibilities for multi-storey timber building designs. It showcases both a robust building design process and an adaptive building system capable of greater column spacing, lower structural ceiling depth, and an integrated approach to building services for greater adaptability in multi-storey timber construction. It will describe and compare four design applications of a novel building system as case studies to explore novel design possibilities and changes of building use. It will focus specifically on change in different operations cycles and building service requirements for different programs, and their impact on the design of the building system.
The authors define adaptability as the ability of the building to accommodate different programs throughout its lifetime with minimal costs or changes to the structure, as well as the ability of the building system to adapt to site and design intent. This paper asks the following questions. (I) How can digital fabrication and computational design methods enable novel multi-storey timber building typologies with innovative building service integration, and (II) what overarching, and timber specific design strategies are needed for a building that will change its program over a 100-year building life span.
The resulting case studies will address these questions as conceptual studies and integrative design proposals.

2 BACKGROUND

The research in this paper was conducted as an extension of that done on a resource efficient timber building system within the Cluster of Excellence on Integrative Computational Design and Construction for Architecture (IntCDC). This mono-material building system prioritizes timber over steel for its elements and joints, in contrast to the conventional mass-timber construction. The research included the development of new design, simulation, and fabrication workflows for this building system, as well as the Co-Design of a robotic prefabrication platform for its construction.
The development builds on top of the overarching methodology of Co-Design pursued within the IntCDC [47], and the integrative design workflows of the Institute of Computational Design and Construction (ICD) and Institute of Building Structures and Structural Design (ITKE) at the University of Stuttgart. These have previously been used in the design of resource-efficient high-performance fibre [48] and segmented timber shell structures [49], [50], and have now been extended to multi-storey timber construction. The design application case studies presented in the paper were developed within the "Integrative Technologies and Architectural Design Research" (ITECH) master's programme 20/21 design studio.

2.1 BUILDING SYSTEM DESCRIPTION

The building system is based on a hollow slab consisting of thin upper and lower cross-laminated timber plates connected by internal shear webs tuned to a column layout and allowing for greater flexibility through multi-directional spans (Figure 1).
This level of customization is possible due to direct feedback via an integrated computational design and engineering workflow, resulting in a differentiated web layout, slab segmentation and joint distribution. Several papers already present the following aspects of the system: conceptual development of two previous hollow and solid slab system iterations [51], structural development and integration of structural principles in a computational design methodology [44], different design and simulation methods for internal web reinforcement placement [52], and agent-based methods for column, plate, and web placement [53].
As described by Krtschil et al. [44], the system consists of a hollow slab, columns, and their connections. The slab itself consists of three layers: a top and bottom CLT plate with shear force transferring webs also made of CLT in the middle layer. The webs are oriented by the flow of forces in the slab. The slabs are connected with a glued, stepped edge connection [44]. The column-to-column and

https://doi.org/10.52202/069179-0508

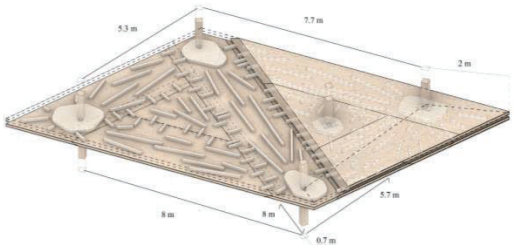

Figure 1: *Multi-directional hollow slab timber building system with internal shear webs.*

column-to-plate connections are reinforced with beech LVL. The columns are connected by a beech LVL pin that transfers the loads through the slab. The column-to-plate connections consist of a solid CLT column crown that brings the high moment and shear forces into the column. The columns can be placed freely inside the slab segments. The system is mono material as it requires no steel connectors.

2.2 STRUCTURAL CAPABILITIES

This first iteration of this building system enables spans up to 8 m and cantilevers up to 1.7 m with a 32 cm deep slab [44]. Further iterations may enable greater spans with only small adjustments in the overall slab depth.
The primary features of the novel system are: (i) large spans with a relatively shallow slab depth, (ii) cantilevers from 0.7 up to 2 m, (iii) corners that can meet at a variety of different angles, and (iv) irregular column placement with varying relations between them.

2.3 ARCHITECTURAL CAPABILITIES

Flat slabs are more flexible than those with beams because they allow greater freedom in partition wall placement. The building system enables design features currently not possible in flat slab timber construction. This includes aspects such as free slab edges, open corners, overhangs, greater freedom and variations in slab outline design and slab openings, non-orthogonal layouts, and large open floors (Figure 2). As such, in contrast to conventional mass timer construction, this building system can adapt to, rather than dictate, the design intent. The hollow cavity within the slab could also be enlarged, to either integrate services or be filled to improve the acoustic behaviour of the slab. The acoustic damping effect would be particularly notable for spans 12 m and above.

3 METHODS

The methods build on top of previous research and explore the application of the proto-architectural timber post and slab building system concept at an architectural scale. They are based on the integrated co-development of the overall building design, building system and building service integration strategies. This process considered robotic fabrication and assembly processes, alongside computational design and engineering methods for multi-storey timber construction.

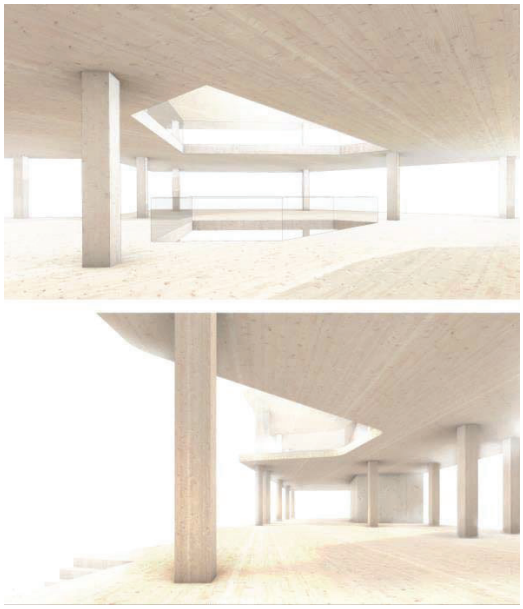

Figure 2: *Interior views of Case Studies 2 (above) and 3 (below).*

3.1 BUILDING DESIGN AND BRIEF

The design brief for the interdisciplinary design studio has been focusing on designing and developing a building system suitable for a long lifespan and change of building program; a “non-programmed” building with a minimum 100-year life span enabling a more flexible and multi-purpose use of space. Therefore, the main interest lies on the exploration of current technical possibilities in timber design and construction rather than on strict adherence to locally applied building codes and regulations.
The four Case Studies are two different architectural building designs on each of two different sites. As Figure 3 shows, the sites were selected due to constraints that typical mass-timber construction would have difficulty adapting to, such as a relatively irregular non-rectangular

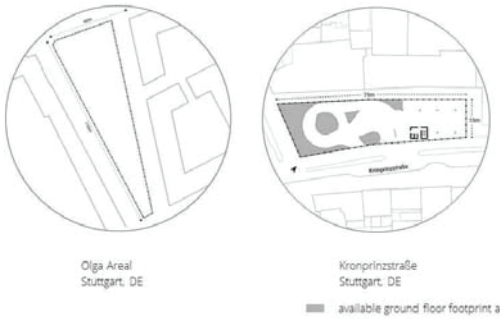

Figure 3: *Sites in Stuttgart, Germany: Olga Areal (left), and Kronprinzstraße (right).*

https://doi.org/10.52202/069179-0508

site form, proximity to neighbouring buildings, and limited footing for construction due to pre-existing construction on site (underground parking).

Within each Case Study the hollow slab building system was extended by considering lateral bracing strategies for the overall structure, building façade design, and an integrated building service distribution strategy.
Each Case Study was then tested in four use cases: (0) the "non-programmed" state, (1) office, (2) residential, and (3) mixed-use program combining commercial with residential, such as a hotel.

3.2 Building System Components and Lifespan

Within this research relative lifespans were established for different building layers or components: permanent structure, semi-permanent building skin and façade elements, and temporary building services frequently adjustable to program changes. Table 2 shows the conceptualized average life span in years.

Table 2: *Relative building elements rate of change*

Building layer	Lifespan (years)
Structure	100+
Building skin	25
Building services	5-15

3.2.1 Structure and Hollow Slab Building System

The focus of the structural system development was to increase lateral stability of the building. Each of the four building designs had their own concepts towards this aim. These included cores, an exoskeleton, shear walls, and timber bracing. Another focus of the building system development was the optimisation of structural timber use, rather than maximising its overall use, with the goal of replacing metal connections whenever possible. The slab system was also reconceptualised to integrate building services, which required new slab segmentation, web placement, and assembly strategy concepts.

3.2.2 Building Skin

The building skin was developed to a conceptual level only, as a semi-permanent substructure that would change minimally regardless of program and service requirements. As detail development was out of scope, this included only aspects such as materiality and modularity. Structural supports are aligned with the façade segmentation and further panel subdivisions are done with future program distribution in mind, as façade subdivision is closely related to internal layout.

3.2.3 Building Services

The following MEP services were considered in the development of the design application case studies: heating, cooling, ventilation, and air conditioning (HVAC), electrical wiring, and plumbing. The focus was on developing overall horizontal and vertical service distribution concepts that would work for all programs despite their different technical needs. Table 3 shows a short overview of these needs. As can be seen, the main challenges were the opposing requirements for quantity of wet spaces, and for centralised versus decentralized HVAC systems, between Office and Residential uses.

Table 3: *Overview of service needs for the programs*

Service type	Office	Residential	Hotel*
Mechanical	centralized	decentralized	both
Plumbing	low	high	high
Electric	exposed	concealed	both

*mixed-use commercial program

3.3 Case Study Comparison

Finally, the four resulting hollow slab building systems are compared from two perspectives: (i) structural, considering slab depth, maximum span, and span directionality, and (ii) building service integration strategy and accessibility concepts in relation to the hollow slab and horizontal distribution of services.

4 Results & Discussion

Figure 4 shows four building designs with different horizontal and vertical building service distribution strategies. Case Study 1 and 2 were designed for an empty wedge-shaped plot. Case Studies 3 and 4 were designed to be built on top of a pre-existing parking lot and to adapt to the car entry and the existing structural grid (Figure 3).

4.1 Case Studies Description

4.1.1 Case Study 1

Case Study 1 relies on its service distribution strategies to create flexibly programmable spaces. This includes cores and temporary shafts for vertical service distribution and a distributed network of services integrated into the hollow slab. The cores' hollow shear walls contain embedded service channels. The temporary vertical shaft locations provide a guideline for partition wall placement, but also act as access points for services in the slab when program change needs horizontal duct rerouting (Figure 4 -I). The partition walls can also provide additional horizontal service distribution. This has several implications on the slab system. One of the most relevant factors determining the possible service locations are the column locations as well as the slab segmentation, as openings for service accessibility need to be carefully considered for structural purposes. The service channels are placed inverse to the column location, which means that the slab openings are located mid span, away from areas with high shear forces, minimizing the structural impact (Figure 5).
The building façade was designed with a varying modular rhythm that matches possible future locations of partition walls. Movable shading modules allow for the enclosing and glazing aspects of the façade to be reconfigured,

https://doi.org/10.52202/069179-0508

reducing the need to disassemble façade panels during use changes. Figure 5 shows how each program can use a different combination of service distribution strategies based on its needs. In the open plan office state wet spaces can be organized around the core with minimal horizontal runs. Electricity can be hung from the ceiling, and HVAC systems can use the core for vertical distribution and the slab for horizontal distribution with ceiling vents at slab access panels. In the residential state, a combination of cores and temporary shafts for vertical distribution and partition walls for horizontal distribution would increase the number of possible wet spaces in the floorplan. HVAC systems would only need to vent kitchens and restrooms, which could be done through the façade by way of partition walls. Electricity could also be integrated in the partition walls. The mixed-use state, such as a hotel, would use the residential strategy for rooms and the office distribution strategy for communal spaces.

4.1.2 Case Study 2

The design of Case Study 2 consists of integrated service channels in the slab for horizontal distribution, and cores and temporary shafts for vertical distribution (Figure 4 - II). Temporary shafts can be deployed when necessary and placed where services from the cores' shear walls cannot reach. Horizontal service lines are branching pathways that run from the cores and cut across the main direction of the webs with access openings carefully positioned between columns. They are arranged based on the shortest path needed to optimize their distribution. The service pathways are envisioned as encased metal ducts ensuring fire and moisture protection. Therefore, in the office state (1), wet spaces are limited to the areas next to the core, while in the residential (2) and mixed-use (3) states the wet space locations can be extended by use of deployable shafts and horizontal plumbing limited to partition walls (Figure 5). HVAC ducts are planned within the slab with venting along the slab edge, while electrical lines are planned within walls and floors. The facade design concept uses a limited number of modular dimensions for easy replacement and maintenance. Only a few custom elements are used, for specific corner conditions, that are expected to have a longer life-span.

4.1.3 Case Study 3

Case Study 3 leverages its site constraints to provide maximum daylighting for both itself and its neighbouring buildings by using terraces and an atrium. The design of the massing, in particular the relatively shallow floorplate depth, enables a thin slab with no integrated services. Services are instead distributed through the cores, while a limited number of temporary shafts link not to the ground but to a service transfer level below the first floor (Figure 4 - III). Wet program placement is therefore limited to the areas within the maximum horizontal run within partition walls from the core and shafts. As such, in the open office scenario (1), plumbing is constrained to areas around the cores, while HVAC systems and electrics are suspended below the ceiling. In contrast, the residential scenario (2)

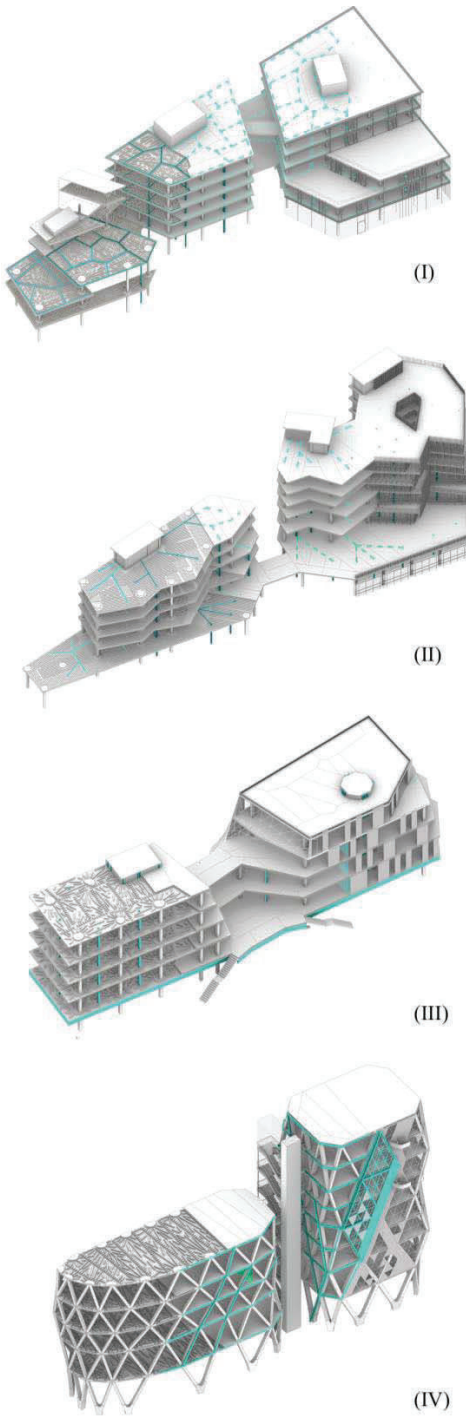

Figure 4: *Case Studies massings and exposed building system with highlighted service integration strategy and building skin design concept.*

Figure 5: *Case Studies plans by different program*

https://doi.org/10.52202/069179-0508

uses a decentralized ventilation strategy in partition walls with exchange vents integrated into the façade. Similarly, electricity and plumbing are mostly integrated into the partition walls. As in other case studies, a mixed-use scenario (3) uses a combination of the two approaches (Figure 5). The façade concept relies on modular segments that can be replaced and swapped over time. The facade provides transparent and opaque modules, and the same system could also integrate new technologies, such as solar panels, as façade elements.

4.1.4 Case Study 4

Case Study 4 is based on the idea of relieving interior space of structural supports for a maximum amount of flexibility and adaptation. Adaptability to the different technical requirements of various programs is achieved through an integrated exoskeleton: the façade, services, and structural supports are organized along the floorplate boundary. Figure 4 - IV show how the façade contains all vertical service distribution channels, while the edge of slab houses the horizontal service runs. From there, partition walls take and distribute the services within the floor plan. As this Case Study's structural core is not within the floor plate, all services are distributed either i) from the façade via partition walls, or ii) as exposed cabling or HVAC ductwork beneath the slab, as is commonly seen in open plan offices, regardless of program. Figure 5 provides an overview of the vertical shafts in the different program states.

The façade is designed to follow the supports, creating areas that are triangulated and subdivided into smaller panels which can be either transparent, for view, or opaque, to conceal services and provide enclosure. The façade frames are perforated to allow (future) services to run freely. The façade layer therefore dictates service placement, level of enclosure needed for the program (transparent or opaque panel), and the rhythm of the partition wall placement.

4.2 Case Study Comparison

4.2.1 Building structure and building system

The Case Studies utilize the circulation core and facades as their primary vertical load-bearing system, with the aim of minimizing the number of internal columns. In Case Study 1, there is only one column placed internally due to span limitations. In Case Studies 2 and 3, column spacing and placement adapt due to design of atriums, terraces, or openings in the slab for increased daylighting. These three studies all use the internal cores for lateral stability. Conversely, Case Study 4 only has structural supports along the façade with no internal columns due to its exoskeleton structure. This choice necessitated longer spans, up to 13.5 m, and therefore also a deeper slab. The case studies all maintained the 110mm dimensions of the top and bottom plates from the previously developed hollow slab system [44] but increased the height of the cavity and therefore the structural depth and the maximum spans (**Feil! Fant ikke referansekilden.**).

Internal web reinforcement and slab segmentation strategies were another factor that varied between Case Studies due to different horizontal service distribution strategies. As can be seen in Figure 5, Case Study 1 has three categories of internal webs based to their structural and service related functions: (i) webs forming closed internal channels to carry ducts for HVAC or electrical cables (plumbing was excluded due to the risk of water damage), (ii) longer span webs which act as internal beams, and (iii) shorter webs that connect different slab panels as well as fill the remaining slab space.

Case Study 2, meanwhile, aims to increase possible cantilevers by placing most webs orthogonal to the direction of the segmented slab. This orientation changes based on stiffness allocation in the slab but is limited to 90° or 45° rotations within the panel (Figure 5). In other Case Studies, slab segmentation and internal web placement are not constrained by service channels. The arrangement of webs is instead governed by the principal moment vectors at their position in the slab, and the slab segmentation is primarily governed by the spanning axis within the floorplate. In Case Study 3 this means a more irregular arrangement of panels, while in Case Study 4 this results in mostly rectangular panels with transitional trapezoidal panels due to the uneven distribution of vertical supports (Figure 5).

4.2.2 Service Integration Strategies

As mentioned in the comparison of internal web reinforcements, the Case Studies show several different approaches for horizontal service distribution within the slab (Figure 6). Case Studies 1-3 all utilize the core as the primary vertical distributor, along with temporary shafts that get utilized based on program needs (Figure 5). These slabs have openings that either are filled by the temporary shafts or act as access panels for maintenance. Whereas Case Studies 1 and 2 concepts embedded both their mechanical and electrical services within the slab, respectively, Case Study 3 relies completely on suspended

Table 4: *Structural depth and maximum span values of the Case Studies.*

Case Study	Structural depth (mm)	Internal cavity (mm)	Maximum span (m)	Service integration	mechanical	electric	plumbing
CS1	420	200	12	within	x	x	n/a

CS4	520	300	13.5	slab edge	x	x	x

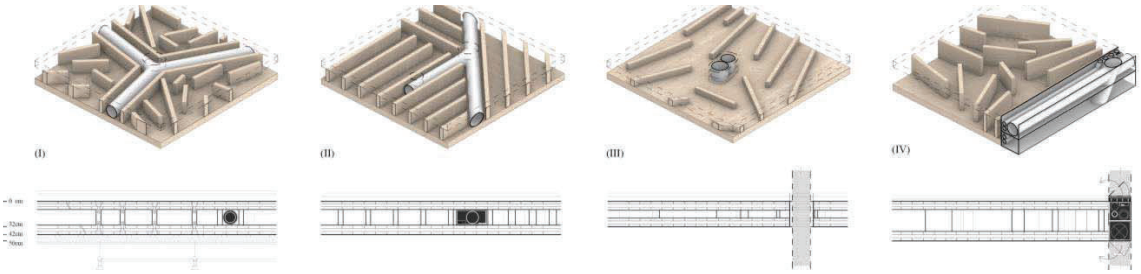

Figure 6: *Case Studies slab comparison with highlighted building service distribution strategies within the slab.*

suspended services or services integrated into partition walls for horizontal distribution. Although Case Study 3 does not integrate any services within the slab, the 100mm shallow cavity could theoretically allow electric cables to pass through. Similarly, Case Study 4 relies on services being integrated into partition walls or suspended below the ceiling. However, due to the façade based vertical distribution strategy, the slab still incorporates full MEP horizontal service distribution along its edge. While other concepts are more embedded or integrated into the slab, services are most separated from the slab in Case Study 4.

5 DISCUSSION

The developed multi-storey timber building system results in multi-directional spans with irregular point support layouts by creating a semi-monolithic slab out of segmented hollow slab plates. Embedding services inside the cavities of these plates results in a smaller overall floor depth, including services and floor and ceiling build-ups, when compared to typical mass-timber construction. This has two effects: the cavity could simultaneously contribute to better acoustic performance; and the system is more complex to fabricate than a solid CLT slab.

5.1 Comparison to common timber systems

As can be seen in Table 5, we compared the performance of some of the timber slab building system products on the market to the performance of the hollow slab system. Although there are products available that offer large spans, they either have greater structural depth, a composite or ribbed structure or offer only uni-directional spans. The most similar product in performance would be the TS3 flat timber slab system which offers bi-directional spanning up to 8x8m grid [54], but further research is being done on TS3 GridBox, a hollow box with a girder grid to reduce costs and save building material [55]. The building system showcased in this study may be more suitable for larger spans of up to 12 m due to increased fabrication complexity and lack of available solid flat slab systems with similar depth and spanning capabilities on the market.

Another aspect gleaned from the comparison is that most systems do not integrate building services in the building system development. This also shows that most building systems today are mainly developed without considering services. As a result, additional height and build-up are needed compared to the case studies of the hollow system where the increased structural height can save overall floor to ceiling height.

5.2 Limitations of the work

The developed case studies are primarily of a conceptual character. They explore novel possibilities for design and construction while considering design, building service, structural, and fabrication limitations. However, they do not provide comprehensive or definitive solutions.

The case studies lack a specific consideration of fire code relating to building class, integration of services and exposure of timber elements. The integration of different elements, such as façade, its' substructure, even partition walls, and their interface with the building system, is also left open.

Our observation is that there are great potentials in integrating service within the structural layer of the slab. However, this development cannot be achieved only by automating service placement and installation in prefabrication. New innovative methods for service rerouting, replacement and maintenance or damage detection with new technologies are needed.

One future promising trajectory of research to address this would be mobile robot service installation or service extrusion. This could expand the possibilities of the timber slab design and make the suggested integration strategies more competitive with systems designed based on and operating on manual serviceability and accessibility. Additionally, it is important to acknowledge that it is very difficult to predict the dimensional, operational, and other requirements of future technologies. Questions about the minimum sizes for internal cavities and access panels for future requirements need to be balanced against structural considerations, particularly spanning performance.

Moreover, there is a trend away from use of suspended ceilings and towards exposed ductworks and services in office environments to gain room height. While in timber construction the use of beams and grid-based design can work in favour of typical ductwork, with a flat ceiling use of conventional service distribution strategies might lead to poor aesthetic quality. Already, enabled by computational design, novel airduct geometries are being developed that enhance air distribution and aesthetic quality [46].

This paper only presents a design proposal and a façade concept. Further analysis is needed on how to integrate lateral supporting structures — such as cores, walls, façade systems, or pre-existing structural elements in other materials — into the building system.

6 CONCLUSION

The presented research shows integrative development of four design applications, and therefore also timber building system variations, of a hollow multi-directional slab for multi-storey construction with structural and building service considerations. The studies showcase novel possibilities for design in timber construction, adapting to conventionally complex site conditions, creating interior spatial situations not currently possible in pure timber construction and change of use during the building life cycle, as well as initial conceptual strategies for building scale application. Compared to typical mass timber systems, the system allows for higher resource efficiency and decreased of wood use due to structurally informed placement of internal reinforcement within a cavity. One of the clear perspectives for new developments in terms of increasing flexibility relates to considering the full life cycle of the system past end of use. The current state of research focused on preventing the necessity of disassembly, however demountability of elements or their reusability were not considered.

The designs leverage complex timber elements that must be prefabricated with strict tolerances. The inherent advantages of integrated design have been used in the design of both the building and the building system. Integrating different phases of program use into the design planning enhances the outcomes of the project and is only possible through an adaptive building system and an adaptive planning process.

ACKNOWLEDGEMENT

The research has been supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy—EXC 2120/1—390831618.

The presented research was partially developed within the master's program "Integrative Technologies and Architectural Design Research" (ITECH) offered by ICD and ITKE at the University of Stuttgart by students of the ITECH 20/21 Design Studio: Pelin Asa, Erik Bauscher, Peng-An Chen, Ayşe Esin Durmaz, Peter Ehvert, Christelle El Feghali, Alan Eskildsen, Michał Gosk, Mengxi He, Harrison Hildebrandt, Matthew Johnson, Hyowook Kim, Philipp Kragl, Chien Chun Kuo, Carolina Leite Vieira, Yuxi Liu, Pinaki Mohanty, Alexandra Pittiglio, Maria Radulescu, Kevin Saslawsky, Ailey Simpson, Tina Soltani, Christian Steixner, Michael Tucker, Tzu-ching Wen, and Seyed Hossein Zargar. Following researchers were involved in the scientific development of the project: Anna Krtschil, Gregor Neubauer, Luis Orozco, and Hana Svatoš-Ražnjević. Special thanks to Visiting Prof. Markus Lager and Visiting Prof. Dr.-Ing. Jochen Stahl, for their timber construction expertise.

All images except for Figure 3 were produced by the authors or adapted and expanded by the authors based on Student Work.

The authors would like to acknowledge our colleagues Cristóbal Tapia and Dr. Simon Aicher (Materials Testing Institute), Theresa Müller and Prof. Philip Leistner (Institute for Acoustics and Building Physics), and Hans-Jakob Wagner (ICD), who developed the novel timber building system as part of IntCDC Research Project 3-1. Additionally, the authors would like to thank the entire class of ITECH 19/20 Studio and the remaining members of the tutor team who contributed to the system development: Simon Bechert and Daniel Sonntag (ITKE) and Dr. Felix Amtsberg (ICD).

Reciprocal frames: an ancestral structural principle to use native wood species in Chile

Suzanne Segeur-Villanueva[1], Natalia Caicedo-Llano[2]

ABSTRACT: Using native wood species instead of introduced wood ones, like Radiata Pine (*Pinus radiata*), has lots of positive consequences from an environmental approach: 1) does not acidifies the soil, 2) makes possible to preserve native flora and fauna. Also, Roble (*Nothofagus obliqua*), Rauli (*Nothofagus alpine*) and Coïgue (*Nothofagus dombeyi*) are the most common native species and have very good structural properties compared to introduced ones. In Chile, regarding primary economic activities, forestry represents 19%. A percentage similar to the contribution to GDP of the agricultural market. However, even if today native species of wood represents 80% of surfaces of forest in the country, the exportation of native wood species represents only 2% of the total wood exportation. Also, in the local market nowadays, native species are used mainly as firewood. Could it be possible, thanks to the study of geometry, specifically an ancestral structural principle called reciprocal frames, to build big spans using only small battens? Is it possible to build structural components avoiding the use of glue or any other chemical products that have negative consequences on the environment? Platform-frame systems in Radiata Pine used for walls or for slabs could be replaced for this type of structural components?

KEYWORDS: nexorade, structural simulations, geometrical studies, revival of ancestral materials

1. INTRODUCTION

We chose wood as the primary material because of its environmental benefits. Wood is: 1) a material that is both renewable and recyclable, 2) one cubic metre of wood stores about one ton of CO_2, as in [1], 3) it has been demonstrated that increasing the use of wood in construction by 17% reduces carbon emissions to the atmosphere by 20%, as in [2], 4) the grey energy required for the transformation of one metre of wood corresponds to 80% of the consumption for concrete transformation and 2% of the consumption for steel transformation, as in [3].

We chose untreated wood, free of glue and free of any other chemical products. We excluded glue because most glues emit formaldehyde, a toxic component that has recently been shown to be carcinogenic, as in [4]. Even though using chemicals products may improve the characteristics of wood, they are also excluded from this research because they are inconsistent with their environmental goals.

We prefer native species of wood because of their natural durability. In other words, they are more resistant to biohazards (termites, bacteria, or fungi) or can withstand them equally to introduced species that have been impregnated. Nonetheless, the most part of impregnation treatments in Chile are with chemical products such as CCA (Chrome, Copper, and Arsenic), which is prohibited in countries such as France due to its toxicity, as in [5]. Some introduced species, such as the Radiata pine (Pinus radiata), present significant biological pollution risks, as in [6].

On top of this, the national native sawn wood production it's been progressively decreasing, preferring Pino Radiata (*Pinus radiata*) and other species. The 2020 formal production of native sawn wood were of 75.714 m3, 34,8% (26,363 m3) Lenga (*Nothofagus pumilio*), 22.6% (17.092 m3) Roble (*Nothofagus obliqua*), and 14.9% (11.282 m3) Coïgue (*Nothofagus dombeyi*), as in [7]. Approximately, 9 million cubic metres of firewood are used per year, as in [9], where 85,9% are native species, as in [8]. On top of this, firewood exploitation is done in an informal way, as in [9], without environmental management, and being the first cause of degradation of the native forest in Chile.

We select a reciprocal frame that is a structural principle made of battens that are supported one after the other. The point where battens meet is called a “nexor”. We divide this structural principle into two categories: one where elements of the structure have a different role, and the other where all elements have the same one, as shown in

[1] Suzanne Segeur-Villanueva, Universidad Politécnica de Valencia, España, susevil1@doctor.upv.es
[2] Natalia Caicedo-Llano, Universidad Tecnológica Metropolitana, Chile, ncaicedo@utem.cl

https://doi.org/10.52202/069179-0509

Figure 1, Figure 2, and Figure 3. We choose this principle instead of another one because it allows us to construct big spans only using short battens. Other structural principles with the same characteristics are tensegrity and interlaced carpentry. The first one is based on a system of isolated components under compression inside a network of continuous tension and arranged in such a way that the compressed members do not touch each other while the prestressed tensioned members delineate the system spatially, as in [10]. The second one is also called interlaced carpentry, in Spanish "*carpintería de lazo*" that means a carpentry made of bows, as in [11]. It is defined also as a combination of "wheels", in Spanish "*ruedas*", as an analogy between the wheel used in mechanics and the wheel drawing method based on the rotation of lines having a point as the centre. Nevertheless, the first one is a system with different materials and different thicknesses and in consequence it has a more complex constructive process. The second one, even choosing the simplest "*rueda*" requires cutting wood on many different angles. In consequence, both constructive systems require more time and are more expensive than the reciprocal frame one.

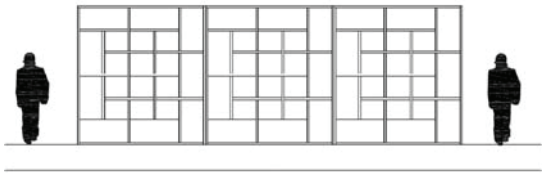

Figure 1. Type A: Reciprocal frame wall, with four jigs

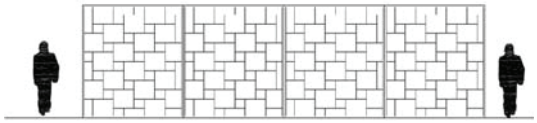

Figure 2. Type B: Reciprocal frame wall, with two jigs

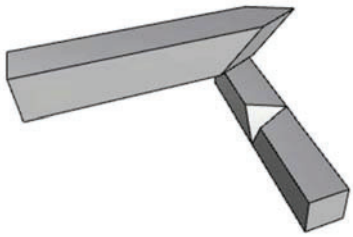

Figure 3. Construction detail of type B jigs

2. METHODOLOGY

We present the criteria considered for the purpose of this paper: a species selection, followed by a geometry selection and at the end a structural selection.

2.1 SPECIES SELECTION CRITERION

To select wood to be used, seven criteria were considered, using the database previously created (Caicedo y Segeur, 2021).

The following criteria, were selected:

C1 Origin of the wood, selecting native wood and excluding introduced species.

C2 Species conservation, excluding species at risk (NT), endangered (EN), or vulnerable (VU).

C3 Mechanical characteristics. The selection was done by their largest compressive parallel to grain stress.

C4 Mechanical characteristics. The selection was done by their largest compressive perpendicular to grain stress.

C5 Natural durability to bio- hazard, avoids the use of chemicals and others to protect the wood from the environmental conditions of the site.

C6 Capacity to dry naturally.

C7 Availability on the market.

Criteria C3, C4, C5, C6, is a numerical ordering value. Criterion C1, C2, C7 is an exclusion selection.

2.2 GEOMETRY SELECTION CRITERION

Several patterns of reciprocal structures were explored, using the geometry of the square as a basis, evaluating the ease of fabrication, assembly, and transport of each one of them. In figure 4 is shown reciprocal frame wall with four jigs. In the circles red and purple are shown the different types of joints. In yellow, pink, blue and green are shown the jigs. In figure 5 is shown a reciprocal frame wall with two jigs. On both examples the joint type is the one that determine the number of jigs. We exclude a different type of jig when the batten only needs to be cut when it is located on the periphery of the panel.

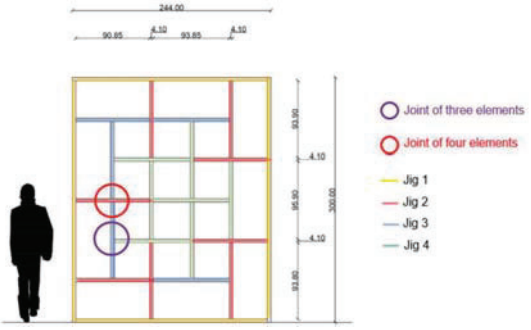

Figure 4. Reciprocal frame wall with four jigs.

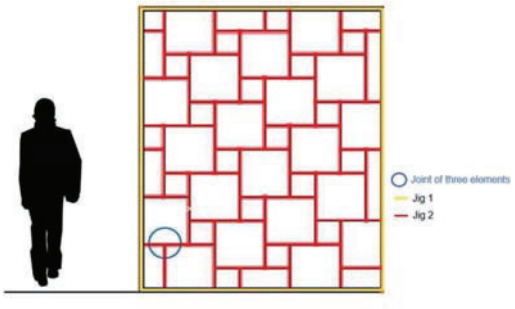

Figure 5. Reciprocal frame wall with two jigs.

To create models with different geometries we parameterized prototypes allowing us to make modifications with relative ease, developing adjustments to improve the performance of the whole system. We used the software Rhinoceros, more specifically a plug-in called Grasshopper as in Figure 6.

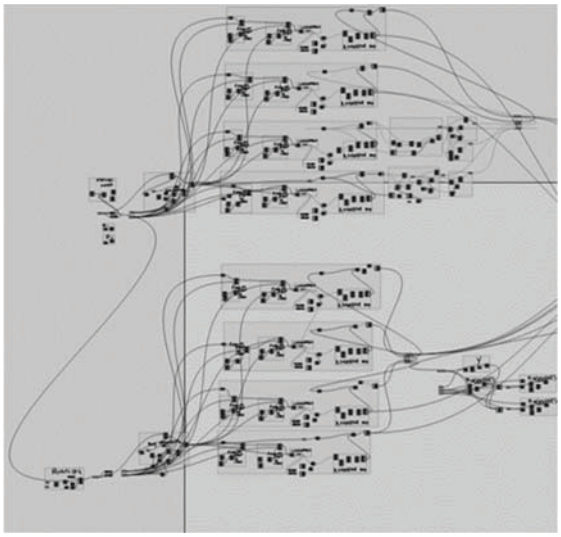

Figure 6. Algorithm wrote in Grasshopper to create different geometries.

Among the parameters used, the following two aspects were considered: batten morphology, and batten geometry. More specifically, the location of joints and the shim between them. In figure 7 is shown a jig modelled in Rhinoceros.

One of the aspects to consider is the size of joints. There is a 0,33 mm gap between the batten and the void where the batten will be placed in the 3D printing prototypes. This gap will have to be adjusted again when changing scale and materiality between models. Reaching a more accurate solution when working with native wood species.

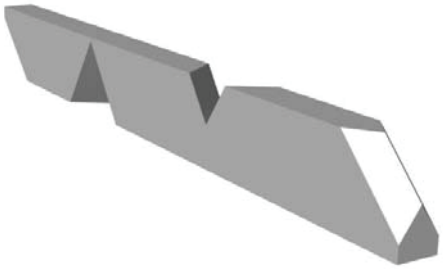

Figure 7. Jig modelled in Rhinoceros

2.3 STRUCTURAL SELECTION CRITERION

The third step was to compare structural simulations and budgets of a typical Radiata Pine (*Pinus radiata*) platform-frame module with a native wood species one based on a reciprocal frame. Because the mechanical properties of native species are better than the Radiata Pine (*Pinus radiata*) ones, the section of the first one is smaller.

For this purpose, preliminary evaluations of the prototype structure were carried out considering a 1.2 * 2.4 metres frame, since this module corresponds to the standardised wood measurements sold in Chile.

3. RESULTS

3.1 SPECIE SELECTION RESULTS

We gathered information from thirty-four wood species. From them, only thirteen can be considered because they fulfil criteria C1 and C2, origin and conservation respectively.

In figure 8 is shown a ranking of compressive parallel to grain stress of Chilean native wood species according to criteria C3.

https://doi.org/10.52202/069179-0509

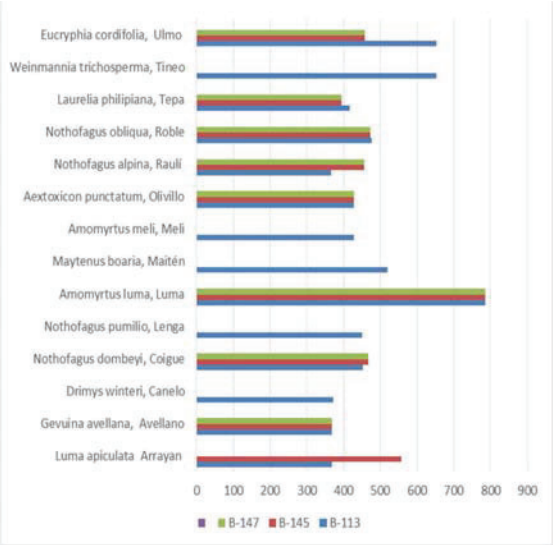

Figure 8 Ranking of compressive parallel to grain stress of Chilean native wood species

In figure 9 is shown a ranking of compressive perpendicular to grain stress of Chilean native wood species, according to criteria C4.

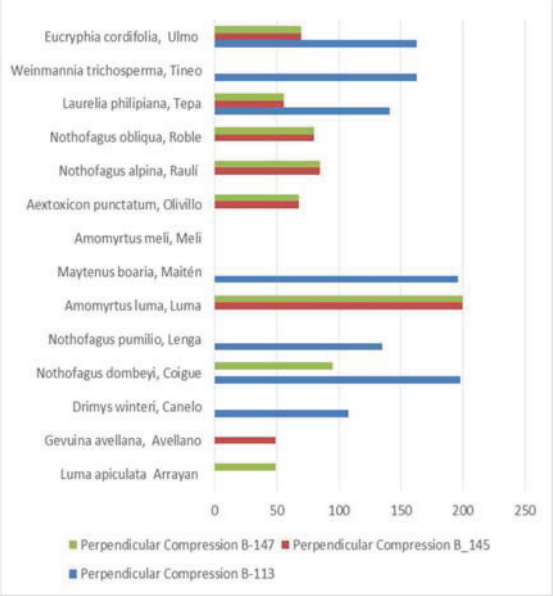

Figure 9 Ranking of compressive perpendicular to grain stress of Chilean native wood species

In figure 10 we present a ranking of natural durability to biohazards of Chilean native wood species

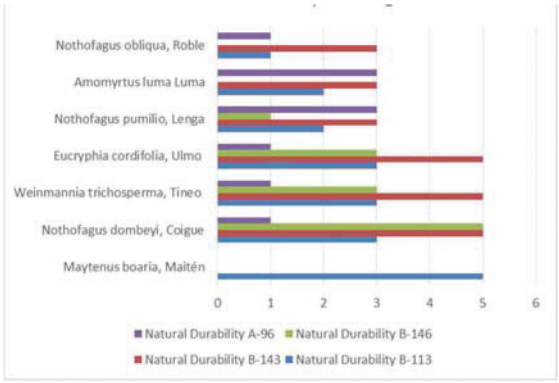

Figure 10 Ranking of natural durability to biohazards of Chilean native wood species

We select the top 7 species from the remaining thirteen species represented in Figures 8, 9 and 10. Based on rankings of compressive parallel to grain stress, compressive perpendicular to grain stress and natural durability. The new ranking is then generated based on a physical attribute of native species that is its capacity to dry easily. The final selection criteria considers seven species. Information is compiled from the following references: [12] corresponding to B-113, [13] corresponding to B-144, [14] corresponding to B-145, and [15]corresponding to B-147.

In figure 11 is shown a ranking of the capacity of drying of Chilean native wood species.

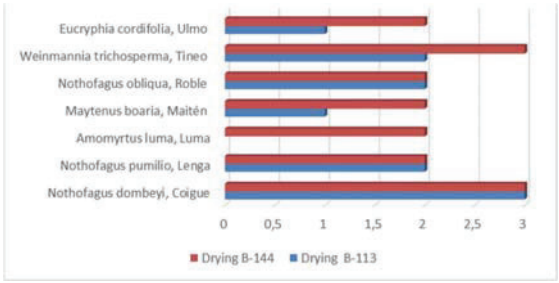

Figure 11 Ranking of the capacity of drying of Chilean native wood species.

The following four species with the best performance were chosen based on the final criterion C7.

Coigue (*Nothofagus dombeyi)*
Tineo (*Weinmannia trichosperma)*
Roble (*Nothofagus obliqua)*
Lenga (*Nothofagus pumilio)*

In table 1 is shown a comparison of Chilean native species filtered by price divided by cubic metre.

Table 1: *Comparison of Chilean native species filtered by price divided by cubic metre ($/m3), own elaboration, according to [7].*

Native species planed and nominal sizes	($/m^3)	Region
Coigue (*Nothofagus dombeyi)*	945	Malleco
Tineo (*Weinmannia trichosperma)*	561	Ranco
Roble (*Nothofagus obliqua)*	919	Llanquihue
Lenga (*Nothofagus pumilio)*	449	Ranco

3.2 GEOMETRY SELECTION RESULTS

Geometry studies were conducted to apply several structural systems to a particular geometry, as shown in the picture. The following literary works served as the foundation for the structure systems under study: reciprocal frame [16], "Armaduras de Lazo" as in [11], and as in Sebastiano Serlio's technique [17]. In Figure 12 is shown how a reciprocal frame based on a square with 2 jigs inscribed in a rectangle.

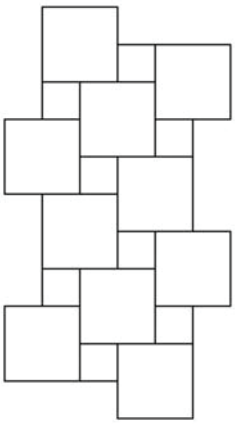

Figure 12 Reciprocal frame based on a square with 2 jigs.

The same wood section, a minimum number of jigs, and the simplest joints were the guiding principles for all geometrical analysis.

In Figure 13 is shown a plan of a standard panel prototype.

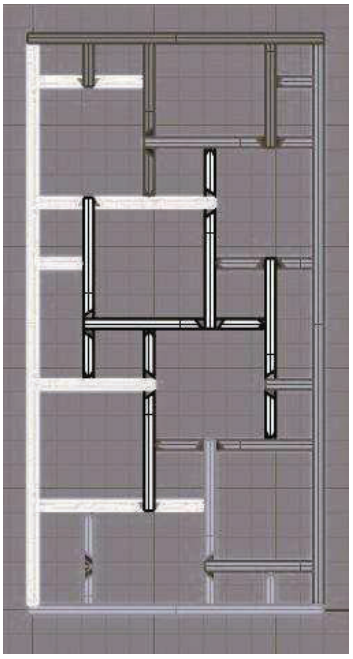

Figure 13 Plan of a panel prototype

When designing joints, we decided to optimise the production selecting 2 diagonal cuts instead of 2 verticals and 2 diagonals, as in Figure 14 and 15 respectively. Using this simplified type of batten fewer adjustments of the full-scale wood prototype are required.

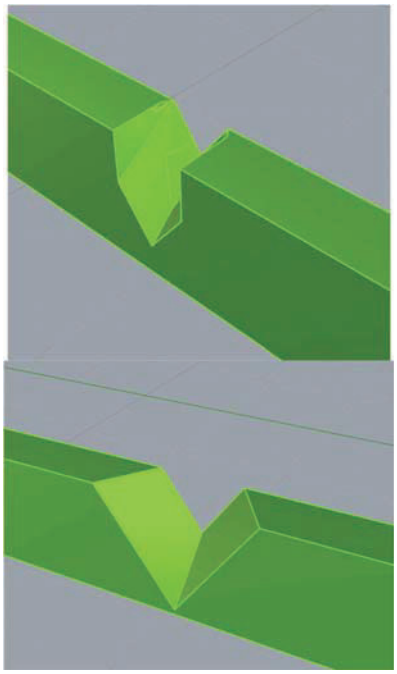

Figure 14 - 15 3D printed batten's prototype.

In Figure 16 is shown a 3D printed joint of two battens. In Figure 17 is shown a 3D printed portion of the prototype panel.

https://doi.org/10.52202/069179-0509

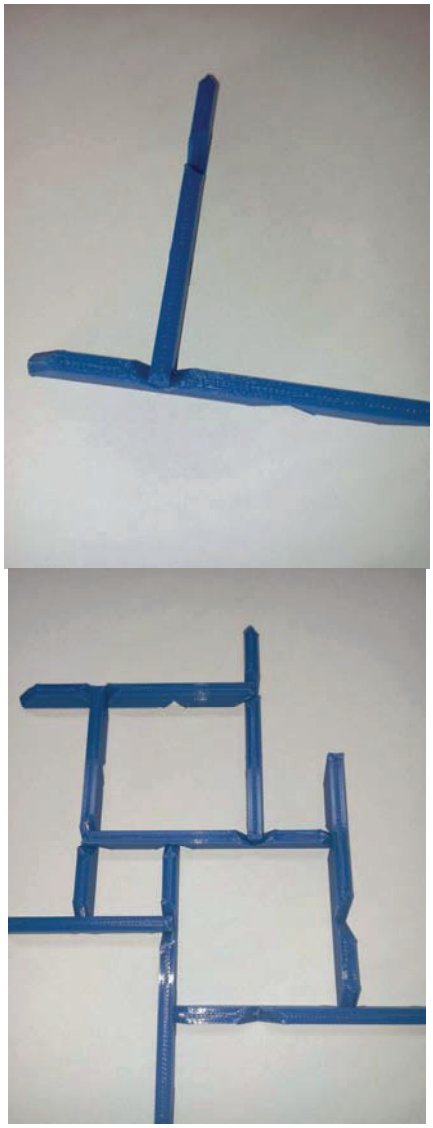

Figure 16 3D printed joint of two battens. **Figure 17** 3D printed portion of the prototype panel.

3.3 STRUCTURAL PRELIMINAR RESULTS

We calculated a traditional Radiata Pine (Pinus radiata) panel, and a Chilean native wood species based on a reciprocal frame geometry.

Seismic and wind loads were considered for the calculation of both panels. We considered a lateral load of 7 kN/m and a vertical load of 12,38 kN/m according to NCh 1537.

The results shown in the preliminary figures 18 and 19, demonstrate a smaller critical reaction in the first panel than in the second one, with 9,33 kN and 15,42 kN respectively. On the opposite, a smaller critical moment in the first panel than in the second one, with 2,03 kN/m and 0,32 kN/m respectively. Because critical reactions and critical moments are very close between both panels, we expect than the section required for the second panel is smaller because the mechanical properties of the Tineo (Weinmannia trichosperma) and the Roble (Nothofagus obliqua) are a lot better than the Radiata Pine (Pinus radiata) ones.

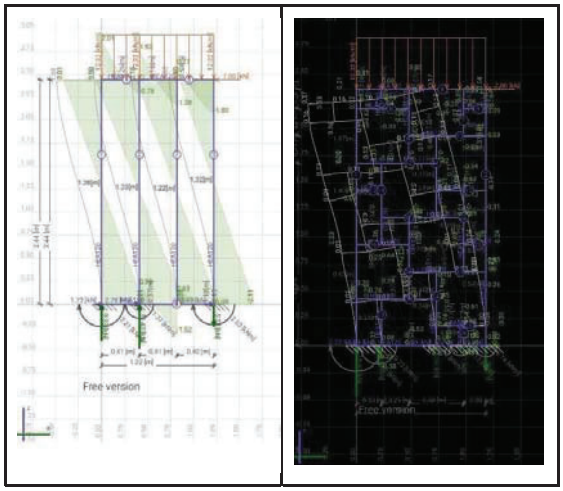

Figure 18-19 Preliminary traditional and reciprocal frame structural analysis

4. CONCLUSIONS

We conclude that it is conceivable to construct with small battens and large spans as a result of the study of geometry, notably the ancient structural principle known as reciprocal frames. Additionally, it is feasible to construct structural elements without using glue or any other chemical substances that have negative consequences for the environment. Radiata Pine (Pinus radiata) platform-frame systems used for walls or slabs can be swapped out for structural elements of a reciprocal frame.

Regarding the selection of native species, we decided to choose potential species that meet specific mechanical properties, a high natural durability, a high capacity to dry, and a low economic cost. We conclude that Tineo (*Weinmannia trichosperma*) is the species best suited for this purpose. His straight trunk can measure 40 m height and 2 m diameter. It would provide structural wood applications instead of current market use like finishes, veneer, or furniture. The second native species is Roble (*Nothofagus obliqua*). It was chosen to facilitate the prototype stage. Although this species has a less good drying capacity, it is easier to get due to its greater availability throughout Chile.

Regarding a geometric criterion, two sizes of square are the basis for the design of the chosen reciprocal frame. They are made from a single batten that is connected at two locations that are equally spaced from its edges. As a result, only two battens are needed, the bigger inner batten and the edge batten

https://doi.org/10.52202/069179-0509

that often makes up a fraction of the batten, need to be built for each panel. The structural frame serves as the foundation for fitting the final panel. The prefabrication of the parts is optimised by this design, resulting in higher quality, more control, and reduced costs.

In terms of joint design, changes must be made to ensure that the shim and pressure prevent slippage and the transfer of mechanical stresses between battens by simplifying the junction with a diagonal cut on both sides. To assess whether additional design modifications or the use of reinforcing dowels are necessary, these alterations should be compared on a full-scale.

One of the research's current constraints is the flexibility provided by the 3D printed members. It only permits a limited fit between parts and requires adjustments in wood size prototypes in order to change the design parameters and enhance the prototype outcomes. The usage of the selected species for the creation of the scaled prototypes and ultimately the full-scale prototypes for testing and assessment will constitute the second stage of the research.

Development of a new type of building in tropical regions based on the energetic performance and recovery of recycled wood

Horly Luzolo Nsumbu[1, 2], Régis Pommier[1], Denis Bruneau [3], Alain Sempey[1]

ABSTRACT: The Congo Basin is the second world largest tropical forest. This world heritage plays a decisive role in the global warming and the services for the world populations. Its management and preservation is one of the success keys in the future. Despite a strong development of the wood industry in the region observed in recent years, almost no waste of products is sustainably recovered for a possible re use. Very few scientific works address the question of the valuation of related products from the wood transformation in Africa. In this present work, several ways of recovering this waste are studied. Based on a wooden made building case study, with local material in Gabon, we measure, simulate and optimize the hygrothermal comfort of the house from its components. The thermo-physical and mechanical characterization of some first materials consisting of Padouk sawdust plus a lime-based mortar are presented. The instrumentation work of the building made of these new materials completes the study in order to know the components best suited for a sustainable construction in tropical regions. Multi-physical measurements and modeling on the prototype building make it possible to propose new constructive solutions integrating the requirements and objectives of sustainable development.

KEYWORDS: re-use of wood waste, circular design for sustainability, building system, timber engineering, hygrothermal comfort, sustainable development, the Congo basin, tropical regions

1 INTRODUCTION

The Congo Basin (CB), the second largest tropical forest massif in the world, just behind the Amazon, extends over 6 Central African countries including the DRC[3], Gabon, Congo, Cameroon, Equatorial Guinea and CAR[4] (fig. 1). Thanks to its area of approximately 6 million km² and its immense wealth of biodiversity (fauna and flora), this world heritage plays a crucial and determining role in climate regulation.

***Figure 1**: Cartography of rainforests of Congo Basin. (Source: G.A. Kombila & al., 2019).*

The importance of these Central African forests on the ecological, economic, social and cultural levels has placed them at the heart of international discussions aimed at preserving these unique ecosystems essential to the proper functioning of the planet (FRM, 2018). The timber industry in most of these CB countries is based mainly on the export of logs abroad. In Gabon, between 2004 and 2009, the annual volume of log exports averaged 1.7 million m3. And it is since 2010 that the export of logs is prohibited. This decision by the public authorities aims to encourage the private sector to carry out local wood processing, potentially generating more added value and better management of the resource (A.G. Kombila, 2019).

This obligation to process the wood locally has a direct impact on the production of logs on Gabonese soil. Indeed, the production of processed wood increased from a collection of 281,331 m3 in 2009 to 824,072 m3 in 2017, an increase of 192.9%. (A.G. Kombila, 2019). The local transformation of wood by total or partial cessation of log exports has become one of the major objectives of forestry development in most countries of the Congo Basin. These wood processing operations generate large quantities of waste (ranging from sawdust, shavings, to pieces of plank).

In Gabon, as in the other CB countries, waste from wood processing is very insufficiently valued. Almost all of it is used by local populations as a source of energy, as a sanitation component in the poultry sector, or else abandoned in wild dumps, thus contributing to environmental pollution. This waste is therefore not recovered under economically and ecologically satisfactory conditions, with a view to reuse by the wood industry or in another sector of crucial importance such as construction. The technologies for processing related products of the tropical timber industry within the reach of the populations of developing countries constitute a field that is very little addressed in the international scientific literature. At the same time, this BC sub-region, like most African countries where the majority of the population is rural, has a great deficit in decent housing. A study led by researchers from the London School of Hygiene & Tropical Medicine on the African continent between 2000 and 2015, estimates that 53 million urban Africans (in the countries analyzed) still lived in slum conditions in 2015 (UN-Habitat, 2016). A situation which should worsen with the strong demographic growth in forecast and which will have to be accompanied by a net increase in basic needs, including food and housing. According to the UN-Habitat report (2016), the African population will approach 2 billion by 2040. In addition, the concern to reduce energy consumption and the carbon footprint of the construction sector around the world and the preservation of exhaustible resources today make the use of bio-based on materials unavoidable. The aim is to integrate the tropical timber processing industry as best as possible into the process of sustainable development in the sub-region, so as not to suffer from waste, but to make it a lever for the development of the circular economy, guarantee of sustainable development.

In this work, we present a successful construction with only made of defects from the sawmill plus a raw red clay. The paper presents the material made and the first results

3 DRC: Democratic Republic of Congo

4 CAR: Central African Republic

https://doi.org/10.52202/069179-0510

on the building performance for which two types of wall are instrumented and the energy performance is analyzed.

2 MATERIALS AND METHODS

2.1 PRESENTATION OF THE STUDIED BUILDING

The building project is located in the special economic zone of Gabon, in Nkok, located 27 km from Libreville the capital (0° 23′ 24″ North, 9° 27′ 15″ East).

***Figure 2**: Prototype wood-frame building*

This wooden frame house, built from wood waste from the wood processing industry in Gabon. This building (R + 1) of approximately 85 m² of total living space, it is one of the first prototypes of an eco-responsible construction with a high rate of valorization of local resources in the special economic zone of Gabon (GSEZ). The species used mainly is Padouk, renowned for its good mechanical performance and its attractive natural durability, which make it the wood of choice for exterior landscaping. It is the wood used at more than 80%, mainly for load-bearing structures; This gives the building good durability in the face of Gabon's harsh climate. The building has two levels: ground floor and first floor. On the ground floor, the building serves as a staff house, consisting of a bedroom, a bathroom, a small living room, an external, independent kitchen, and a courtyard serving as a space of conviviality. Upstairs, there is a large room of around 50 m², which serves as a showroom and meeting room, and a small WC area of around 1 m².

2.2 MATERIAL PROCESSING TECHNOLOGY AND CHARACTERISATION

Large quantities of shavings and sawdust are produced in the sawmill but they are not still used in industry in Gabon. The question is highly critical when short solid woods are considered as a defect and burned in the best situation. Concerning solid wood, the technology used consist by the utilize of the French technology of green finger jointing i.e. wood undried in an undetermined moisture content (high to 15%) (R. Pommier & al) with a Polyurethane specially developed for hardwood from tropical region (R. Lissouck & al.). These solid woods are used in the building as the structural part and the cladding.

The other part of the by-products of the sawmill are used for filling and insulation. With a view to enhancing them effectively, a composite material made up of a mixture of sawdust and wood. An experimental design is made and followed in the next tables. Two categories of composite materials are designed. The first category consists of composite materials made by valuing shavings from Padouk and a hydraulic solution based on slaked lime from the local paint industry, used as a hydraulic binder (Table 1).

***Table 1**: Sample compositions of composite materials - category 1 and processing methods.*

	Wood chips [%.vol]	Sawdust [%.vol]	Aqueous solution of lime [%.vol]	How to implement
M1	50	25	25	Moulding without compaction
M2	50	25	25	Moulding with compaction

The second category (Table 2) includes composite materials made mainly from Padouk wood chips, local raw earth and slaked lime marketed in Gabon.

***Table 2**: Sample formulations of composite materials-category2*

C / F	Wood chips (%.mass)	Sawdust (%.mass)	Earth (%.mass)	Slaked lime (%.mass)
F1	30	0	40	30
F2	30	0	40	30
F3	40	0	40	20
F4	40	0	5	10
F5	0	50	20	30
F6	0	25	50	25
F7	25	0	60	15
F8	20	0	60	20

The goal is to find the right material, that is to say the best suited to the construction method of the chosen building and to the external climatic conditions that the building

https://doi.org/10.52202/069179-0510

must face. Thus, the material should represent a good compromise between thermal inertia and thermal insulation.

2.3 CONSTRUCTIVE MODE AND QUALITY OF THE BUILDING

2.3.1 Constructive mode

In order to reduce construction time and deal with logistical difficulties (for an average wood processing plant), the 1100 mm long panels are manufactured in the workshop and installed on site, thus requiring skilled labor. reduced work. About 12 m3 of wood is estimated for the entire construction, 100 % of which comes from offcuts and wood that cannot be marketed on the market. The wall consists only of an exterior facing (exterior cladding in Padouk), a polyethylene membrane and an interior facing (plywood of 15 mm), between which there is a void, representing an air gap of 80 mm (figure 3).

1: Plywood (15 mm); 2: Air (80 mm) ; 3: Polyethylene membrane (0.5 mm); 4: Exterior cladding in Padouk (10 mm)

***Figure 3**: Initial building wall composition*

2.3.2 Analysis of climate conditions and building quality

According to the Köppen classification, the Libreville region has a tropical savannah climate. Its average annual temperature is 26.3°C and its rainfall averages 1970.6 mm per year (DGMN, 2018). July is the driest month with 14 mm of precipitation, while October is the wettest month with 307 mm of rain. The building must then deal with these waves of heat and humidity, and guarantee to the occupants a good level of comfort. The building being light, the temperatures recorded inside the building are, for the most part, 30 – 33°C, temperatures above the recommended comfort limits (B. Givoni, 1978).

Wood material being a light and relatively rigid material, its acoustic insulation properties are not beyond reproach. In addition, the state of its surface which is compact and relatively smooth does not allow the wood to dampen noise, but it would tend to amplify it. The large hollow (void) in the walls also contributes to the propagation of noise. The integration of a material in the wooden frame structure is one of the possible solutions to optimize the performance of the building (hygrothermal and acoustic). In terms of energy, this material will have to provide, on the one hand, inertia and thermal insulation to limit heat exchange between the building and the outside environment through the walls, and on the other hand, sound insulation and thus improve the comfort of the occupants [17-18] and [21 - 25].

3 THERMAL ANALYSIS

3.1 THEMAL CHARACTERIZATION OF THE COMPOSITE MATERIAL

The guarded hot plate method (ISO 8302 standard) is used to determine the main thermal properties under steady state conditions. The principle of the experimental setup consists in maintaining a temperature difference ΔT between two flat parallel plates brought to constant temperatures T1 and T2. The sample of thickness e is positioned between the two plates (Ting-Ting Wu, 2011).

Several researchers worked on the thermal characterization of tropical wood. R. Mvondo & al. assessed the Influence of moisture content on the thermo-physical properties of tropical wood species; in (P.S. Ngohe-Ekam & al.) and (S.A. Smith & al.), thermal properties of some main tropical hardwood specie are studied and determined. In this current work, we then focus on the characterization of the designed composite material.

Using the thermal characterization bench of the I2M Bordeaux laboratory which is based on the “guarded hot plate” method, we determined the thermal conductivity (λ) and the specific heat capacity (Cp). Bulk density was also determined. Table 3 shows the main values of this characterization.

3.2 INSTRUMENTATION OF WALLS

The objective of the instrumentation is to ensure the measurement of the temperature and relative humidity gradients within the different walls and in the atmosphere, in order to evaluate the damping and the phase shifts in the different transient states studied (figures 5a, 5b and 5c). The selected temperature and humidity sensors are Sensirion SHT 85. These sensors have a standard tolerance announced by the manufacturer of 0.1°C between 20 and 60°C and 1.5% RH in humidity. They have the advantage of having a limited size (7 mm wide) but are sensitive in humid and alkaline environments [F. Collet & al, 2019]. We also use a mini Davis brand weather station which provides us with data on the site's microclimate. These data are temperature and relative humidity of the outside air, sunshine, precipitation, and wind speed and direction. The observation time is 3 days, from January 23 to 25, 2023.

https://doi.org/10.52202/069179-0510

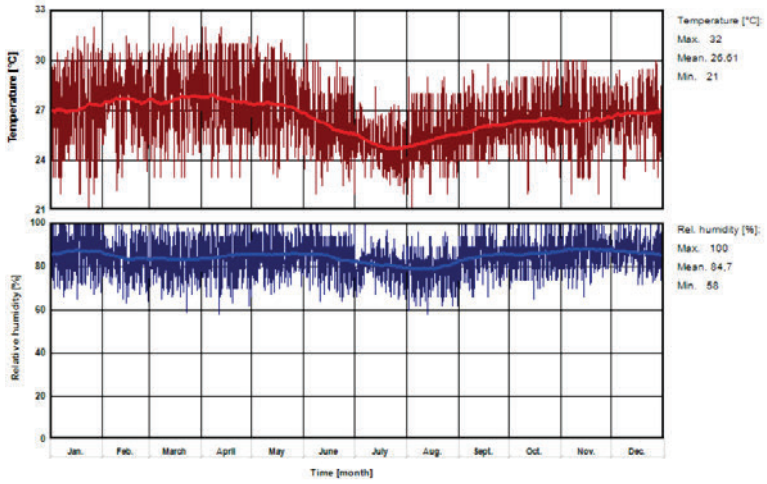

***Figure 4**: Climate conditions of Libreville: (a) Annual temperature; (b) annual relative humidity [ASHRAE].*

3.3.1 Integration of innovative composite material in the wall

***Figure 6**: Installation of materials based on wood chips in the wall and settle of temperature and humidity sensors.*

Blocks of dimensions 14 cm × 7 cm × 7 cm are used to fill one type of wall (wall 2).

For a first test, the installation of these insulating materials is done in a portion of the wall of the prototype building. The choice of the facade is meticulously analyzed by using SunEarthTools which is an open source tool specially designed for the sizing of solar plants. Libreville being at the level of the Equator, the sun passes through its highest trajectory. Consequently, the East and West facades will be the most exposed to sunshine for this geographical location, and therefore the most vulnerable to overheating in a construction in Libreville, while the North and South facades will be the least exposed to the sun. This analysis allows us to choose the west facade as an experimental wall for an analysis of the hygrothermal behavior of the building envelope because of its strong interactions with the outside, resulting from the activity of the sun on it.

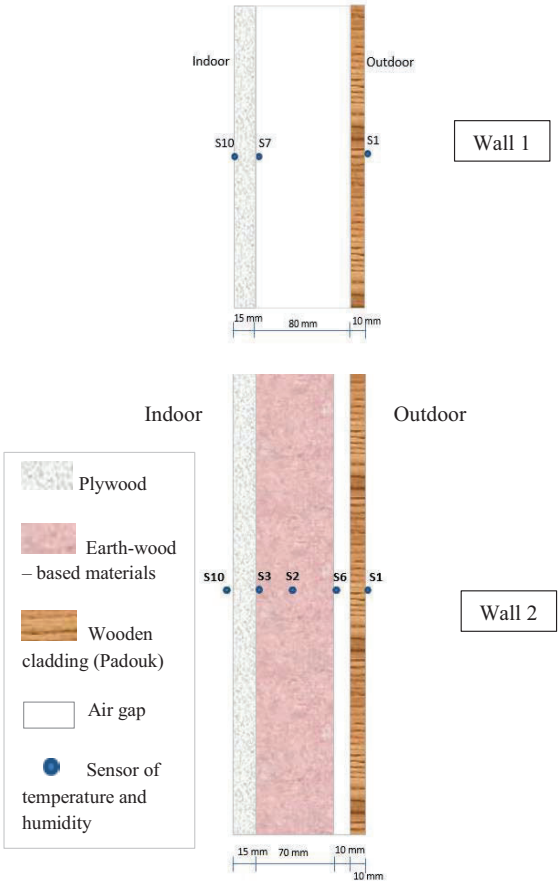

***Figure 5**: Two types of instrumented walls (Wall 1 and Wall 2)*

4 RESULTS AND DISCUSSIONS

4.1 RESULTS

https://doi.org/10.52202/069179-0510

The first results of the thermo-physical characterization of the samples are listed in Table 3.

At this stage, only samples of the first formulation (M1) are tested to determined thermal conductivity and thermal capacity. The analysis of the results from the thermal characterization of this composite material reminds us of chipboard wood panels,–due to the similarity of their thermo-physical properties (ρ, λ and Cp) [13-14].

The composite materials of category 2 (from F1 to F8) presented in the table 3, even without thermal test in the lab, are more cohesive and rigid.

***Tableau 3**: Characteristics of the samples of composite material*

	Apparent Density ρ [kg/m3]	Thermal conductivity λ [W/(m.K)]	Thermal capacity Cp [J/(kg.K)]	Drying time [days]
M1	735	0,1372 – 0.1530	1 500 - 1600	32
M2	850	-	-	32
F1	605	-	-	9
F2	630	-	-	10
F3	515	-	-	10
F4	450	-	-	12
F5	505	-	-	9
F6	520	-	-	9
F7	760	-	-	10
F8	850	-	-	12

These first results allow us to orient the use of the material in the wooden frame structure as filling material. Its low thermal conductivity value of around 0.15 (about ten times less than that of solid concrete) and its good thermal capacity (Cp > 1500 J/(kgK)) give it essential properties of an insulating material.

The figure 7 shows us the evolution of temperatures in the different layers of the wall of the wood frame building. Two cases are presented.

In the first type of wall (Fig. 7.a), the temperature at the surface of the interior facing **S7** varies in the same way as the temperature at the level of the wooden claddings, which constitute the exterior facing. We observe a slight phase shift of the order of 1 to 2 hours between **S1** and **S7** (37th hour and 39th hour of observation). The very low inertia of this wall (wall without heavy materials) promotes a fairly rapid increase in temperature under the influence of external conditions.

The large layer of air (80 mm) inside hardly behaves as an insulator because the inside air is not trapped and therefore subject to heat transfer by convection. This **S7** temperature climbs to reach 36°C on the second day of the observation while the outside air temperature is around 33°C.

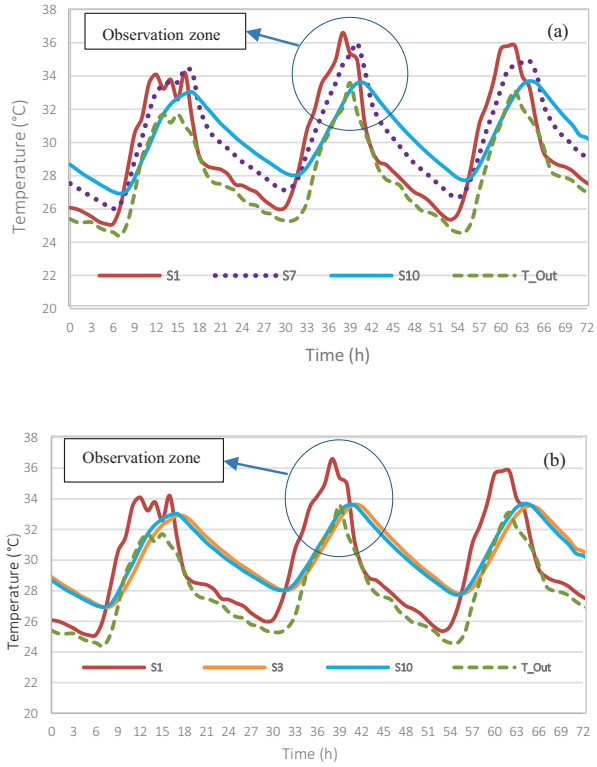

***Figure 7**: Temperatures in walls observed in 3 days: (a) wall 1 and (b) wall 2.*

In the second wall composition (figure 7.b), the integration of earth bricks and chips brings inertia to the wall. This results in a phase shift of 4h, observed between **S1** and **S3**.

5 CONCLUSION AND PERSPECTIVES

This work presented one of the ways of valorization of co-products of the wood processing industry in the construction sector. A prototype timber frame building made of reclaimed wood was presented and analyzed. Two types of vertical walls were considered in this study. The instrumentation of these walls made it possible to evaluate their thermal performance, according to the heat exchanges with the surrounding environment. From this analysis, the second type of wall show out interesting characteristics including thermal inertia, conferred on it by the integration of earth-wood chip bricks. This integration allows a significant phase shift and damping, compared to the first one (wall 1). In addition, these wood-

https://doi.org/10.52202/069179-0510

based on materials, installed in an optimal way, could have a positive effect and then contribute to improving the acoustic comfort of the occupants.

In this study, only heat exchanges were analyzed. The consideration of mass transfers in the evaluation of the comfort of the building could be the subject of a future study. Next research will be made, such as establishing the link between the composition of the earth, its microstructure and the mechanical behavior of these composite earth-wood chip materials. We will aim to extend the study period (over the two main seasons) to get the most exhaustive data possible from physical measurements in situ in order to analyze the hygrothermal behavior of the wall and to assess the impact of these wood-based materials. We will also think about determining the thermal, hydric and mechanical properties in the lab and using them in modeling and numerical simulation at the scale of the building.

ACKNOWLEDGEMENT

The authors would like to thank the E2WP Chair of the University of Bordeaux and the companies Cap Exo, Wood Tech Gabon for the material and financial support.

USING CO-DESIGN FOR DEVELOPING A NEW WOODEN FAÇADE SYSTEM

Camilla Schlyter[1], Karin Sandberg[2]

ABSTRACT: The objective is to demonstrate the co-operative design (co-design) and production development process of a new wooden façade system.

Today, architects and designers are seldom involved in the development process when designing new products within the wood building industry. The architect and the actors in the wood value chain are far from understanding their respective standpoints in new product development, thus creating a gap. This gap between actors hinders innovation and can mean that valuable design knowledge and methods are not used that can promote innovation in the wood building industry.

In this paper we demonstrate how the development process of the façade system is profoundly influenced and improved by incorporating knowledge of the design process.

Product development is becoming more and more complex and therefore more knowledge intense. This was addressed by working in parallel with partners coming from different areas of expertise, resulting in a co-design process considering aesthetic and functional requirements as well as the industrial manufacturing processes, interactively, throughout the entire development process.

Using co-design when designing an adaptable facade system has proven to enable assessment of complex requirements, resulting in a sustainable system that can ensure good quality on material, aesthetics, and functions.

KEYWORDS: Façade design, Cladding, Heartwood, Design process, Co-design, Adaptable design

1 INTRODUCTION

There are many divergent wishes on what a facade system should fulfil. From building regulations, government requirements to societal perspectives, as well as aesthetic and functional requirements such as adaptation to existing contexts.

Architects and builders are showing an increasing interest in using wood as façade material in urban contexts. A modern facade system must be attractive and easy to use for architects to design, easy to manufacture and easy to mount and maintain [1].

New product development in the wood building industry is complex and therefore knowledge intensive. Wood is a complex material that requires many skills in the value chain from the forest to the creation of new products.

Society demands that future building systems provide a well-designed environment, are sustainable, reusable and circular, adaptable design wise to different environments and manufactured in an environmentally sound and resource-efficient manner. This complexity leads to a need for an increased number of involved experts in new product development. According to Perks [2], these rapid changes mean that the demands on design knowledge increase dramatically. Researchers acknowledge that knowledge about design and design processes takes on an increasingly prominent role in product development [3], [4].

Actors in the wood value chain are often far from understanding each other's driving forces and needs, which creates problems concerning new product development. Architects, who are responsible for design, are used to collaborating in collective processes and "raising their gaze" in design processes and thereby contributing to a more holistic approach. The gap between actors hinders innovation in new product development and can mean that valuable design knowledge and methods are not used that can promote innovation in the timber construction industry.

In the project " Facade of the city Swift, Stylish, Smart" hereafter called the project, it was identified how the gap,

more specifically between architects' and industry's perspectives and goals could approach these challenges [5].

Faced with an abundance of classifications of collaborative activities within design, so called co-operative design (co-design), here the definition presented by Saunders and Stappers [6] is used.

Working systematically together using co-design methods has proven to be of vital importance resulting in product innovation and exchange of knowledge between partners. De Vere and Fennessy argues that "If … design has a role to play as an agent for change, an inclination to working in participatory ways with a co-design mindset seems sensible "[7]. The project shows that the architect can have a decisive role in the development of new products within the wood building industry by using knowledge of design and co-design methods.

Adaptable design is a design paradigm aiming at creating designs and products that can be adapted for different requirements and influenced by users. An existing design of a product can be adapted to create a new or modified design based on changed requirements. Adaptive design enables manufactures to produce standardized products that are possible for end users to customize [8].

The objective with this article is to demonstrate the co-design and production development process of a new wooden façade system [9,1]. A co-design process was developed considering design and functional requirements as well as industrial manufacturing processes throughout the value chain interactively and in parallel with partners coming from different areas of expertise. The purpose was creating an adaptable, changeable and flexible design easy to use for architects and still economically viable.

The result is increased knowledge about design processes using co-design methods in new product development within the wood building industry.

2 METHODS

A new wooden façade system must be fast and safe to assemble, there must be a variation in the aesthetical expression, and it must be sustainable, adapted to regulations and possible to manufacture industrially.
