Several studies have been conducted to assess the environmental impacts and resource consumption of UHPC production [e.g. 12–14]. Additionally, standard UHPC mixtures with eventually more sustainable UHPC mixtures have been compared, for example, by partly replacing cement with blast furnace sly or fly ash [13]. The environmental performance of UHPC compared to common concrete is comparatively assessed by, for example, *Sameer at al.* [12] and *Ji et al.* [14]. The results show, that the environmental impacts of UHPC are much higher than of commonly used concrete related to a functional unit of 1 m³ [14]. This is mainly because less than 50 % of the amount of cement used in UHPC is necessary for the concrete [14]. For common German concrete C20/25, the cement production is responsible for 82 % of the global warming potential (178 kgCO2-eq./m³) and approximately 56 % of non-renewable primary energy consumption (912 MJ) of the concrete production [15]. This is significantly influenced by the

https://doi.org/10.52202/069179-0132

deacidification process of limestone as well as the energy required for that process during the production of cement clinker [15,16]. Nevertheless, UHPC shows higher strength properties and hence, dependent on the boundary conditions such as geometry and load, smaller cross-sectional dimensions can be required for an UHPC element than for a common concrete element [13,17].

2.3 Functional equivalency in comparative LCA

For a comparative assessment of different construction components, a functional equivalent must be determined by defining the main functional requirements combined with the intended purpose of use [18,3]. In the study of *Kromoser and Holzhaider* [4] for example, for the comparison of different timber-concrete composite ceilings, the functional equivalent of load-bearing capacity was chosen. In other studies, the U-value of walls is taken into consideration, because outer walls and the secondary structure are considered [e.g. 10]. Nevertheless, it has to be mentioned, that according to the European Construction Product Regulation (EU CPR), construction products have to fulfil several basic requirements at once to ensure "[…] health and safety of persons involved throughout the life cycle […]" [19]. These requirements do not only include static and hygrothermal aspects, but also e.g. fire resistance, sound insulation, energy consumption, health aspects and sustainable resource consumption [19].

3 METHOD – GOAL AND SCOPE DEFINITION

3.1 GOAL

The aim is to conduct a life cycle analysis of the hybrid CLT walls in comparison with CLT and reinforced concrete walls. The comparison is intended to provide a comparative statement on the environmental performance of the walls in terms of the load-bearing capacity. In such way it should be investigated if the hybrid CLT wall brings advantages concerning the environmental impacts.

3.2 SCOPE

3.2.1 Product system

For the comparative life cycle assessment, walls in three different construction methods are evaluated: A hybrid CLT wall, a CLT wall and a reinforced concrete wall (see Figure 3)

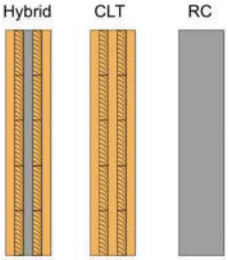

Figure 3: *Vertical sections of the three studies product systems for the comparative LCA*

The hybrid CLT wall consists of lamellas equal to CLT-lamellas, but the core is replaced by ultra-high performing concrete (UHPC) lamellas. The number of layers can, equal to CLT, vary between three, five, and seven layers. In this study, the focus is only on 5 layered CLT and hybrid CLT walls, as this is a very commonly used composition in practice. This study considers a continuous UHPC lamella instead of accounting a squared timber and a specific amount of grout.

3.2.2 System boundaries and data

The LCA is conducted for the functional unit of 1 m² surface area of a wall. The thickness of the wall varies dependent on the applied load and is therefore part of the functional equivalent for the comparison.

For the assessment only *GaBi* Datasets with Germany as regional system boundary are considered.

The LCA covers the manufacturing stage A1-3 (A4-5 is neglected because of lacking data), as well as the deconstruction stage C1-4. The loads and advantages of recycling and recovery are separately shown outside the system boundary in module D [18]. An exchange of the primary load-bearing structure during the life cycle is not necessary (Module B4) because the secondary structure (e.g. insulation, cladding) is responsible for its durable protection during the life cycle. In this study, the consideration of the "full life cycle" refers to modules A1-3 (production stage), module B4 and modules C1-4 (End-of-Life stage).

This study does not consider material losses during production and waste treatment. Further, side streams during the production stage are assumed to be insignificant or are covered by the applied *GaBi* datasets. Moreover, concerning concrete and UHPC, it should be noted that the environmental benefits of carbonation during the life cycle are not considered in this research.

Concerning the consideration at End-of-Life, the instructions of DIN 15804 are followed [18]. The End-of-Life scenarios shown in Figure 4 are evaluated for the walls in different construction methods.

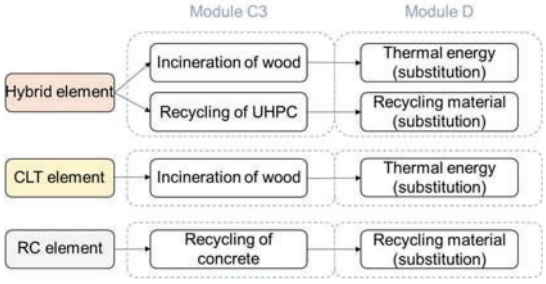

Figure 4: *End-of-Life scenarios for the studied walls in different construction methods*

For the reinforced concrete wall, neither loads nor benefits are accounted for the steel in module C3, similar to the dataset for *ready-mixed concrete C20/25* of the *Ökobaudat* database [20]. Additionally, in the dataset, it is supposed that 25 % of the material is landfilled and 75 % of the inert material is further used as filling material e.g. for streets (substitution) [20]. In this research a

https://doi.org/10.52202/069179-0132

simplified approach is used, assuming that 100 % of the inert material substitutes primary filling material.
For the CLT wall, a thermal recovery scenario is assumed. Hence, the environmental impacts due to the incineration of the wall are accounted in module C3 and only the benefits of the substitution of the recovered energy are accounted in module D.
For the hybrid CLT wall, a separation into wooden lamellas and UHPC-lamellas seems possible, because the two materials could be separated either by e.g. using an excavator to scrape off the wood or by using a mill or a saw to separate the wall. The milling or sawing is possible due to the very precise production of the hybrid CLT wall. In such way the thermal recovery of the wood as well as the treatment and use of the UHPC as filling material is seen as a realistic future scenario. Consequently, the assumptions and simplifications made for CLT and reinforced concrete are also made for the hybrid CLT wall.

3.3 Functional equivalent

Since the load-bearing capacity is the main functional requirement of the considered internal walls, this is the necessary functional equivalent for the comparison.
For this purpose, an equal load is applied to the walls of the different construction methods. This load is then linearly increased until the maximum load-bearing capacity of the walls is reached. The environmental impacts related to the resulting cross-sections of the walls should then give answers to the above-mentioned research questions. For the sake of simplicity, further basic functions required by the EU CPR [19], like fire safety or sound protection are neglected in this article. Moreover, the thermal conductivity is not part of the consideration, because this would be relevant for the assessment of external walls.

3.4 Impact indicators

To calculate information about the environmental impacts, the impact indicator climate change Global Warming Potential (GWP) is considered. As required in DIN EN 15804+A2 [18], the GWP_{total} is separated into GWP_{fossil}, $GWP_{biogenic}$ and GWP_{luluc} (land use and land use change). GWP_{luluc} does not have to be declared when it contributes to less than 5% of the GWP_{total} caused in the declared modules (module D excluded).

4 LIFE CYCLE INVENTORY

4.1 Variations of cross-sectional dimensions

To compare the environmental impacts of functionally equivalent walls in terms of their load-bearing capacity, an equal design load F_d [kN] has been applied, as shown in Figure 2. By stepwise increasing the load, the cross-sectional dimensions of the walls of different construction methods change. Only five layered CLT and hybrid CLT walls were assessed. However, cross-sections of wooden lamellas with a longitudinal layer thickness of more than 40 mm consist of two adhered lamellas (see Figure 5). These seven layered walls were still considered, because the lamella orientation and consequently the load-bearing principle does not change.

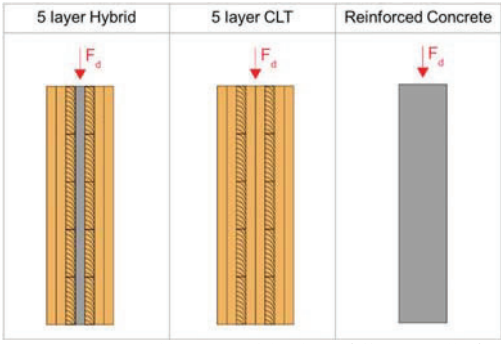

Figure 5: *Vertical sections of the three different walls dependent on the construction method*

F_d was stepwise increased by 100 kN/m considering a 1 m long wall. For dimensioning, a 3 m high hinged column was investigated. This leads to an imperfection of approximately 8 mm regarding 2nd order theory [21]. Fire safety was not included within the calculations.
The CLT and hybrid CLT walls were calculated according to shear-force analogy. All reinforced concrete walls were calculated according to DIN EN 1992-1-1:2011-01 [22]. Table 1 summarizes all strength values and further boundary conditions considered in the calculation.

Table 1: *Boundary conditions for the calculation of the walls under a load increase in steps of 100 kN*

CLT	
•	CLT layers - strength class: C24
Hybrid CLT	
•	Separate wooden layers - strength class: C24
•	UHPC lamella - strength values:
	Youngs modulus: 45000 [MN/m²]
	Shear modulus: 19489 [MN/m²]
	Compressive strength: 132,5 [MN/m²]
Reinforced concrete	
•	Exposure class: XC1
•	Steel grade: S 355
•	Strength class: C 25/30

To obtain functional equivalent results in terms of the load-bearing capacity, the aim was to consider the loads and respective cross-sectional dimensions with, at best, equal performance ratios. Since standard lamella thicknesses were used for the calculations, a performance ratio between 0.75 to 1.0 has been assumed as “equal”. For the reinforced concrete walls, a minimum thickness of 100 mm is required [22,23]. Nevertheless, in this study, a minimum thickness of 150 mm was considered to ensure the practical feasibility of mounting such walls and to compact the concrete despite the required minimum amount of reinforcement. Hence, due to the wall thickness

of the reinforced concrete of 150 mm, the performance ratio is below 0.75 up to a load of 2100 kN.
Figure 6 exemplarily shows the results for different construction methods under increasing loads. Here, the thickness per 1 m² surface area, and hence, the volume of the different walls, is shown.

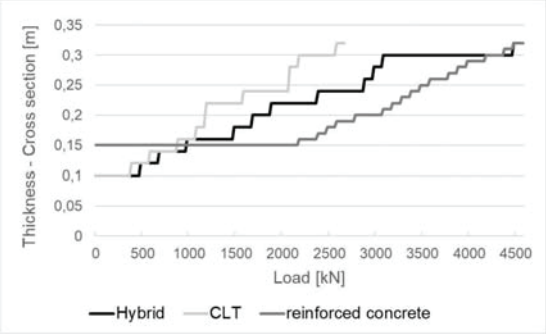

Figure 6: *Wall thickness [m] dependent on the applied load for a hybrid CLT, a CLT and a reinforced concrete wall*

For a standard CLT wall with five layers, the maximum load is reached at 2600 kN (cross-section: 80-40-80-40-80). The hybrid CLT wall with five layers reaches a maximum possible load of 4500 kN. A further increase in the load would lead to larger CLT or hybrid CLT wall cross-sections, which are normally not available on the market. Therefore, no additional cross-sections are calculated for increased loads in the case of these two construction methods.
No such limitation regarding wall thickness exists when considering reinforced concrete. Therefore, the cross-sections for the reinforced concrete wall are shown for loads of up to 4600 kN. At load levels higher than 1000 kN, the cross-section of the reinforced concrete wall is constantly smaller than that of the CLT and the hybrid CLT wall. At 4400 kN, this changes and the cross-section of the reinforced concrete wall becomes ticker than that of the hybrid CLT wall. In this study, the strength class of the concrete is constantly set to C25/30. Under the same load, the use of a higher strength class could lead to thinner cross-sections. However, an equivalent volume of concrete with a higher strength class also has greater environmental impacts [15]. For simplification, the effect of this correlation on the environmental impact results for reinforced concrete, is not part of this study but should be further investigated in detail.

4.2 Production stage - LCI

4.2.1 UHPC lamellas - LCI and LCIA

To calculate the environmental impacts of a hybrid CLT wall, the environmental impacts of UHPC (raw density of 2.500 kg/m³) must be determined. For the LCA modelling of the UHPC, the walls and further background data, the *GaBi Software and Database for Life Cycle Engineering* (*GaBi*) from *Sphera Solutions* was used. The *GaBi* database does not provide any dataset for UHPC. Hence UHPC production had to be modelled.

The calculation of the environmental impacts of 1 m³ UHPC was based on a composition without reinforcing steel fibers, which has been used for the completed research project [1]. Additionally, the research results of *Sameer et al.* [12] for 1 m³ precast UHPC have been considered. The transportation distances as well as the consumption of fuel and electricity are calculated to produce 1 m³ of precast UHPC [12]. Similar to *Sameer et al.* [12], material losses during production are neglected in this consideration. Further, the formwork is not considered because, like for common concrete, it is assumed to have no significant impact due to the number of uses [24]. Moreover, the electricity and fuel consumption for the treatment of the UHPC lamella after stripping the formwork are neglected according to the cut-off criteria of DIN EN 15804 [18], because it is assumed, that they account for less than 5 % of the energy and resource inputs for UHPC production.
Figure 7 shows the GWP_{fossil} results for 1 m³ UHPC in comparison with 1 m³ concrete C25/30. These results are used in the following sections to calculate the environmental impacts of the hybrid walls. Compared to the results for a concrete C25/30, the $GWP_{fossil.}$ of UHPC is nearly 60% higher.

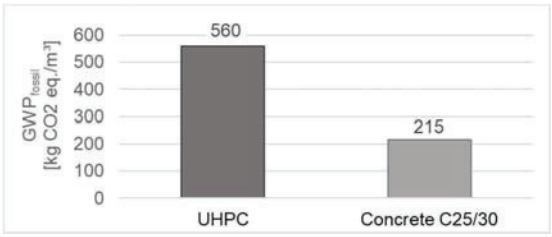

Figure 7: *GWP_{fossil} results for 1 m³ UHPC in comparison to 1 m³ concrete C25/30*

4.2.2 Hybrid CLT wall - LCI

To produce a hybrid CLT wall, the production steps described in the research of *Oberndorfer et al.* [1] are necessary. Table 2 lists the flows and processes required for the production stage of the hybrid CLT wall. Dependent on the cross-sectional dimensions of the wall and the corresponding thicknesses of the lamellas, the quantity of the input flows concerning the UHPC and the wooden lamellas varies.

Table 2: *Input flows to produce 1 m² hybrid CLT wall*

Input flow	quantity	Source
UHPC	*Varies [kg]	[*]
Wooden lamellas (adhesive included)	*Varies [kg]	[*]
Adhesive between UHPC and wooden lamellas	0,34 [kg]	[1]
Truck transport	*Varies [tkm]	[**]

*Dependent on applied load
**Dependent on amount of adhesive and UHPC-lamella thickness

https://doi.org/10.52202/069179-0132

It is assumed that the production of the hybrid CLT wall takes place in a CLT-factory. As the hybrid CLT wall basically is a CLT wall with a different core lamella, the production process is supposed to be equal to the one of a CLT wall, except for the adhesion of the core UHPC-lamellas to the wooden lamellas. For 1 m² surface area, 170 g of adhesive was applied. Hence, both sides of the UHPC lamella require 340 g/m² [1]. As until now, the adhesion process is manually conducted, no further electricity or fuel is consumed.
Due to similar production steps and because the focus is on the comparison of the different construction methods, the data set being used for the CLT wall is used for the bonded lamellas of the hybrid CLT wall. Until now, the *GaBi* database does not contain any dataset for CLT. In the German database *Ökobaudat*, datasets for Glue Laminated Timber (GLT) and CLT can be found. These datasets are based on the findings of *Rüter and Diederichs* [25], who used *Gabi* for simulation. The dataset for modules A1-3 of 1 m³ GLT shows a slightly higher share of GWP_{fossil} and a lower share of $GWP_{biogenic}$ than the dataset for 1 m³ CLT. This might result in slightly higher results for GWP_{fossil} and lower results for $GWP_{biogenic}$. Hence, because the focus of this study is on the comparison of different walls, the dataset for GLT has been used.

4.3 Deconstruction stage - LCI

For the End-of-Life consideration, the deconstruction processes for the walls (module C1) as well as the transportation distances (module C2) are considered as equal for the three different construction methods.
For the demolition scenario, the findings of *Sameer et al.* [12], who focused on the demolition of precast UHPC, are taken into account. Due to lacking robust data for buildings, an average transport distance of 20 km from the demolition site to the waste treatment factory is considered.
For waste separation (module C3) of the hybrid CLT wall an electricity consumption for the milling process of 3,4 kWh/m² is assumed due to lacking robust data.
The benefits from the substitution of gravel as filling material with recycled concrete and the benefits of the energy substituted by the thermal recovery of wood are separately accounted in module D (see Figure 4).

5 ENVIRONMENTAL IMPACT ASSESSMENT AND COMPARISON

5.1 Production stage - LCIA

5.1.1 Hybrid CLT wall - LCIA

With increasing load steps, the UHPC lamella changes its thickness from 20 mm (0-1000 kN) to 40 mm (1000-3100 kN) to 80 mm (3100-4500 kN). Figure 8 presents GWP_{fossil} and $GWP_{biogenic}$ of selected cross-sections. The cross-sections are selected at the minimum and maximum loads resulting in the three UHPC lamella thicknesses.

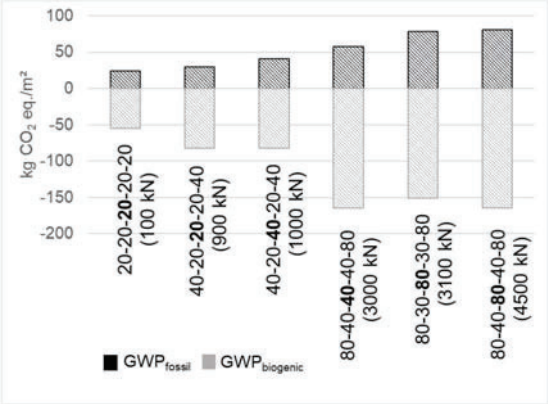

Figure 8: *GWP_{fossil} and $GWP_{biogenic}$ (modules A1-3) of 1 m² hybrid CLT wall for selected cross-sections at the corresponding minimum and maximum loads (UHPC lamella in **bold**)*

With increasing thickness of the cross-section, the GWP_{fossil} increases. This is not only due to the increase in UHPC, but also due to the increasing amount of wood, because an increasing amount of these two materials requires higher process inputs. Moreover, $GWP_{biogenic}$ mainly depends on the overall thickness of the wooden lamellas. Looking at the cross-sections 80-40-40-40-80 (3000 kN) and 80-30-80-30-80 (3100 kN), the UHPC lamella becomes thicker and at the same time the total thickness of the wooden lamellas diminishes. As less carbon can be stored in the wooden lamellas, the $GWP_{biogenic}$ increases.

5.1.2 Comparison of different construction methods

Figure 9 exemplarily shows the results for GWP_{fossil} for life cycle modules A1-3 for the different construction methods under increasing load steps. It must be mentioned that the reinforcement content of the reinforced concrete was constantly set to 4 %.

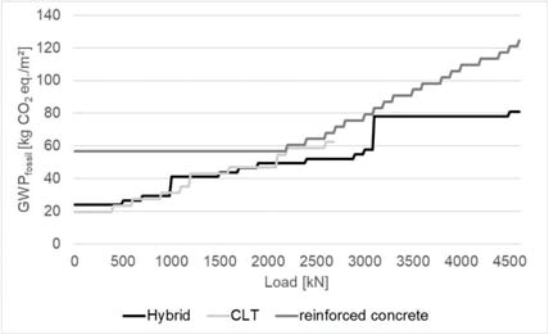

Figure 9: *GWP_{fossil} for 1 m² wall area (modules A1-3) for the different construction methods under increasing load*

The results indicate that, in general, the CLT and the hybrid wall have a lower environmental impact than the reinforced concrete wall. This is under small loads boosted due to the minimum thickness of the concrete wall of 150 mm. At 2100 kN, the GWP_{fossil} of the CLT and reinforced concrete wall is nearly equal due to the difference in thicknesses of the walls. The thicknesses are

directly related to the volume of the wall and hence, the amount of associated environmental impacts resulting from the corresponding production processes.
Until 2100 kN the CLT wall mostly performs slightly better than the hybrid wall. This is because of the comparatively low greenhouse gas emissions during the production processes of the CLT wall. As the environmental impacts of the CLT wall increase relative to the thickness (volume), the increase in the environmental impacts is higher than that of the hybrid CLT walls. Thus, at 2100kN, a tipping point is reached. From that point on, the hybrid CLT wall constantly shows lower environmental burdens than the CLT wall until the maximum carrying capacity of the CLT wall is reached.
As already shown in Figure 8, when the thickness of the UHPC-lamella changes from 20 to 40 mm (1000 kN) and from 40 to 80 mm (3100kN), a strong increase in the GWP_{fossil} of the hybrid CLT wall results. When the UHPC lamella thickness turns to 80 mm, the GWP_{fossil} of the hybrid CLT wall (300 m) nearly becomes as high as that of the reinforced concrete wall (220 mm). A further increase in the load does not change the cross-section of the hybrid CLT wall (300 mm) and hence, its environmental impacts. Simultaneously, the thickness of the reinforced concrete wall and consequently, GWP_{fossil} increases.
To not only assess the $GWP_{fossil,}$, Figure 10 additionally shows the $GWP_{biogenic}$ of the walls for three selected load steps. GWP_{luluc} is not shown, because it is responsible for less than 5 % of the GWP_{total} caused in the considered modules.

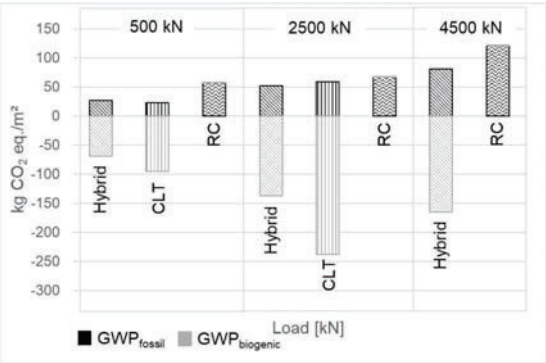

Figure 10: *GWP_{fossil} and $GWP_{biogenic}$ per 1 m² wall area (modules A1-3) of the different construction methods for three selected load steps*

$GWP_{biogenic}$ shows a negative value for both the CLT and the hybrid CLT wall. The reason for this is mainly the carbon stored inside the wooden lamellas during the life cycle. This biogenic carbon leaves the product system at End-of-Life in module C3. During the life cycle of a building the long-term storage of carbon might have a positive effect on counteracting climate change by contributing to cities as global carbon sinks [26].

5.2 End-of-Life - LCIA

To determine the influence of the End-of-Life stage, Figure 11 shows the GWP_{fossil} and $GWP_{biogenic}$ results for the full life cycle as well as for module D (outside system boundaries) for a load level of 500 kN.

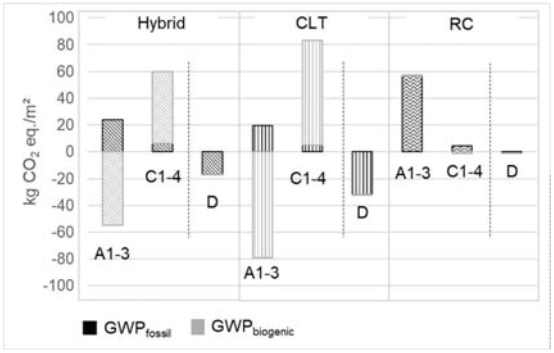

Figure 11: *GWP_{fossil} and $GWP_{biogenic}$ per 1 m² wall area for the full life cycle (modules A1-3, C1-4, D) of the three construction methods*

When considering modules A1-3 and C1-4, the $GWP_{biogenc}$ equals nearly zero, because the carbon stored in the wood is released at the end of the life cycle. This shows that fossil greenhouse gas emissions are dominant for all three walls. The highest share of GWP_{fossil} for every construction method is caused in the production stage and the impact of the deconstruction stage in the case of the walls is comparatively low. For the hybrid CLT wall, the GWP_{fossil} of modules C1-4 accounts for approximately 25 % of the GWP_{fossil} of modules A1-3.
Looking at the benefits and losses outside the system boundaries makes clear that the benefits for the CLT due to the thermal recovery of the wood are the highest, followed by the hybrid CLT wall due to the thermal recovery of the lamellas. The replacement of primary material with recycled concrete at the End of Live brings only a very small amount of benefits. This shows that even if module D is considered separately, it may influence decisions when taking Circular Economy principles into account.
The dominant GWP_{fossil} as well as the considerations of module D point out the importance of enabling separability and hence ensuring a high-level recyclability of the products.

6 CONCLUSION

The LCA results for the full life cycle indicate that, dependent on the load level and the resulting thicknesses, the use of hybrid CLT walls can show less greenhouse gas emissions and can be a structurally reasonable alternative to concrete and CLT.
Regarding GWP_{fossil} for the production stage, the reinforced concrete wall constantly shows the highest greenhouse-gas emissions. Under small loads, the CLT wall emits the lowest greenhouse gases. At 2600 kN, the CLT wall reaches its carrying capacity. At 2100 kN a tipping point is reached and the hybrid CLT wall shows

https://doi.org/10.52202/069179-0132

the lowest global warming potential. At even higher load levels, the hybrid CLT wall shows less environmental impacts than the concrete wall. The change in the thickness of the UHPC lamella in the hybrid CLT wall, has a significant influence on the global warming potential. When the thickness of the UHPC lamella changes from 40 mm to 80 mm, the GWP_{fossil} of the hybrid CLT wall differs only slightly from that of the reinforced concrete wall. However, with further increasing loads, this difference increases again until the hybrid CLT wall reaches its carrying capacity. Applying only the UHPC lamella where high loads are expected (alternating), may lead to a decrease of the environmental impacts of the wall.

A consideration of GWP_{total} or $GWP_{biogenic}$ only for the production stage could be misleading. because of the negative accounting of the biogenic carbon in the wood when entering the product system. The production stage of the hybrid CLT as well as the CLT wall seems to be carbon neutral or even positive, but when accounting for the benefits and loads resulting from the processes and especially from the biogenic carbon leaving the system boundary at End-of-Life, all three construction methods lead to greenhouse gas emissions. Nevertheless, further investigations on long-term carbon storage in buildings and their components should be conducted to explore this possible potential.

These carbon emissions during the life cycle and the End-of-Life considerations for all three construction methods show the necessity to bring solutions into practice that enable high-level recycling, or even reuse of the walls for further cycles instead of final disposal or incineration.

To improve the LCA results, background data, other impact indicators, different End-of-Life options, and practical deconstruction and separation trials of the hybrid CLT wall must be further researched. Dependent on the load level, the thicknesses of the walls can differ from 10 mm to more than 100 mm. The wall thickness is directly related to the volume. This aspect must be further evaluated.

For the comparison of construction components, this study highlights the importance of defining a robust functional equivalent for LCA comparisons dependent on the main functions of the component and the goal of the study. Here, only the load-bearing capacity was considered. To improve the validity of the results, it is further necessary, to consider not only the load-bearing capacity. For the functional equivalence of inner walls especially fire safety and sound protection play an important role. These requirements will be further considered in the ongoing research project as the focus is on the building level. In addition, for the comparison of external walls, thermal behaviour should be considered.

World Conference on Timber Engineering Oslo 2023

GHGs EMISSIONS FROM SAWNWOOD PRODUCTS IN NORWAY– THE IMPORTANCE OF HARMONISED LCA METHODOLOGY IN ENVIRONMENTAL PRODUCT DECLARATIONS (EPDs)

Johann Kristian Næss[1], Ana Maria Santos Bouzada[1], Roja Modaresi [1]*

ABSTRACT: Wood is often considered a low-emission and sustainable material. However, there is always potential for the industry to further reduce environmental impacts if hotspots in the production phases are identified. When a contribution analysis is performed in LCA for building materials, the different processes, raw materials or life cycle stages contribution to a functional unit's overall impact can be compared. However, methodological choices in the LCA can be decisive for how a contribution analysis should be interpreted. This study has two main purposes; 1) to perform a contribution analysis for planed timber products in terms of Global Warming Potential, representative for sawmill industry in Norway, 2) to highlight the importance of harmonised LCA methodology in Environmental Product Declarations (EPDs) by performing a sensitivity analysis for the choice of allocation assumptions, as Product Category Rules (PCRs) can be interpreted differently by EPD practitioners. Calculations are based on data from five timber manufacturers in Norway, whereas three of these also had facilities for surface treatment on site. The uptake of carbon dioxide in the timber products was not considered in the GWP calculations. Results show that forestry and sawlog transport contribute the most to the GWP of planed timber. Furthermore, results for A1 and A2 modules (A1: raw material, A2: transport of raw material) are sensitive to allocation assumptions defined in A3 of the LCA model (A3: manufacturing). Using physical properties instead of economic values for allocation of these upstream emissions in forestry and transport, reduces the GWP emissions by approximately 30%, from 59.1 to 41.6 kg CO_2-eq/m^3. This demonstrates how allocation choices across life cycle stages matters. Inconsistency in allocation practices impairs the comparability of EPDs developed for wood building materials and deteriorates rationale environmental decisioning for the building sector.

KEYWORDS: Sawmills, Emissions, Forestry, EPD, EN15804, Allocation, LCA

INTRODUCTION

Wood increases its legitimacy in comparison to other materials, often associated with relatively low greenhouse gas emissions (GHGs) in processing, in addition to the carbon sequestration possibilities in the use phase [1-4]. Norway has an annual production of about 13 Mm^3 of roundwood [5, 6]. 2.7 Mm^3 of sawn timber are produced in Norway annually by relatively small sawmills, where 75% of the total production is coming from 18 sawmills with a capacity of above 50 000 m^3 [7]. Several LCA studies on forestry have been conducted since the early 1990s, however, there are differences in assumptions, background data, and their subsequent results [8]. GHGs from Norwegian forestry and transport to industry has previously been well documented for roundwood [9]. However, there has been a lack of similar studies that includes downstream production activities from the forest, such as sawmilling and planing of timber. This makes it difficult to compare the GHGs from different stages in the Norwegian value chain for timber building materials. Such an assessment exists for individual sawmills in other countries. For example, Lauri et. al compared different allocation methods for timber products and included results for different life cycle stages, using manufacturers data from three sawmills in Europe [10]. Beside all the existing studies, interpretation of LCA results for the production phases of sawn timber must be made with caution in EPDs and LCA studies. This difference in practice, becomes important when joint co-production processes are present in one or more of these life cycle stages. Such processes can be defined as undividable processes that has more than one output product with positive economic value. In these cases, environmental impacts associated with the joint-co production process including upstream impacts from materials and energy needed, must be partitioned to the products in a rational way. Partitioning of the flows to different products are often referred to as allocation in LCA. Allocation is usually based on physical properties such as mass or energy content. However, flows shall be allocated by economic value for the distinct co-products when the differences in the respective revenues are high, >25% according to a 'Note' in EN 15 804 [11]. A typical joint-co production process in the value chain of wood building materials is the sawing process, with outputs of sawn timber, chips and sawdust. For these co-products, the differences in revenues are relatively high. Different interpretations for the interlink between life cycle stages are made in LCA of wood materials in Nordic countries, where mainly two different methodical frameworks have been established for the development of EPDs. Two

different program operators are publishing EPDs, in Norway (EPD-Norge) and Sweden (International EPD system (IES)). Program operators provides guidelines for the development of EPDs by providing PCRs for specific product groups, but the rules must follow PCRs' higher in the hierarchy, such as EN 15804 [11] and EN 16485 [12], the latter is currently being revised. Rules for accounting of greenhouse gas emissions are also increasingly being governed by law, which can affect the new revisions of EPD standards. LCA is still a field under development, and despite the great number of PCRs that exist to harmonise methods for calculations, rules in standards and Product Category Rules (PCRs) are still open for interpretation [10]. There is a lack of knowledge among the EPD users [13]; and problems especially occurs when EPDs from different program operators are compared, with the aim of selecting a product with a better environmental profile. It is clearly shown in a study of 436 EPDs which were published under two different programme operator and therefore two different PCRs; that almost 90% of EPDs were incomparable [14].

The aim of this study is to perform; 1) GWP assessment for surface treated claddings, and planed timber products produced in Norway, using a contribution analysis format and LCA principles from development of EPDs 2) sensitivity analysis of using two different methodical frameworks that is present in EPD development in Nordic countries.

METHODOLOGY

A cradle-to-gate GHG assessment was made for planed timber and surface treated cladding in a contribution analysis format, meaning that the contribution of different products or processes impacts to the final result can be examined. Furthermore, a sensitivity analysis was performed for different methodical frameworks practiced for EPDs in Norway and Sweden; "NO method", following NPCR 015 and the older version of EN 16485. Also referred to as the traditional value chain calculation, "SE method", which differentiates from the value chain calculation by allocating upstream activities (roundwood) in forestry (A1) and transport of roundwood to sawmills (A2) after mass in joint co-production processes at sawmills.

Contribution analysis

Included activities inventoried in this assessment are highlighted in Figure 1. The system boundary is defined by the outer grid in the figure, which includes processes from rejuvenation activities in forestry until the finished product (planed timber or surface treated cladding) is packaged and stored within the factory gate. The functional units are 1 m³ of planed timber and 1 m² of surface treated timber cladding. Planed timber includes a varieties of untreated timber products that has undergone sawing, drying and planing and are used as building materials for both structural and non-structural purposes, indoor or outdoor. Cladding is used for exterior façade of houses and buildings, and one layer of primer and paint is applied in the manufacturing (industrially coated) for this functional unit. In the contribution analysis for planed timber, the same production activities within the dotted border in Figure 1 represents the grouping of sawmill activities, and in addition, Forestry and roundwood transport are also a separate group. For surface treated cladding, only the timber cladding and the surface treatment constitutes the two contribution groups in this analysis. Other important activities that are not depicted by Figure 1 is the production of paint and diesel, emissions from the manufacturing of these raw materials are included in the analysis groups for surface treatment and internal transport, respectively.

Five sawmills, located in the South-eastern parts of Norway, constitutes the providers of specific manufacturers data in this study. The results are represented by the mid-point category for greenhouse gas emissions, GWP-IOBC (Global Warming Potential assuming instantaneous oxidation of biogenic carbon). This means that the uptake of carbon dioxide into biogenic carbon in the wood material is not included in the GWP result. This indicator is described in more detail in PCR part A from EPD-Norway [15]. The correct characterisation for methane in the PCR is not clear enough. Therefore, this study follows IPCC 2019 guidelines [16], in addition to EN 15 804.

Life Cycle Inventory (LCI)

The background LCI is built on a selection of Ecoinvent v3.7.1 data [17], combined with datasets tailormade for the Norwegian wood industry, e.g. roundwood production [18]. The specific data was gathered in EPD projects, involving five manufacturers of sawn timber, whereas three of these manufacturers had facilities for industrial surface treatment. A flow chart highlighting the included wood value chain activities in this study are presented in Figure 1.

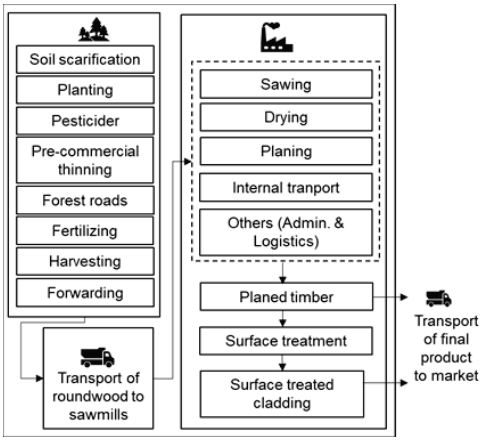

Figure 1: *Flow chart that summarizes included processes for processing of wood throughout the wood value chain.*

The reference year for annual activity data varies for the different subprocesses in forestry, but all are within the years 2016-2020, and based on national statistics data [19-21]. Otherwise, the LCI for forestry processes is taken from previous studies [9, 22]. LCI for fuel used is taken

https://doi.org/10.52202/069179-0133

from Vennesland et al. [23]. Regarding the silvicultural activity of fertilizing, it is assumed that 150 kg of nitrogen are used per ha of forest and that the secondary release of dinitrogen monoxide into the atmosphere due to the added fertilizer are 2,75 kg per ha [24]. The total area fertilized are based on national statistics data from the reference year of 2020 [25]. The allocation between sawlog and pulpwood has been adjusted to be in line with the requirements in EN 15804 [11] and NPCR 015 [26]. This means an economic allocation of silviculture operations and harvesting, except for the activity of forwarding (terrain transport of roundwood from the felling to the forest gravel road). It is assumed that the forwarding is not affected by the demand for roundwood, or pulpwood and these assortments can be transported separately from each other.

The dataset used for the road transport of roundwood is originally Ecoinvent data that has been modified at NTI to be more suitable for roundwood transport in Norway. The adjusted parameter values on fuel consumption, lorry weight, fuel blend, average load weight, and vehicle load capacity are based on information from actors within forestry operating in Eastern Norway (Norsk Virkesmåling, Viken Skog and Trekk Tømmer). A mix of 7% biofuel in the diesel is assumed, following NS-EN 590 [27]. For logs transported by sea, the background data are based on generic Ecoinvent data [17].

The process for industrial heat production, which is generated by the combustion of wood biomass by-products at the sawmill plants, is based on Ecoinvent data [17] for a 5000 megawatt wood furnace. But the process input inventory has been adjusted, by changing the inputs of wood by-products to specific data modelled in the EPD projects. In this way LCI flows are allocated back to the timber production, e.g. in the drying process of timber where heat energy is important. Bark is the most important fuel in the furnaces, in addition to sawdust. The data is validated by using a bioenergy calculator developed at NTI [28].

The upstream data for infrastructure and electricity are taken from Ecoinvent [17]. Data for alkyd coating applied in the surface treatment process are also based on generic Ecoinvent data for both the primer and paint. Similarly, the acryl coatings added for this alternative are based on generic Ecoinvent data for losses of chemicals, energy use and waste treatment, but the components in the acryl coatings is based on literature study [29]. The amount of paint applied on the claddings is based on the dried weight amount of coating on the claddings as stated in the original EPD projects. Furthermore, this amount is assumed for both acryl and alkyd coating application in this assessment, although correct application amounts for such paints can vary between coating manufacturer and type of binder used.

Weighting averages

Weighted average of the five sawmills are calculated based on the production capacity of the factories (total output of finished timber products). The process of industrial surface treatment is averaged by the production capacity of the different factories in terms of finished timber products with coating. The wood timber input in surface treatment (untreated cladding) are however weighted in the same way as for planed timber and in fact are the same cradle to gate (A1-A3) average result for planed timber for the five different factories, only adjusted for conversion to m² assuming a 19 mm thick cladding with a simple profile, giving 0,019 m³/m² of cladding.

Sensitivity analysis for different allocation practices in Nordic countries

Considerable differences in the EPDs' results of similar products from Norway and Sweden were recognized. Therefore, NTI initiated the communication with two national associations, Treindustrien in Norway and SvenskTrä in Sweden, which took over the administrative lead to figure out the differences present between EPD actors and harmonise the methodical differences present. Two different approaches were recognised in the communication, which are applied in this sensitivity analysis carried out for planed timber. All other assumptions in the LCA are kept constant to show how the methodical frameworks may affect the results.

Allocation of upstream emissions from forestry activities and the transport of roundwood (A1 and A2) was different for the two modelling approaches. Minor differences were also present for allocation of emissions occurring in the manufacturing (A3), but this consequence was considered less important for affecting final results and was modelled in the same way for both approaches in the sensitivity analysis.

The model framework applied for the 'NO model' are similar to Ecoinvent models [17], similar approaches are also present in other published LCAs for wood products [30-33]. The main difference of the SE and NO models is that special treatment is made for allocation of upstream emissions in the SE model, i.e., emissions not a part of energy use or direct emissions at the manufacturing. These can be emissions occurring in forestry or transport of roundwood, which are allocated by mass in joint co-allocation processes at sawmill, in contrast to economic value which are used in the NO model.

In the SE model, the roundwood input including transport to the sawmill is held constant at 1.15 m³, where 1 m³ represents the forestry emissions and transport of logs allocated to the climate impact for planed timber, and 0,15 m³ likewise are allocated to bioheat purposes at the sawmill factories, which are then allocated back to the planed timber. This means that also 1,15 m³ of roundwood is assumed transported from the forest to the sawmill, as shown in Table 1. Sometimes additional allocation procedures are made for the forestry part in the SE model, leading to a higher input of roundwood than shown in the table. A perfect mass balance approach was however assumed for SE in this analysis, to recognise the biggest possible differences present for sawn timber products in EPDs today. In the NO model, the wood raw material needed in the timber manufacturing will accumulate throughout the value chain, for every joint-co production process dividing the flow of emissions to main and by-products. This leads to accumulated use of roundwood along the value chain, and as shown in Table 1, 1,65 m³

illustrate the use of roundwood for the 1 m^3 of sawn timber production. While 2,14 m^3 are the use of roundwood produced in forestry, accumulated during the allocation to pulpwood and roundwood from forestry sub processes. NO amounts in Table 1 are approximate amounts used for the harmonisation meetings and planed timber is assessed for this sensitivity analysis and not rough sawn timber (the wood input in the planing process), as in the table. The planing process also leads to accumulation of roundwood needed, following the NO model.

Table 1: *Assumptions for roundwood consumption in the production of rough sawn timber in Nordic countries. The outcome from the EPD harmonisation work by Treindustrien and Svensk Trä.*

Scenario no.	Roundwood (Forestry) (A1) [m^3]	Transport of roundwood (A2) [m^3*km]
NO Method	2.14	1.65
SE method	1.15	1.15

Note: The NO method is not developed in Norway nor limited to EPD development in Norway and the same applies for the SE method, but the abbreviations were used in the harmonisation work, which has been started between the two countries.

RESULTS

The average result of GWP-IOBC for 1 m^2 of planed wood and surface treatment activity for a façade product with a 19 mm thickness is shown in Figure 2. Production of 1 m^2 planed wood correspond to 1.1 kg CO_2-eq. While almost 1 kg CO_2-eq is emitted for the industrial surface treatment process including the production of paint, which are the average result for the three sawmills with surface treatment combination plants.

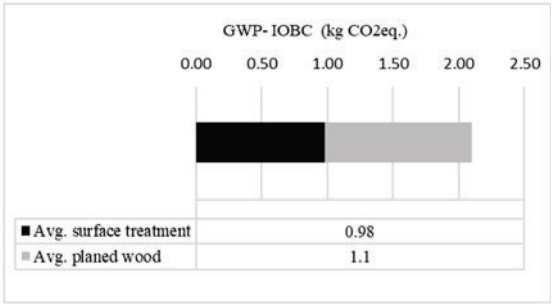

Figure 2: *GWP-IOBC for 1 m^2 of surface treated cladding products for an average of Norwegian sawmills.*

Figure 3 presents the results as a contribution analysis for planed timber production per activity, average for the five sawmills using the two defined methodical frameworks: 'NO method' and 'SE method'. All upstream forestry processes mentioned in Figure 1 are grouped together to represent a single forestry activity. While other sawmill processes are presented separately. Forestry shows the highest contribution, followed by roundwood transport. There is a distinct difference in the result for forestry and roundwood transport for the different methods.

	Admin and log	Internal transport	Planing	Drying	Sawing	Roundwood transport	Forestry
NO method	2.3	6.4	5.3	2.8	2.8	13.6	25.9
SE method	2.3	6.4	5.3	2.8	2.8	8.5	13.5

Figure 3: *Weighted average for GWP- IOBC contribution [kg CO_2 eq] per activity to produce 1 m^3 of planed timber in the five selected Norwegian sawmills.*

The two methods can be compared in Figure 1, by the ratio for contribution for GWP in A1-A3. In the SE method, sawmill activities show the highest share, due to the different approach for calculating upstream emissions. While in NO method, the forestry has the highest share in the overall contribution.

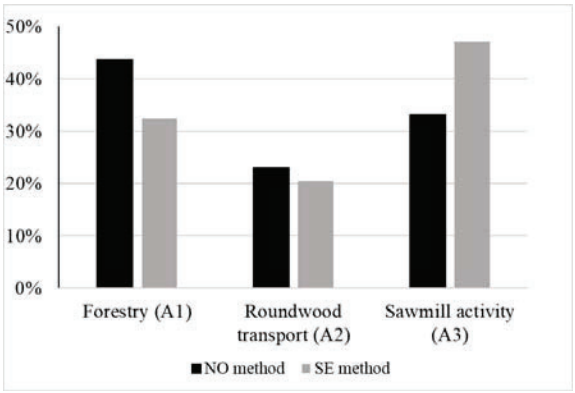

Figure 4: *Contribution by different production stages to GWP-IOBC for planed timber.*

DISCUSSION

The planed wood and surface treatment are having almost equal contribution for production of surface treated cladding. In addition, one layer of surface treatment is advised after the installation, and during each maintenance interval of the façade in the use phase of buildings. Considering the application of paint during the lifetime of a building, a previous study showed that the contribution of paint is dominating throughout the lifecycle [34].

Forestry is the highest contributor for planed timber, because of several energy intensive silvicultural activities. Roundwood transport from forest to sawmills has a considerable effect. However, this can vary depending on the sawmill location and the forest resources.

Results in EPDs are sensitive to the choice of allocation assumptions across the production phases. The author's interpretation is that the EPD standard (EN 15804) is not

https://doi.org/10.52202/069179-0133

explicit enough for the allocation treatment of upstream raw material acquisition and processing, including the transport thereof, and requires a better common understanding between EPD practitioners.

The different production stages (modules) are treated more separately in the SE model compared to the NO model, resulting in a lower amount for the assumption of roundwood consumption in the production of sawn timber. In the harmonisation discussions, argumentation for using the SE method is that forestry products and residues can be input for a wide range of products, and that this is not known at the time of harvest. The owner structure from forest management to the production of wood building materials are often merged in Sweden, which can make it difficult to estimate the economic value of intermediate wood products and therefore apply the allocation principles demanded in EN 15 804. The NO model is the rationale choice for partitioning of emissions throughout the value chain of wood in many trade regions around the world, but this is put on the test by ownership structures in some regions and the market situation for raw wood and intermediate products. However, differences in results that are not due to actual conditions in production are unwanted by anyone producing or using LCA data. Nor is this wanted by regulatory law either, which set new rules for environmental documentation and performance at an increasing rate. Finally, inconsistency in methodology will deteriorate manufacturers possibility of comparing themselves with other manufacturers.

The result demonstrates how methodology choices across life cycle stages matters. Inconsistency in allocation practices impairs the comparability of EPDs developed for wood building materials and deteriorates rationale environmental decisioning for the building sector when performing building LCA. With increasing use of EPDs, it is important to have comparable methods for timber material between different countries. In addition to that, it is important to be able to compare timber material with similar functionality with other types of building materials, such as steel and concrete. EN 16485 is currently under revision, and it may bring the solution for harmonising methodical choices in LCA for EPDs on wood building materials.

INFLUENCE OF DIFFERENT END-OF-LIFE CYCLE SCENARIOS ON THE ENVIRONMENTAL IMPACTS OF TIMBER-CONCRETE COMPOSITE FLOOR SYSTEMS

Hooman Eslami[1], Alireza Yaghma[2], Laddu Bhagya Jayasinghe[3], Daniele Waldmann[4]

ABSTRACT: Timber-concrete composite (TCC) floor systems attracted attention in the construction industry because of their low environmental impacts while demonstrating decent load-bearing capacity. However, the environmental impacts of possible end-of-life scenarios of TCC floors have not been extensively studied. To address this gap, a comprehensive life cycle assessment (LCA) study was conducted on three different slabs: a Reinforced concrete slab, a Steel concrete composite slab, and a CLT-concrete composite slab. The study revealed that the CLT-concrete composite slab has the lowest Global Warming Potential (GWP) among the three slabs. Subsequently, a more detailed LCA is performed on the CLT-concrete composite slab considering three different end-of-life scenarios of the CLT: 1. Energy recovery via incineration, 2. The prevailing scenario in Europe (a combination of energy recovery, recycling, and disposal), and 3. Reuse. The results show all three scenarios are beneficial in terms of GWP whereas the 3rd scenario is the most beneficial one.

KEYWORDS: Timber-concrete composite floor system, Life cycle assessment, Environmental impact, Reusable slab

1 INTRODUCTION

The construction industry is a major consumer of global resources and contributes greatly to waste generation and greenhouse gas emissions [1, 2]. In the last few decades, with the aim to reduce the environmental impacts of the construction industry, the use of renewable and more environmentally friendly materials such as timber and engineered wood products have gained more attention due to their green properties such as low carbon footprint and low embodied energy. Previous studies have shown that Timber-Concrete Composite (TCC) floor systems are promising sustainable solutions since they have decent structural behavior while having low environmental impacts [3].

TCC slabs have several advantages over conventional Reinforced Concrete (RC) slabs. By replacing concrete with timber, the environmental impacts of the floor system can be reduced about 30 to 50 percent [4]. Moreover, TCC can be used for resource-saving and lightweight constructions. These advantages can be expanded if the TCC slabs are designed to ensure the concrete is only subjected to compression and that all or most of the timber is stressed in tension. Consequently, TCC slabs should be designed so that shear between the timber and concrete components is transferred effectively through a proper shear connector system. The degree of composite action of the slab depends on the efficiency of the shear transfer system between the two materials. Furthermore, the connection system influences the sustainability of the TCC slab since it manipulates the fabrication, installation, maintenance, and End-of-Life (EoL) scenario. Hence, important aspects of sustainability such as prefabrication, deconstruction, recycling, and reuse must be considered during the design of the shear connection. A shear connection system that bonds the two materials permanently makes the deconstruction, reuse, or recycling difficult while a demountable shear connection facilitates these processes. This encouraged researchers to develop new shear connections suitable for prefabrication [5–7] and deconstruction [8, 9]. Having these new solutions which facilitate the recycling and reuse of TCC slabs, it is important to evaluate and compare the environmental impact of different EoL cycle possibilities for TCC floor systems.

This paper aims to study the environmental impacts of different floor systems for identical loading and span length. Then, a comparison between different EoL scenarios for the timber used in TCC floors is studied to identify the best solution considering the environmental impacts.

2 ASSESSMENT OF THE ENVIRONMENTAL IMPACT

Life-Cycle Assessment (LCA) is a common method that is used for the analysis of the environmental impact of products [10]. It is an analysis technique that evaluates the environmental impacts of different stages of a designed product during its life cycle. In an LCA study, an inventory of the energy and materials which are used for the product is determined and the corresponding potential environmental impacts are calculated to improve the environmental profile of a product or compare it to another one.

Many studies evaluate the environmental impacts, considering the Global Warming Potential (GWP) and Primary Energy (PE), for some or all of the life cycle stages of a designed product [11]. GWP is a metric to quantify the total global warming effect of a substance over a specified time horizon. The GWP of a substance is defined as the ratio of the cumulative radiative forcing over a specified life cycle stage due to the emission of a unit mass of a substance, relative to the equivalent emissions of CO_2. PE states to the energy that is first extracted from natural sources and then used to generate electricity, heat, or power for other purposes. The sources of primary energy include renewable energy sources such as wind, solar, hydro, and geothermal, as well as non-renewable energy like coal, oil, and natural gas [12]. For construction materials and components, the stages which are mostly considered are Production and Construction (A), Use(B), End of Life (C), and Benefits and Loads (D) [13]. The considered stages in this study are demonstrated in Figure 1 which are the most relevant ones to the floor systems.

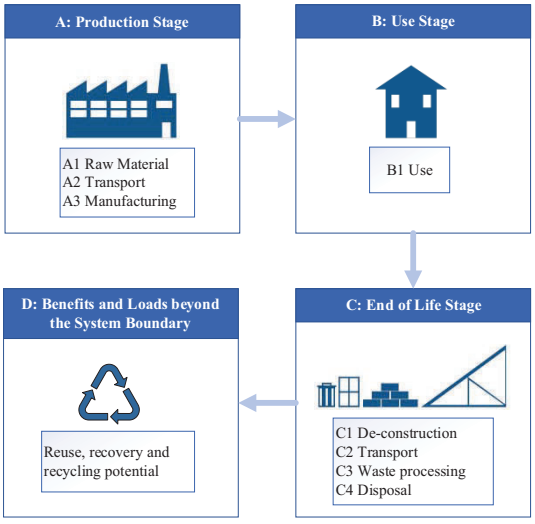

Figure 1: *Lifecycle stages of construction materials and components. Based on [13]*

Stage A includes the extraction and processing of the raw materials, as well as their transportation to the manufactory where the floor component is produced. The construction process stage is not considered here because it does not have a noticeable influence compared to the other stages on a component level of analysis. Stage B only considers the use phase, assuming that the floor systems will not require any maintenance, repair, replacement, refurbishment, energy, or water during their service life. Stage C includes the deconstruction of the component, transportation, waste processing, and disposal. Stage D depends on the method that is used to derive benefits from the materials or components through reuse, recovery, or recycling. Although all the stages influence the environmental impacts of construction materials, stages A, C, and D are the decisive ones since stage B has no or a very small contribution to the environmental impacts.

Depending on the scope of an LCA analysis, different stages are considered in a study. A cradle-to-grave (CTG) scope considers stages A, B, and C, whereas a cradle-to-cradle (CTC) scope includes stages A, B, C, and D. The CTG approach examines the environmental impacts of a product from the extraction of raw materials to its disposal. On the other hand, the CTC approach takes into account the possibility of reusing, recovering or recycling the materials and components of the product at the end of its life. This approach considers the grave of a structure as the new cradle for its materials and components, enabling them to be used again in the manufacturing process of new products, reducing waste and the need for additional raw materials.

3 ASSESSMENT OF DIFFERENT FLOOR SYSTEMS

The Eco-Construction for Sustainable Development (ECON4SD) project at the University of Luxembourg has the objective of advancing toward a sustainable and circular society. This initiative aims to accomplish this goal by developing innovative architectural and structural design models that are resource and energy-efficient. The underlying purpose of this project is to create constructions that utilize sustainable practices, thereby minimizing their environmental impact. This paper study the environmental impacts of different possible floor systems to find a suitable floor system for the prototype 3 building in the ECON4SD project [14], which is a demountable building made of standard prefabricated modules. Each module has a length of 10.8 meters, a width of 10.8 meters, and a height of 3 meters. The building is made by adding these modules and expanding the building horizontally and vertically as it is shown in Figure 2. The architectural concept is designed for adaptive usage over the life cycle such as residential, office, and public buildings. After each lifecycle, the building can be modified for a new purpose or can be demounted and reused in another building site.

To find a suitable floor system for this prototype building, 3 different floor systems are designed statically. Then, the environmental impacts of the floor systems are compared through a cradle-to-grave LCA analysis. The proposed floor systems are Reinforced Concrete (RC), Steel-

https://doi.org/10.52202/069179-0134

Concrete Composite (SCC), and Timber-Concrete Composite (TCC). The floor systems which are depicted in Figure 3, are designed for an office building loading condition and a 10.8 meters single-span system. The design considers both load-bearing capacity and serviceability of the floor for a lifespan of 50 years. Since the building is meant for prefabrication and demounting, floor modules are designed as prefabricated slabs with 1.8 meters in width.

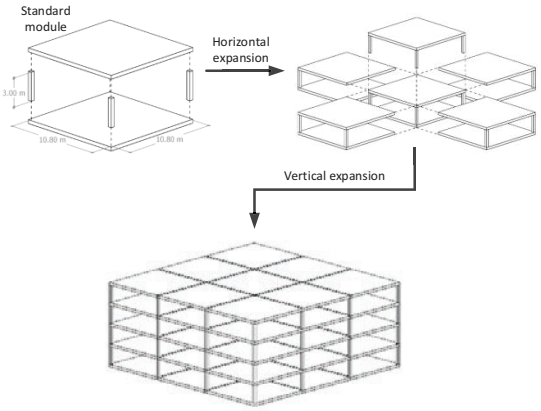

Figure 2: *Architectural concept and standard module expansion for ECON4SD building prototype 3. From: [14]*

The TCC slab includes a 60 mm deep concrete slab on top of a Cross-Laminated Timber (CLT) panel with a thickness of 300 mm. CLT is a type of engineered wood product that is made from layers of solid-sawn lumber and is used in construction as floors, walls, roofs, etc. The layers are stacked in alternating orthogonal directions and then glued together under pressure to form a solid, stable panel. The CLT and concrete are connected by shear connections. The SCC slab is made of an IPE 360 steel profile with a 65 mm deep concrete slab. The RC floor has the highest thickness of 440 mm and The TCC has the lowest thickness of 360 mm.

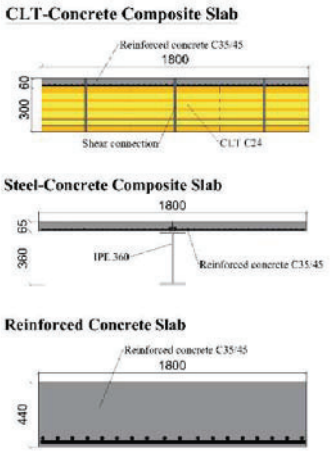

Figure 3: *The investigated floor systems (dimensions in mm).*

Based on the designed floor systems, all material quantities required for each slab module are calculated. Then, the ÖKOBAUDAT German database [15] which provides data on the environmental impacts of the construction products, is used to calculate the GWP and PE of all the materials in each stage except for CLT whose environmental impact is extracted from Stora Enso environmental product declaration [16]. Figure 4 and Figure 5 show the results of the LCA analysis in GWP and PE, respectively. For each floor system, the results are calculated for all stages and the total CTG is presented. The GWP results for the TCC and SCC floors are similar with a small advantage for the TCC slab while the result for the RC slab is about 3 times higher than the other two floors. This is due to the high CO_2 footprint of cement in the production stage. For TCC, the production stage of timber contributes to removing CO_2 from the environment while the EoL stage releases CO_2 back into the environment due to incineration. Since the steel in the SCC slab will be recycled in stage C, the CO_2 contribution comes mostly from the production stage. Stage B contribution for all the slabs is negligible since it counts only the insignificant recovered CO_2 by concrete carbonation during the utilization stage.

The results for PE are different since the SCC slab requires about 30% less energy compared to the TCC slab. Yet, the RC slab requires the highest PE with about 2 times more than the TCC slab. The majority of the demanded PE is used in the production stage for all of the slabs. Only for the TCC slab, there is recovered PE which belongs to the heat recovery of the timber by incineration in stage C. Figure 5 also demonstrates the proportion of the renewable and non-renewable energy. Although the TCC slab requires more primary energy, it is mostly acquired from renewable energy. This is contrary to the SCC slab. Therefore, one can claim that the TCC slab is more sustainable compared to the other two slabs in a cradle-to-grave LCA analysis.

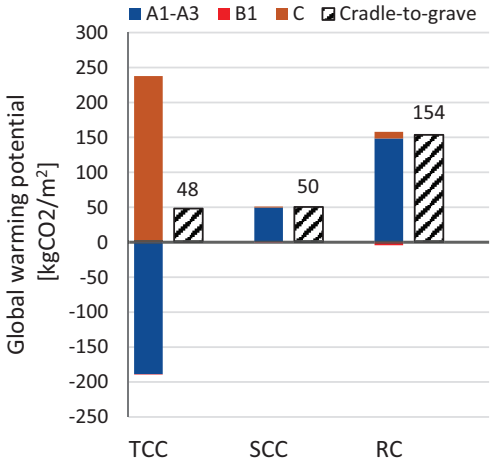

Figure 4: *CTG global warming potentials of TCC, SCC, and RC slabs*

https://doi.org/10.52202/069179-0134

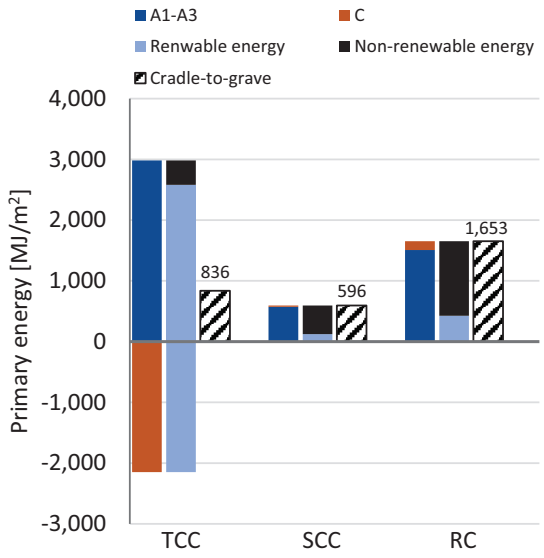

Figure 5: *CTG primary energy of TCC, CLT, and RC slabs*

To have a cradle-to-cradle LCA, the potential GWP and PE relevant to stage D of each slab are calculated to determine the loads and benefits of each substance from its reuse, recycling, or recovery. For both GWP and PE measures, as it is shown in Figure 6 and Figure 7, respectively, the TCC slab stands significantly more beneficial than the other two slabs. For GWP this goes from 6 times compared to the RC slab up to 12 times better compared to the SCC slab. For PE the same trend exists when comparing TCC with RC and SCC slabs with 18 times and 53 times more recovered energy, respectively.

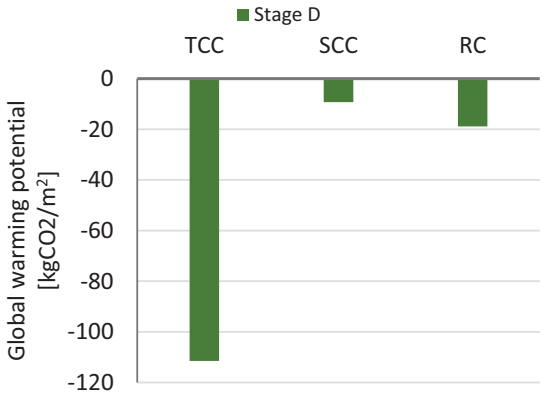

Figure 6: *Comparison of the GWP from benefits and loads beyond the system boundary for TCC, SCC, and RC floor system*

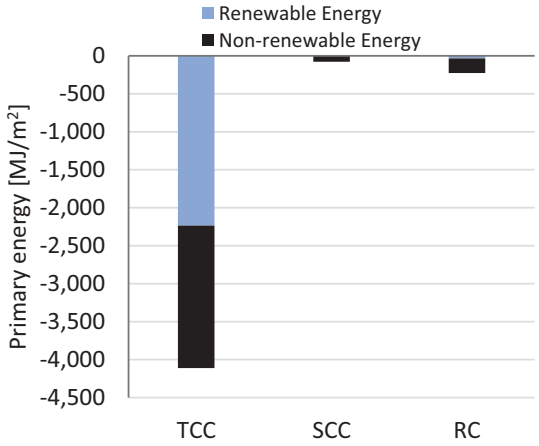

Figure 7: *Comparison of the PE from benefits and loads beyond the system boundary for TCC, SCC, and RC floor system*

4 COMPARISON OF POSSIBLE END-OF-LIFE SCENARIOS FOR TCC

Knowing the TCC floor system has sustainable advantages compared to SCC and RC floors, different possible EoL cycle scenarios can be studied to compare their benefits toward finding a more sustainable solution. The assumed EoL cycle stages are shown in Figure 8. Since the production and use stages are identical, only stages C and D vary between the scenarios. For all the scenarios, the materials in the TCC slab are considered for de-construction (C1), transportation (C2), and waste processing (C3). The steel parts such as reinforcements and the bolts are recycled and the concrete is downcycled. Then, three different scenarios are studied for the CLT panel. The first scenario is identical to the one in the previous part which considers the benefits of timber for full energy recovery by incineration of wood to generate steam heat energy or electricity. On the other hand, a study [17] shows that in Europe on average 37% of wood products go to disposal while 33 % is recycled and the rest is used to produce energy. For disposal, the wood is interred in a landfill where the methane produced from its decomposition can also be harnessed to produce electricity. As for recycling, wood waste can be processed into engineered wood products and paper [18]. Therefore, the second scenario is considered the prevailing scenario in Europe with the combination of the mentioned proportions for disposal, recycling, and energy production. Then again, the environmental impact of a component can be reduced significantly when it is designed for deconstruction and reuse which is the aim of the ECON4SD building prototype 3. Therefore, the third scenario considers that the CLT panel of the composite slab is fully reused with the assumption that the shear connection allows for such operation.

https://doi.org/10.52202/069179-0134

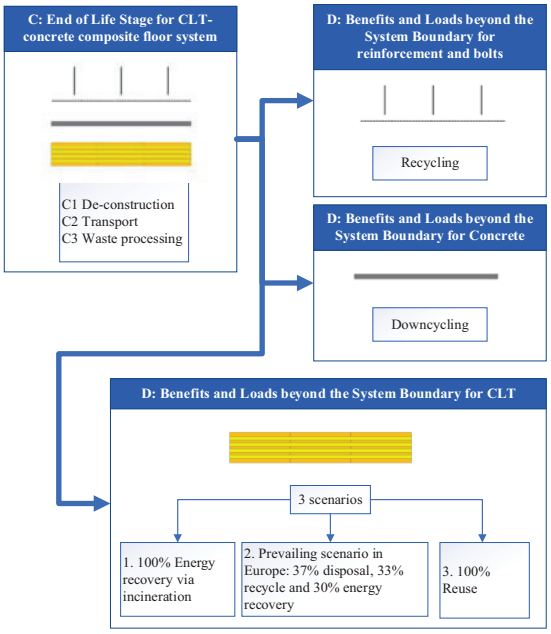

Figure 8: *End-of-life scenarios of CLT-concrete composite floor system*

Although the different EoL scenarios do not affect the environmental impact in C1 and C2 stages, they influence the C3 stage. This impact can be seen in Figure 9 and Figure 10 with the CTG calculation of the GWP and PE. The second scenario has about two times more GWP than the other two scenarios. The third scenario has about 25% less GWP than the first scenario. Considering PE, the renewable required energy is almost the same for all scenarios. However, regarding the non-renewable PE, the third scenario is again the most sustainable solution demanding about 15% and 7% less PE compared to the first and second scenarios, respectively.

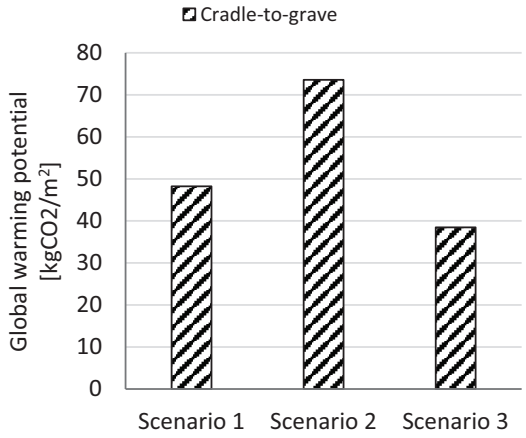

Figure 9: *Cradle-to-grave GWP of the three different EoL scenarios for the TCC floor system*

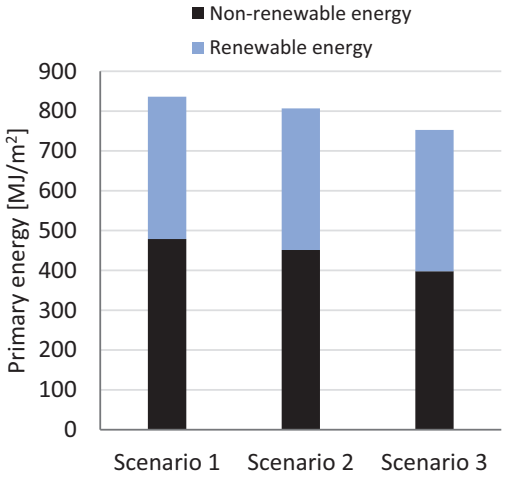

Figure 10: *Cradle-to-grave PE of the three different EoL scenarios for the TCC floor system*

The benefits and loads of the three scenarios in stage D are compared in Figure 11 and Figure 12 as recovered GWP and PE, respectively. The first and second scenarios have almost the same GWP potential benefits while the GWP for the third scenario is more than 2 times higher compared to the other two scenarios. The maximum possible recovered primary energy is from the first scenario followed by the third and second scenarios. This is due to the recovered energy from the incineration of the timber in the first scenario. However, the third scenario has the most renewable energy. Therefore, among the three scenarios, the third scenario has the least environmental impact and the most benefits beyond the system boundary.

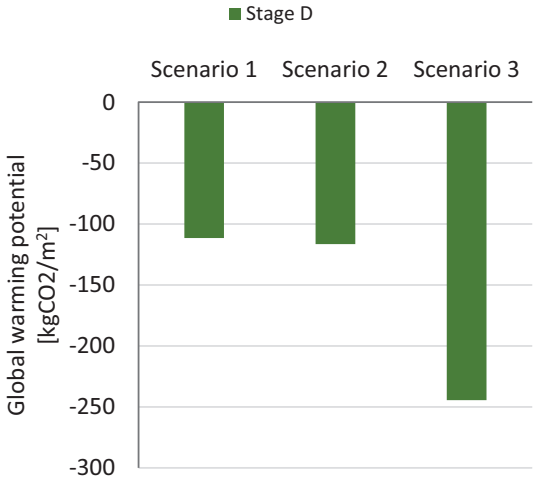

Figure 11: *Stage D potential benefits for GWP of the three different EoL scenarios for the TCC floor system*

https://doi.org/10.52202/069179-0134

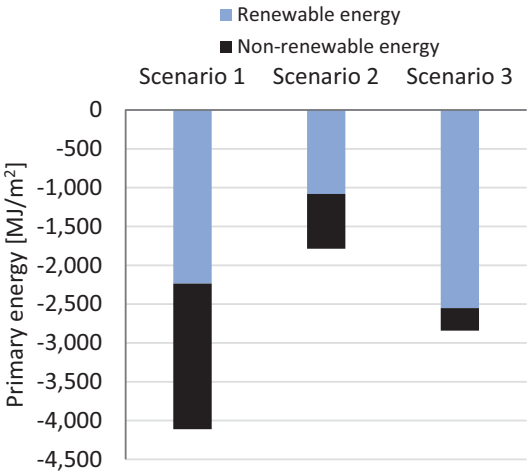

Figure 12: *Stage D potential PE recovery of the three different EoL scenarios for the TCC floor system*

5 CONCLUSION

Three different floor systems are designed for the prototype building of the ECON4SD project considering the same loading condition and life span. The results show that:

- The global warming potential of the TCC floor system is one-third of the RC floor.
- The demanded primary energy of the TCC floor system is half of the RC floor.
- The TCC floor has significantly higher environmental benefits in stage D of the LCA compared to the other two floor systems.

Additionally, three different EoL cycle scenarios are compared for the CLT panel including full energy recovery, the prevailing scenario in Europe with a combination of energy recovery, disposal and recycling, and full reuse of the CLT. The comparison shows that reusing the CLT is the most sustainable solution since it has the lowest GWP and required PE. Also, the environmental benefits of the reuse scenario are more sustainable considering both GWP and PE measures. Therefore, for the studied building, a demountable and reusable TCC floor system is the most sustainable solution.

A STRUCTURAL-MEMBER LEVEL ASSESSMENT OF THE ENVIRONMENTAL IMPACT OF TIMBER, REINFORCED CONCRETE AND STEEL IN BUILDING CONSTRUCTION

Jae-Won Oh[1], Sung-Jun Pang[2], Kyung-Sun Ahn[3], Jung-Kwon Oh[4]*

ABSTRACT: This study evaluates and compares the environmental impact of timber, concrete, and steel as building materials. This study designed a target member (beam) with equivalent structural performance under the same design conditions, such as span and live load, and compared the environmental impact. The carbon footprint analysis was conducted using Life Cycle Assessment (LCA) methodology, with a functional unit of 1-meter length of the designed beam and a cradle-to-gate system boundary. The study found that timber has a lower carbon footprint than steel and concrete, with the lowest carbon emissions during the product stage. Notably, the study also found a significant difference between the two environmental impact comparison methods, unit volume-based and structural performance-based. The findings demonstrate the sustainability of timber in high-rise construction and its potential to contribute to carbon neutrality while offering exceptional engineering capabilities. Further research is needed to improve the structural assumptions and LCA to evaluate the environmental impact of building materials more accurately.

KEYWORDS: Environmental Impact, Timber, Concrete, Steel, LCA, Equivalent structural performance

1 INTRODUCTION

The construction industry has recently been focusing on environmental concerns, such as climate change and global warming, leading to a growing emphasis on assessing the environmental impact of building materials. The building sector dramatically impacts the environment, accounting for over 40% of global energy consumption and roughly 30% of greenhouse gas emissions [1]. As a result, the building sector must take responsibility and play a role in addressing the challenge of climate change. Timber presents a range of substantial environmental advantages over other building materials, emitting fewer greenhouse gases during production and serving as a carbon sink. As a result, timber has gained recognition as an environmentally friendly material that has the potential to contribute to carbon neutrality while offering exceptional engineering capabilities. Despite its potential benefits, the utilization of timber in modern high-rise construction is still in its early stages, and there remains a need for a deeper understanding of its comparative environmental impact when compared to other building materials, such as steel and concrete.

Evaluating timber as a building material from an environmental perspective poses several challenges. One of the significant difficulties is that direct comparison of the environmental impact of buildings is limited. This is because the total environmental impact of a building is influenced by a multitude of factors, such as size, energy consumption during use, and the materials used. It is often difficult to determine the relative impact of each factor. In addition, the number of timber buildings is smaller than that of other buildings, limiting statistical analysis. Some researchers have attempted to address this challenge by utilizing a methodology that compares the environmental impact of existing buildings virtually by redesigning them as equivalent buildings of the same usage and layout [2-3]. However, this methodology may have limitations as there is no guarantee that the structural system of a building designed with a different material will be as efficient as the original building.

Consequently, this study aims to compare the environmental impact of timber as a building material with steel and concrete. Structural members were designed to achieve this with equivalent performance under controlled design conditions while considering the mentioned issues. Furthermore, this study aims to comprehensively understand the sustainability of timber in modern high-rise construction and identify each material's strengths and weaknesses.

2 STRUCTURAL DESIGN

2.1 TARGET MEMBER AND EQUIVALENT STRUCTURAL PERFORMANCE

This study designed members with equivalent structural performances and compared their environmental effects.

To objectively compare the environmental impact of different materials, selecting a target for comparison and defining equivalent structural performance as a criterion is necessary.

As a specific building was not designated in this study, making necessary assumptions may become complicated and increase research limitations. Hence, due to its relatively simple design conditions, the target member was selected as a beam supporting mainly gravity loads.

Even though beams with different materials may have different moment and shear strengths, they can provide the same space and function as long as their design conditions, such as span and load, are the same. Thus, in this study, equivalent structural performance was defined through design conditions, not calculated indicators such as moment and shear strength. Additionally, all members were designed to have similar depth as steel beams using Products produced according to standard specifications, even if the structural performance is the same. This was done to ensure that the overhead clearance is not greatly affected, as a difference in beam depth would result in a difference in usable space, as shown in Figure 1.

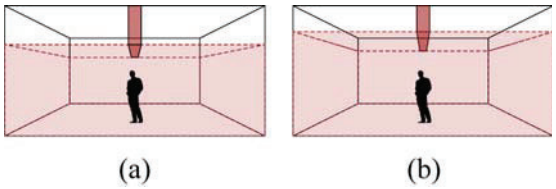

Figure 1: *Example of usable space and overhead clearance according to beam depth: (a) large beam depth, (b) small beam depth.*

2.2 MATERIALS

Three types of materials were used in the beam design: timber, steel, and reinforced concrete (RC). The timber beam was assumed to a glued-laminated timber (GLT) using larch (*Larix kaempferi*), a mechanically graded dimensional lumber. The materials used in the design are listed in the following Table 1, and the design was based on the KS standard [4–7]. All materials were chosen from those commonly used in the industry. The dead load was calculated using the density data from the Ministry of Land, Infrastructure, and Transport [8].

Table 1: *Material properties*

Type	Material	Density [kg/m^3]	Strength [MPa]	MOE [MPa]
Timber	10S-30B	580	10 (f_b)	9,000
Steel	SM355A	7,850	355 (f_y)	210,000
RC	C30	2,300	30 (f_{ck})	27,500
	SD400	7,850	400 (f_y)	200,000

Where MOE=modulus of elasticity, f_b=bending strength, f_y=yield strength, f_{ck}=compressive strength.

2.3 STRUCTURAL MEMBER DESIGN

The beams were designed based on the following structure (Figure 2). In order to simplify, it was assumed that the plane has a square shape and that the beam is located at the center. The design was carried out considering a span ranging from 3 to 8 meters and a live load ranging from 2 to 6kN/m^2. The design followed the Korean design standard (KDS), and the timber structure was designed using the allowable strength design (ASD) method. In contrast, the steel and concrete were designed using the ultimate strength design method (USM) and the load and resistance factor design method (LRFD), respectively. In order to design optimally, All beams were designed with the minimum member weight in each condition.

The following assumptions were additionally made in the design:

1) The shape of the timber and concrete beams was rectangular, and the shape of the steel beams was an I-beam (Figure 3).
2) The beams were assumed to be a simple beam condition in which all boundary conditions are pin connections and were designed only for dead and live loads.
3) The slab's weight was calculated by designing a CLT slab for timber and a concrete slab for RC and steel. The weight of the finishing and equipment was not included.
4) Fire-resistance design was not considered.

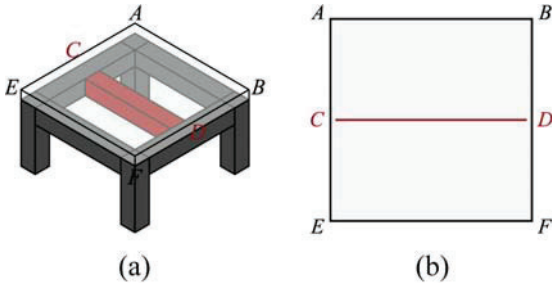

Figure 2: *Assumed structural diagram for the beam design: (a)elevation and (b)floor plan.*

https://doi.org/10.52202/069179-0135

3 CARBON FOOTPRINT ANALYSIS

3.1 FUNCTIONAL UNIT AND SYSTEM BOUNDARY

This study evaluated the environmental impacts by carbon emissions through Life Cycle Assessment (LCA) methodology. To perform LCA, defining a functional unit and a system boundary is necessary. The functional unit was set as the 1-meter length of the designed beam, and the final quantity was calculated by dividing the total quantity of the beam by the span. The system boundary was defined as cradle-to-gate (product stage), and only the environmental impacts during raw material extraction and processing, transportation, and manufacturing were considered (Figure 4). The reference service life of the building was assumed to be 50 years.

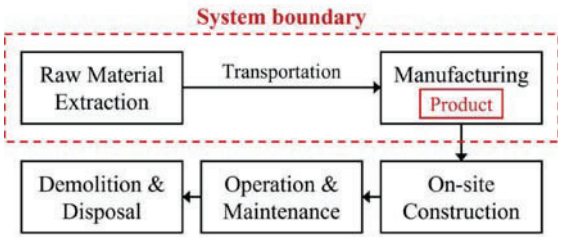

Figure 4: *Building life cycle and system boundary.*

3.2 CARBON EMISSION EVALUATION

The data used to evaluate the carbon emission was taken from a publicly accessible environmental product declaration (EPD) database. The carbon emission data of steel and concrete materials were obtained from the database of the Ministry of Environment. In contrast, data for GLT was taken from the database of the Forest Science Institute, as there was no EPD database available in Korea. The used data is presented in the following Table 2. The total CO_2 emissions were calculated by multiplying the material quantities by the CO_2 emissions factor per unit.

Table 2: *The equivalent carbon emission factor of materials*

Material	CO_2 emission	Unit	Reference
GLT	87.64	$kgCO_2$-eq/m^3	[9]
Steel	11,241		[10]
Concrete	3,532		[10]
Rebar	259		[10]

3.3 LIMITATIONS

This study has similar assumptions as previous studies [11], and similarly, it has the following limitations:

1) This study used the equivalent carbon emission factor from the EPD database developed in Korea. This study did not account for environmentally improved products such as low-carbon concrete. Therefore, it is essential to note that the results may be limited to the conditions of Korea at the time of this study. Production processes, transportation methods, and efficiencies vary by region and time, which may result in different findings from this study.
2) The system boundary of this study was limited to the product stage, from raw material extraction to manufacturing, thereby excluding the impact in the use and disposal stages.
3) The findings of this study should be separate from other building components (e.g., columns) or structural systems (e.g., continuous structural systems). For instance, vertical members, such as columns and walls, are highly influenced by upper-level loads. Thus, an increase in load caused by the building size, material density, and member volume increases, leading to an increase in the cross-sectional size of the vertical member. Additionally, the moment distribution in the member may change for a continuous structural system, which could result in different findings. This study also did not apply any load factor to timber beam design.
4) It is also important to note that this study did not consider the fire-resistance design. Therefore, the findings may not be suitable for fire-resistance design purposes.

4 RESULTS AND DISCUSSIONS

4.1 COMPARISON CARBON EMISSIONS ACROSS SPANS

Figure 5 presents the carbon emissions results along the span for each live load. As the span increased, a greater structural performance was necessary, which led to an increase in the cross-sectional size and quantity of materials, and consequently resulted in a rise in carbon emissions. The analysis indicates that GLT emitted the lowest carbon across all scenarios with equivalent structural performance, while RC and Steel followed in that order.

To clearly compare the ratio between each material, the data was normalized by the steel, which has the highest carbon emission, as shown in Figure 6. The results indicate that, on average, timber and RC exhibited a reduction of 85.52% and 37.29% in carbon emissions compared to steel.

Although no distinct patterns in carbon emissions were discernible across the span, the data indicated the presence of fluctuations. The observed fluctuations in the results can be attributed to discontinuities in the cross-sectional design of the beams. Since steel beams were used as ready-made products, the section properties were not continuous across spans. Furthermore, considering the workability, the cross sections of timber and RC were designed with 10mm increments. Consequently, the strength-to-load ratio of each beam differed across spans, leading to the observed fluctuations.

4.2 COMPARISON CARBON EMISSIONS ACROSS LIVE LOADS

In Figure 7, the equivalent carbon emissions along the live load are shown for a span length of 6m. It was observed that the change in carbon emissions along the live load is

https://doi.org/10.52202/069179-0135

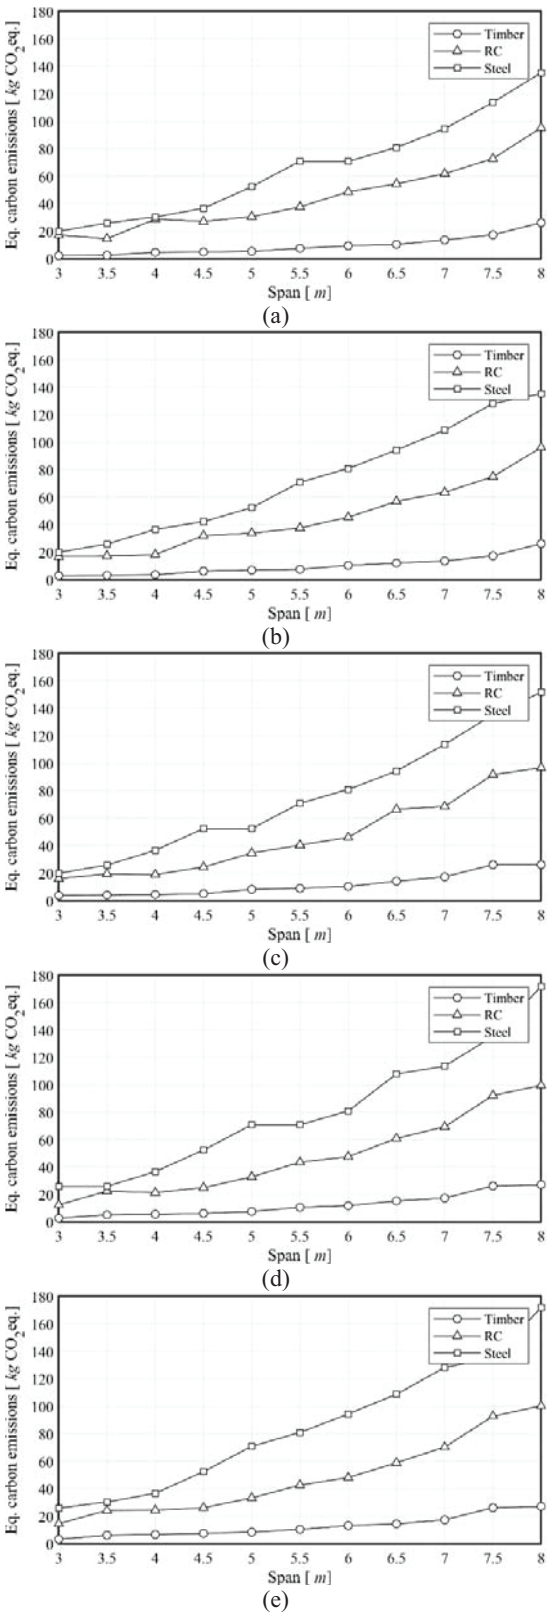

Figure 5: Equivalent carbon emissions along the span when the live load was (a)2kN/m², (b)3kN/m², (c)4kN/m², (d)5kN/m², and (e)6kN/m².

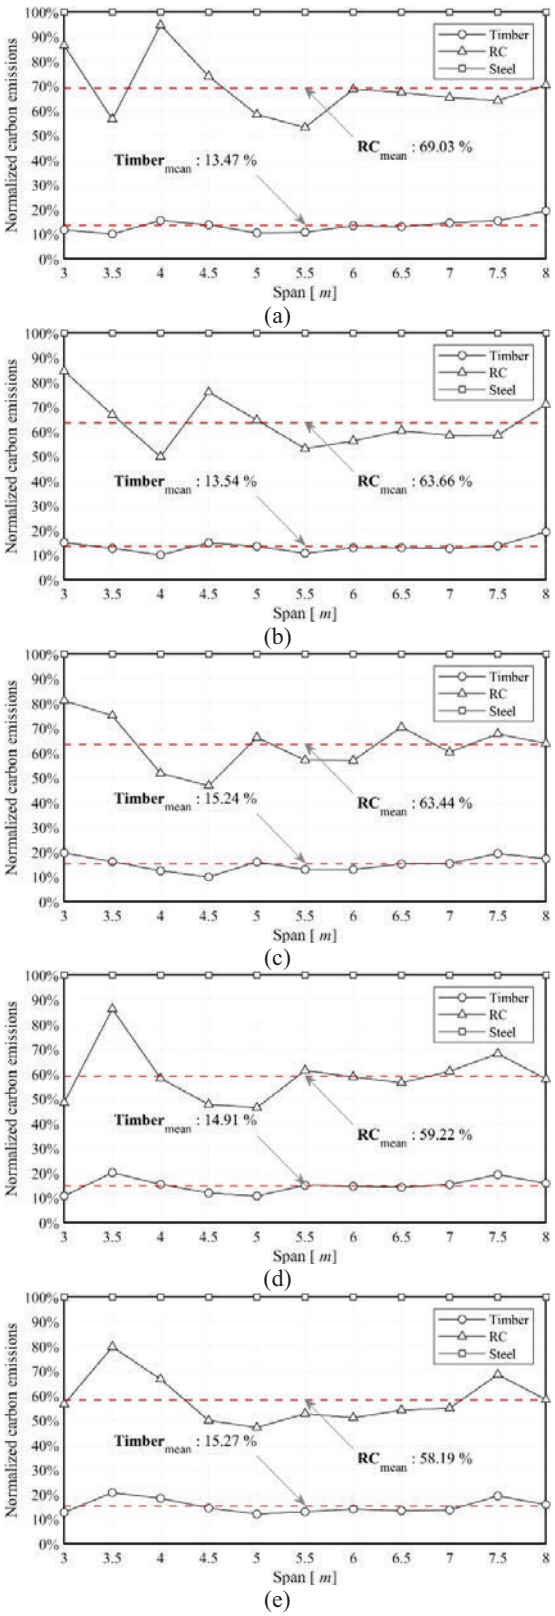

Figure 6: Normalized equivalent carbon emissions along the span when the live load was (a)2kN/m², (b)3kN/m², (c)4kN/m², (d)5kN/m², and (e)6kN/m².

https://doi.org/10.52202/069179-0135

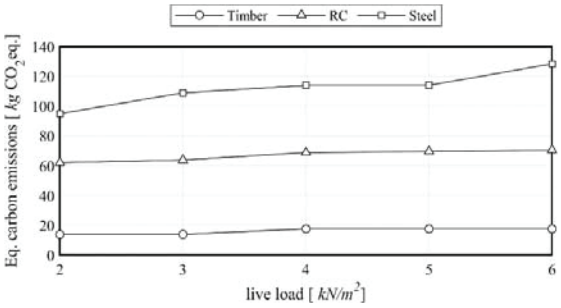

Figure 7: *Equivalent carbon emissions along the live load when the span was 6m.*

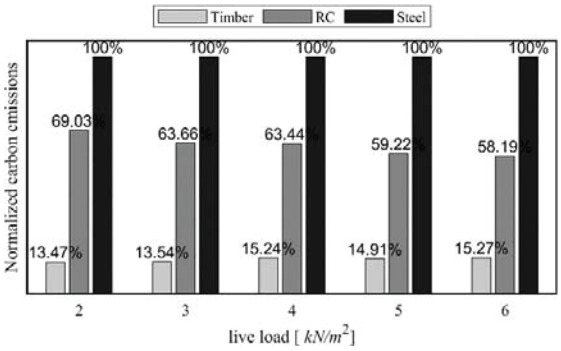

Figure 8: *Comparison of normalized equivalent carbon emissions along the live load.*

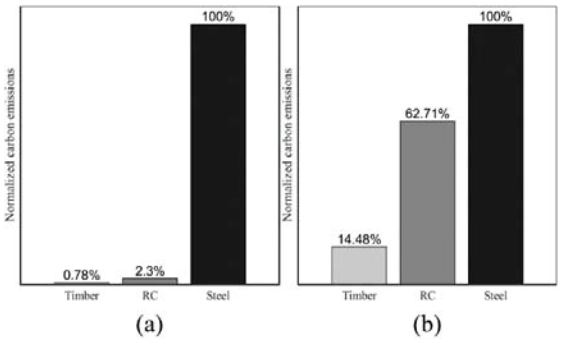

Figure 9: *Comparison of normalized equivalent carbon emissions by (a)volume-based and (b)performance-based comparisons.*

not greater than the change along the span. This arises from the influence of live load and span on required strength and deformation. The required strength and deformation increase proportionally to the load's first power. In contrast, the required strength increases proportionally to the span's square, and the deformation increases proportionally to the span's fourth power. Consequently, the required structural performance was predominantly influenced by the span, resulting in a more pronounced alteration in the environmental impact as the span varied, compared to the effects caused by changes in the live load.

Figure 8 also presents the average normalized equivalent carbon emissions along the live load. In this case, the changes in carbon emissions caused by the live load were not substantial, and no distinct patterns could be identified as well.

4.3 CARBON EMISSION RATIOS FOR SUSTAINABLE BUILDING MATERIALS

Figure 9 reveals that the carbon emission ratio by material varies significantly between a unit volume-based comparison and a structural performance-based comparison. This difference can be attributed to the specific structural performance of each material, indicating that direct comparisons of carbon emissions per unit volume may lead to substantial errors.

Notably, when comparing the results of volume-based and performance-based comparisons, there has been a decrease in the steel/timber ratio and an increase in the RC/timber ratio. This observation may suggest that, from an environmental standpoint, the structural efficacy of timber is relatively inferior to that of steel but superior to that of RC. Such a finding may have significant implications for sustainable construction practices, as it highlights the potential of timber as a viable alternative to traditional building materials, particularly in the context of reducing the carbon footprint of construction projects.

5 CONCLUSIONS

In conclusion, this study analyzed and compared the environmental impact of timber, concrete, and steel in building construction at the structural member level. The results revealed that timber and concrete had significantly lower equivalent carbon emissions than steel, with timber having the lowest emissions. Although the carbon emissions of all materials increased with the increasing span, there was no specific trend according to span and live load.

A significant difference was observed when comparing the environmental impact ratio of volume-based and performance-based comparisons. This indicates that the structural efficiency of timber was found to be relatively inferior to steel but superior to concrete. This finding suggest that timber could be a feasible alternative to conventional building materials and could have important implications for sustainable construction practices.

However, this study has limitations, and further research is required to improve the structural assumption and life-cycle assessment. Future studies should consider diverse structural systems, design conditions, and target members. Furthermore, comprehensive life cycle assessments covering various impact categories should be conducted to obtain a more comprehensive understanding of the environmental impact of these building materials.

World Conference on Timber Engineering Oslo 2023

MEETING THE 2050 PARIS AGREEMENT TARGETS USING MASSIVE TIMBER IN SCHOOL BUILDINGS

Efthymia R. Stæhr[1], Thomas K. Thiis[2],Arnkell J. Petersen [3] Leif D. Houck[4]

ABSTRACT: Due to the importance of global warming and the signature of the Paris agreement, Norway has committed to reducing greenhouse gas emissions by 95% by 2050. Using school buildings that have already been designed with high environmental standards as case studies, one can identify the building elements that contribute the most to embodied energy and develop methods to reduce them even more. This article presents a review of 4 schools that include massive timber elements, the correlation between their CO_2 emissions and the gross floor area per year and compares this ratio to the Paris agreement targets set for 2050. The study revealed that the case studies comply with the current median environmental performance standards but lack to reach the 2050 targets. Added to this, the importance of using more massive timber in school buildings was highlighted and the need for an upgraded timber material was underlined.

KEYWORDS: LCA, timber schools , school buildings, sustainable schools

1 INTRODUCTION

It is widely recognized that the construction industry is greatly contributing to greenhouse gas (GHG) emissions in Europe [1]. The European Union (EU), in recognition of the climatic change and the impact of global warming, decided that impending action is needed to lower GHG emissions in Europe [1]. The Paris Agreement which was signed by a great number of nations represents the decarbonization efforts of the EU and sets a reduction target of GHG emissions by 91-94% of 1990 levels by 2050 [1]. In 2021, Norway updated its intended nationally determined contribution (INDC) to reduce the emissions by 95% in 2050 compared to 1990 levels [2].

The challenge to comply with the Paris Agreement includes reducing the GHG emissions connected with both the operational energy of the building, as well as the embodied emissions associated with the building materials. According to EN 15978:2011 the life cycle of the building materials is divided into different phases: the manufacturing phase (A1-A3), the maintenance phase (B3), the disposal and refurbishment phase (B4-B5) and the end-of-life phase (D) [3].With measures implemented to reduce buildings' operational energy over the last couple of years and with the effort required to reach the Paris Agreement target, the embodied-operational ratio has shifted. Currently, the embodied energy of a building represents a considerable percentage of the total building emissions. [4,5].

In the last 20 years, considerable effort has been made in developing timber structural products which also contributed to the reduction of GHG emissions [6,7]. This has resulted in a variety of engineered wood products (EWP) that have been used broadly in the construction industry. Cross-laminated timber (CLT), also known as massive timber or X-lam [8], is a versatile wood product with properties that make it suitable for the structural support frame of a building [9].

CLT products have been gaining popularity in the Norwegian construction industry. When public buildings and especially schools are concerned, the massive timber usage seems to be increasing. Data indicates that the investment in timber for school buildings from 1,7 billion NOK in 2012 increased to 3,4 billion NOK in 2021 [10].

As sustainability awareness has increased and massive timber construction has risen, a gap has been created in knowledge about whether those newly built school buildings can fulfil the Paris agreement targets.

Scholars have shown that massive timber buildings can have up to 30% lower GHG emissions when compared with conventional materials such as concrete and steel [11, 12]. But even though today much effort has been put

https://doi.org/10.52202/069179-0136

into designing buildings that hold high environmental standards, it is unclear if these buildings can fulfil the 2050 Paris agreement targets [13].

As the world population rises, a great investment is done in school buildings. Norwegian Municipalities have set up high building standards following sustainability commitments. Data from the industry show that more than 339 billion NOK has been invested in school buildings, and from this amount, 218 billion NOK is invested in new buildings [10].

The objective of this work is to present and study a selection of school buildings that include CLT in their construction. A case study of four schools is used to answer the following research questions:

- How do CLT school buildings with high environmental standards perform regarding their GHG emissions?
- How do those results compare with the Paris Agreement sustainability targets for 2050?

2 METHODS

In Norway, GHG emission targets from embodied energy in buildings until recently have been expressed as percentage reductions relative to so-called reference buildings [14]. This approach turned out to be inconclusive since all case studies were evaluated relatively to a customized reference for each building. The Research Centre for Zero Emission Neighborhoods (ZEN) created the only Norwegian GHG emission database by collecting different building typology case studies for both the material production phase (A1-A3) as well as the replacement phase (B4) of the building process. This was done through the usage of different Life Cycle Analysis (LCA) software such as Powerhouse, OneClickLCA, SimaPro and an MS Excel-based ZEN algorithm. Through this method, ZEN managed to depict the GHG 2050 targets for all building typologies. A benchmark of the environmental impact value of 5,4 $kgCO_2/m^2$/year was determined as a 2020 starting point, with an endpoint of 0,4 $kgCO_2/m^2$/year for 95% reduction or 1,4 $kgCO_2/m^2$/year for 80% reduction [15].

The main objective of this study is to establish the environmental impact ratio ($kgCO_2/m^2$/year) of the chosen school buildings and compare it with the 2050 benchmark that has been established by ZEN.

Additionally, the correlation between the materials used and the GHG emissions of each case study will be explored. This will be done, by a case study of newly constructed elementary schools that also include cross-laminated timber in their building modules. In the analysis, the volume of materials per square meter of heated floor area (HFA) will be highlighted ($\frac{m^3}{m^2}$ HFA), so as to give a justification concerning the association between material usage and GHG emissions in the building envelope.

The criteria for choosing the case studies rely on their similar building timeframe (2019-2021), and construction materials (usage of CLT, steel, and concrete). Added to this, all case studies are considered multi-functional buildings which contain teaching areas, sports halls, and cultural spaces.

2.1 DATA COLLECTION

The first step of this study includes the analysis of the building modules using Building Information Modeling (BIM). Through correspondence with the architects, we could acquire the International Foundation Class (IFC) files of the buildings. From there, we created inventories (schedules) in BIM software such as Archicad v. 25 and Solibri v. 9.12.10 that could differentiate the material quantities used in every part of the building. After that, through correspondence with the architects and contractors of the case studies, we acquired some of the Environmental Product Declaration (EPD) of the materials used in the construction. For the building modules that we were not able to acquire the EPD, a standard benchmark was used from the Ecoinvent database v 3.8 [16, 17]. An EPD, also referred to as type III environmental declaration, is *a standardized (ISO 14025) and LCA-based tool to communicate the environmental performance of a product* (Schmincke, 2007). Through the EPD, information was gathered concerning the GHG emissions of each building component. That information included CO_2 quantities from the raw material production to the transport of the processing facilities and finally to the transport of the building site (A1-A3 phase). Additionally, information regarding the replacement and refurbishment phase (B4-B5) was given.

2.2 LIFE CYCLE ANALYSIS (LCA)

To accomplish the scope of the research, a Life Cycle Analysis was next used to determine the overall building GHG emissions of the case studies and which elements of the building envelope contributed the most. Through standardization, LCA has gained global support as the most important tool for furthering more environmentally friendly choices in the sector. The functional unit for this analysis, in reference to the school buildings, was defined

as one square meter of floor area for a period of the lifecycle (1 m2); The life cycle of the school buildings was set to 60 years as this enables comparisons with similar studies. The system boundary for a building's life cycle consists of material manufacturing, transportation, construction, operation(A1-A3), and maintenance phases (B4-B5). The LCA methodology software that was used for all 4 case studies is the OneClickLCA. The specific software was chosen as it follows the requirements of NS 3720 Norwegian standard which is based on EN 15978:2011 and ISO international standard [19].

After the overall GHG emissions of the buildings were calculated, the required environmental impact ratio was established by dividing the CO_2 emissions by the area and the life cycle of the building. The final ratio of $kgCO_2/m^2$/year is compared with the ZEN 2020 median ratio and the ZEN 2050 prognosis.

2.3 THE CASE STUDIES

The criteria of choosing the case studies include the same material choice (a combination of CLT, steel and concrete) as well as the addition of multifunctional spaces (sports and cultural halls). Furthermore, all 4 buildings follow the Norwegian TEK 17 building legislation [20], hence the same regulations on technical requirements. In addition, all school buildings have been designed with high sustainability standards in mind and received sustainability certifications after their completion.

Case A - Flesberg school (2017-2019)

Flesberg is a school building built according to Passive house sustainability standards. It consists of 4 individual building volumes that link together through a connecting area. The concept of this project indicated that each volume has a different purpose; the more acoustically challenging volumes, such as the swimming hall, and the sports hall are isolated from the last two volumes which are used for teaching spaces. The connecting area between the building volumes serves as a common area for students between the library, the amphitheatre and the administrative space. The building is placed partly under the terrain because of the topography of the chosen site. The parts of the building that are under the terrain, are constructed in concrete. Above ground level, massive timber is used in various parts of the building frame, including the walls of the sports hall and the swimming hall.

Case B - Bamble school (2018-2021)

Bamble is a BREEAM -very good accredited school that consists of 3 building volumes; the first two that inhabit the teaching spaces are connected through a common area, while the third one that accommodates the sports, swimming hall and the gym, is independent. The concept has separated the building volumes to protect the main teaching spaces (classrooms) from the more acoustically challenging volumes (sports hall, swimming hall, gym). The building volumes that host teaching facilities are constructed in massive timber, while for the swimming hall, concrete was used. Although the site was flat, a volume was placed under the terrain to host sports facilities.

Case C - Huseby school (2017-2021)

The school received a BREEAM-Very good certification and consists of 2 different building volumes that connect through a concert hall and a sports hall. The school's concept was to separate the different age groups (each age group has a different entrance) but at the same time unite them under the cultural and activity spaces. The main teaching spaces (classrooms) are constructed in massive timber, while the common spaces (sports hall, concert hall) are constructed out of steel and placed under the terrain.

Case D - Nordre Ål school (2017-2019)

Nordre Ål school is built according to Passive house standards and consists of 4 different building volumes. All volumes are connected through an amphitheatre which represents the heart of the school. The foundations, elevator shafts and ground floor slabs are made of concrete, while the remaining structural elements are predominantly made of massive timber.

Table 1. *The table shows an overview of the characteristic parameters for the different cases.*

	Case A	Case B	Case C	Case D
Facilities	Teaching spaces Sports hall Swimming hall Library Cultural space	Teaching spaces Sports hall Swimming hall Gym Cultural space	Teaching spaces Sports hall Cultural space	Teaching spaces Sports hall Cultural space
Building data received	IFC model	IFC model	IFC model	Solibri model
Material data received	EPD massive timber EPD steel	EPD massive timber EPD steel	EPD massive timber EPD steel	EPD massive timber EPD steel EPD plasterboard
Gross Area (m^2)	8884	14565	12933	8109
Sustainability Certificate	Passive house	BREEAM very good	BREEAM very good	Passivhaus
Sub. volumes	yes	yes	yes	no

3 FINDINGS

In this section, the outcomes of the life cycle GHG emissions were analyzed and compared with the given ZEN benchmarks. Additionally, the volume of material per square meter of heated floor area is highlighted.

3.1 BUILDING ENVELOPE FINDINGS

In all four buildings due to the requirement of sustainability certifications, an effort was made for good environmental performance. When embodied energy is concerned, that effort was reflected in the addiction of massive timber in the building envelope.

In the two case studies (Case A and Case C) that we have inclined site topography, the building volumes that are below the earth are made in concrete while the timber is used mainly above terrain levels. That has resulted in a higher concrete volume than massive timber per square meter of HFA. (Table 2). In Case B, even though there wasn't any inclined site topography, a requirement of a basement was made, making the concrete volume almost equal to the massive timber used (Table 2).In Case D, as being the only school without the need for a basement, a great differentiation is shown between the massive timber and concrete volume used per square meter, with massive timber volume being more than double. (Table 2)

Table 2. *The table shows the summary of the environmental data of 4 massive timber school buildings.*

	Case A	Case B	Case C	Case D
$kgCO_2$ (A1-A3)	1,9 million	2,1 million	2,9 million	1,3 million
$kgCO_2$ (B4-B5)	128 407	945 510	195 277	41 448
$kgCO_2/m^2/year$	3,8	3,5	4,1	2,9
Timber ($\frac{m^3}{m^2}$ HFA)	0,18	0,18	0,29	0,43
Concrete ($\frac{m^3}{m^2}$ HFA)	0,32	0,19	0,9	0,17

3.2 LCA FINDINGS

The LCA data showed that all case studies have achieved lower emissions than the median 2020 benchmark of 4.5 $kgCO_2/m^2/year$.

Nordre Ål school (Case D), with the highest percentage of massive timber compared to concrete, and without underground volumes seems to perform the best with a 2,9 $kgCO_2/m^2/year$ while Huseby (Case C) seems to perform the worst with 4,1 $kgCO_2/m^2/year$. When placed in the 2030 and 2050 GHG emission scenario, Huseby's (Case C)ratio depicts the 2025 target, while Flesberg's (Case A) 3,8 $kgCO_2/m^2/year$ ratio is the 2027 target. Bamble school (Case B) , with a ratio of 3,5 $kgCO_2/m^2/year$ represents the 2029 target, while Nordre Ål (Case D) 2,9 $kgCO_2/m^2/year$ ratio for the 2032 GHG reduction, exceeding the 2030 commitment. (Fig 1)

https://doi.org/10.52202/069179-0136

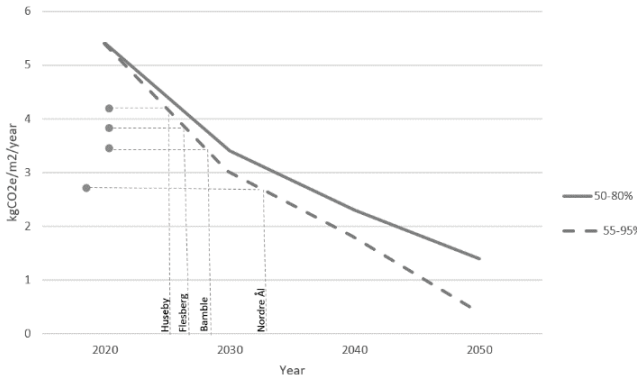

Figure 1. *The Figure shows the comparison of kgCO₂/m²/year ratio of the case studies to the 2030 and 2050 GHG reduction scenarios. The scenario benchmark values were calculated by ZEN (M. Kjendseth Wiik, 2020)*

4 DISCUSSION

As Norway is in the process of lowering its GHG emissions, all four case studies represent newly built sustainable schools. It is greatly understood that massive timber when used as a building material bears environmental benefits [21, 22] hence seems to be promoted for usage in all case studies. The initial results of the research confirm that indeed the percentage of low carbon materials such as CLT that are used in building modules, play the biggest role in the reduction of total emissions, making all case studies perform better than the median set by ZEN.

It is also understood that the overarching goal of these case studies is to achieve the best environmental performance according to the 2020 benchmark standards with great success. But still, fail to reach the 2050 goal. Massive timber, a material with a low carbon footprint, was used mostly in less acoustically challenging areas with smaller span such as classrooms and meeting rooms. Subsequently, if the use of massive timber was greater, the case studies might have shown better lower-emission performance.

Added to this, the preliminary results show that buildings that require subterrain volumes due to the formation of the terrain or due to other circumstances, perform worse emission wise. Concrete, as a building material, is currently regarded as the only option when building volumes under the earth level. Even though great research has been put into reducing its carbon footprint [23], still concrete is concerned a high emission material when compared to massive timber. Although it is difficult to draw definite conclusions, to be able to tackle the 2050 targets, the usage of concrete needs to be further reduced in the building envelope. This may be done by either reducing the number of subterrain volumes or changing the way those volumes are constructed.

5 CONCLUSIONS AND FURTHER RESEARCH

To play a role in restricting the global temperature increase to a safe level of 1.5°C and hence follow the Paris agreement targets, a greater effort in the use of low carbon materials such as massive timber is required. This research revealed that to design a school with high environmental standards, a great percentage of massive timber should be used. But even though those buildings broadcast lower GHG emissions than the average benchmark, they need more improvement to reach the 2050 targets.

For the next step, it would be interesting to address more case studies to examine deeply the connection between the emissions related to material use and the overall GHG emissions in school buildings.

World Conference on Timber Engineering Oslo 2023

HOLISTIC DESIGN OF TALLER TIMBER BUILDINGS – COST ACTION HELEN (CA20139)

Gerhard Fink[1], Robert Jockwer[2], Iztok Šušteršič[3], Mislav Stepinac[4], Pedro Palma[5], Chiara Bedon[6], Daniele Casagrande[7], Steffen Franke[8], Giuseppe D'Arenzo[9], Daniel Brandon[10], Christian Viau[11]

ABSTRACT: With the worldwide construction sector being responsible for one third of carbon dioxide emissions, as well as forty percent of the world's energy use and waste production, a shift to sustainable and renewable construction techniques is crucial. Engineered timber, a champion of sustainable construction materials, has evolved to a stage that enables the construction of not only family housing but also taller buildings so far commonly built from concrete or steel. Designing taller timber buildings made is more demanding than their concrete and steel counterparts. Whereas different design aspects (architectural, structural, fire safety, acoustics, etc.) of concrete buildings can work almost independently, the design of taller timber buildings should be performed with intensive collaboration among the design teams. It is therefore crucial to address taller multi-storey timber buildings from a collaborative and interdisciplinary perspective, considering static, dynamic, fire, acoustic, human health, and other aspects in parallel and not in isolation. Only through interdisciplinary analysis and interaction can a set of holistic design guidelines be developed that will enable the safe construction of taller timber buildings, as well as respect human wellbeing demands. In this paper, the COST Action CA20139 will be presented and the main aims will be discussed.

KEYWORDS: COST, holistic design, tall timber buildings, sustainability, multi-storey timber, robustness, design for adaptability and reuse, deformation and vibrations, durability, seismic design, fire

1 INTRODUCTION

The number and height of multi-storey timber buildings substantially increased over the past decade [1, 2]. The envelope is being pushed every year, and the current record (as of 2020) for a purely timber multi-storey apartment building stands at 18 storeys (85 m), while for a timber-concrete hybrid it stands at 24 storeys (84 m). Hence, timber buildings up to 10 storeys are in the meanwhile already considered as midrise.

Due to targets regarding a more sustainable and healthier environment, contemporary multi-storey timber buildings are being recognised as a long-term sustainable solution, especially in urban areas where they present an environmentally friendly alternative to concrete and steel buildings [3].

The design of taller timber buildings so far has always been made by highly specialised engineering teams that were well aware of the unique demands and challenges that multi-storey timber buildings are associated with. Despite that several midrise and a few taller timber buildings have been already built, the knowledge level as well as the number of recognised experts on taller timber buildings is still far from its concrete and steel counterparts.

Additionally, there are also new and most likely more challenges to be tackled with taller timber buildings [4]. Despite efforts, practically all the worldwide research performed in the field of multi-storey timber buildings was performed partially with intense focus on individual fields (connections, vibrations, acoustics, fire, durability [5-6]) and not considered from a wider perspective, namely in a holistic manner. However, a well-integrated design is absolutely crucial for designing taller timber buildings.

2 CHALLENGES AND AIMS OF THE COST ACTION

COST Action CA20139 – Holistic design of taller timber buildings (HELEN) was started on 12/10/2021 and runs until 11/10/2025. It will try to change the paradigm of building construction research, shifting R&D from isolated topics to an integrated interdisciplinary approach, which is critically necessary to safely design and build as well as correctly maintain and recycle taller timber buildings. There are several reasons why: less general experience with them; codes for timber buildings are not as developed as they are for concrete or steel [7,8]; and less suitable literature is available for practicing designers. However, a key difference is the design complexity of timber buildings due to basic material properties. Whereas different designers (architects and structural, fire and acoustic engineers) of concrete buildings can work almost independently, the design of taller timber buildings should be performed with intensive collaboration among the design team members [9]. Otherwise, serious conflicts can arise (Figure 1) that effect both the load resisting and serviceability criteria of a building.

Counting purely on design codes is not sufficient as the code information and offered solutions only partly address the full range of concerns for timber buildings. Therefore, it is crucial to address taller multi-storey timber buildings from a collaborative and interdisciplinary perspective, considering static, dynamic, fire, acoustic, human health and other aspects in parallel and not in isolation. Only through interdisciplinary analysis and interaction can a set of holistic design guidelines be developed that will enable safe construction of taller timber buildings that respect human well-being demands.

The main objective of HELEN is to foster international interest and effort in developing a shared understanding and deriving common guidelines for the holistic design of taller timber buildings. This will be carried out through the sharing of technical and scientific skills from the different and diverse research profiles within the network as well as their research facilities. Cooperation within this network will allow for coordinated research efforts and achievement of the following objectives:

- Coordinate, compare and bring together results of related research with the aim of defining optimized holistic approaches to improve the performance of taller timber buildings.
- Collect case studies that show flagship examples describing taller timber building design.
- Foster the transfer of knowledge among different actors in order to find suitable applications in various multidisciplinary fields (e.g. vibrations of buildings, material response and influence).
- Serve as a hub to combine existing knowledge and identify common issues and problems in order to develop new holistic taller timber building design guidelines.
- Suggest new design approaches, processes and technologies that can build and improve upon existing best practices and finally presented in the design guidelines suggesting the optimal holistic design of taller timber buildings.
- Identify and address regulatory, governance, financial and legal drivers and barriers for a wider implementation and use of taller timber buildings.

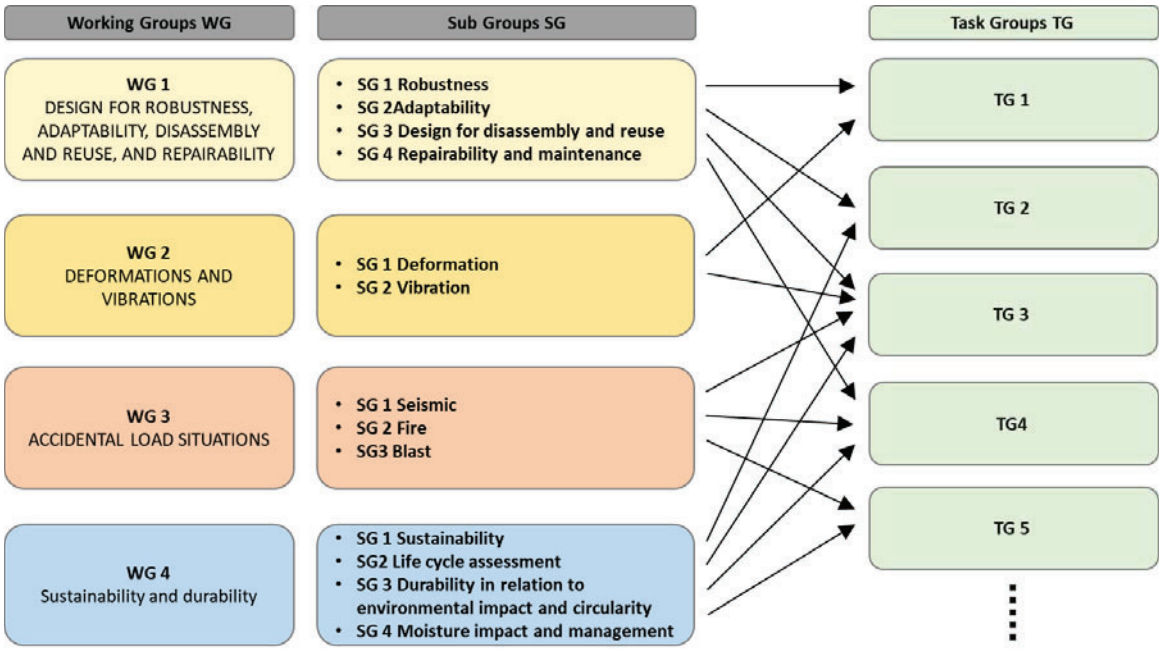

***Figure 2**: Structure of COST Action CA* 20139

3 STATE-OF-THE-ART REPORT

HELEN is organised in four Working Groups (WGs), each containing several subgroups (SGs). An overview is presented in Figure 2. As a result of the multidisciplinary aspects considered in HELEN, the COST Action is rapidly growing with currently 282 members from 44 countries (status March 2023).

One of the first targets on HELEN was the development of a state-of-the-art report in taller multi-storey timber building design fields: 1) Design for robustness, adaptability, and reuse and repair; 2) Deformations and vibrations; 3) Accidental load situations and 4) Sustainability and durability. In this chapter, the WGs and the content of the State-of-the-Art report is shortly introduced.

One of the main activities of the action is the identification of multidisciplinary tasks and research questions, for which the expertise of several WGs can be combined in task groups (TG) in a multidisciplinary effort (Figure 2). The State-of-the-Art Report was a first step in the identification of such multidisciplinary issues.

3.1 WG 1 – DESIGN FOR ROBUSTNESS, ADAPTABILITY, DISASSEMBLY AND REUSE, AND REPAIRABILITY

WG1 deals with aspects related to *robustness, adaptability, design for disassembly and reuse, and repairability*. Given the broad range and interdisciplinary nature of the topics assigned to WG 1, it has members with different backgrounds in both engineering and architecture and in research and practice. WG 1 is organised in four Sub-Groups (Figure 2) i) SG *Robustness*; ii) SG *Adaptability*; iii) SG *Design for disassembly and reuse (DfDR)*; and iv) SG *Repairability and maintenance*. The contribution of WG 1 to the State-of-the-Art Report [10] includes a total of 20 documents from all SGs.

Robustness:

SG *Robustness* deals with the topics of resistance to disproportionate damages, including structural and non-structural robustness and resistance to progressive collapse. The SG has worked on developing a framework for the design of timber buildings against disproportionate collapse, which includes identifying all stakeholders and their interests and responsibilities. Case studies of structural design for increased robustness have been analysed and most important strategies summarised. The key issues identified by the SG are the: experimental validation of sudden element-removal scenarios; simplified structural analysis models for alternative load-paths (ALPs), e.g. with dynamic amplification factors; the behaviour of connections in ALPs; connections as fuse elements in segmentation strategies, which has similarities with *capacity design* for earthquake resistance; "power storeys" for vertical segmentation in taller timber buildings. The members of SG *Robustness* contributed with five documents to the State-of-the-Art Report.

https://doi.org/10.52202/069179-0137

Adaptability:
SG *Adaptability* deals with topics related to changes in the functional use of buildings, how the design of tall timber buildings can account for adaptability-related requirements (e.g. versatility, convertibility, expandability), and with the interactions between these and other requirements (e.g. robustness, durability). The SG created a definition of adaptability of a taller timber building an identified key challenges and advantages of timber buildings. The SG is currently focusing on: identifying spatial structures and constructions that allow for the highest degree of interaction, flexibility and adaptability; identifying key parameters for adaptability; identifying conflicts between adaptability and other requirements (e.g. acoustics, fire safety); socioeconomic factors for higher adaptability; digitalisation, information management and computational methods for adaptability, repairability and reusability of timber buildings; development of reversible connection systems.

Design for disassembly and reuse:
SG *Design for disassembly and reuse (DfDR)* addresses the topics of design for disassembly and reusability in the context of tall timber buildings. This includes the design of new timber buildings taking into account future needs of disassembly and maximising reuse possibilities, but also the reuse of reclaimed materials in new buildings. The SG has been working on: identification of circular materials flows in tall timber buildings; assessment of the mechanical properties of reclaimed timber members; and identification of barriers to the design for disassembly and reuse.

Repairability and maintenance:
SG *Repairability and maintenance* deals with issues of maintenance of buildings during their planned service life and of restoring the original conditions in case of damages. The work of this SG has focused on: maintenance strategies for tall timber buildings; design strategies to take into account eventual need for repairs; repair strategies for tall timber buildings; and how to extend the service life of taller timber buildings.

3.2 WG 2 – DEFORMATIONS AND VIBRATIONS

WG2 deals with aspects and design issues related to *deformations and vibrations* in the framework of taller timber structures. Basically, scientist and professional engineers contributing to the activities of WG2 are representative of research institutions, universities and industrial partners. Actually, major activities of WG2 are divided into two major Sub-Groups: SG1 – Deformations and SG2 – Vibrations, see [11] and Figure 2. Besides, many tasks and sub-topics represent a critical input and vital part of discussion and elaboration in SG1 and SG2.

Deformations:
Talking about *deformations* in tall timber structures, the attention goes to a multitude of aspects and issues that have major effects in research and industrial applications and are often fairly addressed by existing standards and regulations. As a matter of fact, deformations in timber structures are primarily associated to joints and connections. There are however no doubts about the complexity and variability of possible technological solutions in the field of *joints* and *connections* for timber structures. Also, the type of load, the boundary conditions and the assessment of their mechanical performance suggests the need of a robust background in support of optimal and safe mechanical design of these systems.

Vibrations:
The issue of *vibrations*, which is also addressed by WG2 members, is implicitly related to deformations and corresponding gaps in engineering knowledge / design tasks. Starting from the assumption that *vibrations* itself is a rather general definition and can cover a multitude of practical / technical aspects in the framework of timber structures, WG2 members actively contributed to the elaboration of a State-of-the-Art document in which most of engineering terms and problems could be first defined in their context. So far, do we implicitly talk about vibrations in floors or partition walls for timber structures? And which kind of design action should be primarily addressed in terms of vibration serviceability, for the specific solutions in use in tall timber structures? But indeed, how can we monitor and control, or possibly minimize and mitigate the effect of vibrations in typical load-bearing components for tall timber structures?
The first elaboration from WG2 members, in this sense, resulted in the detection of rather wide and complex tasks in which – under the assumption of a joint primary goal of design – basic engineering knowledge for vibration assessment and mitigation is still represented by the need of standardized operational procedures and guidelines which could be efficiently applied to any type of building component (floors for instance, but not only). This need implicitly recalls the complexity of possible design actions (WG3 topic) and their effect and assessment in terms of vibrations. Human-induced loads on timber floors, for example, are totally different in dynamic and mechanical features (and effects) from wind pressure or seismic actions (and corresponding vibrations).
There are no doubts, finally, about the inter-correlation of *vibrations* and *deformations*, which again suggest an intrinsic mutual interaction of load-bearing components for tall timber structures and the final user / the design actions.

3.3 WG 3 – ACCIDENTAL LOAD SITUATIONS

The activities conducted in the first year on accidental load situations have been summarized in the form of a State-of-the-Art report [12]. The State-of-the-Art, developed with the contribution of 45 people from 17 different countries, aims to reflect the current knowledge on the development, design, and construction of taller timber buildings subjected to accidental load situations due to earthquakes, fires, and blasts. Particular attention was paid to the efforts and the proposals made to overcome the limitations for the progress in the

https://doi.org/10.52202/069179-0137

construction market of mid-rise and taller timber building. The report is the result of a deep review of scientific literature, international collaborations, national regulations, design guidelines, as well as case studies. Potential interactions with other fields of design and to the efforts made in the recent years to overcome the limitations for the progress in the construction market of timber buildings were investigated. The indications collected represent the starting point of discussion to identify solutions, research targets, methods, and resources for the future of taller timber buildings under seismic, fire, and blast loads following a holistic design approach. Three different sub-groups (SGs) have been defined for WG3 State-of-the-Art activities, namely SG1 - Seismic Loads, SG2 - Fire and SG3 - Blast. For each SG, different subtopics have been analysed and discussed.

Seismic:

With potentially devastating effects on occupant safety and economic stability, earthquakes represent one the main hazard to consider when designing buildings in seismic prone areas. Despite possessing properties that make them well-suited for seismic design (i.e. lightness), timber structures are not immune to the effects of earthquakes. In light of the current timber construction sector growth, investigating the effects of earthquakes on taller timber structures is crucial to ensure life safety and minimal economic losses.

The primary focus of SG1 was to analyse how seismic activities impact tall timber buildings. In particular, eight topics were identified (Figure 3) and deeply examined, including: Lateral Load Resisting Systems (LLRSs), high performance connections, seismic protection technologies, seismic design strategies and analyses, standards and codes, analysis of case studies, and interaction and conflict in holistic design.

The State-of-the-Art report reveals that different LLRSs including shear walls, heavy frames and hybrid structural systems are typically adopted for taller timber buildings. Regardless of the structural system considered, connections are crucial for the seismic performance of timber buildings, as they determine their stiffness, capacity, and ductility. Two categories of connections were identified, namely traditional and innovative, and the need of connections with significant resistance and ductility was pointed out. Seismic protection technologies such as supplementary damping systems [13] and passive control systems can be used as viable solutions to reduce structural and non-structural damages and related economic losses, especially in areas with high seismic hazard.

The analysis of the design strategies and the seismic analyses indicates that capacity-design principles should be employed to ensure energy dissipation and optimal structural performance. Also, modern performance-based design, both force-based [14] and displacement-based [15], can be adopted to reach specific target performance. However, to date only a limited number of international codes has specific design guidelines for timber buildings

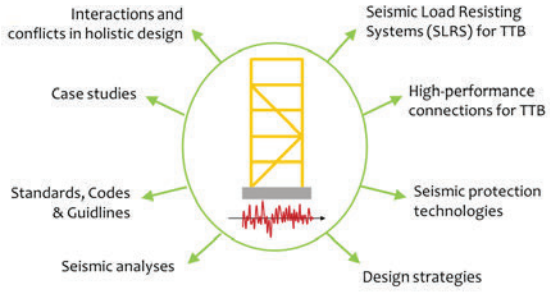

Figure 3: *topics analysed by SG1 for seismic load on taller timber buildings.*

subjected to seismic load. Further research is required in the near future to address seismic design-related issues, such as the in-plane behaviour of floor diaphragms, prediction of connection mechanical properties, and the interaction of structural elements. Finally, the analysis of case studies and discussions with designers emphasized the need for integrated design methodologies that optimize functions, minimize costs and errors, and avoid conflicts between different design strategies.

Fire:

Structural timber is often cited for its carbon storage and subsequently for offering a possible response to the current climate crisis. For fire safety implementation in buildings, it is, however, important to note that the presence of more potential fuel is a consequence of this carbon storage. The State-of-the-Art report indicates that the contribution of structural timber as a fuel to the fire can, among other things, increase the fire growth [16], the structural damage, and the external exposure of fires [17]. However, only a handful of countries to date have adopted provisions aimed at limiting the fuel contribution for the whole duration of the expected fire scenarios, such as by limiting the exposed surfaces of mass timber [18] and preventing glue line integrity failure [19], or accounting for its impact (e.g. by having construction type specific fire resistance requirements [20]). Although most previous research focussed on the performance of timber in standard fire resistance tests, knowledge gaps regarding connections, multi-span structures, point loaded panels, and connections [21] relevant for taller timber buildings were identified. These gaps are especially pertinent when considered for the combined action of earthquakes or blasts and fires. The State-of-the-Art report also indicated that only a small amount of data was found relevant for robustness, post-fire repair, fire suppression strategies, which are topics mainly related to the protection of property.

Blast:

The increase in market share of the timber construction industry brings with it an increase in potential exposure to accidental and intentional blast explosions, such as that emanating from gas leaks and vehicle bombs, respectively. Understanding how wood behaves under high strain-rates and having well-established mitigation

https://doi.org/10.52202/069179-0137

strategies to minimize the risk of progressive collapse is required to ensure occupant safety during these rare events. As an organic material, high strain rate effects and failure modes were found to be affected by the direction and rate of the load in both members [21-23] and connections [24-25]. With that being said, present-day blast design codes were developed based on preliminary data which are no longer applicable to the novel engineered wood products. As in the case of connections for seismic detailing, connections of timber assemblies under blast load must be designed to concentrate the majority of the deformations within ductile connectors, to protect the load-bearing timber element against unwanted damage [e.g. 26- 27].
Particular attention should be given to the brittle behaviour of timber in order to minimize the risk associated with progressive collapse in timber structures. Another consideration was ensuring that connections and main elements had sufficient ductility and strength in addition to ties consideration in the main principal directions [28]. While simplified modelling methodologies were praised for their proven efficacy and low computational costs [29], they lack the ability to consider and capture multiple failure modes. This may be circumvented using finite element modelling (FEM); however, proper attention is required to develop a representative material model that can treat wood and its many failure modes, including both brittle and ductile failure modes.

3.4 WG 4 – Sustainability and durability

A holistic design approach can make taller timber buildings even more sustainable compared to conventional buildings made mainly of steel, concrete, or masonry. Durability is meant in terms of moisture safety for longevity of timber products, assemblies and structures, and the possibility to increase utility by e.g., reuse or quality cascading in upcoming product life. Robustness should express the general resistance of timber against moisture within certain limits. To not exceed these limits, a proper moisture management is necessary and must be considered already in the holistic design for taller timber structures, considering the different stages from factory until operation. Robustness also has to do with the resilience of structures and assemblies and their repairability to maintain most of the moisture affected situations. This robustness concept exercised for entire buildings also enables to additionally lower environmental footprint because it allows to keep buildings in service as long as technically possible. Therefore, many crosslinks with Working group 1 - Robustness, Reuse and Repair of CA20139 exists.

To benefit from these advantages, tall timber buildings must have a similar or almost equal durability compared to conventional buildings. Otherwise, the sustainability advantages would be compromised. Therefore, tall timber buildings must be designed, considering the special properties of timber as construction material. The goal is to maximize resistance of this type of timber structures and envelope systems against various moisture exposure scenarios causing deterioration and damage. Not only design but also execution of timber structures is of relevance namely construction site activities and prevention from severe moisture impact. Further operation and maintenance of large and tall timber buildings need a focus on risk reduction measures.

Despite these special requests for the designers, tall timber structures are already built in Europe, but also North America and Australia are competing since a few years. Thus, a lot of research work and development have been done especially in Europe on this field.

The aim of Working Group 4 is to report the state of the art in terms of research and practice of durability and sustainability of tall timber building systems, in order to summarize the existing knowledge in the single countries and to develop a common understanding of the design for moisture safe and robust execution and operation of tall timber buildings. The State-of-the-art report reflects parts of the work and the discussions within WG 4 [30] and covers the SG topics given Figure 2. It intends to give information and studies available around the world, but especially in Europe through the active contribution and participation of experts from various countries involved in this Action.

Exchanges of experts are planned in order to achieve a harmonisation of concepts, approaches and methods, e.g. in the field of life cycle assessment for taller timber buildings. Gaps in knowledge over all four parts of WG 4 (Figure 2) will be defined and built up the framework for further research projects and collaborations. Existing expertise's are to be presented and passed on to a wider range, of timber engineers and practitioners within training schools, online seminars or specific short term scientific missions educating especially the younger generation, the engineers of our future.

4 SHORT-TERM SCIENTIFIC MISSIONS

Short Term Scientific Missions (STSM) are aimed at supporting individual mobility and at strengthening the existing networks and fostering collaborations by allowing scientists to visit an institution or laboratory in another Participating COST Country or an approved institution. A STSM should specifically contribute to the scientific objectives of the COST Action, while at the same time allowing applicants to learn new techniques or gain access to specific instruments and/or methods not available in their institutions. In doing so, the COST Action addresses with the STSMs in particular the needs of young scientists to build and strengthen their network and supports diversity in the field. In the first Grant period of HELEN (the year 2022), six STSMs were conducted, covering the following topics:

- Experimental and numerical assessment of soundproofing interlayers influence on the

strength and stiffness of timber to steel screw connections
- Fire induced delamination
- Influence of elevated temperature on the adhesive used in hollow glue-laminated timber elements
- State-of-the-art report on realistic fire exposure in fire design of taller timber buildings
- Towards Zero Carbon Buildings: Timber structure for sustainable buildings
- Environmental impact assessment of multi-storey residential timber buildings – integrated approach

The COST Action is committed to promoting the development of novel applications and will consistently allocate additional resources towards new research initiatives.

5 COMMUNICATION

The HELEN COST Action has generated interest from a broad range of stakeholders, who are involved in the WGs, such as representatives of the timber construction industry, architects, structural engineers, consultants, builders, product developers in the sector of timber structures, authorities and policy makers at regional and European levels, research community, relevant standardization bodies and code writers, teachers, lecturers and students of structural design, engineering, and architectural schools.

The COST Action aims at connecting these stakeholders and communicate its activities to the stakeholders, research community, and society, amongst others by:
- Sharing research results
- Stimulating new research projects
- Raising awareness of the Action topics in general public and among scientific societies
- Engaging the stakeholders
- Influencing policy making
- Exchanging ideas on sustainable development of the built environment

The discussion of the research efforts and the development of the research results are realized through workshops, seminars, and STSMs. The consolidated results of the action are disseminated and communicated through conferences, training schools, and the joint elaboration of state-of-the-art papers, best practice examples and final design guidelines for a holistic design and construction of taller timber buildings.

The workshops, conferences, and training schools to be carried out within this Action promote the interdisciplinary research in the fields of wood science and technology, timber engineering and structural reliability. The first training school in 2023 covers the holistic design of connections in timber structures and all WGs are involved in its preparation. Further training schools on interdisciplinary topics are planned for the following years.

6 CONCLUSIONS

The very essence and key to a successful COST Action will be intense interdisciplinary work with in-depth discussions and debate over a series of hypothetical and real case studies, followed by focused research work. Contrary to common building research work done in the past, where individual topics were assessed in depth by specialised teams working on isolated topics (i.e. just timber connections or just vibration of floor plates), research within HELEN will be intensely collaborative and integrated.

ACKNOWLEDGEMENT

This research was funded by the COST ACTION HELEN (Holistic design of taller timber buildings – CA20139): https://cahelen.eu/.

The authors thank all members of the COST Action CA20139, for the discussions, presentations, and contributions. A special acknowledgment is owed to the authors of the documents prepared for the State of the Art Report and the Sub-Group coordinators (listed alphabetically by surname and by Sub-Group): Reinhard Brandner, José Manuel Cabrero, Maria Felicita, Kristina Kröll, Lisa Ottenhaus, Felipe Riola-Parada (WG 1); Thomas Reynolds and Angelo Aloisio (WG 2); David Barber (WG 3); Shady Attia, Bettina Franke, Jens Frohnmüller, and Stephan Ott (WG 4).

DESIGN AND CRADLE-TO-GRAVE LIFE-CYCLE ASSESSMENT: FULL-SCALE SIX-STORY SHAKE-TABLE TEST BUILDING LATERAL SYSTEMS

Steven Kontra[1], Andre R. Barbosa[2], Arijit Sinha[3], Gustavo A. Araujo R.[4], Patricio Uarac P.[5], Nathan C. Brown[6], Jace Furley[7], Tu X. Ho[8], Gustavo F. Orozco O.[5], Barbara G. Simpson[9], John W. van de Lindt[10], Seyed Hossein Zargar[11]

ABSTRACT: This paper describes the lateral force resisting system (LFRS) design in a full-scale six-story shake-table test building and presents a comparative cradle-to-grave life-cycle assessment of alternative LFRSs. The test building features the reuse of material from a ten-story shake-table structure comprised of engineered mass timber (MT) products. These include MT floors (cross-, glue-, nail-, and dowel-laminated timber [CLT], [GLT], [NLT], [DLT]); MT post-tensioned rocking walls (CLT and mass ply panels [MPP]); and a gravity system consisting of laminated-veneer lumber (LVL) beams and columns. Shake-table testing will benchmark innovative, low-damage design solutions for the LFRSs. To supplement this test, the environmental impact of a MT LFRS is determined relative to design alternatives that use conventional materials. The Athena Impact Estimator for Buildings was used to perform a comparative, cradle-to-grave life-cycle assessment (LCA) of the prototype MT LFRS with respect to an alternative, functionally equivalent reinforced concrete (RC) shear wall design. The LCA results showed reduced environmental impacts across some impact metrics, with a significant reduction in Global Warming Potential for the MT LFRS when accounting for biogenic carbon.

KEYWORDS: Engineered wood products; Life-cycle assessment; Rocking wall; Seismic Design; Shake-table test

1 INTRODUCTION

The rapid development of MT engineered wood products has resulted in a suite of new design opportunities for architects and engineers. As many building types using these MT products have not yet been codified, liberty in their use has fuelled the development of new engineering design solutions that strive to meet both resilience and sustainability criteria. These innovative designs would benefit from experimental benchmarking to accelerate acceptance from various regulatory jurisdictions and agencies for design code adoption.

A full-scale six-story MT building testing program will be implemented at the National Hazards Engineering Research Infrastructure outdoor shake-table testing facility at University of California San Diego (NHERI@UCSD) by the Converging Design Project team [1]. The testing program is intended to benchmark low-damage MT LFRS design solutions, provide data for numerical models employing MT, and inform design methodologies and life-cycle analyses.

This paper summarizes the designs of the shake-table specimen LFRS and provides insight into the relative environmental sustainability of these design choices. A cradle-to-grave LCA was used to investigate the

https://doi.org/10.52202/069179-0138

environmental impact of the MT LFRS, as compared to a functionally equivalent RC design solution.

2 SPECIMEN REUSE AND SHAKE-TABLE TESTING

This study highlights a six-story MT test building, which will feature the reuse of a ten-story MT test building from the NHERI TallWood test program [2]. The top four stories and non-structural elements of the original ten-story building will be deconstructed to form the new six-story specimen that will consist of various engineered MT products, as shown in Figure 1.

The ten-story building was designed to feature post-tensioned (PT) MT rocking walls with U-shaped flexural plates (UFPs) as energy dissipators. The four rocking walls are connected to the timber diaphragm through a shear key connection designed for the transfer of horizontal shear forces while allowing for wall rotation and vertical displacement relative to the diaphragm. Self-centering capabilities are included through a series of four PT high-strength steel rods located near the center of the wall section and spanning across the entire wall height. Figure 2 shows the UFP-wall configuration, illustrating key components such as PT rods and shear keys for lateral force transfer.

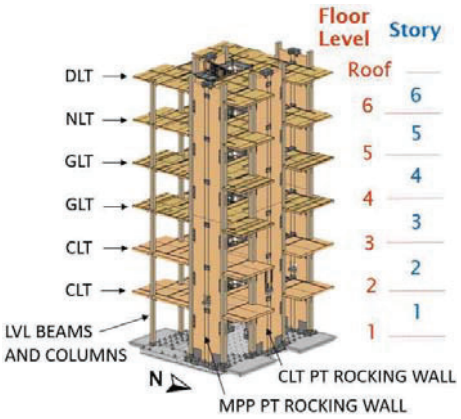

Figure 1: *Six-story MT test building*

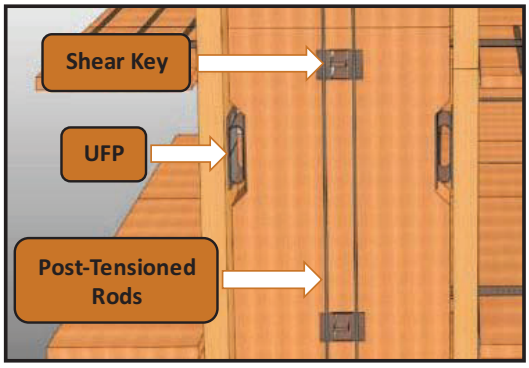

Figure 2: *PT rocking wall with UFPs*

Following deconstruction and inspection for any damage that may have resulted from the ten-story testing program, the new six-story building specimen will consist of three phases, in which three different LFRSs will be tested.

In the first phase of the six-story testing, the inherited shear wall panels in both directions will be cut to size and reused. A new UFP-wall configuration will then be installed, along with a new PT rod setup, based on the Direct Displacement-Based Seismic Design (DDBD) method. This methodology has been proposed as an alternative design procedure that allows the designer to achieve strain-limit- or drift-limit-based performance objectives [3,4]. The UFPs were designed as the main component that will behave in the inelastic range, in which its displacement was defined as the performance objective. The panels and post-tensioned rods are designed and expected to remain essentially elastic. Wall system design limit states and performance objectives are described in more detail in section 3.2.3.

The plan for the second phase of testing involves the replacement of the two MPP walls resisting lateral forces in the N-S direction. In their place, a new LFRS will be installed featuring MPP panels with buckling-restrained braces (BRBs) whose design is informed by LFRS prototype testing at Oregon State University (OSU) [5,6]. The BRBs are installed at the wall boundaries in the first story, acting as high-ductility hold-downs, while the MPP walls are designed to remain essentially elastic above the base [7]. The proposed lateral system takes inspiration from previous research on steel elastic frames, and concrete and mass timber walls employing buckling-restrained columns as energy dissipators [8–10]. The BRBs are bolted at both ends to gusset plates. The top gusset plate is ultimately connected to the MPP wall through steel side plates and 45-deg inclined, fully threaded screws. The design detail takes advantage of the high strength and stiffness of inclined screws in tension [11,12], while compressive forces are transferred through bearing of the MPP on top of the timber to BRB connection.

The planned final phase of testing involves the removal of the LFRS installed in the second phase of testing and installation of a new LFRS design that is still under development.

3 LIFE-CYCLE ASSESSMENT

3.1 BACKGROUND

One of the many aspects driving the innovation and development of new MT design solutions is the potential for enhanced building system sustainability through environmental impact reduction. This relative environmental utility can be quantified and analyzed using a cradle-to-grave LCA – a systematic method for compilation of lifetime product system inputs and outputs, and their potential environmental impacts [13].

https://doi.org/10.52202/069179-0138

Several studies [14–17], using an established LCA framework [13] have investigated the environmental performance of MT building systems with respect to functionally equivalent reinforced concrete and steel design alternatives. Findings from the various studies indicate significant environmental impact savings associated with the use of MT structural systems.

3.2 METHODS

3.2.1 Goal and scope

The objective of this study is to contribute to the existing body of research contrasting the environmental impacts of MT and conventional design alternatives using the LCA framework developed in ISO 14040 [13]. The study scope involves a comparative LCA focusing specifically on the MT LFRS presented for the phase I design (UFP-wall configuration) in contrast with a functionally equivalent RC shear wall design. For this study, functional equivalence is defined as a wall design with a lateral force-resisting ability in compliance with seismic provisions specified in relevant building codes and standards [18,19]. The defined functional unit is a LFRS for a six-story building with approximately 500 square meters of usable space, designed to resist a Risk-Targeted Maximum Considered Earthquake (MCE_R) in Seattle, Washington, USA. This study follows the LCA framework developed in ISO 21930 [20], which defines four life-cycle stages: Production, Construction, Use, and End-of-Life. In addition, the framework includes an option to add Beyond Building Life (BBL) net benefits sourced from reuse, recycling, energy recovery, and carbon sequestration occurring outside the system boundary.

The system boundary defined for this analysis is cradle-to-grave; thus, environmental impacts are tracked from the point of raw material extraction to their end-of-life, with consideration given to BBL net credits from the timber and steel material after departing the defined system boundary. The Use stage is omitted from this analysis, as it relates to building operation. This aspect is not relevant to this study, which focuses solely on the LFRS. Figure 3 summarizes the four life-cycle stages, the modules within each stage, and the study system boundary with the Use stage omitted.

3.2.2 Seismic design parameters

The alternative RC walls were designed to achieve functional equivalence with the MT rocking walls and, therefore, used the same seismic parameters in design, as summarized in Figure 3.

3.2.3 MT phase 1 wall design

As previously described, the MT LFRS used in phase 1 is comprised of four MT rocking walls. A pair of stacked, 9-ply (314 mm) CLT panels [21] resist forces in the E-W direction, while a pair of thinner (233 mm), stacked 9-ply MPP panels [22] resist lateral forces in the N-S direction. For each wall, two UFPs are provided at each level along the height to provide energy dissipation and increase system ductility. The MPP walls include a double UFP configuration at the first story. Four post-tensioned rods are also included for each MT wall to provide recentering capability. These wall systems were designed using the DDBD, considering limit states that enable enhanced resilience performance objectives. Table 2 provides a summary of the considered limit states and performance objectives.

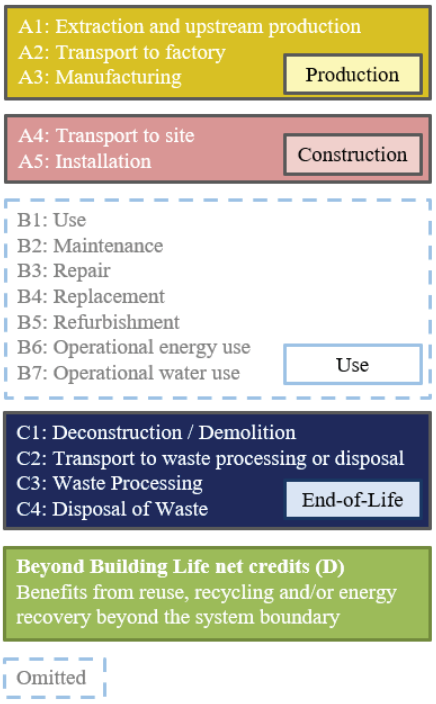

Figure 3: *ISO 21930 life-cycle stages and study system boundary*

Table 1: *Seismic design parameters*

Location	Seattle, Washington (USA)	
Risk Category	II	
Site Class	C	
Importance Factor	1.0	
Seismic Design Ctgy.	D	
MCE_R Hazard Level	$S_S = 1.378$	$S_{1} = 0.48$
	$F_a = 1.2$	$F_v = 1.2$
	$S_{MS} = 1.378$	$S_{M1} = 0.48$

3.2.4 RC shear wall design

To perform the comparative assessment, a functionally equivalent RC shear wall was designed consistent with the previously described functional unit. A design software tool, ETABS [23], was used to determine the required steel reinforcement. Relevant US building codes and standards were followed, including ACI 318-19 [18] and ASCE 7-16 [19]. The wall was designed with 34.4 MPa (5000 psi) concrete and includes special reinforced

https://doi.org/10.52202/069179-0138

boundary elements in the first two stories in accordance with code provisions [18]. Table 3 provides a summary of seismic design coefficients and factors used for a special reinforced concrete shear wall per [19].

Table 2. MT wall seismic design criteria

Limit states	
UFPs	Yielding at SLE, UFP ultimate displacement at MCE_R
PT Rods	Yielding at MCE_R
Walls	Yielding at DE; crushing at MCE_R
Global level performance objectives	
SLE	0.5% roof drift ratio
DE	2% roof drift ratio
MCE_R	4% roof drift ratio*

* Beyond 3% drift limit specified in ASCE 7-16

Response Mod. Coeff.	R = 6
Overstrength Factor	$\Omega_0 = 2.5$
Deflection Amp. Factor	$C_d = 5$

Figure 4 shows the rebar detailing along the height of the N-S RC shear walls. Wall detailing is similar for N-S and E-W walls, with the exception that the N-S walls are 2980 mm (9'-9") and E-W walls 2675 mm (8'-9") in width. All dimensioning and rebar sizing was calculated according to US standards, which are converted to SI units for approximate dimensions, and "soft metric" rebar sizes.

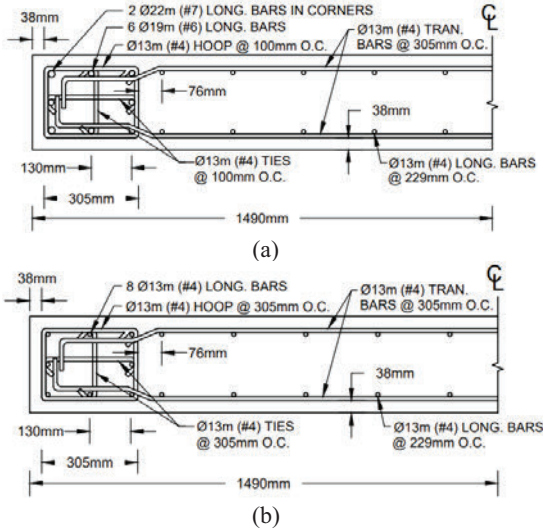

Figure 4: *RC N-S wall steel reinforcement detail (a) Level 1 – 3; (b) Level 3-7*

3.2.5 Bill of materials

Upon design completion, a bill of materials (BOM) was assembled from the RC wall and phase I MT rocking wall designs. Note, although the MT LFRS to be tested in Phase I will contain a steel foundation beam for enhanced compatibility with the shake-table surface, the MT LFRS will be redesigned with a RC foundation, as this is the planned foundation system for future implementation of these LFRSs. Table 4 provides a high-level summary of the timber, steel, and concrete materials and material quantities present in the MT and RC design alternatives.

Table 4: *MT and RC wall BOM summary*

MT rocking wall			
Element	**Mat.**	**Unit**	**Qty**
N-S Rocking Wall	CLT	m^3	37.6
E-W Rocking Wall	MPP	m^3	24.9
Bounding Columns	LVL	m^3	23.3
Out-of-Plane Bracing	Steel	kg	1494
Splice Connections	Steel	kg	2673
Shear Trans. (Found./Wall)	Steel	kg	2793
Shear Trans. (Wall/Dia.)	Steel	kg	4715

Shear Trans. (Wall/Dia.)	Steel	kg	2560
Wall Foundation	Concrete	m^3	5.2
Wall Foundation	Steel	kg	228
Fasteners	Steel	kg	86.2

3.2.6 LCA tools

The comparative cradle-to-grave LCA framework was applied using the Athena Impact Estimator for Buildings (IE4B). This IE4B tool draws upon a highly developed, proprietary life-cycle inventory (LCI) database that complies with the framework used in [13]. The environmental impacts associated with LCI outputs are aggregated following procedures developed in the Tool for the Reduction and Assessment of Chemical and Other Environmental Impacts (TRACI) [24] methodology in accordance with ISO 21930 [20].

IE4B also provides data for energy use, transportation, construction, maintenance, demolition, and other processes in addition to the data developed for building materials [25]. To account for material waste in construction, transport to disposal, and other processes, IE4B also attributes material specific waste factors. At the End-of-Life stage, IE4B assumes that the current practices of material disposal will be the same as in the future. For steel, a "closed material loop recycling methodology" is

https://doi.org/10.52202/069179-0138

followed, where percentages of material recycled are tabulated per [26], and the avoided burdens of steel manufacturing are added to the BBL stage in accordance with [13]. For timber materials, the End-of-Life pathway assumption is 80% landfill, 10% combustion, and 10% recycling, where 77% of the biogenic carbon in the MT sent to landfill remains permanently sequestered, and 23% decomposes and is released back into the atmosphere. This accounting system results in 61.6% of the total initial biogenic carbon being permanently sequestered. IE4B assigns net credits from biogenic carbon sequestration in the BBL stage in agreement with international standards, including [27–29]. In this way, IE4B attempts to capture the holistic environmental impact.

3.2.7 Study limitations

While the IE4B tool can help users get a general sense of the environmental impacts associated with different design alternatives, the results may lack precision due to the assumptions and simplifications inherent within the tool and present in any LCA calculation. Some of these uncertainties arise from the method IE4B uses for determining LCI results, which involves averaging regional data for emissions associated with the modules listed in Figure 3, as well as other simplifications assumed for construction and deconstruction energy. To account for this, the IE4B tool suggests that LCA results be viewed with a 15% margin of error, where alternative designs within this margin can be considered close to equal in terms of environmental impact [25].

Other study limitations involve the simplified design of the RC shear wall in contrast with the MT rocking wall design. This RC design does not include many of the design features that help the MT design achieve enhanced resilience performance objectives. These features include recentering and energy dissipation mechanisms that assist in reducing residual displacements and limiting damage. Lacking these elements, the RC wall does not achieve 100% functional equivalence in design objectives and may provide a conservative environmental impact estimate.

3.3 RESULTS AND DISCUSSION

The environmental impacts of the MT and RC design alternatives were tabulated by way of importing the assembled BOM into the IE4B software program. Data for several evaluation metrics were produced, including global warming potential (GWP), acidification potential (AP), human health particulate (HHP), eutrophication potential (EP), ozone depletion potential (ODP), smog potential (SP), and total primary energy (TPE). While all metrics are important, this study will highlight the associated carbon footprint of each design alternative, best represented by the GWP metric (CO_2 equivalent mass over a 100-year time horizon). Figure 5 presents the comparative life-cycle environmental impacts of the two design alternatives without beyond building life (BBL) net credits added for carbon sequestration and metal recycling. The data was normalized by the greater of the two impacts for ease in comparison.

A mixed result can be observed from the seven environmental metrics analyzed. Note again, a significant amount of steel was added to the MT rocking wall system to meet performance objectives (energy dissipation, recentering, etc.), while the RC wall was designed to be similar to traditional shear wall systems that do not include these elements. Ultimately, without considering BBL net credits, the GWP associated with each wall design is similar. However, when including the BBL net credits in the LCA, the GWP disparity between the two designs grows substantially.

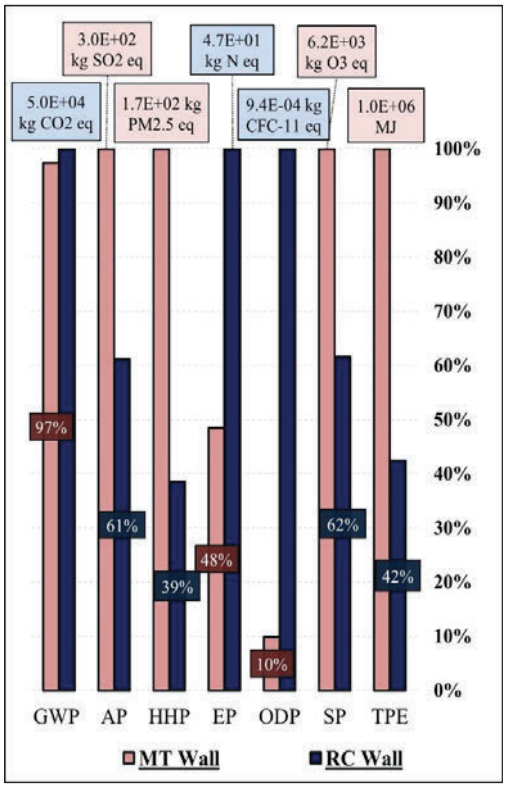

Figure 5: *Normalized impact metrics for MT and RC walls without BBL net credits*

Figure 6 shows the comparative environmental impacts with BBL net credits included. It can be observed that the MT shear wall design has only 42% of the GWP that is associated with the RC design when BBL net credits are included. This decrease in total GWP for the MT design is expected per the IE4B methodology, as described in section 3.2.6., considering permanent carbon sequestration and steel recycling. While knowing the total impact of the seven environmental metrics is important, any steps toward impact mitigation will require a more refined analysis of how each life-cycle stage contributes to the LCA.

https://doi.org/10.52202/069179-0138

Figure 7 shows a comparative breakdown of the GWP impacts from each life-cycle stage. It can be observed that the GWP associated with the Production, Construction, and End-of-Life phases were relatively similar for both designs. However, BBL net credits reduced the total impact of the MT design and increased the total impact of the RC design.

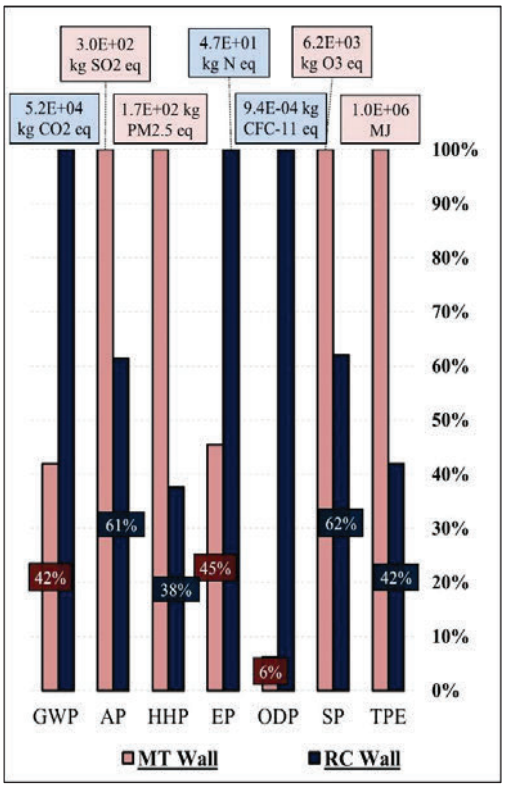

Figure 6: *Normalized impact metrics for MT and RC walls with BBL net credits*

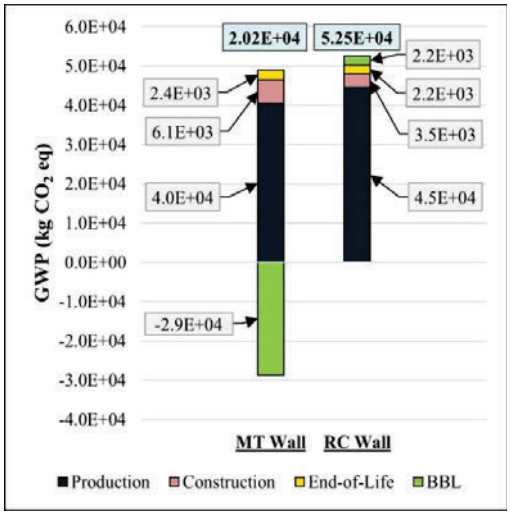

Figure 7: *GWP by life-cycle stage for MT and RC walls*

Figure 8 shows a breakdown of the cradle-to-grave GWP contribution including BBL net credits of each element grouping as described in Table 4. When considering environmental impacts (particularly GWP) associated with the MT wall design, examining how each element grouping contributes to the total GWP can be insightful. The data presented in Figure 8 shows that while the timber elements are associated with a net negative GWP, the large amount of steel in the system significantly increases the total GWP.

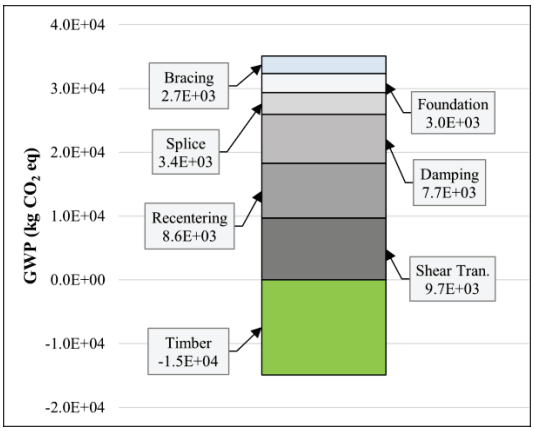

Figure 8: *MT wall: GWP by element grouping*

Beyond the environmental impact metrics discussed in Figure 5 to Figure 8, it is important to interpret LCA results within the proper context. While consideration of environmental sustainability is a growing factor for architects and engineers during the preliminary design stage, it is certainly not the only evaluation criteria, and, most times, not the most important in accordance with current practice. When performing a holistic review of design alternatives, it is not uncommon for sustainability goals to be overshadowed by economic, perception, and logistical design criteria. Thus, while MT designs can be associated with reduced environmental impacts, particularly GWP, it is critical to understand that there are other important design criteria that must also be carefully considered, balanced, and factored into the final design choices.

3.4 FUTURE WORK

The presented cradle-to-grave analysis compares environmental impacts of RC and MT lateral systems using Athena IE4B to give high-level insight into the sustainability of the two design alternatives. The environmental impact metrics were mixed across designs, while the GWP associated with the timber design decreased from 97% to 42% of the RC design when accounting for permanently sequestered carbon and recycled steel.

However, opportunity exists to broaden the study scope and calculate environmental impact metrics with increased precision. Subsequent work will expand the

https://doi.org/10.52202/069179-0138

shake-table specimen case study to include a Whole Building Life-Cycle Assessment (WBLCA) for the six and original ten-story shake-table test building. This study will develop a higher resolution analysis, where opportunities for population of all WBLCA modules will be explored using a mixture of primary and secondary data.

Additionally, the short lifespan of the shake-table test building will be leveraged for insight into the End-of-Life stage for MT construction. Prior to testing, a variety of End-of-Life scenarios for the building material will be examined to determine the most practical and sustainable End-of-Life pathways. Following completion of testing, empirical data will be collected throughout deconstruction, e.g., deconstruction time, labor requirements, specialized equipment needs, transportation, waste generated, and potential material reuse opportunities. Based on the data collected, the LCA will be revisited, and the impact of the information collected evaluated. These efforts will highlight logistical challenges and opportunities associated with various MT End-of-Life pathways, with particular emphasis on the feasibility of MT reuse in the context of circular economy [30, 31].

Ultimately, understanding the relative cradle-to-grave environmental impacts on design choices within building systems has become progressively more relevant for practicing architects and engineers and may become increasingly so as monetary implications of low embodied carbon designs gain traction. In the past several years, many governmental regulatory programs, such as cap and trade [32], have surged in popularity. A primary objective, among many, of these programs has been to assign dollar values to environmental impacts to help provide a business incentive for impact reduction. When applied to the building sector, the usage of renewable, low-impact materials, such as the engineered MT products herein, stand to benefit. Future studies will further explore the convergence of economic and environmental criteria into a singular design methodology.

4 CONCLUSIONS

Shake-table testing of a full-scale six-story MT structure will be conducted to benchmark the design of three LFRSs. All design phases feature PT CLT rocking walls resisting forces in the E-W direction, while three independent LFRSs will be tested for lateral force resistance in the N-S direction for each phase. For these LFRSs, the phase I design will feature MPP walls with UFPs, phase II will consist of new MPP walls with BRBs, and phase III design is still under development.

The LFRS designed in phase I was compared with a functionally equivalent RC design to contrast cradle-to-grave environmental impacts of the two design alternatives. The Athena IE4B tool was employed to tabulate impact metrics and showed a mixed comparative performance between the MT and RC designs, with significant GWP advantage given to the MT solution when accounting for BBL net credits. Examining the GWP at each life-cycle stage, it was observed that the Production, Construction, and End-of-Life stages were similar between design alternatives, with a major disparity in accounted BBL net credits. Considering each element group in the MT wall system, it was shown that the timber elements have a net negative GWP contribution, while the other steel elements contribute significantly to the total GWP.

Overall, this research examines the comparative environmental sustainability of MT design solutions, while also investigating their structural performance in seismic regions.

HYBRID STRUCTURES IN HIGH-RISE BUILDINGS: THE USE OF APPROPRIATE MATERIALS

Guido Nieri [1], Carsten Hein [2], Stuart Smith [3]

ABSTRACT: Architectural and engineering evolution has seldomly been characterised by a smooth transition, but rather by rapid changes. Currently, we are living in the time of a "sustainability revolution" and "timber renaissance". Based on the recently emerging awareness for sustainability, a new architectural and construction language has developed. This requires a complete review of the old materials used in the last two centuries in favour of more "sustainable" and "natural" ones. This new approach has sparked a dynamic debate about construction materials. Since wood is the only regrowing building material, there is a natural inclination to believe that building with wood is good for the environment. But under which conditions is this really the case? What should we build with wood? What is the best way to achieve an optimal solution? This article examines the current state of the building industry with a holistic approach, exploring the use of structural timber and its combination with other materials for the design of medium and high-rise buildings.

KEYWORDS: Sustainability, embodied carbon, circularity, timber, hybrid structures, high-rise building.

1 INTRODUCTION

Timber is without a doubt the oldest building material ever used. However, following the advent of steel and reinforced concrete, the use of this material was almost exclusively limited to small constructions, such as family homes. The recently emerging awareness and profound interest in sustainable development, as well as the introduction of new engineered timber materials, such as Glulam or Cross Laminated Timber (CLT), have given this material a comeback, and as a result the construction of tall buildings made entirely or partly of timber is experiencing a boom on a scale never seen before.

Even though timber is the only renewable building material and there is a natural inclination to believe that building with timber is good for the environment, the environmental benefits of using it are not unequivocal. Critique has been expressed at the fact that only a portion of the harvested wood can be utilised as a building material. Additionally, the high energy demand required for the drying process of the wood as well as the problem of deforestation have sparked interest amongst critics.

Although this article does not aim to find answers to all these complex questions, we examine the benefits and drawbacks of using timber as a building material. This article does not claim to be exhaustive but is merely intended to give the audience an overview and some key points characterising design with timber and timber-hybrid constructions. With a holistic approach, we try to evaluate the feasibility of timber as a construction material in comparison to and in combination with other technical solutions and materials, also analysing environmental and financial aspects to achieve greater benefits for people and the planet.

2 THE CHALLENGE

Rising temperatures, melting glaciers, floods, desertification: All these well-known topics – summarised under the term "climate change" – are no longer just potential problems for the future, but already a reality. As we know, the above-mentioned aspects are closely related to us humans, to our activities and ultimately to the emissions we produce. Accounting for almost 38% of total global CO_2 emissions, the construction industry is one of the main contributors to climate change. From this, 28% is related to the operational energy, while the other 10% are attributed to so-called embodied carbon. This includes energy associated with the construction, demolition, and renovation of buildings as well as the extraction, production, transportation, and installation of all necessary elements [2]. Conventional building materials are responsible for around 2 billion tonnes of CO_2 emissions annually [5]. If we assume that on average, 50 trees would have to grow for one year to absorb 1 tonne of CO2, that would mean that we would require 100 billion trees to offset these emissions.

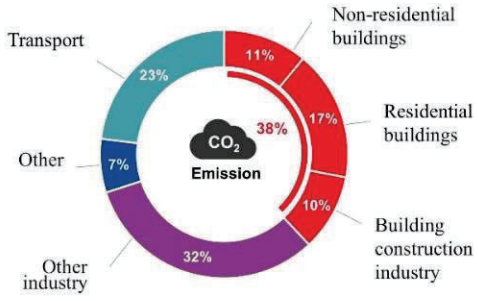

Figure 1: *Emissions in the Building Sector (© Arup)*

[3] Stuart Smith, Arup, Germany, Stuart.Smith@arup.com

https://doi.org/10.52202/069179-0139

These figures alone make it clear that reducing CO_2 emissions is a very ambitious goal. In addition, two other aspects must be considered: exponential growth of the world's population and the limitation of available non-renewable raw materials.

According to the United Nations: Today, the world's population is more than three times larger than it was in the mid-twentieth century. The global human population reached 8.0 billion in 2022 from an estimated 2.5 billion people in 1950. It is estimated to rise to over 10 billion by 2060 [8]. This means that the world's population will have quadrupled in almost 100 years and the demand for buildings and infrastructure – considering the rising standard of living – is going to increase exponentially.

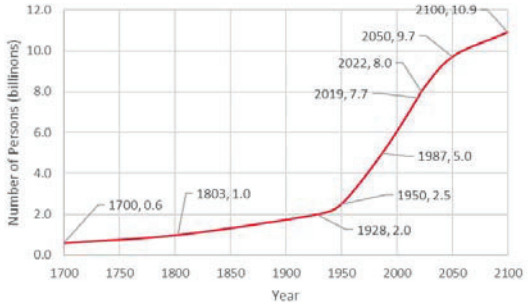

Figure 2: *World's population (©Arup, source: United Nations)*

Conventional building materials like reinforced concrete are composed of slow-renewable or completely non-renewable raw materials such as sand and aggregate. Concrete is one of most used substances in the world, second only to water, and it is the most used building material, twice as much as steel, wood, plastic and aluminium combined. According to the World Economic Forum, demand for sand mining has tripled in the past two decades, reaching 50 billion tonnes per annum in 2019 [7]. Sand mining or aggregate extraction – where sand and gravel are removed from riverbeds, lakes, oceans, and beaches for use in construction – is happening at a rate faster than the materials can be renewed, which is having a huge impact on the environment.

Figure 3: *Sand mining (© Dmitry Rukhlenko)*

For all these reasons, the most important matter of our time is a multiparametric challenge named sustainability: the necessity to build for an exponentially growing number of people using fewer non-renewable raw materials and producing lower emissions.

Dealing with this challenge requires a change in design and construction philosophy, not merely a change in materials. In other worlds, it requires the definition of a new architectural and structural language.

The first step of this revolution should be to consider limiting the construction of new buildings (aiming to the paradox build nothing) and instead transforming, reusing and retrofitting existing structures. In parallel, the focus should be on optimising the structure using materials wisely, using low-emission materials such as timber or recycled materials where appropriate, and conventional materials such as reinforced concrete where necessary.

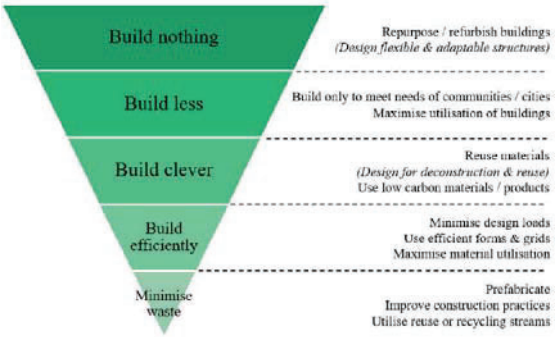

Figure 4: *Sustainable Design scheme (© Arup)*

3 SUSTAINIBILITY

3.1 What really is sustainability?

After decades in which the construction industry – except for few players – only aimed at minimising costs, a reorientation is taking place making sustainability one of the main targets. Defining the goal (e.g., designing a sustainable office building) is easier than defining the objectives or the way to get there. In fact, for each individual project there are a variety of approaches that can lead to a more sustainable outcome, and only the experience of the designers and the wisdom of the client can help to define the right solution for the specific project.

For example, in the project Coal Drops Yard in King's Cross, a derelict industrial site from the 19th century was transformed into a new shopping district for London. The design was refined and engineered to retain as much of the existing structure as possible, while upgrading building performance. In this project, it was possible to achieve an exceptionally sustainable result even with almost no use of timber.

https://doi.org/10.52202/069179-0139

Figure 5: *Coal Drops Yard, London (© Hufton Crow)*

3.2 Industrial-based and / or bio-based material?

The transition between industrial-based materials like concrete or steel, to bio-based materials like timber is a turning point for the entire building industry, affecting investors, architects, and engineers. Engineered timber offers the possibility of creating a new visual language and at the same time poses new challenges in terms of structural design as well as building physics, acoustics, and fire protection. Exposed timber also modifies the internal climate of buildings and has a positive effect on the wellbeing of inhabitants and users (biophilia).

Mass timber has relatively decent strength, but it also has its own specific characteristics and limitations, which call for a change in the construction techniques and design concepts. Currently, we can see a general tendency to replace conventional materials with this "new one" by forcing the "new material" into traditional structural schemes. This leads to a tendency to use timber everywhere without considering whether other materials such as reinforced concrete or steel would be more suitable for a particular purpose, which in turn can lead to significantly higher material quantities, thus having an adverse effect on the costs associated with the construction of the building.

3.3 Materials follow purpose

To achieve a truly sustainable design on a large scale, ideally in every new project, we believe that a new "manifesto" for the use of materials must be established: materials follow purpose. Since the amount of building materials – and this also applies to timber – is limited, we must use them wisely and use timber, concrete, or steel to achieve an overall material reduction. With this principle in mind, we can experiment with new configurations and define a new architectural and structural language that reflects the demands of our time, such as sustainability, while considering the material properties.

3.4 Circularity, prefabrication, and modularity

The use of timber in hybrid structures opens new possibilities for the construction industry, namely prefabrication and modularity. Thanks to these two methodologies, construction time can be drastically reduced, construction costs optimised, and, above all, waste reduced to a minimum. The life-cycle of prefabricated systems can be extended beyond the once-off life of the building. The fact that the elements are not monolithically connected (as opposed to reinforced concrete structures), but can be assembled, dis-assembled, and re-assembled increases the possibility of using the individual components even after their first "life". This transforms the building industry from a linear process from construction to disposal to a circular process in which the individual components can be used multiple times and ideally never become waste. Circular economy principals are driving reuse and recycling of entire areas of the built environment. Refurbishment plays a vital part in this economy, and the whole industry needs to prepare for the future life of buildings. The principles of the circular economy enable far more than just decarbonisation. They help us to keep finite resources and healthy materials in endless loops. They help us to eliminate waste and to regenerate natural systems. Furthermore, they also help us to keep assets flexible and adaptable for any future use.

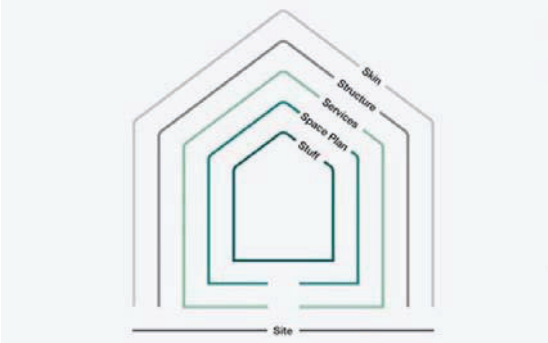

Figure 6: *Circular principles (© Arup)*

Using circular principles, the various components are designed for assembly Design for manufacturing and assembly (DfMA), but also for disassembly (DfD). In addition, the construction-relevant information is retained throughout the life of a building, making its reinvention more likely and less complicated. Under these principles, the different components are designed considering a different lifespan based on the technical possibilities and not only on the first use of the building. In this process, some components such as the structure have a longer lifespan – a correctly designed and maintained structure can last much longer than the typical 50 years specified in the regulations – while others such as the façade or the building services tend to require replacement at shorter intervals (usually 20-25 years). Modular building systems can be added to, expanded, downsized and repurposed, as needed. The modules can even be easily relocated from one place to another as needed. This is, for example, the main concept of the project "Adaptive Buildings", developed by Arup in collaboration with Futur2K, using a modular timber structure as the main part of the project.

https://doi.org/10.52202/069179-0139

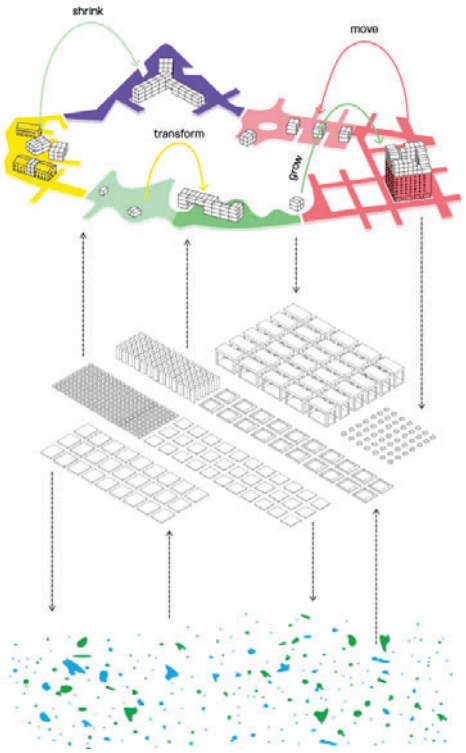

Figure 7: *Adaptive buildings (© Arup)*

3.5 Legislations, certifications, and financial aspects

Emerging sustainability regulations in individual countries are increasingly imposing mandatory sustainability requirements and financial incentives for sustainable design. It has also been proven that sustainable buildings are more attractive on the market and generate higher revenues. These facts have a direct impact on the use of timber, and from various experiences we have found that the additional costs associated with using this material are offset by the financial benefits and higher revenues.

Certifications (BREEAM, LEED, or DGNB) play an important role in defining the materials used. Timber structures can help projects acquire the desired sustainability rating score. For most clients, the direct higher revenues from a Gold or Platinum certified building or the reduction of risk in their investment strategy by decarbonising their portfolio is one of the main reasons for using timber. Other clients really embrace that as a framework for innovation and to unlock new growth opportunities for instance by rethinking their asset operation strategy or by applying new circular business models for the built environment.

Construction-grade timber and engineered forest products are some of the highest valued products from trees. This suggests that the structural use is important for economies that rely on forestry, and to further the development of the forest itself by planting new trees.[9]

4 PURE TIMBER STRUCTURES

4.1 Timber: a lightweight and strong material

Timber has a strength (parallel to grain) similar to reinforced concrete: hardwood is slightly stronger, and softwood slightly weaker, although timber cannot match modern high-strength concrete in compression. Timber is less stiff than concrete, and both materials are far less stiff and strong than steel. However, timber has a low density compared with these other conventional structural materials [9]. For this reason, considering strength-to-weight and modulus-to-weight ratios softwood performs similarly to steel by those measures.

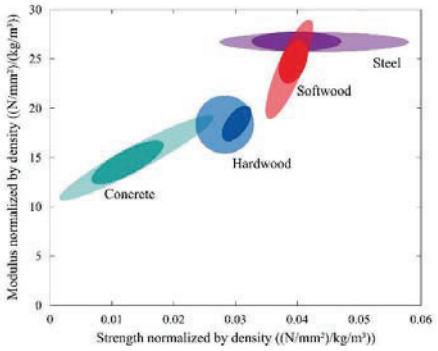

Figure 8: *Compression strength and modulus of elasticity materials normalised by density. (Source: [9])*

This suggests that timber is a particularly structurally efficient material in structures, or parts of structures, in which a high proportion of the load to be resisted is the self-weight of the structure. Examples are roofs, some bridges, and the gravity load resisting system of tall buildings [9]. However, in structures for which the load to be resisted is largely independent of the weight of the structure – such as the wind load on a tall building – the higher absolute strength of steel or reinforced concrete may make them more efficient, in terms of the amount of material required [9].

In an earthquake, the force imposed on the structure depends strongly on its mass, with heavier structures experiencing larger seismic forces. Light timber residential buildings have therefore been observed to perform well in seismic events [9]. The seismic behaviour of taller timber buildings is an active field of research. WG3 of COST Action CA20139 “Holistic design of taller timber buildings”, of which one of the authors (Guido Nieri) is a member, is researching this topic (see [4]).

As wood is 6 times lighter than reinforced concrete and almost 20 times lighter than structural steel, the use of timber as a construction material has numerous advantages. The reduced weight (especially when compared to reinforced concrete) can lead to the reduction in foundation sizes or avoiding the necessity for deep foundations, thus resulting in a more economical design. Furthermore, it increases the possibility for vertical

https://doi.org/10.52202/069179-0139

extensions of existing buildings. Indeed, by using a more lightweight material than concrete or steel, it allows for quicker construction and minimises strengthening of the existing structure. By doing so, structures that might have otherwise been demolished or lain empty can be modernised using eco-friendly building standards. They can retrofit existing structures and create additional income with new leasable area. For example, in the project 80M Located in Washington D.C. lightweight engineered timber was used as a carbon-friendly construction technique to retrofit the existing structure with three additional storeys.

Figure 9: *Project 80M, Washington D.C. (© Ron Blunt)*

Complex geometries can be produced economically and efficiently by utilising timber. This is perhaps wood's most important advantage. Being both lightweight and machined to high tolerances means that wooden buildings can be assembled rapidly when compared to concrete, which requires several activities to construct (falsework, formwork, reinforcement, pouring) and then curing time after construction before follow-on trades can gain access to the structure [1]. BIM to CNC fabrication allow designers and fabricators to create a smooth transition between design and production [1].

Figure 10: *Metropol Parasol, Seville, (© Hufton + Crow)*

4.2 Possibilities and limitations of pure timber structures in medium and high-rise buildings

The use of pure timber structures for medium and high-rise building is still a challenge today, but – up to a certain height – certainly feasible. Projects like the Mjøstårnet tower in Norway, with its 18 storeys, is the best example of today's possibilities but also of the critical aspects. In this case, for example, additional mass (screed/concrete slabs without composite action) have been added to control sway and vibration, and the diagonals of the stabilisation system are visible and sometimes limit functionality.

A structure's complexity increases with the overall height of the building. For low-rise buildings (3 to 5 storeys), where the forces to be resisted are relatively low, shear wall systems mainly made of CLT panels can be used.
The structural and mechanical behaviour of cross laminated timber and its use to support lateral loads has been extensively researched in recent years. Arup department of Specialist Technology & Research in London (Lawrence, Abeysekera, and Smith) has produced detailed research and design guidelines and have published their findings [12] on which this chapter, among others, is based.

To resist lateral loads, the individual walls act primarily as vertical cantilevers subjected to bending. The stiffness of the connections plays an important role in the stiffness of an individual wall and that of the entire system. The fact that each wall is divided into several interconnected panels and that different loads may act on the individual connections, which are characterised by different stiffnesses, leads to quite complex mechanical behaviour even when observing an individual wall. This can be theoretically described by the superposition of 4 different behaviours, which are shown in the following figure.

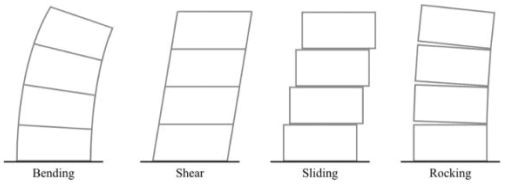

Figure 11: *Mechanical Behaviour CLT walls (© Arup, I. Abeysekera)*

Furthermore, stability systems generally consist of different walls connected to form a statically indeterminate system. However, since timber, like glass, is a brittle material, there is no redistribution of forces based on plasticity, therefore determining the actual load path is not straightforward. For these reasons, the correct dimensioning of the structural components and the connection is very demanding. In addition, questions about the robustness of the system, especially for use in seismic zones, have not yet been clarified and the guidance given in codes is very limited.

https://doi.org/10.52202/069179-0139

As timber structures increase in height, all-timber stability systems can become increasingly expensive (due to the cost of connections). In addition, due to fire safety requirements, CLT walls must usually be completely covered (typically with plasterboard), so that the wooden structure is completely invisible. For these reasons, CLT stability systems are not very common.

Alternatively, timber frame systems arranged around the perimeter can be provided by bracing. The bending moment (e.g., from wind loads) is converted into tension and compression forces in the bracing, but diagonals are required limiting functionality. Moment-bearing structures (rigid frames) rely on the interaction between beams and columns that transfer the moment caused by horizontal forces directly at the connection. The rotational stiffness of the connection influences the horizontal deflection of the building, and the strength of the connection determines the load-bearing capacity of the structure. Due to the typically low strength and stiffness of timber moment connections, this type of system is not very common.

4.3 Key design criteria: acoustics and vibration

Although being lightweight has certain advantages in terms of transportation and erection, it does inevitably make the building more susceptible to dynamic excitation issues and sound transmission. The required acoustics and vibration performance of timber structures can be achieved by careful layout and design and should be addressed at an early stage of the design process so that proper cost allowances can be made.

4.3.1 Vibration

Vibrations are usually the governing factor in the design of mass timber buildings. For slab design, the comfort criteria for human-induced vibrations is reached when the bending stresses in the elements are still far below their load-bearing capacity. Longer spanning floors especially, need careful attention to vibration from an early design stage. Simplified approaches like static deflection methods can, in some cases, lead to lively floors which attract adverse comment. For this reason, conducting a full dynamic computational analysis at an early stage is recommended [1]. Test results on real buildings also demonstrate that damping by structural and non-structural elements also play an integral role in defining the dynamic property of the system.

4.3.2 Acoustics

Best practice in acoustic design of building projects using standard reinforced concrete structures is well established and the regulations cover the typical configurations comprehensively. However, this is not the case when it comes to timber. Due to the low mass, to meet acoustic requirements additional mass may need to be added to the floor build-up. This can be in the form of an additional layer of either concrete, or a similar rigidly bonded mass layer (e.g., bound gravel). A wet screed on sound insulation or a raised floor system with acoustic absorbers are needed to create a mass-spring-mass system which takes away some of the benefit of the low-mass timber slab. Decoupling of floor panels or screed from the CLT slab by using an acoustic batten build up or acoustic insulation on top of the CLT helps to improve acoustic insulation and is an important part of maximising impact sound insulation. Furthermore, it is also important to consider sound flanking transmission.

4.4 Fire protection

In addition to the structural, acoustic and vibration requirements, the building must have sufficient fire safety and fire protection systems for occupant life safety, prevention of fire spread and protection of fire fighters. Considering the brevity of this article and the complexity of the topic fire design in timber construction, only a few comments are addressed here. A detailed analysis of this topic is demanded in separate articles (e.g., Barber et al. [13],[14]). There are a range of fire safety systems that can be implemented to achieve safety goals, such as sprinkler protection, or reducing the area of exposed timber through the installation of non-combustible panels (e.g., gypsum boards). Different local regulations, approaches, and interpretations of some critical aspects of timber design lead to project-specific challenges that affect the design process and the building itself. The requirements for structural fire resistance rating increase with the height of the building and can sometimes even be met without additional protective layers, but only by considering sacrificial depths in the design of the elements.

4.5 Costs

As cost is the driving parameter in the industry, these aspects cannot be neglected. Although for a long time the difference between timber structures and standard structures was relevant, currently it looks like carefully designed timber systems (using timber only where it is possible and really the best choice) can economically challenge traditional concrete structures.

4.6 Holistic approach

As is evident from the topics presented in this chapter, the complexity of timber high-rise buildings is neither linked to individual subjects nor limited to individual disciplines. In each project it is necessary to find bespoke solutions that represents the best compromise between different requirements. Unlike other construction materials, where a single aspect can govern the design, in the case of timber, it is a combination of requirements which drive the design, which in turn is what makes timber unique. As shown by the experience in daily practice at Arup, but also shown by different institutions and research (e.g., COST Action CA20139), a holistic approach is required to improve the performance of taller timber buildings and increase their competitiveness when compared with other materials. For this reason, only with a multidisciplinary design strategy is it possible to maximise the real advantages of timber.

https://doi.org/10.52202/069179-0139

5 HYBRID STRUCTURES

The term “hybrid structures” describes systems that consist of two or more structural materials, in this case: timber and reinforced concrete or steel. The combination of materials can be limited to a single structural component, such as timber-concrete composite panels, or to the entire building, such as the use of reinforced concrete cores as a stability system for horizontal forces. In both cases, the term “hybrid” is used as an antithesis to the purist approach described in the previous chapter. The reason for combining the two materials is the need to improve the properties of timber related to such aspects as acoustics, vibrations or fire performance.

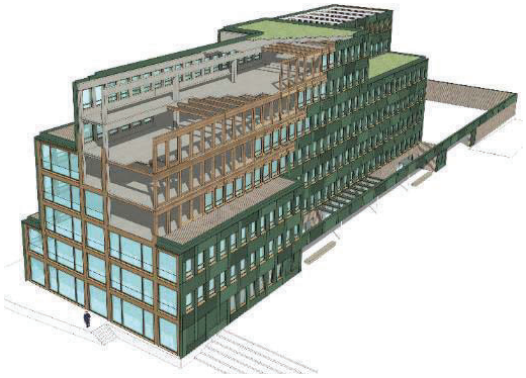

Figure 12: *Projekt H7 in Münster, Germany. (© Andreas Heupel Architekten BDA)*

In projects like H7 in Münster (Germany) or the project HAUT in Amsterdam the design was driven exactly by this priniple: timber where possible, concrete and steel when necessary. As a result, the foundations, basements, and cores were built using concrete. The concrete cores provide stability to the structure and contribute to the fire safety of the building. Based on this it was possible to achieve a highly optimised design with a total embodied carbon reduction of 50% when compared to a conventional building. Furthermore, looking for ways to use as much timber as technically possible, Arup embarked on a quest for an innovative and affordable technical solution comprising almost entirely of precast timber-concrete composite floor systems.

Figure 13: *Project HAUT, Amsterdam (© Jannes Linder)*

5.1 Stability Systems

As introduced in the previous chapter, lateral support for seismic and wind loads is one of the major challenges associated with the design of high-rise buildings in general and for timber buildings in particular. Wood-based lateral timber-bearing systems, such as CLT walls/cores, braced wood frames (but also more advanced post-tensioned/self-centring systems), are feasible design options today. However, the fire safety requirements, the uncertainty about the stiffness of the elements and the connections and thus about the load path, the required tests, and the time and costs involved in obtaining official approvals would have had an adverse impact on the cost and complexity of the building. For this reason, in daily practice for medium and tall timber buildings, the primary lateral support for earthquake and wind forces is usually provided by concrete cores.

As discussed in [11], a typical 50-60 m tall timber high-rise building usually consists of a concrete core (to meet fire protection, acoustic and structural requirements) in combination with timber or timber-concrete composite floors and possibly timber columns along the façade (at relatively short intervals). For taller buildings, additional bracing for sway vibration and comfort requirements or additional stability systems are usually also required.

5.2 Slabs: Timber Concrete Composite (TCC)

Timber Concrete Composite (TCC) consists of a timber beam or panel (glulam or CLT) and a concrete slab mechanically connected by a fastener, e.g., with self-tapping screws and/or notches in the timber beam/panel. From a structural point of view TCC can double the imposed load carrying capacity and have up to three times the flexural rigidity of traditional timber floor systems, when compared to the same depth system acting non-compositely, leading to reduced deflections and decreased susceptibility to vibrations. The combination of timber and concrete is not only an efficient mechanical use of materials, but also offers better fire performance and acoustic properties compared to pure timber systems.

Even though the system itself could be more expensive than a standard slab system, the overall cost of TCC floors can compete with other floor systems when cost savings such as fast construction and reduced foundation costs are considered. There are many variations on the construction market at present, and there are projects where a timber or hybrid floor system are very competitive with conventional reinforced concrete. In addition, the savings in embodied carbon make TCC an attractive construction method compared to concrete/steel counterparts. The concrete topping also provides a good level of thermal mass that can help reduce building operating costs and energy consumption when combined with an effective ventilation system.

Recent research suggests that an optimal slab build-up could consist of two layers: a structural layer of reinforced

https://doi.org/10.52202/069179-0139

concrete, reduced to a minimum to achieve structural performance, and a top layer of wet screed to improve acoustics. The validity of this solution has been corroborated in various projects such as the recently completed 21-storey HAUT in Amsterdam [1]. The deployment of this new technology comes with its own challenges, as these new systems are not fully regulated and different systems with different short- and long-term structural behaviours and costs are available on the market. In addition, as is common with composite structures, the possible future separation of the two materials and their reuse has not yet been fully explored.

Currently, Arup is conducting internal research to incorporate latest design codes and optimise the TCC systems to provide best performance for structures, dynamics, acoustics, and fire.

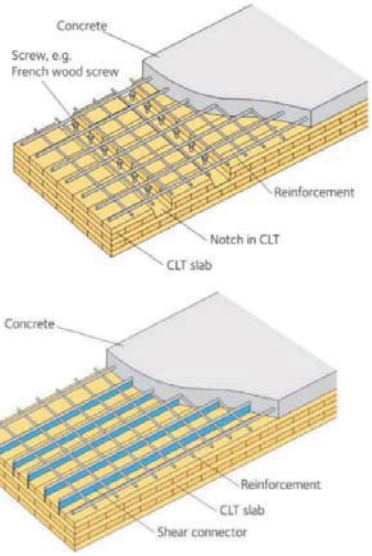

Figure 14: *Timber Concrete Composite Floor System (© Arup, S. Tang)*

5.2.1 The mechanics of the system

The typical shear connections used for TCC are not infinitely stiff. Due to the sliding and creep of the connection, there is only partial composite action. This must be considered when determining the proportion of bending and axial stresses in each element and in the design. Due to the partial shear interaction, the assumption that plane sections remain plane is invalid for the whole composite section. The analysis must check the overall stresses resulting from the bending moments in both the concrete and timber in combination with the axial compression and tension forces respectively owing to the shear transferred across the connection.

The section of the Timber Eurocode (EC5) covering TCCs has been revised and published as a Pre-Standard (CEN/TS 19103:2022-02). This standard has been updated and includes new design methods. This underlines the importance of TCC and will promote its wider application in practice.

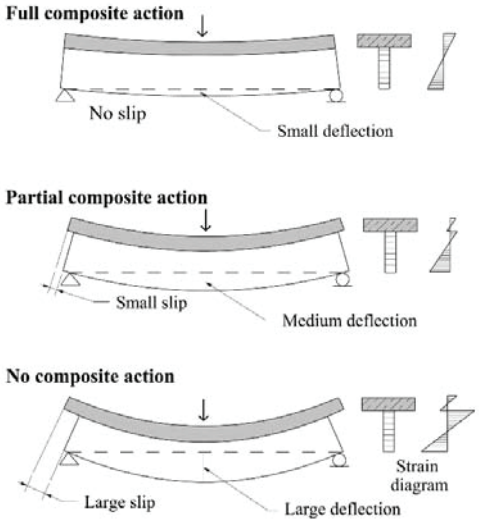

Figure 15: *Mechanical behaviour of TCC (© Arup)*

5.2.2 Possible shear connections

The most important aspects of the Timber Concrete Composites are, of course, the shear connections. These are the elements that connect the timber and concrete layers and allows the materials to act together as one structural material. A stiff connection between the two materials enables a slimmer design of the slab system, whereas a softer connection results in larger cross-sections. Shear connections are not only relevant from a mechanical point of view, but also play a key role for the cost and constructability of the system. The most common shear connectors in TCC are:

- Screws with partial embedment into the timber and partial embedment into the concrete,
- Perforated plates (HBV mesh) glued into the timber and protruding upwards into the concrete,
- Notches (indentations) in the timber beam or panels into which the concrete is poured.

In addition, many combinations of dowels, epoxied bars, nail plates, etc. have been explored in the past. Unique and new types of connections are usually more complex and expensive or lack data from tests. They are also usually not very stiff and sometimes do not have sufficient ductility, which limits the performance of the composite. Two promising new types of connections still being researched are:

- Glued connections: these have almost not slip.
- Micro-notches defined and tested by Prof. Frangi et. Al from ETH Zurich.

https://doi.org/10.52202/069179-0139

5.2.3 Multi-span continuous timber–concrete composite floors

TCC floors which have been researched and built are almost exclusively simply supported single spans. Multi-span continuity can be used to enhance the stiffness, strength, robustness, and ductility of TCC floors [10]. These configurations are currently only being investigated in research or test laboratories, with very few innovative projects exploring their possible applications in practice.

5.3 Vertical structural systems

The vertical system of a building is composed of walls and columns. While the walls can also serve as a stability system (as described in the previous chapter), the columns are usually only loaded in compression. In the case of columns, the material is used as it is in a living tree. Up to 10-15 storeys (30-60 m), the use of timber columns is practically state of the art, although not without challenges. The requirements for fire protection increase with the height of the building and can usually be met without additional protective layers, but only by considering sacrificial depths in the design of the elements. In Germany, for example, the required fire resistance time is 90 minutes up to a height of 60 m, and 120 minutes above 60 m.

The load-bearing capacity of the vertical structural systems is usually not the main challenge. Taller buildings simply require larger cross-sections. The only limits here are the architectural requirements and the costs. Major challenges are the shortening of the timber columns and the definition of an adequate robustness concept that prevents e.g., progressive failure in case of column loss.

5.4 Timber skyscraper

In terms of vertical load capacity, it would be possible to build a skyscraper several hundred metres high entirely with timber columns. However, there are strong reasons associated with fire performance, resistance to disproportionate collapse and carbon impact resulting from inefficient use of the wood for not doing so.
For these reasons it seems much more appropriate to think about hybrid solutions aimed at limiting (but not avoid completely) the use of reinforced concrete on a large scale and defining a smooth transition to the new era. With this vision in mind, it would also be possible to consider implementing the construction principle of medieval towers, with stronger materials (such as reinforced concrete) in the lower part and lighter materials (timber) in the upper parts of the structure. Alternatively, a combination of reinforced concrete superstructure with a modular timber system could also be a viable alternative.

Figure 16: *Case study on combination of reinforced concrete superstructure with modular timber system (© Arup)*

6 Conclusion

Sustainability is no longer a choice, but an obligation for each of us towards future generations. Sustainability cannot be reduced to the simple approach of using a sustainable material but rather is a multi-parametric challenge. Sustainability is a necessity to enable us to build for an exponentially growing number of people using fewer non-renewable raw materials and producing lower emissions. To properly address this challenge, we need to go beyond considering a single aspect such as energy efficiency or embodied carbon and instead approach the multiple faceted issue in a holistic manner to avoid an over-simplistic approach that can only lead to greenwashing.

As with other technical breakthroughs, architects, designers, engineers, and all consultants should explore the limits of technical feasibility for new applications in a safe and responsible manner. This requires a good understanding of the materials and the behaviour of the components, backed up by rigorous analysis and extensive testing. Timber should be used where it adds value to the project, considering all technical, economic and environmental parameters along with the properties and limitations of the material.

Hybrid constructions are one of the best choices for medium and tall buildings, as they use the best properties of timber, concrete, and steel without the need to oversize some components to compensate for the limitations of pure timber (e.g., acoustics, vibrations) or have the high embodied carbon and material consumption characteristic of reinforced concrete construction.

https://doi.org/10.52202/069179-0139

Acknowledgements

The authors would like to thank the company Arup for the support provided for this work globally and furthermore for its commitment to sustainability, efficient structures, and multidisciplinary design.

We would like to extend special appreciation to the entire Arup team for their continuous research and development, which forms the basis for most of the topics covered in this article. The knowledge, dedication and passion of various colleagues and experts from different disciplines, who are not directly mentioned here, have been invaluable to the successful realisation of the projects we are involved in and this article.

Very special thanks go to Andrew Lawrence and David Barber, as main reviewer of this article and also to Ishan Abeysekera, Iris Halm, Ulrike Elbers, Albert Dwan, Stefan Löffel, Tom Finger and Cinthia Buchheister who supported the authors in writing the manuscript and provided valuable comments and feedback.

BENCHMARK LIFE-CYCLE AND CONSTRUCTABILITY ASSESSMENT OF COMPOSITE STEEL-TIMBER SYSTEMS

Emma E. Rohde[1], David B. Roueche[2], Kadir C. Sener[3], Brian K. Via[4]

ABSTRACT: This study presents comparative structural designs and life cycle assessment of the impact of composite steel-timber flooring systems in mid- to high-rise construction. Four architecturally consistent benchmark buildings are analysed, two each with steel-concrete and steel-timber structural systems. Additional comparisons are made between a steel-timber composite and a steel-timber hybrid structural system. The life-cycle assessment focuses primarily on the structural system and its direct impacts, assuming building use and architectural elements remain the same across the structural systems. The Life-Cycle Assessment evaluates global warming impact, total embodied energy, material quantities, combined life-cycle energy, and energy consumption, primarily relying on the commercial LCA software Tally. Contextualization is provided of the steel-timber composite system within recent studies on constructability of mass timber and other modular construction techniques. The study finds significant benefits to the steel-timber composite systems from a life-cycle assessment perspective, with room for further benefits if the systems can be better optimized for vibration.

KEYWORDS: LCA, Composite, Constructability, Mass Timber, Steel.

1 INTRODUCTION

Despite significant advancements in the acceptance and recognition of the benefits of mass timber construction, the building industry in the United States is still dominated by steel and concrete structural systems for non-residential and multi-story residential construction (Figure 1).

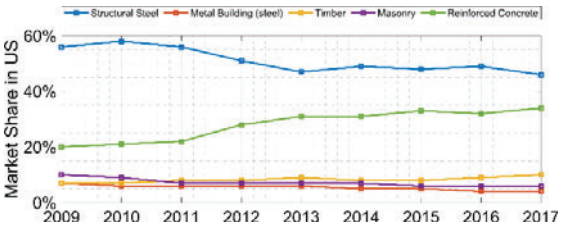

Figure 1. Market share by construction material in the US based on building footprint area. Data from Dodge Analytics [1].

One promising avenue to increasing the use of mass timber in commercial construction is through replacing concrete floors in steel buildings with mass timber floors. This approach has been successfully applied in hybrid steel-mass timber systems, but the structural benefits of the composite behaviour of the mass timber with the steel framing has typically been ignored, despite some recent studies demonstrating feasibility (e.g., [2], [3]). Given the structural benefits, there is a need to quantify the potential global impacts of using composite steel-mass timber systems relative to other common structural systems. In parallel with a separate experimental study being conducted by the authors [4], the objective of this study is to provide benchmark life-cycle assessments (LCA) of composite steel-mass timber systems relative to other traditional structural systems.

2 BENCHMARK BUILDINGS

The focus of this study was on mid- to high-rise commercial and mixed-use buildings. Steel-timber composite (STC) and steel-concrete composite (SCC) structural systems are compared. The steel-timber structural system consisted of steel columns and floor beams with cross-laminated timber (CLT) spanning between floor beams to form the floor system. The benchmark buildings are architecturally consistent, with one seven story building and one eighteen story building for each structural system. All buildings have a story height of 3.66 m and column spacing of 9.14 m (Figure 2) and are assumed to have the same usage (business) and architectural elements. The geometric constraints for the design of the structure were in accordance with IBC 2021, and specifically met the requirements for Occupancy B, Type IV. Total building heights were 25.6 m and 66 m in

the 7-story (conforming to Type IV-C) and 18-story (conforming to Type IV-A) structures. Similarly, 9.1 m by 9.1 m bay sizes were chosen to maintain dimensional consistency in framing plans. Spans of 3.0 m and 4.6 m were chosen for the concrete and timber slabs respectively.

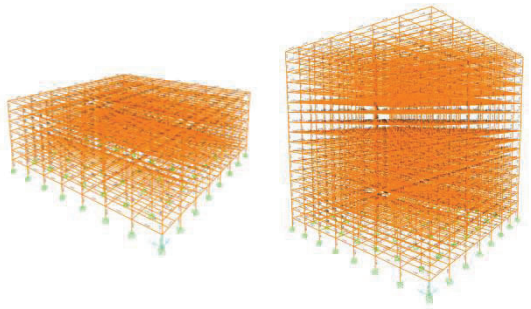

Figure 2. Structural layout of the (left) seven story, and (right) eighteen story benchmark buildings.

2.1 STRUCTURAL DESIGN METHODS

Buildings were structurally designed for gravity loads only, assuming an office occupancy to determine appropriate live loads (3.11 kPa) and superimposed dead load (0.5 kPa). Deflection criteria was considered, including superimposed load deflections and live load deflections. Vibration due to walking excitation was also considered based on a limit of $a_p/g \leq 0.005$, using AISC Design Guide 11 [5] for the steel-concrete floor systems and the US Mass Timber Floor Vibration Design Guide [6] for the steel-timber floor systems. CLT floor slabs were additionally sized to meet fire resistance requirements. Both steel-timber and steel-concrete floor systems utilized a normal weight concrete topping slab, as this is common practice to mitigate vibration, meet acoustical requirements, and support flooring products.

Structural designs were performed using a combination of manual calculations and structural design software, specifically CSI ETABS. Roof and floor beams were first sized for gravity loads, including dead and live loads, and deflection and vibration criteria, using the relevant material-specific design standards. The manually sized floor and roof beams were then defined in the structural analysis software along with the gravity loads, and the software was allowed to optimize the column designs accordingly. Foundations and lateral force resisting systems were not considered.

For steel-timber composite designs, for which no design guides yet exist, a method consistent with steel-concrete composite design was utilized [7]. A partial composite action corresponding to 25% was assumed to be achieved by self-tapping screws transferring interfacial shear that connect steel floor beams/girders and CLT panels. The flexural capacity of a STC member was resultant of the internal resisting force couple and the force couple moment arm. The compressive capacity of the CLT was a summation of the compressive strength of each lamination, which is dependent on orientation to the beam span and therefore varied with panel orientation. Because the STC members were designed to 25% composite action, the depth of the compression block corresponded to 25% of the compressive strength of the full CLT section. Tension in the CLT was ignored in this study; therefore, tension capacity was resultant of the tensile capacity of the steel wide-flange sections alone.

2.2 STRUCTURAL DESIGN RESULTS

Typical beam and girder cross-sections for the STC and SCC systems are shown in Figure 3. All STC floor systems were composed of 5-ply Southern Pine CLT with 38 mm normal weight concrete topping. Typical floor framing consisted of W18x40 beams, framing into W24x55 girders. Typical roof framing consisted of W14x22 beams, framing into W18x35 girders. Columns in the 7-story STC varied in size between W12x26 and W14x61, while in the 18-story buildings, columns varied in size between W12x30 and W14x145. All SCC floor systems were composed of a 127 mm slab on a 51 mm deep 20-gauge steel deck. Typical floor framing consisted of W12x26 beams, framing into W21x50 girders. The roof decking systems were 89 mm slabs on a 38.1 mm deep 20-gauge deck. Typical roof framing consisted of W12x19 beams, framing into W18x40 girders. Floor beams and girders for the SCC system were also designed to approximately 25% composite action. Columns varied in size between W12x30 and W12x65, and between W12x30 and W14x159 for the 7-story and 18-story buildings respectively.

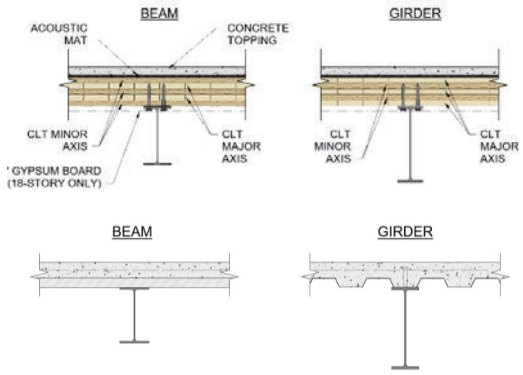

Figure 3. Typical cross-sections for (top) steel-timber composite and (bottom) steel-concrete composite structural floor systems.

The inclusion of the vibration design criteria tended to dominate the beam member for the STC designs relative to the strength and deflection criteria, despite the use of service level live loads (0.6 kPa) and assumption of 100% composite action for vibration design. With the chosen beam span of 9.1 m, the STC beams with 38 mm NWC had a utilization rate (ratio of usage to capacity) of 0.98 for vibration, but only 0.57 and 0.62 for strength and deflection criteria respectively. A parametric study was conducted to evaluate the role of vibration in controlling

https://doi.org/10.52202/069179-0140

member design for a range of beam spans (Figure 4). The parametric study showed that longer beam spans, and increased topping thickness, both helped balance the utilization ratio across all three criteria. More rigorous studies are needed, but the preliminary results highlight the importance of the architectural layout of the building in optimizing the utilization of steel-timber composite systems.

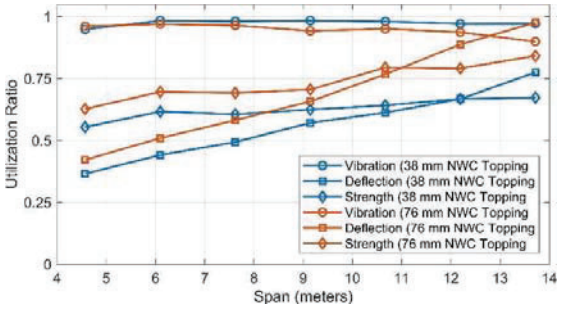

Figure 4. Utilization ratios considering vibration, deflection, and strength criteria for STC beams with 38 mm and 76 mm topping slabs and variable CLT floor spans.

2.3 STEEL-TIMBER COMPOSITE VS HYBRID

While steel-timber composite floor systems are a relatively new structural system, steel-timber hybrid (STH) floor systems have become relatively popular in mass timber construction. In the STH system, CLT floor slabs are still mechanically fastened to the steel beams and girders, but the composite behaviour is ignored in the design. The current study provided an opportunity to evaluate the benefits of composite design by taking the beam sections required to meet the vibration criteria and comparing their utilization rate for strength and deflection criteria both with and without consideration of composite action (i.e., 25% composition action compared to 0% composite action) for two different concrete topping slab thicknesses. The results showed that if the composite action were ignored in the design, the deflection and strength utilization ratios began to govern the design over the vibration criteria. For spans greater than 6.1 m, utilization ratios for deflection criteria were greater than 1.0 (Figure 5), indicating the steel beams would need increased cross-sections if designs assumed hybrid performance. In summary, explicitly accounting for composite action in the steel-timber floor systems likely provides marginal benefits if vibration criteria is part of the design, but stands to provide much greater benefits if vibration criteria is not necessary in the design.

3 LIFE-CYCLE ASSESSMENT

3.1 METHODS

The environmental impacts of the STC and SCC systems were quantified using LCA. The LCA was constrained to include cradle-to-gate (which measures the environmental footprint up to the point where it leaves the manufacturing facility), construction transportation, and end-of-life impacts [8]. The LCA did not include operational use of the buildings, nor the environmental impacts of on-site construction, as these are assumed to be nominally independent of the structural system relative to the impacts in the other stages. The building life expectancy was taken to be 60 years for all structures. Biogenic carbon was accounted for in the cradle-to-gate phase. The study includes raw materials supply, transport, manufacturing, construction process, and end of life stage.

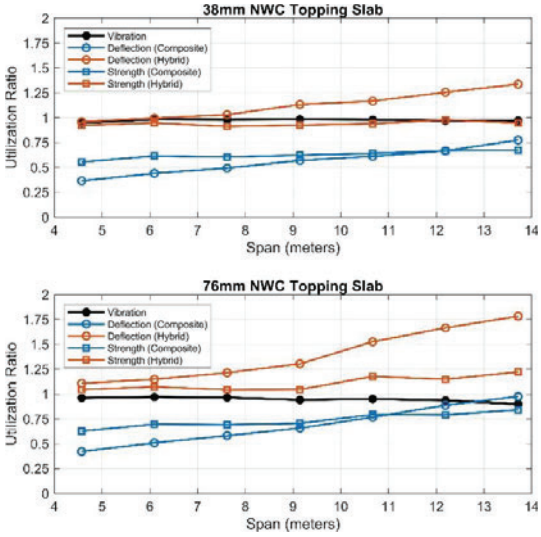

Figure 5. Utilization ratios for composite and hybrid STC designs considering vibration, strength, and deflection with 38 mm and 76 mm topping slabs for variable CLT spans.

To conduct the LCA study, the structural analysis models for the benchmark buildings that were generated using the structural design software ETABS were then imported into Revit, where the Tally Revit application was used to perform the LC assessments, which is widely used for comparative building LCA ([9], [10]). The outputs considered are mass, embodied carbon, and embodied energy, both as raw values and normalized by the net floor area (28,679 m^2 and 73,746 m^2 for the 7- and 18-story buildings respectively) or material mass.

The life cycle inventory (LCI) was compiled using Revit's built-in capabilities to calculate total material quantities based on the defined structural sections and geometries. Tally leverages the commercial GaBi 8.5 database along with the EC3 Environmental Product Declaration (EPD) database to perform LCA. Review of the environmental impacts assigned to the various materials used from the GaBi database found that a few manual adjustments were needed. Specifically, the generic CLT in the GaBi database reported environmental impacts were not representative of the EPDs from US CLT manufacturers (primarily with respect to the embodied energy), and further, the database lacked a suitable rubber material analogous to an acoustic mat. The CLT environmental impacts reported by Tally were therefore scaled to match the unit environmental impacts reported in the EPD from a CLT manufacturer in the Southeast US. A similar

https://doi.org/10.52202/069179-0140

procedure was used for the acoustic mat, adjusting the environmental impacts of a rubber high-traffic commercial flooring product to match the EPD from a US-based acoustic underlayment mat.

Several assumptions were required to complete the LCA analysis, most of which followed the assumptions standard to the Tally software. It was assumed that all individual elements have life spans greater than or equal to the building service life; essentially ignoring repair and replacement activities. Hot-rolled steel and steel decks were assumed to have been fabricated with 100% and 28% recycled material, respectively. Average transportation distances for each product for the US as estimated by Tally were used rather than tying transportation distance to a specific site. This resulted in transportation distances of 332 km for CLT, 431 km for the steel, and 24 km for concrete materials. End-of-life scope varied by material. For CLT, 14.5% was assumed recovered, 22% incinerated with energy recovery, and 63.5% landfilled. Steel was assumed to be 98% recovered. Concrete was assumed to be 55% recycled and 45% landfilled.

3.2 LCA RESULTS

LCA results are presented for the 7-story steel-timber composite (STC), steel-timber hybrid (STH), and steel-concrete composite (SCC), and 18-story steel-timber composite (STC) and steel-concrete composite (SCC).

The total mass varied only slightly across the various structural systems as presented in Figure 6. The STC system had the lowest mass for both stories considered, but the total mass in the 7-story STH and SCC were only 2% and 11% higher than the 7-story STC. Only a 4% increase in total mass was observed in the 18-story SCC relative to the 18-story STC. Floor systems, including the CLT, acoustic mat, metal deck, concrete slab and topping, and gypsum, accounted for between 84% and 87% of the total mass of the structure for all systems considered. Ignoring the composite action in the STC resulted in a 12.7% increase in steel framing mass, but this difference would be significantly higher if vibration criteria were ignored and utilizations were optimized for strength and deflection criteria only.

Differences in environmental impacts, specifically embodied carbon (Figure 7) and embodied energy (Figure 8) were more pronounced between the structural systems for the scope considered (cradle-to-gate, construction transportation, and end-of-life). Total embodied carbon was lowest in the STC, with the SCC system containing almost 200% of the total embodied carbon for the 7-story building, and 171% for the 18-story. Conversely, embodied carbon and embodied energy were 40% and 22% lower in the 18-story STC compared to the 18-story SCC respectively. Most of these differences are driven by the choice to include biogenic carbon in the CLT embodied energy, which results in a net negative effect from the CLT. The differences between the 7-story STC and STH are less pronounced, with only 10% higher embodied carbon in the STH compared to the STC. The high embodied carbon density of steel is clearly evident, with the steel framing accounting for between 41% and 82% of the total embodied energy in each structural systems despite only accounting for less than 15% of the total mass.

Environmental impacts for the studied structural systems were also quantified for each considered LCA stage in terms of embodied carbon (Table 1) and embodied energy (Table 2). According to Table 1, carbon sequestration of lumber products causes the largest portions of the STC structures' carbon footprints to appear at the end-of-life stages. This is because extraction of lumber avoids net carbon emissions due to the large amount of carbon sequestered in lumber. Conversely, the SCC structures' carbon footprints are heavily front-loaded. This is due to the production stages accounting for the bulk of SCC structures' embodied carbon. Conversely, the end-of-life and post-life stages of concrete are associated with the material's environmental credits, due to recycling and re-use. Similarly, the energy required to produce CLT is relatively low compared to the energy required to produce concrete and metal decking. However, the STC structures have no avoided energy burdens throughout their life cycles; whereas, the SCC structures have a net negative embodied energy value in the reuse and recycling phase.

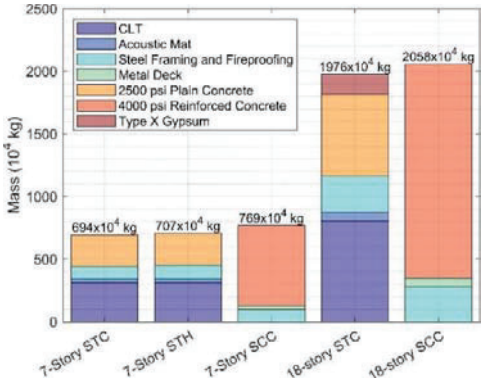

Figure 6. Total mass by structural system and material type.

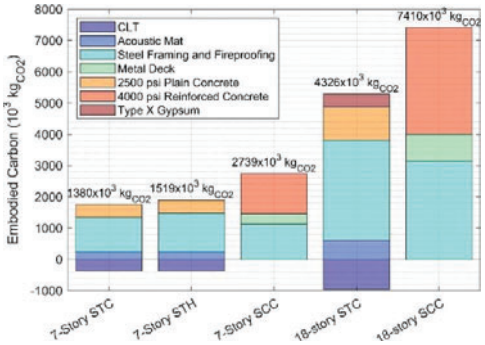

Figure 7. Total embodied carbon by structural system and material type.

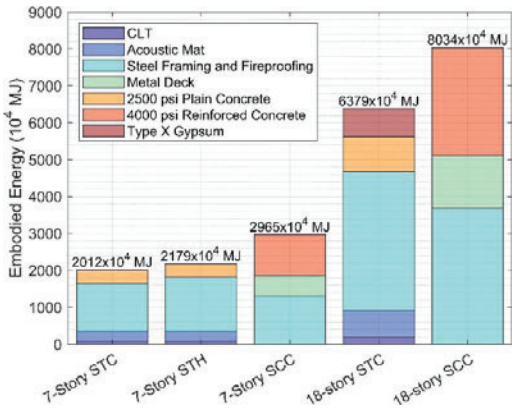

Figure 8. Total embodied energy by structural system and material type.

The net effect is that embodied energy is also heavily concentrated in the Production stage for all systems (Table 2), with the lower energy requirements for CLT production reflected in the slightly lower concentration of embodied energy for the STC and STH systems in the Production stage relative to the SCC systems.

Table 1. Distribution of embodied carbon in each structural system by LCA stage.

Structural System	LCA Stage			
	Production	Transportation	End-of-Life	Post-Life
7S STC	-120%	5%	195%	20%
7S STH	-101%	5%	177%	19%
7S SCC	96%	1%	10%	-8%
18S STC	-83%	4%	161%	17%
18S SCC	96%	1%	10%	-7%

Table 2. Distribution of embodied energy in each structural system by LCA stage.

Structural System	LCA Stage			
	Production	Transportation	End-of-Life	Post-Life
7S STC	90%	2%	6%	2%
7S STH	90%	2%	5%	2%
7S SCC	96%	2%	8%	-6%
18S STC	89%	2%	7%	2%
18S SCC	96%	2%	8%	-5%

4 CONSTRUCTABILITY

Beyond biophilic aesthetics and a decreased environmental impact, the use of mass timber panels in composite timber-steel floor systems has become increasingly attractive to owners, installers, and designers because of its benefits for on-site safety and scheduling efficiencies [10]. These benefits are largely attributed to the modular installation process, which decreases the number of required employees and can reduce construction schedules by 30 to 50 percent [11]. Given the potential constructability benefits, there is a need to quantify the potential labour hours and schedule duration of composite steel-mass timber structural systems relative to other common structural systems.

Unfortunately, such studies are difficult due to lack of building-specific construction data and lack of established modelling methods, although a few limited studies do exist. Bhandari et al. [12] evaluated construction duration per 1000 m^2 of actual buildings that used CLT and reported 10 hybrid CLT with concrete mid-rise buildings were constructed in under 4 weeks. However, no steel-CLT hybrid buildings were included in the dataset. Brisland et al. [13] found daily productivity rates between 67 m^2 and 111 m^2 for multi-story mass-timber buildings. Mirando and Onsarigo [14] tracked construction progress in a multi-story mass timber building and measured a productivity rate of 33 m^2 per person-day, a rate nearly three times that estimated by the authors for cast-in-place concrete based on literature reviews. Real-time data was collected through daily reports generated by the onsite foreman, digital photographs taken by two time-lapse cameras placed on the jobsite, and a 360-degree construction photo documentation system. Tavares et al. [15] evaluated life-cycle effects of prefabrication across a range of building materials and reported that pre-fabrication reduces construction time by between 33-50%. The study did not explicitly consider steel-timber hybrid or composite structures though, and primarily focused on low-rise buildings. Reduced waste, material use, and environmental impacts were also noted in prefabricated structural systems. Mofolasayo [16] noted the benefits of modular construction were closely tied to transportation distances, with long transportation distances limiting the benefits of modularity. In this regard, the constructability of steel-timber composite may be negatively affected relative to steel-concrete composite, given the longer transportation distances typically associated with mass timber relative to concrete (see Section 3.1).

In summary, a literature review of constructability reveals clear benefits to modular construction, which steel-timber systems would benefit from, in terms of costs, erection time, and environmental impacts. These benefits are limited if transportation distances are long. Constructability data is still relatively scarce however, particularly for steel-timber hybrid or composite systems.

https://doi.org/10.52202/069179-0140

Future efforts are needed to collect research-suitable data during actual construction projects.

5 CONCLUSIONS

Structural designs for gravity loads were completed for functionally-equivalent 7-story and 18-story buildings with steel-timber and steel-concrete structural systems. Lateral force resisting systems and foundation designs were ignored at this time. Life-cycle assessment was then performed on the structures using the material inventories from the structural designs and environmental product declarations primarily obtained through the GaBi database integrated into the Tally LCA software. The following conclusions can be formed from the analysis:

1. Vibration dominated the sizing of steel beam elements in the floor for the considered spans and spacings, with steel members underutilized for strength and deflection criteria as a result. Better understanding of vibration behavior of steel-timber composite systems is needed to develop more optimized design guidelines and enable more efficient overall designs.
2. CLT panel depth was controlled by fire-resistance requirements, resulting in 5-ply panels for all systems. The fire requirements led to an optimal floor panel span of 4.5 meters, demonstrating how secondary design considerations such as vibration, fire, and even acoustics can oftentimes control the overall framing layout in steel-timber composite systems.
3. Significant advantages were found to be associated with STC design relative to non-composite (hybrid) design, with larger beam sizes being needed for the hybrid design relative to the composite design.
4. Embodied carbon and embodied energy were both lower in the steel-timber composite systems relative to the steel-concrete composite systems, with differences in the 18-story buildings as much as 40% for embodied carbon and 22% for embodied energy.
5. The environmental impacts of all structural systems were disproportionately driven by the steel framing, despite its low mass relative to the other building materials.
6. Steel-timber composite structural systems are expected to be advantageous from a constructability standpoint due to the potential for modular construction, but relative to other modular construction techniques, may still be limited by the longer transportation distances associated with steel framing and mass timber procurement.

While this study provides an initial life-cycle assessment of steel-timber structural systems, many knowledge gaps remain. Better guidelines for vibration design of steel-timber composite systems are needed. The relative impacts for lateral force-resisting systems and foundations are also needed. And finally, attempts to evaluate constructability would greatly benefit from focused studies tracking scheduling and manpower for real construction projects.

DEVELOPING AN APPLICATION FOR MASS PLYWOOD PANELS IN SEISMIC AND ENERGY WALL RETROFITS

Mark Fretz[1], Jason Stenson [2], Gustavo Fernando O. Orozco[3], Payton Narancic[4], Flynn Casey[5], Dale Northcutt[6], Kevin Van Den Wymelenberg[7], Judith Sheine[8], Andre R. Barbosa[9]

University of Oregon and Oregon State University are collaborating through the TallWood Design Institute (TDI) to upgrade aging multi-family housing, which is energy inefficient and does not meet current code lateral force resistance, by developing a mass ply panel (MPP) façade retrofit panel assembly that employs digital workflows and small diameter logs (down to 127mm) to create an economically viable energy/seismic retrofit model for the West Coast of the United States (U.S.) and beyond. The design and testing of the retrofit panelised system for upgraded energy and seismic resilience of existing light-wood-frame multi-family housing stock were completed at TDI's Emmerson Laboratory for a full-scale one-story mock-up. The research program includes structural and energy performance design, and benchmarking of digital to physical workflows and construction methods. The next iteration is a three-story prototype fabricated by a commercial contractor to validate the design, scanning techniques, fabrication, construction, and cost models resulting from the initial prototype construction, with the intent of commercializing designs for immediate adoption.

KEYWORDS: Seismic Resilience, Energy Upgrades, Retrofits, Mass Plywood Panels

1 INTRODUCTION

In the past decade, humans have witnessed the convergence of global, regional, and local natural and human-made crises. On the U.S. West Coast, extreme weather events, forest fires, and power outages have exposed millions of Americans to the loss of life, property, and livelihood. Skyrocketing housing prices have depleted the market of available housing that is affordable, exacerbating social inequities and homelessness [1]. Moreover, reductions in timber harvest have depressed rural manufacturing and economic development. Therefore, the building design and construction industry, manufacturing, and government agencies are working to respond to multiple crises simultaneously by developing creative solutions to multifaceted problems.

The U.S. Forest Service has responded to extreme forest fires with healthy forest initiatives [2] that include selective harvesting of small-diameter trees to reduce fuels and wildfire risk; however, this form of harvesting is labour intensive, costly, and the resulting harvest of small-diameter logs has low market value [3], resulting in this wood fibre being commonly sold for products that have only short-term biogenic carbon storage (e.g., paper, biomass fuel), thus, reducing the climate benefit of wood to sequester carbon dioxide. Thus, there is great interest in finding higher value utilization of small-diameter logs that provide long-term carbon sequestration in building materials.

At the same time, local, state, and federal investments in energy efficiency and decarbonization have been increasing. At the local level, the City of Portland, Oregon created and approved in 2018 a unique funding stream to support climate action by providing clean energy home upgrades and associated jobs to vulnerable communities [4]. The fund, called the Portland Clean Energy Fund (PCEF), initially anticipated local investments of USD 44-61 million annually [5]; however, in 2022, the fund made its largest award of USD107 million to 65 projects fighting climate change [6]. The State of California is also aggressively pursuing an energy code to achieve zero net energy to mitigate climate change. The California Energy Commission is advancing novel energy efficient technologies through Electric Program Investment Charge (EPIC) funding to develop and commercialize

deep energy retrofit solutions for existing buildings [7]. In August 2022, the U.S. Congress passed the Inflation Reduction Act, which includes USD369 billion for energy and climate resilience, targeted at building decarbonization, energy efficiency, and affordability [8].

In the U.S., buildings account for approximately one-third of carbon dioxide equivalent emissions each year [9]. Moreover, existing low-rise multifamily building stock is ubiquitous and much of it is affordable but also aging and not climate resilient. According to the Northwest Energy Efficiency Alliance (NEEA) Residential Building Stock Assessment, 88% of this housing stock in the Pacific Northwest is one- to three-story light-wood-frame and was constructed between 1960-1994 with very low wall insulation levels (64% had R8-R12 wall insulation) [10].

While urgent, the focus on building energy and decarbonization does not address the other critical West Coast need for seismic retrofits for pre-1990's era buildings [11]. In Oregon, the building seismic code has evolved since the 1970s to include a better understanding of seismic risks and associated base shear forces, beginning at 5% in the 1973 Uniform Building Code (UBC) [12], slowly ramping to 16.41% in the 1997 UBC following an initial understanding of the Cascadia Subduction Zone risk, and back down to 11.30% in the 2003 International Residential Code (IRC) [13]. Unfortunately, the preponderance of existing multifamily housing units in the Pacific Northwest was constructed well before the increased base shear code requirements ramped up in the 1990s [10]. Moreover, many low-rise multifamily buildings typically found in this housing group include a soft story, such as open bays without horizontal bracing or shear walls to accommodate parking at the ground level, further escalating the urgency of seismic retrofit.

Although there is increased recognition of the need to address multifamily housing climate and seismic resilience in the Pacific Northwest, the states of Oregon and Washington currently do not require these upgrades and there has been resistance to making these retrofits mandatory due, in part, to their construction costs and potential for tenant displacement. Prevailing seismic upgrade techniques often require extended building vacancy or at least significant occupant disturbance, which cannot be tolerated in an environment of housing scarcity. In fact, due to years of housing underproduction on the U.S. West Coast, Oregon alone predicts that it will need 584,000 new homes over the next 20 years [14]. To meet that goal, existing housing must be maintained, in addition to creating new housing units. Therefore, there is an urgent need for cost-effective, low-impact energy and seismic upgrades to extend the useful life of this critical housing stock.

Housing projects in Europe have begun to address deep energy upgrades with minimal tenant disturbance using prefabricated façade retrofits. For example, the *Energiesprong* [15] method developed in the Netherlands employs a technique of digital scanning of existing facades and using these scans to fabricate new façade systems off-site, complete with insulation, high-performance windows, doors, and cladding. Since the panelised systems are manufactured in a factory, fabrication can employ digital workflows, such as computer numerical control (CNC) machining, with high environmental and quality control over the manufacturing process. The resulting products are then applied over the existing facade with minimal time and occupant disruption on site.

While the *Energiesprong* method provides many lessons for the U.S., deep energy façade retrofits on the West Coast must also contend with seismic activity; adding an increase of 10% to an existing building's weight in an insulative wall system triggers seismic upgrade requirements in many jurisdictions. The mass ply panel (MPP) system that is described in this paper is a building assembly that could provide for both energy and seismic resilience while minimizing occupant disturbance with few necessary interior disruptions through off-site prefabrication. MPP, developed in rural Oregon by Freres Engineered Wood, is a veneer-based mass timber panel that utilizes small diameter logs (down to 127 mm), which can be sourced from healthy forest initiatives, thereby making forest restoration products more economically viable while providing a building product that supports the housing industry. Since panels are available in nominal sizes as large as 3.7 m x 14.6 m with thicknesses starting at 52 mm and increasing by additional lamella thicknesses of 26 mm, there is a wide range of flexibility for their use as secondary facade systems.

The estimated total available U.S. multifamily market for the MPP panel system is close to 18 million housing units [16]. Even narrowing this to the serviceable available market (California/Oregon/Washington region, pre-1990 construction in a high seismic zone, not previously upgraded seismically), there are slightly more than 3 million housing units. By employing MPP that are 52 mm to 78 mm thick using an efficient process of prefabrication with digital workflows, retrofit wall panels spanning one- to three-stories can be efficiently constructed and provide both energy upgrades and seismic resilience to aging multifamily housing.

The project is a collaboration between the University of Oregon (UO)'s Energy Studies in Buildings Laboratory and Oregon State University (OSU) through the TallWood Design Institute (TDI), a collaboration between UO's College of Design and OSU's College of Forestry and College of Engineering that advances engineered timber products and their application through research and testing. This project demonstrates a system of prefabricated panels built with MPP that can be rapidly applied onsite over existing building cladding to upgrade older light-wood-frame one- to three-story buildings to meet or exceed current energy and seismic codes.

https://doi.org/10.52202/069179-0141

2 METHODS

To develop the panelised wall system, we divided the project into discrete phases: *predesign, structural design, envelope design*, then created an existing condition mock-up to test digital workflows during *panel fabrication and construction.* Structural connection and envelope details were developed over a series of iterations and a full-scale mock-up resulting in construction and assembly details.

2.1 PRE-DESIGN

At the outset of the project, we surveyed the morphologies of pre-1990 multifamily housing in Portland, Oregon USA to characterize common aspects of building, site, and existing utility infrastructure that would impact or even preclude a façade retrofit. We found predominantly two-story light-wood-frame structures with repeated stacked housing units and regular façade elements, such as window size and placement. Concrete stem wall foundations with a shallow crawlspace were most common, though slab-on-grade was found as well.

Often units were sited with priority given to on-site vehicle surface parking, leaving limited lot building setbacks and minimal landscaping. Access to upper-floor units is typical via exterior stairs with circulation zones occurring either between sets of units or by incorporating an outdoor walkway in front of units.

Electrical service in the area is from overhead power lines but is brought to larger multifamily structures below grade from the street. On-site distribution usually incorporates an exterior façade-mounted electric meter for each unit. Natural gas service is not typical for this housing typology in this location in Portland, Oregon. Additional façade penetrations may include exhaust fan venting, which predominantly occurs through the roof, but can be found located at the façade for ground floor units.

Figure 1: *Visualization of case study multifamily building used for façade retrofit study, pre-retrofit*

The case study building selected, pictured in Figure 1 and detailed in Figure 2, offers an example of typical existing multifamily construction found in the study region while also representing a reasonable candidate for façade retrofit. Exterior circulation occurs between units, leaving the façade unobstructed by walkways or other large overhangs. Window openings are large, but sufficient two-story wall area remains between openings to locate full-height shear panels. Furthermore, the building is set back sufficiently far from the property line, so additional wall thickness will not encroach into the setback zone.

The central on-site parking area offers a straightforward staging and crane location, eliminating the need for crane access from multiple street frontage locations or over other structures not involved in the retrofit. The location of electric meters, distribution conduit, and exhaust vents, though spread across the structure, are all found on the façade opposite the parking area, which minimizes the continuous lineal footage of the façade where services will need to be factored into more complex retrofit panel design and installation.

2.2 STRUCTURAL DESIGN

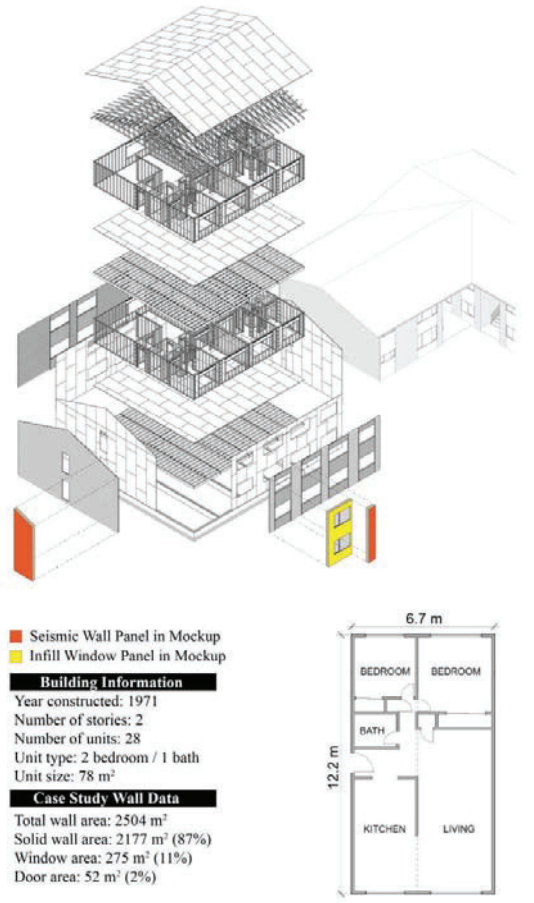

Figure 2: *Case study multifamily building: building information, typical unit design, exploded view of existing light-wood frame structural system, wall area data and panels tested during mock-up.*

With the focus of structural design on the development of a façade retrofit lateral force resisting system (LFRS) which incorporates the use of MPP, a foundation upgrade

https://doi.org/10.52202/069179-0141

was identified early on as a requirement to both account for the added gravity load of the MPP and new façade elements, but also to help resolve concentrated seismic loads delivered through the stiffer and stronger MPP as compared to the conventional plywood shear walls found in existing light-wood-frame structures.

The MPP could be attached to this additional concrete footing which would be tied back into the existing foundation, but a solution would also be required to transfer lateral loads between the existing wood structure and the MPP. At the elevation of each floor diaphragm, as well as at the roof diaphragm, a transition joist was planned to wrap the entire existing building and be securely fastened to the building's existing load-carrying elements. The MPP would then be attached to these transition joists to accomplish the load transfer between the existing structure and the retrofit LFRS.

The entire façade would not need this type of LFRS; infill panels could be used in between these panels and would not require the same level and type of connection. Infill panels could still be designed with MPP to simplify the material palette and assembly complexity.

The lateral resistance provided by an MPP LFRS is expected to significantly reduce inter-story drifts and overall building deformation in the event of a seismic event. This should limit overall damage to the building, including interior finishes, and could shorten the timeline for re-occupancy of light-wood-frame multifamily housing, therefore providing for a more resilient design.

2.3 ENVELOPE DESIGN

The wall insulation of existing pre-1990 multifamily housing in the study region can be assumed to be below the current code requirements of RSI-3.7 for new construction, and the degree to which the walls are insulated is a primary design criterion for a façade energy upgrade. Leaving the existing wall in place minimizes renovation disturbance, and adds the existing insulation value to the overall effective insulation value of the retrofit solution.

With the MPP façade retrofit panel, insulation can be included on either or both sides of the MPP. A natural insulation cavity is created behind the MPP where the depth of the transition joist at each diaphragm location holds the MPP off the existing façade everywhere else. A compressible insulation allows for managing some of the inevitable construction irregularities of the existing façade, such as areas with trim elements protruding or an area being out of true. It also offers a location for new services to be run, should they be required. The depth of insulation added outboard of the MPP can be easily modified in the design phase to meet the energy code needs of a different climate zone or to increase the thermal performance target of the envelope. Table 1 lists a range of performance criteria by level of retrofit target.

Table 1: *Range of Energy Retrofit: Comprehensive, Moderate, Low-Cost and Current Energy Code Standard. [1]Indicates typical existing conditions per NEEA Residential Building Stock Assessment.*

New windows offer the most tangible feature of energy upgrades for occupants through perceptibly improved thermal comfort. Installing them in the MPP retrofit panel in the factory as part of a prefabricated façade assembly allows for greater quality control and speed of on-site installation. Existing windows would be removed just prior to retrofit panel installation, and interior finish carpentry would immediately follow the panel installation, minimizing occupant disturbance. The precision CNC fabrication of the MPP also achieves a very predictable tolerance for window rough openings in the panels so that gaps between the window and MPP can be far smaller than site-built rough openings.

Air tightness or infiltration is another key envelope criterion for reducing operational energy use in buildings for heating and cooling. The large format, multi-story MPP limits the number of joints where air leakage can occur. Panel-to-panel joints closed in the field become critical details that need to be executed precisely to achieve anticipated performance.

One concern in covering the existing envelope with new additional enclosure layers is that moisture could become trapped in the combined wall assembly. For this reason, we used WUFI 2D (version 3.4) moisture transmission simulation [17] and analysis for the proposed retrofit solution over an existing wall assembly. All materials were assumed to have an elevated starting water content

https://doi.org/10.52202/069179-0141

equivalent to 80% relative humidity and the simulation was run for one year with modelled climate and weather. For each material in the assembly and every hour over one year, the duration at a given water content is converted to mould index ranging from 0 - no growth to 6 - 100% coverage with visible growth [18]. Results for all materials demonstrate that moisture is not being trapped in the overall wall assembly at any time, which translates to <1% coverage of microscopic growth. At the conclusion of the one-year simulation, all materials have dried, having a mould index of 0, or no growth.

2.4 EXISTING CONDITION MOCK-UP, PANEL FABRICATION AND CONSTRUCTION

We constructed a full-size mock-up using a corner and window condition from the case study building (Figures 2, 3) to test design, detail, fabrication, and installation assumptions. Research questions addressed with the mock-up included: 1) how much data generated from the scan of an irregular building topography can and should we ignore with the high tolerance capabilities of CNC; 2) what digital actions can minimize our time on site through the use of a digital model compared to simple physical interactions with the existing physical object; 3) what are the out of plane tolerances of an existing building; 4) how do we make structural connections while prefabricating and closing as much of the panel as possible; and 5) how do we rig and lift the panel in a vertical orientation to not damage foundation connections and navigate the eave. We used video and still photography to capture key elements and events during the testing process.

First, we created a mock existing condition. Although the shear panel foundation connectors were sized for the two-story case study building, we determined that a one-story section of the existing structure was sufficient to allow us to test the foundation, roof eave, rake details, and a panel-to-panel field and corner condition. The existing structure included plywood T1-11 siding, a typical vinyl frame sliding window, gutter, downspout, dryer vent, and trim.

Next, we scanned the existing condition as in Figure 3a. We evaluated different scanning techniques, including Matterport Pro2, Leica BLK360, and Artec Ray. The Matterport Pro2 camera is a professional, high-resolution 3D camera. Both the Leika BLK360 and the Artec Ray are Light Detection and Ranging (LiDAR) equipment. The Leica BLK 360 provides 3D captures with indoor and outdoor capabilities and excellent measurement accuracy for an extended range of 20 m. However, the Artec Ray is designed for large objects with up to 110 m distance and proved to work well with the large scale of a building façade, yielding clean, complete scans. The point-cloud software, Artec Studio, was used to merge Artec Ray scans into a singular model (Figure 3b) and to fit planes through the existing T1-11 wall surface (Figure 3c). Once planes were established, we could develop a topographical map of wall surface tolerance (Figure 3d) and use Autodesk ReCap Pro (Figure 3e) to link the model

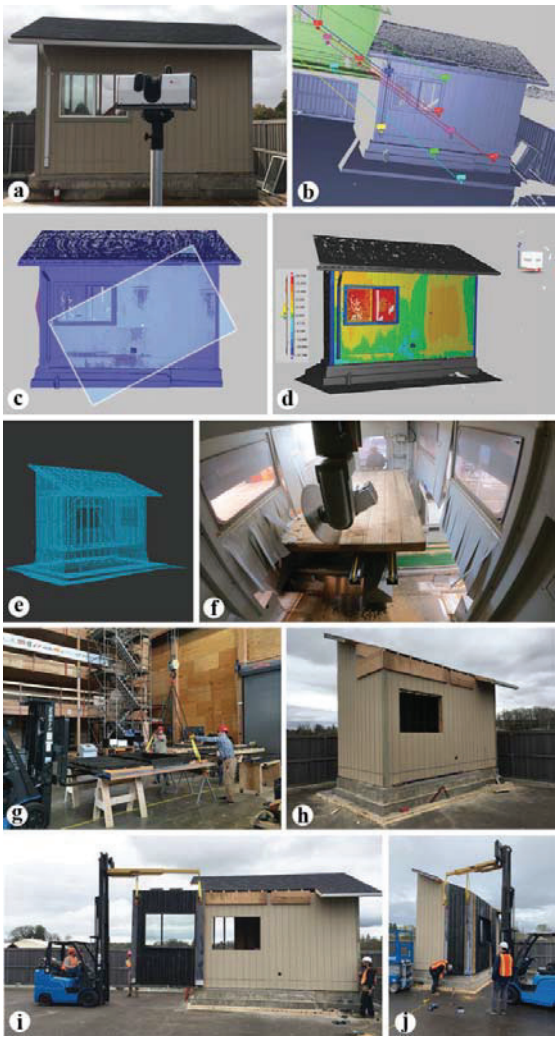

Figure 3: *Process for facade energy + seismic panelized retrofit: a) LiDAR scan existing building; b) process multiple scans into singular digital model; c) fit plane to wall surface; d) surface irregularity establishes tolerances; e) digital scan to Autodesk ReCap Pro; f) digital CNC fabrication of MPP structural core for facade panel assemblies; g) factory pre-assembly of facade panels with weather barriers, insulation, windows and cladding; h) site preparation including removing eave, trim, existing window and installation of MPP transfer joists at roof diaphragm; i) individual panels lifted into position on existing façade; j) panel connections completed at foundation beam and transfer joists. Panel-to-panel joints completed with elastomeric sealant, WRB, connector plates, insulation, and cladding.*

into Autodesk Revit 2022, in which we modelled the new facade. The façade models were exported from Revit and imported into DDX EasyWOOD for the generation of CNC toolpaths. CNC processing (Biesse Uniteam UT-9) of MPP occurred at TDI's Emmerson Laboratory at OSU (Figure 3f) along with the subsequent addition of weather barrier, window, flashing, insulation, and cladding (Figure 3g).

https://doi.org/10.52202/069179-0141

Finally, we tested prefabricated panels for ease of installation. On-site work included the installation of a 52 mm MPP transfer joist at the roof diaphragm, removing the existing eave for ease of installation, then gutter, downspout, trim, dryer vent, and existing window (Figure 3h). Once the existing condition was prepared, we flew panels into position, beginning with the infill window panel to align the window with a framed rough opening (Figure 3i) and continued with the seismic shear panels at the corner and panel-to-panel location with approximately 6 mm tolerance between panels. After completing all structural connections, we closed the joints with sealant, weather barrier, in-plane panel-to-panel plates, insulation, and cladding (Figure 3j). Lastly, we installed the roof blocking, sheathing, shingles, and the foundation rigid insulation with cementitious board over the newly installed seismic connections.

3 RESULTS

The main structural components of the system include an upgraded foundation system using a new 102 mm concrete beam and footing bonded to the existing stem wall and footing using epoxy rods. Wall panels consist of a rocking shear wall panel that resists panel flexural and shear forces, two hold-downs connected to an upgraded concrete foundation, resisting design forces induced by rocking of the wall either in tension (T) or compression (C), and a shear plate that transfers the horizontal base shear (V_b) between the wall and the concrete foundation. Forces between the shear wall panels are transferred to steel plates through fasteners (screws). Forces between the steel plates and the concrete foundation are transferred by the concrete shear anchor bolts (Figure 4b). At floor levels, shear wall panels are connected to the MPP transfer joist via eight fasteners at each edge of the panel, transferring diaphragm forces between the building and the shear wall (Figure 4a). Infill wall panels are connected to the MPP transfer joist via slotted steel plate connections (not shown in the figure).

The MPP walls selected for the two-story case study building are 1.22 m in width, 6.10 m in height, and 78 mm thick. The design of the shear wall panel followed existing standards, including ASCE 41-17 [19] and ASCE 7-16 [20], and consisted of determining (1) the tributary seismic weight to be resisted by the shear wall panel, (2) the seismic base shear, (3) forces and verification of the design of the main elements of the wall lateral force resisting system, (4) a drift analysis, and (5) capacity-based design of elements that are designed to remain essentially elastic. For a total base shear of 7.88 kN, tension and compression forces equalling 36.61 kN are generated at the base of the wall. Further description of the structural analysis of the system, and details on connections are described in the structural retrofit paper of the project [21].

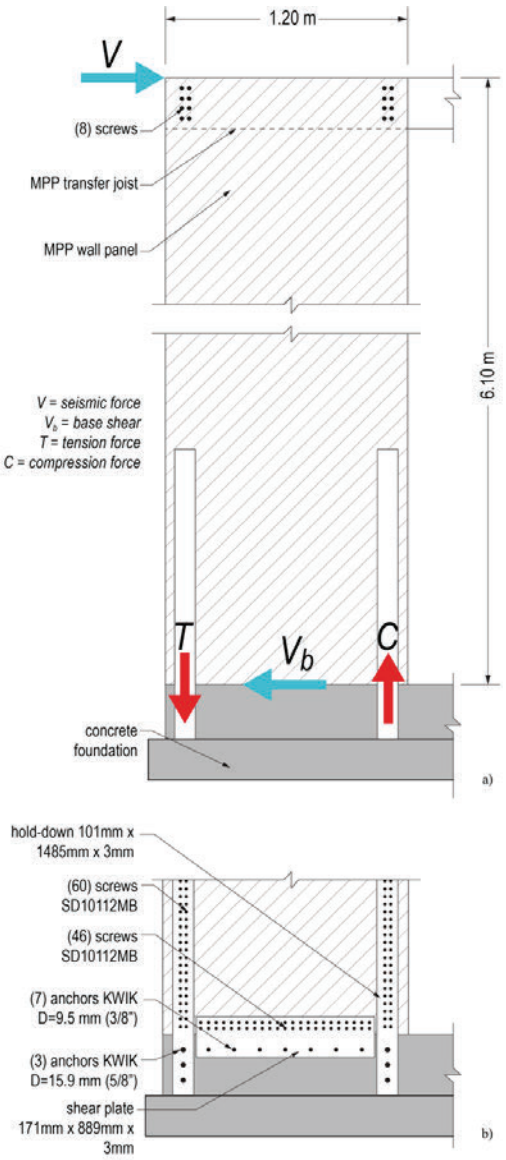

Figure 4: *a) Panel dimensions and reaction forces for connection design, b) foundation connection design*

Due to the MPP structural core, the panel system is designed to accept a wide range of outboard insulation levels, thus, a wide range of energy performance possibilities for a given climate. The existing case study wall assembly included (from inside to outside) 13 mm gypsum board, 89 mm stud frame with fiberglass batt insulation, and 13 mm T1-11 plywood siding for an insulation value of RSI-2.5. The retrofit system developed for the case study included (from inside to outside) 60 mm Steico flex wood batt insulation, 78 mm MPP, 60 mm Steico special dry board insulation, Soprema VP Sopraseal weather barrier, 19 mm ventilated cavity and 16

https://doi.org/10.52202/069179-0141

mm T1-11 plywood siding for an insulation value of RSI-3.1 (Figures 5-7). The combined system (existing condition and retrofit assembly) insulation value exceeded code in Portland, Oregon for a wall insulation value of RSI-5.6.

4 DISCUSSION

4.1 CONSIDERATIONS FROM MOCK-UP

Several light detection and ranging (LiDAR) scanning technologies are commercially available with a wide range in both capability and cost. Of the three systems we tested for this project, we found the Artec Ray (Artec 3D, Senningerberg, Luxembourg) to provide a suitable solution for our intended use case. This three-dimensional scanner is intended for large objects and in our experience

captured high quality dimensionally accurate information of building facades. In addition, the ease and sophistication of post-processing into one clean usable model and compatibility with other software required for panel design and fabrication was an important consideration in developing the digital workflow used in the project. The scan resolution allowed irregularities in the finish of the retrofit concrete foundation to even be translated to a cut file and milled into the bottom edge of the MPP for an exact fit when installed.

Figure 8: *Mock-up pre-retrofit (top image) and Mock-up post-retrofit (bottom image).*

Where deep overhangs from existing eaves impede retrofit façade panel installation, two methods are possible. Some *Energiesprong* projects in Europe have employed specialty lifting attachments for crane-assisted positioning of panels that keep the attachment clear of the eave while allowing the suspended panel to be placed flush against the existing wall. We chose the other method: removing the existing eave so retrofit panels can be placed by conventional lifting attachments (Figure 8).

Though the scope of the current project is limited to façade retrofit only, it is reasonable to assume that if a building were to undergo such a retrofit the roof may also be considered for an upgrade. In this case, a parallel chord roof truss may be selected to span the existing roof while adding space for additional roof insulation and transferring the added load to the perimeter walls where façade retrofit panels can be designed to accommodate this. In this whole building retrofit scenario, the removal of existing eaves would be advantageous for more than just ease of placing retrofit wall panels.

Figure 9: *Reflected view of installed seismic retrofit panel.*

In rigging the panels for lifting and installation two Dragon lifting belts (Rothoblaas, Cortaccia, Italy) were used suspended from a boom (Figure 3i). This method required 35mm through-holes to be drilled through the MPP panel. The method was successful from an installation perspective, with the lifting belts easily retrievable and reusable once the panels were secured. However, the two holes are large envelope penetrations that must be properly sealed in the field as part of completing the panel-to-panel joints. An alternative approach to rigging attachments that eliminates these through holes would be desirable as a future installation refinement to avoid any possibility of these penetrations being missed or improperly finished.

https://doi.org/10.52202/069179-0141

Some elements of façade panel assemblies are best accomplished with panels oriented flat. For example, bonding wood fibre insulation to the MPP prior to CNC milling of the composite panel was piloted and proved a successful means of reducing the overall fabrication labour. The panels not only need to be rotated in the factory for fabrication, but also for transportation, and again while being lifted into place. The panel stiffness, factoring in window openings and added weight from the built-up façade assembly, must be sufficient to allow for panel rotation in any configuration. Panel flex is also undesirable for machining operations. If the panel must be stiffened or attached to a spoil board to be accurately cut, this will add time and in turn cost.

One important consideration concerning the positioning of steel seismic connectors on each panel is that some of each connector must be left exposed for attachment to the building and to adjacent panels during installation. The plates must then be covered as part of the process of sealing and finishing panel-to-panel joints once attached to the building. Limiting the size and location of these areas to be finished in the field reduces installation time and complexity. It also should be part of a cohesive design strategy focused on how panels and seams are conceived to work visually with the overall completed façade aesthetic. Seismic connectors were intended to be limited to exposed vertical edges of each panel (Figure 9), with field-installed vertical siding elements used to conceal panel-to-panel joints on the completed façade. However, the seismic connection to the foundation is best accomplished with the inclusion of a horizontal steel plate at the base of the MPP panel (Figure 4b). This area, if left exposed for installation, needs future consideration for how it will be detailed to be incorporated into the overall façade design.

4.2 FUTURE RESEARCH DIRECTION

We are now planning to construct and test a three-story prototype fabricated and installed by a commercial contractor to test the validity of design, scanning techniques, fabrication and construction methods, and cost models resulting from the initial prototype construction. Construction-ready documents will be made publicly available and given the potential market for these retrofits, a significant market increase for mass timber products is anticipated.

Along with this project, the team is exploring mass timber façade retrofits for energy and seismic resilience in low-rise commercial buildings. Other future related research may include designs for a prefabricated MPP roof retrofit with insulation and integrated photovoltaics.

5 CONCLUSIONS

This project produced a physical demonstration mock-up of a seismic/energy panelised retrofit, utilizing MPP as the structural core, with performance upgrades to meet U.S. Department of Energy Zero Energy Ready Home (ZERH) Standard [22] and current seismic code, that is capable of initially being rolled out across U.S. West Coast markets and beyond. The desired result is to use the innovative design solution produced by UO/OSU as a demonstration and cost model for industry adoption, including manufacturers, developers, and contractors.

Figure 10: *Visualization of case study multifamily building using the façade retrofit system developed.*

We recognize that each retrofit project will need this prototype design adapted for each existing building. In particular, the seismic design will vary depending on the existing conditions in the building, including its size and shape. Some buildings may need additional structural interventions across floors to connect to exterior walls and these will have to be designed to cause minimal interior disruption. However, using scans of existing buildings, translated into digital files for fabrication and panel assembly in a factory setting, we believe that the custom solutions can be more efficiently accomplished than with each project constructed on-site. With the substantial need for upgrading this existing stock of housing for energy and seismic resilience, this solution can have a significant impact on lowering carbon emissions and extending the useful life of much-needed existing housing.

ACKNOWLEDGEMENT

We would like to acknowledge Phillip Mann, technical director of the Emmerson Lab, for his assistance in CNC file preparation, milling, panel construction, and installation, and Mark Gerig, lab technician at Emmerson Lab, for his assistance with panel construction and installation. We would also like to acknowledge Carly Loving, MS graduate student at Oregon State University, for her assistance with the Leica BLK360 scans. This work was generously supported by a U.S. Forest Service Wood Innovation Grant #2020-DG-11062765-737 and by the TallWood Design Institute. This work was further supported by generous donations from HawkRidge Systems, who donated equipment, software, time, and support using the Artec Ray scanner; New Energy Works, who donated Steico wood fibre board insulation; Bensonwood, who donated wood fibre batt insulation, Simpson Strong-Tie, who donated mechanical fasteners and Soprema, who donated Sopraseal Stick VP weather barrier.

EMISSION OF VOLATILE ORGANIC COMPOUNDS FROM WOOD MATERIALS AND IMPACT ON INDOOR AIR QUALITY

Ingrid Bakke[1], Anders Nyrud[2], Roland Kallenborn[3], Lina Aarsbog[4]

ABSTRACT: The main purpose of this study was to investigate the emission of volatile organic compounds (VOCs) during construction of a cross-laminated timber (CLT) building. Bjølstad student housing complex was built in 2020, with a main frame of Norway Spruce (*Picea abies)* CLT. Emission concentrations of six selected VOCs (hexanal, α-pinene, camphene, β-myrcene, β-pinene and 3-carene) were measured during the nine last weeks of construction, in dormitories with different loading rates of visible CLT. All VOCs were detected above limits of quantification, although 3-carene and β-pinene were detected above the linear ranges in some samples. The variation and trends in VOC emission indicated considerable sources in addition to CLT. None of the measured VOC concentrations exceeded the recommended LCI values.

KEYWORDS: VOC, Engineered Wood, Indoor Air Quality, Human Health, Environmental Impact

1 INTRODUCTION

Outdoor air pollution has long been a topic of concern while indoor air pollution has been paid too little attention, especially considering the higher concentration of air pollutants indoors and the fact that most people spend 90% of their time in indoor spaces [1]. With energy efficient building designs comes airtight buildings and accumulation of pollutants in the indoor environment. To guarantee sustainable building designs both regarding low carbon footprint and good occupant health it is important to consider sources and sinks of air pollutants to the indoor environment. Volatile organic compounds (VOC) make up a main group of indoor air pollutants and are of high concern as some VOCs are considered leading causes of SBS (Sick-Building-Syndrome) and other negative health effects from air pollution. VOCs can originate from multiple sources, such as outdoor air, cleaning agents, personal hygiene products, paint, wood furniture and building materials. The relative impacts of these sources on indoor air quality differ greatly, but in most cases outdoor air dilutes the polluted indoor air.

Cross-laminated timber (CLT) has good thermal and mechanical properties and is easily cut to preferred dimensions. In addition to wood being more sustainable material than other building materials such as concrete or plaster, the quick assembly, prefabrication, and lighter weight of CLT often makes it more beneficial alternative for construction. The solid wood surface of CLT introduces a buffer capacity with the surrounding environment, establishing an equilibrium of physiochemical properties between the wood surface and ambient air. This buffering property can impact the long-term emission of VOCs and it is hypothesized that low-emitting wood surfaces adsorb VOCs from highly polluted air [2].

Previous studies have shown that different wood building materials have different emission concentrations of VOCs and indicate that untreated wood surfaces lead to high emissions compared to coated wood [3]. In addition, the profile of VOC emission from solid wood surfaces differs from that of other building materials and of glued or surface treated wood materials. Coniferous wood surfaces emit mostly terpenes such as mono-, di- and sesquiterpenes followed by aldehydes such as hexanal and pentanal. These biogenic VOCs occur naturally in green vegetation, while anthropogenic sources of VOCs include petrochemical refinement, burning of fuels and manufacturing and use of consumer products [1]. Engineered wood building materials may emit VOCs originating from anthropogenic activity and may pose a different environmental impact on the indoor air. Liu et al. (2020) found that the largest contributor to VOC emissions from particle board was 1,2-dichloropropane, which is most likely not a compound found naturally in wood as it is halogenated [4]. It is classified as hazardous to human health and there are indications that it might be a carcinogen. Liu et al. (2020) found in total 11 hazardous air pollutants emitted from wood-based panels and found that approximately 50% of the total VOC was aldehydes,

https://doi.org/10.52202/069179-0142

while less than 40% was terpenes. This difference in VOC emission profile between solid wood and highly processed wood products is largely due to the physiochemical conditions wood chips are subjected to during production [1, 5].

Previous studies have found that emission of VOCs from wood construction products decrease over time after installation. The European Standard 16516 limits the measuring period to 28 days, indicating that the VOC emissions will have stabilized 28 days after production or processing of the wood surface [6]. As VOC emissions are highest right after installation it is relevant to measure the VOC emissions during construction of a wood building, to maximize the indoor air concentrations and regard the associated risk. Usage and surface planing of wood construction materials influence the subsequent VOC emissions strongly as creating a new surface gives rise to a new source of VOC emission. As wood surfaces are in equilibrium with ambient air temperature, relative humidity along with other physiochemical parameters also impact VOC emissions [7, 8].

High exposure of VOCs in a short period of time is associated with negative health effects such as SBS [9]. SBS is allocated to buildings where symptoms like headache, irritation of nose, eyes and throat, nausea and asthma have been reported by building users without other probable cause [9, 5]. One study showed an increase in eye dryness and xylene metabolite in urine for test subjects exposed to new buildings containing high levels of VOCs [10]. A Swedish study showed an increase in prevalence of asthma and inflammatory symptoms in airways related to exposure to newly painted surfaces [11]. In the Swedish study, the VOC levels increased by 100 $\mu g/m^3$ in the newly painted dwellings compared to prior to painting. High exposure to VOCs over a long period of time is associated with more adverse health effects like damage to liver, kidney, and carcinogenic effects [1, 9].

On the other hand, recent studies have reported health benefits from exposure to solid wood surfaces and to VOCs emitted from wood [12]. Grote et al. found that test subjects sleeping in beds of *Pinus cembra* solid wood had improved cardio-respiratory interactions, decreased heart rate, and increased vagal activity compared to sleeping in chipboard beds [12]. Another study showed that wood odor such as α-pinene had a positive psychophysiological effect on test subjects [13]. The VOCs emitted from wood products are what give rise to the characteristic pleasant smell of wood, and Dematté et al. (2018) found that a higher level of comfort was induced in wooden rooms compared to plaster rooms [14]. There are indications that monoterpenes such as α-pinene and limonene may decrease heart rate and have anti-inflammatory effects [15]. Skulberg et al. (2019) investigated the respiratory health effects and neuropsychological performance of participants exposed to fresh Scots pine (*Pinus sylvestris*) and aged Norway spruce (*Picea abies)* as a control. The study was double-blinded and randomized, and they found no significant difference in physical health or test performance between the spruce control room and the pine room with much higher VOC concentrations [16]. The perception of wood surfaces is closely interrelated to the psychophysiological effects of wood. Alapieti et al. (2022) reported a positive perception of indoor air quality in wooden rooms. VOC concentrations and perceived air quality (percentage of people dissatisfied) was measured in pine and gypsum board rooms [17]. At low ventilation rates the gypsum board room had lower satisfaction rates than pine room, though the pine room had higher VOC concentrations. Although indoor air quality perception and psychophysiological effects are connected, factors such as culture and background influence consumer's perception of wood building materials [18]. Interestingly, Matsubara et al. (2018) reported that women were affected by the presence of wood in indoor environments to a higher degree than men [19]. In a study where an environment with VOCs from Japanese cedar (mainly sesquiterpenes such as δ-cadinene) was compared to a control environment, women experienced a suppression of α-amylase in saliva in the cedar room and an increase of cortisol in the control room. It was also noted that men experienced a similar suppression of the nervous system at higher VOC concentrations rom cedar, indicating that the relaxation effects from wood VOCs such as δ-cadinene occur at lower concentrations for women than for men [20].

Several European certificates for building materials have now included criteria for VOC emissions in their evaluation. There are over ten different voluntary classification schemes from various European countries, which all include a limit value for TVOC and a weighted evaluation of the health risk of each VOC present, called the R-value. This R-value is based on substance-specific Lowest Concentrations of Interest (LCI), derived by the European Commission [21]. LCI values are based on toxicological data of VOCs from 12 different compound groups.

2 METHODS

Measurement of VOC concentration in indoor air was performed following the Norwegian standard NS-EN 16516:2017+A1 [6]. The student housing at Bjølstad had a supporting structure in Norway Spruce (*Picea abies*) CLT, and all indoor ceiling in addition to some walls was left visible. After inspection of the site, two dorm rooms were chosen as sampling locations. One room had visible CLT in the ceiling (H0310d of 10.8m^2) and the other in one wall and ceiling (H0311d of 9.4m^2).

2.1 SAMPLE COLLECTION BJØLSTAD

Air samples were collected from the construction site between 24.06.2020 to 11.08.2020. At this point the floor was cast, and plaster walls were painted. Samples were collected on conditioned sorbent tubes with 300mg Tenax

https://doi.org/10.52202/069179-0142

TA using handheld SKC pumps. Each sample was collected by pumping approximately 16L of air at a flowrate of 250mL/min. A total of 36 samples were collected on site: two samples from each dorm room for each of the nine weeks of sampling. Blank samples were collected by opening sorbent tubes at the sampling location without starting the pumps. Sorbent tubes were kept in the freezer before subsequent analysis on TD-GC-MS. Temperature and relative humidity sensors were placed in the common area outside dorm rooms, registering the temperature and relative humidity four times a day from 05.05.2020 to 10.07.2020.

2.2 MEASUREMENT OF VOC CONCENTRATIONS

Chemical analysis was performed at NMBU, using an Agilent 7890B GC coupled to a 7000C QQQMS and a Perkin Elmer ATD-400 injector [22]. The sorbent tubes were desorbed for 30min at 250°C and transferred to the GC by a heated deactivated silica transfer line. The GC was equipped with an HP-VOC column (60m, 0.2mm, 1.1µm) and the flow rate was set to 1mL/min. The temperature program was started at 50°C, heated to 150°C at a rate of 5°C/min before heating to 290°C at 50°C/min and holding for 10min. The MS was operated in EI mode (70eV), the source temperature and the quadrupole temperature were set to 200°C. Agilent MassHunter Quantitative Analysis B.07.00 was utilized for method evaluation and quantification of analytes. Concentration, *C*, of an analyse, *i*, in the sampled air, was calculated by equation (1).

$$C_i = \frac{m_i}{V_i} - \frac{m_b}{V_b} \quad (1)$$

Where m = mass, V = air volume and b = blank. The R-value for evaluation of risk of negative health effect is shown in equation (2).

$$R = \sum \frac{C_i}{LCI_i} \quad (2)$$

Where *C* = concentration of compound *i*, *LCI* = Lowest Concentration of Interest of compound *i*.

3 RESULTS AND DISCUSSION

VOC concentration measurements in indoor environment in the student dormitories resulted in the detection of five terpenes and one aldehyde. The six individual VOCs were detected above the limit of quantification in all samples, although 3-carene was only semi-quantified as the concentrations exceeded the linear range in all but one sample. β-pinene concentrations exceeded the linear range in two samples. LOQ and linear range data is shown in Table 1. Average concentrations of the six VOCs during the sampling period 24.06.2020 to 11.08.2020 are shown in Figure 1. All six VOC concentration profiles followed similar trends in the dormitories, indicating common sources of the substances in both rooms, either placed inside the rooms or originating from a common outside source. The changes in VOC concentrations in the two rooms over time were similar. The VOC concentrations reached a maximum during week 6 and 7.

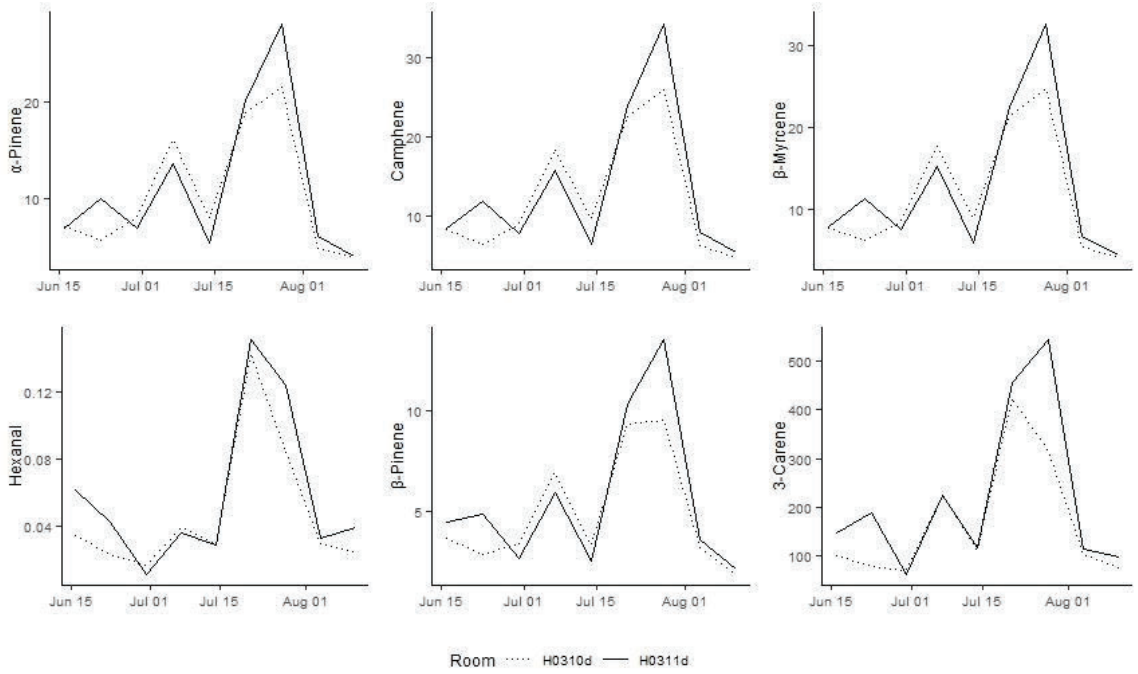

Figure 1. *VOC emission [µg/m3] measured during nine weeks of construction in room designed with visible cross-laminated timber in ceiling (H0310d) and in ceiling and wall (H0311d).*

https://doi.org/10.52202/069179-0142

Table 1. *Limits of quantification and linear range for the six target VOCs.*

	LOQ [µg/m^3]	Linear range [µg/m^3] (min – max)
Hexanal	$2.2 \cdot 10^{-4}$	0.00063 – 0.19
α-Pinene	$1.4 \cdot 10^{-1}$	0.031 – 63
Camphene	$2.2 \cdot 10^{-2}$	0.063 – 63
β-myrcene	$4.3 \cdot 10^{-2}$	0.31 – 63
β-Pinene	$6.4 \cdot 10^{-3}$	0.013 – 63
3-Carene	$1.5 \cdot 10^{-2}$	0.031 – 63

As VOC emission from wood surfaces has shown to decrease over time in a handful of published work emissions from CLT would be expected to decrease after time of installation at the Bjølstad site as well. VOC concentrations measured at the construction site were therefore presumed to come from additional sources.

The concentrations of individual VOCs differed greatly; hexane emitting at the lowest concentration and 3-carene at the highest for all samples. High concentrations of terpenes and low of the aldehyde hexanal coincides with the previously reported emission profile of spruce wood [23]. However, the concentration of 3-carene was almost tenfold that reported from spruce heartwood by Czajka et al. (2020) [24].

The VOC concentration in the room with a larger surface area of CLT (CW) were slightly higher than in the room with less wood surface (C) in week 2 and after week 5. However, during weeks 3-5 VOC concentrations were slightly higher in the room with less visible CLT, indicating a source of VOCs other than the spruce wood and adhesive in CLT. As the room with visible CLT in wall and ceiling was smaller it had a considerably higher loading rate of solid spruce surface, approximately 0.95m^2/m^3 in room H0310d, compared to 0.45m^2/m^3 CLT in room H0311d.

As the VOC concentrations varied greatly during the sampling period the construction site activities were registered in Table 2.

Table 2. *Overview of visits to construction site, including purpose (I=inspection, TRH=placing (1) and removing (2) of sensors for temperature and RH measurement, S=sampling) and description of construction site activity.*

Date	Purpose	Construction site progress
29.04	I	Visible CLT in floor, ceiling, and selected walls
06.05	TRH1	Preparation for casting of floors
16.06	S (W1)	Floor casting done. Wardrobe and kitchen cabinets
23.06	S (W2)	Shelf and bathroom doors
30.06	S (W3)	Closet doors and more kitchen furniture
07.07	S (W4)	-
10.07	TRH2	-
14.07	S (W5)	Plate tops in kitchen
21.07	S (W6)	Curtains and sofas
28.07	S (W7)	Desk and office chair
04.08	S (W8)	Table, chairs and wood wool ceiling in common area, beds in rooms
11.08	S (W9)	-

During the weeks of maximum VOC concentrations, week 6 (21.07) and 7 (28.07), the rooms were furnished with curtains, desks and office chairs, and sofas were placed in the common area. To assess the additional VOC emission from these changes at the construction site, the textiles and pieces of furniture must be tested for their individual VOC emissions separately.

Besides the introduction of furniture and appliances at the construction site, factors such as human activities, use of cleaning agents and rate of ventilation shortly before collection of air samples most likely has an impact on the subsequent VOC concentration in the rooms.

3.1 HEALTH IMPACT OF MEASURED VOCS

When evaluating the health impact of VOCs in indoor environments it is imperative to regard effects from individual volatile compounds. According to Salthammer et al. (2022) total VOC (TVOC) concentration cannot be used as an indicator of health in an indoor air study [25]. TVOC concentrations are not always comparable as there is inconsistency in the four methods for measuring TVOC specified in the indoor air standard ISO 16000-6. Additionally, the additive dose approach used when evaluating mixed effects of VOCs with their respective LCI values does not account for cocktail effects and different modes of action of the volatile compounds. Lastly, the LCI values established by the European Commission are mostly based on safety data sheets and animal studies which are not always transferrable to human toxicology. In this study, individual LCI values were compared to the maximum concentrations of individual VOCs, as shown in Table 3.

Table 3. *Maximum VOC concentrations and LCI values.*

	Maximum conc. [µg/m^3]	LCI [µg/m^3] [a]
Hexanal	0.17	900
α-pinene	32	2500
Camphene	39	1400
β-myrcene	37	1400
β-pinene	15	1400
3-carene	622	1500

[a] LCI values from the European Commission [21].

All individual VOC concentrations were below recommended LCI values, indicating no risk related to occupying the building during the last weeks of construction. The R-value for the VOC concentration at the student housing was 0.49. In most voluntary classification schemes the criteria for VOC concentration is an R-value less than or equal to 1. However, as 3-Carene was only semi-quantified and detected in high

https://doi.org/10.52202/069179-0142

concentrations, further measurements are recommended to confirm concentrations were below LCI for this compound.

4 CONCLUSIONS

The results from VOC measurements at Bjølstad showed indications of VOC sources in addition to the spruce CLT surfaces. Concentration profiles with regard to chemical species, loading rates and increase in concentration over time was not characteristic for spaces where spruce is the main source of VOCs. To assess this issue a chamber test of the spruce CLT is necessary. A more comprehensive approach to better map the VOC profile at Bjølstad student housing may also be beneficial. However, all individual VOC concentrations were detected below LCI values, and no health risk was associated with the investigated VOC levels in the student housing. Source appointment of VOC emission in a wooden indoor environment is a difficult task as both natural and anthropogenic sources are present at all times and testing uncertainties for available methods are high. More knowledge of the toxicity of characteristic VOC emission from spruce is needed to ensure safe use of building materials such as CLT in the future.

ACKNOWLEDGEMENT

This study was supported by grants from the Norwegian University of Life Sciences, Skogtiltaksfondet and Innovation Norway. Sample collection and analysis of air samples from the construction site in Bjølstad, Fredrikstad was conducted by Lina Aarsbog.

COMBINED EFFECTS OF VISUAL AND OLFACTORY STIMULATION BY INTRODUCING WOOD WHILE WORKING OR RESTING

Takashi Shima[1], Katsuhiko Sakata[2], Motoki Yairi[3], Daisuke Fujii[4], Haruki Momose[5], Yuko Tsunetsugu[6]

ABSTRACT: This study aimed to investigate the impact of visual and olfactory stimulation related to wood on subjective evaluation indices by incorporating wooden interiors and wood scents in simulations of real-life work and rest scenarios. We conducted subjective evaluations while participants performed tasks on a computer or rested to assess the combined effects of visual and olfactory stimulation. The working and resting rooms were either covered with wooden material or concrete-looking wallpaper, and the scent of Hinoki cypress (*Chamaecyparis obtusa*) was introduced into some of the rooms. The results of the experiment suggest that the introduction of both the Hinoki scent and wooden panels may enhance the olfactory impression during work and weaken it during rest, but the visual impression remains unchanged. Additionally, the results of the mood states suggest that the combined introduction of visual and olfactory stimulation from wood may improve mood state during work and rest. The results of the subjective fatigue also suggest that individual stimuli can affect subjective feelings of fatigue, and the Hinoki cypress scent may have potential in reducing various forms of fatigue. Overall, the results indicate that the combined visual and olfactory stimulation from wood may affect individuals differently depending on their activities.

1 INTRODUCTION

An increasing number of companies have been prioritizing environmentally friendly practices, including the development of eco-friendly materials and space design. The demand for low-carbon, CO2-emitting wooden structures has increased as companies aim to become more carbon neutral, which has enhanced the value of wooden spaces. Furthermore, wooden spaces may potentially have a stress-relieving effect on people.

Lowering stress is of great significance in contemporary society. In Japan, a significant portion of employees are reported to endure high stress levels in their jobs and daily life. A space that fosters a strong connection to nature can serve as an effective setting for individuals to recuperate from stress [1].

The suitability of wood as a material for stress relief is being explored in various studies [2]. These studies focus on examining the comfort provided by spaces that utilize wood and the stress-reducing effects of the material.

While many studies have explored the visual and olfactory effects of wood [3-4], most have centered around a single stimulus, and few have investigated the combined effect of both the visual and olfactory elements. To effectively utilize wooden stimuli in the workplace, the psychophysiological effects of incorporating wood and utilizing wooden spaces (e.g., for work and rest) need to be understood more comprehensively.

In this study, we aim to examine the impact of both visual and olfactory stimulation related to wood by incorporating wooden interiors and wood scents into simulations of real-life work and rest scenarios. The findings of this study are focused on the effects of the combined stimulation on subjective evaluation indices.

2 MATERIALS AND METHODS

2.1 PARTICIPANTS

Twelve adults (three men and three women in their 30s, and three men and three women in their 40s) were recruited for this study. All participants were confirmed to not have a habit of smoking. In addition, they did not have any symptoms of nasal inflammation or consume alcohol the day prior. This study was performed in accordance with the regulations of the Ethics Committee of Kajima Technical Research Institute.

2.2 STUDY PROTOCOL

In this experiment, the ambient conditions in the rooms were maintained at 23–26 °C and 40–60% relative humidity. The illuminance near the participant's head was

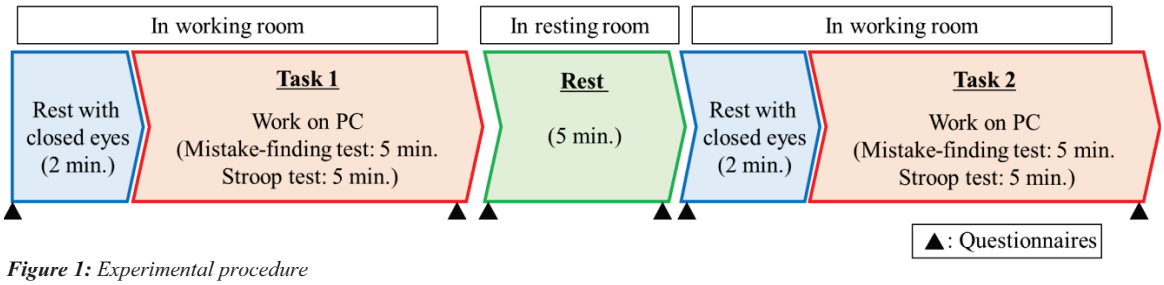

Figure 1: *Experimental procedure*

maintained at about 500 lx. The overall experimental procedure is illustrated in *Figure 1*. The experiments were conducted every other day for seven days. On the day of the experiment, each participant entered the room to work on a PC. The participants were instructed to close their eyes for 2 min and then start working on the PC (Task 1). After working for 10 min, each participant left the room and entered the resting room, where they rested for 5 min (Rest) before returning to the working room. The participants were again instructed to close their eyes for 2 min and work on the PC for 10 min (Task 2).

The experimental conditions are listed in *Table 1*. Except for Condition I, either or both the visual stimulation by the wooden room and/or the scent of Hinoki cypress were introduced in the experiment.

Table 1: *Experimental conditions*
(words in red indicate introduction of wooden stimulation)

Conditions	Working room stimulation		Rest room stimulation	
	visual	olfactory	visual	olfactory
Ⅰ: N-N	Concrete	None	Concrete	None
Ⅱ:W-N_Work	Wooden	None	Concrete	None
Ⅲ: N-H_Work	Concrete	Hinoki	Concrete	None
Ⅳ: W-H_Work	Wooden	Hinoki	Concrete	None
Ⅴ:W-N_Rest	Concrete	None	Wooden	None
Ⅵ:N-H_Rest	Concrete	None	Concrete	Hinoki
Ⅶ: W-H_Rest	Concrete	None	Wooden	Hinoki

2.3 VISUAL STIMULATION

Two rooms of 10 square meters each were set up and furnished with wooden (walnut) paneling and concrete-style wallpapers on the ceilings and walls, as illustrated in *Figure 2*. To enhance the illusion of open space behind the walls, photos of the company's training center were affixed to the front and right sides of the rooms. The training center was designed with a wood-like texture, and in the room with concrete wallpaper, a grayscale version of the same photo was used.

2.4 OLFACTORY STIMULATION

The scent of Hinoki cypress (*Chamaecyparis obtusa*) was introduced into either one or none of the rooms using an aroma diffuser (Tree of Life Co., LTD; *Figure 2*). For the wood condition, 1 ml of Hinoki essential oil was mixed with 10 ml of water, and water (without essential oil) was used in the control conditions. The concentration of the mixture was determined through a preliminary experiment conducted on 12 individuals in their 20s, separate from the main experiment. The participants performed 10 deep breaths in the room where the scent of Hinoki cypress was generated, then responded to a subsequent survey on the odor intensity. The concentration that fell between the average range of "weak odor" to "easily noticeable odor" was used. The composition of the odor was analyzed by collecting air at nose level and conducting gas chromatography. When introducing the scent of Hinoki cypress, we confirmed that the concentration of the main aromatic component, α-pinene, did not exceed the concentration described in previous papers as "slightly unpleasant".

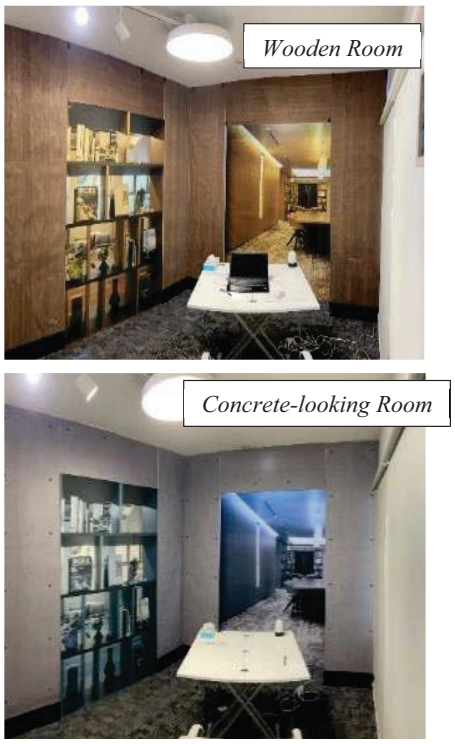

Figure 2: *Experiment rooms covered with sliced walnut veneer (wooden room) (top) and concrete-patterned wallpaper (concrete-looking room) (bottom)*

https://doi.org/10.52202/069179-0143

2.5 PC TASKS

The study required the participants to perform two PC tasks. In the first 5 minutes, the participants were asked to compare two slips on a PC and identify a character that was different, which they entered using a keyboard. For the latter 5 minutes, a Stroop test was administered. Participants are presented with color names written in a color and it evaluates the phenomenon where naming the color takes longer when the color and the written word do not match compared to when they do match. The Stroop test is originally designed to assess selective attention [5], but in this study, it is introduced as a stress task. In this experiment, characters written in red, blue, yellow, and green were displayed every second. There were 16 possible combinations of colors and characters. Participants were required to read the characters as they were displayed and respond by pressing the corresponding key on a keyboard to match the character's color.

2.6 MEASUREMENT

Three questionnaires for subjective evaluation were administered before and after the participants entered the rooms. Subjective ratings were given on a 7-point scale to describe the effects of visual or olfactory impressions. The visual impression was evaluated using six items, which were "like-dislike," "familiar-unfamiliar," "settling-unsettling," "luxurious-simple," "spacious-small," and "natural-artificial." The olfactory impression was evaluated using six items, which are "good-bad," "like-dislike," "familiar-unfamiliar," "settling-unsettling," "luxurious-simple," and "mild-pungent."

The Japanese version of the Profile of Mood States 2nd Edition Short Form (POMS2; Kaneko Shobo Co., Tokyo, Japan [6]) was administered to assess negative mood states. The POMS2 evaluates the state of mood and emotion using seven scales: “anger-hostility,” “confusion-bewilderment,” “depression-dejection,” “fatigue-inertia,” “tension-anxiety,” “vigor-activity,” and “friendliness”. There are five questions for each scale, and each question is evaluated on a scale of 0 to 4, representing the individual's mood. The Total Mood Disturbance (TMD) score, indicating a comprehensive negative mood, is calculated by the scores of all scales except "friendliness."

The Jikaku-sho Shirabe (Industrial Fatigue Research Committee of Japan [7]) was utilized to measure subjective fatigue. This tool provides a subjective evaluation of fatigue on five scales, i.e., drowsiness, unsteadiness, discomfort, sluggishness, and haziness. Each dimension comprises five questions, to which the participant answered on a five-point scale from 1 to 5. By observing changes in scores over time, the extent of the participants’ fatigue complaints can be assessed.

2.7 STATISTICAL ANALYSIS

We conducted statistical tests between the conditions to determine the differences in impression scores after Task 1, after rest, and after Task 2. To verify the effects of visual stimulation alone and the combination of visual and olfactory stimulation, statistical tests were performed between conditions I, II, and IV after the tasks and between conditions I, V, and VII after rest for the visual impression items. To determine the individual effects of olfactory stimulation and the combined effects of visual and olfactory stimulation, statistical tests were conducted between conditions I, III, and IV after Task 1 and between conditions I, VI, and VII after rest for the olfactory impression items.

Statistical tests were performed between each condition regarding the changes in scores of the Jikaku-sho Shirabe and POMS2 before and after Task 1, before and after rest, and before and after Task 2. To compare the effects of individual and combined stimulation, the changes in scores before and after tasks were compared between conditions I, II, III, and IV, and those before and after rest were compared between conditions I, V, VI, and VII.

The differences between the conditions were tested using the Wilcoxon signed-rank sum test (Bonferroni correction) (SPSS 28.0.1.1, IBM). The significance in difference was set at 5%.

3 RESULTS AND DISCUSSION

3.1 IMPRESSION EVALUATION

The visual impression scores after the tasks and rest are shown in *Figure 3*. After Task 1, the impression scores of settling-unsettling were significantly higher in both conditions II (introduced only wooden panels) and IV (introduced both wooden panels and the scent of Hinoki cypress) than in condition I (nothing introduced). The scores of luxurious-simple were significantly higher in condition II (p<0.05) than in condition I. After rest, the scores of like-dislike significantly increased in condition VII (introduced both wooden panels and the scent of Hinoki cypress) compared to condition I (p<0.05). After Task 2, the scores for the impression of luxurious-modest significantly increased compared to condition I in both conditions II and IV (p<0.05).

The olfactory impression scores after tasks and rest are shown in *Figure 4*. After Task 1, the scores of like-dislike and luxurious-simple were significantly higher compared to condition I in both conditions III (introduced only the scent of Hinoki cypress) and IV, and the scores of good-bad were significantly higher compared to condition I in condition IV (p<0.05). After rest, the impression score of luxurious-simple was significantly higher compared to condition I in both conditions III and IV, and the scores of good-bad, like-dislike and familiar-unfamiliar were significantly higher compared to condition I in condition III (p<0.05). After Task 2, the scores of good-bad, like-dislike, settling-unsettling, and luxurious-simple were significantly higher in both conditions VI (introduced only the scent of Hinoki cypress) and VII than in condition I (p<0.05).

The results of this experiment showed that the visual impression after the tasks and after rest did not differ. On the other hand, the assessment of olfactory impression

showed that during tasks, most items tended to be higher when both stimulations were introduced compared to when only olfactory stimulation was introduced, whereas during rest, the condition in which only olfactory stimulation was introduced showed a significant improvement over the control condition.
The results of this study suggest that the introduction of both the scent of Hinoki cypress and wooden interior did not alter the visual impression but led to an improvement in the olfactory impression during work, while the olfactory impression may have weakened during rest. This implies that the combined stimulation of the wooden material and scent may have an impact on the perception of the space.

3.2 MOOD STATES

The changes in the mood state scores before and after the tasks and rest are shown in *Figure 5*. The changes in scores on the anger-hostility, confusion-bewilderment, fatigue-inertia, and TMD scales depicted in *Figures 3-5* showed significant differences between the conditions. The change in scores of anger-hostility was larger in condition I (nothing introduced) than in condition IV and VII (introduced both wooden panels and the scent of Hinoki cypress) during both Task 1 and rest, with a significant increase during Task 1 and a significant decrease during rest (p<0.05). The change in confusion-bewilderment scores was significantly smaller for condition II (introduced only wooden panels) compared to condition I during Task 1 (p<0.05), while during rest, condition VII showed a larger decrease than condition V (introduced only wooden panels) (p<0.05). During Task 2, condition IV as found to have a smaller increase compared to condition I (p<0.05). The change in scores of fatigue-inertia was significantly smaller for condition II compared to condition I during Task 2 (p<0.05). The change in TMD scores was significantly smaller for condition IV compared to condition I during Task 2 (p<0.05). No significant differences were observed in the changes in the depression-dejection, tension-anxiety, and vigor-activity scores between conditions.
In many evaluation scales of POMS2, introducing visual or olfactory stimulation, or both, has been observed to improve mood states during both work and rest. Additionally, the improvement in mood states was significantly higher only in the confusion-bewilderment scale when both visual and olfactory stimulation were introduced compared to when only visual stimulation was introduced. No significant differences were observed between the conditions of introducing only olfactory stimulation and introducing both stimulation in all scales. However, significant differences were observed between the conditions where both visual and olfactory stimulation

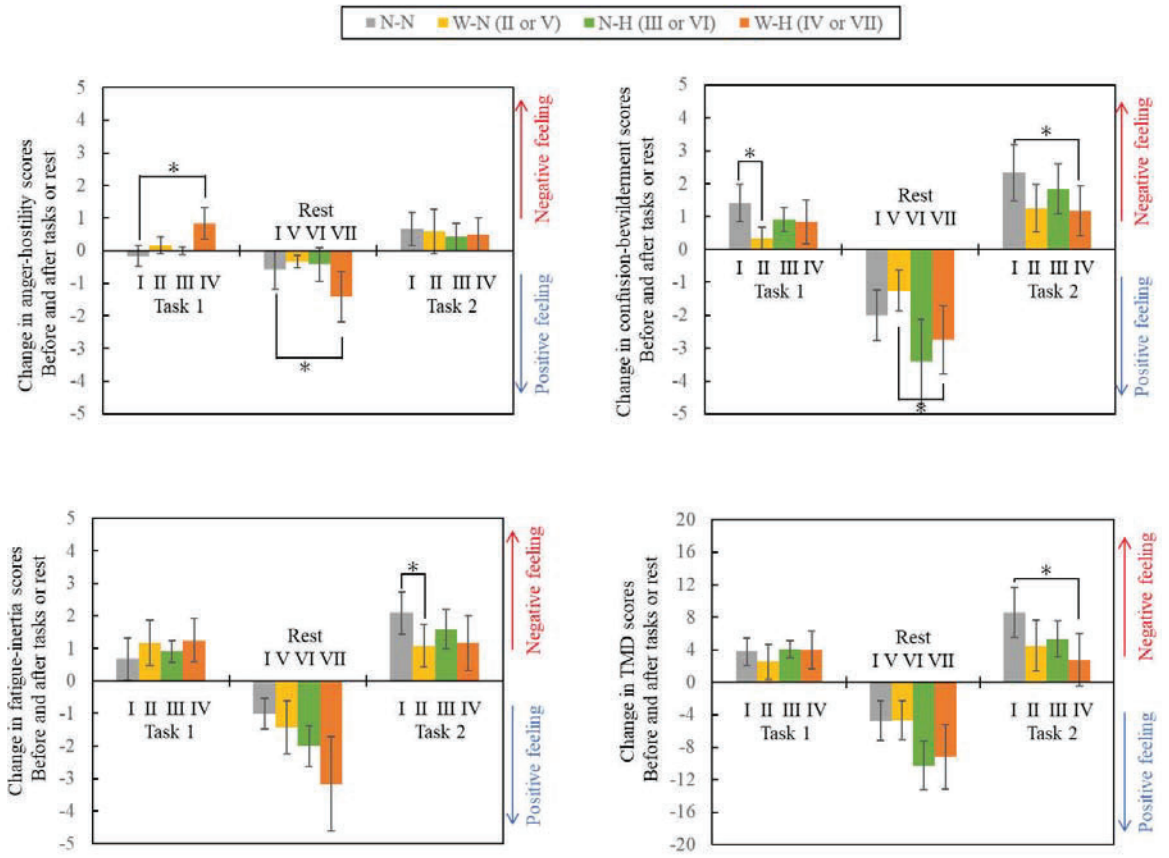

Figure 5: *Changes in mood state scores ("anger-hostility," "confusion-bewilderment," "fatigue-inertia," and TMD) before and after tasks and rest with different olfactory conditions as mean ± S.E. (n=12).*
** $p<0.05$, Wilcoxon signed-rank sum test (Bonferroni correction)*

were introduced and the control conditions on many scales, indicating the potential to enhance stress relief during work and rest by incorporating both visual and olfactory stimulation of wood in the office space.

3.3 SUBJECTIVE FATIGUE

The changes in the subjective fatigue scores (from the Jikaku-sho Shirabe) before and after tasks and rest are shown in *Figure 6.* The changes in drowsiness, discomfort, and haziness scores depicted in *Figures 3-5* showed significant differences between conditions. The change in drowsiness scores was found to be significantly larger for condition III (introduced only the scent of Hinoki cypress) compared to condition II (introduced only wooden panels) during Task 1 ($p<0.05$). The discomfort scores significantly decreased more in condition III than in condition I (introduced nothing) during rest ($p<0.05$). Condition VI (introduced both wooden panels and the scent of Hinoki cypress) showed a larger decrease than condition V (introduced only wooden panels) ($p<0.05$). The haziness scores showed significantly less change compared to condition I during Task 2 in conditions II and III. No significant differences were observed in the score changes of unsteadiness and sluggishness between the conditions.

In the Jikaku-sho Shirabe, the scale of discomfort showed a reduction in fatigue during rest in the condition where the scent of Hinoki cypress was introduced compared to when nothing was introduced. The scale of haziness indicated that fatigue from the task was relieved in the condition where visual or olfactory stimulation was introduced. On the other hand, during Task 1, the increase in drowsiness after Task 1 was greater in the condition where the scent of Hinoki cypress was introduced than when the wooden panels was introduced. While the results might seem conflicting when considering subjective fatigue as a whole, drowsiness can occur as a feeling state even during relaxation. Therefore, this result aligns with previous research [4] and demonstrates the relaxing effects of the scent of Hinoki cypress.

The combined effects of both olfactory and visual stimulation were not observed in this measurement. The subjective fatigue was affected by the individual stimulus,

and the potential for reducing various types of fatigue was particularly evident when the scent of Hinoki cypress was introduced.

4 CONCLUSION

The aim of this study was to examine the combined effects of olfactory and visual stimulation derived from wood materials. We conducted a subjective experiment where participants performed tasks and rested in a space containing wood panels and the scent of Hinoki cypress. The results of the experiment suggest that when both the Hinoki scent and wooden panels were introduced, the visual impression did not change, but the olfactory impression may improve during work and weaken during rest. The results of the POMS2 also suggested that the combined introduction of visual and olfactory stimulation from wood into the space may further improve mood state during work and rest. The results of the Jikaku-sho Shirabe suggest that individual stimuli can impact subjective feelings of fatigue, and the introduction of Hinoki cypress scent shows potential in reducing various forms of fatigue. The results suggest that the combined visual and olfactory stimulation from wood may affect individuals in different ways, depending on the activities in which they are engaged.

WOOD INTERIORS IN ARCHITECTURE: AN EYE-TRACKING STUDY

Pasi Aalto[1], Martin Steinert[2]

ABSTRACT: In this architecture study, we examine the gaze patterns of participants (n=20) when presented with a selection of images featuring building materials (concrete, stone, brick, wood and painted wood) and interiors (church, lobby and work area with high, medium and low levels of wood use). We utilize eye-tracking to quantify the fixations, saccades, blinks, and pupil dilations within the participants gaze pattern. This gaze pattern is then compared to the participants perception of naturalness and pleasantness. We show that naturalness and pleasantness strongly positively correlate with each other, and that material choice plays a role in the participants perception of these values. Gaze patterns do not clearly correlate with naturalness nor pleasantness, although we report indications that pupil diameter, blink count and saccade amplitude should be investigated further in separate experiments.

KEYWORDS: Eye-tracking, Architecture, Wood, Materials, Cognition

1 INTRODUCTION

First discovered in the 1970's [1] by examining the views from hospital patients windows, a significant body of research has been developed to better quantify and understand the positive effects of nature on building users [2], [3]. More recently, the use of wood has become more prevalent in the Nordic building industry due to its cultural acceptance, low emissions, and increased availability. This has also spurred research interest into the health effects of wood use on the habitants of buildings [4]–[7] that seem to suggest that multiple positive effects are achievable through thoughtful use of building materials. At the same time, more research is needed to better understand and quantify the effects.

1.1 RESEARCH QUESTIONS

In this study, we examine the relationship between gaze patterns and participant perception of naturalness and pleasantness. We hypothesise that and strive to answer the following research questions:

RQ1: Is there a correlation between naturalness and pleasantness?
RQ2: Is there a correlation between wood use and perceived naturalness and pleasantness?
RQ3: Do different building materials have a different gaze response?
RQ4: Is there a correlation between a gaze response and the perception of naturalness and pleasantness?

2 THEORY

Quantifying the perception and impact of architecture has gained more research interest in the recent years [2]. Two central aspects of this development have been the validity and usability of different quantifying methods as well as connecting the research to an existing body of research in environmental well-being.

2.1 EYE-TRACKING

The use of eye-tracking (ET) is an effective method to determine the gaze pattern of a person, which mainly consists of rapid movements with intermittent stops. Fixations are instances where the gaze dwells on a specific area, such as a flower or an oncoming car. Fixations vary in length but are generally in the 80-300ms range and indicate where the participants cognitive system engages with the visual stimuli. The opposite, a saccade, is a rapid eye-movement between fixations where the participant is not consciously registering what the eyes are looking at [8]. In Video Oculography (VOG) – based eye-tracking [9], a video recording of the eyes, when calibrated, analysed and correlated with a synchronized video of the world view in front of the participant allows for a relatively easy analysis of gaze patterns at both individual level and in a group, even with idiosyncratic differences between the participants.

Several measurements are available from current ET devices. Reduced saccade amplitude can indicate during increased mental effort, inspection, or high-frequency visual information. Alternatively, saccadic velocity decreases with low vigilance. Pupil dilation increases with arousal and mental workload. Long fixation durations indicate low arousal and shorter fixations can indicate stress responses. For a more thorough discussion on measures, see Holmqvist et al., part III [8]. Additionally, more complex relations are being investigated, such as the correlation between participants preferences and their gaze patterns [10].

2.2 NATURE, WOOD USE AND HEALTH

Previous ET research into architectural material use is inconclusive, and it is difficult to examine the validity and generality of using ET to examine materials in architecture. The general correlation between pupil dilation and emotional reactions has been observed when looking at architectural interiors [11] and also linked to preference to stay [12]. When comparing natural environments to urban settings, [13] and in interiors [14], fewer but longer fixations were observed. Contrastingly, fixation time was found to be independent of vegetation when looking at indoor workplace design and the amount of vegetation in front of the participant [14]. Also material choice might be a factor as average fixation duration has been shown to differ between stone and mixed material facades, as well as experts and non-experts [15].

Wood materials exhibit positive effects similar to nature [4], are preferred by participants [7] and generally considered natural materials [16]. Eye-tracking studies of wood interiors has so far received little interest in research, although there are indicators that wood exhibits a similar gaze pattern as nature [17] and affect staying durations [12].

3 METHOD

This experiment is a within-subjects laboratory experiment using gaze pattern and survey answers as data.

3.1 STIMULI

The experiment used 2 sets of stimuli. For the 5 most common architectural materials in the Nordics (concrete, stone, brick, untreated and painted wood), 5 images of each were selected to cover the innate variation in the use of the material in a building context. This also provided an extra control to examine variations within material groups and to compare this to results between groups. Additionally, two images were baseline photographs, one of plants (i.e., purely nature stimuli) and another of a graphical plate with multiple overlays of texts (i.e., high visual density stimuli). The total amount of images in the first set of stimuli was 27. An example of material stimuli is seen in Figure 1.

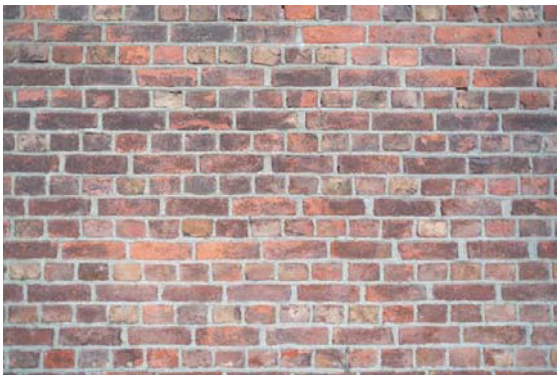

Figure 1: *Example image of a material stimuli, brick-3.*

Material images were taken with a Nikon D750 digital SLR with a 20mm f2,8 Nikon AF Nikkor lens. Both camera and lens were optically clean. The images were taken from a distance of 1.2 - 1.4 meters with suitable exposure settings to avoid clipped highlights or movement artefacts.

The second set of stimuli consists of 17 interior images showing 5 images each of 3 distinct spaces: church/sacral, lobby and an informal learning space in academia. Each group has 1 stimulus with high level of wood use, 2 with medium levels and 2 with low levels or no wood use at all. In addition, 2 baseline images were included, a nature image displaying a beautiful waterfall as well as a high visual density stimuli image of a city scape in Trondheim, Norway.

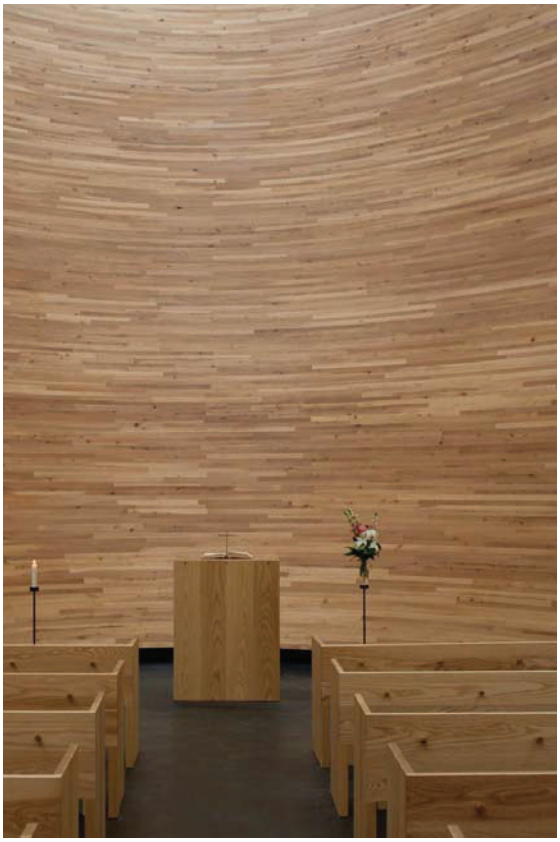

Figure 2: *Example image of a interior stimuli, church-2, exhibiting high level of wood use.*

The interior images were taken with either a Nikon D750 or D700 digital SLR with a 20mm f2,8 Nikon AF Nikkor or 17-35 f2,8 Nikon AF-S Nikkor lens. Both camera and lens were optically kept clean and suitable exposure settings were used to avoid clipped highlights or movement artefacts.

Each image was edited in Adobe Lightroom with a profile-based correction to chromatic aberration as well as

https://doi.org/10.52202/069179-0144

distortion and vignetting. The images were manually corrected for residual distortion, vertical and horizontal parallel lines as well as image rotation. The exposure, contrast, texture, and clarity were adjusted to ensure an even lightness and tonality across images, as well as a natural look. Finally, the images were cropped to the same format, 3:2 landscape for the material images and 3:2 portrait for the interior images.

3.2 PARTICIPANTS

This study included 20 healthy participants of which 8 were female. The participants had either perfect eyesight or their eyesight was corrected with contact lenses. The average age of the participants was 23,5 years (SD=4,49). 3 participants had an educational background focused on buildings. Four of the participants were left-handed.

3.3 PRESENTATION

The participants were welcomed to the experiment space where they receive a short formal introduction to the study and give consent. Eligibility to the study is confirmed. The participants are fitted with a Pupil Labs Core [18] mobile binocular eye-tracking glasses recording 120 Hz video with 192x192 pixels of each eye. In addition, a 1280 x 720 world cam at 30 Hz is recorded. The participants view stimuli shown on a 27" Dell ultrasharp U2719DC screen with 1920 x 1200 pixels at 60 Hz. Each participant underwent a calibration and verification procedure to ensure accuracy of the recorded data (0.5 - 1.5 degrees from eye-tracker, corresponding to approx. 7-25mm accuracy on screen with 80 cm viewing distance). All images and survey are displayed using PsychoPy stimuli presentation software [19] linked with Pupil Capture through dynamic link. For each ET capture, Apriltag36_11 QR codes were present in the corners of the screen to allow surface tracking of the screen as seen in Figure 1.

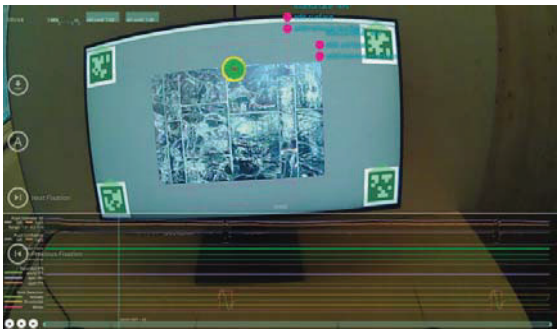

Figure 3: *Experiment setup from Pupil Player as seen by the participant world camera, showing Apriltag36_11 QR codes around stone-1 image. On screen is also pupil dilation, confidence, and blink data, while fixations are shown with a yellow circle around the gaze point when active.*

After setup, each participant is first presented with the 27 material images in randomized order. Each image is displayed for 10 seconds with a 2 second pause between images showing a re-focusing cross in the middle of the screen. The images were 1076 x 690 pixels, giving an on-screen size of 21 x 14 cm in landscape format. This approach leaves ample grey background area on screen to minimize luminosity changes from the stimuli, as this might affect pupil dilation. The stimuli size corresponds to approximately 10 x 15 degrees eye movement when viewed from 80 cm away.

In the second part, the participant reviews the re-randomized images one at a time and ranks them with 2 sliders, unnatural (0) – natural (10) and unpleasant (0) – pleasant (10), verified by an OK button.

In the third part, the participant similarly first views the interior images, followed by the fourth and final part where they assess the interiors with the same sliders. Before each part, the participant is given clear instructions on screen as to the next part of the experiment.

3.4 RESPONSE DATA ANALYSIS

Participants evaluation of the naturalness and pleasantness of each stimulus is recorded in PsychoPy as a value of 0-10. The sliders are by default valued as 5 (middle) and if the participant does not move the slider but clicks OK, this number is used in the analysis.

3.5 ET DATA EXTRACTION AND STRUCTURING

For each participant, 33 trials were captured, consisting of one video for each eye and one world view video per trial. Pupil Player was used to analyse each trial. The first analysis included fixation detection using 1,5-degree movement threshold and 100-500ms as duration, both on stimuli surface as well as during the entire trial. Secondly, gaze positions and pupil dilation were extracted. Finally, a blink detection analysis was performed to count the number and duration of blinks in each trial.

Exported data from Pupil Player and PsychoPy was structured into folders per participant and a custom Python script was developed to extract, structure, and output a joint CSV that included all trials for all participants. The data was structured by case, where each row represented a single stimulus, viewed by a single participant. For each case, the dataset included averages over the entire viewing duration of a given stimuli by the given participant. The structured data included average saccade amplitude and velocity, blink count and duration, average and total fixation duration, and count for both surfaces and in total, average pupil dilation for both eyes as well as participant responses and the order the stimulus was presented.

3.6 ET DATA ANALYSIS

SPSS (Version 29) was used for the statistical analysis. To explore the relationship between variables, partial correlation was used while controlling for the presentation order of the stimuli. To assess outliers and anomalies,

SPSS' Identify unusual cases-function was used and the identified data checked to ensure correct representation.

4 RESULTS

The data quality of the experiment was assessed to be good. All participants responded to the survey. During material and interior trials, 93% and 90% of fixations were within the presented stimuli boundaries, respectively. This indicates that the participants were actively engaging in the task.

4.1 CORRELATION BETWEEN NATURALNESS AND PLEASANTNESS

To explore the relationship between naturalness and pleasantness responses from the participants, two-tailed partial correlation was used while controlling for the presentation order of the stimuli. Statistical assumptions of normality and linearity were assessed.

When looking at material images (n=27), there is a strong, significant partial correlation between perceived naturalness and pleasantness when controlling for stimuli order, $r = .513$, $n = 540$, $p < .001$, where high levels of naturalness are associated with high levels for perceived pleasantness.

This partial correlation also held true when looking at interior images with an equally strong correlation, $r = .547$, $n = 340$, $p < .001$, indicating that naturalness and pleasantness are strongly positively related.

4.2 WOOD USE, NATURALNESS AND PLEASANTESS

A one-way ANOVA was conducted to examine the effect of material use on naturalness and pleasantness. During the first trial presenting only groups of materials, a statistically significant result was found for both naturalness, $F (6, 533) = 32.758$, $p < .001$, and pleasantness, $F (6, 533) = 15.574$, $p < .001$. A post-hoc Tukey test indicated distinct, homogenous subsets in the groupwise comparison for both naturalness and pleasantness as presented in Tables 1 and 2. However, when investigating the responses for each stimuli using a Tukey test, the results show that images within each group can be assessed very differently, although similarities exist within groups as well. To exemplify, concrete scored poorly in groupwise naturalness and pleasantness while the individual images of concrete also were among the bottom 6 in naturalness and bottom 7 in pleasantness, together with the graphic stimuli. Contrastingly, the wood-5 stimuli, showing OSB is ranked 10th in unnaturalness and 4th in unpleasantness, while wood-4, showing a worn, slightly damp, pressure treated wood cladding, was ranked second only to nature in pleasantness and 4th most natural stimuli.

Table 1: *Homogenous groups based on groupwise Tukey analysis on means of naturalness scores from 0 (unnatural) to 10 (natural).*

Wood Paint	100			5.6	
Stone	100			5.7	
Nature	20				9.6

An ANOVA looking at the wood-use in interiors revealed similar results. First, groupwise analysis between high, medium, and low wood use, as well as a nature image and an image of Trondheim city was conducted. Naturalness, $F (4, 335) = 15.691$, $p < .001$, and pleasantness, $F (4, 335) = 9.148$, $p < .001$, both showed significant differences between the groups. A post-hoc Tukey test showed that in both cases, the nature image was distinctly both more natural and more pleasant than the other images. In pleasantness, all other images showed the same grouping regardless of wood use, while in naturalness, both low and medium wood use scored lower than high wood use. An alternative grouping of the space functions (lobby, church, and work area) was conducted to compare results. This yielded similar results for both naturalness, $F (4, 335) = 22.323$, $p < .001$, and pleasantness, $F (4, 335) = 18.956$, $p < .001$, with work areas and lobbies scoring less than churches and the city, while nature again was the most natural and pleasant choice. Finally, the images were analysed individually using a Tukey test to see whether the defined groups were coherent as evaluated by the participants. In both naturalness and pleasantness, spatial functions and wood-use groupings showed variation within the groups.

4.3 GAZE RESPONSES

The participants gaze responses were examined using a one-way ANOVA, followed by a post-hoc Tukey test if the significance was nearing $p < .05$.

https://doi.org/10.52202/069179-0144

4.3.1 Material trials

The ANOVA test showed no significant differences ($p < .05$) between gaze responses between the material groups, nor the individual stimulus, apart from the pupil dilation of eye 1 ($F\ 6, 553) = 2.232$, $p < .039$ for groupwise analysis, $F\ (26, 513) = 1.493$, $p < .057$ for individual stimulus analysis. When examining the Tukey post hoc test, the most significant difference was found to be between nature and concrete groups. Contrastingly, the dilation of eye 0 differed widely, $F\ (6, 553) = .659$, $p < .683$ for groupwise analysis, $F\ (26, 513) = .644$, $p < 0.914$ for individual stimulus analysis but this eye was considered more uncertain due to a single participant having a miscalculated 3d gaze parameter resulting in a very small pupil diameter.

4.3.2 Interior trials

Three ANOVA tests were conducted to examine gaze variables in interior images. The factors considered were the level of wood use (no significances $p < .05$), the spaces function (no significances $p < .05$) and individual images (no significances $p < .05$). However, a 2-tailed partial correlation test showed a weak negative correlation between blink count and naturalness, $r = -.153$, $n = 340$, $p = .005$, as well as a weak negative correlation between saccade amplitude and naturalness, $r = -.098$, $n = 340$, $p = .071$.

5 DISCUSSION

The aim of this study was to examine possible relationships between perceived naturalness, pleasantness, and gaze patterns in an explorative manner.

5.1 NATURALNESS, PLEASANTNESS AND WOOD

The participants show a strong positive correlation between perceived naturalness and pleasantness. The most consistently perceived stimulus, regardless of the stimulus set, are the 2 images of nature. When viewing material surfaces, a picture of chaotic graphic is clearly perceived as both unnatural and unpleasant, while an image of the city is more ambiguous as a baseline when compared to interiors.

A significant finding is the variation within material groups. While concrete surfaces were perceived as uniformly unnatural and unpleasant, wood surfaces varied to a larger degree. This internal variation should be expressly addressed in future experiments by selecting multiple stimuli within each material group. This affects both the validity and generality of the experiment as variation within groups can be better understood and the results be discussed in relation to practical everyday utilisation of building materials.

5.2 GAZE PATTERN, NATURALNESS AND PLEASANTNESS

The relationship between gaze patterns, naturalness and pleasantness is inconclusive. The study cannot confirm the relationship between saccade amplitude, blinks, pupil dilation and the survey responses, nor can we outright reject them. More advanced analysis might be needed to discover relationships between the variables. We have however identified some patterns that could help design better experiments in the future. Firstly, the viewing behaviour between purely material stimuli and interiors varies. Pupil dilation was found to be significant in viewing materials but not to the degree that it could differentiate multiple material groups. For interiors, blinks seem significant, as well as saccade amplitude. Secondly, variations within material groups needs to be accounted for. Thirdly, comparisons across studies will be essential to build systematic knowledge over time. Reporting threshold values, dispersion factors and specific analyses performed will speed development.

5.3 LIMITATIONS

Our approach has several limitations. Firstly, it was designed to explore potential gaze patterns rather than targeting a single measurement. The experimental setup for some of these measurements are contrary. To exhibit large saccade movements when searching, a bigger stimulus should be used. At the same time, pupil dilation will be affected as the size of the stimuli on screen increases to the grey background.

While a balance between trial length and the number of stimuli was necessary in this study, increasing the amount of images in fewer material categories would increase generality and validity of the results.

Finally, increasing the number of participants will provide a sounder base for statistical analysis that might uncover more nuanced results.

6 CONCLUSIONS

In this study, we performed a controlled within-subjects ($n=20$) laboratory experiment using gaze pattern and survey answers as data. We used 2 sets of stimuli, consisting of materials ($n = 27$) and interiors ($n = 17$). Our results show a strong positive correlation between naturalness and pleasantness when viewing images of both materials and interiors. We also demonstrated a that material groups score differently on naturalness and pleasantness, although variation within material groups exists.

We cannot confirm differences in gaze patterns between different building materials, nor a correlation between gaze response and naturalness or pleasantness. However, indications of pupil dilation, blink counts and saccade amplitudes being affected by materials were found.

7 ADDENDUM

7.1 AVAILABILITY OF MATERIALS

We support the replication and verification of experiments. The used images, data, PsychoPy files and Python scripts, as well detailed analysis files are available upon request.

7.2 CONFLICT OF INTEREST AND FUNDING

The authors declare no conflict of interest. This study was in its entirety funded by the Norwegian University of Science and Technology, NTNU.

CROSS-LAMINATED WOOD PANELS IN A PATIENT ROOM AND STUDIES OF INTERIOR ENVIRONMENT

Bror Sundkvist [1], Olena Myronycheva [1], Sarka Langer[2], Ingrid Liljelind[3], , Bo Glas[3], Tomas Nord[4], Björn Nordin[5]

ABSTRACT: Studies on the effect from biobased materials and products on humans have indicated positive effects. This has earlier been shown in studies for e.g. hospitals, where indications of lower stress and pain in patients with wood as part of interior solutions.

This paper describes the first step of a larger study that investigates the interior environment and the response of patients. The study presented here measured RH, temperature, emissions of volatile organic compounds (VOC) and microbial activities in two rooms at a hospital in Skellefteå, Orthopaedic ward. One room had a cross-laminated wood panel covering 42% of walls, window reveal and doors, and the other a control room with standard coverings.

Results indicated only a small difference between the rooms in terms of temperature and RH. VOC emissions varied in both rooms but all concentrations were lower or much lower than threshold values for interior air quality standard limits. Biological contamination of the surfaces and from air sampling was also performed.

Conclusions of this experimental study shows that from a regulatory perspective it is possible and safe to use wood as interior product.

KEYWORDS: wood, hospital environment, volatile organic compounds, ozone, microbial populations

1 INTRODUCTION

Studies on the effect of biobased materials and products on humans have indicated positive effects. What properties of wood as a material give these positive results? Do they come from what [1] showed as being natural (less strong medication to patients with a forest view compared with a "built" view), or what [2] measured as indications of lower stress and pain in patients with wood as part of interior solutions? Or is it from the anisotropic and hygroscopic properties affecting the interior air quality [3]. Hospital care is currently often performed in very sterile indoor environments with smooth painted walls and no components with natural materials. Applying a biophilic approach in places of recovery and recuperation has been considered as a means of improving recovery and reducing durations of stay. This was illustrated recently in a paper [4] that considered the contrasting effects of Sick Building Syndrome (SBS) and Building Related Illnesses (BRI) and a high Indoor Environmental Quality (IEQ). The use of wooden materials has been related to positive effects in terms of aesthetics, smell, air humidity and well-being [5].
The aim of this study is to investigate indoor air quality in two patient rooms in Skellefteå Hospital. One room (Room 4) is an ordinary patient room with painted concrete walls, while wooden wall panels have been installed in the other room (Room 5).

2 MATERIALS AND METHODS

2.1 SUB-CHAPTER TITLE

The measurements of indoor climate parameters temperature, relative humidity (RH) and concentration of carbon dioxide (CO_2) as well as concentrations of air pollutants nitrogen dioxide (NO_2), ozone (O_3), volatile organic compounds (VOCs) and aldehydes have been performed in the two rooms during one year. NO_2 and ozone were also measured in the outdoor air, and outdoor temperature and relative humidity were retrieved from SMHI:s measurement station at Skellefteå airport. Temperature, relative humidity and concentration of CO_2

[5] Björn Nordin, Swedish Wood, Sweden, bjorn.nordin@svenskttra.se

https://doi.org/10.52202/069179-0145

were measured with Wöhler CDL 210 CO_2-logger with a time resolution of 2 minutes. The chemical compounds were measured by passive/ diffusive samplers.

For measurements of NO_2 and ozone concentrations, IVL passive/ diffusive samplers were used [6]. These compounds were analysed by wet chemical techniques using a spectrophotometric method (NO_2) and ion chromatography (O_3). The analytical procedures are accredited by the Swedish accreditation agency SWEDAC.

Volatile organic compounds were passively sampled on Tenax TA (Perkin-Elmer) adsorbent tubes and analysed in compliance with the standard ISO 16017-2 [7]. The Tenax tubes were thermally desorbed (Markes International, Unity 1 and Ultra) and analysed by gas chromatography/ mass spectrometry (GC/MS) in electron impact ionization mode. The sum of individual VOCs in a sample (TVOC, Total Volatile Organic Compounds) was quantified in toluene equivalent, *i.e.* using the uptake rate and the response factor of toluene.

Formaldehyde was measured using passive samplers – DSD-DNPH Aldehyde Diffusive sampling Device (Supelco, Bellefonte,PA). The sampling period and the analytical technique (solvent extraction and high-performance liquid chromatography) followed the ISO 16000-4 standard [8].

The estimation of the water amount in dry air was done by using Mollier-Diagram [9].

Enumeration of the moulds in indoor and outdoor air was done by SS-ISO 16000-17:2008 [10]. The data represents the number of colony-forming units (CFU) of fungi or bacteria per sample. The malt-extract agar, potato-dextrose agar, dichloran 18% glycerol agar (DG18 agar) and nutrient broth agar were used as culture media. The plates were checked regularly for up to 7 days. The temperatures 25°C and 37° were used for the incubation. Calculations of the results were based on the colony count of the agar where the best growth occurs. The results are presented in colony-forming units per cubic meter.
The sampling from the walls and other surfaces was done according to ISO 16000-21:2013(E) [11] by sterile cotton swabs cultured on malt extract agar nutrient media. Incubation was done at 25°C.
The Adenosine Tri-Phosphate ATP bioluminescence was used to rapidly evaluate material surface cleanness [12]. The method is based on the correlation of biological residuals with the light generated during the reaction with luciferin/luciferase enzyme and measured by a luminometer 3M Clean-Trace™ Luminometer, St. Paul Minnesota, USA. The general acceptance for the cleanness is below 20 RLUs or Relative Light Units.
The sampling locations for swabbing and ATP measurement were:
- left and right dry walls of the left window
- left and right dry walls of the right window
- left and right walls of the room ca. 1.5 m from the floor
- left and right sides of the ceiling about 1 m from the ventilation channel
- nearby the ventilation channel
- doors of the patient lockers

The sampling periods are summarized in Table 1.

Table 1: *Sampling periods*

3 RESULTS AND DISCUSSION

3.1 INDOOR CLIMATE PARAMETERS

The values of temperature (Figure 1) were within the range of 20–24 ◦C defined by the EN 16798 standard [13] and by the Swedish regulations [14,15] during the whole period of measurements for one year. The values of relative humidity (Figure 2) were within the range defined by the EN 16798–1:2019 standard (25–60% RH) only during the non-heating season. During the heating season, the RH was <20%.

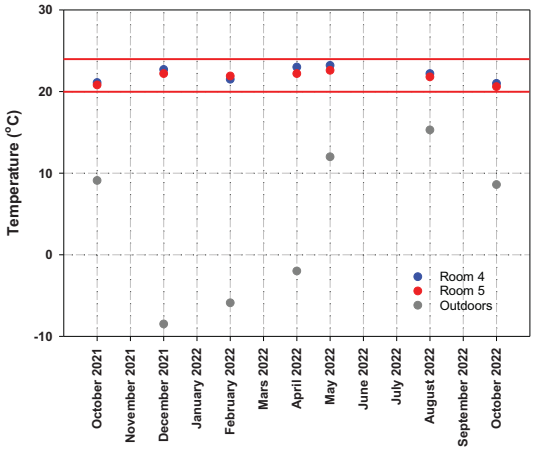

Figure 1*. The temperature in the studied rooms and in outdoor air. The full red lines indicate the range of comfortable indoor air temperature stated in standards.*

https://doi.org/10.52202/069179-0145

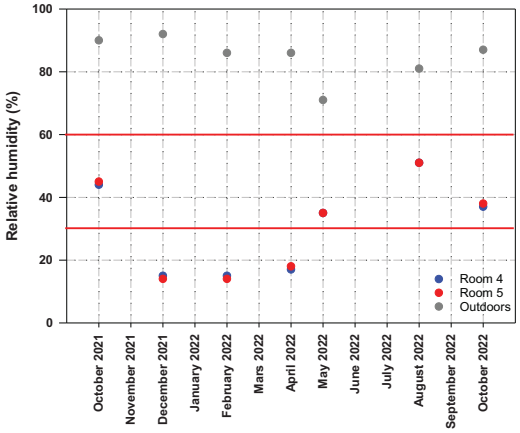

Figure 2. *Relative humidity in the studied rooms and in outdoor air. The red line indicates the range of comfortable indoor air relative humidity stated in standard.*

3.2 INDOOR AIR POLLUTANTS

The TVOC concentrations (Figure 3) were below the recommended long-term guideline value of 300 µg/m^3 in both rooms [16]. The TVOC concentrations did not differed significantly between the two rooms.

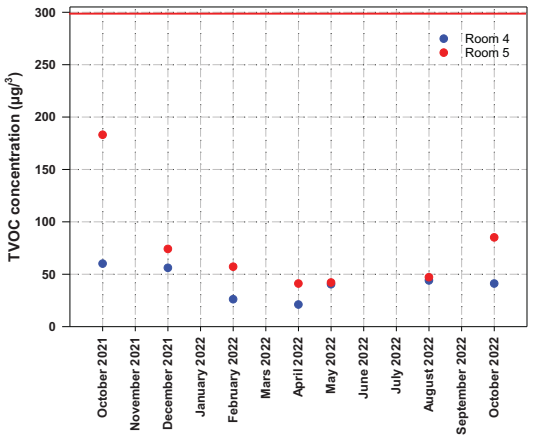

Figure 3. *Concentration of TVOC in the studied rooms. The red line indicates the recommended guideline value for TVOC of 300 µg/m^3.*

3.3 OUTDOOR/INDOOR WATER CONTENT IN DRY AIR

According to Swedish Public Health Agency's general advice on moisture and microorganisms "that the average value of the humidity should not exceeds 7 g water/kg dry air for a longer period during the heating season, which corresponds to approx. 45% relative humidity at 21° C" in a public building [17]. Such conditions might be favorable for microbial growth [19].

The evaluation of the climate was done to find the risk dates. The graph is presented in Figure 4.

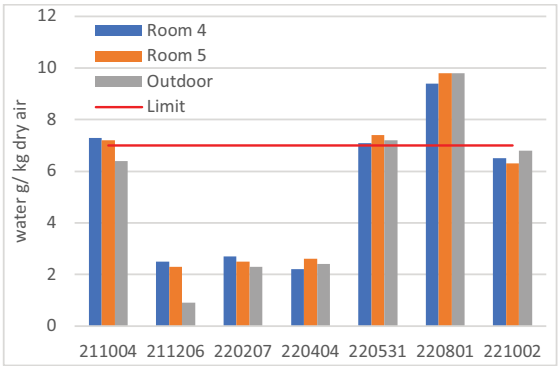

Figure 4. *The amount of water in g per 1 kg of dry air. The red line is a limit and parameters above are favourable for the microbial growth.*

3.4 INDOOR AIR MICROORGANISMS

The threshold limit values for biological contaminants such as microorganisms are difficult to define, and particularly for mould fungi the World Health Organisation (WHO) did not provide such values in their Indoor air quality guideline [18]. The threshold amount > 1000 CFU/m^3 in the whole mould is proposed as considered for dwellings at risk for allergic patients [19]. The total amount of microorganisms in the air of the sampling areas grown at 25°C and 37°C is presented in Figure 5 below.

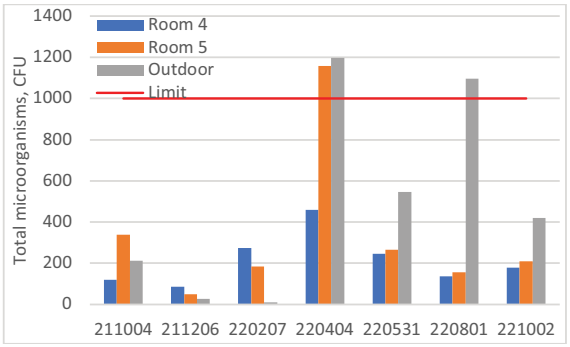

Figure 5. *Total amount of microorganisms CFU/m^3 grown at the temperature 25°C and 37°C. The red line shows the threshold value.*

The dominating effect of indoor/outdoor fungi is proposed for the determination of dominating effect of the microbial concentrations for the data interpretation [20]. The indoor: outdoor (I/O) concentration ratios related to the presence of indoor sources of microorganisms. I/O ratios are typically less than 1.0. However, if there is a strong microbial source indoors exists the ratio can exceed 1.0. Table 2 represents the ration of total microorganisms in the rooms for the sampling time.

https://doi.org/10.52202/069179-0145

Table 2. *The I/O concentration ratio for sampled time and locations in air samples of the microorganisms*

Day	I/O	
	Room 4	Room 5
211004	0.6	1.6
211206	3.3	1.9
220207	27.3	18.3
220404	0.4	0.9
220531	0.5	0.5
220801	0.1	0.1
221002	0.4	0.5

3.5 MICROBIOLOGICAL ASSESSMENT OF MATERIAL SURFACE

The ATP bioluminescence is applied essentially for hygiene status of the surfaces. It is an effective system to verify cleaning of surfaces from biological residues and microorganisms. The value below 20 RLU is considered moderate clean, when below 5 it is efficiently clean. Since the hospital environment is quite full of biological contaminations the value showed that surfaces are unclean. The distribution of the contaminated areas in the room showed in Figure 6.

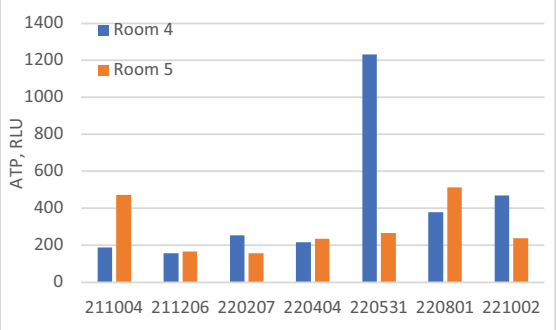

Figure 6. *The average value of ATP per room in RLU.*

The total amounts of the colony-forming units for fungal and bacterial microbial species are presented in Figure 7 and the number of fungi was much less than the amount of bacterial species on material surfaces.

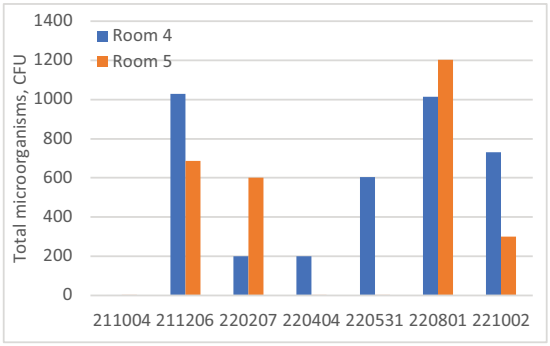

Figure 7. *Total amount of microorganisms CFU isolated from the material surface.*

4 CONCLUSIONS

The temperature was within the recommended comfort limits. The relative humidity was also within the recommended comfort limits with exception for the heating season (low RH) when the outdoor temperature was low.

The concentrations of all the TVOCs were low and below recommended guideline values and quite similar in both rooms.

The microbial contamination was low regarding generally suggested limits but influenced by indoor microbial source during heating season. The material surface was subjected to microbial contamination but mainly by bacterial isolates in both rooms.

From both the indoor climate and microbiological measurements, the values are within or well below limits for what standard regulations require for an acceptable indoor climate. Moreover, there was no or little difference between the rooms, this shows that it's possible to include biophilic design also in hospital environments.

These findings are a part of an ongoing study, and more results will be published, that involves clinical trials on patients and a survey for the staff of their perception of the rooms investigated. For the whole study at the hospital, we hope to gain new results and findings that clarifies the relation between indoor environments and human well-being.

ACKNOWLEDGEMENT

The research for this article was funded by Swedish Wood and EU regional funds. We would like to thank the persons involved from Skellefteå Hospital for their effort, support, and patience during difficult pandemic situations.

CIRCULAR WOOD CONSTRUCTION – EXPECTATIONS, EXPERIENCES AND ACCEPTANCE AMONG USERS, ARCHITECTS AND INDUSTRY REPRESENTATIVES

Kaja Heltorp[1], Ute Groba[2], Anders Q. Nyrud[3]

ABSTRACT: Circularity approaches aim at keeping resources "in loop" as long as possible, both resulting in a more efficient use of resources and in avoiding waste production. A prolonged and repeated use of wood-based construction materials enhances their function as carbon sinks and as replacements of more harmful materials. Aiming to systematize circularity measures within the building sector, this paper proposes four different fields of ambition as consecutive focus areas during the life cycle of wooden building materials. The first one of these ambitions, prolonging a building's life span, depends not only on the construction's robustness and maintenance or the layout's adaptability, but also on the building's overall "lovability" and acceptance. This renders the user perspective an important part of understanding building performance and architectural quality. Based on interviews and focus groups from 2016 and 2017, insights have been gained about the experiences, expectations, preferences and values tied to wooden materials both among users and architects and how these impact the acceptance and choice of materials. Substantiated by new data collected in 2022 with architects and wood industry representatives, this paper discusses the expectations, experiences and acceptance of re-used and recycled wooden materials among different stakeholders, and how these may affect all four circularity ambitions. Results suggest that language, together with professional background, experience and responsibility inform the acceptance of re-used and recycled wood both in a short-term and in a long-term perspective; they need to be taken into account when aiming for advancing circular wood construction. The user adds an important perspective on circular wood construction that is not covered by industry representatives.

KEYWORDS: Circularity, reclaimed wood, engineered wood, wood construction, user perspective, qualitative research

1 INTRODUCTION

A circular economy (CE) signifies the continuous use of objects and materials. CE has been gaining increasing attention within the building sector. Circularity approaches aim at keeping resources "in loop" as long as possible (ideally forever, as formulated in "cradle-to-cradle"), both resulting in a more efficient use of resources and in avoiding waste production [1]. A maximised life span is not only highly important for the use of finite resources, but also enhances the ecological benefits of renewable resources. In the case of wood-based construction materials, a prolonged and repeated use increases their function as carbon sinks and the replacement of more harmful materials. It is, however, unlikely that a construction from virgin or pre-used wood will last forever. In order to avoid the dead end of cascading use scenarios in a landfill, wood's circular life involves its combustion or composting at some stage. A number of treatments for aesthetic reasons or to make wood more durable result in turning wood into hazardous waste. In order to establish a circular value chain, it is important to keep all use stage scenarios in mind from the outset when designing wooden architecture, and to avoid harmful treatments.

Aiming to systematize circularity measures within the building sector, this paper proposes four different fields of ambition as consecutive focus areas during the life cycle of wooden building materials.

The first aim ("Plan A") is to prolong a building's life span, which depends on its construction's robustness and its maintenance, the layout's adaptability, and its overall "lovability" and acceptance [2]. When a building nevertheless needs to be taken down at some point, the second focus is on re-using the building's components in the least processed way possible ("Plan B"). The third goal is to recycle the materials contained in building components that are not possible to re-use any longer ("Plan C"). In the fourth and last stage, building materials are composted for soil amendment or combusted to obtain energy, both of which are needed in the production of resources that feed into a new cycle ("Plan D").

In general, in this context, the main focus has been on physical and mechanical properties of materials, and the same is true for wooden materials, both virgin and re-used. However, also the materials' non-physical characteristics determine their life span, as they are part of how users experience and value materials, and partake in informing the users' acceptance of both virgin and re-used materials. The user's acceptance also influences the treatment and detailing of wooden materials, which then inform the material's further potential for circular use.

https://doi.org/10.52202/069179-0146

Circular wood construction can therefore not only rely on the physical and mechanical performance of materials, but must include experience and value based concepts. While the user perspective tends to be underrepresented in conventional design processes, it is however gaining recognition as important part of understanding building performance and architectural quality [3].

The questions this paper addresses include how different stakeholders and decision makers understand, perceive and value wooden materials, and especially their reuse and recycling.

2 METHODS

Qualitative approaches, such as semi-structured interviews and focus groups, have been used both in the precursory studies on wooden building materials that this paper builds on, and in a follow-up study that addresses re-used wooden materials.

2.1 Semi-structured qualitative interviews with architects and inhabitants of urban timber buildings conducted in 2017

27 inhabitants of urban residential timber projects by recognized contemporary timber architects have been interviewed as part of a doctoral research project conducted at The Oslo School of Architecture and Design [4].

The interviewees were chosen on the background of their homes that complied with a number of common denominators, such as timber as the main construction material; housing on an urban scale as a functional typology; and Austria, Germany and Norway as comparable climatic and cultural contexts. Other aspects were deliberately chosen to differ, such as the construction system (massive timber, column-and-beam systems or hybrid structures); the urban typology (referring to building geometry and access system); the type of occupancy (rental or owner-occupied); and the exposure of wooden construction members (covered by gypsum, painted, glazed or with wood's natural surface). The cases' maximum variation strengthens the findings' significance in qualitative research where, as opposed to quantitative research, a limited number of strategically chosen cases is investigated with many variables [5].

Set up as semi-structured qualitative interviews, the conversations were organised around a predefined set of themes and consciously left time to explore topics of special interest to the interviewees in greater detail. Without the presumption of any theoretical framework, the open-ended questions addressed more general architectural values and qualities first, before turning to how these relate to wooden materials. The interview data was analysed by structuring the transcribed conversations according to the topics addressed, and by pinpointing corresponding and contrasting statements.

2.2 Focus groups with users conducted in 2016

Focus groups are carefully planned group discussions, typically with 5–10 participants, that are designed to gather participants' views and opinions on specific topics. The group discussion is led by a moderator. Results from focus groups cannot and should not be generalized to the population as a whole but should rather be seen as the opinions of a small subset that merit further investigation to determine their validity for the population as a whole.

Focus groups were conducted in 2016 in Norway with inhabitants and wood related professionals. The interview guide was directed at gauging the participants' perceptions of topics related to the use of natural materials, and particularly wood, in the interior built environment [6].

2.3 Semi-structured qualitative interviews with architects and stakeholders in the Norwegian sawnwood industry in 2022

As part of a pilot study on drivers of the future demand for sawnwood, another series of semi-structured interviews with industry experts (3), industry representatives (3) and architects (4) was conducted via Teams video calls in 2022. The reuse and recycling of wooden construction parts were part of the topics included in the interview guide developed for the study, aiming to map i. weather and why (or why not) participants believed wood should or could be re-used or recycled, ii. barriers they perceived as preventing the reuse and recycling of wood, and iii. how they envisioned wood to be re-used or recycled. In addition, all participants were asked to appraise the current market value, i.e. the willingness to pay for used wood. Rather than defining a theoretical framework or hypothesis prior to the study, it had an explorative set-up. The industry experts and representatives were purposely sampled based on their assumed knowledge of the industry and the market. Likewise, the architects were sampled because of their experience with wood-based constructions.

The interviews were not recorded; instead, the interviewer took extensive notes. The interview data was assessed by structuring the notes by themes and analysing the content with a focus on i. identifying common perceptions and attitudes and assessing the degree of consensus, and ii. describing the spread or extremes in perceptions and opinions.

3 RESULTS

3.1 Addressing wood through three dimensions of materiality (2016 and 2017)

Two preceding studies have established the importance of involving users (e.g. inhabitants), professionals and other stakeholders in the wood-based construction industry when aiming to understand their perspective on wooden construction materials and to advance the implementation of these. Insights have been gained about the experiences, expectations, preferences and values tied to wooden materials and how these impact the acceptance and choice

https://doi.org/10.52202/069179-0146

of materials. The studies also revealed diverging ways of talking about material related issues.

The focus groups conducted in 2016 in Norway focused on users´, professionals´ and stakeholders´ perception of wood in the interior environment [6]. The study concluded that both professionals and non-professionals can identify and explain relevant physical and immaterial properties of wood, but that the way these properties are expressed differ between professional stakeholders and non-professionals.

Likewise, the interviews conducted in 2017 found that inhabitants and architects talk about the same thematic dimensions when discussing wooden construction materials, but with different views on them, weighting them differently, and with a different vocabulary **[4]**. Three overarching and overlapping thematic dimensions were identified in the interview material, relating to wood's *properties*, *experiences* and *values*.

- Mechanical *properties* were identified as important in the semi-structured interviews, such as the ones that allowed inhabitants to use or modify the wooden structure. Their interpretation as either robust, safe and reliable in the long run, or as unsettling, unstable and vulnerable influenced the users' acceptance. For the interviewed architects, constructive efficiency and systematization was important. Apart from atmospheric qualities, some favoured exposing wooden construction elements as a risk-minimizing measurement, as potential water damages would be detected earlier.
- The *experiences* of wooden materials as something living, healthy, warm and comforting or in contrast as pressing, overwhelming or dated were often tied to associations and memories that would co-determine the acceptance of wooden surfaces. Some inhabitants appreciated the stories weathered or worn surfaces exhibit and how this individualizes buildings, for example through traces of use or from weather exposure. Others wished they could maintain wooden surfaces in such a way that the materials would appear to be new and untouched. They also described bodily reactions to wooden materials. The architects' answers were less detailed and exhaustive in this realm, and not all architects expected the users to be concerned with or sensitive to experiential qualities.
- The *values* associated with wooden building materials included sustainability, a connection to nature and life, and local identity. A personal connection to the materials' origin, to the neighbourhood community the architectural design fostered, and an understanding of leading design principles and ideals were found to impact the users' acceptance and appreciation of the project's materiality in its various dimensions. For architects, important wood related values also included the status of wood related professions and workmanship quality.

3.2 Attitudes among professionals in the wood-based construction sector (2022/2023)

In the follow-up interviews from 2022/23, the four interviewed architects agreed without any reservation that wood always should be re-used if possible. To their mind, burning wooden materials from demolished or deconstructed buildings in heating plants (combustion power plants) for district heating should be the very last option and only considered when all other alternative usage was unrealistic. As of today, burning used wood in heating plants is the most common utilization of this resource in Norway [7,8]. For all architects, minimalizing resource use and waste production as well as limiting carbon emissions were the main motivation for their view. In addition, one architect mentioned the need for limiting the harvesting of fresh wood to preserve natural habitats and to protect vulnerable species.

Among the industry experts and representatives, one participant was uncertain whether the reuse of wood was environmentally and economically sound and thus not convinced that systems for wood reuse or recycling should be implemented. This participant reasoned that as fresh wood from sustainable forestry already had a very low carbon footprint, it was likely that the process of deconstructing, transporting, sorting, rinsing, testing and then possibly processing, producing or reworking the materials into new products would cause more carbon emissions than using fresh wood. The industry representatives also believed that said process would be rather costly and time consuming, so that products from used wood would have a hard time to be economically sustainable and competitive compared to products from fresh wood. Another participant shared some of these doubts, claiming that to be environmentally and economically sound, transportation, processing and handling would need to be kept at a minimum. In addition, they claimed that for some segments of used wood, reuse and recycling would be technically challenging or risky due to a lack of knowledge on for example pre-existing treatments. They argued that using such materials for energy recovery (i.e. district heating) was a sound and established option. Apart from these two, the industry experts and representatives conceded that wood, if possible, should be re-used or alternatively recycled – either because of the need for all industries to minimize carbon emissions, or because external pressure, for example from the EU, would force the sector to do so. However, compared to the architects, the participants from an industry background were more focused on barriers and quick to elaborate on practical issues, obstacles and prerequisites that would need to be addressed before the reuse or recycling on a larger scale would be practically feasible.

Barriers and obstacles towards reuse and recycling surfaced repeatedly throughout most of the interviews, without the interviewer asking. In addition, these themes were a predefined topic in the interview guide, so that all participants assessed barriers and obstacles at least once during the interviews. Barriers and obstacles that surfaced in nearly all the interviews included:

https://doi.org/10.52202/069179-0146

- The lack of infrastructure/ a system for collecting, transporting, testing and sorting, rinsing, processing etc. used materials or alternatively the (perceived) high cost of (establishing infrastructure/ a system for) collecting, transporting etc. wood materials.
- The lack of knowledge regarding the amount of, state of, and quality of used wood materials from demolition and deconstruction, making it challenging to estimate the potential for different types of reuses and recycling.
- The (poor) quality and heterogeneity of (proportions of the) used materials, due to e.g., maintenance level throughout the lifespan of the buildings, impacts like leakages, rot, fungus etc. and the current practice of demolishing rather than deconstructing buildings, resulting in materials being destroyed, poorly sorted or contaminated.
- The (perceived) high cost of changing demolition practices.
- Lack of knowledge about previous treatments and/or lack of ability to/methods for/cost of determining pervious treatments, limiting the potential for reuse and recycling (e.g., due to potential health hazards).
- The notion that used materials lack strength and tolerance which would limit potential uses, and the cost associated with testing these characteristics.

Other, less frequently mentioned barriers included high energy prices and thus the potential competition for the materials from other usages including export for bioenergy purposes. In addition, the relatively cheap price of wood might limit how much effort or resources would be sound to invest in systems for the re-use and recycling of used wood.

Apart from this, several participants mentioned the established conventional building practices and a lack of focus on deconstructability and reusability when the buildings had been planned and built. Interestingly, opinions on whether the more recent building practices (i.e., after 1950) or the older ones constituted the biggest challenges for reuse differed. Some participants argued that prior to around 1950, buildings were generally constructed in a way that allowed deconstruction and reuse. In addition, their opinion was that building materials used in older buildings often were of great quality. Others argued that the knowledge about construction and thus materials used in buildings from before 1950 was neglectable, making it necessary to sort and test all materials and to plan each deconstruction process in detail. Deconstructing newer, more standardized houses and reusing the well-documented materials from them would therefore be more straightforward and less demanding.

Finally, representatives from the sawnwood industry mentioned the high costs of processes such as joining smaller pieces and lengths of wood into more usable dimensions and materials, e.g., using techniques like finger jointing, glue laminating (glulam) and cross laminating timber (CLT). In addition, they thought that such elements and materials engineered from used wood might possibly have poorer properties in terms of strength, tolerance etc. than when using fresh wood. In addition, testing such products would be essential to ensure so that customers could trust their capacity, which again would add costs to the process.

Quite often in the conversations, views on how used wood materials could be re-used or utilized in other ways surfaced without encouragement. In addition, the participants were directly asked to give their view on this. Two of the participants displayed a high level of technical insight on the subject and based their answers on this knowledge. These two gave relatively detailed answers, e.g., they differentiated between materials, gave examples and were quite specific. The other participants talked more generally of wood materials, differentiated less, and although some displayed technical knowledge and based their assessments on this knowledge, there was still a clear difference between these and the first two in how specific and detailed their views and underlying reasonings were.

A common reply to questions regarding how the participants visioned materials being re-used or recycled was “in any way possible”. Elaborating, participants explained that if technically possible, materials should be re-used in the same way they were originally used, i.e., “direct re-use”, keeping handling and processing to a necessary minimum. Materials no longer meeting requirements for the original use, e.g., requirements for load tolerance, should be processed as little as possible and then utilized for the second-best alternative e.g., cladding, cross laminated timber (CLT) or glulam elements. One of the architects stated that if utilized as a layer in CLT-elements, used wood would add extra aesthetical interest.

Shorter bits of wood of high quality could e.g., be joined together using techniques like finger jointing in what several participants called “reversed sawmills”, making new, strong, materials. However, according to sawnwood-industry experts and representatives, the most likely and realistic first step towards more circularity would be the recycling of untreated, used materials in wood-based panels. This alternative was considered the most likely because of the (perceived) low costs and effort required for processing used wood into raw materials for wood-based panels, and the (relatively) low requirements in terms of material heterogeneity (e.g., length, strength, moisture, condition) for this usage. One of the experts was of the opinion that wood-based panels would be the prevalent utilization of used wood materials in the near and intermediate future, together with continuing to burn them in heatplants for energy purposes. In the more distant future, i.e., around 70 years, this would shift, and more direct uses would dominate.

They thought 70 years to be a likely timeframe for such a shift, believing that by then, the majority of buildings to be deconstructed would have been built with techniques and materials intended for deconstruction and reuse. One of the architects believed that planning for reuse soon would become an integrated part of building standards and already had some experience with planning such buildings due to the clients’ requirements.

Table 1: *Table summarizing if and how participants signalled that sawnwood, engineered wood and wood-based panels could be reused, recovered, recycled, composted, or put to other usages.*

	Reusable	Recoverable	Recyclable	Compostable	Other usages
Sawnwood	Yes, a proportion of used sawnwood is almost directly reusable (endings may need to be adjusted etc.), provided that materials are controlled and meet quality standards. In a short-time perspective, increasing the reusable proportion requires a shift from demolition to deconstruction. To upscale the reusable proportion, reuse must already be considered when planning and constructing buildings.	Yes, a proportion of used sawnwood is recoverable, provided that materials are controlled and meet quality standards. Examples of recovery include processing loadbearing wood into cladding, interior products or engineered wood products. In a short-time perspective, recovering more sawnwood requires a shift from demolition to deconstruction. Upscaling requires already considering recoverability when planning and constructing buildings.	Yes, a proportion of used sawnwood may be recycled into wood-based panels or materials for pallets, provided that materials are free from metals and contaminations. Recycling into wood-based panels is considered the most likely and easiest way of keeping the resource in circulation longer at present.	Not discussed	Energy-recovery i.e., burning in heatplants for district heating, is the most likely usage of a considerable part of used sawnwood in a short-time and medium-term perspective.
Engineered wood	Yes, a proportion of used engineered wood is reusable, provided that materials are controlled and meet quality standards. Requirements for increased reuse were not discussed.	Recoverability of engineered wood products were not discussed.	Yes, may be recycled, provided that materials are clean (e.g. glue must be biobased and not constitute a health hazard). Examples of uses were not explicitly mentioned apart from general statements, implying that the participants assumed that if meeting health- and technical requirements, all wood-based materials could be recycled into wood-based panels.		Not explicitly discussed, but general statements implied that the participants assumed that most used wood could be converted into energy.
Wood-based panels	Not explicitly discussed. However, implicitly included as one of the materials when discussing the need for a shift from demolition to deconstruction, i.e., if new, gentile practices are introduced, a larger proportion of used wood-based panels might be reusable.	Recoverability of wood-based panels were not discussed.	Examples of recycling were not explicitly mentioned, apart from general statements implying that the participants assumed that if meeting health- and technical requirements, all wood-based materials could be recycled into wood-based panels.		Not explicitly discussed, but general statements implied that the participants assumed that most used wood could be converted into energy.

https://doi.org/10.52202/069179-0146

Table 1 summarizes the possible forms of re-use discussed by the participants, sorted into the categories "re-usable", "recoverable", "recyclable", "compostable" as proposed by the International Organization of Standardization [9], and "other usages". Most participants focused implicitly or explicitly on sawnwood, while none included explicit details on how wood-based panels could be re-used. From the general statements however, it could be derived that participants assumed that wood-based panels meeting health requirements, e.g., not treated with products or coating containing dangerous chemicals, could be recycled. None of the participants mentioned composting wood-based materials, suggesting that the participants did not associate composting of wood materials with circular economy.

As to whether there was an added value in used wood materials visually appearing to be used, the participants, with a few deviations, suggested that this would depend on the segment, purpose and use of said materials, and the timeframe. For visible materials, at present, many thought that there could be some market advantages if used wood looked used. For non-visible wood, and in a longer perspective, the participants doubted that there would be any such advantage. The few interviewees with a different view focused solely on visible wood and the present market and agreed that used wood with vintage patina would be beneficial. One participant explained how a product literally had been driven over and tossed around by the manufacturer to achieve the desired used look and thought that since this was a product that was popular with some segments, genuinely used materials would probably also be popular with some costumers. Regarding the willingness to pay for used wood, all participants assumed that it would be lower than the willingness to pay for fresh wood.

4 Discussion

Wooden materials can be re-used in many valid ways and play an important role in replacing more harmful materials and in prolonging the storage of CO_2 as "climate sinks" – both when the constructive elements are exposed and when not visible in the building.
The materials can be:

- Hidden between gypsum boards.
- Treated / repaired / refined / renewed, visible and recognizable.
- Recycled, hidden or visible but unrecognizable (e.g. in particle boards).
- More or less in their original state, and visible and recognizable.

Both the precursory interviews and focus groups and the recent interviews showed a tendency among architects and industry representatives to mostly talk about tangible, technical aspects, both when discussing wooden construction materials in general, and the reuse and recycling of such materials. The values they focused most on also coloured their view on the feasibility and the time aspect of reusing and recycling wooden construction materials – some focused more on the short time economic risks and gains for their company and were more sceptical about re-use and recycling becoming common practice before circular construction had become the common and possibly prescribed way to build. These participants were mainly industry representatives. Others highlighted more idealistic values, and ideals that would benefit society at large. They were more prone to seeing opportunities rather than obstacles, to start at a small and experimental scale at once in order to actively contribute to making a change, and to invest in future and more common gains. A subsequent more in-depth analysis of the interview data could include information on the participants being employees or company owners. This might influence how positively one looks at risks – an employee does not have the same responsibilities as a company owner.

In the study from 2022, the interviewer noticed that the architects described qualitative aspects of the material in ways that surprised her and that she hadn't considered herself or not formulated in that way, while interviewees with a technical focus (naturally) focused more on the technical than on the experiential or idealistic aspects, but also used a different and more straightforward language.

However, the experiences of re-used and recycled materials were barely addressed in the recent interviews. In the preceding research cited here [4], it was discovered that the users' (inhabitants') statements about their experiences with wooden construction materials were much more articulate, specific and rich than the architects' (and also than some architects expected). It stands to reason to assume that users also could fill a gap in understanding the experience-related acceptance of re-used and recycled wooden construction materials.

In the previous research, it was argued that these qualitative aspects were an essential part of architecture's "lovability", influencing the life cycle of a building. As cited before [2], loved buildings are expected to motivate the user to a greater degree to adapt to the building even when it is not a perfect match for the user's need any more, to take better care of the building, and to find new functions for the building when users change.

"Lovability" includes tangible, experiential and value related aspects of materiality. Based on interviews with inhabitants. these include:

- Sensory perceptions that cause bodily response (e.g. effects on heart-beat rate, sleep quality, recovery) and mental responses (e.g. stress level, behaviour, interaction with others).
- Associations, either with earlier experiences and memories, or with acquired ideas; these will influence the acceptance and appreciation of materials, of their state and treatments, and of their changing appearance when ageing.
- Individualisation of materials and products – even industrial, standardized products will become unique when weathered and used, and display their situatedness

in a geographical and in a cultural context (e.g., their orientation towards the sun/wind/rain, and habits of use entailing repeated touch).
- Atmospheric qualities
- Narrative (e.g. about the materials' earlier location or user)
- Affordance: the possibilities of use that a material signals. For example, a massive wooden wall suggests which loads it can carry and which tools to use, while a gypsum wall could either cover a void that makes it difficult to hang heavier things (curtains, pictures, furniture), or a concrete wall that requires heavier tools.

In the earlier study, "lovability" has been used in an argument for prolonging the life cycle of buildings, and for including the users' experiences [2,4]. It can also be a useful term when aiming at a greater degree of reuse and recycling.

In the interviews from 2022, architects tended to focus more on the possibilities and were optimistic about the realization of new ideas, while industry representatives tended to focus more on possible obstacles, risks, costs and how long it would take to implement new ways of doing things. A reason may be that architects and industry representatives have different roles in a project - architects are more used to selling new ideas, and industry partners must make ensure the financial feasibility; furthermore, they are already selling wooden products and do not depend on new markets for the re-use and recycling of wood.

A note on value: one interviewee said that materials were handled harshly to create a more used look. Then, "Plan A", the option to give the material a long life in a primary function and in its pristine state, is passed by. Hereby, the values tied to the re-use and recycling of materials are foiled. Then, the entire universe of interrelated material aspects (tangible, experiential and value related) are reduced to visual characteristics.

5 Conclusion

Precursory studies have established that physical properties, sensory and intellectual experiences, together with associated values and narratives are important dimensions to consider when understanding expectations towards and the acceptance of wooden materials. It is important to include the user in the group of stakeholders when discussing these dimensions. It is expected that this is also valid for re-used and recycled wooden materials. Furthermore, in order to include the entire value chain in circular models for wooden construction materials, the combustion for energy gain and the composting of wooden materials have to be part of all considerations.

The recent set of interviews presented in this paper focused on how professional decision makers (stakeholders from the wood industry and architects) relate to the wood-related properties, experiences and values established by users when discussing re-used and recycled materials.

Important findings were that the professionals were detailed and explicit when focusing on mechanical and physical properties, and that their assessment of whether and how to pursue circular construction goals (and how soon) were guided by values, ideals and convictions, and in addition colored by their professional roles and responsibilities. Experiential aspects were largely absent from their statements. However, when developing new products and areas of application for re-used and recycled wooden construction materials, all three wood-related dimensions should be considered; besides properties and values, experiential aspects should be included, and the user perspective should complement the knowledge and insights already at hand in the wood industry.

Among others, this plays an important role when deciding if and how to process and treat wooden materials for aesthetic reasons, as this is greatly based on the users' assumed acceptance and appreciation of wooden materials but might impact the combustibility and compostability of wooden materials negatively. If the full cycle in a circularity perspective is part of how products both from new and from recycled wooden construction materials are promoted, this may also influence public taste and trends. When considering the full cycle of wooden material flows that includes their burning or composting, and when asking oneself if one would like to eat or to breathe in one's building (materials), then preferences of varnish, paint and other decorative treatments may be judged anew and change.

FUNDAMENTAL STUDY ON REPAIR BY EPOXY RESIN MIXED WITH CELLULOSE FIBER TO RECOVER BENDING PERFORMANCE OF WOODEN PARTS

Akiko Ohtsuka[1], Nozomi Satou [2], Naoyuki Itagaki[3], Run Minoura[4], Shinichi Terasaki [5]

ABSTRACT: This study conducts basic research on the reinforcement effect achieved by mixing epoxy resin and cellulose fiber to gauge the bending performance. Flowability tests indicated that increasing the amount of cellulose fiber relative to epoxy resin decreases flowability, and resins containing approximately 5% cellulose fiber are easier to apply. The compression test results indicated that the compressive strength of the material decreased upon mixing epoxy resin with cellulose fiber. However, the test piece containing cellulose fiber showed higher compressive strength than Cedar and Douglas fir. Compression test results confirmed that when the wood was filled with epoxy, the reinforcing effect achieved was greater than that of sound wood; it was sufficiently effective as a compression repair material. Furthermore, bending test results showed repair work utilising epoxy resin helped recover the bending performance of the test pieces with a 35% defect. Thus, the composite resin of cellulose fiber and epoxy resin is effective as a repair material for the bending material.

KEYWORDS: Cellulose fiber, Epoxy resin, Termite, Repair method

1 INTRODUCTION

1.1 BACKGROUND

Several historical and cultural properties constructed out of wood still exist in Japan. However, the strength of the wood of these buildings has decreased over time due to decay, insect damage, and deterioration. Therefore, appropriate repairs and restoration should be carried out to preserve the original timber used. Wood deteriorates in several ways; termite damage deteriorates the wood from the inside while fungal decay begins on the surface.

Current methods of repairing degraded areas include traditional techniques, such as root joints, and scientific techniques using synthetic resins and carbon fiber [1]. While each repair method has its advantages, cosmetic surface, workability, construction period, and cost can be concerns. Yamada et al. [2] examined the compressive strength of simulated deteriorated pieces to confirm the reinforcing effect of synthetic resins and the compressive and bending strength of wood exposed outdoors like pine wood, which deteriorates in a short period by Formosan subterranean termites. Their examination confirmed that the repair method using epoxy resin had a stronger reinforcing effect on the compressed material than on sound material; however, no reinforcing effect was confirmed on the bent material.

1.2 PURPOSE OF STUDY

This study aims to focus on the recovery of bending performance of wooden structures and propose a more appropriate and effective repair method. We conducted a basic study on the reinforcing effect achieved by mixing cellulose fiber with epoxy resin. The bending performance of the repair structures was confirmed after evaluating the material performance of the resin mixed with the cellulose fiber by conducting compression tests.

1.3 RESEARCH CONTENT

In this report, the material performance of the resin is evaluated by compression and fluidity tests, and the bending performance of the repaired member is confirmed by ultrasonic propagation velocity measurement and bending test, especially to examine the repair method using synthetic resin.

2 CONSIDERING REPAIR METHODS

Based on the literature survey [1]-[10], the characteristics of repair methods used in the past for cultural property buildings are shown in ***Table 1***. Carbon fiber repair methods are mainly classified as bonding, filling, or strengthening methods. Epoxy resins are often used for bonding and filling, and synthetic resins, such as isocyanate-based prepolymers, are often used for strengthening. The latter penetrate the interior of wood by application or impregnation and react with moisture and cellulose to strengthen the interior of the resin, thereby restoring the strength of the degraded wood [6, 7]. Sekino et al. [6, 7], stated concerns that the excessively high hardness of the resin and the fact that when impregnated,

if the surface is not finished again, the texture of the resin may not match with the weathered surface.

Recent research has examined carbon fiber repairs for cultural properties constructed out of wood [8, 9]. There are two types of repair methods using carbon fiber: the external adhesive type of carbon fiber board and the embedded type into the member, and the rolled type and auxiliary type of carbon fiber sheet [8]. Externally bonded molds and sheet-wound molds of carbon fiber board can be used to attach to damaged members. The external adhesive type of carbon fiber board is made by impregnating carbon fiber with epoxy resin, hardening it, and then affixing it with an adhesive. This makes it easy to install. However, since it is plate-shaped, the use of external adhesive type carbon fiber board is limited to smooth areas. v but they are thin, flexible, and can handle complex shapes. Auxiliary types include the use of carbon fiber rods as anchors or braces. Moreover, except in the case of embedding, the carbon fibers are exposed to the surface, which may prove to be an unsuitable design from design perspective.

Filling termite damage with synthetic resin can be done to prevent wood degradation caused by decay, and insect damage. Yamada et al. [2, 10] investigated the compressive and flexural strengths of pine wood exposed outdoors to Formosan subterranean termites, and that of small pieces subjected to simulated deterioration to confirm the reinforcing effects of synthetic resins. Results revealed that the repair method using epoxy resin was more effective for compressive materials than for sound materials, but not for flexural materials.

3 CELLULOSE FIBER

Cellulose fiber is biomass material derived from plants. Attention to plant biomass materials such as cellulose fiber was sparked by the depletion of oil resources. Consequently, biomass became much discussed whenever crude oil prices soared, leading to calls for the development of technologies to replace petroleum-derived plastics with renewable biomass resources as fuel and raw materials for chemical products [11].

This study also investigated the reinforcing effect of adding cellulose fiber to epoxy resin. Additionally, the cellulose fiber used in this study was extracted from rice straw produced at the University of Tokyo. The materials used in the production process have extremely low environmental impact.

The process of cellulose extraction is as follows:

(1) After adding distilled water into the rice straw and letting it stand, the process of pulverizing the rice straw with a mass collider is repeated to remove lignin and hemicellulose from the cellulose surface in the cell wall. This exposes the cellulose to the surface. The material input is shown in ***Photo 1***.

Photo 1: *Separation work*

(2) Using a vacuum and a flask, only the crushed rice straw is removed from the liquid in the rice straw and distilled water. ***Photo 2*** shows the separation process.

Photo 2: *How the ingredients were added*

(3) Dry in a drying oven (60 °C).

The cellulose condenses and hardens when the cellulose fiber is dried. They are broken up after drying to finish the process. ***Photo 3*** shows how it looks after drying.

Photo 3: *Cellulose fiber after drying*

https://doi.org/10.52202/069179-0147

4 MATERIAL PERFORMANCE OF RESIN

4.1 EPOXY RESIN

4.1.1 Outline of compression tests

To confirm the reinforcing effect of blending epoxy resin with cellulose fiber, test pieces containing a blend of epoxy resin with cellulose fiber by 2%, 5%, and 10% were prepared and subjected to compression tests. The size of each test piece was 20 × 20 × 40 mm compared with the previous studies [2, 10]. ***Photo 4*** shows the state of fabrication. We used formwork plywood wrapped with silicone resin-treated glassine paper to prepare the pieces. The curing period was 23°Cfor four days plus 60°Cfor three days. Additionally, the cellulose fiber B was mixed with the main agent and hardener. We made three pieces for each repair method.

We used a two-liquid mixture (main curing agent) resin. The component of the main agent was an epoxy resin, and that of the curing agent was a polyamine. To confirm the original performance of the epoxy resin used this time, a test piece N without compounding cellulose fiber was prepared, and the compression test was performed.

Photo 4: *The state of fabrication of test pieces*

4.1.2 Compression test results

Figure 1 shows the compression test results**.** Adding cellulose fiber to epoxy resin increased the strength of resin containing 2% cellulose fiber. Contrarily, the resin containing 5% or 10% cellulose fiber decreased compressive strength. However, it acts as an effective repair material for compression in this study because it has a higher value than the design basis quasi-compressive strength of Douglas fir (27.0 N/mm^2). Its compressive strength was about 40 to 50 N/mm^2, which was confirmed to be similar to the experimental results of past studies in which wood was filled in with epoxy resin. [2].

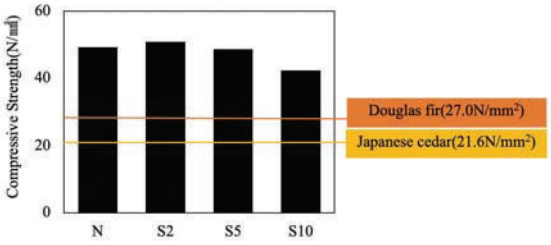

Figure 1: *Results of compressive strength tests*

4.2 WORKABILITY

Viscosity measurements were performed using a B-type viscometer. The B-type viscometer is shown in ***Photo 5***. To measure the viscosity, a sample liquid was placed in a container such as a beaker and the spindle was immersed in the liquid. When the motor was rotated, the spring and spindle also rotated; however, the spring is twisted by the flow resistance of the measured sample. This twist is detected by a torque sensor and obtained as a torque value. The viscosity is calculated from the constant determined by the combination of this torque value and the spindle speed.

Photo 5: *B-type viscometer [13]*

The viscosity values of each resin obtained from the flowability test results are shown in ***Figure 2***. The change in resin fluidity was confirmed by mixing different percentages of cellulose fiber with epoxy resin. The results showed that the more cellulose fiber was added, the higher the viscosity and the lower the fluidity.

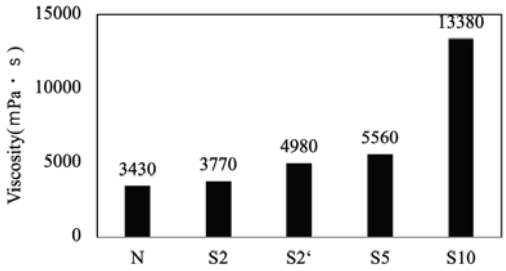

Figure 2: *Viscosity values of epoxy resin and cellulose blends*

As shown in ***Figure3***, it can be confirmed that the fluidity of the pieces with 10% cellulose fiber added to epoxy resin was greatly reduced compared to the pieces with 2% or 5% cellulose fiber added.

It is considered that a highly flowable repair material, which is easy to fill to the back against deterioration of termite paths, is more effective as a repair material at the time of resin filling in deteriorated materials. Contrarily, a less flowable repair material is more effective at the time of curing until the filled resin hardens.

https://doi.org/10.52202/069179-0147

The general liquid viscosity [14] is comparable to a resin containing 10% of the thickest cellulose fiber. It is considered difficult to fill wood materials with this viscosity value. Contrarily, epoxy resin with 2% or 5% cellulose fiber shows the same viscosity value as strawberry jam, and with this viscosity, the resin can be filled deep into the termite path against deteriorated components. Thus, this viscosity is suitable for filling.

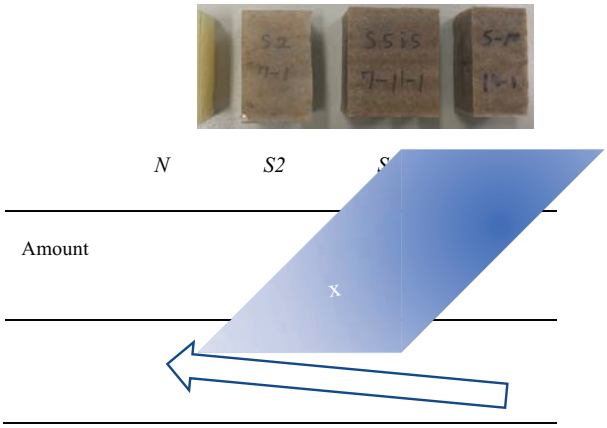

Figure 3: *Relationship between the amount of cellulose fiber and liquidity*

5 VERIFICATION OF BENDING PERFORMANCE FOR SIMULATED DETERIORATED PIECES

5.1 OUTLINE OF BENDING TESTS

A simulated deterioration test piece similar to termite damage deterioration was produced, and a bending test was performed. The bending test was carried out according to JIS Z 2101. ***Figure 4*** shows the parameters of the flexural pieces. To reproduce the wood degradation from termite damage, the simulated degradation test piece was produced. The shape of the test piece was a column of square cross-section with side length a = 20 mm, a total length L = 320 mm, and load span l = 280 mm.

Table 2: *Pieces for bending strength tests*

Piece	Defect (%)	Number
B-0	0	3
None		
	20	3
BS2-20	20	3
	20	3

A longitudinal slit was inserted symmetrically as shown in ***Figure 4***. The defect ratios to the volume of each piece and the wood opening area were about 20%, 30%, and 35%. Pieces were prepared by mixing 2% and 5% cellulose fibers with epoxy resin as shown in ***Photo 5***.

Additionally, to confirm the bending performance recovery before and after each repair method, bending tests were also conducted on sound materials without repair and at each defect rate. The first and second parts of the test piece names in ***Table 2*** indicate the repair method and defect rate, respectively. B is unfilled, BN is filled only with epoxy resin, and BS2 and BS5 are filled with epoxy resin containing 2% or 5% of cellulose fiber, respectively. In this study, Douglas fir was used as the tree

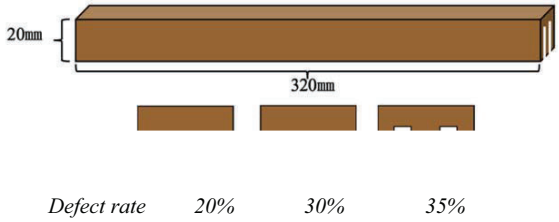

Figure 4: *Shape of the piece*

Photo 5: *Pieces for bending strength tests*

Photo 6: *Conducting bending strength tests*

5.2 BENDING TEST RESULTS

Figure 5 shows the bending test results at each defect rate for each repair method. The results were compared with B-0 (the sound). The bending strength decreased with increasing defect rate. Considering the unrepaired test pieces (B), the bending strength of B-20 (the 20% defect) is decreased by 11% compared to B-0, B-30 (the 30% defect) is decreased by 18%, and B-35 (the 35% defect) is decreased by 20%. The average repair effect at 20% defect across resin-filled pieces(BN, BS2 and BS5) changed compared to the unrepaired piece little.

As for the resin-filled test pieces (BN, BS2, and BS5) with 20% defect, no repair effect was confirmed compared to the unrepaired material (B) regardless of the repair method. On the other hand, in the resin-filled test pieces

https://doi.org/10.52202/069179-0147

with 35% defect, strength recovery was observed in all test pieces compared to the unrepaired test piece (B-35) with the same failure rate. Additionally, with a 35% defect, the test pieces that mixed the cellulose fiber (BS2 and BS5) showed a higher reinforcing effect than the one containing only epoxy resin (BN). It was indicated that the reinforcing effect was higher as the mixing quantity of the cellulose fiber became larger from 2% in BS2 to 5% in BS5. From these results, it is considered that resin mixed with cellulose fiber is an effective repair material for recovering the bending performance in material with a 30% and 35% defect rate. However, there is a dispersion in the obtained strength, and further examination is necessary.

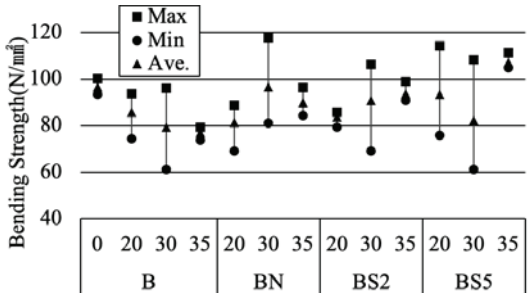

Figure 5: *Results of bending strength tests for repair methods*

To confirm whether the filling was sufficient, ultrasonic propagation velocity measurement, which is a non-destructive diagnosis, was performed before and after filling, and sufficient filling was confirmed from the change in velocity. The height of the terminal was placed at the center of the piece (20 mm each in the short-side direction), and an ultrasonic propagation velocity measuring instrument was used.

The ratio of the ultrasonic propagation velocity measurement results performed after epoxy resin filling of the simulated deteriorated piece to the ultrasonic propagation velocity of the sound piece is shown in ***Figure 6***. The experimental results showed that the rate of change in velocity is comparable or higher for sound pieces. This suggests that the simulated deteriorated pieces were sufficiently filled with epoxy resin.

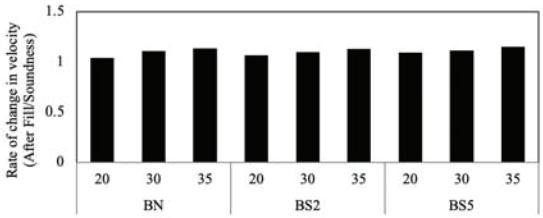

Figure 6: The ratio of ultrasonic propagation velocity after epoxy resin filling to that of the sound piece

The rate of change in ultrasonic propagation velocity before and after resin filling is shown in ***Figure 7.*** In the pieces with a defect rate of 30% and 35%, an increase in the ultrasonic propagation velocity due to resin filling was confirmed. This suggests that ultrasonic propagation measurement may be an effective method for confirming whether defects are sufficiently filled. Contrarily, no significant change was observed in the rate of change in velocity before and after resin filling in the 20% defect piece. It is inferred that the depth and width of the defect at the measurement position affected this as shown in ***Figure 8***.

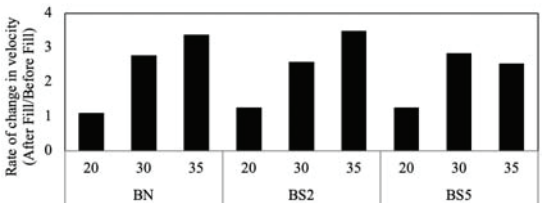

Figure 7: The rate of change in ultrasonic propagation velocity before and after resin filling

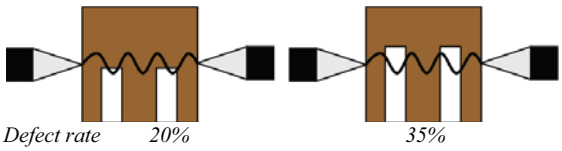

Figure 8: *Results of bending strength tests by defect rate*

6 CONCLUSION

This study mainly focused on the bending performance and carried out basic research on the reinforcing effect of mixing plant-derived cellulose fiber into epoxy resin for the proposal of more appropriate and effective repair.

A literature search revealed that although the winding form of carbon fiber sheets is effective in improving bending performance, design problems remain in cosmetic materials, and no reinforcement effect has been confirmed for bending materials in repair methods using epoxy resins.

From the results of compression tests on resins, it was found that compounding cellulose fibers with epoxy resin tends to reduce the compressive strength. However, the test pieces with cellulose fibers were found to have high compressive strength compared with the standard compressive strength of Cedar and Douglas Fir. Furthermore, the results of ten compression tests conducted when wood members were filled with epoxy resin with a compressive strength of ~40-50 N/mm^2 have confirmed that these materials are more effective than sound materials in reinforcing wood.

Flowability tests showed that with the increase in the amount of cellulose fiber relative to epoxy resin, the flowability decreased. When deteriorated materials are filled with resin, it is considered that highly flowable repair materials, which are easy to fill deep against deterioration of termite, are more effective as repair materials. Less flowable repair materials are more effective when considering the curing time until the filled

https://doi.org/10.52202/069179-0147

resin hardens. Therefore, resins containing about 5% cellulose fiber are the easiest to apply.

Ultrasonic propagation velocity measurements showed a large rate of change before and after filling, suggesting the effectiveness of resin filling in pieces with a defect rate of 30% and 35%.

The results of the bending tests showed that the repair with epoxy resin had a higher reinforcing effect on the members with larger defect rates. Additionally, the recovery of bending performance was confirmed by combining epoxy resin with cellulose fiber for 35% deficient pieces. The composite resin of cellulose fiber to epoxy resin is an effective repair material for bending materials.

ACKNOWLEDGEMENT

This work was supported by JSPS KAKENHI Grant Number 20K14872. We would like to thank Kohshin. H. C Co., Ltd., and other related parties for their great cooperation in the studies presented in this report. We are grateful for the cooperation rendered to us by Associate Professor Eiichi Sakai, Department of Mechanical Engineering, School of Systems Science and Technology, Akita Prefectural University, and the members of the laboratory for the cellulose fiber presented in this paper. The content of this report is based on the research results of Akita Prefectural University graduate Shuto Ochiai. We would like to express our deepest gratitude to everyone involved.

QUALITY ASSURANCE OF TIMBER STRUCTURES BY NEW MONITORING METHODS FOR THE MOISTURE CONTENT OF WOOD

Bettina Franke[1], Steffen Franke[2], Marcus Schiere[3], Andreas Müller[4]

ABSTRACT: Wood is a hygroscopic material and can absorb or release moisture from the surrounding climate. The wood moisture content (MC) influences the material strengths and stiffnesses as well as the long-term load-bearing behaviour. For this reason, the continuous monitoring of wood moisture content is a suitable early warning system to increase the quality of wood structures in a pioneering way and to detect changes in time. The paper presents several suitable measuring methods for the MC and explains their advantages, accuracies, and applications. The explanations are supported by case studies.

KEYWORDS: wood, quality assurance, moisture content, measuring methods, monitoring

1 INTRODUCTION

The continuous monitoring of wood moisture content is a suitable early warning system. The importance of wood moisture in relation to possible damage in timber construction is shown by Frese & Blaß [1], where 50 % of all investigated objects show damages or failures due to wood moisture changes or low and high wood moisture contents. Dietsch & Winter [2] shows that 30% of these objects are damaged due to seasonal or climate-induced wood moisture changes.

Since the distribution of wood moisture is often not constant across the cross-section, internal stresses perpendicular to the grain (moisture-induced stresses, MIS) arise due to the anisotropic moisture-strain behaviour. These stresses can easily exceed the characteristic tensile strength perpendicular to the grain and lead to crack development, [3]. In curved glulam beams, these stresses can also lead directly to the total loss of load-bearing capacity, as shown in [4], [5].

First, the focus must be on the design regarding the load bearing capacity and serviceability. Therefore, the service classes according to the EN 1995-1-1 needs to be considered. For a more detailed assessment of the expected climate, the results from Franke et al. [6] can also be used. Here, continuous monitoring data for one year was evaluated for different uses, such as sports halls, ice rinks and riding arenas, but also storage buildings, bridges, or mountain stations. The curves obtained show the range of variation and the expected wood moisture content per object.

Second, the condition of the structure must be ensured during the whole life cycle - 50 years for buildings and up to 100 years for infrastructural objects. This is usually done by regular visual checks and inspections combined with control measurements. If the control measurements are carried out continuously by means of a monitoring system, trends in the behaviour, damaging events or even damages can be derived from the data and inspections can be planned more time and cost efficiently.

The control of timber structures over ice rinks, riding surfaces, in warehouses and production halls, for facades made of wood, or flat roofs are engineering applications to ensure the quality of timber construction. The variety of monitoring possibilities is e.g., demonstrated at the "House of Natural Resources" at ETH Zurich, [7]. A dense sensor network was installed to measure, among other things, the prestressing force, the deformation, or relative displacements in addition to the wood moisture content to record the behaviour of the building over several years and to quantify the long-term behaviour of this wooden structure.

Monitoring systems can also be used for system controlling. In an apartment building in Büren in Switzerland, four apartments were equipped with sensors to measure air quality, [8]. Air quality has direct effects on the people who spend time indoors. Measurements of air temperature, air quality, CO_2, and volatile organic compounds (VOC) can be used to assess air quality. The air exchange rate can be reduced to the necessary/optimal amount and the control of the air exchange units can be optimized. The result is a constantly very good air quality with simultaneous energy savings due to the reduction of the air exchange rate when no people are in the apartment.

2 MEASURING METHODS FOR THE WOOD MOISTURE CONTENT

2.1 GENERAL TO THE MEASURING METHODS

For the measurement of wood moisture content, single point and laminar measuring systems can be used, as shown in overview in Figure 1. For the monitoring of small critical areas, the resistance measuring method, the sorption isotherm method and the passive RFID tag method are available. The principal description of the measurement techniques for wood moisture content is given e.g. in [9], [10]. Specifics for monitoring purposes is discussed below.

2.2 ELECTRICAL RESISTANCE METHOD

The electrical resistance method is the most common non-destructive method to monitor moisture content developments. The method allows measurement of moisture content in different depths from the surface and measured resistances can logged over extended periods of time. The principle is to measure the electrical resistance between two installed electrodes, [9]. The electrical resistance depends on the moisture content, temperature, and wood species. The accuracy of the method is about 1 to 2 M% [9]. Factors affecting the accuracy concern the grain orientation, type of electrodes, wood density, and temperature as well as surrounding electrical installations, permanent fitting/bond of electrodes to wood. Resistance between two electrodes roughly ranges between 100 kΩ to 100 GΩ from the fiber saturation point to about 5 M%, respectively. Once resistances are large, electrical currents are extremely small and electrical fields around the monitored structure are considered a possible source of error.

The choice and installation of electrodes should be done carefully, especially for objects subjected to outdoor climate, strong climatic variations, or direct weathering. Due to the shrinkage and swelling of the wood, normal wood screws or nails may have no or poor contact with the wood or the cable. Both lead to distortion of the resistance measurement and mostly indicate lower wood moisture contents than in reality. The use of hanger bolts and a protective box has proved to be successful, see Figure 2. The hanger bolts must be insulated with suitable material except for the tip. The cables are fixed directly to the hanger bolt with nut and locknut. The shrinkage and swelling of wood have almost no influence on the required good electrical contact between wood and electrode. All metallic parts of the electrodes should be made of stainless steel, if possible, [11].

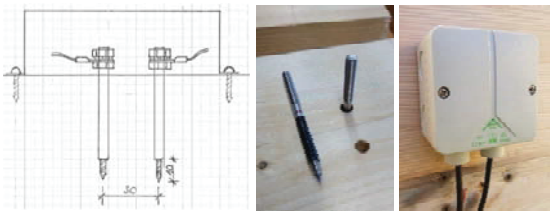

Figure 2: *Principal sketch and photos of the installation of the hanger bolt electrodes and protective box, [11]*

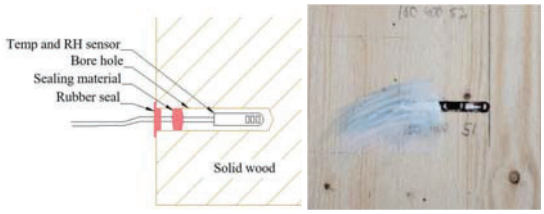

Figure 3: *Installation of air temperature and relative humidity sensors in solid wood*

2.3 SORPTION ISOTHERMS

2.3.1 General

The equilibrium moisture content in the wood can be derived from the temperature and relative humidity, [12]. The implementation of sensors in small, closed cavities in the wood is called the sorption isotherm method. The sorption isotherm method is most suitable in the presence of glue joints, the influence of salts, the use of protective and impregnating agents, or even in the presence of prolonged temperatures below 5 °C. All these factors do not influence the measurement by means of sorption isotherms. The application and implementation of the measuring probe requires a cavity size of 8 to 10 mm in diameter, whereby the depth of the measuring probe can be controlled as desired, see Figure 3.

2.3.2 Moisture sensor developed at BFH-AHB

To simplify the application of the sorption isotherm method, a special very small sensor was developed at Bern University of Applied Sciences, the Institute for Timber Construction, Structures and Architecture and the Institute for Electrical Engineering and Information Technology. An extra small battery-operated sensor for wood moisture measurement with radio data transmission was developed, see Figure 4. The sensor is located at the tip of the pin shaped extension below the electronic facing

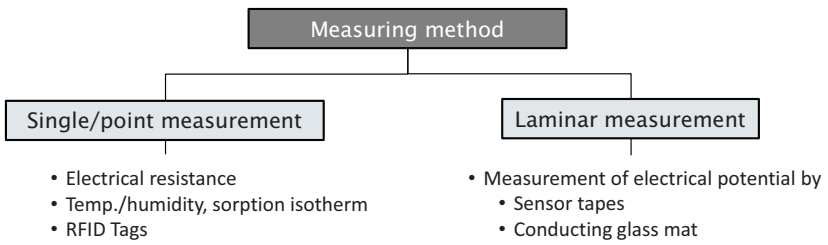

Figure 1: *Overview of selected measurement methods for wood moisture content in the monitoring application*

https://doi.org/10.52202/069179-0148

outwards. The extension which will be screwed into a drill hole. Different extension lengths could be realized to measure in different depths. The device is inexpensive, easy to apply, and measures, the air humidity, and the temperature in a cavity in any material, and transmits it by radio (LoRa) directly to the cloud or to a gateway (Figure 5). The measurement results can then be processed and visualized.

While every node could work and transmit its data individually, the results of several nodes can be synchronized and collected by using a Gateway. It receives the data by LoRaWAN, saves it and transmits them at once via 4G data net. The gateway also provides a remote access for checking the system conditions. Measurements up to two years can be made with one battery.

2.4 RFID SENSORS

Radio Frequency Identification (RFID) sensors are small devices that use low-power radio waves to receive, store, and transmit data to nearby readers (Figure 6). The basic types of RFID sensors are passive, active, and semi-passive or battery-assisted passive (BAP), [12].

- Passive RFID sensors do not have an internal power source but are powered by electromagnetic energy transmitted from an RFID reader.
- Active RFID sensors have their own transmitter and power source on board the tag.

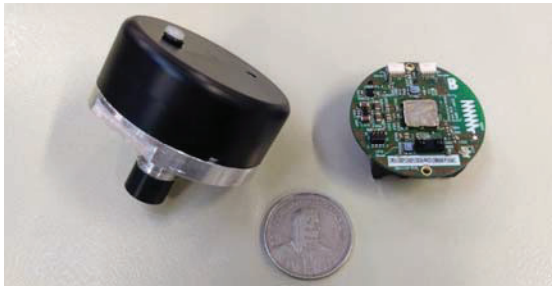

Figure 4: *Moisture-Sensor, system with waterproof housing (left), electronic (right).*

Figure 5: *Gateway to use and control several sensor nodes*

- Semi-passive or battery-assisted passive (BAP) sensors consist of a power source integrated into a passive tag configuration.

In addition, RFID sensors operate in three frequency ranges:

- Ultra-High Frequency (UHF),
- High Frequency (HF) and
- Low Frequency (LF).

RFID sensors can be attached to a variety of surfaces and are available in different sizes, designs, and shapes (e.g. dogbone or patch, Figure 6). Dimensions vary from a few millimeters to several centimeters. The Smartrac company or RFMicron are already provide passive RFID sensors for capacitive measurement of moisture or humidity. These tags have been successfully applied in the fields of construction, energy, but also healthcare.

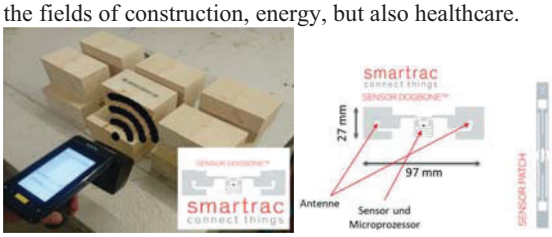

Figure 6: *Simultaneous measurement of several RFID sensors installed in the wood specimen (left) and RFID sensor shapes (right)*

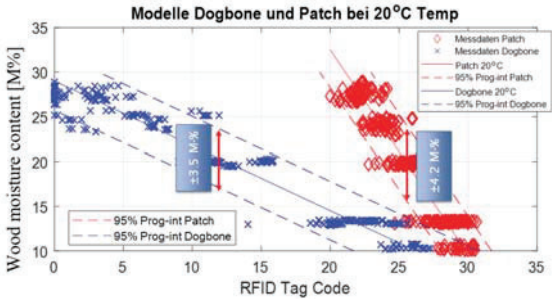

Figure 7: *Correlation between RFID sensors code vs. wood moisture at 20 °C for the dogbone and patch sensor*

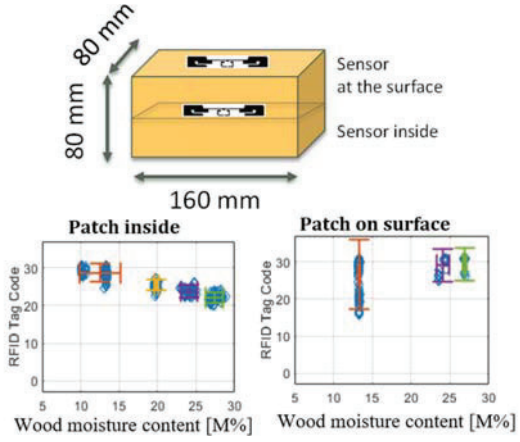

Figure 8: *RFID sensor tests at surface and inside, setup (top), correlations (bottom)*

https://doi.org/10.52202/069179-0148

Figure 9: *Bridge Rupperswill, application of sensor band on the wooden panel of a timber bridge (left) and detail of senor band (right)*

The applications of RFID-sensors have shown that the punctual measurement of the wood moisture content is suitable, but with a greater measurement uncertainty than the electrical resistance or sorption isotherm method. The correlation between the read-out sensor code and the wood moisture must currently still be determined on the basis of reference checks. Figure 7 shows an example correlation between sensor code and wood moisture together with the prediction interval. The width of the prediction interval results from the scatter of the measurement data used to derive the correlation. Depending on the application, temperature compensation of the measurement must also be considered. The application range of the model is between 10 M% and 28 M% for the wood moisture. The measurement error of the dogbone shaped sensor and patch sensor is ± 3.5 M% and ± 4.2 M% respectively, derived from the width of the prediction interval. To improve the measuring accuracy, the RFID sensors should be embedded inside the component. The results of a comparative study show lower variations in the measured values, Figure 8.

Due to the very low price of RFID sensors and their small size, several sensors can be installed at each measuring point and an average of the sensor codes could then be calculated. In this way, a higher measurement accuracy can be achieved, and the system is less susceptible to the failure of individual RFID sensors. RFID- sensors make it possible to monitor hard-to-reach and invisible components even without a power supply. The RFID sensors are said to have a service life of 50 years.

2.5 LAMINAR LEACKAGE MONITORING

2.5.1 Sensor tapes

With sensor tapes, it is possible to detect high moisture or wetness in a linear manner, e.g., under a waterproofing layer of flat roofs or road pavements [14]. This measuring method is mainly used in places where water or moisture can spread under the waterproofing. Depending on the spacing and arrangement of the individual tapes, quasi-laminar monitoring can be achieved with the sensor tapes. During monitoring, a potential measurement is made between two wires in the sensor band. The presence of water causes the electrical resistance to drop and can be detected.

For the application in timber bridge structures, a roadway structure with an unbonded waterproofing layer must be used for a two-dimensional leakage detection with linear sensor tapes. Because, depending on the planned transverse and longitudinal slope of the bridge, any water that has penetrated the separating layer between the waterproofing and the deck slab would flow in the direction of the slope and could be detected here, e.g., at a bridge edge or deck transition.

The foot and cycle path bridge between Rupperswil and Auenstein was equipped with sensor tapes, see Figure 9. The monitoring system monitors the possible leakage of the waterproofing and additionally records climate data, material temperature and wood moisture. The on-site measuring unit evaluates the measurement data and sends it to a cloud. The measurements values can be retrieved worldwide at any time using a browser. Warnings and alarms are triggered when critical values are reached.

2.5.2 Conductive fleece

For laminar leakage detection like in flat roofs or landfills, a conductive glass fleece is installed under the waterproofing and above the insulation, [14], [15]. In an intact waterproofing, there is no water flow and therefore no electrical current flow. In case of a leakage in the waterproofing, water penetrates the waterproofing layer and allows the conduction of electric current in the conductive fleece underneath the waterproofing. The presence of water in the case of a leakage changes the electrical properties, respectively the measured value, thus leakages can be detected. After drying out, the original values are restored. Early detection and the detection of hidden water damage are possible.

3 DATA TRANSFER AND SAVING

For the planning, implementation and evaluation of a monitoring system, an exchange with appropriate experts should take place, [16]. At the beginning, the choice of the measured quantity is a first important step next to the definition of the control points and their number. The density of measurement data must be defined individually from object to object or from control point to control point. Specialists in this field can assist and advice in deciding on a suitable system.

The installation of measurement sensors enables the acquisition of measurement data at defined intervals. Data can be transmitted from individual measuring points, e.g., by WLAN, LoRaWan or LPWan to a central module (gateway) and further to a WebPortal, as shown in Figure 10. If the measurement data are stored on a WebPortal, they can be viewed in quasi real time from the workplace and are available worldwide. The server can evaluate the measurement data and trigger warnings or an alarm. Storage and evaluation of the measurement data can also

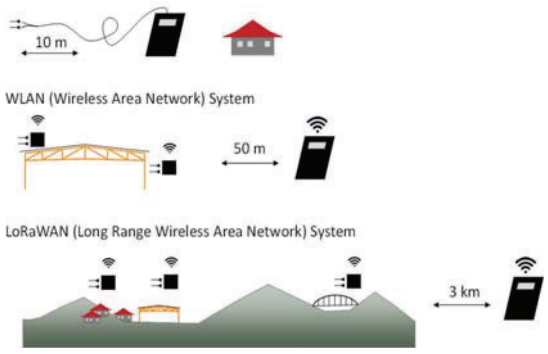

Figure 10: *Application of sensor band on the wooden panel of a timber bridge*

take place directly on the gateway or other measurement/ storage units and release warnings or alarms (e.g., via SMS). After commissioning, these systems operate autonomously.

The various components (measuring points, measuring device, gateway and user interface) form the monitoring system. Battery-powered systems can operate maintenance-free for up to several years, depending on the system and the number of measuring points.

4 CASE STUDIES

4.1 SOLID WOOD WALL MONITORED BY SORPTION ISOTHERM METHODE

The monitoring results for a solid wood wall show the very good functioning of the sorption isotherm method over different component depths, compare Figure 11. The diagram shows the measured wood moisture content and the calculated equilibrium moisture content (green line) from the room climate over a period of two years. It can be seen very clearly that the sensor near the surface in the wall at a depth of 5 - 10 mm (orange line) reacts very quickly to the room climate with a similar rate of change and amplitude as the calculated compensation moisture. Only in the summer months, when the indoor climate becomes more humid very quickly, there are differences between the orange and green lines. However, these differences quickly equalize. In this construction, for example, plaster-board and abrasion are very diffusion-open materials.

Furthermore, the diagram contains the measured wood moisture contents at depths of 20 - 30 mm, 70 - 80 mm and 95 - 105 mm. Already from a depth of 20 mm (purple line), a "damped" behaviour of the wood moisture with respect to calculated equilibrium moisture can be observed. Here, the wood moisture values are lower in summer and higher in winter than the calculated equilibrium moisture. In this case, the sorption isotherm method allows very precise evaluations of the wood moisture content and the interaction between the room climate and the water content in the solid wood wall.

4.2 TIMBER BRIDGE OBERMATT MONITORED BY ELECTRICAL RESISTANCE METHODE

The bridge Obermatt is monitored over several years within the framework of research projects, by the Institute for Timber Construction, Structures and Architecture at the Bern University of Applied Sciences. Some irregularities could be detected in time, as shown in Figure 13. The measuring points are located at different critical points and in different depths. Figure 12 contains the measurement locations shown on the bridge cross-section.

The wood moisture content was measured near the surface, approx. 20 mm deep, and in the cross-section with a depth of 200 mm. The diagram in Figure 13 shows the change of the air temperatures and relative humidity measured on site together with the calculated equilibrium moisture content on the surface of the wood for the timber bridge Obermatt. The wood moisture content measured in the cross-sections are shown in Figure 14. In addition, the

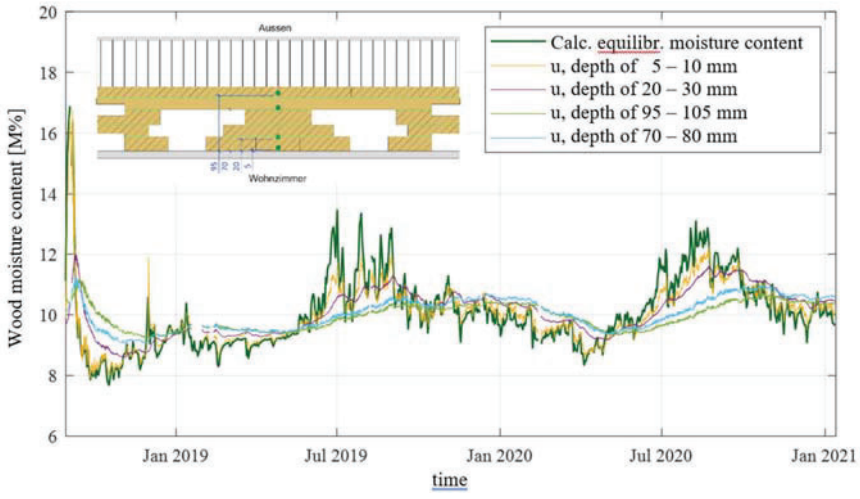

Figure 11: *Evaluation of the wood moisture content measured with the sorption isotherm method at different depths in a solid wood wall, [8]*

https://doi.org/10.52202/069179-0148

calculated equilibrium moisture content was determined for each measuring point; a time delay due to the moisture transport in the wood and the duration of exposure to the climate was not considered. The graph of the measured wood moisture content shows a delayed and damped behaviour compared to the calculated equilibrium moisture content.

On the south side, an increase in wood moisture content for one measurement sensor can be observed from August 2013. This is associated with a partial structural leakage, which has since been corrected and the wood is allowed to dry out again. In this case, the installed monitoring system has acted as an early warning system and later serious structural damage could be avoided at an early stage. Further monitoring results and case studies are explained and shown in [17].

5 CONCLUSIONS

Wood is a living and recognized construction material. However, wood is also a hygroscopic material and can absorb or release moisture from the surrounding climate. The so-called wood moisture content (MC) influences the material strengths and stiffnesses as well as the long-term load-bearing behaviour. As studies showed, half of the cause of damage to wood structures is due to a change in wood moisture content or seasonal and climate-related changes in wood moisture content. For this reason, continuous monitoring of wood moisture content is a suitable early warning system to increase the quality of wood structures in the future in a pioneering way and to detect changes in time.

The control points in the monitoring should be placed in possible danger zones/hot spots. These can include roadway crossings, support areas, transition areas and penetrations. The various point and area methods presented are suitable for measuring wood moisture content. For the planning, implementation and evaluation of a monitoring system, the number of measuring points, the accuracy and the data storage/transmission should always be defined with a view to the objective. At this stage, an exchange with appropriate subject matter experts can provide positive support.

The electrical resistance measurement method is technically very simple to implement, easy to install and can be replaced from the outside. The sorption isotherm method provides high accuracy by measuring relative humidity and temperature in an insulated cavity. An RFID sensor measures the humidity in the immediate vicinity of the sensor averaged over a certain component depth using the principle of capacitive sensing. The use of RFID sensors is inexpensive and wireless but with less accuracy. Passive RFID sensors even do not require an external power supply or battery and can be used in many applications.

ACKNOWLEDGEMENT

The presented research results have been generated in the projects "Quality Assurance of Wooden Structures" of the Forest and Wood Research Promotion Switzerland (WHFF-CH) of the Swiss Federal Office for the Environment and the "Sealing Systems and Bituminous Layers on Bridges with Pavement Slabs", VSS2016/326 of FEDRO. The funding bodies and accompanying business partners are thanked here for their support.

CURRENT STATUS OF MAINTENANCE OF THATCHED ROOFS IN SHIKOKU

Naoki Kakehashi[1], Miyako Kamatoko[2]

ABSTRACT:

The use of the traditional Japanese construction method, "thatched roofing," is steadily declining despite its considerable environmental performance. Here, thatched roofs in Shikoku were re-roofed without subsidies to clarify preservation of these roofs. We conducted a hearing survey with officers of the city engaged in activities related to the traditional Japanese construction method and obtained opinions on the maintenance method of thatched roofs and the implemented policies in the city. Thatched roof maintenance is possible without subsidies by maintaining and managing roofs that have existed for generations, and thatching replacement, such as procuring thatched roofs independently. Policy implementation, such as increasing the number of thatched-roof events and increasing the subsidy rate for thatched-roofing work, positively impact residents. Three teahouses were re-roofed as demonstration during a workshop. We confirmed the records of traditional construction methods and established the measures of roofing that can be adapted. For durability, the traditional construction method to firmly fix thatched roofs to the base and minimize the influence of rainwater were followed, screws and reinforcing bars were used, and the roof slope was changed. Furthermore, new technology increases the durability of the roof and prolong the number of years before re-roofing is required.

KEYWORDS: Thatched roof, sustainable resource, Chado

1 INTRODUCTION

Grass is sometimes used as a material for thatching walls and roofs. One such grass is *Imperata cylindrica*, or Cogon grass. Thatching has existed as a construction method in various parts of Japan since BC.

Using LC(Life Cycle) system analysis, according to Naoki, the amount of carbon fixation per hectare in grasslands is approximately 8,514 tCO_2/year [1]. In addition to their role in fixating carbon, grasslands also serve as habitat for unique organisms, who in turn play a role in maintaining biodiversity. Moreover, a 2014 study by a Danish research institute performed a life cycle assessment (LCA) of the environmental impact of thatched roofs from pampas grass and reeds growth, thatch field management, thatch transport, and construction. Results showed that, even if domestic and overseas transportation energy is included, these values are negative [2].

After the thatched structure is taken down, the old thatch can be used as fertilizer in the fields. Ando stated, “When re-roofing, the large amount of old thatch produced is decayed to a moderate degree, with a large amount of soot from the hearth adhering to it, making it a great fertilizer.” He also noted that “old thatch from roofs are better as a fertilizer than freshly cut thatch applied directly to mulberry fields” [3].

However, the use of thatched roofs are on the decline. According to a questionnaire survey conducted by Takamido, Takahashi, and Shigematsu, 71.4% of structures in Miyamachō had thatched roofs in 1945, but this number dwindled to only 23.7% by 1986. In addition, a questionnaire survey was conducted on the reasons households had changed from thatched to tin roofs, with 38% of respondents indicating that thatch was hard to acquire, and that it was difficult to find help to install thatched roofing. However, it has become clear that good quality thatch and neighbors that are willing and able to lend a hand, which were easy to obtain in the past, have declined due to labor shortages and changing times (Table.1) [4].

In addition, tiled roofs became the trend around 1930. Furthermore, rapid economic growth, chemical fertilizers, and mechanization due to the modernization of agriculture reduced grassland values.

However, in European countries, the environmental performance of thatched roofs is being reassessed, with thatched roofing still being used in modern buildings. This is especially true in the Netherlands, where some 2,000 to 2,500 structures are outfitted with new thatched roofs annually. These structures include public buildings and housing complexes, in addition to alone standing houses. Below is an example (Figure 1).

In Japan, there is also an environmental-based movement underway to preserve thatched roofs, with

[1] Naoki Kakehashi, Graduate student, Kagawa University, Japan, s22g256@kagawa-u.ac.jp

https://doi.org/10.52202/069179-0149

methods suitable to contemporary lifestyles, the environment, and resources.

In this study, we focused on Shikoku, where the numbers of craftsmen and thatched buildings are declining rapidly. We clarified what kind of measures are currently being taken where frequent re-roofing is not possible, and examined possibilities and issues involving the use of thatch in modern society moving forward.

2 METHODS

A hearing survey with related parties and a construction method survey at the construction site of active craftsmen were conducted. The surveys were conducted between 2019 and 2022. The hearing survey was conducted on all the subjects who are currently involved in the maintenance of thatched roofs, i.e., the owner, craftsman, and government. Specifically, the survey was conducted on two houses and four residents namely: Ino Town, Kochi Prefecture, Kumakogen Town, and Ehime Prefecture. The houses were re-roofed with active Kabuki craftsmen and without subsidies. One of the masters (Yusuhara Town, Kochi Prefecture) and two local governments (Miyoshi City, Tokushima Prefecture and Seiyo City, Ehime Prefecture) were working on the preservation of thatched roof in the cultural property department in Shikoku. In the construction method survey, there was only one active thatched-roof craftsman in Shikoku. Therefore, the construction process performed on the thatched roof of the three buildings (Yasuo Chado, Katahira Chado, Koyamati Chado) by the Yusuhara craftsman was recorded in video, and drawings were constructed by an actual measurement. The changes from the traditional construction method were confirmed. The survey area is shown in the Figure 2 below.

Figure 2: *The survey sites*

3 HEARING SURVEY

3.1 OWNERS WHO CONTINUE TO RE-ROOF THATCHED HOUSES

In a previous study [4], reasons that justify the decrease in thatched roofs were "I cannot get thatched roofs" and "I do not have any help when changing the thatched roofs." The two houses that had their homes re-roofed had personally prepared a thatched roof (Figure 3), and spent several years collecting thatched material, saving the material, and re-thatching. In addition, the owners were foresters by profession, and had experience in re-thatching with aid from the village. They also aided craftsmen by assisting their families when re-roofing at a home rice field.

Figure 3: *Kayaba*

3.2 THATCHERS IN YUSUHARA

The only active thatched-roof craftsmen who inherited traditional techniques in Shikoku are the craftsmen in

https://doi.org/10.52202/069179-0149

Yusuhara Town. We interviewed one of the masters regarding the people who often go to the site among the members, and Table 2 outlines our findings. Here, *tego* refers to craftsmen who gather the thatch and *jibashiri* refers to those who clean it. Professional proficiency increases as one moves to the left-hand side of the table. All of them, including their masters, make a living from agriculture, and the average number of thatched-roof jobs is three or four per year. The types and sizes of buildings they re-roof vary from small buildings such as *Chado* to main buildings of about 200 m², Kaya uses Yoshi from Watarase Retarding Ground in Tochigi Prefecture (Figure 4). Unlike Japanese pampas grass, this grass grows in water from May to September, and is harvested after being dried during the dry conditions of October. Although the cost is higher if transportation costs are included, the overall stretch is longer than the local pampas grass and can cover a large area. It is also excellent in durability, hence it is economical in the long run.

3.3 CULTURAL PROPERTY-RELATED DEPARTMENT

There are many thatched-roof buildings in Miyoshi City and Seiyo City that are making advanced efforts regarding thatched roofs. In Miyoshi City, under the historical scenic maintenance and improvement plan, thatched roofs were secured to cover the amount required for re-thatching 17 thatched-roof buildings (Table 3). Residents were hired to collect thatched roofs. In case of a surplus of the thatched roof, the building material was sold outside the city. As a future policy, the city is planning to continue its current thatch cutting activities, providing events where local elementary and junior high school students and others who do not know about thatch can learn more about this resource. Premised on a desire to preserve thatched roofs, the city shared its opinion that it would like to continue the maintenance of thatched roofs, using this as a catalyst for the prosperity of the local community and to attract migrants from other regions. In Seiyo City, there are more than 10 thatched-roof teahouses, which are common property in the village. Teahouses are a place of customs for "intangible folk cultural properties for which measures, such as creating records, should be taken." At that time, a mechanism was created to assist the cost for Kaya and others. In addition, in August 2014 a regional development group held an exchange between residents of urban areas and local residents at Yasuo Chado, the aim of which was to utilize thatched roofs as a symbol of farming villages. Using vacant houses and abandoned farmland, the group is busy with revitalization efforts that center on holding migrant exchange meetings, mainly for people living in urban centers.

4 CURRENT THATCH CONSTRUCTION METHODS

The construction method used in the re-roofing work of three buildings (Yasuo Chado, constructed in 2019; Katahira Chado, constructed in 2020; and Koyamachi Chado, constructed in 2021) in Shirokawa-cho, Seiyo City, was implemented by the aforementioned master of Yusuhara Town. The method was plotted based on interviews with craftsmen and actual measurements (Figure 5, 6, 7, 8). Due to the traditional technique of the right person in the right place, the construction method slightly differed depending on conditions such as the amount of kaya gathered and the skill of the builder even in the construction of the three teahouses of the same scale that we witnessed. There have been some changes from traditional methods. First, reinforcing bars were used for the top oshiboko (pressed bamboo) on which the ridge is placed (or Iribanachi [Yokotake at the top of the eaves] depending on the construction) (Figure 9). In addition, the inside of the house and the first Iribanachi were connected by a number line (Figure 10). All of them are particularly strengthening the members that received the load. When fastening the thatched roof to the rafters, instead of rice straw, a thinner and stronger sisal rope was used to improve workability and durability (Figure 11). In addition, we tried to follow the traditional Ehimeroofing method of fixing the rope to the kaya bundle in the corner without penetrating the rope into the hut so that water is not used when fastening the corner (Figure 12). The construction method was selected with consideration of performance improvement and regional characteristics. Next, we summarize the differences in the items noted below for the three *Chado*.

***Figure 11**: Using a sisal rope as a substitute*

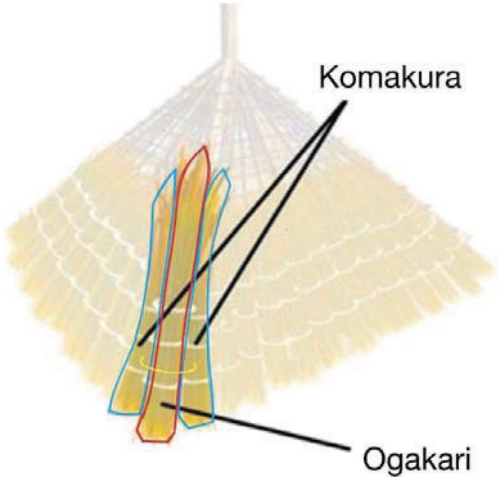

***Figure 12:** Fixing mackerel tuna bundle*

4.1 THATCH THICKNESS

A thatch thickness of 560 mm was recorded for Katahira Chado, which was re-roofed in 2020. This was the only record of thatch thickness exceeding 500 mm. This was thicker than the roofs of other Chado when it was first re-roofed, likely because the site where it was built has better sun exposure than the sites of the other two Chado. Both Yasuo Chado and Koyamachi Chado are flanked by mountains and trees. Just as with the thatch-roofed main house, which had a hearth, thatch is not moisture-resistant and will rot faster if it is not kept dry. For this reason, the thatch of the Katahira Chado, which receives good sun exposure, remained thick. Yasuo Chado and Koyamachi Chado have similar site conditions, but the thatch on Yasuo Chado grew thinner.

4.2 THATCH MATERIALS

All thatch is made from pampas grass or reeds. There is no difference between the two but, as the area is characterized by plentiful rain, Craftsman K said, “Rather than removing the undergrowth, we will leave it and bring the thatch with the undergrowth on to the outside. This will prevent the rain from penetrating.” Thatch roofing naturally has a water-conducting effect, but as the years pass, the thatch becomes thinner, and rainwater begins to penetrate. This undergrowth will fill the gap and prevent leaks.

4.3 EAVES/CEILING

There are two types of ceilings: joist ceilings where the ceiling is closed off with boards, and decorative attics where the beams are left exposed. These differences do not in any way affect the durability of the roof; the joist ceiling prevents birds and animals from entering the roof, while the decorative attic emphasizes ventilation and promotes the drying of the thatch. Hence, each type presents some advantages and disadvantages.

4.4 BASE MATERIAL

The base material consists of a lattice-like structure made of bamboo and rafters and is made at lengths of approximately 200–400 mm or less. Since wood is more durable than bamboo, when bamboo is used, six pieces are used per interval, while for wood, only five are used. For Yasuo Chado (girder line length: 2,133 mm) nine cedar posts are used, while for Katahira Chado (2,193 mm) one cedar post is positioned in the center, surrounded by eleven bamboo posts. For Koyamachi Chado, nice bamboo posts were used, but those had a thicker diameter than the ones used for Katahira Chado, and the interview survey revealed that this was because the craftsmen believed that the robustness would be sufficient.

4.5 MUNESHIMAI

Since the tin originally used for the muneshimai of Yasuo Chado was peeling off, this was repainted the original color. Bamboo and cedar bark were used on the muneshimai of Katahira Chado and Koyamachi Chado. However, as these could not be reused, muneshimai were created using water jars provided by local residents. Because these jars have such wide mouths, they are filled with thatch bundles. The culture of using recycled materials on the muneshimai runs deep.

4.6 ROOF SLOPE

Thatch does not leak because the thin, straw-like strands have a water-conducting effect and thus serve as an effective roofing material. However, if the slope of the roof is too gentle, rainwater will collect in the gaps of the thatch, allowing rot to establish. Based on the slopes of the three buildings, it is thought that a thatched roof slope of 45° or more is preferred.

5 CONCLUSIONS

With clarity on the information on thatched roofs, owners, craftsmen, and governments are exploring and practicing methods of maintaining and organizing thatched-roof buildings with consideration that modern thatched roofs, materials, and craftsmen are limited. Considering the situation of the owner who faces challenges in re-roofing frequently, the craftsmen have devised their construction method to improve durability, reduce the frequency of repairs, and tried to replace the material as much as possible. Moreover, present Shikoku craftsman methods can be applied to thatched roofs anywhere in the country, and if these methods can be properly disseminated, we believe that they can greatly contribute to the maintenance of thatch.

In the future, the conditions necessary for growing thatch suitable for roofing require clarification. This is because if thatch, which serves as the chief material of thatched roofs, cannot be harvested, properly maintaining such roofs becomes impossible.

ACKNOWLEDGEMENT

This research was supported by JSPS Grant-in-Aid for Scientific Research JP19K12460 and Nippon Life Foundation. We would like to thank the families of the owners of the thatched-roof houses used in the study, the residents of Shirokawa area who maintain the thatched houses, the thatched-roof craftsmen of Yusuhara town, and the Board of Education of Miyoshi City and Seiyo City rice fields. We would like to thank Editage (www.editage.com) for English language editing.

POSSIBILITIES TO PROMOTE CIRCULAR ECONOMY IN MID-RISE TIMBER CONSTRUCTION IN THE PROJECT PLANNING AND EARLY DESIGN PHASES

Ninni Westerholm[1], Juha Franssila[2]

ABSTRACT: This paper examines the client's decisions and actions taking place in the early project planning phase that could promote a circular economy in mid-rise timber construction projects. During the early planning phase, the client has an integral role in setting targets for circularity that the assembled construction actor-network carries out and tries to accomplish. However, the current research lacks concrete conceptualization and categorization of how circular economy principles can be carried out by the client in mid-rise timber projects. Therefore, the paper analyses one mid-rise timber construction project that has promoted circularity in all the life cycle stages. The study is conducted using a qualitative single case study method to identify which actors, resources, and activities can be utilized in the construction actor-network to achieve circularity targets set in project brief. The main finding is that a single actor in the construction actor-network has limited resources to promote circular economy in a mid-rise timber construction project and collective activities among project members are required to achieve circular economy targets. To conclude, the paper adds to the existing research by clarifying the client's role in utilizing the full circular economy potential of the construction actor-network.

KEYWORDS: circular construction, timber buildings, actor-network analysis

1 INTRODUCTION

Globally, the buildings and construction sector uses 36% of the energy, produces 39% of emissions [1], up to 40% of waste [2] and uses 50% of all the extracted materials [1]. Raw material extraction and processing cause 90% of biodiversity loss [3] and it is estimated that only 9% of the extracted resources are circular, meaning that is the amount re-used annually [4]. These numbers highlight the connection between the buildings and construction sector and three current predicaments: climate emergency, resource scarcity and the biodiversity crisis.

Using engineered timber for construction has great potential in climate change mitigation. If 90% of the new urban population would be housed in mid-rise timber buildings, 106 Gt of carbon dioxide emissions could be saved by 2100 [5]. Besides increasing the use of timber in construction, a transition from the now dominant linear economic model towards a circular economy could significantly lower the negative environmental impacts of construction.

A circular economy is based on the principles of designing out waste and pollution, keeping products and materials in use, and regenerating natural systems [6]. In a circular economy, materials and products are not taken out of the loop, but they are kept in the economy for as long, as efficiently and at the highest utility as possible. The emissions and use of virgin and non-renewable resources are minimized and the recycling of materials and products is maximized.

This paper presents design strategies that have been identified in the literature [7–11] to promote circularity in the built environment. Thereafter, circularity targets are presented that can be set to assure or promote the realisation of the strategies.

The paper focuses on the project planning and early design phases and the client's possibilities to promote circularity in the construction actor-network. Three key aspects support the chosen focus. First, research shows that most of the decisions that affect the circularity in construction projects are done in the early design phase [12]. Second, it is advocated in the project management and infrastructure project literature that the project planning phase is where the involved stakeholders have the best possibility to affect the final project and its outcomes [13]. Third, the clients are in a key position,

[1] Ninni Westerholm, Tampere University, Finland, ninni.westerholm@tuni.fi
[2] Juha Franssila, Tampere University, Finland, juha.franssila@tuni.fi

https://doi.org/10.52202/069179-0150

since they can include circularity as a goal in a construction project at an early stage [14].
The role of the client and the requirements and objectives they set for a project are obscure in the transition from linear to circular construction. Therefore, by identifying applicable circularity targets in realized construction projects and key activities in achieving them, a client can make early-phase decisions promoting circular economy during the building's entire life cycle.
This article identifies and describes how the client can utilize assembled construction actor-network to promote a circular economy in mid-rise timber projects. The following research questions were formed for the article: which circularity targets are present in the selected case study's project brief and how have they been met in the final construction (1), which are the key actors in the early design phase to promoting circularity in mid-rise timber projects (2), and what resources are required from the gathered actor-network to carry out the needed activities to reach the set circularity targets (3).
The article is divided into five chapters: introduction, literature survey, research methodology, results and discussion and conclusion. The literature review presents a summary of the identified circular economy strategies and related targets and gives an overview of the actor-network literature. The research method describes the selected case study and how it was analysed. The result chapter consists of three sub-chapters that will present the findings for the set research questions. The aim of the single case study analysis is to understand how the construction actor-network was able to realize the circularity targets in the early design phase of the project. Finally, the article presents a discussion of the findings.

2 LITERATURE SURVEY

2.1 CIRCULARITY STRATEGIES

This chapter discusses and describes design strategies that have been identified to promote circularity in the built environment. These strategies are then combined into a conceptual framework for this research.
The definitions of circular economy vary but optimising resource consumption, waste generation and/or embodied environmental impacts and regenerating natural systems target the main principles of a circular economy [15]. In the buildings and construction sector, circular strategies are of such nature that they promote one or more of the key aspects of a circular economy. 16 circularity strategies were identified through the literature survey (Table 1). Strategies focus on design aspects that can be implemented in the early design phase of the project.

Table 1: *Circularity strategies and their short descriptions. Sources:* [7–11]

Strategy	Description
Design for assembly/ disassembly	Reversible connections that allow easy reuse of components.
Design with circular materials	Choosing or substituting conventional materials with materials that are local, renewable and/or have low negative environmental impacts.
Design for adaptability/ flexibility	Designing buildings that can adapt to future changes regarding use, function, and available materials.
Design with modularity	Lean production and standard solutions that allow easier replacement, flexibility, and recycling.
Design for prefabrication	Off-site construction that allows material and time optimisation.
Design with secondary materials	Using recycled or reused materials instead of virgin materials.
Design for durability	Designing long-lasting buildings with long-lasting components.
Design with standardised solutions	Using standardised solutions (dimensions of components or connections) to ease efficient replacements and recycling.
Design for component and material optimisation	Reducing the amount and variations of materials and components used.
Design optimised shapes/ dimensions	Design with precision and specification to optimise the use of material and space.
Design for accessibility	Providing easy access to connections of components to ease maintenance, repairs, and recycling.
Design for layer independence	Making components and materials independent from each other's lifespan.
Design for short use	Designing buildings for their specific performance span.
Design symbiosis	Using resource outputs from one building as feedstock to other buildings.
Design energy-efficiency	Designing buildings that operate energy-efficiently.
Design for sharing	Buildings where spaces or equipment are in common use and thus reducing the need for private ownership.

2.2 ANALYSING ACTOR-NETWORKS

One way to approach network-based research analysis is to identify and examine the combination of activities, resources and actors that have been organized to work toward a specific goal. This is a focal approach applied in IMP research[16] and is identified as the ARA model focusing on industrial networks where actors undertake

activities using various resources [17]. Actors are individuals, companies or firms [18], resources can be defined as a different mix of competencies and set of assets that are used in conjunction [19] and activities as actions carried out by the actors to reach a specific target [20].

Networks are a general and abstract concept that can be used all the way from describing and modelling a complex business market to understanding a specific relationship between companies [21]. This paper focuses on understanding how a specific group of actors have been promoting circularity in a mid-rise construction project. The article incorporates the ARA-model approach to network analysis to examine the transition from identifying circularity targets in the competition brief to designing how they can be achieved.

3 METHODOLOGY

There is a lack of understanding of how circularity targets can be implemented into mid-rise timber construction projects. Therefore, this paper incorporates a qualitative single-case study [22] to examine one mid-rise timber construction project that has implemented multiple circularity strategies. Therefore, this study examines qualitatively one mid-rise timber project that promotes circularity in many ways [22]. The case study approach was chosen since it provides rich descriptions of the phenomena in the real-world context and is suitable for exploring new research areas where little is known about the subject [23,24]. Additionally, the case study research strategy can be used to investigate and retain information on organisational processes [22,25] by incorporating questions of “how” and “why” to reach a complete understanding of the studied real-world phenomena [32].

The selected case project consists of a densely built cluster of social housing buildings. The 3–4 story buildings have a hybrid structure consisting mainly of timber, concrete, and steel. The buildings have post-and-beam frames of glulam timber, glulam timber slabs, steel connectors, and a concrete core. Additionally, cross-laminated timber (CLT) walls are used in the buildings for stiffening the structure and steel beams are used in places where extra strength is needed. Moreover, the project represents mid-rise timber construction that has been designed and constructed by accounting for the following circularity characteristics:

- low carbon footprint
- energy-efficiency
- the use of renewable low-carbon construction materials
- material-efficiency.

Furthermore, the selected case study has received praise for its architectural design in the media and in the scientific community. Architectural design can be identified as one of the key activities in the project's early design phase but requires other activities' support to reach different circularity targets.

The competition brief was identified as the main data source for understanding the circularity targets set by the client. To complement the case study analysis, photographs of the project during construction were studied and one semi-structured interview was carried out to collect data from one of the key actors in the early design phase. Interviews have an essential role in case studies to fully understand the studied phenomenon [22,26]. The project manager of the design phase was selected as the interviewee because people in this role generally have a good overview of the early design phase of the project. The design phase project manager also acted as the leading architect in the case project.

Interview questions focused on finding out which circularity targets were eventually reached and what activities, resources and capabilities were required from the early design phase actor-network. The interview was audiotaped, transcribed and analysed.

Case studies incorporate different analysis methods such as a thematic analysis where collected case data is categorized into themes through coding [25]. The selected and formed themes were based on the literature survey and two main categories were selected: circular economy and actor-network. The circular economy theme was divided into sub-categories: circular spatial solutions, circular construction materials and circular connections. Firstly, circular spatial solutions prolong the building's lifespan or lower the users' negative environmental impacts, for example, flexible and adaptable spaces, spatially efficient spaces, or spaces in common use. Secondly, the characteristics of circular construction materials can be defined as renewable, low-energy, low-emissions, carbon-storing, healthy, durable, local, resource-efficient, recycled and recyclable (a material does not have to be all the above to be considered circular). Finally, circular connections include joints and other means of assembly that are durable and allow flexibility, disassembly, replacements, and maintenance with little or no loss of the building's or its components' value.

Similarly, the actor-network theme was divided into sub-categories: actors promoting circular economy, activities promoting circular economy and resources required to promote circular economy. The aim is to link the identified actions promoting circular economy to a specific construction actor and understand what resources were required to realize the set circularity targets.

The results chapter is divided into three sub-chapters. The first sub-chapter presents circularity targets found in the competition brief and circular design strategies they promote. The second sub-chapter presents how these targets have been met in the project. The third sub-chapter identifies the key actors in the actor-network and their activities and resources that enabled achieving a circular project.

4 RESULTS

4.1 IDENTIFIED CIRCULARITY TARGETS IN THE COMPETITION BRIEF

This section presents how circular economy has been included in the competition brief. Table 2 summarizes identified targets and connects them to strategies presented in Table 1.

Holistic sustainability, which includes ecological, economic and socio-cultural sustainability is a key goal in

https://doi.org/10.52202/069179-0150

the competition brief. The different aspects of sustainability are repeated throughout the brief, though it is not defined in greater detail how holistic sustainability should be achieved in the project. Even though the brief asked for holistic sustainability, this paper focuses on identifying how environmental sustainability was promoted.

The competition program states that the proposals are evaluated based on environmental quality, economic quality, sociocultural and functional quality, technical quality, process quality, and the quality of the area, including social and locational aspects. How these aspects have been considered must be shown in the requested drawing material and corresponding descriptions. The competition brief also states that interdisciplinary design efforts are highly appreciated.

The program asks for proposals that have a minimal burden on the global and local environments. They have specified that this includes resource-saving principles both during the construction and operation of the buildings and their external areas. Additionally, materials must be selected based on an LCA approach where the focus is on using building materials that can be produced locally or regionally with low energy consumption, and where materials from a renewable raw material resource are preferred. When choosing materials, consideration must also be given to robustness against expected wear and tear, which steers towards durability.

It is also stated that the project must consider efficiency in energy consumption, water consumption, waste management, materials, and land use. The buildings must reach at least a low-energy class in 2015. In addition, an environmental vision for the entire building is desired and its resilience to and handling of climate change is also included.

The competition brief also recommends pursuing a DK-DGNB silver or gold certificate. The competition organizers emphasized that the desire for a certain certification must not be perceived as something limiting further sustainability measures in the answer to the competition task. The DK-DGNB system is a Danish-adapted evaluation system that is based on the DGNB system developed in Germany. The DK-DGNB system is based on the three central pillars of sustainability: ecological, economic and socio-cultural sustainability, and these three are weighted equally in the evaluation process. Therefore, ranking in DK-DGNB can be seen as a tool to measure how well the competition proposal delivers holistic sustainability.

The competition program also included flexibility. The brief describes that apartments should provide space to live that is flexible and has the possibility of adaptation in case living situations change over time. The brief does not directly say that flexibility should be considered in the structural design, but the DNGB classification considers this aspect of flexibility and thus designing with it in mind helps achieve good scores in the ranking, which was required in the brief.

The competition brief also included targets supporting design for layer independence and accessibility. First, by specifying that all materials that have a shorter expected life span than the building must be able to be replaced easily, economically and with little inconvenience for the residents. Second, by stating that easy replacement of parts is highly appreciated.

Design for material and component optimisation is also vaguely promoted in the brief since it is stated that simple construction systems are preferred. Besides simplicity, the brief considers proven constructions preferable, which connects to standardised solutions and modularity.

One of the focuses of the brief is on social sustainability and some aspects of social sustainability promote circularity. Without directly demanding a sharing economy, the brief discusses its benefits and gives examples of it, such as sharing cars, shared guest rooms, and shared spaces to organize events. Moreover, the brief includes the option of constructing a separate community house, which can be used to facilitate sharing.

Table 2: *Targets from the competition brief and connected circular strategies*

Target	Strategy
Flexible apartments that can adapt to changing life situations	Design for adaptability/ flexibility, design for assembly/disassembly
Renewable materials	Design with circular materials
Local or regional materials	Design with circular materials
Materials with low embodied energy	Design with circular materials
Robustness against wear and tear	Design for durability
Low-energy class	Design energy-efficiency
DK-DNGB gold or silver certificate	Design with circular materials, design for assembly/ disassembly, design for durability, design energy-efficiency
Materials with short service-life must be easily replaced	Design for accessibility, design for layer independence
Simple solutions	Design for component and material optimisation
Common spaces	Design for sharing

The competition brief included sustainability targets in various ways. The project that won the competition and got built used a circular economy approach to respond to many of the things asked in the brief. It is to be noted that the brief never actually mentions circular economy. Nonetheless, the key aspects of the economic model were included and described with varying detail.

4.2 IDENTIFIED CIRCULAR ECONOMY RESPONSES IN THE CASE PROJECT

Table 3 explains how the project has responded to the targets set in the competition brief and how these responses have promoted circularity. The table also shows whether the targets were met, exceeded or undershot. In

Table 3: *Identified circular solutions in the case project and how they respond to targets set in the brief and how they promote different circular strategies*

Target	Response	Strategy
Flexible apartments that can adapt to changing life situations	Walls and openings can easily be altered, and apartments can be combined vertically and horizontally	Design for adaptability/ flexibility, design for assembly/disassembly, design for accessibility, design for layer independence
Renewable materials	Timber-based frame, CLT walls that are exposed on the interior, unplaned lye-treated timber boards in the interior, and exterior facades of untreated wood. Because of the vast use of natural materials the carbon footprint is estimated to be 50-70% of the conventional solution.	Design with circular materials
Local or regional materials	Using local or regional materials. The timber was mainly from Sweden and Germany.	Design with circular materials
Materials with low embodied energy	The structure is timber-based and has slow embodied energy	Design with circular materials
Robustness against wear and tear	CLT is used in walls and left exposed. Other interior surfaces of lye-treated timber. Maintenance is limited mainly to sanding and redoing the lye-treatment.	Design for durability
Low-energy class	Energy-efficient buildings with lots of daylight	Design energy-efficiency
DK-DNGB gold or silver certificate	DK-DNGB gold	Design with circular materials, design for assembly/ disassembly, design for durability, design energy-efficiency
Materials with short service-life must be easily replaced	Timber facades and interior panelling are designed to be easily replaced	Design for accessibility, design for layer independence
Simple solutions	Repetitive post-and-beam grid. Exposed CLT walls, untreated facades, lye-treated interior surfaces. Less material-layers than in conventional construction.	Design for component and material optimisation, design with circular materials, design for adaptability/ flexibility, design for assembly/ disassembly, design for accessibility, design for layer independence
Community house	Community house with common activities and community space with kitchen and toilets. Additionally, there is a maintenance-room for sharing of used objects, furniture, books etc	Design for sharing

some cases, when comparing the response to a target, the project delivered solutions that were better at promoting environmental sustainability than what was asked for. For example, the brief asked for flexible apartments that can adapt to changing life situations but the project consists on flexible buildings, in which changes can be made within apartment but also through combining apartments in various ways. However, it is to be noted that it was stated in the competition brief that proven structures are preferred and that the project is contradicting this as the proposed structural system is piloted in this project. However, the new system was deliberately chosen because the benefits to be achieved with it, such as flexibility, were well in line with the other targets in the brief.

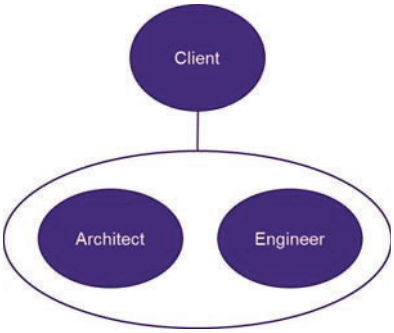
4.3 ACTOR-NETWORK AS A CIRCULAR ECONOMY PROMOTER

The single case study revealed that three key actors can be identified from the early design phase that are responsible for promoting circular economy (Picture 1). All the actors were in tight collaboration throughout the design phase with varying roles and complementing resources.

Firstly, the client can be seen as an enabler for the project by first setting targets in the project brief and later collaborating with other network members to achieve and approve a quality product for the tenants. Even though the client's role is more passive than those of the architects and engineers, the choices made by the client have a great impact on the overall sustainability of the process. Specifically in this project, the client was open-minded and allowed the architect and the engineer to create innovative solutions as part of promoting circularity. The client was, understandably, sceptical about some of the suggested solutions, especially of those concerning the

https://doi.org/10.52202/069179-0150

maintenance phase of the building. Nonetheless, with an active discussion between the actors, enough reassurance was produced to clear out doubts concerning for example different material choices and surface treatments. Overall, the client approved all the suggested decisions by the actor network after going through all the possible operational scenarios during the maintenance phase.



Picture 1: *Key actors in the design phase promoting circular economy targets*

Secondly, the architect and the engineer combined their resources during the planning phase of the project and the interviewee described the collaboration as a 50/50 relationship. However, the architect was the official project manager during the planning phase and took more responsibility for the finalized solutions. The engineer had a role to supplement the actor-network with technical capabilities that enabled the detailed level of planning and provided an additional understanding of the regulatory framework. In particular, the engineer had more understanding of acoustic and fire requirements that are key aspects in timber construction but the architect made sure that the surface materials matched the client's requirements. The interviewee summarized that experience in timber construction and collaboration with the engineer in previous projects enabled the providing of circular solutions for the sustainability targets set by the client.

Thirdly, innovative construction projects are typically perceived as high-risks and high-cost in comparison to conventional solutions. This was also a concern highlighted by the interviewee during the project. However, the project team was able to reach cost-effective results and reach the financial requirements for social housing. To meet the set financial requirements, the interviewee described that they focused resources in the early design phase on understanding how the project contractors should be tendered to reach an optimal outcome. The architect and the engineer came up with a

Table 4 *Activities, resources and actors promoting circular economy in the mid-rise timber construction design phase*

Activities	Resources	Actors
Sustainable material selection	Experience and specialization in timber construction and a circular economy in housing projects to optimize material selection and use with fire and acoustic requirements in mind	Architect, engineer
LCA	Understanding of the building component life spans, environmental impact, cost of their replacement and the possibility to replace them if needed. Collaboration with the client to communicate and ensure good quality building component life cycle performance	Architect, client
Maintenance planning for tenant turnovers	Understanding how wood material will behave under tenant use and agreeing on the surface material tolerance with the client	Architect, client
Design for disassembly and flexibility	Utilizing the spatial expertise of the architect and combining it with the technical understanding of engineers on how timber structures can be designed with mechanical joints	Architect, engineer
Design solutions that enable easy construction phase assembly	Designing the solutions with the tendering process in mind, market must have the operators to realize the design solutions	Engineer, architect
A structural system that enables good-quality moisture control in the building phase	The possibility to erect the building without moisture damage in the structures by using skeleton structure and taking care of façade elements' moisture control	Architect, engineer
Innovation during the design phase to develop solutions for circularity	Collaboration with client to ensure the functionality of new approaches and solutions. Enough financial understanding and resourcing in working with development projects	Client, architect, engineer

solution where the tendering was divided into three tenders, while conventional projects only use one main contractor. This enabled the actor-network to acquire more specialized contractors for the building phase that were able to produce cost-effective solutions. However, the required additional design work affected the architect's commission negatively. Overall, the case project was financially successful.

Finally, a more specific collection was produced from all the identified circularity promoting activities, resources, and the actor responsible for them (Table 4). The interviewee was able to describe how each identified circularity activity was combined with a specific resource to reach the set circularity targets described in Table 3. As a result, a description of how each actor can contribute to promoting a circular economy in the early design phase.

In the interview, it was also mentioned that it would be good to get the product manufacturers involved in the early design stage. It was also noted that this is usually difficult because the product manufacturers are typically selected based on tenders at a later design stage. However, this prompts us to discuss if the tendering and selection of manufacturers should be done earlier or if it would be possible to get product manufacturers involved in early planning by other means.

5 DISCUSSION

The case study analysis showed that it was possible to design a project that is contradicting the competition brief by introducing a new system though the brief clearly states that proven systems are preferred. However, the design team has successfully argued that their system is more in line with sustainability than conventional solutions. The used hybrid construction system is based on mechanical metal connectors that allow easy assembly and disassembly and it is the result of tight cooperation between architects and engineers. Though the system has not been used and proven to function well in advance, the joint effort of the architects and engineers is in line with the competition brief where it was claimed that interdisciplinary cooperations are highly appreciated.

The case study project represents design for disassembly (DfD) even though this was not directly required in the competition program. However, the client and the competition organisers could include DfD in the brief to promote material efficiency. DfD improves the possibilities of reusing the materials, as well as the flexibility of the project.

The strategies to promote a circular economy are many and some are easily measurable, which makes it easier to set targets in the project brief that assure circular measures. For example, if the goal is to use secondary materials, an amount of reused or recycled content can be defined in the project brief [8,27]. Setting a low carbon footprint or carbon balance in the brief would, besides promoting secondary materials, also promote the use of renewable and local materials because of their generally lower carbon footprints [8,28–30]. Setting carbon demands that include Module D (Benefits and loads beyond the system boundary) favour the use of bio-based materials such as timber (carbon storage) and DfD that allows easy reuse and value retention of components.

Whereas recycling targets and carbon goals increase the use of materials with low negative environmental impacts, material passports have been identified to promote circularity after deconstruction. Requiring materials passports means encompassing the life cycle of construction materials during the design phase, making it easier to design for reuse and disassembly and to plan the future of the materials in case of deconstruction [11,31]. Reversible design can also be promoted in the early project planning phase by requiring detailed demolition plans in the design phase and mechanical joints in construction.

Defining technical solutions precisely is challenging in the project planning phase, as it complicates the tendering that takes place later in the project. However, in the project planning phase, the pre-fabrication, modularity and repeatability, which have been identified to promote resource efficiency, can be determined to some extent.

Material efficiency can be promoted through technical design but also through high-quality architectural design. Well-designed buildings are more likely to be well taken care of, which prolongs the buildings' lifespan. Architectural quality can be increased by organizing architecture competitions and selecting the most promising plan and design teams. Additionally, designers can promote sustainability by preparing for possible future scenarios by designing buildings that can adapt. Adaptability or flexibility can be considered in the early project planning phase. In apartment buildings, this could be done by requiring plans for how to combine apartments vertically or horizontally, which was done by the architects in the studied case even though it was not required.

This study was based on only one case project. Therefore, the conclusions from this study cannot be generalized and assumed to be valid in all projects. To form a more generalized understanding of how different construction actor-networks can reach ambitious circularity targets a broader data collection and analysis is required. However, there are a limited amount of realized mid-rise timber projects that follow the key principles of a circular economy. In conclusion, the results of this paper should rather be read as indicative than absolute.

6 CONCLUSIONS

The studied case project showed various ways of promoting circular economy in mid-rise timber buildings. Many key aspects of a circular economy were already present in the early project planning phase. This paper set out to investigate how clients can include circularity in project briefs and how these can be met in the final project, who are the key actors to promote circularity in mid-rise timber projects and what resources are needed for the actors to deliver a circular construction project. The main findings are:

- The client can include targets steering towards circular solutions in the project planning phase by writing them into the project brief. Such targets include: flexibility, local and renewable

https://doi.org/10.52202/069179-0150

materials, materials with low embodied energy, robustness against wear and tear, energy-efficiency, sustainability certificates, easy replaceability of components, simple structural solutions and common spaces.

- The identified key actors from the early design phase that are responsible for promoting circular economy are the client, the architects and the engineers.
- The client's role is more passive in the design phase in comparison to those of the architects and engineers but acts like the enabler of circular solutions
- Even though the client can include circularity in the project brief, a competent design team can exceed the targets and deliver more circular solutions
- When realising circular mid-rise timber buildings, previous collaboration between the architects and engineers, experiences with timber buildings and complex buildings, knowledge of LCA, and a deep understanding of circularity in construction are beneficial for the design team.

ACKNOWLEDGEMENT

We would like to acknowledge Antti Tuure, Aku Aspila, Jesse Lietzen and Harri Sivu from the Graduate School of Industrial Timber Construction, as well as professor Sofie Pelsmakers and post-doctoral researcher Jukka Puhto for the questions they raised and the thoughts they shared that helped shape this research.

EFFECT OF RESIN IMPREGNAITON INTO WOOD CELL ON LATERAL RESISTANCE OF SCREWED JOINT CONNECTING SOLID WOOD AND STEEL PLATE

Keita Ogawa[1], Kenji Kobayashi[2], Satoshi Fukuta[3]

ABSTRACT: During lateral loading to dowel-type timber joints, embedment deformation occurs around the contacting parts of dowels and wood. Hence, the embedment properties of wood are vital to the development of joints with high lateral resistance. In this study, the potential of resin impregnation for strengthening the embedment properties is analyzed. A lateral loading test is conducted using a screwed joint connecting solid wood and a steel plate. Resins are impregnated into the cell walls around the screws. Test results indicate that the initial stiffness is twice that of the control specimen. The yield load and maximum load are not significantly affected by the resin impregnation. Additionally, the resin-impregnated specimens indicate brittle fracture and low deformability, particularly in the case involving sapwood screwing.

KEYWORDS: Screwed joint, Lateral resistance, Resin Impregnation, Initial stiffness

1 INTRODUCTION

Owing to increasing interest in large-scale timber buildings, the development of timber joints with higher resistance performance has received significant attention. Dowel-type joints are one of the most general connecting methods used not only in housing, but also in large-scale buildings.

The lateral resistance of the joints significantly affect the seismic performance of buildings constructed using them. When a lateral load is exerted on a dowel-type joint, the dowel locally embeds the wood member around the contact part between the dowel and wood. Therefore, the strengthening of wood against embedment loads is effective for developing joints with higher lateral resistance.

Based on a micro-level observation of wood embedment, embedment can be regarded as the crushing of wood cells (Figure 1), and a method for preventing this crush is desired. In this regard, the authors investigated the potential of resin impregnation [1], which allows the local impregnation of resin into wood cells. If the wood cells around the dowel are filled with resin before the lateral load is applied, then an improvement in the embedment property can be expected.

Previously, the authors attempted to apply resin impregnation techniques to bolted joints [2]. Consequently, the initial stiffness and yield load improved significantly, i.e., by 104% and 73%, respectively. Additionally, the embedment properties of Japanese cedar (*Cryptomeria japonica* D.DON) were revealed using an embedment test [3], i.e., its stiffness improved by 278% and 94% under parallel and perpendicular loading, respectively. Resin impregnation is expected to improve other dowel-type joints.

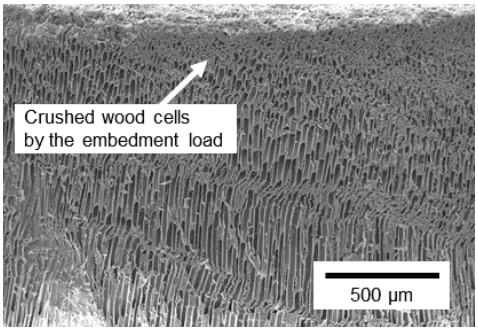

Figure 1: *Crushed wood cells under the embedment load by dowel-type fasteners*

Screwed joints are typically used in modern timber construction. Although the diameter of a screw is smaller than that of a bolt, their main mechanism is similar. In this study, the authors attempted to apply a resin impregnation to a screwed joint. A lateral load test was conducted to evaluate the effects of the impregnation.

2 MATERIALS AND METHOD

2.1 SPECIMEN PREPARATION

A lateral load test with screw joints was conducted based on ASTM D1761-20 [4], as shown in Figure 2. Air-dried

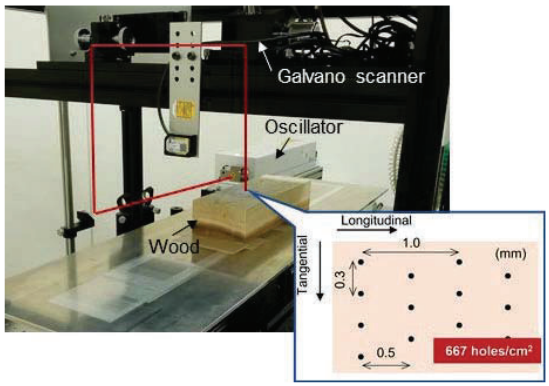

Figure 3: *UV laser incision. Red line shows trajectory of UV laser from oscillator to wood surface*

Japanese cedar (*Cryptomeria japonica* D.DON), a steel plate measuring 2.3 mm thick, a TB-45 screw (Tanaka Co. Ltd.; diameter: 5.1 mm; length: 43 mm) were used. To assemble the joint specimen, Teflon sheets and grease were inserted between the wood member and steel plate to prevent friction [5].

The wood members were treated via resin impregnation on their surfaces. First, microscopic incisions were created using an ultraviolet (UV) laser around the area where the screw was tapped. As shown by the red square in Figure 2, the area measured 30 mm × 30 mm. A diode-pumped solid-state Q-switched laser (Talon355-15SH, Spectra-Physics) was used for laser oscillation, and a Galvano scanner was used to create the incision pattern, as shown in Figure 3. The diameter, depth, and density of the incision were approximately 80 µm, 10 mm, and 667 holes/cm^2, respectively.

Next, the resin was impregnated from the incised area by brush painting operation. Two types of resins were used in this study: acrylic monomers (DIAKITE PE-2730, Toeikasei Co. Ltd.) and urethane prepolymers (PS-NY6, Kotobukikakoku Co. Ltd.); hereinafter, they are referred to as acryl and urethane, respectively. In the case of acryl, 2.2'-azobisisobutyronitrile (0.6 parts by weight) was incorporated as a polymerization initiator; it was heated at 140 ℃ and cured for 30 min. In urethane, the wood members were cured for one week in a testing room. The evaporation residue of urethane was approximately 40%.

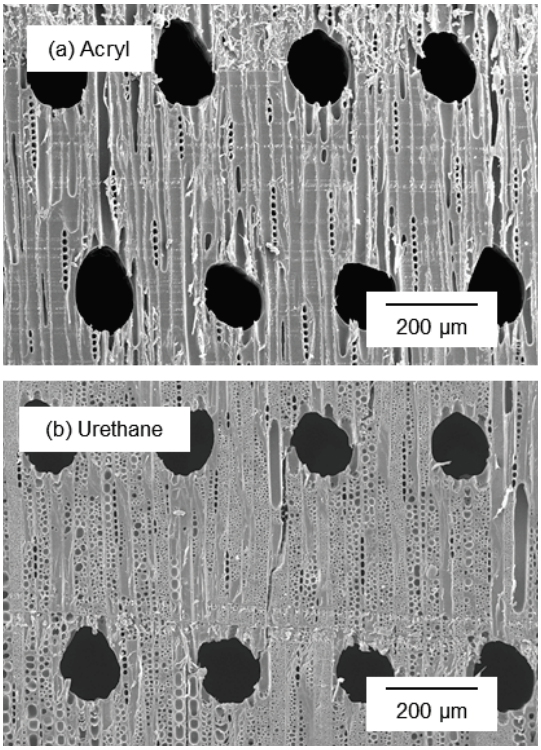

Figure 4: *Holes created using UV laser and resins filled into wood cells*

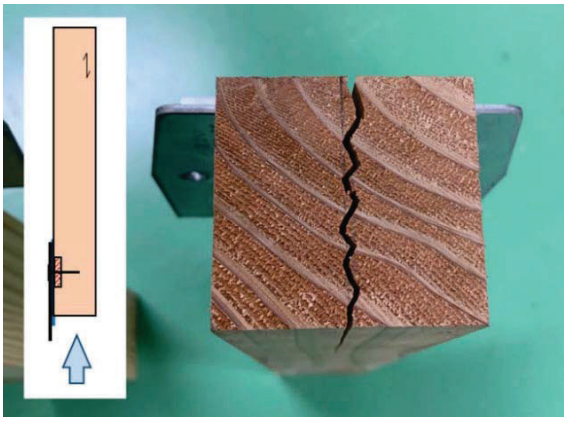

Figure 5: *Crack observed (from blue arrow) at screwing location in test groups with resin impregnation.*

Examples of scanning electron microscopy images are shown in Figure 4. Both images show that the resins filled the wood cells.

The amount of impregnated resin differed for each specimen. As described in our previous study [2], resins impregnate more in sapwood than in heartwood. The specimens used in this study exhibited the same tendency. In one incision area (represented as the red square in Figure 1), 16.32 ± 3.43 g of acryl was impregnated into the sapwood. Subsequently, the amount R per incision volume was calculated as follows:

$$R = \frac{W}{V} = \frac{W}{A \times d}, \quad (1)$$

https://doi.org/10.52202/069179-0151

Table 1: *Number of spesimen for each specimen group*

Group	Resin	Number of speciems			
		Prepared		Tested	
		Heartwood	Sapwood	Heartwood	Sapwood
Control	None	10	8	9	8
Acryl	Acryl	10	8	10	4
Urethane	Urethane	10	8	9	0

where W is the mass of the impregnated resin; V is the incision volume; and A and d are the incision (30 mm × 30 mm) and depth (10 mm), respectively. Using the equation above, the R of acryl impregnated into sapwood was calculated to be 1813 ± 381 kg/m^3, whereas that impregnated into heartwood was 430 ± 413 kg/m^3. Meanwhile, 1971 ± 576 kg/m^3 and 318 ± 2.93 kg/m^3 of urethane were impregnated into the sapwood and heartwood, respectively.

Three testing groups were prepared for this study: two types of resin (acryl and urethane) and a control group. Eighteen specimens were prepared for each group. However, a prominent crack beginning from the screwed point to the bottom face of the wood member occurred in some specimens, as shown in Figure 5. Subsequently, lateral loading tests were halted on the specimens. The replicates for each group are presented in Table 1. Cracks occurred in many specimens of sapwood. This implies that a higher amount of resin impregnation may cause brittleness in wood.

2.2 TESTING METHOD

The lateral loading test was conducted using a universal testing machine (AG-I 250kN, Shimadzu Co., Ltd.), as shown in Figure 6. A steel plate was fixed to the testing machine and an upward load was applied to the wood member. During the test, the load and relative slip between the wood member and steel plate were recorded. A load cell equipped with a testing machine (SFL-50kNAG, Shimadzu Co. Ltd.) was used to measure the load. To measure the relative slip, a displacement transducer (SDP-100CT, Tokyo Measuring Instruments Lab.) was attached to the wood member and the target was attached to the steel plate. The alignment support was adjusted to correct the load axis during the testing.

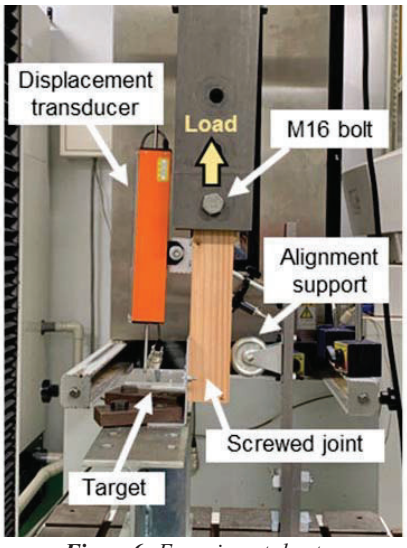

Figure6: *Experimental setup*

3 RESULTS AND DISCUSSIONS

3.1 RELATIONSHIP BETWEEN LOAD AND SLIP

The relationship between the load and slip for each specimen group obtained via the lateral test is shown in Figure 7. For the control group (Figure 7(a)), the load increased linearly with slip at the beginning of testing. When the load reached approximately 1.5 kN, the slope began to decrease. When the slope decreased, the load did not decrease, and most specimens maintained their load until the slip reached approximately 30 mm.

Compared with the control group, acryl and urethane indicated higher slopes at the beginning of the test. However, the load decreased significantly in some specimens after linearity was observed. Cracks occurred from the screwed point to the bottom surface of the wood member. The loads of four of the specimens decreased significantly before the slip reached 5 mm. These specimens were screwed onto sapwood. This result shows that even though cracks did not occur during the joint assembly, the joint was in the limit state of brittle failure. The load of most joint specimens screwed onto the heartwood did not decrease drastically until the slip reached approximately 20 mm.

3.2 CHARACTERISTICS

To evaluate the characteristics of the joint specimens, the relationship between the load and slip was further analyzed using a perfect elasto-plastic model [6, 7]. The method to obtain the characteristic values is explained below and shown in Figure 8. The black line indicates the relationship between the load and slip obtained from the lateral loading test. Here, P_{max} and δ_{max} are the mean maximum load and the slip at the maximum load, respectively. First, a direct line is drawn between $0.1P_{max}$ and $0.4P_{max}$, and between $0.4P_{max}$ and $0.9P_{max}$; the lines drawn for the former and latter are referred to as lines I and II, respectively. Line II shifts until it satisfies the load-slip relationship, and the shifted line is named Line III. Subsequently, a new line parallel to the horizontal axis that passes through the intersection of Lines I and III is

https://doi.org/10.52202/069179-0151

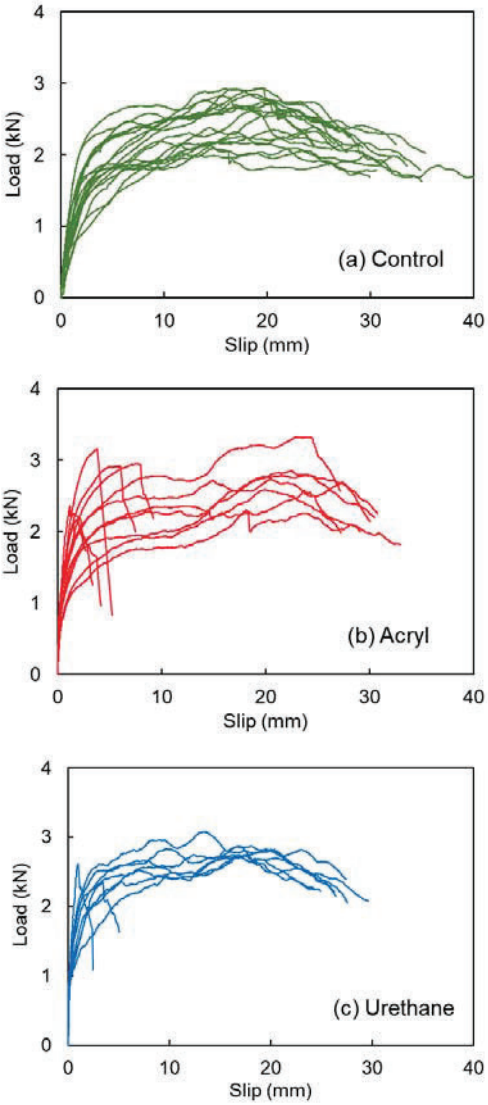

Figure 7: *Relationship between load and slip*

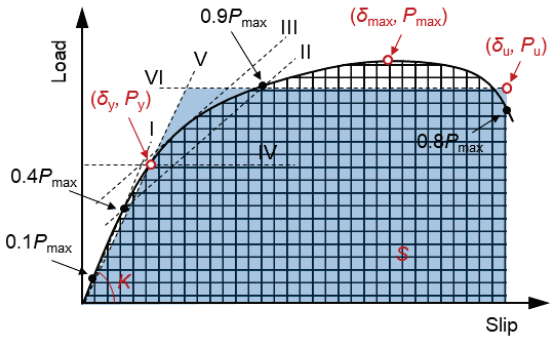

Figure 8: *Perfect elasto-plastic model [7]*

drawn and named Line IV. The intersection of Line IV with the load-slip relationship is regarded as the yield point, and the abscissa and ordinate of the point are the slip at yielding δ_y and the yield load P_y, respectively. The line connecting the origin and yield point is named Line V, and the slope of Line V is regarded as the stiffness K. Next, the slip at the ultimate load δ_u is determined as the abscissa of a point when the load is decreased to $0.8P_{max}$ after surpassing the maximum load. If the load does not decrease until the slip reaches 30 mm, then $\delta_u = 30$ mm is used instead of the point at $0.8P_{max}$. Subsequently, the energy based on the load-slip relationship from the origin to δ_u (hatched region in Figure 8) is determined and denoted as S. Next, a line parallel to the horizontal axis, named Line VI, is drawn such that the area of the trapezoid, which comprises Line V, Line VI, the horizontal axis, and the line $X = \delta_u$ (blue region in Figure 8), is equivalent to the energy S. The ordinate of Line VI is regarded as the ultimate load P_u. The characteristics obtained using the model are listed in Table 2.

The most improved characteristic owing to resin impregnation was the initial stiffness. Whereas the initial stiffness of the control was 0.75 kN/mm, those of acryl and urethane were 1.57 and 2.01 kN/mm, respectively. This implies that the initial stiffness was more than doubled by the resin impregnation. Table 2 shows similar average values for the parameters related to the load, i.e.,

Table 2: *Characteristics obtained using perfect elasto-plastic model*

Group		P_y (kN)	δ_y (mm)	K (kN/mm)	P_{max} (kN)	δ_{max} (mm)	P_u (kN)	δ_u (mm)
Control	Average	1.60	2.47	0.75	2.50	17.78	2.27	30.06

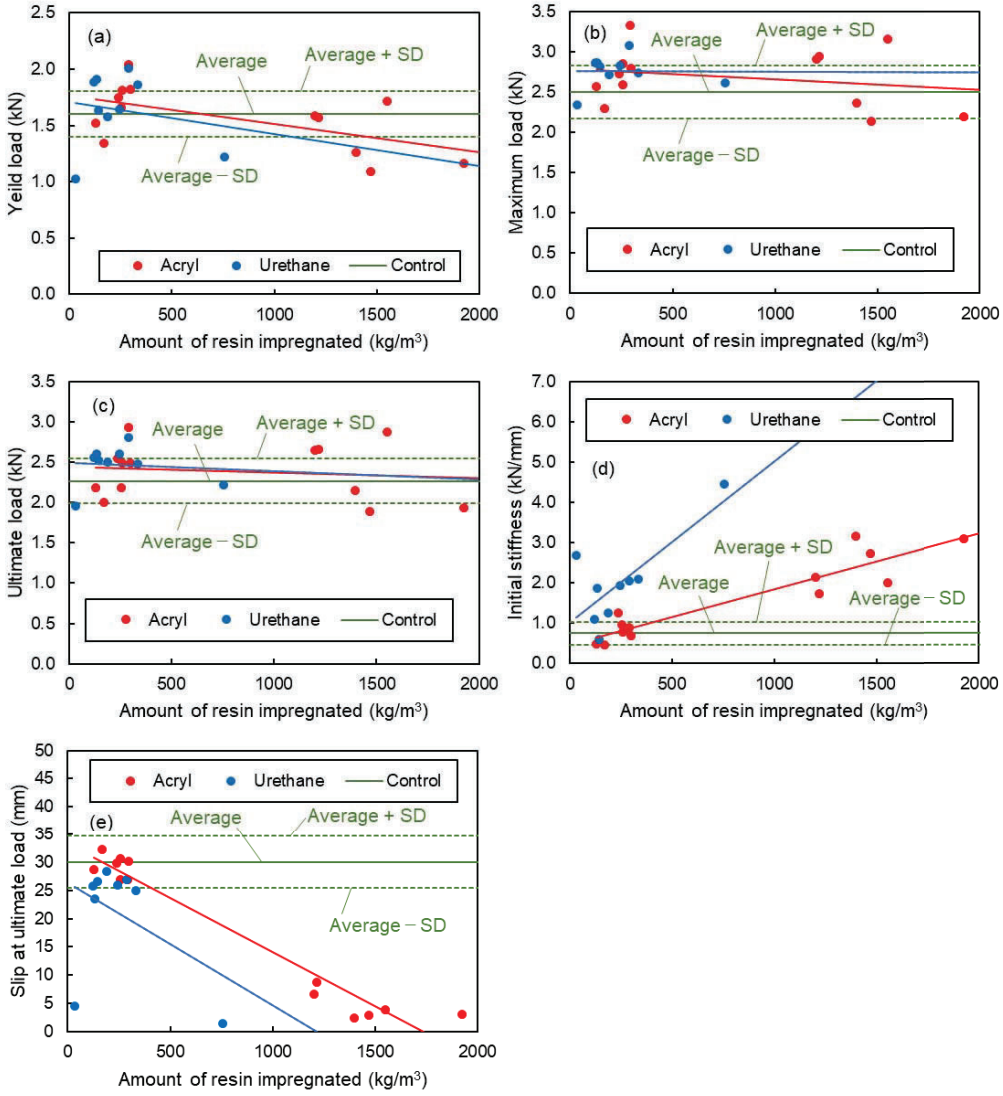

Figure 9: *Relationship between characteristics and amount of resin impregnated*

the yield load, maximum load, and ultimate load. In summary, resin impregnation can improve the lateral resistance of the joint; however, the effect was limited to the range of small slips. Meanwhile, the values of parameters related to deformation, such as slip at yielding, slip at the maximum load, and slip at the ultimate load, decreased due to resin impregnation. This shows that resin impregnation results in decreased deformability. The result indicating the increasing brittleness of the joints is a critical issue that must be addressed closely.

3.3 INFLUENCE OF AMOUNT OF IMPREGNATED RESIN ON CHARACTERISTICS

As described in Section 2.1, the amount of impregnated resin differed between sapwood and heartwood. In this section, the effect of the amount of impregnated resin on the characteristics of sapwood and heartwood is discussed.

Figure 9 shows the relationship between the characteristics and amount R of impregnated resin calculated using Equation (1). The characteristics related to the load, yield load, maximum load, and ultimate load are shown in this figure. Figure 9(a) shows that the yield load decreased as the impregnated resin increased. Specimens with a higher amount of impregnated resin exhibited higher brittleness, and micro-level cracks were assumed to have occurred in the small slip. Meanwhile, the maximum and ultimate loads decreased slightly (as shown in Figures 9 (b) and (c), respectively), as the amount of impregnated resin increased.

As described in the previous section, resin impregnation significantly affected the initial stiffness. Based on Figure 9(d), the initial stiffness increased with the amount of impregnated resin. When a low amount of acryl (less than 500 kg/m^3) was impregnated, the initial stiffness did not differ significantly from that of the control. In specimens with a high amount acryl (more than 1000 kg/m^3), the

initial stiffness increased significantly. Meanwhile, the impregnation of a low amount of urethane resulted in a higher initial stiffness.

To investigate the deformability, the authors examined the relationship between the slip at the ultimate load and the amount of impregnated resin (see Figure 9(e)). In both resins, the slip at the ultimate load decreased as the impregnated amount increased. The specimens with small amount, slip at ultimate load was almost similar with control specimens. In specimens with a high amount of resin (more than 500 kg/m^3), a decrease in slip was clearly observed.

4 CONCLUSION

In this study, the effect of resin impregnation on the lateral resistance of screwed joints connecting wood and steel plates were investigated. Screwed joint specimens impregnated with acryl- and urethane-type resins were tested via lateral loading tests, and the results obtained were compared to those of the control specimen.

A significant improvement in the initial stiffness was indicated. Based on the average value, the initial stiffness more than doubled owing to resin impregnation. For the case of acryl impregnation, the initial stiffness of the specimen was higher than that of the control specimen when the impregnated amount was high. For the case of urethane, the specimen indicated a higher initial stiffness was observed even if the impregnated amount was low.

Additionally, resin impregnation resulted in decreased deformability. When the amount of impregnated resin exceeded 500 kg/m^3, the slip at the ultimate load became much lower than that of the control. The result indicating the increasing brittleness of the joints is a critical issue that must be addressed.

STRUCTURAL PERFORMANCE OF GLULAM TIMBER-STEEL BRACE CONNECTIONS REINFORCED WITH SELF-TAPPING SCREWS

Thomas Breijinck[1], Joshua Woods[2], Colin MacDougall[3]

ABSTRACT: Modern mass timber braced frames rely on connection yielding to provide ductility and energy dissipation capacity under earthquake loads. However, the ductility and energy dissipation capacity of steel dowel connections can be limited by the onset of a brittle failure mechanism in the timber (e.g., row-shear, group tear-out, or tension failure) prior to significant dowel yielding. To address this challenge, this paper presents experimental results on the structural performance of timber-steel dowelled connections reinforced with self-tapping screws. Four full-scale connections were tested under monotonic loading with and without reinforcing screws. The tested connections had two internal steel plates that were fastened to the timber using steel dowels. The unreinforced connection was intentionally designed to exhibit a brittle row shear failure prior to yielding of the steel dowels. Results of the study demonstrated the brittle nature of row shear in timber connections and the potential for using self-tapping screws to promote a more ductile failure. While the unreinforced connections exhibited no ductility, the reinforced connections had an average ductility of 4.8. Overall, results of this study demonstrate the potential for using self-tapping screws to retrofit and reinforce a timber-steel brace connection for situations in which a connection may be predisposed to brittle row shear failure.

KEYWORDS: Mass timber, connections, internal steel plates, self-tapping screws, row shear, ductility

1 INTRODUCTION

In the last twenty years, the use of mass timber in mid-rise and high-rise buildings has increased dramatically and is expected to continue to grow in the coming decades [1]. In Canada, the maximum permissible height for mass timber buildings was recently increased to 12 storeys, which is expected to continue to fuel this demand [2]. However, as the height of tall mass timber buildings increases, so does the demand on the structural elements, requiring larger section sizes and higher-capacity connections to safely transfer loads to the structure's foundation. These connections are also key elements of a structure's seismic force resisting system (SFRS), which must be designed to have sufficient ductility in the event of a design-level earthquake. A European study analysing failures in 127 timber structures found that about one quarter of collapses occurred as a result of connection failure, more than half of which occurred in dowel-type connections [3].

One commonly used SFRS for tall timber structures are braced frames. In the seismic design of mass timber braced frames, the brace connections are typically designed to act as fuses, yielding during a large earthquake, dissipating seismic energy, and protecting surrounding structural elements. A common connection detail used in mass timber braced frames involves the use of steel dowel-type fasteners (e.g., bolts, dowels, or drift pins) in combination with steel plates that are inserted into slots in the timber. This type of connection is appealing because high strength and stiffness can be achieved by incorporating multiple slotted-in steel plates, and these plates are inherently protected from fire by the surrounding timber.

Under axial load, these connections can experience a variety of failure modes, including ductile failure through yielding of the steel fasteners and brittle failure of the timber member. Brittle failure modes include fracture over the net section, row shear failure, or group tear-out. In the design of these connections for tall timber frames, which require high-strength brace connections, one convenient approach to increase capacity is to introduced multiple slotted-in steel plates into the connection. However, this reduces the dowel bending length and results in the potential for brittle shear failure (e.g., row shear or group tear-out) with little-to-no ductility if careful attention is not paid to the design and detailing of the connection.

In the literature, there are few reported experiments on timber connections with multiple slotted-in steel plates and dowel-type fasteners tested at scales required for tall timber structures. Furthermore, there is an increasing need to better understand the behaviour of brittle failure modes in these connections and to develop novel strengthening approaches to improve their seismic performance, including ductility and energy dissipation capacity. One such approach that has been proposed in the literature but not studied in large-scale timber brace connections with

slotted-in steel plates is the use of self-tapping screws as reinforcement. This study aims to address these knowledge gaps through experimental testing of four full-scale glulam timber connections with multiple slotted-in steel plates both with and without reinforcement under monotonic loading. The specific objectives of this study are to: (i) study brittle failure mechanisms in a full-scale timber connection with slotted in steel plates, (ii) determine if the use of self-tapping screws can prevent brittle failure in the tested connection and improve ductility and energy dissipation capacity, (iii) study the influence of end distance on the connection behaviour and the performance of the screw reinforcement.

2 BACKGROUND

There have been few studies reported on glulam timber connections for a multi-storey mass timber braced frame with multiple slotted-in steel plates and tested experimentally at full-scale. Several researchers have investigated the performance of small-scale timber-steel connections with a single slotted-in steel plate [4-8]. These studies have shown that the connection ductility depends largely on the connection geometry, fastener spacing, and material properties of the timber. A study by Yurrita et al. [9] examined the potential for brittle failure in large-scale pine glulam and laminated veneer lumber connections with two slotted-in steel plates and nine steel dowels. Fastener spacing and timber thickness were varied, and the results showed that block shear, row shear, net tension, and a combination of block and net shear failure were the observed failure mechanisms.

To determine the potential contribution of self-tapping screws to connection strength and ductility, Piazza et al. [10] tested timber-to-timber self-tapping screw connections with several orientations relative to the shear plane. The results found that that increasing the installation angle of the screw from 0° to 45° improved the load capacity and stiffness of the tested connections. Some researchers have also used reinforcing screws in timber connections with slotted-in steel plates and dowel-type fasteners to prevent brittle failure. In some connections tested by Dorn et al. [11], a clamp was used to simulate the reinforcement provided by self-tapping screws and the results showed the potential for improvements in strength and ductility. Lathuillière et al. [12] tested bolted moment-resisting connections reinforced with self-tapping screws under shear and moment. Although the connections did not simulate a brace connection under direct axial tension, the results did show that reinforcement through self-tapping screws was effective at controlling crack propagation and improving connection ductility.

Studies on small-scale timber connections reinforced with self-tapping screws have also been carried out. Zhang et al. [13] tested small-scale single dowel connections with a single slotted-in steel plate under direct axial tension. The results once again showed potential for reinforcing screws to improve connection ductility.

3 EXPERIMENTAL PROGRAM

The experimental program described in this paper consisted of 4 tests performed on full-scale glulam timber connections with multiple slotted-in steel plates and steel dowel-type fasteners. The specimens included two control connections (without reinforcing screws) and two reinforced connections. Other investigated parameters included the loaded end distance.

3.1 TEST SPECIMENS

Figure 1 shows the geometry of the slotted-in steel plate connections tested in this study. The glulam timber member measured 266 × 265 × 1300 mm. The holes and slots in the glulam member were fabricated using a computer-numerical control (CNC) machine. At one end, each glulam member had two 12 mm wide slots and 6 – 16 mm (5/8”) holes perpendicular-to-grain, for the installation of the steel dowels. At the opposite end of the connection, 16 – 22 mm (7/8”) diameter holes 310 mm (12”) long were drilled in the parallel-to-grain direction for a glued-in-rod connection used to fix the specimen to the test frame, which was fixed to the laboratory floor.

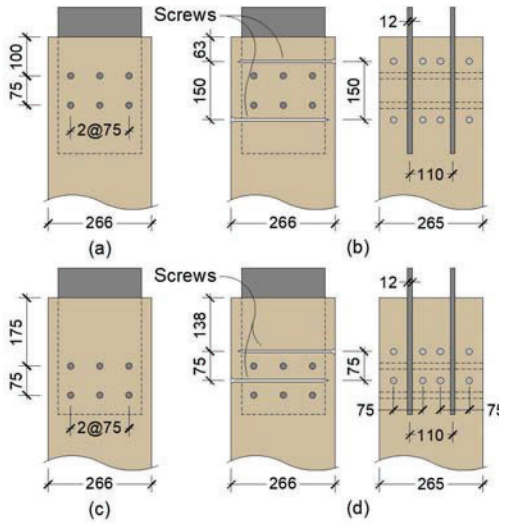

Figure 1: *Tested connections with slotted-in steel plates: (a) C100, (b) C100-R, (c) C175, (d) C175-R*

The tested connection included two 12 × 214 mm internal slotted-in steel plates. The slotted-in steel plates were connected to the timber using 16 mm diameter (*d*) steel dowels that were 266 mm long. The connection, based on the geometry in Figure 1, has a slenderness ratio (λ) of 6.9 (110/16 = 6.9), calculated as the ratio of the thickness of the timber (*t*) between the slotted-in steel plates (110 mm in Figure 1) divided by the dowel diameter (*d*).

Connection tests included those with and without self-tapping screws. The two control connections (without reinforcing screws) were denoted C100 and C175, in which the ‘100’ or ‘175’ is the loaded end distance in each

https://doi.org/10.52202/069179-0152

connection. The two other connections had identical geometry to the control connection but were reinforced with self-tapping screws. These connections are referred to as C100-R and C175-R in this paper.

All connections with screw reinforcement had 8 - 250 mm long fully threaded 11 mm diameter Rothoblaas VGS 9380 self-tapping screws with a countersunk head. The screws were installed in pre-drilled holes measuring 6.35 mm (1/4") in diameter, according to the manufacturer's recommendations [14]. Figure 1 shows the configuration of the screws in the reinforced connections. The goal of this screw orientation was to strengthen the shear failure plane and arrest crack development in the direction of the load. Connection C100-R was reinforced with 4 screws across the shear plane and an additional 4 screws outside the loaded end to prevent timber splitting along the length of the member, which was observed in previous tests. In connection C175-R, 8 screws were placed across the shear plane, to examine the influence of additional screws on connection stiffness, strength, and ductility.

3.2 MATERIAL PROPERTIES

The glulam connections were fabricated of 24f-ES Spruce-Pine-Fir (SPF) glulam supplied by Nordic Structures and produced as per CSA O177-06 [15], as specified by CSA O86-19 *Engineering Design for Wood* [16]. This glulam grade has a density of 560 kg/m^3, a mean relative density (G) of 0.47, and a moisture content of 12%. Typical design characteristics are a modulus of elasticity of 13.1 GPa, a parallel-to-grain tension strength of 20.4 MPa, and a shear strength of 2.5 MPa [17].

The material properties of the steel dowels were determined by conducting direct tension tests on three coupons according to the guidelines in ASTM E8 [18]. Figure 2 shows the stress-displacement response of the dowels used in this study. The 16 mm dowel had an average yield strength, determined using the 0.2% offset method, of 825 MPa and an ultimate strength of 946 MPa. The Rothoblaas VGS 9380 reinforcing screws have a manufacturer's reported characteristic yield moment of 45.9 N-m and a yield strength of 1000 MPa [14].

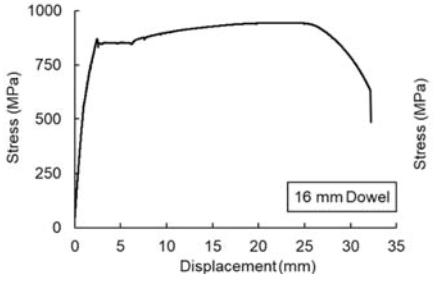

Figure 2: *Stress-displacement behaviour of steel dowel*

3.3 CONNECTION STRENGTH

Prior to the experimental testing, calculation of connection capacity was carried out according to the Canadian Wood Design Standard (CSA O86-19). Table 1 summarizes the calculated resistances of each connection for each failure mode. Additional information on these design calculations is available in [16]. Based on the design provisions in CSA O86-19, the unreinforced connections were expected to fail in brittle row shear Furthermore, the ratio of brittle to ductile failure (φ), taken as the row shear strength divided by the yield resistance, was approximately 0.6 for all of the tested connections. The reinforced connections had additional capacity against row shear and group tear-out because of the self-tapping screws. The results in Table 1 suggest that connection C100-R is still susceptible to row shear failure (φ = 0.9) while connection C175-R had yielding of the steel dowels as a predicted failure mode (φ = 1.2), and thus, was expected to exhibit the highest ductility amongst the tested connections.

Table 1: *Connection design strength*

Specimen	*Net Tension* (kN)	*Row Shear* (kN)	*Group Tear-out* (kN)	*Yielding* (kN)
C100	1071	304	684	501
C100-R	1071	446	826	501
C150	1071	304	684	501
C150-R	1071	589	969	501

3.4 EXPERIMENTAL TEST SETUP

Figure 3 shows the experimental setup for the connection tests. The connections were tested under direct axial tension. At one end of the timber member, a 1350 kN hydraulic actuator was used to apply the load, to which a steel double lap splice connection was used to connect the actuator to the slotted-in steel plates in the timber connection. The slotted-in steel plates were bolted to the actuator connection using two 25.4 mm (1") diameter high-strength (Grade 12) steel bolts.

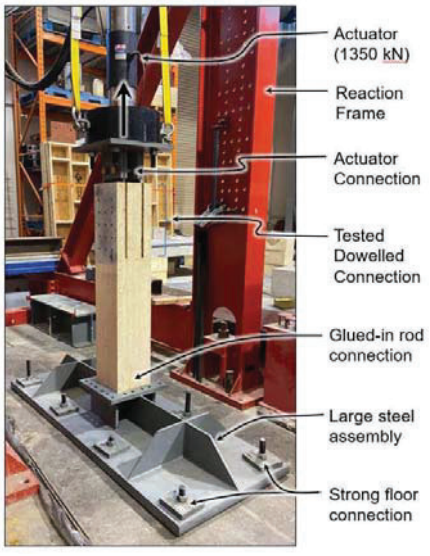

Figure 3: *Experimental test setup*

The connection was fixed to the lab strong floor using a large steel assembly that included a 50.8 mm (2") thick base plate and was connected to the laboratory strong floor using 8 – 28.1 mm (1.5") diameter B7 threaded rods. The timber connection was attached to the steel assembly using a glued-in-rod connection, which was intentionally overdesigned to ensure it remained elastic during the test. The glued-in-rod connection consisted of 16 – 19.1 mm (3/4") threaded rods embedded 305 mm (12") into 22 mm (7/8") holes in the glulam timber. The rods were glued in the timber using Sikadur-35 Hi-Mod LV, which is a two-part high modulus and strength, low-viscosity epoxy resin intended for grouting bolts or dowels in wood [19]. According to the manufacturer, the epoxy has a modulus of elasticity of 2.41 GPa, a tensile strength of 58 MPa, and an elongation at break of 4.2% [19].

3.5 TEST PLAN AND INSTRUMENTATION

The connections were tested under monotonic loading at a constant rate of 1 mm/min up to failure. Figure 4 shows the instrumentation used to measure the response of the connections during the test. The connection deflections were measured using nine linear potentiometers (LPs). Four LPs were installed at the top and bottom of the connection on opposite faces. These LPs were used to measure the displacement of the glued-in rod and actuator connections. Two string potentiometers (SPs) were also used to measure the displacement of the connection. The SPs were affixed beneath the dowelled connection and connected to the underside of the steel plate connected to the actuator. A 2000 kN load cell connected to the hydraulic actuator was used to measure the load applied to the connection during each test. The data was collected at 1 Hz for each test.

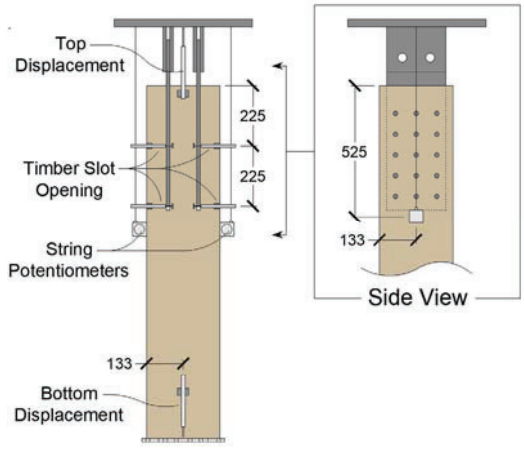

Figure 4: *Typical connection instrumentation*

4 RESULTS AND DISCUSSION

Figure 5 shows the connection force-displacement behaviour, measured using the SPs (see Figure 4) and Table 2 shows the structural response parameters for each connection, including the yield displacement, ultimate load, and ultimate displacement. It is noted that the ultimate displacement was determined as the displacement after the load dropped 20% from the ultimate load. In addition, to assess the potential for the use of self-tapping screws to improve the seismic performance of timber-steel connections, Table 2 also shows the displacement ductility of the connections, which was determined as the ratio of the yield displacement to the ultimate displacement ($\mu_\Delta=\Delta_u/\Delta_y$).

Table 2 *Structural Response Parameters*

Specimen	Δ_y (mm)	P_u (kN)	Δ_u (mm)	μ_Δ (mm/mm)
C100	-	730	2.4	-
C100-R	4.0	671	14.5	3.6
C150	-	692	5.2	-
C150-R	5.3	715	31.8	6.0

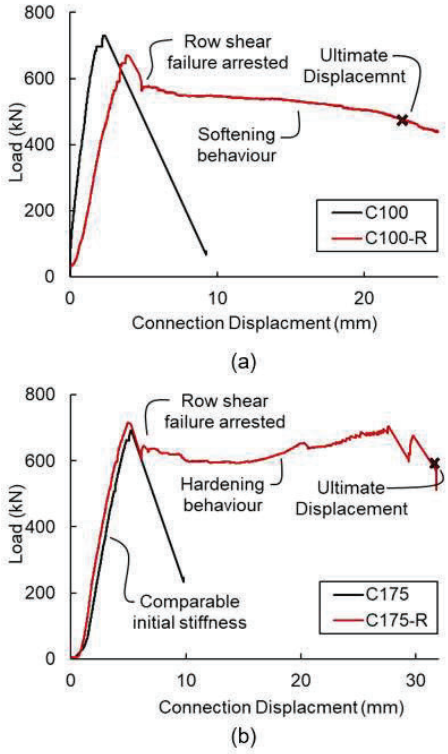

Figure 5: *Connection force-displacement behaviour (a) C100 and C100-R, (b) C175 and C175-R*

4.1 UNREINFORCED CONNECTIONS

The force-deformation responses in Figure 5 show that both unreinforced connections fail in sudden and brittle row shear failure, and as a result, had no ductility. Comparing peak load, the unreinforced connections had an average strength of 711 kN, and the strength of C100 was approximately 5% larger compared with connection C175. The ultimate displacements of the connections were 2.4 and 5.2 mm, respectively, demonstrating the

https://doi.org/10.52202/069179-0152

high stiffness exhibited by these connections as well as the potential for very brittle failure if careful attention is not paid to their detailing during design.

Figure 6 shows the row shear failure for connection C100, which was similar to that of C175. The result shows the formation of a distinct shear failure plane for each row of fasteners. In some cases, timber 'plugs' protrude from the specimen along the shear failure plane. Distinct timber plugs were generally observed in the central portion of the connection (between the steel plates), in which the dowel is supported by the slotted-in steel plate on either side. In the timber side members, the row shear failure plane formed as either a timber plug or as a single splitting crack through the centre of the holes, depending on the row of fasteners in the connection.

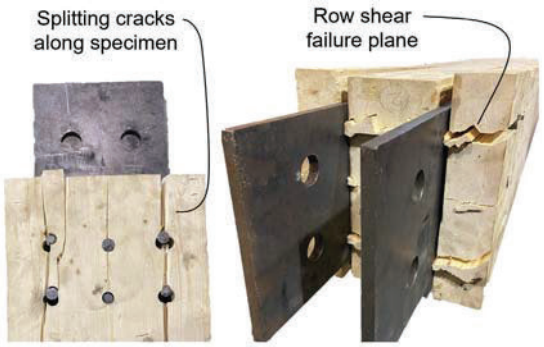

Figure 6: *Row shear failure of connection C100*

Comparing the strength of the unreinforced connections with the design values according to the Canadian Wood Design Standard (CSA O86-19), the results show that the code did correctly predict the mode of failure. However, the observed row shear strength of connections C100 and C175 were 2.4 and 2.3 times greater than the predicted design strengths, respectively. The main difference between connections C100 and C175 was the loaded end distance, which were 100 mm and 175 mm respectively. Despite the increase in loaded end distance, connection C100 had a row shear strength that was within 5% of C175. This suggests that the code requirement that the minimum of the loaded end distance and fastener spacing is an adequate approach to calculating the row shear capacity of the connection. Despite the fact that these design values are based on the characteristic strength of the timber, the results do suggest that current provisions in CSA O86-19 for large timber-steel connections with multiple slotted-in steel plates may be conservative.

4.2 REINFORCED CONNECTIONS

Figure 5 compares the response of the connections reinforced with self-tapping screws with their respective controls. Overall, the results show that the self-tapping screws were effective at altering the behaviour of the connections and preventing sudden and brittle row shear failure. The reinforced connections had ultimate strengths that were within 10% of their respective controls, suggesting that the presence of the self-tapping screws did not have a significant effect on the connection strength. Furthermore, the results also show that the addition of the self-tapping screws also did not have a significant effect on the stiffness of the connections. This could be attributed to the fact that the self-tapping screws were not installed directly adjacent to the fasteners, something that is commonly done in practice. Despite not having a large influence on strength or stiffness, the addition of the self-tapping screws did result in large increases in ductility, as connections C100-R and C175-R had a displacement ductility of 3.6 and 6.0, compared with the unreinforced connections which did not exhibit any ductility. The connections also exhibit large increases in dissipated energy of 22.2 kN-m and 18.3 kN-m, for connections C100-R and C175-R, respectively, which is 5.67 and 7.30 times higher than their respective control connections.

With respect to observed behaviour, Figure 7 shows the failure mode for connection C100-R. At a displacement of approximately 4 mm, connection C100-R experienced a small drop in load carrying capacity (~15% from the maximum load), highlighted on Figure 5, which corresponded to the initiation of a row shear failure in the timber. However, the presence of the reinforcing screws effectively prevented propagation of the shear failure plane to the edge of the timber, which is highlighted in Figure 7(a), which prevented further drop in load carrying capacity.

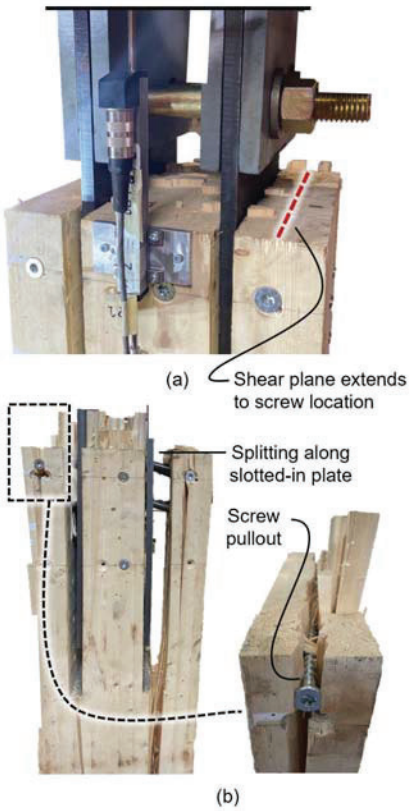

Figure 7: *Glulam timber test specimen*

After the initial drop in load carrying capacity, the force-displacement response of the connection shows a post-peak plateau up to approximately 20 mm, during which the load dropped by 20%. Beyond 25 mm of displacement, the connection exhibited gradual softening to a displacement of 75 mm, at which point the connection was able to carry 15% of its peak load carrying capacity and did not experience any sudden drops in load carrying capacity, and the test was stopped. Gradual softening of the connection was attributed to embedment failure of the self-tapping screws, shown in Figure 7(b), which occurred parallel to the load in a crack along the row of fasteners. Under increasing displacement, the screws (as well as the dowels) were forced out of the splitting cracks in the timber, resulting in a gradual loss in load.

Connection C175-R, which had 8 screws providing additional row shear reinforcement had comparable behaviour to connection C100-R up to the peak load, but the post-peak response was markedly different. Figure 8 shows the failure mode for connection C4-6R. At the peak load, the force deformation behaviour showed a ~15% drop in load carrying capacity which, similar to connection C100-R, corresponded to the formation of a shear failure plane parallel to the load, identified in Figure 8(a). Comparing the deformation patterns in Figure 7(a) and 8(a), the results show indicate that the damage to connection C175-R was much smaller when compared with connection C100-R, which is likely the result of the additional reinforcing screws.

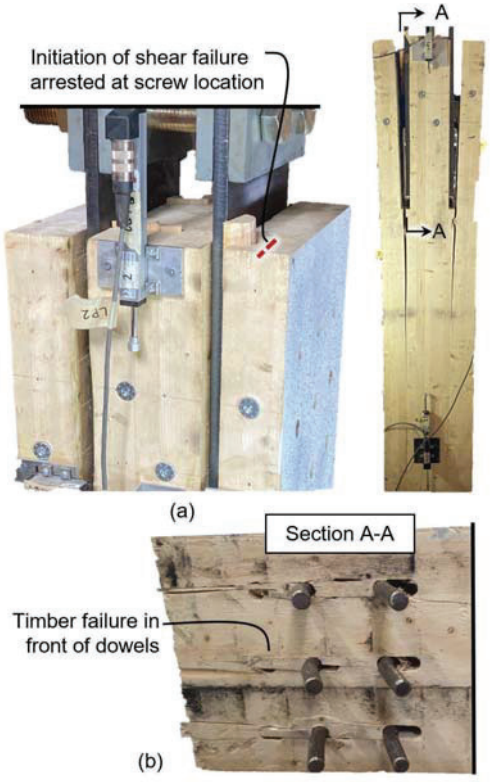

Figure 8: *Glulam timber test specimen*

Examining the force deformation response of connection C175-R in Figure 5, the results once again show that the reinforcing screws were effective at preventing brittle row shear failure of the connection and the force-deformation response shows a relatively constant post-peak plateau following the initial drop in strength up to a connection displacement of approximately 15 mm.

At displacements beyond 15 mm, C175-R shows a hardening response, characterized by an increase in stiffness and strength up to a local maxima of 703 kN, representing 96% of the maximum load, at a connection displacement of 27.5 mm. This behaviour is attributed to interaction between the self-tapping screws and the steel dowels, which come into contact with one another once significant dowel bending has occurred. Eventually, splitting along the length of the slotted-in steel plates resulted in the timber side members separating completely from the main timber member between slotted-in steel plates, shown in Figure 8(b), causing a drop in load carrying capacity of 20% from the peak load. It is worth noting that even after failure of the timber side members, the main member was still capable of carrying over 500 kN of load (roughly 70% of the ultimate capacity).

5 CONCLUSIONS

The goal of this research project was to study the behaviour of large-scale timber-steel connections with multiple slotted-in steel plates and dowel type fasteners prone to brittle row shear failure and investigate the potential use of self-tapping screws to improve their ductility and energy dissipation capacity. The study included tests on 4 large-scale connections under axial monotonic loading. The following specific conclusions are drawn:

1. Connections tested without reinforcing screws failed in sudden and brittle row shear failure with no ductility and little-to-no energy dissipation capacity. The larger loaded end distance in connection C100 was not found to have an influence on the load carrying capacity of the connection.
2. The CSA O86-19 design standard was found to be able to determine the mode of failure in the connections tested without reinforcing screws, however, the standard over-predicted the row shear strength of the connections by 2.3 times on average.
3. The use of self-tapping screws was found to be an effective approach for preventing premature row shear failure and shift the failure mode, permitting a more ductile response. The studied connections with 4 and 8 reinforcing screws had displacement ductilities of 3.6 and 6.0, respectively, a significant improvement in performance when compared to the connections tested without reinforcing screws.
4. The use of self-tapping screws was also found to increase the energy dissipation capacity of the connections by 5.67 and 7.30 times for connections

https://doi.org/10.52202/069179-0152

C2-6R and C4-6R, respectively, compared with the control connections without reinforcing screws.

Overall, the results suggest that timber-steel connections with multiple slotted-in steel plates have the potential to meet the large force demands required for tall mass timber braced frames. However, careful attention must be paid to ensure the connections are detailed to prevent brittle row shear failure. Furthermore, in connections that may be prone to brittle shear failure, results of this study show that the use of self-tapping screws is a feasible approach to shifting the failure mode to a more ductile failure with additional energy dissipation capacity. However, more testing on large-scale connections with varying geometry, dowel slenderness ratio, and self-tapping screw configurations is required.

PREDICTION OF WITHDRAWAL STIFFNESS OF SELF-TAPPING SCREWS

Md Abdul Hamid Mirdad[1], Jan Niederwestberg[2], Arman Jucutan[3], Ying Hei Chui[4]

ABSTRACT: Self-tapping screw is a new generation of fasteners which is often inserted into the face of timber members at an angle to develop stiff and strong connections. The withdrawal stiffness of self-tapping screws is an important property that influences the performance of the connection. The designs of composite timber hybrids incorporating inclined self-tapping screws, such as timber-concrete and timber-steel, can be governed by the stiffness of their connections, which is in turn influenced by the fastener withdrawal stiffness. This study proposes empirical equations for directly predicting the withdrawal stiffness of the self-tapping screws, based on wood density, fastener diameter, insertion angle and penetration length. These empirical equations were developed based on an analysis of withdrawal test data from several test programs, covering two wood species and two screw diameters. They could be used in conjunction with appropriate models to predict the stiffness of connection containing self-tapping screws inserted at an angle to the wood member surface.

KEYWORDS: Withdrawal stiffness, Non-linear regression, Self-tapping screw, Insertion angle

1 INTRODUCTION

Self-Tapping Screw (STS) is an improved threaded fastener specifically developed for mass timber and is the key factor contributing to the emergence of modern tall mass timber structures. STS mostly features a continuous thread over the whole or partial length leading to a uniform load transfer between the screw and the wood material specifically under withdrawal action while the special self-drilling tip helps to avoid pre-drilling in timber members [1, 2, 3]. Many experimental and theoretical studies of STS connections conducted in timber-to-timber, steel-to-timber and concrete-to-timber have concluded that there is a substantial increase in the strength and stiffness of the STS connection if the screws are installed at an angle (e.g., 45° or 30°) to the surface of the timber member, instead of normal (90°) to the surface [4, 5, 6, 7, 8]. Stiffness of connections is a critical design property that governs the structural performance of timber structures, such as drift of lateral load resisting system, deflection of composite systems under gravity load and dynamic response of structural systems. Despite this, it is a property that is not given much attention in timber design standards compared to strength properties [9, 10, 11]. Withdrawal stiffness is an important input parameter for the evaluation of connection stiffness containing the self-tapping screws, which are measured by conducting tests following standards, such as ASTM D1761-12 [12] and EN 1382 [13]. There is currently limited information in timber design standards on withdrawal stiffness properties to allow designers to utilize any analytical solutions to calculate connection stiffness containing self-tapping screws. Therefore, in this study, withdrawal test data were accumulated from various studies and non-linear regression analyses were performed to derive equations for predicting the withdrawal stiffness of STS, based on wood density, fastener diameter, and angle.

2 WITHDRAWAL TEST

Withdrawal tests of the screws from timber at various angles to the grain were performed according to EN 1382 [4] procedure to evaluate the withdrawal stiffness. With this test setup, the measured withdrawal deformation includes both slips between the wood and screw and the axial elongation of the screw. Fully threaded self-tapping screws with a countersunk head and self-drilling tip were selected. Two screw diameters of 9 and 11 mm from a single manufacturer were tested at five different insertion angles, 0°, 30°, 45°, 60° and 90°. Wood specimens were cut from spruce-pine-fir (SPF) and Douglas fir (DF) Glued Laminated Timber (GLT). Two penetration lengths were studied for each combination of screw diameter and insertion angle. Five replicates were used for each combination of parameters, giving a total of 100 withdrawal tests. The mean density of the SPF and DF woods were 429 kg/m^3 and 533 kg/m^3 respectively. The mean moisture content of SPF and DF woods was 8.3% and 9.2% respectively based on measurements using an electrical resistance moisture meter. Each wood specimen was pre-drilled with a diameter equal to the shank diameter of the screws to avoid any splitting. In each wood specimen, three screws were placed on one side and two on the opposite side at 10d spacing to reduce the amount of wood specimen preparation. The spacing of the fasteners meets the requirement of EN 1382 [13], to avoid any splitting and optimize the wood-effective areas. It should be noted that the wood members were cut to allow the load to be applied which simulates the withdrawal of a screw in a connection when it is inserted at an angle to the wood member surface. A typical withdrawal test setup at a 45° insertion angle is shown in *Figure 1*.

The test specimen was first attached to a 75 mm thick steel plate with a 20 mm hole that was created to accommodate different screw diameters. The steel plate was anchored to

the laboratory floor. The screw head was then locked to a 50 mm thick steel plate which was attached to the actuator of the test machine. Two Linear Variable Differential Transformers (LVDTs) were attached to the same steel plate which was connected to the test jack to measure the relative displacement between the two steel plates. The tests were conducted at a constant displacement rate of 1.5 mm/min. The load and displacement were recorded during the test and the test was stopped after the withdrawal failure of the screw from the wood. The slope of the load-displacement response at between 10% and 40% of the maximum load was used to calculate the stiffness. The withdrawal stiffness, K_{ax} in N/mm^3, was calculated using equation (1).

$$K_{ax} = \frac{S}{\pi d l_e} \quad (1)$$

where S is the slope of load-displacement response between 10% and 40% of the maximum load (N/mm), d is the nominal thread diameter of the screw (mm) and l_e is the effective penetration length (mm) excluding the length of the tip.

Figure 1: *Withdrawal test of screws at 45 °angle to timber grain*

Table 1: *Withdrawal stiffness of self-tapping screws in timber*

Diameter (mm)	Angle	Penetration Length (mm)	Mean Density (kg/m^3)	Mean Stiffness (N/mm^3)	CoV (%)
11	0°	70	429	4.8	21.2
	30°			4.6	5.5
	45°			4.0	15.8
	60°			4.1	17.5
	90°			3.5	15.1
11	0°	90	429	4.8	11.5
	30°			4.7	11.8
	45°			3.8	11.0
	60°			3.9	11.1
	90°			3.6	14.4
9	0°	80	533	5.7	9.9
	30°			5.4	22.8
	45°			5.0	17.8
	60°			5.0	15.0
	90°			5.2	16.3
9	0°	100	533	6.9	14.7
	30°			6.0	20.0
	45°			6.5	8.2
	60°			5.5	13.5
	90°			5.6	12.6

Withdrawal test results are summarized in *Table 1* for different configurations and the mean wood density for each species. The results are graphically represented in *Figure 2*. Mean withdrawal stiffness per unit area (K_{ax}) are shown with their CoVs in the table, which was calculated using equation (1). It should be noted that the small sample size influences the CoV which is within a range of 5%-22% for stiffness. From the withdrawal test results, it can be seen clearly that the withdrawal stiffness decreased with the increase of insertion angle for both SPF and DF specimens. For each screw diameter, the highest stiffness was found at 0° angle and the lowest was noted at 90° angle. DF specimens showed higher stiffness compared to SPF specimens.

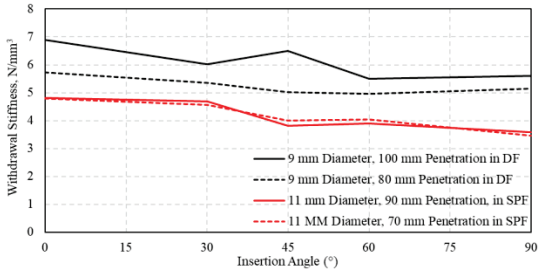

Figure 2: *Withdrawal stiffness of self-tapping screws for different parameters*

The main reason for testing each species/diameter combination with effective different penetration lengths was to explore if the withdrawal stiffness is directly proportional to penetration length, as is commonly assumed in design standards [14] for other dowel-type fasteners such as lag screw, wood screw and nail. To explore this issue, the measured stiffness property at the longer effective penetration length was divided by that at the shorter effective penetration length for each screw diameter/species/angle combination as shown in *Figure 3*. As can be seen in the figure, for the SPF wood with an 11mm screw, the penetration length had practically no impact on withdrawal stiffness, even for a 30% increase in length. For the DF wood with a 9mm screw, the withdrawal stiffness increased with a larger penetration length. However, the property increase does not appear to be directly proportional to the length increase. This issue will require further investigation given that the finding is not in line with the common assumption for other threaded fasteners such as lag screws and wood screws [14].

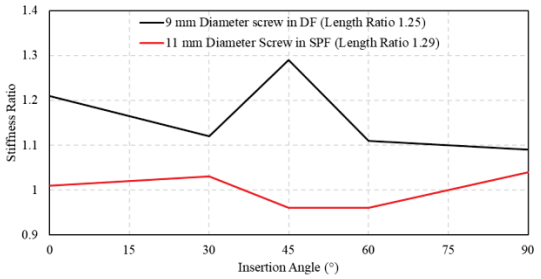

Figure 3: *Influence of the screw penetration length on the withdrawal properties of self-tapping screws*

https://doi.org/10.52202/069179-0153

3. PARAMETRIC ANALYSIS

Parametric analyses were performed by curve-fitting the measured withdrawal stiffness data to develop predictive equations for stiffness. MATLAB programming was used to perform non-linear regression analyses to determine the influence of density, diameter, penetration length and insertion angle on the withdrawal stiffness of the self-tapping screw. Initially, two different regression analyses were performed for SPF and DF data sets to evaluate any potential differences between the two groups. Then, regression analyses were conducted on the combined SPF and DF data to come up with the general stiffness equation.

Non-linear regression analysis was carried out using the SPF and DF data and the following equation was used to determine the relevant coefficients and quantify the results of the test series. The withdrawal stiffness mostly depends on the diameter, penetration length and insertion angle of the screw and density of timber. Therefore, the equation format for the withdrawal stiffness, $K_{ax,\alpha}$ is shown in equation (2).

$$\boldsymbol{K_{ax,\alpha}} = \frac{w_1\ {l_e}^{w_2}\ \rho^{w_3}\ d^{w_4}}{w_5\ cos^2(\alpha) + w_6\ sin^2(\alpha)} \tag{2}$$

where α is the insertion angle to timber grain, d is the nominal diameter of the fastener, l_e is the fastener penetration into wood excluding the tip and ρ is the timber density.

After performing the non-linear regression analysis with the SPF test data, the screw withdrawal stiffness in the SPF timber can be expressed as shown in equation (3).

$$\boldsymbol{K_{ax,\alpha,SPF}} = \frac{0.30{l_e}^{-0.01}\ \rho^{0.18}\ d^{1.09}}{2.37cos^2(\alpha) + 3.22sin^2(\alpha)} \tag{3}$$

The coefficient values and their related errors and p-values are presented in *Table 2*. Analysis of the coefficient of determination (R^2) has revealed a strong correlation, with a value of 0.9. The root mean square error (RMSE) was found to be 0.152. The p-values associated with the length of Equation (3) for SPF data were found to be high indicating that the influence of length was less significant compared with other parameters based on the SPF test results.

Then, a non-linear regression analysis was carried out with the DF test data and the screw withdrawal stiffness in the DF timber can be expressed as shown in equation (4).

$$\boldsymbol{K_{ax,\alpha,DF}} = \frac{0.44{l_e}^{0.69}\ \rho^{2.93}\ d^{-7.82}}{5.32cos^2(\alpha) + 6.32sin^2(\alpha)} \tag{4}$$

The coefficient values and their related errors and p-values are presented in *Table 2* where, the analysis of the coefficient of determination (R^2) has revealed a reasonable correlation, with a value of 0.83. The root mean square error (RMSE) was found to be 0.249. The lower p-value associated with the length of equation (4) indicates that the influence of penetration length in withdrawal stiffness is high based on the test results.

Finally, after performing the non-linear regression analysis with all the SPF and DF test values in this study, the screw withdrawal stiffness for both SPF and DF timber can be expressed as shown in equation (5).

$$\boldsymbol{K_{ax,\alpha,G}} = \frac{0.17{l_e}^{0.41}\ \rho^{0.72}\ d^{-0.51}}{5.09cos^2(\alpha) + 6.35sin^2(\alpha)} \tag{5}$$

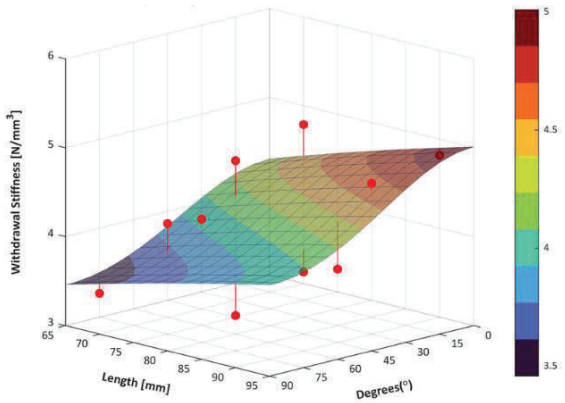

Figure 4: *Surface of withdrawal stiffness vs insertion angle and penetration length for 11 mm diameter SPF data using combined coefficient (ρ=429 kg/m³)*

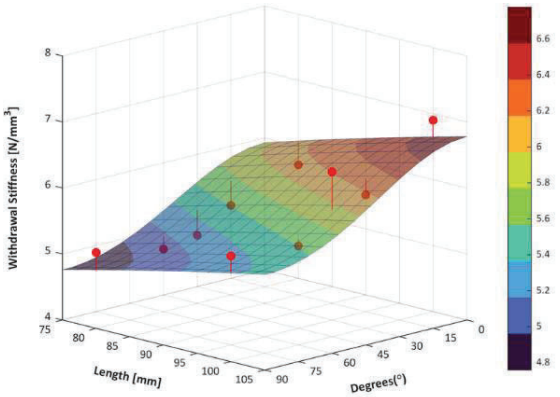

Figure 5*: Surface of withdrawal stiffness vs insertion angle and penetration length for 9 mm diameter DF data using combined coefficient (ρ=533 kg/m³)*

The coefficient values and their related errors and p-values are presented in *Table 2*. Analysis of the coefficient of determination (R^2) and the root mean square error (*RMSE*) has revealed a strong correlation, with a value of 0.885 and 0.315 respectively, which is promising. The standard errors are found within an acceptable range which subsequently yielded a smaller range for a 95% confidence interval for all the coefficients. The surface of the withdrawal stiffness values represented by equation (5) for SPF and DF data associated with their respective diameter are shown in *Figure 4* and *Figure 5* respectively. The surface depicts expected values based on equation (5)

https://doi.org/10.52202/069179-0153

while individual data points depict the experimental withdrawal stiffness. The mean density of 429 kg/m^3 and 533 kg/m^3 was considered for the SPF and DF wood samples in *Figure 4* and *Figure 5* respectively following the test data.

Table 2: *Coefficient estimation for each data set of withdrawal stiffness after parametric studies*

Equation	Species	Coefficients	Values	p-Value	Standard Error	Lower 95%	R^2	RMSE
3	SPF	w_1	**0.30**	0.495	0.419	-0.661	0.900	0.152
		w_2	**-0.01**	0.930	0.118	-0.283		
		w_3	**0.18**	0.621	0.340	-0.607		
		w_4	**1.09**	0.012	0.306	0.382		
		w_5	**2.37**	3.47E-08	0.067	2.214		
		w_6	**3.22**	1.30E-09	0.053	3.096		
4	DF	w_1	**-0.44**	2.09E-06	0.031	-0.515	0.830	0.249
		w_2	**0.69**	0.002	0.150	0.337		
		w_3	**2.93**	4.79E-09	0.086	2.724		
		w_4	**-7.82**	3.24E-15	0.030	-7.888		
		w_5	**-5.32**	2.57E-09	0.142	-5.652		
		w_6	**-6.32**	2.32E-10	0.120	-6.599

		w_2	**0.41**	0.011	0.142	0.101		
		w_3	**0.72**	0.271	0.626	-1.551		
		w_4	**-0.51**	0.473	0.696	-3.054		
		w_5	**5.09**	9.511E-16	0.147	-0.566		
		w_6	**6.35**	1.466E-18	0.118	-0.706		

Based on equations (3)-(5), a comparative study was undertaken for all diameters, insertion angles, penetration length and wood species to compare the effectiveness of the general combined equation which is shown in *Figure 6*. The statistical analysis for SPF and DF data concluded that the combined general equation (5) can be used for both the SPF and DF wood species instead of using individual equations (3) and (4) for SPF and DF separately. Therefore, to predict the withdrawal stiffness of the screws with known insertion angle and penetration lengths within the diameter of 9-11 mm, and wood density of 429-533 kg/m^3, the general equation (5) may be utilized based on the parametric studies conducted in this study. However, further studies are required with a wider range of test data to cover more diameter, penetration length and density. In the case of CLT, as long as the input parameters are within the mentioned range, the average value of withdrawal stiffness of all penetrated screw layers can be considered as the final withdrawal stiffness.

Also, the withdrawal stiffness of all possible screw diameters ranging from 8-12 mm at 0°, 30°, 45°, 60° and 90° insertion angles, penetration length from 50-200 mm in SPF and DF wood with a density of 425 and 525 kg/m^3 is calculated and presented in *Figure 7*. From the figure, it can be seen that the withdrawal stiffness decreases with increasing insertion angle to timber grain and the screw diameter but increases with the increase of wood density and screw penetration length. Therefore, withdrawal stiffness is sensitive to the screw penetration length and wood density.

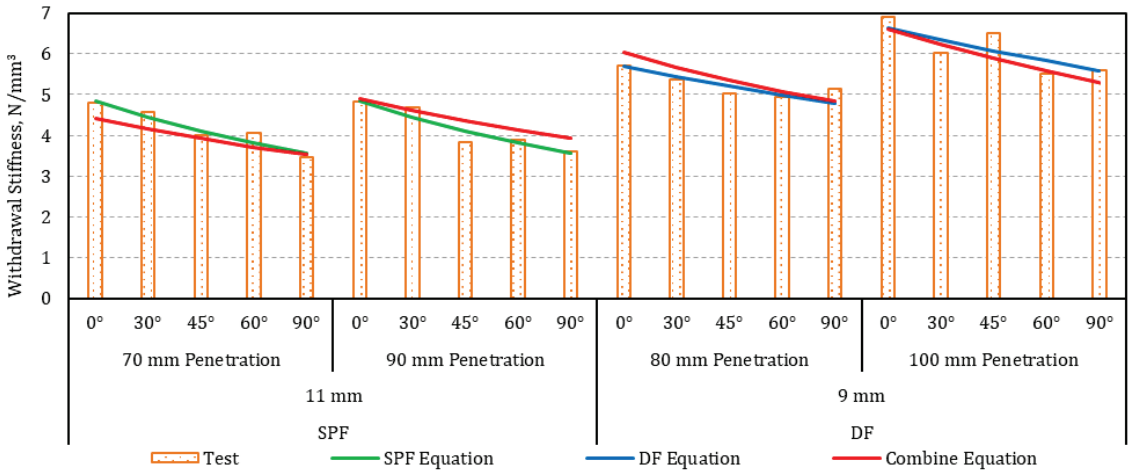

Figure 6: *Withdrawal stiffness comparison*

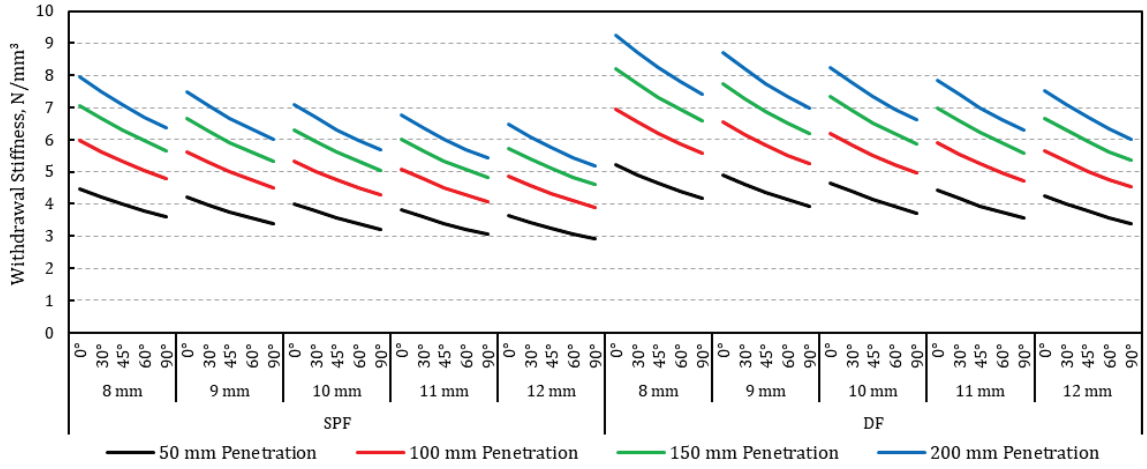

Figure 7: *Predicted withdrawal stiffness of different diameter screws in SPF and DF using general withdrawal stiffness equation for different penetration lengths (ρ_{SPF} = 425 kg/m^3 and ρ_{DF} = kg/m^3)*

4. CONCLUSIONS

Self-tapping screws are often inserted into the face of timber members at an angle to take advantage of their high withdrawal strength and stiffness to resist lateral loads. Because of the inclined arrangement, the calculation of the stiffness of such self-tapping screw connections requires knowledge of withdrawal stiffness at various insertion angles relative to the grain of wood on the timber member surface. From a design calculation perspective, it would be beneficial to express these stiffness properties in terms of wood density and fastener diameter, similar to parallel expressions for withdrawal strength, as well as the insertion angle. The main goal of this study was to provide a preliminary indication if it is feasible to develop empirical equations to express withdrawal stiffnesses in terms of the geometry of the fastener, wood density and insertion angle. Although the databases used in this study were limited in terms of the range of parameters studied, results from non-linear regression analyses performed on the collected data have shown that the withdrawal stiffness of self-tapping screws could be estimated from wood density, screw diameter, insertion angle, and effective penetration length. While the influences of wood density and screw diameter are as expected, it was noted that insertion angle influences withdrawal stiffness directly. Based on this study, withdrawal stiffness decreases with increasing insertion angle.

RNN-BASED MONOTONIC LOADING BEHAVIOR PREDICTION OF CLT JOINTS

Yewei Ding[1],Haibei Xiong[2],Cheng Yuan[3],Lin Chen[4],Yurong Lu[5]

ABSTRACT: Cross-laminated timber (CLT) joints play an essential role in ensuring co-working performance between CLT structural parts and dissipating seismic energy when structures suffer earthquake. The variation of mechanical properties of CLT joints would further affect the whole structural safety. Thus, evaluating and predicting the loading behaviors of CLT joints is critical. In this research, the authors proposed a recurrent neural network (RNN)-based method to predict monotonic loading behaviors of CLT joints. Two RNNs models were adopted, including long short-term memory (LSTM) and gated recurrent unit (GRU). Further, the prediction performance of two RNNs models was compared using statistical and mechanical property index. Prediction results demonstrate that both LSTM and GRU models can predict the failure stage of the CLT joint with R^2 more than 0.90, λ_S and λ_T larger than 0.98. In the statistical index, the GRU model outperformed the LSTM model, although both models achieved the same accuracy in the mechanical property index. Overall, the RNN-based prediction method proposed in this study can provide an outstanding prediction performance for the monotonic mechanical behavior of CLT joints.

KEYWORDS: CLT joint, Mechanical properties, Monotonic loading, Recurrent neural networks (RNNs)

1 INTRODUCTION

Cross-laminated timber (CLT), as an engineering timber product, has recently become more popular in high-rise building construction due to its low carbon footprint and excellent mechanical properties[1]. For high-rise CLT constructions, joints play important roles in structural safety. Thus, it is significant to understand and predict mechanical properties of CLT joints.

To obtain loading behaviors of the CLT joint, many mechanical researches have been conducted. He et al. tested 3-layer and 5-layer CLT panels for bending, shear, and compressive strength. The research revealed the various failure modes of CLT bending and shear specimens, suggesting that the numerical model of the CLT bending specimens can predict initial elastic stiffness K_e and ultimate load-resisting capacity F_{max} [2]. Dong et al. taken research on the CLT shear wall anchored with tensile connections. The strength, stiffness, and ductility of sixty-eight groups of hold-down connections were investigated. The result demonstrated that the connections employed in their test could produce reasonably high ductility while avoiding the metal bracket fracture failures [3].

Mechanical tests can undoubtedly determine the loading behaviors of the CLT joint, but they are destructive and time-consuming. With the emerging improvement of artificial intelligence, machine learning algorithms have been utilized in predicting loading behaviors non-destructively and validated their feasibility. For example, Chen et al. evaluated and predicted damage degree of the bolt joint in glulam timber constructions via machine learning and received a high predicting accuracy of 96% [4]. When utilized for data-driven prediction, recurrent neural networks (RNNs) have the advantage of boosting efficiency and extracting damaged information from data as one of the machine learning algorithms [5]. In civil engineering, RNN models used to predict loading behaviors have made substantial progress. High accuracy prediction in hysteretic or constitutive behavior and nonlinear seismic response is made using RNN, such as long short-term memory (LSTM) and gated recurrent unit (GRU) [6]. However, no research towards predicting CLT joint loading behaviors has been published.

The purpose of this article is to predict the monotonic loading failure procedure of the CLT joint. Section 2 describes the mechanical tests of the CLT joint and explains the theory of the RNN models utilized in this paper. Section 3 displays the RNN model parameters and prediction result evaluation indexes. Section 4 and 5

contain the discussion and conclusion of the prediction results.

2 METHODOLOGY

Experiments were carried out in the methodology to determine the mechanical properties of the CLT joint and the materials. The tested values were then trained by two RNN models to predict the failure stage in the loading procedure. Finally, multiple indexes were used to evaluate the predicted load value. Figure 1 depicts the methodology's flowchart.

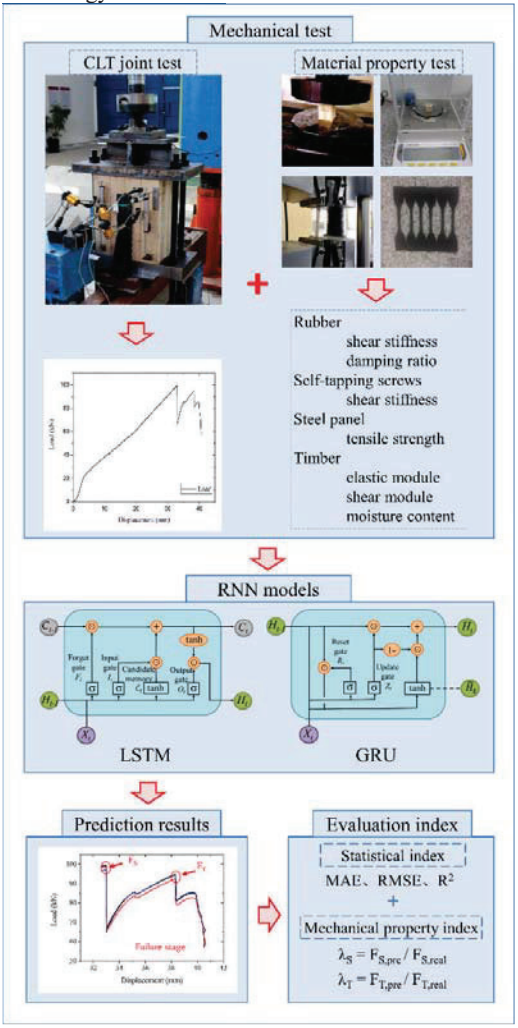

Figure 1: *Flowchart of the methodology*

2.1 MATERIALS AND PROPERTIES

The CLT panel was made with Canadian hemlock lumber and had a width of 300 mm and a height of 400 mm. Each panel was fabricated with 35/35/35 mm layups and a total thickness of 105 mm. According to the formal research, the connection used in this study employed energy-consuming rubber to reduce the interlayer displacement and improve the anti-seismic property, as shown in figure 2 [7]. The loading procedure in Hassanieh and Zhou's study included CLT joint failure with steel panel yielding, self-tapping screw cutting, and CLT panel broking [8,9]. So the mechanical properties of the steel panel, self-tapping screws, and CLT panels would influence the performance of the CLT joint. The mechanical properties of timber, self-tapping screws, and steel are tested according to the relevant standards and listed in table 1.

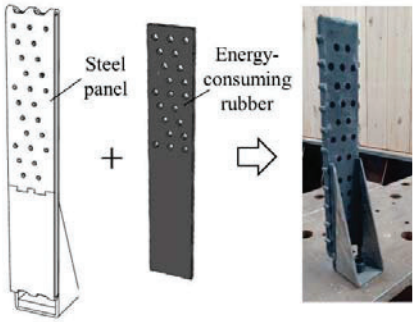

Figure 2: *Connection with energy-consuming rubber*

Table 1: *Value of material properties*

Material properties	Value
Shear stiffness of rubber	0.6 GPa
Damping ratio of rubber	0.2
Number of self-tapping screws	25
Shear stiffness of self-tapping screws	0.31 GPa
Tensile strength of steel	0.32 GPa
Elastic module of timber	15.31 GPa
Shear module of timber	1.17 GPa
Moisture content of timber	10.39%

2.2 TEST SETUP AND PROCEDURE

The monotonic loading approach used a two-stage displacement-control method (preloading procedure and formal loading procedure) according to ASTM D5652 [10]. The load was raised to 10% of the estimated peak load value during the preloading procedure, then unloaded after 2 minutes. In the formal loading procedure, the load was stopped when the joint reached the peak load or the displacement of 60 mm. Throughout the procedure, the loading speed is 1.5 mm/min. The CLT joint specimen and loading equipment are shown in figure 3.

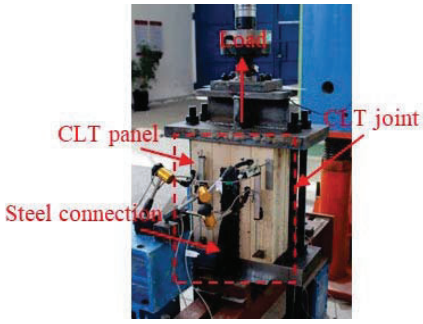

Figure 3: *CLT joint specimen and loading equipment*

2.3 TEST RESULTS

Figure 5 depicts the load-displacement curve of the monotonic loading procedure. The entire procedure, as

shown by the curve, is divided into three stages: elastic, plastic, and failure.

The wood fibers began to cut and crackle when the displacement reached 3 mm, and the joint entered the plastic stage. Following that, a part of the steel panel of the connection broke, causing the load suddenly decrease at the displacement of 33 mm, indicating that the procedure had entered the failure stage. The load was then supported by the energy-consuming rubber, the remaining steel panel, and the self-tapping screws. Finally, at the displacement of 38 mm, shear failure of the self-tapping screws resulted in the joint breaking and the load dropping precipitously.

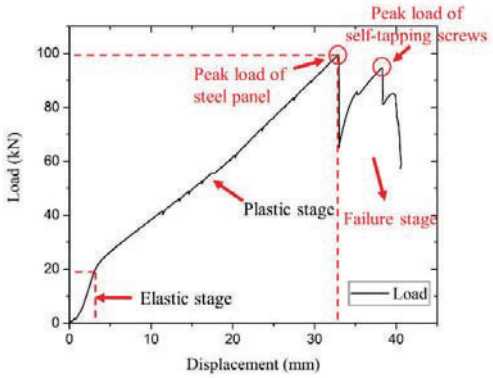

Figure 4: *Load-displacement curve*

2.4 RECURRENT NEURAL NETWORKS

Recurrent neural networks (RNNs) have been widely adopted as a kind of machine learning algorithm to predict sequential data [11]. One of the most widely used RNNs models is long short-term memory (LSTM). Long-term dependencies in the LSTM model are improved over traditional RNN models due to the gate functions introduced in the cell structure. Compared with the LSTM model, the gated recurrent unit (GRU) model has one fewer gate function, which may reduce the computational burden [12]. The LSTM model has been utilized to predict fracture growth rates of L-shape concrete specimens as well as the dynamic response of the nonlinear structure [13,14]. The GRU model has also been used in structural health monitoring (SHM) of civil structure buildings [15]. As a result, both the LSTM and the GRU models are effective methods for predicting loading behavior in civil engineering.

2.4.1 LSTM model

The LSTM model was initially introduced in 1997 and has received much attention in sequence prediction [16]. As shown in figure 3, variable weight matrixes are implemented by adding the input gate (I_t), forget gate (F_t), and output gate (O_t) in LSTM. Each gate includes a σ neural network layer and a pointwise multiply operation:

$$I_t = \sigma(X_t W_{xi} + H_{t-1} W_{hi} + b_i) \quad (1)$$

$$F_t = \sigma(X_t W_{xf} + H_{t-1} W_{hf} + b_f) \quad (2)$$

$$O_t = \sigma(X_t W_{xo} + H_{t-1} W_{ho} + b_o) \quad (3)$$

where X_t means input. H_{t-1} means the hidden state. σ is the activation function. W means the weight matrix, the first subscript of W refers to the input, and the second subscript refers to the gate. b means bias, and the subscript of b refers to the gate.

Candidate memory $\tilde{C}_t$ is expressed as:

$$\tilde{C}_t = tanh(X_t W_{xc} + H_{t-1} W_{hc} + b_c) \quad (4)$$

Memory cell C_t is expressed as:

$$C_t = F_t \odot C_{t-1} + I_t \odot \tilde{C}_t \quad (5)$$

Hidden state H_t is expressed as:

$$H_t = O_t \odot \tanh(C_t) \quad (6)$$

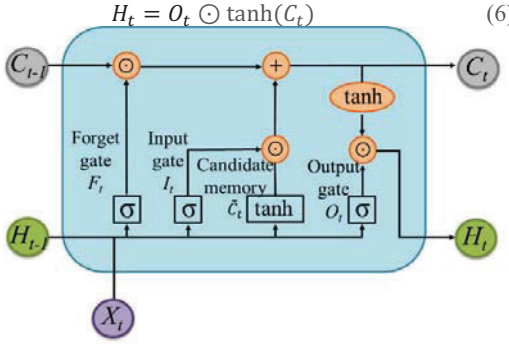

Figure 5: *Frame diagram of LSTM models*

2.4.2 GRU model

To decrease the computation burden, the LSTM model was improved into the GRU model with some cell states improved [17]. As shown in figure 6, the three gates in the LSTM model are integrated into the reset gate (R_t) and the update gate (Z_t) in the GRU model:

$$R_t = \sigma(X_t W_{xr} + H_{t-1} W_{hr} + b_r) \quad (7)$$

$$Z_t = \sigma(X_t W_{xz} + H_{t-1} W_{hz} + b_z) \quad (8)$$

where σ refers to the activation function, X_t means input, H_{t-1} means the hidden state, W represents the weight refers to different inputs and gates, b refers to bias.

The candidate hidden state $\widetilde{H}_t$ is expressed as:

$$\widetilde{H}_t = \tanh(X_t W_{xh} + (R_t \odot H_{t-1}) W_{hh} + b_h) \quad (9)$$

The hidden state H_t is expressed as:

$$H_t = Z_t \odot H_{t-1} + (1 - Z_t) \odot \widetilde{H}_t \quad (10)$$

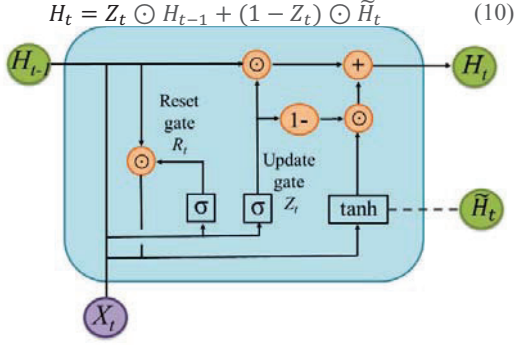

Figure 6: *Frame diagram of GRU models*

3 PREDICTION SETTINGS AND EVALUATION INDEX

3.1 PARAMETER SETTINGS

The load-displacement data obtained from the monotonic loading test are time-sequential. The mechanical testing

https://doi.org/10.52202/069179-0154

machine collected 300 data points per minute, fro a total of 8207 data points in the dataset. At that point, each data point contains the corresponding load, displacement, and material parameter. Although some parameters, such as the mechanical properties of CLT and steel, would change when entering the plastic stage, this study assumes that these material parameters would not change for simplification. In both LSTM and GRU models, the number of neurons is 8. The proportions of training and validation sets are 0.8 and 0.2, respectively.

In this research, rectified linear unit (ReLU) was adopted as the activation function to avoid the problem of disappearing gradients and to speed up training. Explained by equation (11) and figure 7:

$$f_x = \max(0, x) \tag{11}$$

where x is the output value from the previous layer.

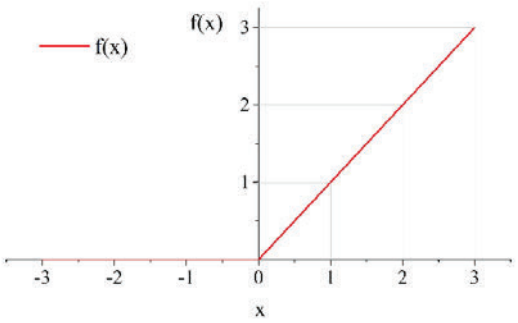

Figure 7: *Function image of ReLU*

Mean square error (MSE) is taken as the loss function in order to facilitate convergence:

$$MSE = \frac{\sum_{i=1}^{n}(y_i - x_i)^2}{n} \tag{12}$$

where x_i means real value, y_i means predicted value, n is the number of data.

Adaptive momentum is adopted to optimize. Furthermore, early stopping is employed for defending overfitting. Other parameter settings are listed in Table 2.

Table 2: *Parameter settings in RNN models*

Parameter	Value
Time step	40
Dropout	0.1
Epoch	100
Validation split	0.1
Batch size	32

3.2 EVALUATION INDEX

This paper presents two kinds of performance evaluation indexes (statistical and mechanical property indexes). Statistical indexes assess the fitness between predicted and real monotonic behavior obtained during the test. Mechanical property indexes are proposed as a mean of estimating predicted mechanical properties.

3.2.1 Statistical index

The statistical index contains mean absolute error (MAE), root mean square error (RMSE), and coefficient of determination (R^2). MAE and RMSE both indicate the error to the real value. Lower values of MAE and RMSE mean better prediction performance. The degree of fitness between predicted and real values is donated by R^2. When R^2 is close to 1.00, the prediction is more accurate. Three indexes are listed in equation (13-15):

$$MAE = \frac{\sum_{i=1}^{n}|y_i - x_i|}{n} \tag{13}$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(y_i - x_i)^2}{n}} \tag{14}$$

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(x_i - y_i)^2}{\sum_{i=1}^{n}(x_i - \bar{x})^2} \tag{15}$$

where x_i means real load value, $\bar{x}$ means mean real load value, y_i means predicted load value, n is the number of data in the load-displacement curve.

3.2.2 Mechanical property index

It is significant to evaluate the mechanical properties of the predicted results, which represent the loading behavior of the actual experiment. The broken steel panel and self-tapping screws of the CLT joint caused a sudden drop in load. As a result, the load value at these two points is adopted to evaluate the mechanical properties during the failure stage.

Based on the formal research [7], this study takes the coefficient of peak steel panel load λ_S as the normalized value of the predicted peak steel panel load based on the real value:

$$\lambda_S = F_{S,pre}/F_{S,real} \tag{16}$$

where $F_{S,pre}$ means the predicted peak steel panel load, the $F_{S,real}$ means the real peak steel panel load.

The coefficient of peak self-tapping screws load λ_T is similar to λ_S:

$$\lambda_T = F_{T,pre}/F_{T,real} \tag{17}$$

where $F_{T,pre}$ means the predicted peak self-tapping screws load, the $F_{T,real}$ means the real peak self-tapping screws load.

The closer λ_S and λ_T get to 1.00 representing a higher prediction accuracy.

4 RESULTS AND DISCUSSION

Figure 8 depicts the loading behaviors predicted by the LSTM and GRU models. Only the failure procedure is predicted. Load curves predicted by the LSTM and GRU models are both fit closely to the real load curve. Table 3 lists three statistical evaluation indexes. Both MAE and RMSE of the GRU model are lower than LSTM model's, while R^2 is higher, indicting that the GRU model's predicted results are statistically more precise than the LSTM model's.

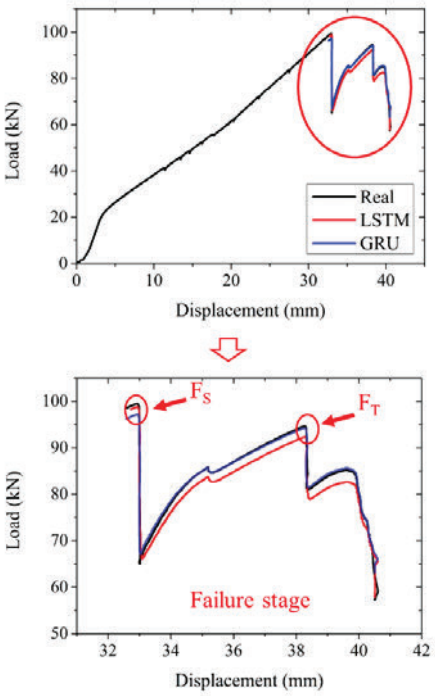

Figure 8: *Real and predicted load-displacement curve*

Table 3: *Statistical index*

Statistical index \ Model	LSTM	GRU
MAE (kN)	2.14	0.67
RMSE (kN)	2.58	1.62
R^2	0.91	0.97

Table 4 lists the peak loads predicted by the LSTM and GRU models for the steel panel and self-tapping screws, respectively. λ_S and λ_T are calculated according to the real and predicted load values. The λ_S and λ_T of the LSTM and GRU model are both higher than 0.98, which are close to 1.00. The LSTM model achieves λ_S of 0.99, which is higher than the 0.98 predicted by the GRU model. While the values of λ_T are the opposite. The high value of mechanical property indexes demonstrates the precise prediction ability of LSTM and GRU models.

Table 4: *Mechanical property index*

Mechanical property index \ Model	Real	LSTM	GRU
F_S (kN)	99.50	98.80	97.20
F_T (kN)	94.61	92.30	94.20
λ_S	--	0.99	0.98
λ_T	--	0.98	1.00

As stated in section 2.4, the GRU model has a lower computational burden than the LSTM model. The LSTM model consumed 14 seconds and 92 milliseconds in this study, while the GRU model took 14 seconds and 54 milliseconds. Given that the number of predicted data points in this monotonic loading test is 1641, the GRU model consums only 38 milliseconds less than the LSTM model. In case of tests containing a large amount of data points, such as hysteretic loading tests or other complex and time-consuming tests, the computation reduction and time-saving effect of the GRU model will be more obvious.

5 CONCLUSIONS AND PROSPECT

The authors proposed an RNNs-based prediction method for the failure procedure of CLT joint under monotonic loading in this paper. Statistical indexes (MAE, RMSE, and R^2) and mechanical property indexes (λ_S and λ_F) are used to evaluate the predicted load-displacement curves.. The MAE of the LSTM and GRU model are both no higher than 2.14 kN, while the RMSE of the two RNN models is no higher than 2.58 kN, and R^2 is greater than 0.91. The values of the three statistical indexes indicated that the error between the predicted value and real value is small. Furthermore, both λ_S and λ_T of the LSTM and GRU model are greater than 0.98, indicating that the two models predict the peak load of the steel panel and self-tapping screws of the joint with a high accuracy . The high value of the prediction indexes demonstrates that both the LSTM and GRU models accurately predicted the failure procedure of CLT joint under monotonic loading precisely, with the GRU model outperforming the LSTM model in terms of statistical indexes.

Prediction accuracy demonstrated the feasibility and effectiveness of using the RNN-based method to predict the failure procedure of CLT joints, providing a reference for CLT construction mechanical properties research.

The mechanical properties of the materials in the RNN model, on the other hand, remained constant throughout the loading procedure, whereas the stress varies with strain during the actual loading procedure. Therefore, in the future work, the constitutive model of the materials would be considered for more accurate physics expression and prediction results.

CYCLIC BEHAVIOR OF MORTISE-TENON JOINTS REINFORCED BY SELF-TAPPING SCREW

Tianxiao Yin[1], Chenyue Guo[2], Zhiqiang Wang[3,*], Wei Zheng[4], Jianhui Zhou[5], Meng Gong[6]

ABSTRACT: In this study, fully-thread countersunk head self-tapping screw (STS) with outer diameter of 6 mm and 8 mm were used to reinforce the mortise-tenon (MT) joints with horizontal and inclined insertion methods. A total of fifteen cyclic loading tests were carried out for one group of unreinforced joints and five groups of reinforced joints, and the load-carrying capacity, strength, stiffness, ductility and energy dissipation of these joints were evaluated. The results showed that larger diameter STS and more STS could improve the load-carrying capacity and initial stiffness of the joints, although it might accelerate the damage to the joints and change the failure modes of MT joints. In addition, different reinforcement methods had different improvement effect, as the joints reinforced by STS horizontal insertion had a more significant improvement in the load-carrying capacity, while the inclined insertion of STS had a more significant improvement in the initial stiffness. This study provides data for reinforcement of MT joints with STS, and different reinforcement methods can be selected according to different engineering requirements.

KEYWORDS: Timber, Mortise-tenon (MT) joint, Self-tapping screw (STS), Reinforcement, Cyclic loading

1 INTRODUCTION

As a kind of essential connection in Chinese traditional architecture, mortise-tenon (MT) joints are the main energy dissipation components in wood construction, which are easy to install and have good rotation ability [1]. Previous research found that MT joints belongs to semi-rigid joints [2,3]. With the development of modern timber construction, the bearing capacity and stiffness of traditional MT joints can hardly meet the engineering requirements. In order to improve the mechanical properties of MT joints, kinds of different reinforcement methods have been carried out for MT joints.

Currently, the reinforcement methods designed for MT joints can be categorized as three types according to the materials applied: wood component [4,5], metal connector [6-8] and new composite material component [9-11]. However, these methods have some shortcomings to some extent. For instance, the durability of wood components is not ideal, and the appearances of the MT joints reinforced by metal connectors (e.g. steel plate) and composite material (e.g. fiber reinforced polymer) are not clean and tidy. Thus, some new reinforcement methods need to be carried out.

Inspired by the connections in modern timber construction, some new dowel-type connectors can be considered for application in the reinforcement for MT joints. Among them, self-tapping screw (STS) is widely recognized as the state-of-the-art connector for timber construction, for its economic cost and convenient installation as well as its excellent mechanical properties [12-15]. According to former scholars' researches, carpentry joints reinforced by STS can achieve good performance, especially the stiffness and load-carrying capacity, which can compensate for the shortcomings of traditional MT joints [12-16]. Furthermore, previous researches found that the insertion angle of STS had a significant influence on the mechanical properties of those reinforced joints [14, 17-20]. At present, it is generally believed that the STS inserted perpendicular to the surface of the components can obtain better ductility, while STS inclined insertion can achieve better stiffness, both of which can improve the load-carrying capacity of the joints.

This paper presents glulam MT dovetail reinforced by STS with horizontal (perpendicular to the timber surface)

and inclined insertion methods. Cyclic loading testes were carried in this study for both unreinforced (CG) and reinforced joints to evaluate their load-carrying capacity, strength, stiffness, ductility and energy dissipation capacity.

2 MATERIALS AND METHODS

2.1 MATERIALS

Four-layer Glulam made of NO.2 SPF (*Spruce-pine-fir*) dimension lumber were used for process of MT joints. The moisture content and density of glulam were 13.3% (COV=6.7%) and 449 kg/m^3 (COV=4.8%), respectively. Fully-thread countersunk head STS (grade 1022 [21]) with a diameter of 6 mm and 8 mm were used in this study. The yield moment ($M_{y,R}$) and the pull-through capacity (F_{head}) of STS were tested and evaluated respectively [22, 23], and the characteristic values were calculated [24], as shown in Table 1.

The dimension of the components was designed according to the Qing Dynasty " *Gong Cheng Zuo Fa Ze Li*" [25] and is shown in Fig. 1. The different reinforcement methods for MT joints are shown in Fig. 2. In order to ensure the uniformity of materials for specimens, the beam, column and crosser (a tamping placed in the groove of mortise upon tenon) used the same material and were assembled without adhesive.

Table 2 shows the grouping of specimens. It should be noted that in the preliminary tests, the tenon would split when the STS with 8mm diameter was applied for inclined insertion, so this diameter was not considered for use as inclined-insertion reinforcement for MT joints in the formal tests.

Table 1 *Properties of STS*

	Outer diameter d (mm)	Length l (mm)	$M_{y,R}$ (N·mm)	F_{head} (N)
STS-6	6	140	11090	3261
STS-8	8	140	34406	3927

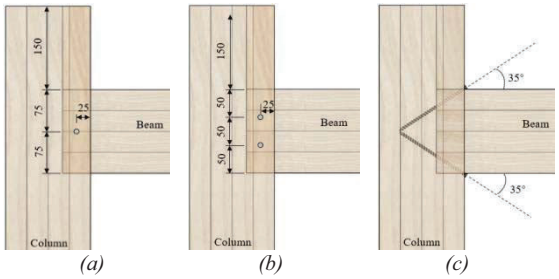

Figure 2: *different reinforcement methods: (a) one STS with horizontal insertion, (b) two STS with horizontal insertion and (c) two STS with inclined insertion.*

Table 2 *Specimen grouping*

Group	Number of STS	Diameter of STS (mm)	Insertion angle (°)	Replicates
CG	/	/	/	3
RSV6	1	6	90°	3
RSV8	1	8	90°	3
RV6	2	6	90°	3
RV8	2	8	90°	3
RI6	1	6	35°	3

2.2 TEST SETUP

During tests, the columns were placed horizontally and horizontal force was acted on the beam end by hydraulic actuator. The rightward push was recorded as positive direction and the leftward pull was recorded as negative direction. Approximately 10 kN horizontal load was applied at the end of the column through a hydraulic jack to simulate the load of the column under actual situation. The whole test setup is shown in Fig.3. The loading protocol referred to ISO-16670 [26]. The cyclic loading tests were repeated three times for each group.

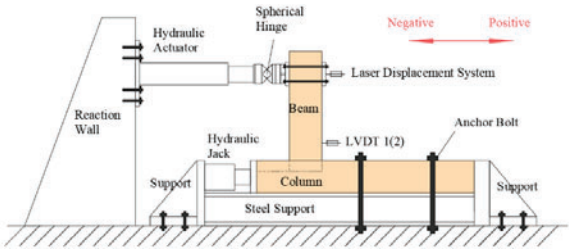

Figure 3: *Test setup.*

2.3 DATA ANALYSIS

The bending moment (M) and the corresponding rotation (θ) in this study were calculated by geometric relations as:

$$M = P \cdot H \quad (1)$$

$$\theta = \frac{\Delta}{H} \quad (2)$$

where P is the load applied, H is the distance between the joint and loading point (400 mm in this study), Δ is the displacement of the loading point in horizontal direction. The yield moment (M_y) of these joints was determined according to EEEP method [27] as:

$$M_y = (\theta_u - \sqrt{\theta_u^2 - \frac{2A}{K_e}})K_e \quad (3)$$

where M_y is the yield moment, θ_u is the ultimate rotation angle, A is the integral area under envelop curve in the interval of [0, θ_u], K_e is the initial stiffness which equals to 0.4 M_m/θ_e, where M_m is the maximum bending moment and θ_e is the rotation angle at 0.4 M_m.

Strength degradation factor (λ) was used to characterize the behavior that the strength of the joints decreases as the number of cycles increases [10], which was calculated as:

$$\lambda_i = \frac{M_{i,3}}{M_{i,1}} \quad (4)$$

where λ_i is the strength degradation factor in the i th displacement amplitude, $M_{i,1}/M_{i,3}$ is the peak bending moment of the first cycle in the i th displacement amplitude.

Stiffness degradation of joints was referred to evaluate the stiffness decreases in this study [28]. The secant stiffness K_i was calculated as:

$$K_i = \frac{|+M_i|+|-M_i|}{|+\theta_i|+|-\theta_i|} \quad (5)$$

where M_i is the peak bending moment of joints at the 1st cycle in the i-stage displacement amplitude while θ_i is the relevant rotation angle of M_i.

The ductility coefficient (D) of the joints in this study was evaluated as the ratio between the ultimate rotation (θ_u) and yield rotation (θ_m):

$$D = \frac{\theta_u}{\theta_y} \quad (6)$$

The ductility of joints into four scopes from brittle ($D \leq 2$) to high ductility ($D > 6$) according to their ductility coefficient [29].

The equivalent viscous damping coefficient (v_{ep}), which is a dimensionless coefficient, can be employed to assess the energy dissipation capacity of these joints [30]. The calculation of the equivalent viscous damping coefficient is as follows:

$$v_{ep} = \frac{E_d}{2\pi E_p} \quad (7)$$

where E_d is the energy dissipated per half cycle, E_p is the available potential energy.

3 RESULTS AND DISCUSSIONS

3.1 FAILURE MODES

The typical failure modes of the CG group were push out of crosser and pull-out of the tenon, together with splitting and crack on the column, as shown in Fig. 4.

As regards to the reinforced groups with STS horizontal insertion, split of the column and yielding of STS were the typical failure modes. Apart from this, the crack and crush of wood on the column below the joints area were also observed in these groups. For RSV6 and RSV8 groups reinforced with one STS, they had similar failure modes during the tests, which were the pull-out of the tenon and splitting on the side of the column, together with the yielding of STS, as shown in Fig. 5 and Fig. 6. Due to the larger diameter of STS, the amount of the pull-out of tenon in RSV6 group was larger than that in RSV8 group. The phenomenon of RV6 and RV8 groups during the initial loading phase was similar to RSV6 and RSV8 groups. Benefitted from the more rigid connection provided by two STS, the amount of tenon pull-out was decreased, compared with that in RSV6 and RSV8 groups. However, on account of the more STS inserted, the joints might suffer more damage at the late loading stage, for example, the column would split or even fracture. The two STS inserted in RV groups were yielded at the late loading stage. Typical failure modes of RV6 and RV8 are shown in Fig. 7 and Fig.8.

Similar to other groups, the pull-out of tenon and crack on the column appeared in RI6 group with STS inclined insertion. However, the difference between RI6 group and other groups was that there was no split on the side of the column in RI6 group and the STS used in it was not found yielding. After cutting the specimens, the withdrawal of STS was found in the RI6 group. The failure mode of RI6 group was shown in Fig. 9.

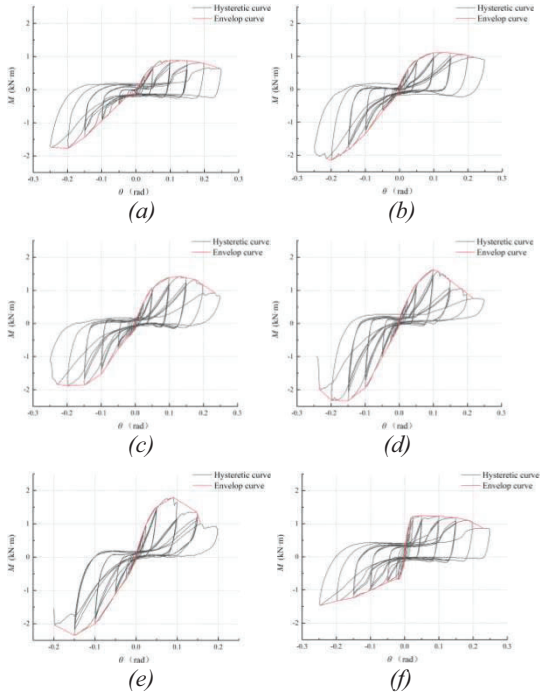
3.2 HYSTERETIC AND ENVELOP CURVES

The average hysteretic curves of each group showed different degree of pinching effect and exhibited asymmetry in positive and negative directions, as shown in Fig. 10.



(a) (b) (c) (d) (e) (f)

Figure 10: *Hysteretic curves of: (a) CG group; (b) RSV6 group; (c)RSV8 group; (d) RV6 group; (e) RV8 group and (f) RI6 group.*

These hysteretic curves showed a similar trend. To be specific, the slope of hysteretic curve was small at the initial loading stage because of the processing gap between mortise and tenon. As the increment of displacement amplitude, the friction area between mortise and tenon increased thus caused the rapid increase of the bending moment. It can be obviously seen that the hysteretic curves of each joint have asymmetry, and the absolute value of the peak point of the negative loading curve was higher than that of the positive loading curve, which indicated that the negative loading process had a higher load-carrying capacity. The reason for this was the tenon was constrained differently under these loading directions. Specifically, under positive loading, the pushing out and loosening of the crosser would lead to a decrease in the load-carrying capacity, on the contrary, the rigid constraint had a positive effect on the improvement of the load-carrying capacity under negative loading tests. Different from the curves of the joints with horizontally inserted STS, the hysteretic curve of RI6 group exhibited excellent initial slope and alleviate pinching effect.

For easy comparison, the envelop curves of each group have been extracted and drawn in Fig. 11. It is clear from this figure that the RV groups had the largest load-carrying capacity, followed by the RSV groups and the RI6 group. In a homogeneous group, it can be found that a bigger diameter could provide higher load-carrying capacity. For example, as regard the RV groups, the RV8 group had a higher maximum bending moment than that of RV6 group. In general, the joints reinforced with STS horizontal insertion had significant improvement in terms to load-carrying capacity, while those with STS inclined insertion had obvious improvement in initial stiffness.

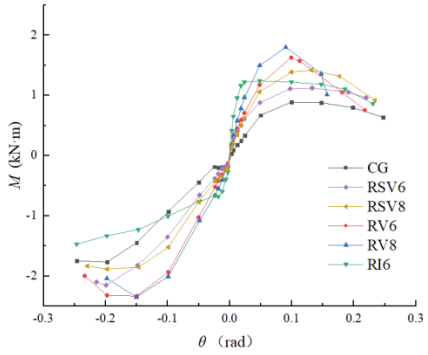


Figure 11: *Envelop curves of each group.*

3.3 MECHANICAL PROPERTIES

The average maximum moment (M_m), ultimate moment (M_u), yield moment (My) and their corresponding rotation together with the initial stiffness (K_e) and ductility coefficient (D) during two loading directions of each group are summarized in Table 3.

The load-carrying capacity and stiffness of MT joints have been improved significantly after being reinforced by STS. Two STS with horizontal insertion (RV group) had obvious improvement in load-carrying capacity, and STS with larger diameter had more improvement. Compared with the CG group, the load-carrying capacity of the RV group joints was 102% and 33% higher in positive and negative loading directions, respectively. As mentioned above, a larger diameter of STS can improve the load-carrying capacity due to its larger bending strength. Moreover, compared with RV groups and RSV groups, it can be concluded that the number of STS had a significant

https://doi.org/10.52202/069179-0155

effect on the load-carrying capacity of MT joints, although it did not meet a liner rule. From the results, it can be seen that the improvements of load-carrying capacity brought by RSV groups were not as good as that brought by RV groups. For instance, the maximum bending moment of the RSV8 and RSV6 groups increased by 59 % and 26%, respectively, which was smaller than the improvement of MT joints in RV groups. Furthermore, the reinforcement effect of RI6 group was small, under positive loading, the load-carrying capacity of MT joints was increased by 39%, while under negative loading, the load-carrying capacity of which was close to that of CG group. This means for this kind of MT joints, using horizontally inserted STS can achieve a higher improvement on load-carrying capacity compared with inclined insertion STS.

Table 3 *Mechanical properties of MT joints*

Group	Loading direction	M_m (kN·m)	θ_m (rad)	M_u (kN·m)	θ_u (rad)	M_y (kN·m)	θ_y (rad)	K_e (kN·m·rad^{-1})	D

RI6		1.47	0.25	1.47	0.25	1.11	0.02	48.93	10.91

The strength degradation of each group between -0.15 rad to 0.15 rad is shown in Fig. 12. It can be easily seen that the strength degradation factor of each group decreased with the increase of loading amplitude. The strength degradation of CG group was more minor before rotation reached 0.15 rad, which may prove that the wood damage inside the unreinforced joints was slighter. Afterward, the strength of CG group degraded greatly due to the significant increase of tenon pulling out. It is worth noting that the strength degradation of RV groups was more prominent in this test, verifying that those joints suffered more damage in loading. On the contrary, the strength degradation of RSV and RI groups tended to be stable at the late loading stage.

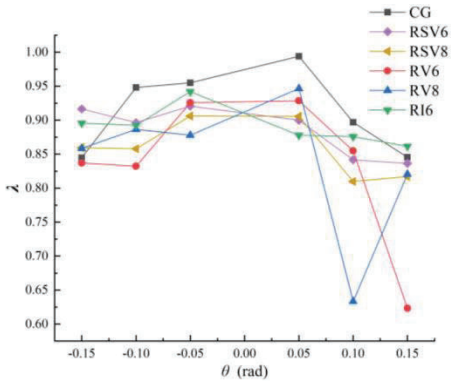

Figure 12: *Strength degradation of each group.*

The stiffness degradation of each group is shown in Fig. 13. In general, the stiffness of each group showed similarity before the rotation came to 0.05 rad, which decreased and then remained stable. When the rotation came to 0.25 rad, each group exhibited similar stiffness in the end, indicating that significant failure had occurred in each group. During the whole loading process, the unreinforced CG group showed a markedly lower stiffness than those of the reinforced group. In the reinforced groups, RI6 group exhibited very large stiffness in the initial loading stage, which could significantly improve the initial stiffness of MT joints, up to 842% and 433% higher than those of CG group, respectively in two loading directions. Comparing the RV groups with RSV groups, it can be found that MT joints reinforced with two STS can obtain higher initial stiffness than that of those reinforced with one STS. Besides, a bigger diameter of STS can also effectively improve the initial stiffness.

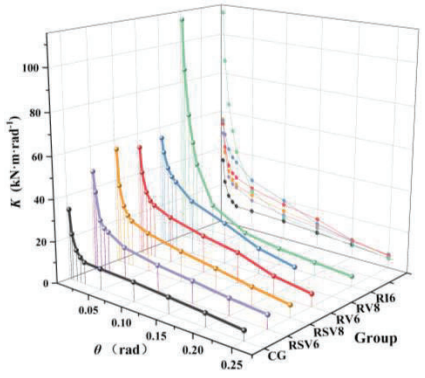

Figure 13: *Stiffness degradation of each group.*

As shown in Table 3, the ductility coefficient (D) of each group under positive loading was higher than that under negative loading. The reason for this was that the joints entered yield stage earlier when they were loaded in positive direction, due to the different constraints under

https://doi.org/10.52202/069179-0155

the two loading directions. It is worth noting that under positive loading, RSV groups had higher ductility coefficient than RV group, while under negative loading the situation was the opposite. The reason for this could be that, as mentioned, the constraints under negative loading were more rigid, thus leading to plastic deformation of wood in RV groups. As a result, RV groups entered the yield stage earlier, which makes the calculation result of ductility coefficient larger. Among these groups, the ductility of RI6 was significantly higher than that of other groups, while the ductility of CG group without reinforcement was relatively lower. According to the classification of ductility proposed by Smith et al. [29], except the RI6 group belongs to high ductility, other groups were classified as low ductility.

The equivalent viscous damping ratios curves of each group during tests are shown in Fig. 14. These joints exhibited similar energy dissipation trend during the whole loading test. To be specific, the energy dissipation capacity was low when the rotation was about 0 rad, before or after that, the energy dissipation capacity reached a high level. Combined with the damage of wood, it is easy to understand that when the rotation angle was about 0 rad, the joints were loose due to the repeated extrusion, leading to a low friction effect. As the displacement amplitude increased, the joints got close contact with surrounding components, the friction effect was enhanced, so the energy dissipation capacity increased. As regards reinforced groups, since joints experienced different extent of damage during loading process, the energy dissipation capacity has not got obvious improvement at late loading stage. On the contrary, CG group showed a stable energy dissipation during tests, and at late loading stage, its energy dissipation capacity was better than that of reinforced groups, even though its cumulative energy dissipation was not as good as others'. Among reinforced groups, RI6 group had the best energy dissipation capacity, especially when the rotation was not large. It can be considered that the friction between the thread of STS and wood hole contributed a lot to the energy dissipation. Generally speaking, the factors that influence the energy dissipation capacity of MT joints were friction and fracture of wood. In this study, the initial energy dissipation of joints depended mostly on the friction between mortise, tenon and STS, as loading continued, the damage of wood could absorb part of the energy, meanwhile, the joints began to loosen.

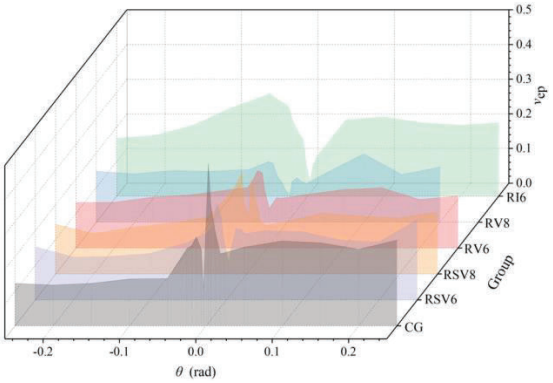

Figure 14: *Equivalent viscous damping ratios of each group.*

4 CONCLUSIONS

The MT joints reinforced by STS with different insertion methods could obtain an improvement on connection performance. Below are some conclusions summarized from this study:

(1) The typical failure modes of the unreinforced joints were the pull-put of tenon and the split on the column. Regarding the reinforced joints, the application of STS could significantly lower the pull-out amount of the tenon, especially when STS were inserted horizontally. On the other hand, the insertion of STS could also accelerate the damage of wood.

(2) Using more STS or increasing the diameter of STS could effectively improve the load-carrying capacity of MT joints, although this might hasten their failure.

(3) Inclined insertion of STS could help the MT joints obtain higher initial stiffness, stable strength degradation and better ductility and energy dissipation capacity.

(4) Further study about the configuration of MT joints and effect of the type of STS are worth conducting.

SERVICEABILITY STIFFNESS OF TIMBER CONNECTIONS WITH DOWELS AND SLOTTED-IN STEEL PLATES

Kjell Arne Malo[1], Haris Stamatopoulos[2], Francesco Mirko Massaro[3], Saule Tulebekova[4]

ABSTRACT: The paper presents experimental stiffness measurements from large scale tests on dowel connections with both single and double slotted-in steel plates. The intended use of the results is quantification of the effect connections have on the stiffness of trusswork in glulam buildings. An engineering model of the connection stiffness is proposed and evaluated in view of the test results. The paper also shows comparisons of measured results to guidelines in European standards for timber engineering.

KEYWORDS: Stiffness, connection, dowel, serviceability, experiment, model

1 INTRODUCTION

The height of timber buildings has increased significantly within the last decennium. Several buildings with 10 to 20 stories using load carrying systems purely in wood have been built at various locations throughout the world. However, very little experience has been reported with respect to their in-service properties - like wind-induced vibrations. Dynamical properties are dependent on mass, stiffness and damping properties of the buildings. Several high-rise buildings, like "Treet" (14 stories, 2014) [1], and "Mjøstårnet" (18 stories, 2019, see Figure 1) [2], have used large trusswork in glulam with connections of slotted-in steel plates and dowels. The most exposed connections in the Mjøstårnet trusswork (see Figure 2) have in the order of 800 shear planes in a single connection. Although the stiffness of a single shear plane for a single dowel is given in [3], it is known from experiments that connections having large numbers of dowels cannot be sufficiently evaluated as only a summation of single dowels, see for example [4]. This is an important issue for high-rise buildings as the stiffness of joints is crucial for their dynamic response.

The objective of the experimental investigation has been to perform series of tests to get experimental results for quantification of elastic stiffness of connections with multiple dowels, suitable for modelling of connection stiffness for serviceability evaluations. The test series consists of experiments ranging from a single dowel and one slotted in steel-plate, up to connections with 2 slotted-in steel plates and 35 dowels. The investigation is limited to dowels having 12 mm diameter, which is most used in the Nordic countries.

2 MATERIALS AND METHODS

2.1 MATERIALS

The wooden materials used was glulam GL30C according to [5]. This type of glulam usually consists of combined lay-up of two or more different strength classes of lamellas. In this case the outer lamellas are of strength

class T22, and the inner lamellas T15. However, as the majority of the dowels usually are located in the inner lamellas, the tests have been performed on T15 lamellas and material properties for T15 lamellas are used throughout this paper, see [5]. The mean stiffness moduli are $E_{0,mean} = 11500$ MPa, $G_{mean} = 720$ MPa, while the density is $\rho_{mean} = 430$ kg/m^3.

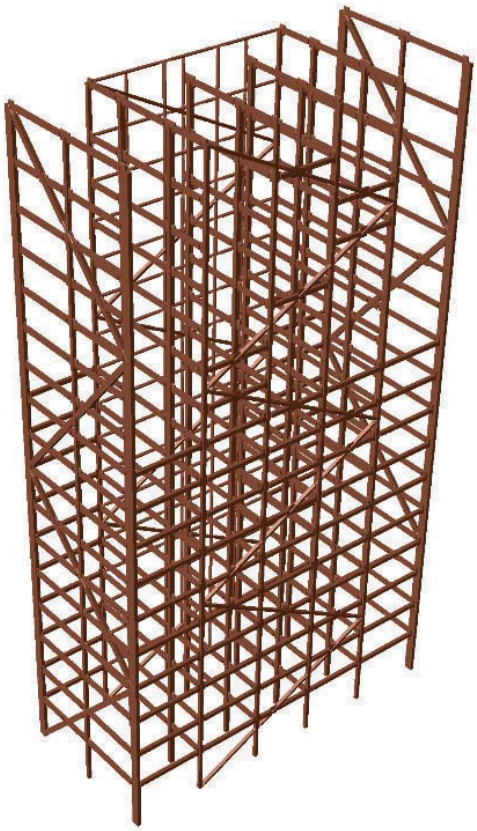

Figure 2 *Numerical model of the glulam trusswork used in Mjøstårnet.*

The steel plates in the slots are of quality S355 and have thickness 10 mm. All dowels have diameter of 12 mm and are of high strength stainless steel (class EN 1.4418) with yield strength 755 MPa. For all specimens the dowel spacing is 60 mm in the grain direction (a_1) and 55 mm in the perpendicular direction (a_2), which is a very common spacing for this type of dowel connections.

2.2 SMALL SCALE AXIAL TESTS

Two series of small-scale tests with one steel plate have been performed: the first is uniaxial tests loaded in the grain direction, confer Figure 3, while the second, shown on Figure 4, is in principle a three-points bending test. Both test series contain results from 1 dowel and up to 3 x 3 dowels, arranged in various layouts and loaded along grain direction, see Figure 3, or perpendicular to grain direction, see Figure 4. The notation used is as follows; a capital indicates a line in the grain direction, while a number indicates a row perpendicular to grain. A dowel in the middle will hence have identification B2, a row of 3 dowels in the middle in grain direction B123, a row perpendicular in the middle A1B1C1, while all dowels in the group becomes A123B123C123.

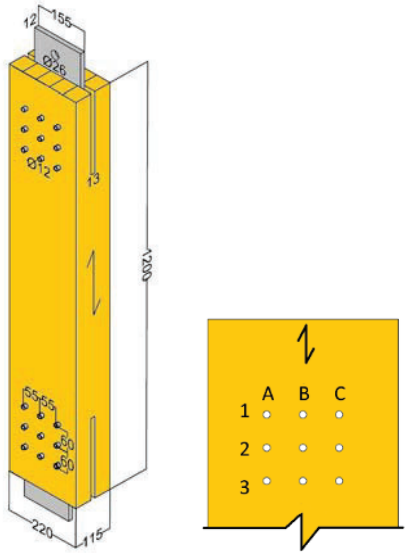

Figure 3:*Specimene for loading parallel to grain and to the right, naming of dowel configurations.*

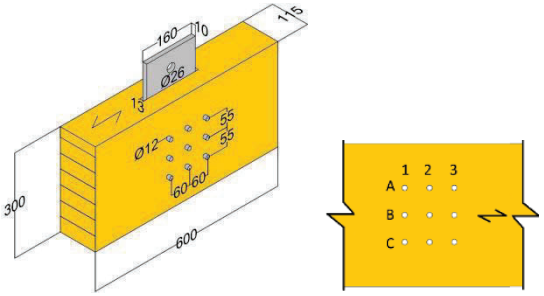

Figure 4:*Specimene for loading perpendicular to grain and to the right, naming of dowel configurations.*

2.3 LARGE SCALE COMPONENT TESTS

The second test series contains three types of connections with two slotted-in steel plates, see Figure 5, and up to 5x7 dowels arranged in various patterns, confer Figure 6. The experimental setup for these tests is depicted in Figure 8. Note that the "Bottom" connection shown in Figure 5 is not evaluated herein.

2.4 INSTRUMENTATION AND MEASUREMENTS

All test setups are statically determined and hence the force distribution is well known. The stiffness is characterized by the applied load and the relative displacement between the steel plate (or plates), and the surrounding wood close to the steel plates. Each steel plate has two LVDTs, one at each edge, in order to cancel

https://doi.org/10.52202/069179-0156

out any rigid body motion by averaging the measurements from the two sides, confer Figure 7 and Figure 8.

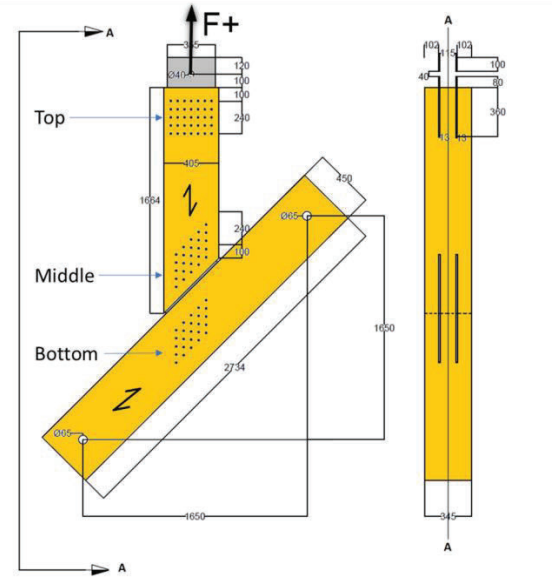

Figure 5:*Setup for large scale glulam diagonal components. Three different connections in one setup; TOP connection, MIDDLE connection and BOTTOM connection.*

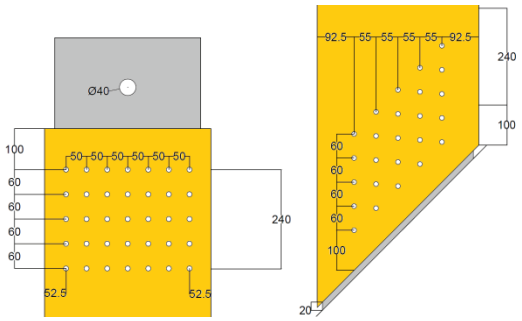

Figure 6:*Lay-out for the diagonal connections loaded along grain. Left: TOP connection and right: MIDDLE connection.*

A connection is here defined as the transfer of forces between a steel plate(s) and a glulam component by use of shear loaded dowels. The steel plates have two connections, either to another glulam component or to the loading or reaction devices.

Figure 7: *Small scale test setup and instrumentation.*

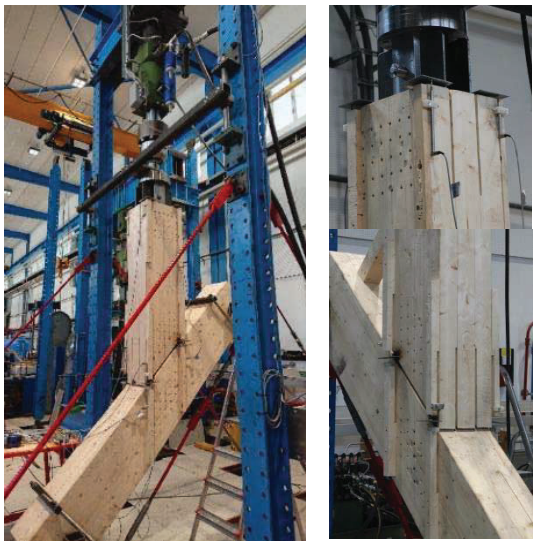

Figure 8: *Diagonal test setup with three dowel connections*

2.5 TEST PROGRAM

For the small-scale tests with loading in grain direction, three glulam specimens with a connection in each end were used (total six different connections). Eight different dowel configurations were used, confer Figure 9.

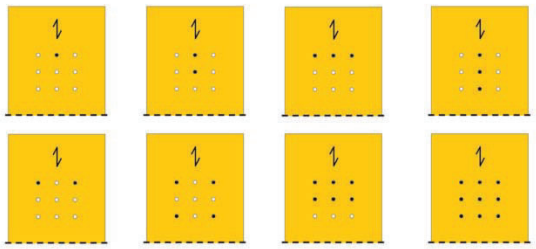

Figure 9: *Dowel configurations for small scale tests, loading in grain direction.*

https://doi.org/10.52202/069179-0156

For loading perpendicular to grain, six configurations shown in Figure 10 were tested, using in total three specimens.

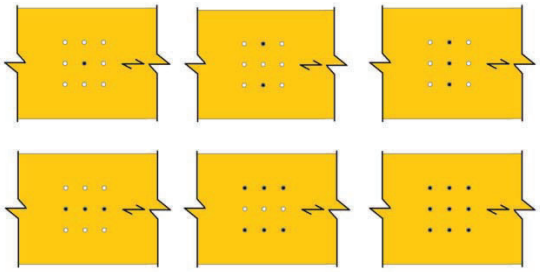

Figure 10: *Dowel configurations for small scale tests, loading perpendicular to grain.*

Only one specimen for the large-scale diagonal test setup was available, and here 5 different configurations were tested. The tests were performed by sequentially installing an additional row of dowels along the grain, starting from the ends of the connections. For the TOP connection the number of dowels perpendicular to grain $n_{90} = 7$ was kept constant, while the MIDDLE connection had $n_{90} = 5$ constantly.

2.6 LOADING PROTOCOL AND EVALUATION

The initial stiffness is not necessarily representative of a building in a wind exposed situation. Wind loading has usually a quasi-static part in addition to the turbulence causing vibrations. Therefore, the zero mean force situation is not likely to occur, as the quasi-static part of the wind loading is commonly large. Consequently, the effect of initial slips is of minor importance in this context.

The methods for evaluation of stiffness in ISO 6891 [6] do not fully cover the needs for quantification of stiffness for dynamic response evaluation. Therefore, a more suitable loading and evaluation protocol has been worked out for the test series and presented in Figure 11. The loading protocol is based on cycling the load between 10 and 40 % of the estimated maximum load, both on the tensile and compressive side. Finally, the load is cycled between +40 % and -40 %, passing through the domain of zero force. As it may be observed from Figure 12, or better from Figure 13, it takes a few cycles before the cycles stabilize and they appear on top of each other on the plots.

The plots in Figure 12 show tensile cycling corresponding to the first sequence in Figure 11, while the second block with cycling on the compressive side is shown on Figure 13. The plots show quite considerable hysteretic loops and picking specific points for stiffness calculation might lead to unnecessary large scatter in results, dependent on the choice of points (shown as pink dots on the plots). In the authors opinion it is much better to utilize all the information in the cycles and use the method of least squares to fit a straight line to the stable cycles (the cycles after stabilization).

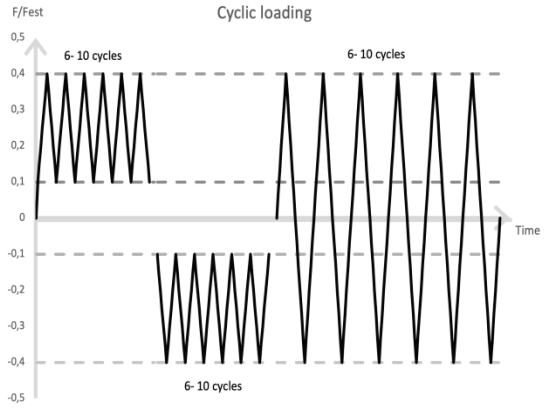

Figure 11: *Loading protocol for stiffness evaluation*

This is shown as dashed lines in the plots, and this stiffness measure is also more consistent with the numerical modelling of structures. Consequently, the latter method is used herein, and typically four values for the stiffness are determined. In the results section, stiffness evaluated from cycling in tension in denoted *tension* (tens), cycling in the compressive domain is denoted *compression* (comp). The large cycles passing through zero force, are called *Fully Reversed* and these cycles are evaluated separately both on the tensile side (FRt) and on the compressive side (FRc), as visualized on Figure 14.
The horizontal distance between the two dashed stiffness lines for fully reversed cycles shown on Figure 14 is a measure of the initial slip in the connection. The initial slip is not further reported herein, but a treatment of this issue can be found in [7].

3 RESULTS

The experimental results are given in tables and plots, where n_0 denotes the number of dowels in grain direction, while n_{90} is the number of dowels perpendicular to grain. As explained in Section 2.6 the stiffness has been evaluated in four different domains, one-sided cycling in tension (tens), in compression (comp), and fully reversed cycling evaluated separately both on the tension side (FRt) and on the compressive side (FRc). The columns denoted “Aver” or “Average” are the average of the four evaluated stiffnesses. All stiffnesses are given as stiffness per fastener and shear plane in kN/mm. For comparison, the Eurocode 5 [3] expression for this is

$$k_{ser} = 2 \cdot \frac{\rho_{mean}^{1.5} \cdot d}{23} = 2 \cdot \frac{430^{1.5} \cdot 12}{23} = 9.304 \text{ kN/mm} \quad (1)$$

where ρ_{mean} is the mean density of wood (kg/m^3) and d is the dowel diameter (mm). The total stiffness of the connection Eurocode 5 [3] is calculated by multiplying the stiffness k_{ser} with number of shear plane per fastener, herein either 2 (small-scale) or 4 (large-scale), and multiplied with the total number of fasteners $n_0 \cdot n_{90}$.

3.1 RESULTS FROM SMALL-SCALE TESTS

Table 1 gives the measured stiffnesses per fastener and shear plane with loading in grain direction. The number of dowels in the grain direction is varied, keeping the number of fasteners perpendicular fixed, either one or three. The average results are plotted in Figure 15, and it may be observed that the stiffness decrease with the number of fasteners in the grain direction n_0. Comparing the blue line having $n_{90} = 1$, to the red line having $n_{90} = 3$, also an interaction between n_0 and n_{90} is probable.

Table 1: *Small scale specimen, loading in grain direction, stiffness per fastener and shear plane.*

Configuration	n	n0	n90	tens	comp	FRt	FRc	Aver
B1	1	1	1	24.64	25.98	19.26	21.69	22.89
B12	2	2	1	14.71	16.50	13.28	14.33	14.71
B123	3	3	1	12.77	15.92	12.05	14.31	13.76
A1B1C1	3	1	3	19.04	19.96	16.33	17.29	18.16
A12B12C12	6	2	3	14.19	15.18	12.88	14.11	14.09
A123B123C123	9	3	3	12.12	14.09	10.98	12.75	12.49

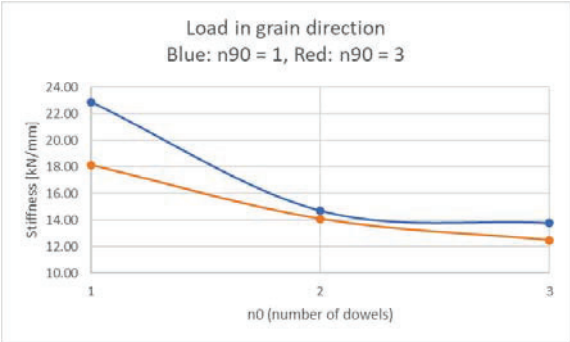

Figure 15: *Average stiffness from small scale specimens, loading in grain direction.*

Configurations with loading perpendicular to grain are given in Table 2 and the average stiffness is plotted in Figure 16, keeping the number of fasteners in grain direction n_0 constant. An increase of fasteners n_{90} in the load direction (here perpendicular) decreases the stiffness. From the plot it is suggested that an increase of n_0 will further decrease the stiffness.

Table 2: *Small scale specimen, loading perpendicular to grain*

Configuration	n	n0	n90	tens	comp	FRt	FRc	Aver
B2	1	1	1	10.51	11.59	10.17	11.27	10.89
A2C2	2	1	2	9.84	11.18	9.52	11.14	10.42
A2B2C2	3	1	3	9.28	10.38	9.16	10.11	9.73
A123C123	6	3	2	7.72	9.08	7.81	9.03	8.41
A123B123C123	9	3	3	6.02	6.87	5.94	6.93	6.44

https://doi.org/10.52202/069179-0156

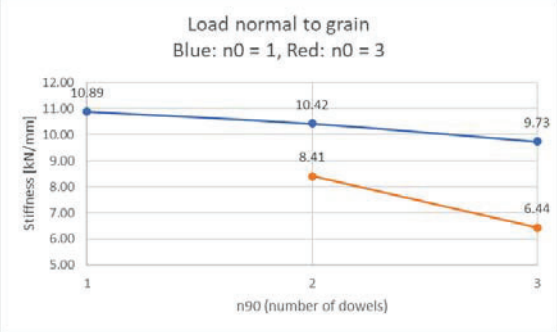

Figure 16: *Small scale, loading perpendicular to grain*

The configurations highlighted with yellow colour in Table 1 and Table 2 are comparable. Letting the stiffnesses obtained for perpendicular loading be scaled with the comparable stiffness obtained for loading in grain direction, we obtain the ratio of stiffness between loading perpendicular and along the grain and these ratios are presented in Table 3. The stiffness ratios based on the average data are between 0.48 and 0.54, i.e. the stiffness for loading perpendicular to grain is roughly only half of the stiffness for loading along the grain.

Table 3*: Stiffness ratios for loading perpendicular to grain vs loading in grain direction. Small scale specimen with comparable configuration*

n0	n90	tens	compr	FRt	FRc	Average
1	1	0.4265	0.4461	0.5280	0.5196	0.4755
1	3	0.4874	0.5200	0.5609	0.5847	0.5360
3	3	0.4967	0.4876	0.5410	0.5435	0.5158

3.2 RESULTS FROM LARGE-SCALE TESTS

The different configurations for the large-scale tests differ only by the number of installed dowels in the grain direction, n_0, while keeping the number of dowels perpendicularly constant at the maximum, which is 7 and 5 for the TOP and MIDDLE connections, respectively. Note that the loading for the TOP and MIDDLE connections is along the grain, while the BOTTOM connection has loading at 45 degrees relative grain and is therefore not included herein. The experimental results are given in Table 4.

The stiffnesses obtained from the four evaluation schemes (cyclic tension, cyclic compression, fully reversed compression and fully reversed tension) are plotted as separate curves in Figure 17 for the TOP connection. Note that the top connection has $n_{90} = 7$ and a rectangular lay-out of dowels. The lay-out for the MIDDLE connection is close to a parallelogram with 45 degrees between crossing lines. The loading for the MIDDLE connection is also along grain and the results for increasing number of dowels along grain n_0 are plotted on Figure 18. All these evaluations and measurements are in good agreement, and there is a clear trend of decreasing stiffness with increasing number of dowels in the grain direction.

Table 4: *Large scale specimen, vertical loading, stiffnesses in kN/mm per fastener and shear plane.*

Connection	n0	n90	tension	compr	FRt	FRc	Average
Top	1	7	7.93	12.49	9.07	11.08	10.14
Middle	1	5	15.15	21.23	10.23	12.30	14.73
Top	2	7	4.23	8.02	4.61	6.45	5.83
Middle	2	5	10.51	12.90	9.07	8.00	10.12
Top	3	7	2.60	5.83	3.72	5.43	4.39
Middle	3	5	7.47	8.53	5.64	6.49	7.03
Top	4	7	2.64	3.66	3.45	3.12	3.22
Middle	4	5	6.06	7.93	5.55	6.58	6.53
Top	5	7	1.99	3.78	2.53	2.95	2.82
Middle	5	5	4.92	6.91	3.82	5.76	5.35

The comparable stiffness from Eurocode 5 is 9.3 kN/mm, Equation (1), and it is obvious that this stiffness can only be achieved for connection having few dowels, roughly 10 dowels at most, independent of configuration. For more dowels the stiffness per fastener and shear plane will be considerably smaller. All configurations for the large-scale tests (and small-scale tests as well) show the same decreasing stiffness with increasing number of dowels in the grain direction.

From the small-scale tests presented on Figure 15 and Figure 16, for loading in grain direction and perpendicular respectively, it seems necessary to take into account the number of dowels in both directions (n_0 and n_{90}) as there is a clear interaction between them.

The obtained stiffness measurements were averaged and are presented on Figure 19, one curve for each large-scale connection. The average stiffness per fastener and shear plane is larger for the MIDDLE connection than for the TOP connection, but they are almost parallel and clearly show the same tendency of decreasing stiffness with increasing n_0. Furthermore, there is a clear trend to approaching an asymptotic value for $n_0 \geq 5$.

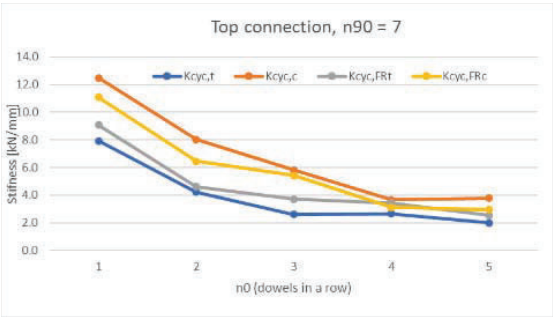

Figure 17: *Large scale diagonal test, TOP connection, loading in grain direction.*

https://doi.org/10.52202/069179-0156

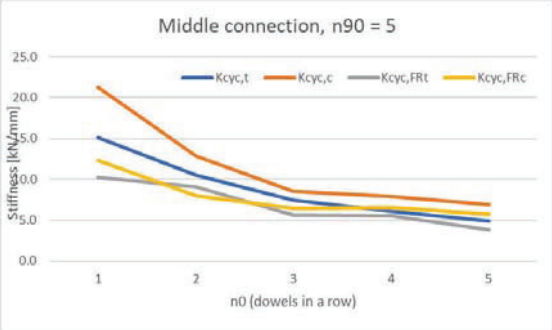

Figure 18: *Large scale MIDDLE connection, loading in grain direction.*

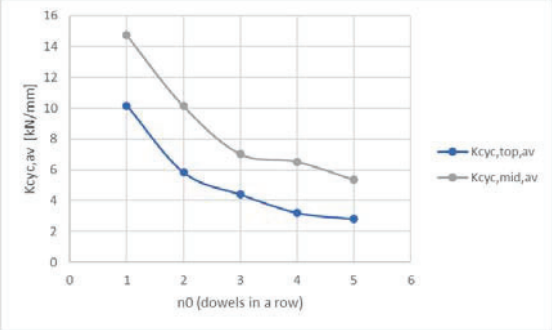

Figure 19: *Stiffness per fastener and shear plane for the two different dowel connections in the diagonal test setup.*

By scaling all stiffnesses with the stiffness value for one dowel in the grain direction, we can express the results by a relative ratio of effective numbers of dowels, depending on the number in grain direction, see plot on Figure 20. Note that the information used here involves the effect from both along and perpendicular to the grain and thus shows the sum of the effects from the number of dowels in both directions simultaneously. The MIDDLE connection has in all cases number of dowels perpendicular grain $n_{90} = 5$, and shows a decreasing trend with n_0. The TOP connection, which has $n_{90} = 7$, shows in comparison smaller effective numbers.

By combining the results from small-scale and large-scale tests, we have configurations which clearly show that there is similar trend from the number of dowels perpendicular to grain, see graphs on Figure 21, where the number of dowels along the grain is kept constant for each curve.

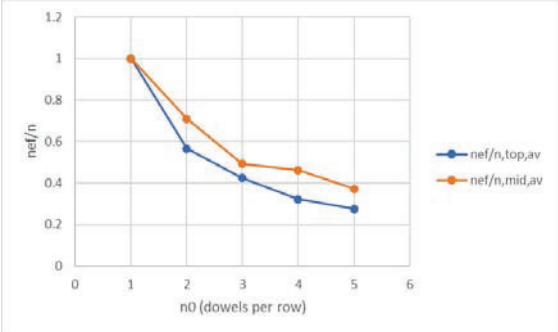

Figure 20: *Effective number of dowels in the grain direction in the diagonal test setup with three different dowel connections.*

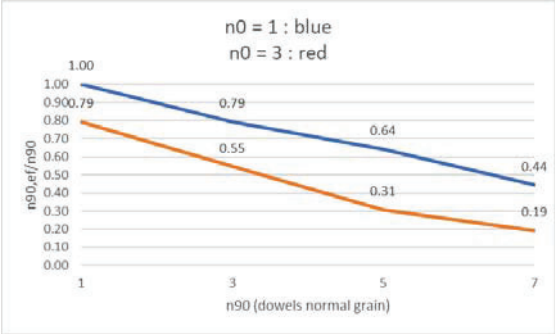

Figure 21: *Effective number of dowels perpendicular to grain, combination of small and large scale tests.*

4 MODEL FOR CONNECTION STIFFNESS OF DOWEL JOINTS

4.1 Model considerations

The stiffness of the dowel connections is dependent on the layout and cannot, with sufficient accuracy, be calculated just by a linear addition of the shear planes. Eurocode 5 [3] underestimates the stiffness for a single dowel, while the stiffness is severely overestimated for connections with large number of dowels. Herein, the number of wooden specimens is low. Therefore, effects of varying embedding stiffnesses of wood, thicknesses of layers and varying spacing cannot be determined from the present test series. The focus has only been on the effect of the number of dowels, keeping all other parameters constant.

4.2 Model

The idea behind the model is to use the information already available in codes like Eurocode 5 [3] together with simple modifications. Hence, the stiffness for a single steel-to-wood dowel connection k_{ser} is modelled by Equation (1).

Assuming that all shear planes contribute with the same stiffness, the method for stiffness evaluation from Eurocode 5 [3] is

$$K_{ser,EC5} = k_{ser} \cdot n_{spd} \cdot n_0 \cdot n_{90} \quad (2)$$

where n_{spd} is the number of shear planes per dowel. A regular dowel pattern is assumed herein such that the total number of dowels equals the product $n_0 \cdot n_{90}$.

Considering all plots on Figure 15 to Figure 21, a decaying behaviour of the average shear plane stiffness is observed. It will be unphysical that the decaying behaviour with increasing number of dowels ends up with zero average stiffness, so an asymptotic behaviour is expected, confer Figure 19.

The introduction on an effective number of fasteners also for stiffness evaluation has been proposed by several authors, see for example [8]. This can simply be introduced in Equation (2) by a non-dimensional modification factor M on the number of fasteners. A simple asymptotic expression for dowels on a single row along the grain can be:

$$M_0 = m_0 \cdot \left(q_{0,1} + q_{0,2} e^{\frac{1-n_0}{r_0}}\right) \quad (3)$$

where m_0 is the calibrated value for one dowel in grain direction. The parameter r_0 together with the parameters $q_{0,1}$ and $q_{0,2}$ govern the non-dimensional asymptotic decrease. A similar approach in the transvers direction reads:

$$M_{90} = m_{90} \cdot \left(q_{90,1} + q_{90,2} e^{\frac{1-n_{90}}{r_0}}\right) \quad (4)$$

By replacing n_0 with the product $n_0 M_0$ and n_{90} with $n_{90} M_{90}$ in Equation (2), the model stiffness becomes:

$$K_{ser,mod} = k_{ser} \cdot n_{spd} \cdot n_0 m_0 \cdot \left(q_{0,1} + q_{0,2} e^{\frac{1-n_0}{r_0}}\right) \cdot n_{90} m_{90} \cdot \left(q_{90,1} + q_{90,2} e^{\frac{1-n_{90}}{r_{90}}}\right) \quad (5)$$

For a single dowel, the exponential term equals unity, and therefore for easy calibration, we let always

$$q_{\alpha,1} + q_{\alpha,2} = 1 \quad (6)$$

Here α denotes 0 or 90 directions and $q_{\alpha,1}$ is the asymptotic value. Furthermore, for only one dowel Equation (5) reduces to

$$K_{ser,mod} = k_{ser} \cdot n_{spd} \cdot m_0 \cdot m_{90} = k_{ser} \cdot n_{spd} \cdot m \quad (7)$$

Equation (7) can be used for calibration in the two orthogonal directions, but as it herein is only dealt with either loading in the grain or perpendicular to grain direction, only one parameter is needed, and hence the simplification $m_0 \cdot m_{90} = m$ has been made.

From Table 1 and configuration B1 (one single dowel), the stiffness per shear plane is about 23 kN/mm and taking $k_{ser} = 9.3$ kN/mm from Equation (1), the parameter m becomes $m = 2.5$. Similarly, utilizing the results in Table 3 and Figure 16, the parameter m for a single dowel loaded perpendicular to grain is $m = 1.3$.

The model for serviceability stiffness of a dowel connection with multiple slotted in steel plates and multiple dowels, loaded either along grain or perpendicular to grain, then becomes:

$$K_{ser,mod} = k_{ser} \cdot m \cdot n_{spd} \cdot n_0 \left(q_{0,1} + q_{0,2} e^{\frac{1-n_0}{r_0}}\right) \cdot n_{90} \cdot \left(q_{90,1} + q_{90,2} e^{\frac{1-n_{90}}{r_{90}}}\right) \quad (8)$$

where k_{ser} is calculated according to Eurocode 5, see Equation (1), and n_{spd} is the number of shear planes per dowel. The effect from an increasing number of dowels in the grain direction has been evaluated from the measured results plotted in Figure 19, while for the effect from the number of dowels perpendicular to grain, the information presented in Figure 21 was used. The resulting model parameters for 12 mm dowels embedded in Norway spruce GL30c are specified in Table 5.

Table 5 *Model parameters for 12 mm dowels*

	Along grain			**Perpendicular grain**		
Number of dowels	n_0			n_{90}		
Model symbols	$q_{0,1}$	$q_{0,2}$	r_0	$q_{90,1}$	$q_{90,2}$	r_{90}
Model values	0.3	0.7	2	0.3	0.7	4
Loading direction	$m = 2.5$			$m = 1.3$		

The resulting model stiffness per shear plane and dowel for loading along grain and for varying number of dowels in grain direction is shown with dashed lines in Figure 22 for the two different diagonal connections, note the difference in n_{90}. For comparison, the continuous lines show the measured stiffness.

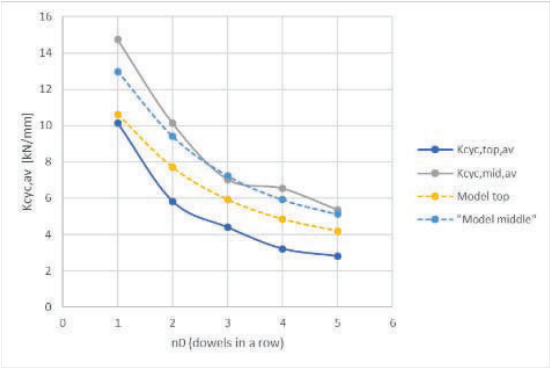

Figure 22 *Modelled and measured stiffness per shear plane and dowels (* $\boldsymbol{n_{90,top} = 7}$ *and* $\boldsymbol{n_{90,middle} = 5}$*.)*

Keeping the number of dowels constant in grain direction and varying the number of dowels in perpendicular direction, the relative reduction in modelled stiffness is shown on Figure 23 using dashed lines, while the measured results are shown with continuous lines.

https://doi.org/10.52202/069179-0156

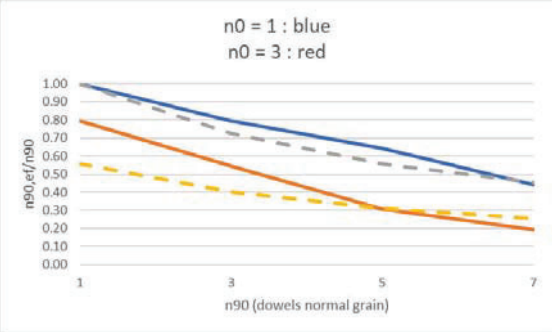

Figure 23 *Relative reduction of stiffness per shear plane and dowel for varying number of dowels perpendicular to grain.*

In the present test series, it has been emphasized to only vary the number of dowels and keep all other parameters constant. However, the test series contain two different lay outs of tests; the small-scale tests having a single slotted in steel plate, and large scale having two plates. The wooden materials are from the same production, but, of course, considerable variation is to be expected due to many local effects like knots etc. Most of the results have been obtained by just installing more dowels in the same specimen. However, for the small-scale specimen several specimens had to be used in order to get the desired configurations without removing any dowels. Therefore, higher variability must be expected in the regime with few dowels. For the determination of the model parameters, most emphasis has been put on the domain where the total number of dowels exceeds 10.

4.3 Verification

Stiffnesses from the connection measurements are compared to the model results in Table 6. Here, Equation (8) has been used with the parameters specified in Table 5 and, and with k_{ser} from Equation (1), (Eurocode 5, [3]). The measured and the modelled stiffness for loading along and perpendicular to grain show the same ratio of stiffness, the grain direction is about 1.9 times stiffer than perpendicular.
Eurocode 5 shows about the same stiffness for loading along grain as the model when the total number of dowels is around 10. For higher number of dowels Eurocode 5 largely overestimates the stiffness, while the developed model is in good agreement with the measurements.

Table 6 *Comparison of connection stiffness from measurements, analytical model and Eurocode 5.*

	Connection			Stiffness kN/mm		
Load directio	n_{spd}	n_0	n_{90}	Measured	Model	EC5
0	2	3	3	225	169	168
90	2	3	3	116	88	168
0	4	5	7	540	586	1303
n	4	5	5	522	512	930

To get a better understanding of the dependency of the number of dowels in the two directions in the model, a plot of the reduction in stiffness is shown on Figure 24 for up to 100 dowels using the parameters from Table 5. The asymptotic value of the reduction of stiffness in the model given by Equation (8) is in this case

$$\frac{K_{ser,mod,asymptote}}{k_{ser} \cdot m \cdot n_{spd} \cdot n_0 \cdot n_{90}} = q_{o,1} \cdot q_{9o,1} = 0.09 \qquad (9)$$

Compared to the Eurocode 5 stiffness computation by Equation (2), the asymptotic value in the model becomes 0.225, as the parameter $m = 2.5$ is required for the fitting of the present model to a single dowel.

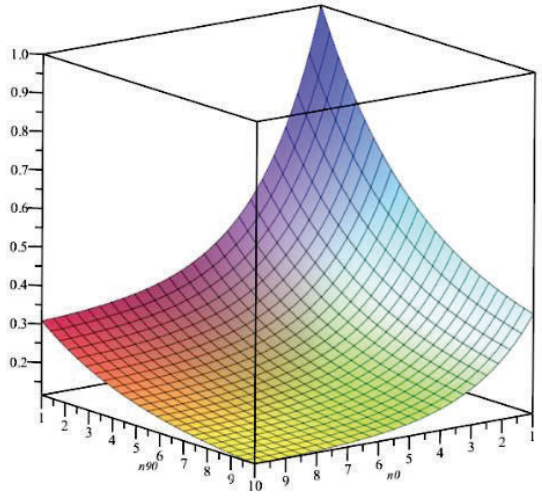

Figure 24 *Average relative stiffness dependent on dowels in the two directions.*

4.4 Limitations and extensions

Available number of tests having many dowels in both directions and multiple slotted in steel plates are few. Furthermore, stiffness measurements are not very well defined and are sensitive to the load level as well as to experimental conditions. Furthermore, the variability in wood material properties is large, and makes comparisons between various tests hard.
The proposed model herein is made in a multiplicative way, such that the various effects might be treated separately. The parameters in Table 5 are given for $a_1 = 60 = 5d$ and $a_2 = 55 = 4.6\,d$. Probably, the q and r parameters in Equation (8) will be dependent on the spacing between the dowels, and this effect can be considered by modifying the parameters and make them dependent on the spacing. This is not a part of the present paper and consequently the bottom connection shown in Figure 5 is not included herein.
Moreover, it is well known that inner and outer parts of a dowel connection with multiple steel plates seldom have the same stiffness per shear plane. This effect can be considered by using an effective number of shear planes n_{spd}. Dowel diameter dependency and dowel surface properties (friction) can put into the k_{ser} parameter.

https://doi.org/10.52202/069179-0156

5 CONCLUSIONS

The paper presents and discusses an approach for stiffness estimation of large dowel connections. Input parameters are the number of dowels on rows parallel and perpendicular to grain, and the number of shear planes per dowel. Both loading along and perpendicular to grain can be evaluated. The shear plane stiffness, and thereby the dependency on dowel diameter and density, is calculated by use of Eurocode 5 [3]. The model is compared to experimental results as well as the simple approach in design standards like Eurocode 5 [3].

The model is developed for dowel connections with 12 mm dowels and commonly used spacing in the Nordic countries.

ACKNOWLEDGEMENT

This research has been conducted as part of the Dynamic Response of Tall Timber Buildings under Service Load project (Dyna-TTB). In Norway, funding was provided by the Norwegian Research Council, grant no. 297513. The master students Elisabeth Frette, Amund Heggheim and Thomas Munkeby are highly acknowledged for their contributions to perform the tests and preparing drawings and photos.

MOISTURE AND ASSEMBLY HISTORY EFFECTS ON EMBEDMENT PROPERTIES OF STEEL DOWELS IN SPRUCE AND BIRCH LOADED IN GRAIN DIRECTION

Michael Schweigler[1], Romain Lemaître[1,2], Zijad Shehadeh[1], Thomas K. Bader[1]

ABSTRACT: Embedment strength and stiffness of steel dowels in spruce and birch solid wood were investigated in an experimental study, taking into account the moisture and connection assembly history. Thus, in addition to the effect of different mechanical properties of wood at different moisture contents, the effect of changes in the moisture content between the steps of: drilling the dowel hole, assembly of the dowel, and testing of the specimen on the embedment strength and stiffness was studied. Full-hole embedment tests with 12 mm steel dowels showed a decrease in embedment strength with increasing wood moisture content, while the elastic embedment stiffness was not influenced. Drying the wood specimens after the dowel was inserted yielded up to 50% higher elastic embedment stiffness compared with connections drilled and assembled when the equilibrium moisture content was reached. Application of an artificial crack showed only a moderate effect on embedment strength and stiffness, while the ductile embedment behavior was maintained.

KEYWORDS: Embedment strength and stiffness, experiments, spruce, birch, moisture content, assembly history

1 INTRODUCTION

Structural timber elements undergo from their production, over drilling boreholes for the fasteners, transportation, to the joint assembly, as well as during the service life, multiple changes in the ambient climate (temperature and relative humidity). This results in changes of the moisture content (MC) in the joint area, which influences the mechanical properties of the wood and thus the mechanical behavior of the joint. In addition, variations in MC lead to geometrical changes of the timber around the steel dowels by means of shrinkage and swelling, while the geometrical shape of the steel dowel itself is unaffected. This can lead to moisture induced pre-stressing of the wood matrix around the dowel, or to shrinkage cracks when the tensile strength of the wood perpendicular to the grain is exceeded.

The embedment strength is the parameter, which represents the mechanical response of wood loaded by a dowel-type fastener in the European Yield Model. The latter is used for the calculation of the capacity of a single-fastener connection according to Eurocode 5 [6]. A possibly reduced capacity due to an increased MC (and the load duration) is considered by multiplication of the characteristic connection capacity with the modification factor, k_{mod}, when calculating a design capacity of a connection. For service class 3, the embedment strength is thus indirectly decreased due to the higher MC, while no reduction due to MC is considered for service classes 1 and 2 [6]. This is however in contradiction to findings from [1]-[4], who found a decreased embedment strength, f_h, for increasing MCs within service classes 1 and 2. Hardly investigated is the influence of the MC on the embedment stiffness, k_{el} (e.g. [4]). In the studies [1]-[4], test specimens were produced after the targeted equilibrium MC was reached, and thus the history of moisture changes was not considered. In contrast, Sjödin et al. [5] conducted an experimental study to investigate the influence of a decreasing MC after assembly of a multi-dowel steel-to-timber connection on the connection capacity, while the connection stiffness was not studied. A decrease in connection capacity with decreasing MC was found, which was explained by moisture gradient induced stresses, initiating small cracks in the connection area. However, to the best of our knowledge such a study was not yet carried-out on the embedment level.

In this contribution, the aim is to investigate the influence of the moisture and assembly history on the embedment strength and stiffness in grain direction by means of an experimental study. Thus, not only the influence of the MC on the embedment properties, but also the influence of different MCs in combination with the manufacturing and assembly history: drilling of the dowel hole, assembly of the dowel, and embedment testing, including even the influence of a crack underneath the dowel-wood interface, is investigated.

2 MATERIAL AND METHODS

2.1 Experimental program and materials

To study the influence of the moisture and assembly history on the embedment strength and stiffness in grain direction, seven groups of ten spruce and birch specimens each, with similar density distribution, were created (Figure 1). These groups differed by the moisture content (MC) of the specimen at the time: the dowel hole was drilled, the dowel was inserted, and the specimen was tested. In total, three different MCs, corresponding to ambient climates of 20°C and 65% RH (MC20/65 as a standard climate condition for testing), 20°C and 85% RH (MC20/85 as a condition with a higher MC), and 20°C and 38% RH (MC20/38 as a condition with lower MC) were used in the experimental program. These three ambient climates could be seen as representative for service class 1-3 in the current European design standard for timber structures, Eurocode 5 [6].

Series (1) served as a reference series, at which drilling, assembly and testing were done at the same MC, i.e. MC20/65 (standard climate condition for testing). The same procedure was followed for Series (5) and (6), but at a condition with high MC (MC20/85), and low MC (MC20/38), respectively. For Series (2) and (3), drilling and assembly were done at the reference condition (MC20/65), while testing was carried out in high MC (MC20/85) and low MC (MC20/38) conditions. Series (4) represents the situation of drilling right after production (MC20/65), assembly on-site after exposure to rain (MC20/85), and subsequent indoor application (testing at (MC20/38)). In addition, Series (7) investigates a damaged state, by application of an artificial crack parallel to the grain underneath the dowel-wood interface and aligned with the dowel hole center (see Figure 1), at MC20/65.

In total, 140 tests were conducted, uniformly distributed over seven different test series, with ten tests each, and two wood species, namely spruce and birch. Embedment test specimens were produced out of solid timber boards according to the corresponding European test standard, EN 383 [7]. Systematic selection of the specimens allowed for similar mean density and similar density distribution in the seven test series (Table 1). This was achieved by sourcing specimens from ten different boards, where each board provided one specimen per test series. The careful specimen selection was of importance in order to avoid large variations in wood characteristics that could influence the embedment properties. More details about the specimen sourcing are given in [8].

The mean density at an ambient climate of 20°C and 65% RH, amounted to 468.4 kg/m^3 (CV= 10.0%) for spruce, and 623.2 kg/m^3 (CV= 5.6%) for birch. The mean moisture content (MC) of the specimens at the time of testing is given per test series and species in Table 1. For determination of the MC, the oven-dry method according to EN 13183-1 [9] was used by placing the specimens in an oven at 103 ± 2°C directly after the embedment test. An ambient climate of 20°C and 65% RH resulted in a mean MC of 13.7% (CV= 2.7%) for spruce, and 11.0% (CV= 3.2%) for birch, while an ambient climate of 20°C and 85% RH resulted in a mean MC of 16.6% (CV= 1.2%) for spruce, and 14.9% (CV= 1.8%) for birch. An ambient climate of 20°C and 38% RH resulted in a mean MC of 8.6% (CV= 2.1%) for spruce, and 7.8% (CV= 2.6%) for birch.

Specimen dimensions followed the rules of EN 383. Thus, for a dowel with a diameter of d=12 mm, loaded in grain direction, the specimen height, h, (in grain direction) was 168 mm (twice 7d), the width, w, was 72 mm (twice 3d), and the thickness, t, was chosen to 36 mm (3d). All boards were stored in a climate chamber at an ambient environment of 20°C and 65% RH until the equilibrium moisture content was reached. Thereafter, the specimens for all test series were cut, and further processed according to the test program given in Figure 1. Equilibrium moisture content was assumed to be reached when two successive weightings, at an interval of 24 h, did not differ by more than 0.1% of the specimen mass, which is stricter than the rule given in EN 383 [7].

Immediately before testing, all specimens were reinforced with two partly-threaded screws (d=6 mm), to avoid early brittle failure of the specimen, i.e. before the targeted maximum embedment displacement of 15 mm was reached, as it was seen e.g. in [1] and [3]. Two screws, one above and one below the dowel were inserted at a distance of 36.5 mm from the dowel axis (Figure 2). The distance was decided based on results from Lederer et al. [10], to allow for a minimum distance between dowel and screw of one time the dowel diameter, i.e. 12 mm, at the end of the test. Thus, ductile behavior is ensured while a strength increase by the reinforcement screw is avoided. Moreover, this distance is far enough to not affect the elastic behavior of the wood-to-dowel contact.

Depending on the test series, the electrogalvanized dowel of steel quality S235, with d=12 mm was inserted either before the moisture content in the wood was adjusted or directly before testing. The borehole for the dowel was drilled to 12 mm in diameter without any clearance.

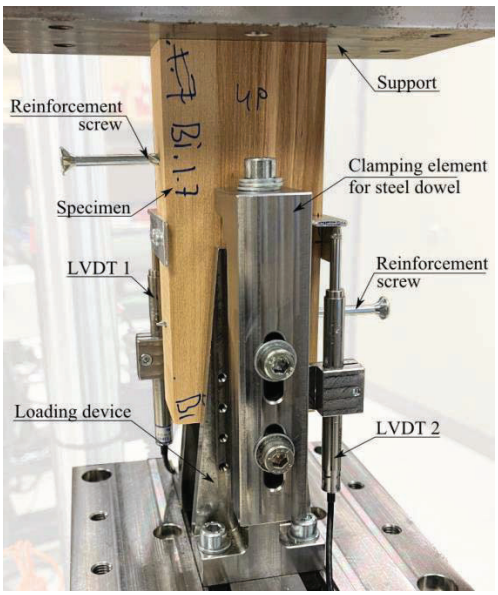

Figure 2: *Embedment setup for loading in grain direction according to EN 383 [7], including reinforcement screws to avoid premature splitting and 2 LVDTs for local displacement measurement.*

An artificial crack below the dowel with a length of 15 mm and a width of 0.5 mm, over the full specimen depth was added for Series (7). For this purpose, a small precision band saw was used. For more details, the reader is referred to [8].

2.2 Test setup and loading protocol

Full-hole embedment tests according to EN 383 [7], of 12 mm steel dowels embedded in spruce and birch specimens, loaded in grain direction were carried-out. The specimens were placed in a uniaxial testing machine (MTS 810, MTS Systems Corporation), by clamping both dowel ends in the loading device (Figure 2). Clamping of the dowel was used to minimize the effect of elastic bending of the dowel to ensure a uniform load transfer to the timber specimen along the dowel. A gap of 1 mm at each side between specimen and loading device was ensured to avoid friction between these elements.

On each side of the test setup, one displacement transducer (LVDT) was attached to measure the relative local displacement, u, between specimen and the loading device, and thus between the dowel and the timber specimen. For this purpose, steel angle brackets were diagonally mounted on the timber specimen's sides, in line with the dowel, to act as counterparts for the LVDTs mounted to the loading device. The force, F, as a result of embedment loading was directly measured by the load cell of the machine. In addition, the displacement of the actuator giving the machine displacement, u_{MTS}, was recorded.

The loading procedure followed the regulations of EN 383 [7], with small modifications. Loading was applied in grain direction until a machine displacement, u_{MTS}, of 17 mm, to ensure a local embedment displacement, u, of at least 15 mm.

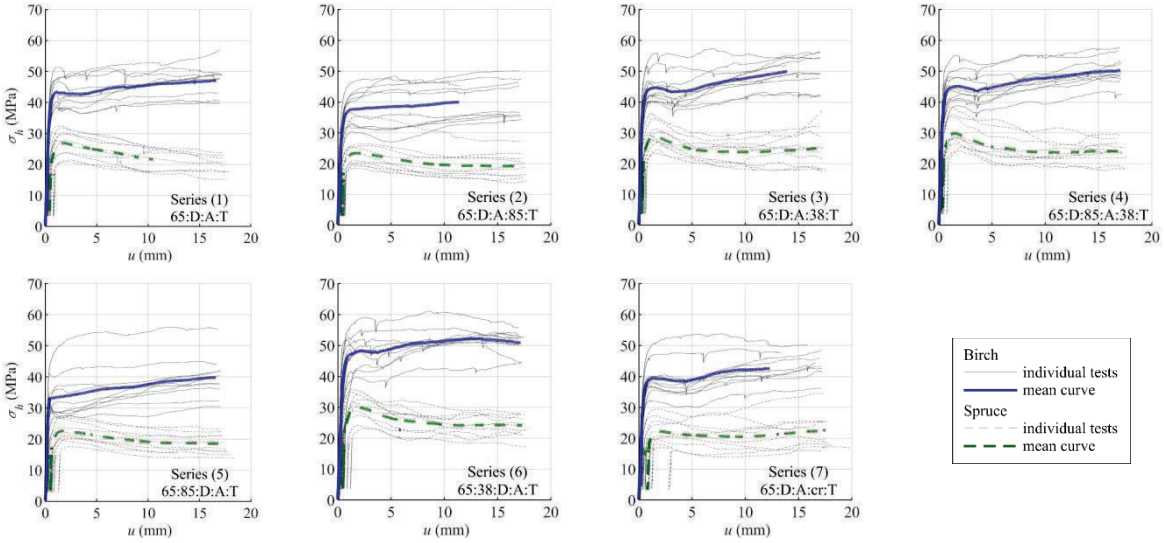

Figure 3: *Embedment stress-displacement curves for Series (1)-(7) of spruce (dashed lines) and birch specimens (continues lines).*

The displacement limit was increased compared to the 5 mm limit in EN 383 [7], to give access to the embedment behavior after yielding to serve as input for numerical models. The specimen was loaded force-controlled until a load level of 50% of the estimated maximum force, F_{est}, within 150 sec. This was followed by a 30 sec holding phase before the specimen was unloaded force-controlled with the same force rate to a force level of 10% of F_{est}. After a 30 sec holding phase, the specimen was re-loaded displacement-controlled with a displacement rate of 1.2 mm/min until u_{MTS} reached 17 mm.

2.3 Test evaluation

The local displacement, u, was determined as the average displacement measured by the two LVDTs. The embedment stress, σ_h, was calculated as the measured force, F, divided by the nominal contact surface of the dowel, i.e. the dowel diameter, d, times the specimen thickness, t. This gives access to the embedment stress-displacement curve for each test, from which the mean curve was determined by taking the average over the ten experiments per series.

The embedment strength, f_h, was defined according to EN 383 [7] as the maximum embedment stress up to a local displacement, u, of 5 mm. The elastic embedment stiffness, k_{el}, was defined as the inclination of the line, resulting from linear regression of the embedment stress-displacement curve between 10% and 40% of f_h as suggested in [8].

3 RESULTS AND DISCUSSION

3.1 Embedment stress-displacement curves

Embedment tests showed a pronounced global ductile behavior until the final displacement of more than 15 mm, thanks to the applied reinforcement screws. Most of the experiments showed local cracks in the wood below the dowel-wood contact surface, which however did not lead to global splitting of the specimen, as cracks were stopped at the reinforcement. These local cracks can be seen by load drops in the embedment stress-displacement curves illustrated in Figure 3. However, it also can be seen, that the force recovered after the crack-initiated load drop, reaching the load level before cracking.

Embedment stress-displacement curves for all seven test series, for both wood species (spruce and birch) are illustrated in Figure 3. Thin gray lines represent the individual tests, while thick green and blue lines give the mean curves of the individual test series per wood species. As typical for the embedment behavior of wood in grain direction, an almost linear behavior, representing the elastic range was observed for the first loading part. As soon as the elastic limit is reached, the stiffness decreases. For most of the tests, a local maximum is seen at this transition between elastic and plastic curve part, which is confirmed by previous tests [4,10,11]. Interestingly, spruce showed for most of the tests a continuous decrease in the embedment stress with increasing displacement, while the opposite was seen for birch, i.e., an embedment stress increase after the local maximum (see Figure 3). As expected, substantially higher embedment resistance was seen for birch compared to spruce, which confirms the correlation of the embedment resistance with the wood density [12,13].

3.2 Embedment strength and elastic stiffness

The embedment strength, f_h, as defined by EN 383 [7] (see Section 2.3), is given for Series (1)-(7) for both wood species, by its mean value and corresponding coefficient of variation (CV in %), in Table 2. For spruce specimens, a mean embedment strength, f_h, of 22.77 MPa to 30.34 MPa was found. The CV amounted to values below 20.5%. Birch specimens showed an f_h of 36.24 MPa to 49.24 MPa, with a CV of less than 19.9%. The difference in the mean embedment strength reflects the difference in MC between the test series. The about 60% higher embedment strength for birch compared to spruce is based

on its higher density, even if the magnitude in f_h-difference cannot fully be explained by the density difference, which was only about 30%. One explanation could be the untypical low f_h-results measured for spruce for its corresponding density. Furthermore, different correlations between f_h and density might be applicable for softwoods (e.g. spruce) and hardwoods (e.g. birch) as it was proposed by Ehlbeck and Werner [12].

The elastic embedment stiffness, k_{el}, as defined in Section 2.3, is given for all test series in Table 2. For spruce, a mean elastic stiffness, k_{el}, of 40.18 to 73.29 MPa/mm was found. The CV amounted to values up to 44.4%. Birch specimens showed a k_{el} of 89.40 to 133.52 MPa/mm, with a CV of up to 31.5%. Interestingly, birch specimens showed consistently lower variation in k_{el}-results compared to spruce specimens, while in general the variation for the embedment stiffness was higher than for the embedment strength. This confirms the sensitivity in measuring embedment stiffness, as it was already seen in previous studies [4,11], resulting among others from inaccuracies of the specimen preparation, dowel hole drilling, test setup, and displacement measurement. Birch specimens showed an elastic stiffness, k_{el}, of about twice the stiffness of spruce. This indicates a considerably stronger increase of the elastic stiffness with increasing density as it was found in [13].

3.3 Influence of moisture content

Results form Series (1), (5) and (6), are compared to study the influence of the moisture content (MC) on the embedment behavior, embedment strength, f_h, and elastic embedment stiffness, k_{el}. In these test series, the steps of (i) drilling the dowel hole, (ii) assembly of the dowel, and (iii) testing, were carried out after the equilibrium moisture content was reached. Thus, the only difference between these test series is their MC, while the assembly history and average specimen density was the same for all series. Series (1) corresponds to the standard climate of 20°C and 65% RH (MC20/65), Series (5) to a condition of a higher MC at 20°C and 85% RH (MC20/85), and Series (6) to a condition with a lower MC at 20°C and 38% RH (MC20/38). Corresponding MCs are given in Table 1.

The embedment stress-displacement curves in Figure 4(a) show a clear difference in the embedment resistance when reaching the yield limit. Higher embedment stresses can be reached, the lower the MC of the wood specimen is. Similar curve shapes can be seen for the different MCs, while distinct differences are found in the curve shape between spruce and birch, as discussed in Section 3.1.

The embedment strengths, f_h, presented in Figure 4(b) reflect the increase of resistance with decreasing MC. Series (5) (MC20/85), showed a decrease in the average f_h of about 15% (spruce) and 19% (birch) compared to the reference MC (MC20/65) in Series (1). This corresponds to a decrease in f_h by 5.8% (spruce) and 4.6% (birch) per 1% decrease in MC. Series (6) (MC20/38), showed an increase in the average f_h of 11% (spruce and birch) compared to the reference MC in Series (1). This corresponds to an increase in f_h by 2.0% (spruce) and 3.4% (birch) per 1% decrease in MC. Thus, results from this study suggest a nonlinear correlation of the embedment strength, f_h, with the corresponding wood MC, as well as differences between the two investigated wood species. Nevertheless, values are overall in line with findings from Hübner et al. [3], Sandhaas et al. [2] and van Blokland et al. [4], who found a strength increase of 3-4%, 2%, and 4-7% per 1% MC increase, respectively.

The elastic embedment stiffness, k_{el}, is illustrated in Figure 4(c). Interestingly, neither spruce, nor birch showed a distinct correlation of k_{el} with the corresponding MC. The difference in the average stiffness between Series (1), (5) and (6) were lower than 2% (spruce) and 8% (birch). Results need to be interpreted with care, since the stiffness parameter, k_{el}, showed for most of the test series a considerable variation in the results. These results are to some extend in contradiction to findings from van Blokland et al. [4], who found a significant influence of the MC on the elastic embedment stiffness for the first loading sequence, while almost no influence was seen for the following unloading/reloading sequence.

3.4 Influence of assembly history

Results from Series (2) and (5) are compared in Figure 5 to study the influence of the assembly history at a higher moisture content MC, i.e., at a MC corresponding to an ambient climate of 20°C and 85% RH (MC20/85). The influence of the assembly history at lower MC (MC20/38) is studied by comparing Series (3), (4) and (6) in Figure 6. In series (5) and (6), respectively, the steps of drilling, assembly and testing were done after the equilibrium moisture content was reached, and thus could be seen as reference cases. In contrast, in Series (2) and (3), respectively, the steps of drilling and assembly were done before the MC was adjusted. Furthermore, in Series (4) drilling was done at MC20/65, assembly at MC20/85, and testing at MC20/38. Thus, the only difference between

https://doi.org/10.52202/069179-0157

the series compared in this section, is the assembly history, while the MC at testing (either high or low MC) and the mean specimen density are always the same.

The embedment stress-displacement curves in Figure 5(a) and Figure 6(a), show for both wood species similar shapes and stress levels independent from the assembly history. Curves for spruce exhibit an almost perfect overlay. Curves for birch however show small differences, where for high MC condition the reference curve showed lower resistance, while for the low MC condition the reference curve exhibited higher resistance compared to the corresponding reference series.

The embedment strengths, f_h, illustrated by boxplots in Figure 5(b) and Figure 6(b), reflect the observations from the embedment stress-displacement curves. For spruce, the difference in the average f_h between the series was smaller than 5%, in low and high MC conditions. The corresponding difference for birch was slightly larger amounting up to about 10% in the low and high MC cases. Thus, a significant influence of the assembly history on f_h was not observed.

The elastic embedment stiffness, k_{el}, shown in Figure 5(c) and Figure 6(c), exhibited a different behavior for the high and low MC situation. While hardly any influence of the assembly history was seen when the specimens were moistened (less than 10% difference), a more distinct influence was seen when the specimens were dried, especially for spruce. For the cases at which the dowel was assembled before the specimen was dried, namely Series (3) and (4), an about 50% higher average k_{el} was found for spruce (for birch up to 20% difference) compared to the reference case (Series (6)). This might be explained by pre-stressing of the wood matrix around the steel dowel, due to shrinkage caused by decreasing MC. Thus, small gaps might be closed during drying of the specimen, resulting in a tighter fit at testing, and additional friction at the sides of the dowel due to shrinkage in transverse fiber direction, might result in a higher k_{el}. However, results should be treated with care, since the stiffness parameter k_{el} exhibited a considerable variation in the results.

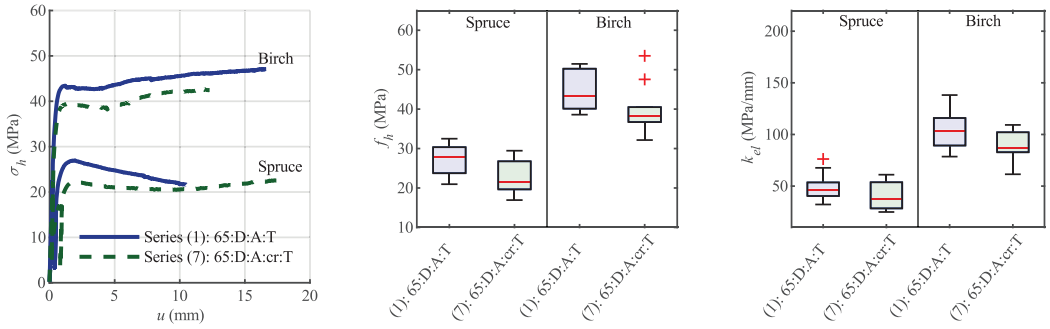
3.5 Influence of artificial cracks

Results from Series (1) and (7) are compared in Figure 7 to study the influence of an artificial crack on the embedment behavior. For both series, all the steps of drilling, assembly and testing were done at a moisture content corresponding to an ambient climate of 20°C and 65% RH. Compared to Series (1), specimens of Series (7) had an artificial crack in the wood below the dowel, representing a crack, which could develop at connectors during the service live of a building, e.g. due to moisture changes.

The embedment stress-displacement curves in Figure 7(a) show a clear difference in the embedment resistance when reaching the yield limit. A consistently higher embedment resistance was seen for the case without artificial crack (Series (1)). Both cases exhibit a similar curve shape, and a similar ductile behavior. Thus, also Series (7) did not show any global brittle failure, which can be explained by the applied reinforcement screws.

The embedment strengths, f_h, illustrated by a boxplot in Figure 7(b), reflect the observations from the embedment stress-displacement curves. Application of an artificial crack reduced the average embedment strength by about 10-15% for both investigated wood species. This might be explained by the reduced contact area below the dowel, and the reduced clamping effect of the dowel, since no tensile forces perpendicular to the grain can be transferred below the dowel, due to the artificial crack.

The elastic embedment stiffness, k_{el}, shown in Figure 7(c), was found to be slightly stronger influenced by the artificial crack as it was found for the embedment strength. The artificial crack reduced the average k_{el} by 15-20% compared to the uncracked case for both wood species. This might be explained by the aforementioned reduced clamping effect, which might affect the embedment stiffness more than the strength.



(a) (b) (c)

Figure 7: *Influence of artificial cracks on (a) embedment stress-displacement curve, (b) embedment strength, f_h, and (c) elastic embedment stiffness, k_{el}. For spruce and birch tested in Series (1) and (7), mean curves are given in (a), while boxplots in (b) and (c) express the median values and variation (25th and 75th percentile) for f_h and k_{el}, respectively.*

https://doi.org/10.52202/069179-0157

4 CONCLUSIONS

The comprehensive experimental testing program gave valuable insights into the embedment strength and stiffness, as regards the influence of the moisture conditions relevant for practical applications during production, assembly, and testing. Similar observations for spruce and birch indicate validity of the findings for different wood species with different density. Thorough sampling and accurate production of the test specimens were key to isolate the influence parameters of (i) moisture content, (ii) assembly history, and (iii) artificial cracks, from other major influence parameters like wood density.

The wood moisture content had a distinct influence on the embedment strength. For increased moisture contents compared to the reference MC at 20°C and 65% RH, an increase in strength of 2-4% per % MC was found, while for decreased moisture contents a decrease in strength by 4-6% per % MC as compared to the reference MC. In contrast, no distinct influence of the moisture content on the embedment stiffness was seen.

The assembly history did not show a distinct influence on the embedment strength. However, an increase in the average elastic embedment stiffness of up to 50% was found when drying the specimen after assembly of the steel dowel at the reference condition. In contrast, no influence was seen when the specimen was moistened after dowel assembly.

The artificial cracks applied below the steel dowel over the entire specimen depth resulted in a reduction of the average embedment strength by 10-15%. An even stronger effect was seen for the elastic embedment stiffness, which was reduced by 15-20% by the artificial crack. Due to reinforcement of the specimens, no global brittle failure was seen, despite application of an artificial crack.

These findings are expected to give valuable information for numerical modelling of dowel-type connections, as well as for engineering design. Furthermore, the results of this study might help to interpret findings from structural health monitoring and field measurements, as it shows the development of local connection stiffness with moisture changes in respect to the assembly history. In addition, the study highlighted the challenge of accurate stiffness measurement, which was reflected in a comparable high variation in stiffness results. It is proposed that more attention should be paid to embedment stiffness determination for future experimental studies and to the development of future testing standards, since the need for suitable connection stiffness prediction increases with the development of complex modern timber structures, like taller timber buildings.

ACKNOWLEDGEMENT

EXPERIMENTAL AND NUMERICAL ANALYSES OF A CONNECTION FOR CLT STRUCTURES

Lars Blomqvist[1] , Roberto Crocetti[2], August Claesson[3], Zakaria Ben Osmane[4], Rune Ziethén[5], Marie Johansson[6]

ABSTRACT: Although building systems made of cross-laminated timber (CLT) have become common in Sweden in the past 20 years and they have developed rapidly during the same period, steps remain to be taken to simplify the assembly of such systems, especially at construction sites. Current construction methods, however, remain labour-intensive and thus show room for improvement.

This paper describes a novel connection for the assembly of building elements made of CLT. Simple and inexpensive, the connection is fairly insensitive to manufacturing tolerances and enables rapid, more efficient construction than the connections for CLT structures currently used. Test results show the excellent strength and stiffness of the connection, which also allows the replacement of numerous fasteners, including nails and screws, with only a single steel rod.

KEYWORDS: assembly, connections, cross-laminated timber

1 INTRODUCTION

The deficit of affordable housing in Northern Europe requires the rate of housing production to increase in parallel to a decrease in production costs. Beyond that, construction needs to be more resource-efficient and, as such, more environmentally friendly.

The construction of residential timber buildings with different structural systems has recently increased significantly in Europe. In Sweden, the development of structural systems for timber buildings has taken two paths: one driven by the single-family house industry with industrially built volume elements (i.e. also used for multi-storey buildings) and one driven by manufacturers of engineered wood products such as glulam and cross-laminated timber (CLT).

In CLT's case, the building method is well-suited for traditional construction industries, primarily due to its similarity to the building method used in prefabricated concrete. In Sweden, buildings made of CLT began being built approximately 20 years ago. In that context, the manufacture of CLT has recently shown significant intensification, with several production plants being launched in the past few years. Although CLT construction systems have developed rapidly during those years, steps remain to be taken to simplify the assembly of the CLT elements, especially at construction sites.

This paper reports the development of a connection for the assembly of building elements made of CLT. The proposed connection provides greater precision and enables a faster, more efficient process than typical connections used today. We have already reported a feasibility study [1] which, among other things, revealed how the inspiration of the presented connection comes from the furniture industry.

2 MATERIALS AND METHODS

The tested specimens were cut from five CLT panels of Norway spruce (*Picea abies* L.) into a nominal thickness of 120 mm. The panels were produced with five laminations with a C24 strength class. Regarding thickness, the two outer layers were 30 mm, while the three inner layers were 20 mm. The layers were bonded with a polyurethane reactive adhesive free of urea-formaldehyde, for a bonding that complied with EN 14080, type 1, according to EN 15425. Meanwhile, the density of the panels was in the range of 457–510 kg/cm^3. The two outer layers and the central layer had their grains oriented in the direction perpendicular to the load,

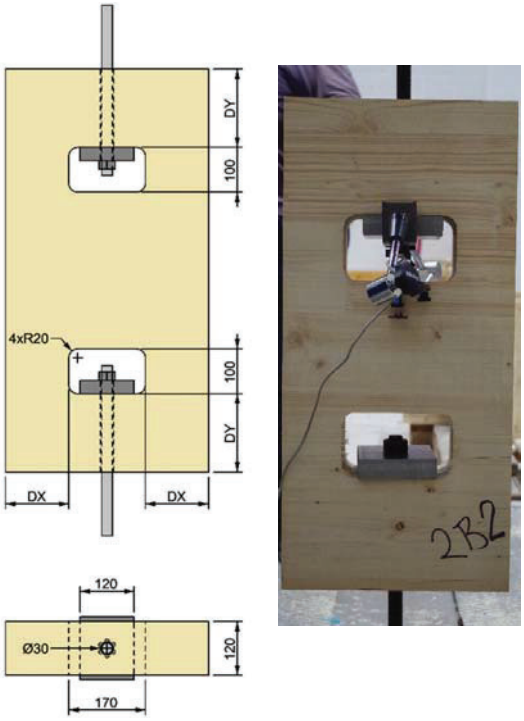
https://doi.org/10.52202/069179-0158

whereas the other two layers were oriented in the direction of the applied load. Last, the laminations were finger-jointed lengthwise but not edge-bonded.

Our study was performed on connections with varying geometries (see Figure 1a and Table 1), chiefly to assess the strength and stiffness of the proposed connection by varying two parameters: distance to end grain (DY) and lateral width (DX).

Altogether, seven specimen types were investigated experimentally, analytically and numerically. Two to three laboratory test repetitions on nominally identical specimens were performed in order to achieve satisfactory statistical relevance, which resulted in a total of 18 tested specimens.

Before commencing the laboratory tests, simplified hand calculations were performed in order to gain an approximate estimation of possible failure modes and corresponding failure load.



a b

Figure 1: *a) Dimensions of test samples*
b) Test set-up

Table 1: *Dimensions that varied in the samples by group*

Specimen group	DX (mm)	DY (mm)	Quantity (pcs)
1	90	100	3
2	165	100	3
3	90	175	3
4	238	175	3
5	90	250	2
6	155	250	2
7	238	250	2

Specimens were tested in a universal testing machine, and loads and corresponding displacement were recorded during the laboratory tests. The tensile axial load was applied to the specimens through a pair of steel rods 24 mm in diameter that were inserted in holes with a 30 mm diameter vertically drilled into the upper and lower parts of the specimens. The rods were fixed to the specimens by means of rectangular anchoring steel plates with a bearing area of 120 × 120 mm^2 and nuts at the end of the rods. The anchoring plates were allocated in openings made in the specimens that were rectangular in shape and had rounded off corners (Figure 1). Local displacements were measured using linear variable differential transducers (LVDT) placed directly above or directly below the rod's anchoring plate at each opening (Figure 1b). To avoid possible damage, the LVDTs were removed from the specimens when the load was approaching the predicted failure load of the connection.

2.1 The numerical model

Every specimen type was subjected to FE modelling with the commercial software Abaqus. The gap between the laminations within each layer was created by extruding a cut 0.01 mm wide. For each model, only half of the sample was modelled explicitly, and symmetry boundary conditions were used to represent the other half. All models used linear 8-noded brick elements with reduced integration and hourglass control. For groups 1, 3 and 5 of specimens, the FE mesh size was set to 6 mm.

The elastic material properties were the same for all models and are shown in Table 2. The properties are based on ones previously published [2]. For each layer, Direction 1 was oriented parallel to grain, Direction 2 was oriented in the direction perpendicular to the grain, and Direction 3 was set to point out of the plane of the panel.

Table 2: *Material properties, with E_i, υ_{ij} and G_{ij} indicating Young's modulus, Poisson's ratio and the shear modulus, respectively, in Directions 1, 2 and 3*

Name of the mechanical property	Numerical value
E_1	12,000 MPa
E_2	500 MPa
E_3	500 MPa
υ_{12}	0.3
υ_{13}	0.3
υ_{23}	0.3
G_{12}	600 MPa
G_{13}	600 MPa
G_{23}	60 MPa

The load was applied to the rod by using a reference point with a rigid body constraint, which allowed the load to be more evenly distributed over the end face of the rod. The load was modelled as a concentrated force acting on the reference point, its magnitude was set to the max load for each sample, and it was applied incrementally.

The boundary conditions used were different symmetry conditions applied to the symmetry surface of each sample.

https://doi.org/10.52202/069179-0158

The glued interaction between the layers of the CLT was handled by using a cohesive contact condition implemented in the FE software. Following past investigations [2], the bonded connection was given a stiffness of 1000 N/mm^3 in every direction; that condition was applied to all flat face surfaces of CLT, and no interaction between the lamination edges was used. The contact area between the steel anchor plate and the CLT was also simulated by using a special contact condition with hard contact typically for the surfaces and with a frictional behaviour tangential to the surfaces. The coefficient of friction between the steel and the timber was set to 0.4, and the penalty friction formulation was used.
A static general step was used in numerical simulations with Abaqus and with non-linear geometric effects toggled on. The increment was controlled to give curves without significant leaps and to apply the load in reasonably small steps.
The load displacement curves were defined based on displacement at the top edges of the plate and the hole to thereby measure displacement in the same location as the transducers used in the experiments.
For areas with significant tensile stress concentration, a linear elastic stress check based on beam theory was performed, namely by isolating the area of interest (e.g. a single lamination) and using a free body cut to find the forces and moment acting on the cut section with the highest stresses. Those values were subsequently used to determine stresses using Navier's equation.

3 RESULTS AND DISCUSSION

The load capacity of the studied connection in panels 120 mm thick is shown in Figure 6. The results reveal variation in load capacity depending on the geometry of the connection. Nearly all of the tested specimens failed in shear. Both rolling shear failures (i.e. at the bonded area between two adjacent laminations) and planar shear failure (i.e. with a crack parallel to the grain in laminations oriented perpendicularly to the direction of the applied load) were observed (Figure 2). However, it remains unclear which of the two shear failures occurred first.

Figure 2: *Failure mode of a type 1 specimen. The pictures show typical failure modes observed in most of the tested specimens. Both rolling shear in the outer horizontal laminations (upper picture) and longitudinal shear in the two internal vertical laminations (lower picture) can be seen*

https://doi.org/10.52202/069179-0158

The way in which the load is transferred from the openings where the anchoring plates are placed to the surrounding structure can be explained by the simplified model shown in Figure 3.

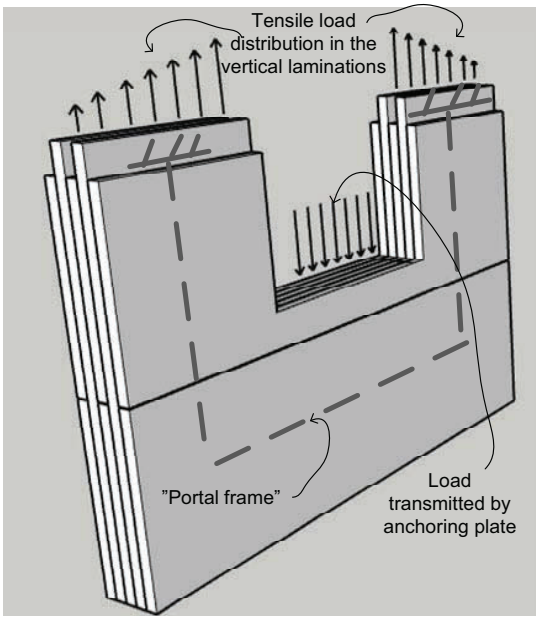


Figure 3: *Simplified model showing how the load is transmitted from the point of its application to the surrounding structure*

The part of the connection shown in Figure 3 suggests that the connection's structural behaviour is rather similar to that of an (upside-down) portal frame loaded with a distributed load at mid-span and rotationally restrained at the bases of the two frame columns. At the column bases, the bending moment and axial force generate a distribution of the reaction forces (virtually taken only by the vertical laminations) similar to that shown in the figure.

During loading, the portal frame is subjected to axial forces, shear forces and the bending moment. Those actions are most prevalently borne by the laminations of the portal frame with the grain parallel to the major stresses. For example, regarding the bending moment action in the frame, it will essentially be resisted by lamination 4 in the rafter part of the frame and by lamination 1 in the columns (Figure 4).

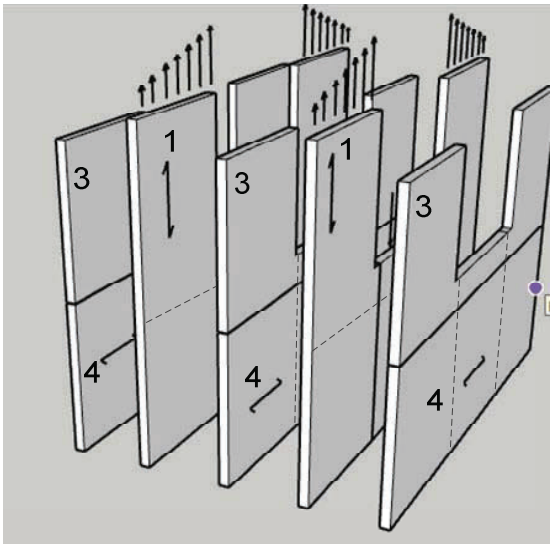

Figure 4: *Exploded sketch of the model shown in Figure 3. Laminations 3 and 4 have the grain in the direction perpendicular to the applied load, whereas Lamination 1's is in the direction parallel to the applied load*

However, because the vertical and horizontal laminations are bonded together, the bending moments and the consequent bending deformations in the load-bearing laminations are restrained by the cross-laminations. That dynamic generates torsional (shear) stresses at the bonded area between two adjacent laminations that might lead to failure due to rolling shear.

Similar considerations apply to the shear force in the frame. When the shear is transferred from the rafter (i.e. lamination 4) to the column (i.e. lamination 1), aside from rolling shear at the bonded areas, planar shear also occurs in lamination 1 (i.e. vertical shear) and in lamination 4 (i.e. horizontal shear) due to the moment gradient.

Finite element simulations revealed especially high shear stresses in all analysed specimens for loads close to the failure load. For example, for specimen type 1, the rolling shear and planar shear stresses at failure load are shown in Figure 5.

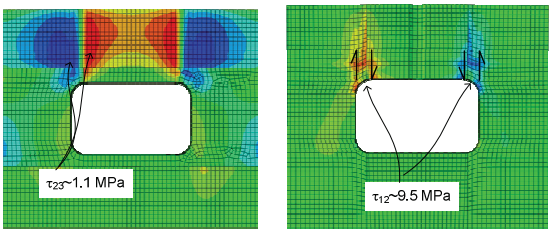

Figure 5: *Left: Rolling shear in outer horizontal lamination at failure load. Right: In-plane longitudinal shear in longitudinal lamination at failure load*

https://doi.org/10.52202/069179-0158

As shown in the analyses, shear stresses close to shear strengths are achieved for both rolling and planar shear, respectively.
In some of the sample with higher shear strength (i.e. specimens with larger DY), local bearing failure under the steel anchoring plate could be observed as well.
Our analysis of the results of laboratory tests suggests that the lateral distance, DX, within the tested range of 90 mm to 238 mm, had very little influence on the load-bearing capacity of the connection (Figure 6).

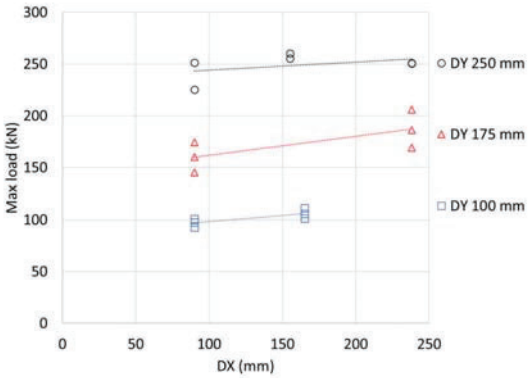

Figure 6: *Load capacity of the different tested specimens as a function of DX*

By contrast, there was also a clear increase in load-carrying capacity as the distance increased between the outer part of the anchoring plate and the upper (or lower) part of the specimen, DY (Figure 7).

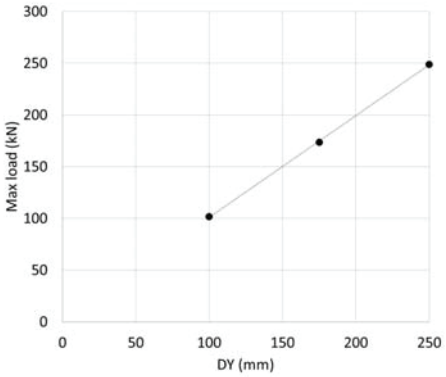

Figure 7: *Mean load capacity of the different tested specimens as a function of DY*

The stiffness of the connection was calculated as the ratio between the applied load and the local deformation measured underneath the anchoring plate. The maximum recorded local deformation for all of the tested specimens was generally small (i.e. approx. 1 mm), which led to very high axial stiffness of the connection. The stiffness was primarily influenced by the distance, DY, and to a lesser extent by DX. Moreover, the greater the distance, the lesser the influence of DX on the stiffness of the connection (Figure 8).

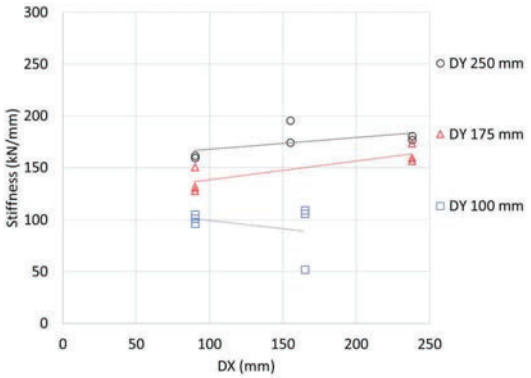

Figure 8: *Stiffness measured from local deformation.*

In terms of load displacement behaviour, FE analyses afforded highly accurate predictions. For example, a comparison of FE analysis and the laboratory results for one of the specimen groups is shown in Figure 9.

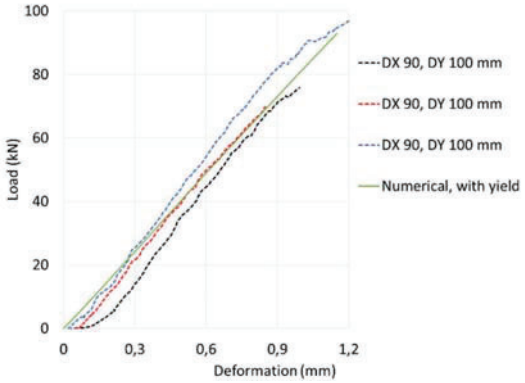

Figure 9: *Load versus local deformation for specimen type 1: comparison of experimental and FE results*

For the tested geometries, a pronounced linear relationship can be observed between the load-carrying capacity of the connection and the distance, DY. That condition, together with the fact that essentially all of the specimens failed in shear, lead to the formulation of a very simple verification model that was valid at least for a preliminary design of the connection within certain geometry boundaries. According to the model, the connection's capacity can be checked similarly to a check of the shear capacity of the rafter of a portal frame (Figure 10).

https://doi.org/10.52202/069179-0158

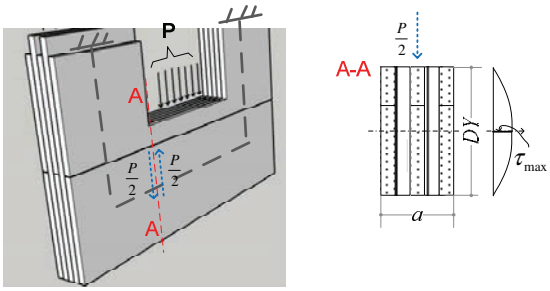

Figure 10: *Simplified verification model for the preliminary design of the proposed connection*

According to the model, the load carrying capacity, P, of the connection can be estimated as:

$$P = \frac{4}{3} \cdot a \cdot DY \cdot f_v \qquad \text{Eq 1}$$

in which a and DY are as explained in Figure 10, and f_v is the shear strength of the gross cross-section. For the tested specimens, the mean value of f_v was approximately 6.2 MPa. That relatively high value of shear strength, however, is suitable only for predictions of the realistic capacity of the connection. For a design situation, a lower shear strength value, presumably in the range of 3 to 4 MPa, is advisable.

4 CONCLUSIONS

The chief findings of our study were that:

- DX's influence on the load bearing capacity of the investigated connection is rather slight
- DY has significant influence on the load bearing capacity of the connection and
- Failure modes and corresponding failure loads are predictable for the geometries tested.

The novel structural connection demonstrates properties of strength and stiffness that are adequate for applications in connections between wall elements and between floor and ground foundations in multi-storey building. A single connection of this type can thus replace hundreds of conventional fasteners such as screws and nails.

ACKNOWLEDGEMENTS

Our research received financial support from the Kamprad Family Foundation (Ref. No. 20200013). We also wish to thank the Södra Skogsägarna forestry cooperative, especially Daniel Anderson and Kristoffer Segerholm, for the CLT used in the specimens.

ROBUSTNESS OF ADHESIVELY BONDED PANEL-TO-PANEL CONNECTIONS IN CLT FLOORS

Lei Zhang[1], Muster Marcel[2], Thomas Tannert[3], Hercend Mpidi Bita[4]

ABSTRACT: Cross-laminated timber (CLT) panels are increasingly used in floor construction with the individual panels often connected with self-tapping screws (STS) through surface spline, half-lap, and butt joints. An alternative solution is provided by using the Timber Structure 3.0 (TS3) technology that connects butt joints through high-performance adhesives and creates a near-rigid connection; therefore, two-way resistance of CLT panels can be utilized. However, TS3 joints fail in a brittle manner, and floor diaphragms lose integrity after crack develops. In this study, measures to improve the robustness and prevent floor collapse after TS3 joint failure were investigated. Seven panel-to-panel connections with TS3 and a secondary connection system were fabricated and tested under bending to evaluate the joint behaviour and observe crack propagation. After TS3 failed, bending or shear tests were conducted to test the residual strength of the secondary connections. The tests showed that it is possible to increase the robustness of TS3 joints by using additional mechanical connectors; i.e., the secondary connections exhibited residual strength after the TS3 joints failed. More tests are planned to further investigate measures to improve the robustness of TS3 joints.

KEYWORDS: Cross-laminated timber, TS3, Self-tapping screw, X-fix, Robustness

1. INTRODUCTION

1.1 BACKGROUND

Cross-laminated timber (CLT), a plate-like material made from layers of dimension lumber glued crosswise to one another, is commonly used in walls, floors, and roofs [1]. Due to prefabrication limitations, CLT panels are manufactured with width up to approximately 3.4 metres and assembled with panel-to-panel connections on-site. When used as floor diaphragm, the panels resist out-of-plane gravity loads and in-plane lateral (wind and seismic) loads. To successfully build CLT floors, connections between individual panels need to be designed for appropriate strength, stiffness, and ductility.

Traditional panel-to-panel connections employ dowel-type fasteners such as self-tapping screws (STS) to transfer in-plane shear forces. Tests have shown that screw connections display desirable structural performance under in-plane loads [2,3]. An alternative to STS in connecting CLT panels is the X-fix connector [4], which is a double dovetail-shaped wood wedge made of birch or beech veneer plywood.

The desire for open space and clear storey height favours the use of flat-plate system where CLT panels are point supported by columns and span two ways. In such systems, the out-of-plane performance of connections is critical to engage two-way behaviour. However, screw connections have limited moment capacity under out-of-plane loads [5]. As a result, CLT panels are often designed as one-way systems without considering the load-sharing action in the transverse direction.

1.2 TIMBER STRUCTURE 3.0 TECHNOLOGY

The Timber Structure 3.0 (TS3) technology provides a viable alternative to connect butt joints on-site using two-component Polyurethane adhesive [6]. TS3 butt-joints provide near-rigid connection performance under bending moments and shear forces and can realize the biaxial load-carrying timber flat slabs with a column grid up to 8 m × 8 m and a live load of 5 kN/m^2. This construction technology contributes to CLT replacing concrete in constructing large-scale flexible floor slabs.

However, under seismic loads, the ductility of CLT diaphragms relies on the connections, and engineers are reluctant to use adhesive connections due to their brittle failure. The combination of TS3 and mechanical fasteners such as STS or X-fix provides a possible solution for achieving both high stiffness and high ductility in the joints. In this hybrid system, TS3 provides stiffness for the connections under the service loads while STS or X-fix acts as a backup system and can be designed only for the failure loads. The combination of TS3 and STS joints has been successfully utilized in the floor construction of ON5 building in Vancouver, Canada [7].

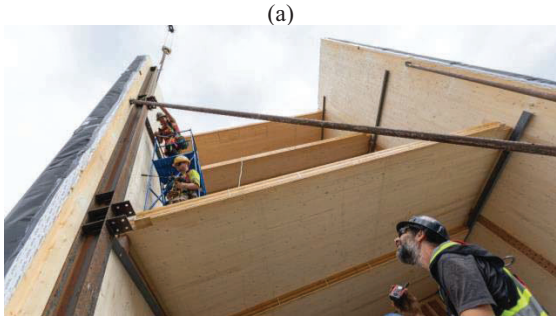
1.3 ON5 MASS TIMBER BUILDING

ON5 is an 840 m^2 innovative four-storey mixed-use commercial and office building located on a 7.6 m wide infill lot, as shown in Figure 1. The building was designed to Passive House principles by Hemsworth Architecture, engineered by Timber Engineering Inc., and constructed by Naikoon Contracting Ltd.

(a)



(b)

***Figure 1**: ON5 (a) Completed building (b) During construction (credit KK Law courtesy naturally:wood)*

The building was constructed with three-storey mass timber on top of a concrete and masonry podium. The gravity load-resisting systems of the mass timber portion are the CLT floors, roof, and walls, while the lateral load-resisting system relies on a CLT core, shear walls, and diaphragms. The CLT core uses innovative resilient slip friction hold-downs by Tectonus [8] at four corners to dissipate energy and reduce lateral drift. The CLT floor, roof, and wall panels are 5-ply (175 mm) E1 grade [9] while CLT core has both 7-ply (245 mm) and 5-ply (175 mm) running in East-West (short) and North-South (long) directions, respectively.

CLT floor panels spanning 7 m along East-West direction were sitting on balloon-type CLT walls along North-South direction. Under gravity loads, the design of CLT floor panels is governed by deflection and vibration requirements, while the strength requirements can be met when designed as one-way panel in the major strength direction. To achieve the required span with 5-ply E1 grade, the stiffness of CLT in the secondary direction was engaged by employing TS3 connection between panels. This way, the flat slab system was achieved without additional beams. As shown in Figure 2, the adhesive was injected into the gap between panels, creating a seamless connection. In addition, 220 mm FT/CSK screws [10] with a diameter of 10 mm were installed in 45° at a maximum spacing of 500 mm as the backup to TS3 joints in the event of a failed TS3 connection.

Along East-West direction (short direction), the CLT diaphragm cantilevered about 15 m on both sides of the core. Under seismic loads, CLT diaphragm can deflect due to slips between panels. The TS3 joints between panels eliminate slip of diaphragm between panels and control lateral deflection of floors and roof. With the rigid connection solution, a rigid diaphragm is achieved, and forces are transferred to stiffer CLT walls and core.

***Figure 2**: Application of TS3*

1.4 FLOOR ROBUSTNESS

In addition to the lack of ductility, another challenge towards the widespread adoption of TS3 is the loss of floor integrity after initial failure. At the ultimate strength level, cracks of TS3 appear at locations of imperfect bonding and wood defects. Initial cracks from extreme or abnormal loadings not considered in the design stage have a risk of propagation, which can lead to floor collapse. This is especially important for mass timber floors as existing studies on disproportionate collapse prevention on mass timber buildings are scarce [11-13].

Implementing structural robustness as a floor property is considered the best-suited method for disproportionate collapse prevention. With structural robustness, the floor can withstand initial damage and stop propagation by developing alternative load paths. A floor is considered robust if it can develop collapse-resistance mechanisms to absorb the initial local damage without collapse [14].

For a continuous TS3 joint, it is beneficial to install crack stoppers that block the crack propagation. The goal of crack stoppers is to physically divide the TS3 joints into different sections and allow stress redistribution after some sections fail. The floor should be able to resist dead and live loads without collapse. The simplest crack stoppers could be gaps or dowels that isolate TS3 into different sections. These simple measures can be combined with mechanical connectors that are often used as secondary connections to TS3, such as STS or X-fix, to provide additional strength.

https://doi.org/10.52202/069179-0159

2. EFFECTIVENESS OF CRACK STOPPERS

2.1 OBJECTIVES

For the acceptance of TS3 in CLT panel connections, it is necessary to demonstrate the robustness and ductility of the joints and provide adequate technical information for designers and engineers to use. This study focuses on the effectiveness of crack stoppers in preventing the progressive collapse of TS3. Tests were conducted on seven panel-to-panel connections with combined TS3 and a secondary connection system. The bending stiffness, strength, and shear strength of the joints were determined and compared with each other.

2.2 MATERIALS

The panel-to-panel connections with combined TS3 and a secondary connection system were fabricated and tested at ETH Zurich. The CLT panels were 5-ply with a thickness of 150 mm and a lamella grade of C24 [15]. The panels were 1.3 m long and 1.5 m wide, and connected by butt joints in the major strength direction. The TS3 joints had a thickness of 4 mm. The cross-section of the tested joints is shown in Figure 3. Crack stoppers were spaced 750 mm and divided the joint into three sections. To initiate the crack, two external sections were weakened by drilling holes with a diameter of 5 mm at the bottom after TS3 was cured.

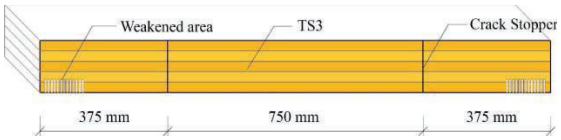


***Figure 3**: Cross-section of tested TS3 joints*

The specimens used the following crack stoppers:

1) Specimen 1 (SP1) was connected with two pairs of STS.
2) Specimen 2 (SP2) was connected with two X-fix connectors, glued to the bottom of the specimen with PU adhesive, as shown in Figure 4(a).
3) Specimen 3 (SP3) was connected with two pairs of STS. In addition, a 20 mm hole was drilled next to each pair of screws, as shown in Figure 4(c).
4) Specimen 4 (SP4) was connected with two mechanically inserted X-fix at the bottom, as shown in Figure 4(b).
5) Specimen 5 (SP5) and specimen 6 (SP6) comprised two pairs of STS. In addition, vertical beech dowels were installed next to screws to separate TS3, as shown in Figure 4(d).
6) Specimen 7 (SP7) was connected with two mechanically inserted X-fix at the top. At the bottom of each connector, a 20 mm hole was drilled.

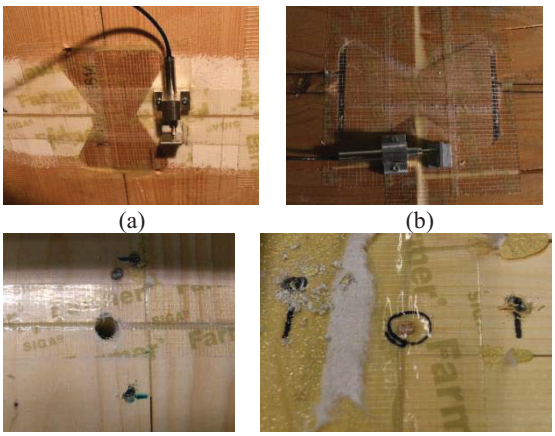

***Figure 4**: Crack stoppers used in the specimens (a) Glued X-fix in SP2; (b) X-fix in SP4 (c) Self-tapping screws and 20mm hole in SP3 (d) Self-tapping screws and beech dowel in SP5.*

Pairs of double-thread SFS WT-T screws [16] with a diameter of 8.2 mm and a length of 160 mm were installed at 45°. The X-fix connectors were 90 mm high, 130 mm long, and 96 mm wide. In SP4 and SP7 where the X-fix was not glued to CLT, the connector transferred tensile forces through interlocking and shear forces through friction. The 20 mm holes in SP3 and SP7 were drilled after TS3 adhesive was cured. The beech dowels in SP5 and SP6 were installed before the application of TS3. The holes and vertical wood dowels only serve as crack stoppers while STS and X-fix can provide additional tensile and shear strengths to the joints. The effectiveness of the crack stoppers is evaluated based on the following criteria: 1) A crack stopper should stop the continuous crack propagation from one section to another; 2) Load increase should be observed between individual cracks.

2.3 METHODS

The specimens were tested under four-point bending and Iosipescu shear as shown in Figure 5 and Figure 6, respectively. Instead of applying loads over the whole width of the panels, loads were only applied at edges of the panels with steel plates under the steel beams to provoke the failure of the glue line in the weakened region. The loading protocol was following the procedure in EN 26891 [17]. The load was applied to 40% of the estimated peak load and maintained at this level for 30 s. The load was then reduced to 10% of the estimated peak load and maintained for another 30 s. Thereafter, the load was increased monotonically until failure. To observe the crack propagation, servo-hydraulic with a displacement control was adopted. The loading rate varied in the range of 1-2 mm/min and was adapted to each specimen so that the specimens failed within 10 min.

https://doi.org/10.52202/069179-0159

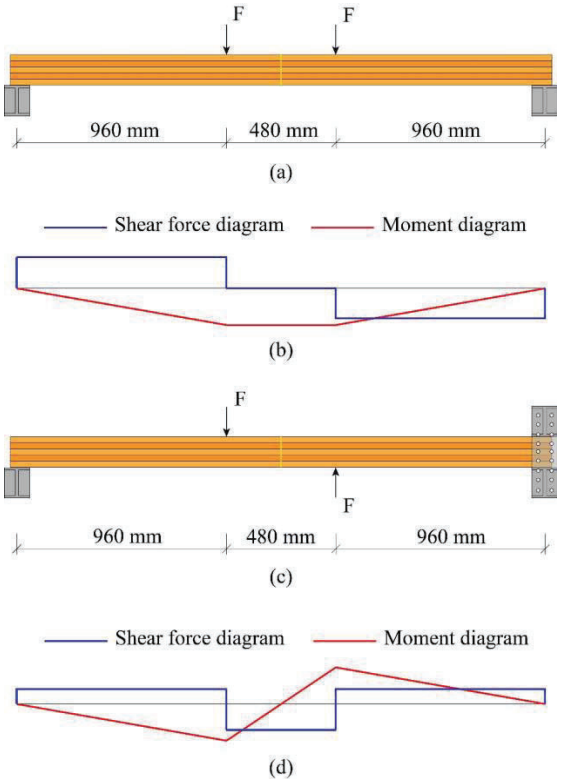

***Figure 5**: Bending and shear tests on panel-to-panel connections (a) Out-of-plane bending tests; (b) Moment and shear diagrams in bending tests; (c) Out-of-plane shear tests; (d) Moment and shear diagrams in the shear tests*

Four Linear Variable Differential Transformers (LVDTs) were mounted at the bottom of the specimens along the glue line to monitor the crack opening. LVDTs were mounted at two edges and locations of crack stoppers, as shown in Figure 7. The vertical deflection of the joint was measured by two LVDTs mounted on the top two edges.

After TS3 joints failed under bending, specimens SP1, SP2, SP5, SP6, and SP7 were re-tested under shear to determine the residual capacities of the secondary connections. The right hydraulic cylinder was kept in position by mounting the steel plates to the panel while the left hydraulic cylinder applied a downward force. The rightmost support was designed in such a manner that it can resist uplift forces. Under the new loading protocol, the joint in the middle was subjected to pure shear forces without any moment, as shown in Figure 5(d). For specimens SP3 and SP4, second bending tests on the failed TS3 joints were conducted to test the residual bending capacities of the secondary connections.

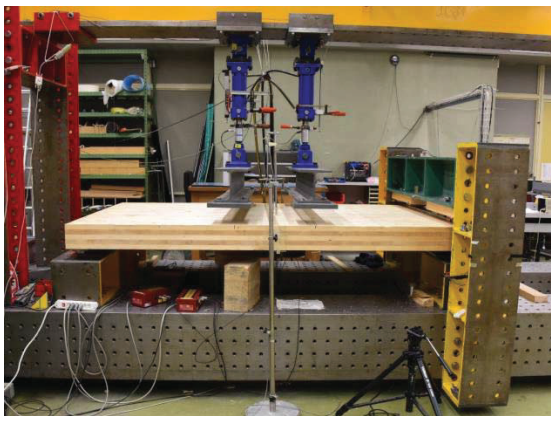

***Figure 6**: Laboratory bending test setup on panel-to-panel connections*

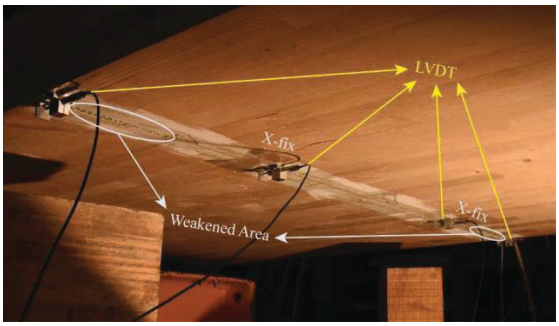

***Figure 7**: LVDTs mounted at bottom of specimens to measure crack opening*

2.4 RESULTS OF FIRST BENDING TESTS

Under bending, the failure of the TS3 joints started from one end at the location of the weakened area. The crack then appeared at the other end and finally in the middle of the joints. An example of crack opening at the bottom of the joint is shown in Figure 8 for SP2. It can be seen that there were three major cracks happening one after another in SP2 before the failure of the entire TS3.

The initial crack of TS3 did not cause the failure of the joint, but resulted in a drop of the applied load, as shown in the load-deflection relation of SP2 in Figure 9 where the vertical deflection was taken as the average of two deflections measured at two edges of the specimen. Following the first crack, the load rose again to the peak load. For most specimens, the second crack happened at the peak load. With more cracks appearing, the TS3 joints failed completely. The failure of a typical TS3 joint under bending is shown in Figure 10. No complete collapse of the specimens was observed due to the secondary connections.

https://doi.org/10.52202/069179-0159

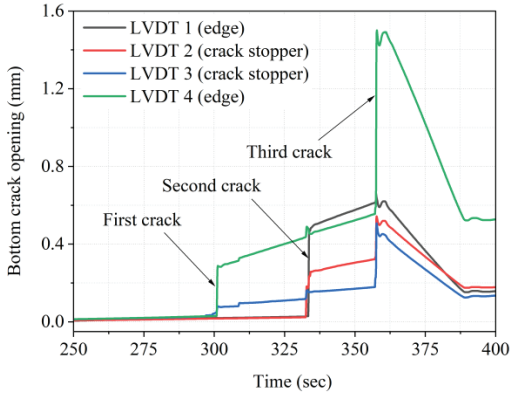

***Figure 8**: Bottom crack opening in SP2*

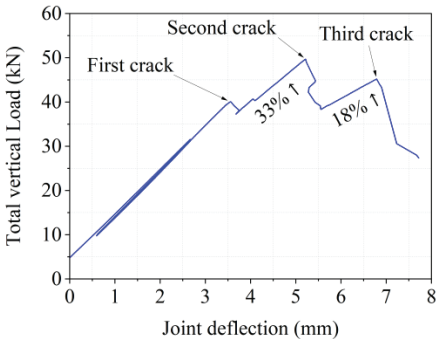

***Figure 9**: Load-deflection relation of SP2*

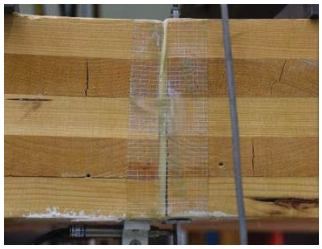

***Figure 10**: Failure of SP5 under bending*

Based on the crack opening and load-deflection relations of specimens, the number of cracks, the load level of each crack, and the load increase after each crack are listed in Table 1. The load level is the ratio between the load when the crack happened and the peak load. The load recovery represents the maximum increase of load following the load drop due to crack. Most specimens had 3-4 major cracks before TS3 failure. SP6 exhibited only two cracks while SP4 had five. It can also be observed that the peak load usually happened at the second crack except for SP5. The load recovery after each load drop indicates stress redistribution in the joints. On the contrary, a continuously decreasing load after the final crack suggests the complete failure of TS3. The most effective crack stopper was found in SP4 with two X-fix at the bottom, while the least effective crack stopper was found in SP6 which contained STS and vertical beech dowels.

***Table 1**: Effectiveness of crack stoppers*

	Crack openings	Load level	Load recovery after crack
SP1	1st	100%	1%
	2nd	100%	16%
	3rd	71%	/
SP2	1st	81%	33%
	2nd	100%	18%
	3rd	91%	/
SP3	1st	99%	1%
	2nd	100%	5%
	3rd	95%	6%
	4th	78%	/
SP4	1st	68%	52%
	2nd	100%	7%
	3rd	97%	17%
	4th	87%	19%
	5th	42%	/
SP5	1st	78%	16%
	2nd	82%	11%
	3rd	77%	34%
	4th	100%	/
SP6	1st	66%	63%
	2nd	100%	/
SP7	1st	85%	23%
	2nd	100%	10%
	3rd	73%	8%
	4th	69%	/

The mechanical properties of the panel-to-panel joints are listed in Table 2. P_{max} is the maximum total vertical load the specimens sustained during bending tests. Based on the maximum load, the moment capacity of TS3 joints can be determined as

$$M_{max} = \frac{P_{max} L_1}{2} \times \frac{2}{3} \quad (1)$$

where L_1 is the distance between loading point and the nearest support, which was 960 mm. The moment resistance has been normalized to 1 m width in Eq. (1). As shown in Table 2, the moment resistance of the joints was in the range of 11.3-20.6 kNm. As a reference, the design strength of C24 CLT is 72 kNm [15]. The lowest bending strength was found in SP5, which was attributed to the defects of TS3 joint. The failed section of TS3 in SP5 showed there was trapped air in the joint during TS3 application process.

The stiffness K of the joints was determined by calculating the slope of load-deflection relations of the specimens in the initial pre-loading phase. From Table 2, it can be observed that the stiffness of the joints showed less variation (COV=13.3%) than the moment resistance of the joints (COV=20.9%). Based on the joint stiffness (K in kN/mm), the apparent bending stiffness EI of the tested cross-section can be determined as:

$$EI = \frac{K}{48}(3L^2 - 4L_1^2)L_1 \quad (2)$$

https://doi.org/10.52202/069179-0159

where L is span which was 2.4 m. The apparent bending stiffness $(EI)_{ap}$ of C24 CLT under four-point bending load can be determined from shear analogy method as

$$(EI)_{ap} = \frac{(EI)_{eff}}{1 + \frac{24(EI)_{eff}}{(3L^2 - 4L_1^2)GA}} \quad (3)$$

where $(EI)_{eff}$ is the pure bending stiffness and GA is the term accounting for shear deformation. The determined bending stiffness of the TS3 joints according to Eq. (2) is in the range of 1122-1818 kNm^2 with an average value of 1560 kNm^2. The determined bending stiffness of C24 CLT according to Eq. (3) is 1916 kNm^2. It can be concluded that TS3 joints can reach more than 80% of the continuous CLT bending stiffness.

***Table 2**: Summary of test results*

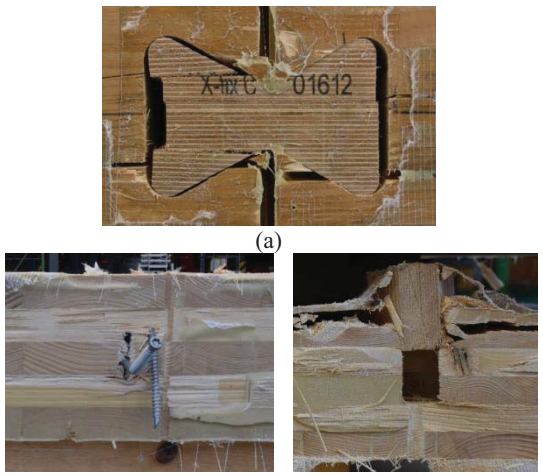
	P_{max} kN	M_{max} kNm	K kN/mm	EI kNm^2	M_{re} kNm	V_{re} kN
SP1	52.4	16.8	9.6	1744	/	15.6
SP2	49.7	15.9	10.0	1818	/	58.5
SP3	42.2	13.5	8.1	1469	2.2	/
SP4	38.6	12.4	6.2	1122	3.7	/
SP5	35.4	11.3	8.6	1566	/	45.5
SP6	64.4	20.6	8.6	1558	/	46.8
SP7	37.7	12.1	9.1	1644	/	53.8

Note: P_{max} is the maximum total vertical load the specimens sustained during bending; M_{max} is the moment capacity of TS3 joints normalized to 1 m width; K is the stiffness of TS3 joints based on total vertical load and deflection; EI is the bending stiffness of TS3 joints normalized to 1 m width; M_{re} is the residual moment resistance of the secondary joints normalized to 1 m width; and V_{re} is the residual shear capacity of the secondary joints.

2.5 RESULTS OF SECONDARY TESTS

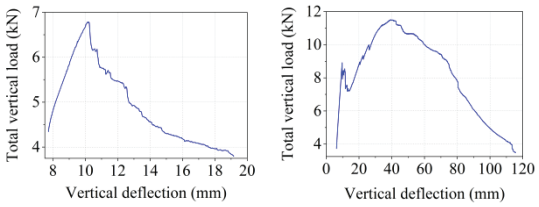
For specimens SP3 and SP4, bending tests were conducted again on the failed TS3 joints to test the residual moment capacities of STS and X-fix. The failure of X-fix under bending is shown in Figure 11(a) which shows the shear failure of plywood in the wedge and local shear failure of CLT. For the rest of the specimens, shear tests were conducted on the secondary connections and the shear failure of STS and X-fix under out-of-plane shear are demonstrated in Figure 11(b) and (c), respectively, from which the bending of screws, embedment of screws into wood, and sliding of X-fix can be observed.

The load-deflection relations of SP3 and SP4 under secondary bending are plotted in Figure 12. The moment resistances of two secondary connections are listed in Table 2 as M_{re}. While the moment resistances of STS and X-fix were both significantly lower than TS3, X-fix had a higher moment resistance than STS. More importantly, the failure of X-fix joint under bending was in a more ductile manner, as can be seen from the large deflection of the joint in Figure 12(b). The ductility came from bearing of wood fibres between CLT and X-fix.



(a) (b) (c)

***Figure 11**: Failure of secondary connections (a) X-fix at the bottom of SP4 under bending (b) STS in SP5 under shear (c) X-fix in SP7 under shear*



(a) (b)

***Figure 12**: Load-deflection relations in secondary bending tests on (a) STS in SP3 (b) X-fix in SP4*

The residual shear strengths of STS in SP1, SP5, and SP6, and X-fix in SP2 and SP7 are listed in Table 2 as V_{re}. The shear capacities of X-fix in SP2 and SP7 were similar, while the shear capacities of STS in SP5 and SP6 were close to each other. According to [16], the characteristic shear capacity of two pairs of WT-T screws is 19.3 kN which is less than half of the tested values of SP5 and SP6. It should be noted that X-fix connectors have no technical approval for out-of-plane shear loading. Nonetheless, the tests showed that the X-fix connectors had higher shear strength than STS. It is not obvious why the STS in SP1 had a much lower shear strength than the rest of the specimens. As the shear tests were conducted on the failed TS3 joints, it is possible that STS were already loaded in the first bending test.

3. ONGOING EXPERIMENTAL WORK

The experimental study discussed in Section 2 focused on the potential of using crack stoppers to prevent the complete collapse of floors with TS3 joints. The tests were limited to joints in the major strength direction under out-of-plane loading, while TS3 performances in minor strength direction of CLT and under in-plane loads were not investigated. Another critical property of the panel-to-panel connections is the ductility under in-plane and out-

https://doi.org/10.52202/069179-0159

of-plane loads, especially under seismic loads. However, the failure mode of the tested joints was brittle in general.

To address the brittle failure pattern of TS3, metal fasteners such as STS can be installed in a closer spacing than the tested specimens in this study, thus STS is not only used as crack stoppers after TS3 fails, but also as additional fasteners to provide ductility. A research program is underway at University of Northern British Columbia (UNBC) to study the performance of combined TS3-STS joints in connecting CLT panels. The testing program includes combined TS3-STS in both major and minor strength directions under in-plane and out-of-plane loads, as well as two test series under long-term bending load. Figure 13 depicts the proposed testing plan on CLT panel-to-panel connections. The complete testing matrix is shown in Table 3.

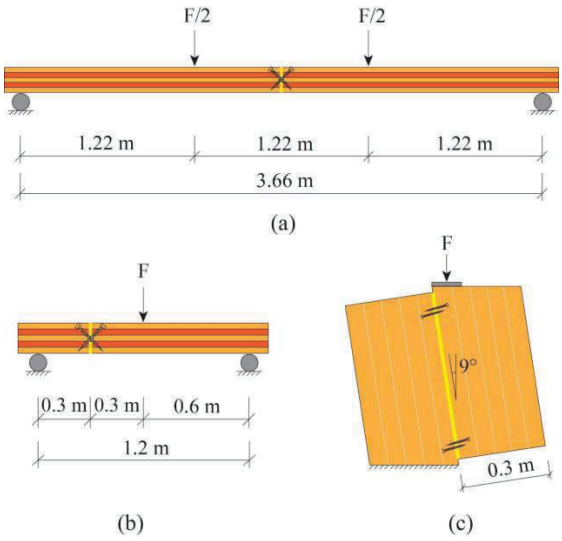


***Figure 13**: Proposed testing on CLT panel-to-panel connections (a) Out-of-plane bending test (b) Out-of-plane shear test (c) In-plane shear test*

Out-of-plane bending tests will be conducted on the panel-to-panel joints, see Figure 13(a). Four-point bending tests will create a pure bending zone for the joints. The variations of the specimens are the CLT layup (5-ply and 7-ply), joint type (TS3, STS, combined TS3 and STS), and panel orientation (major direction and minor direction). Most specimens will be tested under short-term loading while two series will be tested under long-term loading with load levels of 25% and 50% of the short-term peak load, respectively.

The shear tests on the joints will be conducted on a reduced variation of joints. The main variations in the shear tests are the CLT layup and orientation, while only the joints with combined TS3 and STS will be tested. The out-of-plane shear tests on the connections are shown in Figure 13(b). The load applies in the mid-span and the joint is located at a quarter span from the nearest support. This way, the joint is subjected to the highest shear force and reduced bending moment. The combined shear and bending moment mimic the loading case for the joints in real structures. The in-plane shear test is illustrated in Figure 13(c) where the specimen contains a single shear plane, and the vertical load aligns with the centre of the shear plane.

***Table 3** Test matrix of ongoing work*

Series	CLT ply	CLT direction	Load duration	Joint
B5PSA	5	//	ST	TS3
B5PSS1	5	//	ST	STS
B5PSAS1	5	//	ST	TS3+STS

I5PSAS1	5	//	ST	TS3+STS
I5TSAS1	5	⊥	ST	TS3+STS
I7PSAS2	7	//	ST	TS3+STS
I7TSAS2	7	⊥	ST	TS3+STS

Note: // and ⊥ represent the major and minor strength directions of CLT, respectively; ST stands for short-term loading; and LT stands for long-term loading.

In all the specimens, the width of CLT is 600 mm. STS are installed in pairs and inclined 45°. For each test series, six replicates will be tested. The connection stiffness, strength, and failure pattern will be evaluated, and then the characteristic values of connections will be provided for the engineering design of connections. The goal of the proposed research is to provide adequate technical guide for designers and engineers to use, thus promoting a growing application of mass timber panels in two-way flat slab floor systems.

4. CONCLUSIONS

The effectiveness of crack stoppers in preventing the collapse of TS3 joints was examined by testing seven panel-to-panel CLT connections under bending and shear. Test results showed promising performance of STS and X-fix as secondary connections in transmitting shear forces and bending moments after TS3 failure. Therefore, in floor construction, X-fix or STS can be used as a

temporary measure to connect CLT panels and hold the panels in position for TS3 applications. In the event of TS3 failure, these connections serve a second purpose as the backup system to maintain the integrity of the joint. Overall, X-fix showed better mechanical performance than pairs of STS as secondary connections. However, due to the limited number of specimens tested, no recommendation concerning the design of secondary connections can be provided. Ongoing experimental work will provide data for the robust design of TS3 joints.

ACKNOWLEDGEMENT

The research project on the crack stoppers was funded by Innosuisse and supported by Timber Structures 3.0 AG, Schilliger Holz AG, and Henkel & Cie AG. The research project was a collaboration between ETH Zurich and the Bern University of Applied Sciences. Funding for the research project on the hybrid joints has been sought from the Natural Sciences and Engineering Research Council of Canada for an Alliance project in collaboration between Timber Engineering Inc. and the University of Northern British Columbia and supported by Timber Structures 3.0 AG.

EXPERIMENTAL INVESTIGATIONS ON THE STIFFNESS OF STEEL-TIMBER DOWEL-TYPE CONNECTIONS IN BEECH LVL

Lea Buchholz[1], Ulrike Kuhlmann[2]

ABSTRACT: With the increasing complexity of timber structures, accurate computational prediction of the load-deformation behaviour of joints is becoming more important for design. In particular, the initial stiffness is a relevant parameter. Therefore, a detailed knowledge of the parameters influencing the connection stiffness is required, but is currently not available for hardwoods. A comprehensive database on the load-deformation behaviour of steel-timber dowel-type connections in beech LVL is being developed on the basis of experimental tests currently being carried out at the University of Stuttgart. The aim is to enable the efficient use of hardwoods in high-performance yet easy-to-manufacture connections by realistically predicting connection stiffness. This paper will give an overview on the first results.

KEYWORDS: Steel-timber dowel-type connections, connection stiffness, beech LVL, experimental testing

1 INTRODUCTION

In times of climate change, timber structures are coming under increasing political and social focus as a sustainable and resource-efficient construction method. At the same time, the forest structure in Germany is changing due to extended drought, with the high proportion of spruce being replaced mainly by beech. As a result, beech will have to be increasingly used in construction practice. The prerequisite for this is a reliable and economical design, also for hardwoods. In particular, the prediction of the load-deformation behaviour of high-performance joints is crucial for the design of complex timber structures. However, the current database on the connection stiffness in hardwoods is far too small to derive reliable predictions.

Therefore, the research project "Innovative timber joints by modelling the stiffness for high-performance timber structures made of hard- and softwood" [1] was started at the Institute of Structural Design at the University of Stuttgart in 2021. The aim is to increase the database of stiffness values of steel-timber dowel-type connections in beech laminated veneer lumber (beech LVL) through experimental investigations. This will enable more accurate predictions in order to provide design recommendations for the new version of Eurocode 5 [2].

This paper deals with the first results of these experimental investigations. After an overview of the current normative regulations for stiffness calculation and the state of the art, the test programme and setup as well as the geometry and the material of the above-mentioned tests are described. Afterwards, the first experimental results are presented and discussed.

2 STATE OF THE ART

For the determination of the slip modulus K_{ser} for steel-timber dowel-type connections in the serviceability limit state (SLS), Equation (1) is given in Eurocode 5 [2]. Thus, the slip modulus depends only on the timber density ρ and the fastener diameter d. Other influencing factors such as the load-to-grain angle, the number of fasteners and the slenderness of the connection (failure mode) are not considered.

$$K_{ser,EC5} = \frac{2}{23} \cdot \rho_m^{1.5} \cdot d \tag{1}$$

In comparison, the Swiss standard SIA 265 [3] defines the above-mentioned slip modulus K_{ser} according to Equations (2) and (3). Unlike Eurocode 5, a distinction is made between fasteners loaded parallel and perpendicular to the grain.

$$K_{ser,0,SIA} = 6 \cdot \rho_k^{0.5} \cdot d^{1.7} \tag{2}$$

$$K_{ser,90,SIA} = 3 \cdot \rho_k^{0.5} \cdot d^{1.7} \tag{3}$$

Several studies (see [4]-[9]) have shown that the stiffness calculated according to Eurocode 5 [2] is quite inadequate, even for softwood connections. First experimental investigations on steel-timber dowel-type connections in beech glulam and LVL mainly examined the load-bearing capacity (see [10]-[12]). This is underestimated by approximately 33 % for connections in beech glulam [10]. Kobel et al. [12] have shown that veneer cross-layers have a positive effect on the load-bearing capacity of connections in beech LVL by preventing the timber from

splitting. As a result, higher loads can be achieved with significantly improved ductile behaviour. The aim of the research project presented in this paper [1],[13] is therefore to verify the positive influence of cross-layers on the stiffness. Initial investigations on the stiffness of steel-timber dowel-type connections in beech LVL have already been carried out by Misconel et al [14]. According to this, the formula for stiffness calculation in Eurocode 5 [2] is insufficient for connections in beech LVL. Comparable results were obtained in tests carried out at the University of Stuttgart as part of IGF project no. 20625 N [4]. In addition to a large number of tests on steel-timber dowel-type connections in spruce glulam (GL 24h and GL 28h), tests were also carried out on 12 connections in beech LVL. Table 1 shows the results of two series of tests on spruce glulam and beech LVL and compares them with the corresponding values determined according to Eurocode 5 [2]. The average load-bearing capacity F_{max} of the connection in beech LVL is underestimated by 54 %. This tendency is also in line with the results of Franke & Franke [10]. It is also shown that the initial stiffness K_{ser} is better represented normatively than the reloading stiffness K_e, which is underestimated by 60 % in beech LVL. However, the large scatter of the test results with coefficients of variation (COV) of around 25 % and the small number of tests do not yet allow any precise recommendations to be made with regard to the computational prediction of the connection stiffness in beech LVL. Fundamental investigations of the stiffness of steel-timber dowel-type connections in beech LVL are therefore necessary and are being carried out in an ongoing research project at the University of Stuttgart [1]. The first results of these investigations are presented in this paper.

3 EXPERIMENTAL RESEARCH

3.1 TEST PROGRAMME AND SETUP

Based on a completed research project at the Institute of Structural Design [4],[5], which mainly investigated the stiffness of dowel-type connections in glulam made of spruce, a further 172 tensile tests are carried out on steel-timber dowel-type connections in beech LVL. The aim is to obtain a comprehensive database on the load-deformation behaviour of dowel-type connections. Figure 1 shows the test setup for the single fastener specimens with a load-to-grain angle α of 0° (top) and 90° (bottom). All tensile tests with grain parallel loading are double symmetric, allowing two connections to be tested simultaneously. Therefore, a total of four displacement transducers per specimen (two per connection) were applied. Only two displacement transducers are used for the tensile tests with a load perpendicular to the grain, as the modified test setup tests a single connection. The displacement transducers measure the relative deformation between the slotted-in steel plate and the timber at the level of the centre line of the dowel.

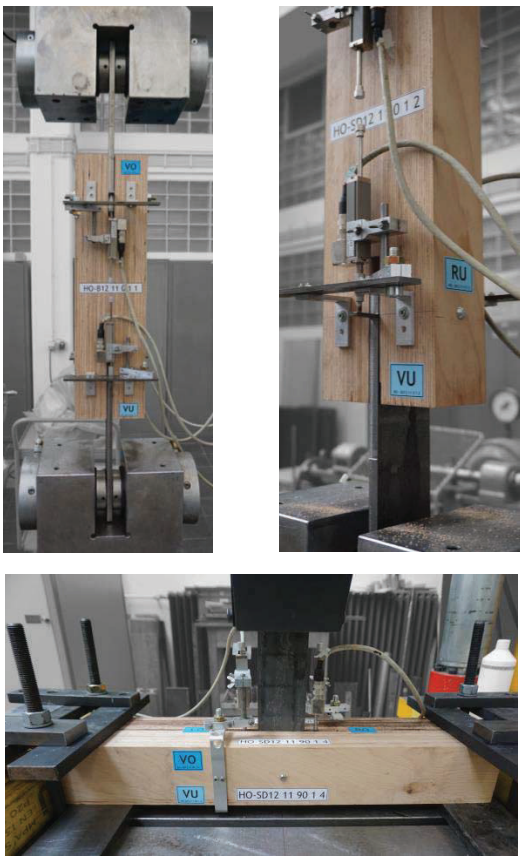

Figure 1: *Test setup for the specimens with a single fastener and load parallel to the grain (top) and with a load-to-grain angle α = 90° (bottom)*

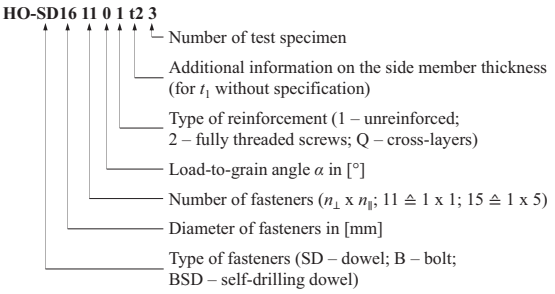
The experimental programme is given in Table 3. In addition to the number of fasteners, the type and diameter $Ø$ of the fasteners, the load-to-grain angle α, the type of reinforcement of the timber element and the side member thickness $t_{1\text{-}3}$ are varied. The reinforcement of the timber is partly achieved by fully threaded screws and partly by internal reinforcement using veneer cross-layers (GL 60Q). The designation of the test specimens is designed as:

https://doi.org/10.52202/069179-0160



The different side member thicknesses $t_{1\text{-}3}$ are intended to induce all three possible European Yield Model (EYM) failure modes according to Eurocode 5 [2] in the tests. For this purpose, preliminary numerical investigations were carried out using a Beam-on-Foundation (BoF) model already implemented in RFEM (Dlubal) (see [4]-[6]). Figure 2 shows as an example the numerically calculated deformation of the dowel with a diameter of 16 mm plotted over the width of the test specimen for different side member thicknesses with a maximum deformation of the connection of 4 mm.

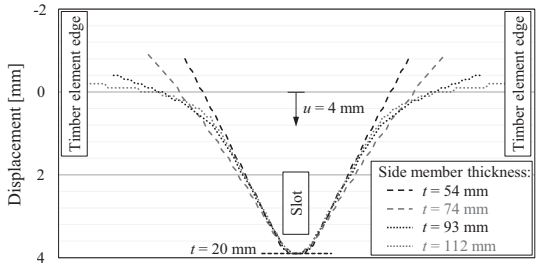


Figure 2: *Deformation of the dowel (Ø = 16 mm) calculated with RFEM plotted over the width of the test specimen for various side member thicknesses (connection deformation 4 mm)*

Using the BoF model, a side member thickness of 20 mm leads to embedment failure in timber (t_1). As the side member thickness increases, the transition from initially one (t_2) to two (t_3) plastic hinges per shear plane can be observed. The BoF model was also used to estimate the load-bearing capacity F_{est} of the connections, which is required for the loading and evaluation according to EN 26891 [15]. The tests were carried out displacement-controlled.

3.2 GEOMETRY AND MATERIAL

An example of a tensile test specimen parallel to the grain with 1 x 5 fasteners per connection and reinforcement with fully threaded screws is shown in Figure 3. Due to the symmetrical design, there are two sets of data for each specimen for the evaluation of the connection stiffness. The *timber elements* with a grade of GL75 and GL 60Q were prefabricated with a fully automated joinery machine. The slots for the slotted-in steel plates were made with a width of 14 mm. Fastener holes were pre-drilled to the appropriate nominal diameter from both sides of the timber member. ASSYplus VG 4 CSMP (countersunk head) type screws according to ETA-11/0190 [16] with diameters of 6 mm and 8 mm were partially used for reinforcement. The fully threaded screws were also pre-drilled with diameters of 5 mm and 7 mm to facilitate insertion. For technical reasons, the diameter of the boreholes was slightly larger than recommended in [16]. In addition to screw reinforcements, some specimens were also reinforced with veneer cross-layers. For this purpose, standard Q-boards in beech LVL were produced with a thickness of 42 mm and a cross-layer content of 14 %. Several Q-boards were glued with melamine to the required cross sections.

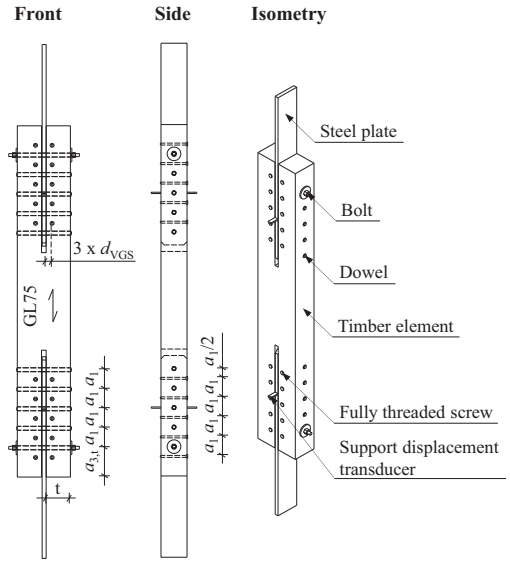

Figure 3: *Example of a tensile test parallel to the grain specimen with 1 x 5 fasteners per connection and screw reinforcement*

The *steel plates* with a grade of S355J2 were manufactured with a thickness of 12 mm. The *fasteners* ordered in S235JR (electrolytically galvanised) steel were made from cold drawn bars. Tensile tests were carried out according to EN ISO 6892-1 [17] on five to six randomly selected samples for each diameter to determine the material properties of the fasteners. The results are summarised in Table 2. Due to the cold forming process of the steel, the technical elastic limit of 0.2 % was taken as yield strength. Compared to the normative values according to EN 1993-1-1 [18], there is a clear overstrength of the steel, where the experimental tensile strength is up to 690 N/mm². This overstrength is also described in the literature (see [4],[5],[19]-[21]).

Table 2: *Mean values of fastener material properties from tensile tests according to EN ISO 6892-1 [17]*

4 RESULTS OF THE CONDUCTED TENSILE TESTS

4.1 GENERAL OVERVIEW

Currently (February 2023), 112 out of 172 planned tests have been carried out. The tests of connections with groups of fasteners are planned to be conducted in spring 2023. Table 4 summarises the already experimentally determined initial stiffnesses $K_{ser,test}$ for connections with single fasteners and compares them with the stiffnesses calculated according to Eurocode 5 [2].

4.2 FAILURE MODES

The failure mode of the connections depends, on one hand, on the side member thickness (EYM). On the other hand, the type of fastener (dowel or bolt), the load-to-grain angle α and the timber reinforcement also influence the load-displacement behaviour in the range of the ultimate limit state (ULS).

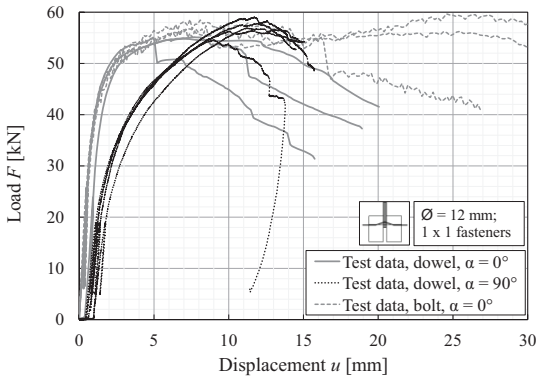

Figure 4: *Load-displacement curves for connections with single fasteners (dowels and bolts) of 12 mm diameter and loading parallel and perpendicular to the grain*

Figure 4 shows the load-displacement curves for connections with single fasteners (dowels and bolts) of 12 mm diameter and loading parallel and perpendicular to the grain. The load-bearing capacity is in a similar range for all of the connections. However, there is a pronounced plastic plateau for connections loaded parallel to the grain rather than perpendicular to the grain. This applies in particular to connections using bolts due to the rope effect.

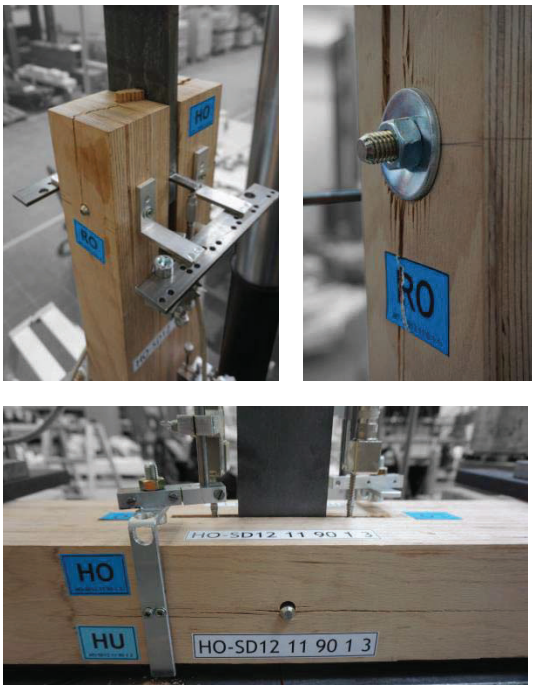

Figure 5: *Top left: Splitting of the timber after ductile deformation of the dowel (α = 0°); Top right: Deformation of a bolt and the washer (α = 0°); Bottom: Lateral splitting of the timber after ductile deformation of the dowel (α = 90°)*

https://doi.org/10.52202/069179-0160

The failure modes associated with the load-displacement curves (Figure 4) are shown in Figure 5. The washer of the bolt is deformed and slightly pressed into the timber (Figure 5, top right). Compared to the failure of bolted connections in spruce glulam due to head pull-through (see [22]), the deformations at the washer in beech LVL are significantly smaller. The splitting and partial block shear failure of the timber occurs after the formation of plastic hinges in the dowel (Figure 5, top left) as well as in the bolt for large side member thicknesses and loading parallel to the grain. Figure 6 shows the deformation figure of a dowel after these tests. Two plastic hinges occured per shear plane. There is also a clear indentation in the area of the steel plate. Shearing-off of the dowels, as observed by Franke & Franke [11], did not occur in any of the tests. In contrast, the connections loaded perpendicular to the grain showed lateral splitting of the timber (Figure 5, bottom). This results in a relatively brittle failure after about 11 mm of deformation at the dowel. The splitting of the timber can be prevented by reinforcing the timber with screws or veneer cross-layers. Often no cracks were externally visible, especially on specimens with cross-layers. Plastic deformations of up to 18 mm were achieved in these tests with a 12 mm diameter fastener.

Table 4: *Initial stiffness $K_{ser,test}$ and comparison with Eurocode 5 [2] for connections with single fasteners*

4.3 FACTORS INFLUENCING THE INITIAL STIFFNESS

4.3.1 Diameter

The diameter of the fasteners is already included as an important parameter in the Equations for determining the slip modulus according to Eurocode 5 [2] as well as to SIA 265 [3]. Figure 7 shows the initial stiffness K_{ser} plotted against the fastener diameter d. The test data of the connections loaded parallel to the grain and for all three different types of reinforcement are represented by black crosses (test series for connections with single fasteners). It is worth noting that the connections using fasteners of 20 mm diameter and reinforced with cross-layers achieved significantly higher stiffnesses compared to the other tests. While the dashed black trend line is derived from the data points of all the tests mentioned, the solid trend line is derived by neglecting the circled data points of the connections reinforced with cross-layers. These trend lines are compared with the results obtained from

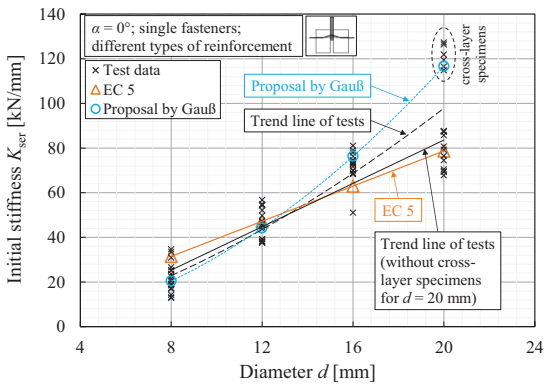

Figure 7: *Influence of the fastener diameter d on the initial stiffness K_{ser} and comparison of the test data with stiffnesses according to Eurocode 5 and to a proposal by Gauß [5],[6]*

https://doi.org/10.52202/069179-0160

the calculated stiffness values according to Eurocode 5 [2] for the corresponding diameters (orange line). The results of Eurocode 5 [2] agree relatively well with the solid trend line of the test data without the circled data points. However, if these data points are included in the trend line, the initial stiffness K_{ser} is underestimated for the tests with a fastener diameter of 16 mm and 20 mm. For this reason, a second comparison with the Equation according to Eurocode 5 [2] modified by Gauß [5],[6] (blue dotted line) is shown. In tests on steel-timber dowel-type connections in spruce glulam, Gauß [5],[6] showed that there is more a quadratic rather than a linear effect of fastener diameter on initial stiffness. For this context, the following proposal for the calculation of the stiffness of steel-timber dowel-type connections based on the Equation according to Eurocode 5 [2] is given by Gauß in [5],[6]:

$$K_{ser,proposal,Gauß} = \frac{2}{230} \cdot \rho_m^{1.5} \cdot d^{1.9} \quad (4)$$

For this approach, the increase in stiffness as the diameter increases can be better described by a trend line which is a power law of the form $y = cx^b$ (blue dotted line). A comparison of the stiffnesses calculated by this approach for the corresponding diameters with the test data in Figure 7 (incl. circled data points) shows, that the curve progression fits well for fastener diameters smaller than or equal to 12 mm. For larger diameters, the proposal according to Gauß [5],[6] overestimates the mean values of the stiffnesses derived from the tests. Maybe an independent treatment of cross-layer specimen should be considered.

4.3.2 Load-to-grain angle

The load-to-grain angle α is not yet considered in the calculation of the slip modulus K_{ser} according to Eurocode 5 [2]. However, tests on steel-timber dowel-type connections in spruce glulam carried out by Kuhlmann & Gauß [5] have shown that there is a non-negligible influence on the stiffness of the connection. For a load perpendicular to the grain, these results suggest that the stiffness is only half of that for a load parallel to the grain, as already considered in the SIA 265 [3]. This relationship is now to be verified for the connections in beech LVL as well. Table 5 indicates the ratios of the initial stiffness K_{ser} for load-to-grain angles of 90° and 0° for all the diameters investigated. A distinction is made between unreinforced connections and connections reinforced with cross-layers. It becomes apparent that for most of the test series the stiffness decreases by about 50 % for a load perpendicular to the grain as compared to a parallel loading. The higher ratios of the 8 mm diameter reinforced series and the 20 mm diameter unreinforced series can be explained by the fact that the mean stiffness values of the respective tests with a load-to-grain angle of 0° are lower than expected. It is also worth mentioning that the decrease in stiffness applies equally to both the unreinforced series as well as the series reinforced with cross-layers. Therefore, a reduction of the initial stiffness by 50 % for a load perpendicular to the grain should also be discussed for connections in hardwood.

Table 5: *Ratios of initial stiffness K_{ser} for load-to-grain angles $\alpha = 90°$ and $\alpha = 0°$ for unreinforced connections and connections with cross-layers*

Diameter	Unreinforced	Cross-layers
d [mm]	$K_{ser,90}/K_{ser,0}$	$K_{ser,90}/K_{ser,0}$
8	0.48	0.74
12	0.52	0.54
16	0.43	0.52
20	0.63	0.52

4.3.3 Side member thickness

Figure 8 illustrates the load-displacement curves of connections with a single dowel of 8 mm diameter and a load parallel to the grain for all three side member thicknesses $t_{1\text{-}3}$ tested. The three different failure modes for steel-timber dowel-type connections can be clearly identified in the load-deformation behaviour. There is a brittle behaviour due to embedment failure and splitting in timber with small side member thicknesses. As the side member thickness increases and plastic hinges are formed in the dowel, a plastic plateau developed and a ductile load-bearing behaviour was achieved. It is noticeable that especially for the large side member thickness t_1 the load can be increased even further in the area of the plastic plateau. This is a typical behaviour for dowel-type connections in hardwood and was also observed by Kuhlmann & Gauß [4].

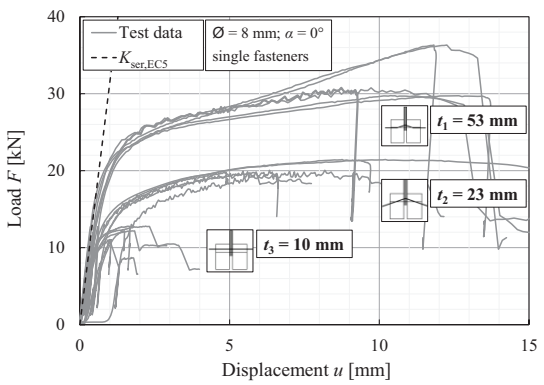

Figure 8: *Load-displacement curves of connections with a single fastener of 8 mm diameter and a load-to-grain angle α of 0° for various side member thicknesses $t_{1\text{-}3}$*

The effect of the side member thickness on the load-displacement behaviour in the range of the SLS is significantly smaller. However, as shown in Table 4, there is a tendency for the initial stiffness to decrease with decreasing side member thickness.

4.3.4 Type of fastener

In addition to connections with dowels, connections with bolts were also tested. Table 4 shows that there is a trend towards a slight increase in initial stiffness for connections using bolts. Nevertheless, the effect of the different types of fasteners is almost negligible. Similar to the side member thickness, the type of fastener has a greater effect on the load-displacement behaviour in the area of the plastic plateau due to the rope effect.

https://doi.org/10.52202/069179-0160

4.3.5 Reinforcement

Unreinforced connections, connections reinforced with fully threaded screws as well as with veneer cross-layers were tested. It was expected that the reinforcement methods would lead to an increase in stiffness. However, the results according to Table 4 do not show a clear relationship between the reinforcement and the initial stiffness. In some cases, even higher stiffnesses were achieved for unreinforced connections. There is currently no explanation for this unexpected effect. However, the progression of the load-displacement curve in the service load range for connections with cross-layers differs from that of unreinforced connections. Figure 9 shows the load-displacement curve of one of the specimens with cross-layers.

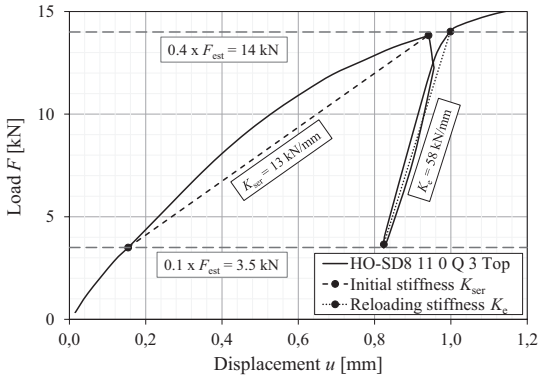

Figure 9: *Load-displacement curve in the service load range and evaluation of the stiffnesses K_{ser} and K_e for the test HO-SD8 11 0 Q 3 Top*

The initial stiffness K_{ser} is evaluated according to EN 26891 [15] by the slope of the curve between 10 % and 40 % of the estimated maximum load F_{est}. It is noticeable that for some connections with cross-layers, the load-displacement curve in this area is not linear but has a convex shape. As a result, the stiffness of these connections is clearly higher in the range between 10 % and 30 % of F_{est} (not shown in Figure 9). However, this cannot be taken into account in the evaluation.

5 CONCLUSIONS

Accurate computational prediction of the load-deformation behaviour of joints in timber is becoming increasingly important for the economic design of complex timber structures. In particular, the connection stiffness is a relevant parameter. Therefore, a detailed knowledge of the parameters influencing the connection stiffness is required, but is currently not available for hardwoods. In this paper, first investigations of a large number of tests on steel-timber dowel-type connections in beech LVL are evaluated and discussed regarding the initial stiffness K_{ser}. An overview of the Equations given in Eurocode 5 [2] and SIA 265 [3] for the calculation of the slip modulus shows that the Equations depend on only a few parameters, such as the timber density and the fastener diameter. In addition, the Swiss standard [3] distinguishes between loading parallel and perpendicular to the grain. This paper summarises several studies indicating that the stiffness calculated according to Eurocode 5 [2] is relatively deficient, even for softwood connections. Recommendations from these studies suggest that additional factors should be considered, such as load-to-grain angle and group effect.

The aim of the investigations presented in this paper is thus to determine the factors influencing the stiffness of connections in beech LVL and to compare the results with the Equation according to Eurocode 5 and with the recommendations given in the literature. The test results indicate, in line with other studies, that there is a large effect of the load-to-grain angle. For most of the test series, the stiffness is reduced by approximately 50 % for a load perpendicular to the grain as compared to a parallel load. Therefore, the implementation of a reduction factor as in SIA 265 [3] of about 0.5 for a load perpendicular to the grain should also be discussed for connections in hardwood. Furthermore, the fastener diameter is an important parameter whose effect on the stiffness tends to be normatively (according to Eurocode 5 [2]) underestimated in the tests, especially for larger diameters. A possibility to better represent the influence of the diameter is to modify the Equation in the Eurocode 5 [2], as proposed by Gauß [5],[6]. The exact value of the exponent implemented in this proposal for the diameter should be investigated in more detail by comparing a large number of experimental data with connections in soft- and hardwoods. For the other parameters investigated, the changes in stiffness did not have a clear trend. For example, there was no clear relationship between the reinforcement and the initial stiffness. In some cases, contrary to expectations, even higher stiffnesses were achieved for unreinforced connections. The type of fastener and the side member thickness have little effect on stiffness, but a greater effect on the development of the plastic plateau and the ductility of the connection.

Within the framework of the current research project, additional tests with groups of fasteners will be carried out in order to be able to estimate the influence of a possible group effect on the stiffness. Furthermore, all test results should also be evaluated in terms of the reloading stiffness K_e, as this may also be relevant for practical applications. The test results will therefore help to increase the data base on the stiffness of dowel-type connections, particularly for hardwoods, and thus enable their efficient use.

ACKNOWLEDGEMENT

This project is supported by the *Ministry of Food, Rural Affairs and Consumer Protection* of the State of Baden-Württemberg as part of the "*Timber Building Initiative*". We would also like to thank Pollmeier Massivholz GmbH & Co. for providing the beech LVL and Adolf Würth GmbH & Co. KG for donating the screws and self-drilling dowels.

SEISMIC PERFORMANCE OF BOLTED GLULAM TIMBER BRACE CONNECTIONS WITH INTERNAL STEEL PLATES

Zoe Baird[1], Joshua Woods[2], Christian Viau[3], and Ghasan Doudak[4]

ABSTRACT: Mass timber braced frame systems achieve their ductility through the brace connections. Canadian design standards currently lack guidance on how to detail bolted brace connections to achieve a target system-level ductility as defined in the National Building Code of Canada. The objective of this research is to develop guidelines on how to detail bolted glulam timber brace connections to achieve moderate or limited ductility. To accomplish this objective, a 4-storey prototype building was designed to determine realistic brace design forces as well as investigate how different parameters (e.g., fastener diameter and number of slotted-in plates) can impact the design of a timber braced frame. Based on the prototype structure, a connection with two internal steel plates was designed and detailed, which included consideration for the fastener slenderness and spacing to achieve ductile behaviour. To validate the performance of the proposed connection, full-scale testing under monotonic and cyclic loading was conducted. This paper discusses the results of the experimental testing, including connection stiffness, strength, ductility, as well as its energy dissipation capacity.

KEYWORDS: Mass timber, Braced frames, Connections, Ductility, Seismic loading, Experimental test

1 INTRODUCTION

Over the last 10 years, there has been a rapid increase in the number of mass timber buildings constructed in Canada [1], largely due to the environmental benefits of building with wood. Recent national and international climate change initiatives, including the *Canadian Net-Zero Emissions Accountability Act* and the *Paris Agreement*, strive to achieve net-zero emissions in the next three decades and emphasize that a key requirement in that effort is to increase carbon-neutral construction practices [2,3]. The International Panel on Climate Change (IPCC) recently published their list of strategies to reduce emissions by 2030 and "enhanced use of wood products" was one of 5 options in the buildings category [4]. Despite the environmental benefits of building with wood, questions remain surrounding the performance of tall wood structures, particularly under seismic loads.

Modern capacity-based seismic design guidelines allow engineers to detail specific structural elements or connections, commonly referred to as fuses, to dissipate energy during an earthquake in a ductile manner, while protecting brittle elements by designing them to higher seismic load levels through the use of overstrength factors. In the design of mass timber braced frames, steel-timber connections are typically relied upon to act as fuses, providing ductility and energy dissipation capabilities to the system. However, design and detailing considerations ensuring ductile behaviour and capacity-based protection against brittle failures of such connections are required to ensure adequate seismic performance, including the ability to achieve appropriate connection-level ductility to meet system-level demand.

The National Building Code of Canada (NBCC) recognizes both limited and moderate ductility braced frames for multi-storey mass timber structures up to 15 m and 20 m in height, respectively, in areas of high seismicity, and specifies respective system-level ductility modification factors (R_d) of 1.5 and 2.0 [5]. However, no guidance currently exists in the Canadian wood design standards (e.g., CSA O86) on how to design and detail the connections in braced frames to achieve the required system-level ductility [6]. This lack of design guidance can lead to inefficient design, excess material use, and inaccessibility of the structural system to designers [7].

There are several reported studies in the literature focused on bolted timber connections [8-14]. However, few studies have investigated axially-loaded timber brace connections at an appropriate scale for use in mid- and high-rise timber frames under cyclic loading. To address these gaps, the aim of this research is to develop connection design requirements for timber braced frames in taller timber structures, with the long-term goal of providing practical detailing requirements within the CSA O86 framework to achieve the system-level ductility modification factors in the NBCC. The specific objectives of this paper are to: (1) design a prototype mass timber braced frame structure in a Canadian region of moderate seismicity, (2) study the influence of connection design parameters, including bolt diameter, number of slotted-in plates, and bolt spacing, on the design strength and anticipated failure mode for the connection, and (3) evaluate experimentally the behaviour of a full-scale

braced connection from the prototype structure under monotonic and cyclic loads.

2 BACKGROUND

There have been a number of studies that have focused on the behaviour of connections in mass timber structures, most of which involving small-scale connections (capacities ranging from 60 kN – 200 kN) [8-14]. These studies examined the influence of several connection design details, including dowel slenderness, fastener spacing, end distance [8,9], strengthening using self-tapping screws [10-12], effect of bolt pre-tension [13], and dowel material type, including shape-memory alloy [14]. These studies have considered a range of loading conditions to evaluate connection behaviour, including monotonic loads [8,11,12], cyclic loads [9,14,15], blast loads [16], and fire scenarios [17].

Beyond small-scale connection testing, there has been limited experimental research into the performance of large- to full-scale braced frame subassemblies or systems. Chen and Popovski [11] conducted testing on a multi-tier and single-storey braced timber frame with riveted connections, while Popovski et al. [18] conducted shake table testing on a single storey braced frame with bolted and riveted connections. These studies concluded that brace end connections can experience significantly different deformation levels, even if the two connection details are identical, and thus, the deformation capacity of a brace may not be equal to twice the capacity of a single connection [18]. A recent report by FPInnovations highlights the need for continued study into timber braced frames, particularly research on large-scale connections for multi-storey timber frames and their system-level behaviour [19].

2.1 DUCTILE DESIGN OF TIMBER FRAMES

Review of the literature has identified that there is a need to better understand the relationship between system-level behaviour of timber braced frames and the connection ductility demand, as well as the specific connection detailing needed to achieve the required system-level ductility. To address this concern, it is important to identify the hierarchy of ductility used in building design, which has been summarized by Gioncu [20]:

1. *Material ductility:* plastic deformation capacity of the materials (e.g., timber or steel);
2. *Cross-section ductility:* also referred to as curvature ductility, it is the plastic deformation capacity of the cross-section, considering interactions between elements of a cross-section (e.g., flange and web);
3. *Member ductility:* also referred to as rotation or displacement ductility and considers the properties of the member (e.g., length) and the formation of plastic hinges. In an axially loaded element, this could include deformation capacity of the connections; and
4. *System Ductility:* considers the displacement ductility of the entire structure under a lateral load distribution.

In this hierarchy, as one moves from material ductility to system ductility, the overall ductility decreases as it is often difficult to utilize all of the available ductility for complex structures (variability amongst connections and elements) under complex loading. Furthermore, this hierarchy was developed with steel or concrete structures in mind, in which the ductility of the system is typically achieved through yielding of the structural members (e.g., the brace in a steel braced frame or the beam in a reinforced concrete moment frame).

Capacity-based design of timber structures presents a unique challenge when compared with steel structures because of the brittle nature of timber in tension, which means that timber members are typically assumed to remain elastic while the connections are relied upon to act as fuses, providing ductility and energy dissipation capacity to the system. It has been shown by Chen and Popovski [7] that the system-level ductility of a multi-storey braced timber frame is a function of connection ductility, stiffness ratio between the connections and the brace, as well as the number of storeys in the structure. The system-level ductility of a timber frame, assuming all tiers yield simultaneously and that the structure behaves in the first mode, can be computed using Equation (1) [7]:

$$\mu_s = \frac{(\mu_{c1}+\mu_{c2})+k_r}{2+k_r} \quad (1)$$

where μ_{c1} and μ_{c2} are the ductility of the connections at either end of the brace, k_r is the ratio of the stiffness of the connection to the axial stiffness of the diagonal brace, equal to k_c/k_b where k_c is the stiffness of the connection and k_b is the stiffness of the brace.

While Equation (1) assumes that all storeys in a multi-storey braced frame yield simultaneously, this may be difficult to ensure in practice because of the uncertainty and variability surrounding connection capacity, as past tests have shown that there is the potential for only one connection in a brace to yield [7]. At the system-level, complex load distributions and the need to have several different connection designs over the height of a timber frame make it particularly challenging to ensure that all tiers in a braced frame will yield simultaneously. In such cases, a conservative approach to estimate system-level ductility would be to assume that only a single storey yields, and the system-level ductility can be computed using Equation (2) [7]:

$$\mu_s = \frac{(\mu_{c1}+\mu_{c2})-2}{m(2+k_r)} + 1 \quad (2)$$

where m is the number of storeys. To validate these proposed relationships, Chen and Popovski [11] conducted pushover analysis on five building archetypes while varying number of storeys, the ratio of the stiffness of the connection to the stiffness of the diagonal brace, and the connection ductility. In all cases, the braced frames had ductile riveted connections and the results showed that for a moderately ductile braced frame (R_d = 2.0) in which only one of the two brace end connections yield, a connection ductility of 11.5 is required. For situations in which both brace end connections yield, a minimum connection ductility of 6.3 is required. For limited ductility frames, connection ductility of 5.4 and 3.2 are required when one or both connections yield, respectively. An aim of the current research study is to

https://doi.org/10.52202/069179-0161

investigate how to achieve these connection-level ductility requirements for bolted brace connections.

3 PROTOTYPE BUILDING DESIGN

A prototype 4-storey mass timber braced frame structure was designed for a site in Ottawa, Ontario, a region of moderate seismicity in Central Canada, where timber braced frames with moderate or limited ductility would be commonly utilized. The prototype structure was designed to determine realistic design forces and brace connection.

Figure 1 shows a plan and elevation view of the prototype structure, which includes 7 – 6 m bays in each orthogonal direction (42 m × 42 m total building footprint). The dead loads on the roof and floors were 1.88 kPa and 2.64 kPa, respectively, the snow load on the roof was 2.32 kPa for the building location, and the live load for a typical floor was 2.4 kPa for office occupancy, as per the NBCC [5].

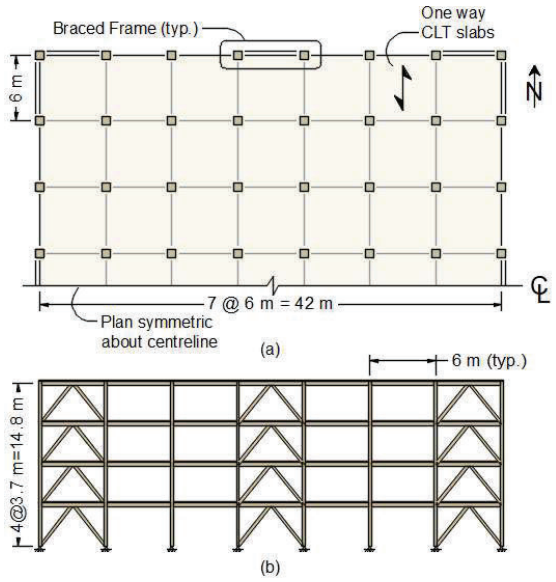

Figure 1: *Prototype structure: (a) plan view; (b) N-S elevation*

The gravity load resisting system in the prototype structure consisted of cross-laminated timber (CLT) slabs with glulam beams and columns. Based on the spans and loads, the selected CLT slabs were 5-layer (35 mm ply) 175 mm thick panels. The glulam beams and columns were grade 20f-E and 12c-E, respectively, and their respective sizes for each storey level are shown in Table 1. All structural members were sized according to the Canadian wood design standard (CSA O86) [6].

Seismic design of the prototype structure was carried out using the equivalent static force procedure outlined in the NBCC [5]. The base shear was determined for Ottawa (City Hall) and the building was assumed to be on a site designated as class C, corresponding to "firm ground". The seismic weight was assumed to be 100% of the dead load plus 25% of the roof snow load. The fundamental period (T) used in the design of the prototype structure was assumed to be $T = 0.1N$, where N is the number of storeys in the structure [5].

Table 1: *Member selection summary (units in mm)*

	Storeys 1-2	Storeys 3-4
Brace	265 × 304	215 × 266
Interior Beam	265 × 456	
Exterior Beam	175 × 380	
Interior Column	265 × 304	
Exterior Column	265 × 266	

The lateral load resisting system for the prototype building consisted of mass timber braced frames in a chevron configuration in both orthogonal directions. For the frame design, the connections between the beams and columns were assumed to be pinned and the columns were continuous over the building height. Slotted-in steel plates were considered for the brace connections. Figure 2 shows an example of the brace connection with two slotted-in steel plates. This type of connection is appealing due to the high connection strength and stiffness while allowing the wood to protect the steel components against fire. This type of connection is used with dowel-type fasteners, such as bolts or tight fit pins. Bolts were used in this research over tight-fit pins because of the beneficial roping effect provided by bolts, which may lead to improved connection performance.

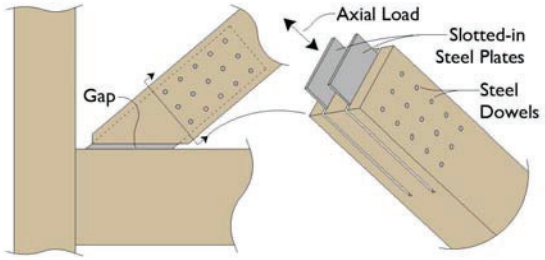

Figure 2: *Timber slotted-in steel plate connection*

One important consideration in the detailing of a timber braced frame is the need to leave a gap between the end of the brace member and the surrounding timber frame (illustrated in Figure 2). The gap allows the connections to deform and yield in both tension and compression, enabling the connection to achieve the required ductility and dissipate the maximum input energy. If no gap is provided, the brace element will be very stiff in compression, which would induce larger forces than expected under earthquake loads leading to less ductility and the potential for bending deformations in the columns which could lead to potential safety concerns [19].

3.1 CONNECTION DESIGN

The brace design forces were determined using the results of the equivalent static force procedure in the NBCC [5]. The resulting brace design force at the first storey of the prototype structure was approximately 250 kN, which was the target design force for the connection. To design the connection, five different failure mechanisms were considered: (1) net tension, (2) row shear, (3) group tear-out, and (4) fastener yielding. Figure 3 illustrates these failure modes.

https://doi.org/10.52202/069179-0161

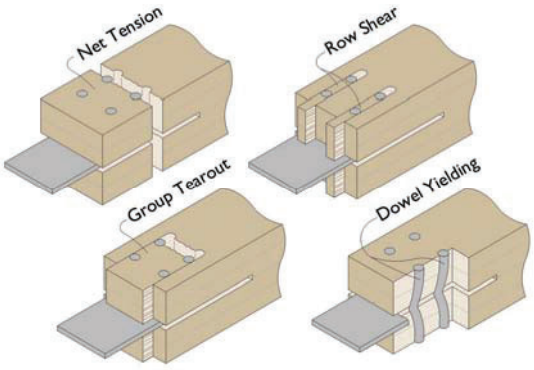

Figure 3: *Connection failure modes*

To initiate the connection design process, the number of fasteners required to achieve a yielding capacity approximately equal to the brace design force was determined, resulting in a 265 mm × 304 mm cross section being chosen. Two internal steel-plates with 10 mm thickness were used, which resulted in timber side member thicknesses of 71 mm [(304 – 2×10)/ 4 = 71 mm]. The fastener diameter was determined by setting a target slenderness ratio of 10 or higher for the connection, which is in line with recommendations from Eurocode 8 [21], which suggests fasteners with a diameter of less than 12.7 mm (1/2") and a slenderness ratio greater than 10 be used for ductile timber connections. The bolts were grade ASTM A307 steel, with a specified yield strength (F_y) of 310 MPa. The yield resistance of the connection was determined according to the provisions of CSA O86 [6]. Ultimately, it was determined that 16 - 9.53 mm (3/8") diameters fasteners were required to carry the factored load, which resulted in a yield capacity of 286 kN.

The capacity of the brittle failure modes (net tension, row shear, and group tear-out) were determined. In the initial design iteration, the minimum fastener spacing according to the Canadian design standard (CSA O86-19) of 4 times the fastener diameter (resulting in a minimum spacing of 38 mm) was used to layout the bolts. Based on this fastener spacing, the resulting row shear, group tear-out, and net tension resistances of the connection were 362 kN, 516 kN, and 1054 kN respectively.

While use of the minimum fastener spacing was satisfactory from a design perspective, it was anticipated that the actual yield resistance of the connection would be higher than the design yield resistance based on the code calculations because of higher yield strength of the bolts. Additionally, the potential for post-yield hardening behaviour in the connection response, could result in premature brittle failure. Consequently, a target minimum overstrength factor of at least 2, computed as the ratio of the resistance of the most critical brittle failure mode (e.g., lowest of the row shear, group tear-out, and net tension resistances) to the yield resistance of the connection was desired. To accomplish this objective, the bolt spacing was increased. Because net tension resistance was found to not govern the brittle failure mode, both row shear and group tear-out resistances could be increased by increasing the fastener spacing. Ultimately, a fastener spacing of 100 mm, which is more than twice the minimum fastener spacing specified in the Canadian wood design standard was selected, which resulted in row shear and group tear-out resistances of 905 kN and 652 kN, respectively, corresponding to an overstrength factor of approximately 2.3.

Finally, compression (i.e., buckling) and gross tension failures were considered in the brace member, which had capacities of 1162 kN and 1054 kN, respectively. Figure 4 shows the connection design proposed for the 4-storey prototype building.

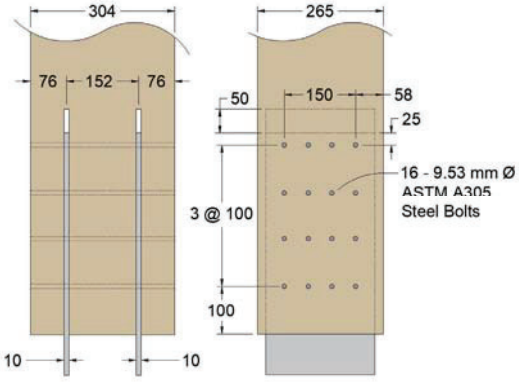

Figure 4: *Prototype connection design*

4 EXPERIMENTAL PROGRAM

To evaluate the ductility of the proposed connection design shown in Figure 4, full-scale connection tests were conducted. The connections were fabricated using grade 24f-E spruce-pine-fir (SPF) glued-laminated (glulam) timber supplied by Nordic Structures (Québec, Canada). The glulam had a density of 560 kg/m^3, a bending strength of 30.7 MPa, a longitudinal shear strength of 2.5 MPa, a compression perpendicular to grain strength of 7.5 MPa, and a modulus of elasticity of 13.1 GPa according to the manufacturer [22]. The bolts were grade ASTM A307, and from testing were found to have an average yield stress of 400 MPa (standard deviation = 16 MPa).

Figure 5 shows a typical specimen in the testing frame. Each specimen included two identical connections (details illustrated in Figure 4), with an overall length of 1350 mm to fit into the experimental testing frame. The holes in the timber were 10.7 mm (27/64") in diameter, which is approximately 1.2 mm larger than the diameter of the bolts. The holes in the steel plates were 12.7 mm (1/2") in diameter to allow for erection tolerance. The results of two specimens are presented in this paper. The first specimen, hereafter referred to as specimen M1, was tested under monotonic load, while the second specimen, referred to as specimen C1, was tested under simulated seismic load using a cyclic loading protocol.

4.1 EXPERIMENTAL TEST SETUP

The connection was tested in a frame with a capacity of 1350 kN in tension and the actuator had a stroke of +/- 250 mm. Figure 5 shows a typical test setup for the connection, which was used for both the monotonic and

https://doi.org/10.52202/069179-0161

cyclic tests. Lateral bracing was installed at the top of member to prevent any out-of-plane deformation during testing. The slotted-in steel plates were attached to the actuator at one end and to a steel assembly at the other end. The steel assembly was fixed to the laboratory strong floor using 8 – 31.8 mm (1-1/4 in.) steel grade B7 rods.

A load cell mounted to the hydraulic actuator was used to measure the force and 12 potentiometers were used to measure the displacement response of the connections, which included two string potentiometers on each connection (top and bottom) to measure their individual displacement response. Linear potentiometers were also mounted across the slots in the timber for the steel plates to measure any potential opening during testing.

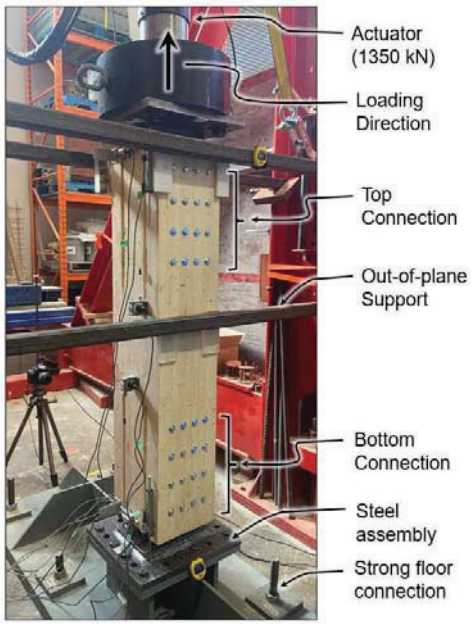

Figure 5: *Test specimens and experimental test setup*

4.2 LOADING PROTOCOL

Monotonic and cyclic loading tests were conducted based on the European Test Standard EN12512 – *Cyclic Testing of Joints made with Mechanical Fasteners* [23]. Monotonic testing was conducted to evaluate the connection strength and failure mechanism, as well as to determine the connection yield displacement (Δ_y) to be used in defining the cyclic loading protocol. The monotonic tensile test was conducted at a constant rate of 2 mm/min, which resulted in a total test time of approximately 20 minutes.

Based on the results of the monotonic test, a cyclic loading protocol was developed to study the connection behaviour under simulated earthquake loads. Figure 6 shows the cyclic loading protocol used in this study. The cyclic tests were executed in displacement control based on increments of the Δ_y of the connection determined from the monotonic test, which included displacement levels of 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, and 2.0 times Δ_y, followed by cycles at increments of Δ_y to failure.

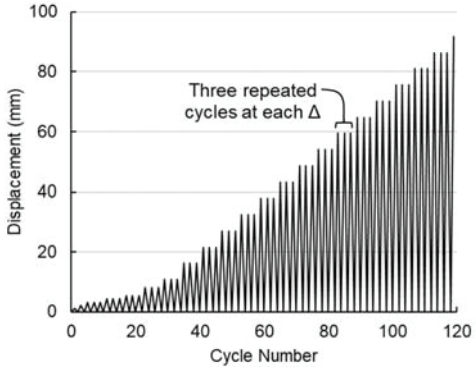

Figure 6: *Tension cyclic loading protocol* [22]

5 EXPERIMENTAL RESULTS

Table 2 summarizes the key structural response parameters for the specimens described in this paper, including the yield load (P_y), peak load (P_{peak}), and ultimate load (P_u) as well as the yield displacement (Δ_y), peak displacement (Δ_{peak}), and ultimate displacement (Δ_u). The yield load and displacement were determined using the method proposed by Yasumura and Kawai [24], which has been shown to produce consistent results for a range of force-displacement behaviours in the past [25]. The peak load was defined as the maximum load achieved during the test. The ultimate load and displacement were defined as the point when the load dropped by 20% from the peak load.

Table 2: *Connection structural response parameters*

	Specimen M1		Specimen C1	
Parameter	Top	Bottom	Top	Bottom
P_y (kN)	557	550	506	506
Δ_y (mm)	3.4	2.4	2.7	3.2
P_{peak} (kN)	1024	1024	775	775
Δ_{peak} (mm)	20.6	16.5	21.3	22.1
P_u (kN)	819	819	620	620
Δ_u (mm)	24.2	16.6	21.4	22.7

5.1 MONOTONIC TEST RESULTS

Figure shows the force-displacement response of the specimen tested under the monotonic load. The results for the top connection show a gradual increase in the load at small displacement levels, which corresponds to the closing of any gaps between the steel plates, timber, and the bolts, which are required for constructability of the connection. After closing any gaps, both top and bottom connections have an elastic behaviour followed by a gradual softening, which results from yielding of the bolts. Following bolt yielding, the connection exhibits post-yield hardening behaviour, which is attributed to embedment stiffness of the timber, which interacts with the bolts even after significant yielding of the fasteners. At a displacement of approximately 23 mm, several bolts in the top connection of the specimen fractured, resulting in a significant drop in load carrying capacity of the specimen.

https://doi.org/10.52202/069179-0161

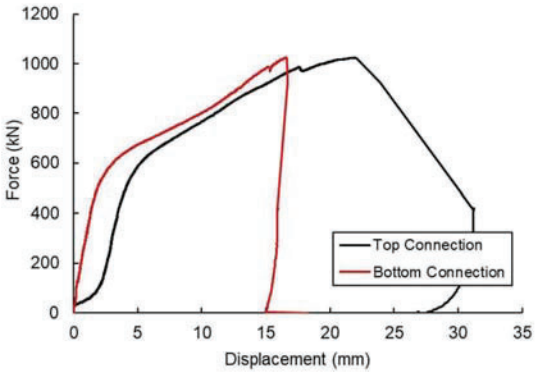

Figure 7: *Connection M1 force-displacement response*

Figure shows sample bolt deformation patterns from the monotonic test and the results show that bolts from both the top and bottom connections had significant plastic deformations and the bolts form six plastic hinges at the locations of the slotted-in plates

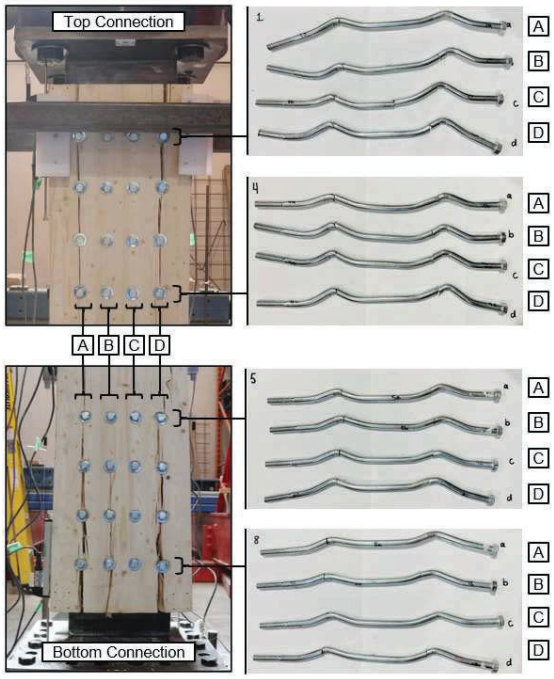

Figure 8: *Connection M1 bolt deformation patterns*

5.2 CYCLIC TEST RESULTS

Figure 9 shows the hysteretic force-displacement response of the bottom and top connections for the second specimen. The results show that the cyclic backbone curve was similar to that of the monotonic test, characterized by an initial gradual increase in stiffness as the bolts engage with the slotted-in plates followed by an elastic and post-yield hardening behaviour up to failure, which occurred due to excessive splitting of the wood. The hysteretic behaviour of the connection shows a highly pinched response, with stiffness degradation under repeated load cycles. This behaviour is attributed to crushing of the wood surrounding the dowel during the initial cycle and on the second cycle the dowel must close a gap before re-engaging the wood, at which point the stiffness of the connection increases. Both connections yield and achieve ductility of 7.1 and 8.1, which is attributed to the post-yield hardening behaviour of the connections. This level of ductility is within the required range suggested by Chen and Popovski [7] to meet the system-level ductility requirements for a moderately ductile timber braced frame according to the NBCC [5].

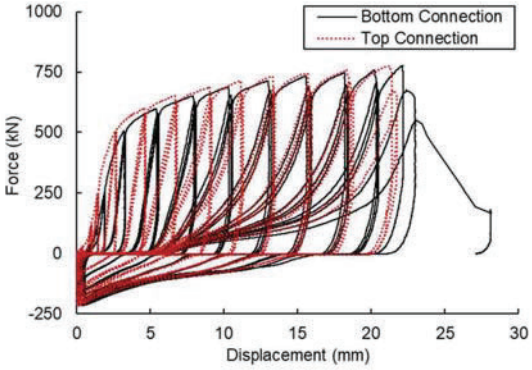

Figure 9: *Connections C1 force-displacement response*

Figure 10 shows the progression of splitting in the connection at various displacement levels throughout the cyclic loading protocol. The results show that no splitting occurred up to a displacement of approximately 13 mm. However, even after the onset of splitting, it did not result in any significant strength degradation and the connection maintained similar hardening behaviour up to failure.

6 CONCLUSIONS AND FUTURE WORK

The use of mass timber braced frames is rising in Canada, but knowledge gaps remain on how to design timber connections to achieve system-level ductility levels in the NBCC. Through experimental testing of a connection based on the design of a 4-storey prototype structure, the conclusions of this study are as follows:

1. Bolted glulam timber connections with slotted-in steel plates can meet the strength requirements for multi-storey mass timber structures.
2. Emphasis should be placed on the ratio of ductile to brittle failure modes during the connection design phase. In this paper, connections tested with a capacity ratio of 2.3 resulted in high ductility.
3. Connection-level ductility requirements can be achieved to meet the system-level ductility demand for moderate and limited ductility braced timber frames.

The work presented in this paper is part of a larger study focused on the behaviour of bolted glulam timber connections with slotted-in steel plates. Future work includes experimental testing of connections with varying fastener diameter, bolt spacing, and number of slotted-in steel plates. The goal is to better understand the key factors that contribute to the design of a ductile timber connections so that design guidance can be provided in CSA O86 on how to detail timber connections to achieve the required system-level ductility levels in the NBCC.

DEVELOPMENT OF A NOVEL JOINT SYSTEM FOR MID-TO-HIGH-RISE CLT WALL BUILDINGS IN SEISMIC REGIONS

Ahmad Ghazi Aljuhmani[1], Eito Atsuzawa[2], Arata Minegishi[3], Kazuki Tsuda[4], Yutaka Goto[5], Masaki Maeda[6]

ABSTRACT: In Japan, the possibility of multi-story timber buildings is not yet practiced at a large scale due to the complex structural design process and construction cost. In conventional CLT buildings in Japan, a high number of complex steel connections are required. In this practice, complex processing of CLTs panel is also required. The objective of this paper is to propose easy-to-apply and easy-to-design steel joints. The proposed joint is designed to resist both shear and tensile forces to reduce complex steel parts. Single-bolt element tension tests were conducted to investigate the effect of the fibre direction, bolt diameter, and bolt embedded length. Cyclic loading for single and coupled CLT walls with the proposed joints was also conducted. The failure characteristics and strength of single-bolt connections could be predicted by the ratio of bolt embedded length and diameter. The fibre direction was found to have a minor effect on the connection strength. The proposed joint system showed high strength and ductility as found by the cyclic loading. The lateral strength of a wall with two panels was double the single wall case, indicating the lack of interaction between the two panels.

KEYWORDS: Cross-laminated Timber, Hybrid structure, Steel plate-bolt connections, Shear walls, Rocking walls

1 INTRODUCTION

Timber, as a construction material with its carbon-storing capability and renewability, can play an essential role in reducing GHGs emissions related to the construction sector. In Japan, although 66% of the total land area is covered by forests (Japanese Forestry Agency (JFA)), these renewable resources are not being used to their full potential. Buildings higher than three stories (mid-to-high-rise buildings) are mainly non-wooden structures [1], with a share of only 0.06% for timber buildings. This is attributed to the strict seismic and fire protection requirements. To overcome these challenges, Cross-laminated Timber (CLT) is considered a promising engineered wood product (EWP). When compared to sawn timber, CLT can secure the structural and fire safety requirements more efficiently. The laminated structure of CLT helps control the strength, reduces the effect of defects, and increases the dimensional stability of the element [2]. In Japan, the self-sufficiency rate of wood is only about 41%. The commonly used wood in Japan is cedar, which has relatively lower strength and larger number of knots and defects compared to other species. In addition, due to the high cost of timber production and inefficient forest management, imported timbers are more competitive in terms of cost and quality. Therefore, recently, the Japanese government has been putting many efforts to increase the use of domestic forest resources. For example, a law for promoting the use of timber in public buildings was enacted in 2010. By using CLT as a construction material, it is believed that we can ensure utilizing the domestic wood resources, as high strength of the CLT members can be achieved with relatively low-strength wood raw material.

In Japan, in order to fulfil the seismic requirements for the CLT walls, connections with high shear and tensile strength are generally required. However, in the common design practice for CLT buildings, an unreasonable amount of CLT walls (i.e., to compensate for the low strength and stiffness connections), and a large number of complex connections and CLT processing are needed.

In light of these problems, and in order to promote mid-to-high-rise CLT buildings, CLT-steel hybrid structures can be a possible solution. Combining CLT as a low carbon footprint material with a high strength-to-weight ratio with steel which has high ductility and recycling potential would result in a superior structural system in terms of structural performance (i.e., stiffness, strength, ductility, and energy dissipation) and environmental impact. The seismic behaviour of the structure using innovative CLT-steel hybrid systems was investigated by several researchers in the past years [3][7]. Kanazawa et al. [8] experimentally investigated the structural

performance of several steel frames with CLT infill using small-diameter drift pin connections. They found that the use of CLT walls can increase the stiffness and strength by 1.5 to 2.3 times and 1.2 to 1.4 times, respectively, compared to the bare steel frame. In the previous studies, existing connection detail, such as tensile bolts, have been considered and the high strength and stiffness of CLT panels have not been fully utilized. Therefore, the objectives of this study are 1. Development of an easy-to-apply bolt-type steel joint system for CLT-steel hybrid buildings that can utilize the strength of CLT. 2. Experimentally investigate the structural performance of the bolted connection (i.e., strength, failure mechanism, and effect of fibre direction). 3. Experimentally investigate the structural performance of the proposed joint system by full-scale CLT wall-steel beam tests.

2 OUTLINE OF PROPOSED JOINT

In this research, a CLT wall-steel frame hybrid structural system was proposed, as shown in Figure 1. In this system, CLT walls are inserted into the steel frame to increase their seismic capacity. To connect the CLT wall with the steel beams of the structure, a joint system using bolted CLT connections was proposed and developed. The proposed joint system consists of four connections which are located at the four corners of the CLT panel, as shown in Figure 2.a. For each connection, a steel plate is connected to only one side of the CLT wall panel by large-diameter high-tensile bolts (HTBs), that work under shear (i.e., the HTBs resist the forces applied on them mainly by shear stresses only and not with friction stresses). Large-diameter bolts were used to achieve high strength and stiffness of the joint in order to utilize the structural advantages of CLT. The panels are then connected to the steel beam with these connections. Compared to the conventional connections (e.g., tensile bolts, Figure 2.b) the proposed joint system has the following advantages: 1. Relatively high stiffness and strength with a ductile behaviour are expected. 2. Resisting of bidirectional force that is resulted from shear and tension (uplift) forces induced by the horizontal load applied on the wall. 3. Simple connections with less complex CLT processing, such as cutting work, with high repairability of the damaged walls.

Under horizontal shear forces (Q) a moment is generated at the bottom of the wall ($M_{W\text{-}B}$). As shown in Figure 3, on the compression side of the wall, the bolts are assumed to resist only shear forces while the compression forces are resisted by the CLT wall. On the tension side of the wall, the bolts resist bidirectional forces of vertical forces (tension) and horizontal forces (shear). For each bolt, the resistance force of the bolt (P_θ, grey arrow in Figure 3) is a combination of vertical and horizontal forces, and thus it is tilted with an angle (θ). The shear and tensile strength of the connections are calculated by taking the result of P_θ on the vertical and horizontal axis multiplied by the number of bolts (n), as shown in Equations (*1*) and (*2*).

$$T_y = n \times P_\theta \times cos\theta \quad (1)$$

$$Q_y = n \times P_\theta \times sin\theta \quad (2)$$

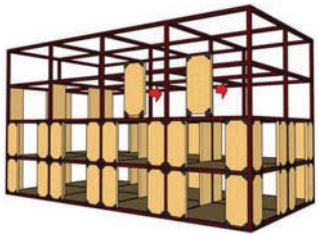

Figure 1: *Basic concept of the proposed CLT-steel hybrid structure*

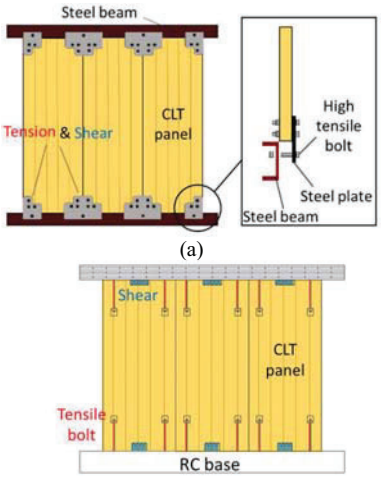

Figure 2: *Comparison between (a) the proposed joint system, and (b) the conventional connections system of CLT panels*

In the case of one-bolt connections, shear brittle failure or ductile embedment failure are considered possible failure modes, as shown in Figure 4. The type of failure can be controlled by changing the embedment length of the bolt (L_n) and the bolt diameter (Φ). The strength (P_θ) for each bolt is calculated as the minimum of CLT shear strength (Q_s) and CLT embedment strength (Q_{cv}), as (Equations (3)-(5)). The (L_n/Φ) ratio for the proposed joint is designed to have ductile embedment failure.

$$P_\theta = \min(Q_s, Q_{cv}) \quad (3)$$

$$Q_s = \tau \times 2 \times L_n \times t \quad (4)$$

$$Q_{cv} = \sigma_{cv} \times \phi \times t \quad (5)$$

Where τ and σ_{cv} (N/mm^2) are the shear and embedment strength of CLT, respectively. t (mm) is the thickness of CLT.

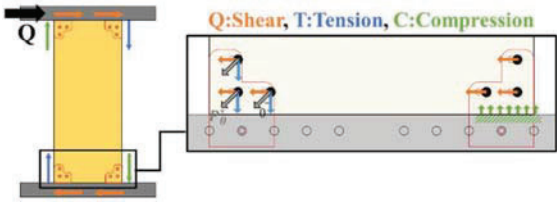

Figure 3: *Load transfer mechanism of the proposed joint system*

https://doi.org/10.52202/069179-0162

To calculate the yielding flexural moment capacity and rotation angle of the CLT wall, the following approach is used. In Japan, in CLT-panel system design practice, in order to ensure ductility, the strength of the wall is generally determined by the yielding of the tensile connections of the CLT wall panel. Minegishi et al. [9] proposed a method to calculate the bending moment capacity of the CLT wall in the same approach as calculating the bending moment of reinforced concrete columns. The calculation approach is illustrated in ***Figure 5***.a. The flexural yielding moment of the wall (M_y) is calculated by Equation (*6*). The shear strength of the wall at flexural yielding (Q_y) is calculated by Equation (7) using M_y. The yielding rotational angle of the wall (θ_y) and rotational stiffness (K_θ) is calculated by Equation (8) and (9), respectively. The neutral axial distance (x_n) is calculated using Equation (10) by taking the equilibrium of the compressive force of the CLT wall (C), the axial force (N), and the tensile yield force (T_y) (***Figure 5***.a.)

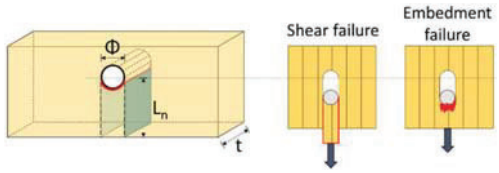

Figure 4: *Expected failure modes for one-bolt connection*

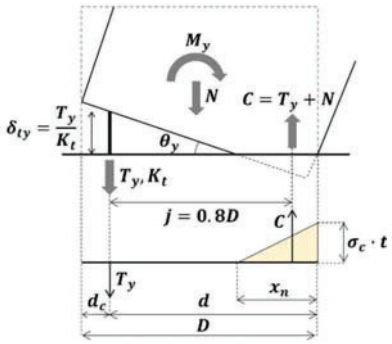
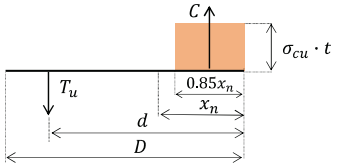


(a) allowable stress condition



(b) ultimate state

Figure 5: *Stress condition of CLT wall, based on [9]*

$$M_y = T_y \times 0.8D + N \times 0.4D \quad (6)$$

$$Q_y = M_y/h \quad (7)$$

$$\theta_y = \delta_{ty}/(d - x_n) \quad (8)$$

$$K_\theta = M_y/\theta_y \quad (9)$$

$$x_n = 2(N + T_y)/\sigma_c t \quad (10)$$

Where D and t (mm) are the width and thickness of the wall, respectively. h (mm) is the inflection point height, and δ_{ty} (mm) is the deformation of the tensile connection. d (mm) and x_n (mm) are the distance from the tensile connection and neutral axis to the compression edge of the wall, respectively. σ_c (N/mm^2) is the allowable compressive strength of the CLT and it is equal to two-thirds of the compressive strength of CLT.

3 SINGLE-BOLT CONNECTION TEST

3.1 MATERIAL PROPERTIES

Material tests were conducted to get the embedment and shear strength of CLT based on the testing procedures mentioned in [10]. The tested CLT panels were five-layer 150 mm thick, made from Japanese cedar with Mx-60-5-5 (5-ply 5-layer) grade and composition [11]. The average CLT density was 400 kg/m^3, and the average moisture content was 12.0%. Three identical specimens were used for each material test, and the results are summarized in Table 1.

Table 1: *Results of the CLT material tests for single-bolt connection specimens*

Strength (MPa)	Shear		Embedment	
	Major	Minor	Major	Minor
	3.2	2.9	18.6	15.9

3.2 TEST MATRIX

In this study, component-level tests on double plate one-bolt connections were conducted (i.e., two steel plates on both sides of the CLT panel were fixed with a HTB). All the tested specimens have the same dimensions as shown in Figure 6 and were tested under monotonic loading. the tested specimens are summarised in Table 2. In order to investigate the effect of the embedment length (L_n) on the failure mode (as explained in section 2), the experimental parameter was the (L_n/Φ) ratio. In addition, to investigate the effect of fibre angle (i.e., loading direction) on the load-bearing capacity, the outer layer fibre direction (θ) was taken as another parameter. A bolt with a diameter of Φ=40 mm was installed into the specimens. For each type of specimen, three replicates were tested.

3.3 LOADING SET-UP

The loading set-up of the tested specimens is shown in Figure 7. The CLT panel was fixed on top of two steel bases with two threaded rods at each side to prevent out-of-plane deformation. A single 300 kN jack was used to apply a monotonic downward force on the connection's steel bolt, and the loading rate was in the range of 0.15–0.2 mm/s. The vertical displacement of the bolt was taken as the average value of two LVDTs that were attached on both sides of the specimen.

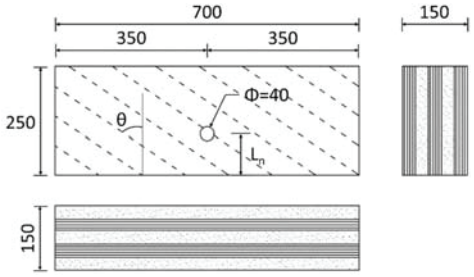


Figure 6: *Dimensions of the tested specimens (mm)*

https://doi.org/10.52202/069179-0162

Table 2: *Test matrix of the CLT panels*

Specimen name	Panel thickness [t] (mm)	Bolt diameter [Φ] (mm)	Embedment length [L_n] (mm)	Fiber angle [θ] (°)	$L_n/Φ$	No. of specimens
40-0-50				0		
40-30-50				30		
40-45-50	150	40	150	45	1.3	3
40-60-50				60		
40-90-50				90		
40-0-100				0		
40-30-100				30		
40-45-100	150	40	150	45	1.3	3
40-60-100				60		
40-90-100				90		
40-0-150				0		
40-30-150				30		
40-45-150	150	40	150	45	1.3	3
40-60-150				60		
40-90-150				90		

3.4 TEST RESULTS

The relation between $L_n/Φ$ ratio and the load-bearing capacity of the tested specimens and fibre direction angle (θ=0° and θ=90°) is shown in Figure 8. All specimens with $L_n/Φ$=1.3 had a shear failure with the lowest load-carrying capacity. Most of the specimens with $L_n/Φ$=3.8 showed ductile embedment failure. For specimens with $L_n/Φ$=2.5, about half of the specimens showed bearing failure, and shear failure was observed for the other half. A comparison between the experimental results and the calculation methods explained in section 2 is shown in Figure 8. The calculated values have a similar tendency to the experimental values and are generally conservative (lower) than experimental values. The failure mechanism can be predicted, and the connection can be designed to have ductile embedment failure by designing $L_n/Φ$ ratio. The load-bearing capacity of a one-bolt connection can be roughly estimated by equations (4) and (5). As shown in Figure 9, the maximum strength obtained from the tests is almost the same regardless of the fibre direction angle (θ). It can be said that the influence of (θ) is almost negligible.

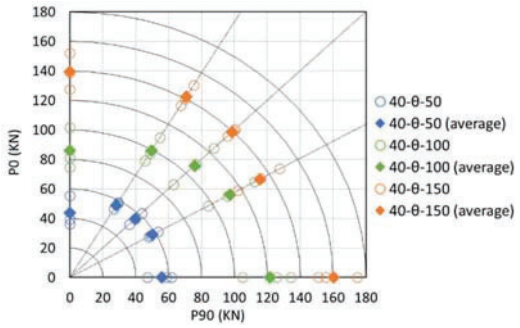

Figure 9: *Effect of loading angle relative to CLT fibre direction on the strength of the drift pin*

4 SHEAR WALLS TESTS

4.1 MATERIAL PROPERTIES

In order to investigate the structural performance of the proposed hybrid structural system, quasi-static cyclic loading tests on three different CLT wall-steel beam specimens were conducted. 90 mm thick CLT panels made from Japanese cedar with Mx-60-3-3 (3-ply 3-layer) grade and composition [11] were used for shear wall tests. The average CLT density was 393 kg/m^3, and the average moisture content was 12.2%. Material tests were conducted to obtain compression, embedment, and shear strength of CLT based on the testing procedures mentioned in [10]. Three identical specimens were used for each material test, and the results are summarized in Table 3.

Table 3: *Results of the CLT material tests for CLT wall tests*

	Compression		Shear		Embedment	
Strength (MPa)	Major	Minor	Major	Minor	Major	Minor
	23.7	10.9	3.8	2.6	21.6	15.5
	Compression [E]		Shear [G]		Embedment stiffness	
Modulus (MPa)	Major	Minor	Major	Minor	Major	Minor
	5926.9	2322.5	299.5	199.2	1767.2	1188.9

4.2 TEST MATRIX

Three CLT wall-steel beam specimens with different connections and wall configurations were tested. The details of the specimens are shown in Table 4. For all tests, 90-mm thick, 1000 mm by 2400 mm CLT wall panels were used. For the steel beams, two-meter C-section steel beams (200 × 90 × 8 × 13.5 in the Japanese Industrial Standards (JIS G 3192)) were attached to the top and bottom of the wall. One of the specimens contained a single CLT wall with the proposed bolt connection (SSB). The second specimen consisted of two CLT wall panels connected in plain using the proposed joint (SCB). SCB wall specimen was tested to investigate the coupled-wall behaviour of the proposed joint system. The third specimen (SSS) is identical to specimen SSB except for the CLT wall-to-beam connections. In the SSS specimen, conventional screw connections were used (i.e., steel plate fixed to one side of the wall using self-tapping screws). The details and dimensions of the connections are shown in Figure 9. 9-mm thick steel plate was used for all the connections. For the bolt connections, three 20-mm HTBs were used, and ($L_n/Φ$) ratio was chosen as $L_n/Φ$=3.5 to

https://doi.org/10.52202/069179-0162

ensure the targeted embedment failure. For screw connections, STS C65 screws with 5.5 kN strength were used, according to the Japanese CLT Design Manual [11]. The number of screws (9) was chosen so that the load-bearing capacity of the conventional connection is equal to that of the bolt connection. The CLT wall was connected to the steel beam using 24-mm HTBs.

4.3 LOADING SET-UP

The CLT wall specimens were tested under quasi-static cyclic loading with the set-up shown in Figure 11. The specimens were loaded by two 200 kN centre-hole jacks at each side of the specimen (pull forces were applied). The two jacks were connected to the steel beams using wire ropes, and a pre-tension force of 10 kN was applied to the two wire ropes in order to prevent the twisting of the specimen in the out-of-plane direction. No axial load was applied to the wall; however, four tie bars were attached to the top steel beam as an uplifting constraint. each tie bar was pre-stressed with a 5 kN tensile force. The lateral load was applied as an incremental cyclic loading based on the loading protocol provided in [12]. Three cycles for each peak drift were adopted.

Table 4: *Test matrix of the CLT wall tests*

Specimen name	SSB	SCB	SSS
Number of panels	1	2	1
Connection type	Bolt (HTB)	Bolt (HTB)	Screws (STS ∘ C65)
Bolts/screws diameter (mm)	20	20	6.5
No. of bolts/screws	3	3x2 (6)	9

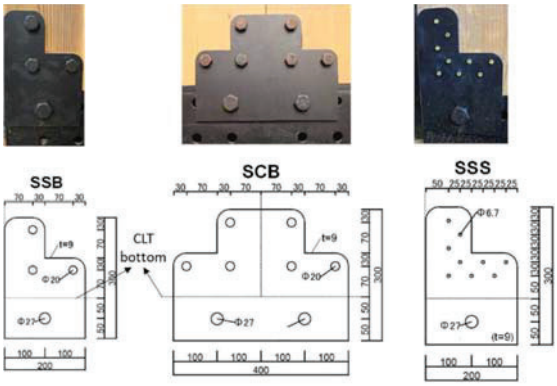

Figure 10: *Details of the steel plates used in the connections*

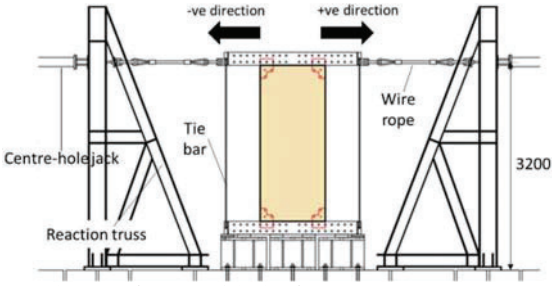
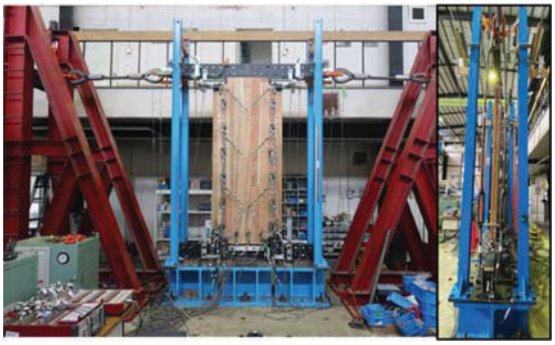
4.4 INSTRUMENTATION

The applied lateral load was measured using a centre-hole load cell. A typical instrumentation layout for the CLT wall tests is shown in Figure 12. LVDT sensors were attached to the tested specimens to measure story drift, and the story drift angle was calculated by considering the story height between the middle of the top and bottom beam (i.e., calculated by dividing the lateral load by the story height (2600 mm)). Rocking, sliding, shear, and bending deformation of the CLT wall panel were also measured. LVDT sensors to measure the neutral axis of the wall were also attached to the top and bottom of the wall. In addition, to calculate the axial forces in the tie bars, strain gauges were attached to all the bars. The axial force of the tie bar can be calculated as shown in Equation (11). The flexural moment in the bottom of the CLT wall ($M_{W\text{-}B}$) is then calculated using Equation (12) by subtracting the moment caused by the tie bar M_r from the moment of the entire system (M_{total}).



(a) Schematic diagram of the loading set-up



(b) Photo of the loading set-up

Figure 11: Loading set-up of shear wall tests

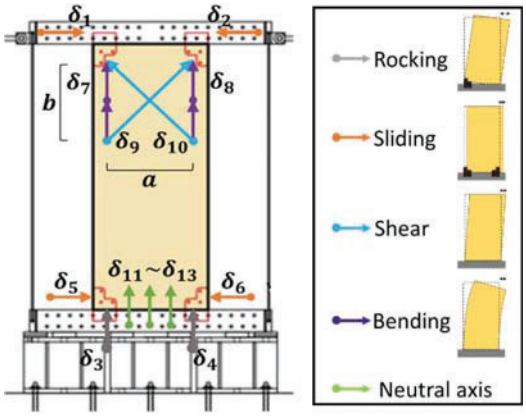


Figure 12: *An example of single wall (SSB) instrumentation*

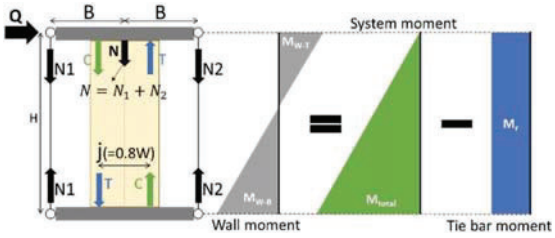

Figure 13: *Calculation method of the wall moment*

$$N_i = \varepsilon \times E \times A \quad (11)$$

Where ε (mm/mm) is the strain of the tie bar as measured, E (N/mm^2) is Young's modulus of the steel bar (2.05×10^5 N/mm^2), and A (mm) is the cross-sectional area of the tie bar (478.8 mm^2).

$$M_{W-B} = M_{total} - M_r \quad (12)$$
$$M_{total} = Q \times H \quad (13)$$
$$M_r = (N_1 - N_2) \times B \quad (14)$$
$$T = M_{wb}/j - 0.5N \quad (15)$$

Where H (mm) is the story height (2600 mm), N_1 and N_2 (kN) are the axial forces in the left and right tie bars, respectively. B (m) is the distance between the tie bar and the centre of the wall (1.025 m). N (kN) is the axial force applied to the wall and is equal to N_1+N_2. j (m) is the distance between the two connections at the bottom of the wall (0.8×D (1.2) =0.96 m), as explained in section 2.

4.5 RESULTS AND DISCUSSION

4.5.1 Failure characteristics

Photos of the failed single wall and coupled wall specimens (SSB and SCB, respectively) are shown in Figure 14. For the SSB specimen, at the bottom tensile connection, the outer layer of the wall (i.e., the outer lamina) failed in plug shear-out failure at 1% story drift angle. After that, a decrease in stiffness was observed; however, the load-bearing capacity of the wall continued to increase. This increase can be attributed to the effect of the compression strut inside the CLT wall, which appears as compression stresses at the compression side of the top and bottom part of the wall. At 5% story drift, the steel beam yielded in flexure (Figure 14.a), and the loading was terminated. For the SCB specimen, the outer lamina of the CLT wall at the tensile connection had a plug shear-out failure at 1.3% story drift. The load-bearing capacity continued to increase after the shear failure. At 4.8% story drift, the tensile connection in the middle of the wall had block shear failure, as shown in Figure 14.b, and the loading was terminated at 5% story drift. For the single wall with screw connections specimen (SSS), at 3% story drift, the screws of the bottom tensile connection started to fracture (2 screws). At 3.7% story drift, a large number of screws in the top and bottom tensile connections were broken and the test was terminated.

Although the expected failure type was supposed to be a uniform embedment failure, the bolt was tilted to the steel plate side of the CLT panel during the experiment. This failure mode was not considered in the design of the connections. In Europe, to calculate the load-bearing capacity of one-bolt connections for ductile failure the European yield model (EYM) is used. Using EYM the strength and failure mode of the connection are mainly governed by the bolt diameter to CLT panel's thickness ratio (Φ/t). When the EYM was applied to the connection used in this test, it was found that the expected failure is bolt-yielding failure (mode 2, Φ/t= 0.22), as shown in Figure 15. The ductile failure strength of the proposed joint was calculated based on the EYM equations provided in [13] and was compared to the experimental results. In order to apply the EYM to CLT, the average embedment strength across the width of the CLT panel was used, instead of lamella-by-lamella calculation. The values of the embedment strength of CLT provided in section 4.1 were used.

(a) SSB specimen

(b) SCB specimen

Figure 14: Failure characteristics of the tested specimens

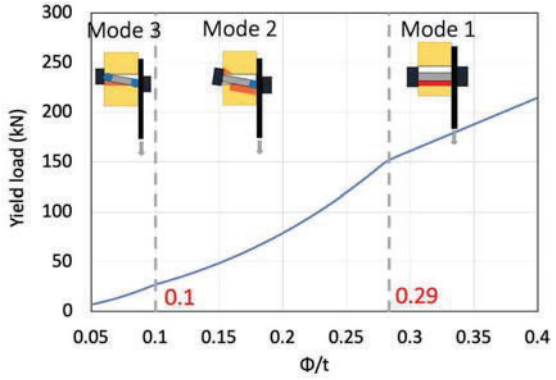

Figure 15: *Failure modes based on the EYM [13]*

4.5.2 Load-deformation response

The shear force-story drift curve for the SSB specimen is shown in Figure 16. The difference between maximum strength in the positive and negative direction was within 8%. When compared to calculation values based on uniform embedment failure (as explained in section 2), the experimental maximum strength (P_{max}) was 38% smaller. However, when compared to strength derived from the EYM, the experimental maximum strength was 18% larger. The EYM model can predict the load-bearing capacity of the proposed joint system with an acceptable accuracy. In addition to that, it was found that high shear strength per wall (τ=0.84 MPa) can be achieved, compared to 0.15 MPa for the wall with a conventional tensile bolt connection. This value (0.15 MPa) is calculated based on the standard strength of the CLT wall used in the simplified design method that is provided in the Japanese CLT Design Manual [11]**.**

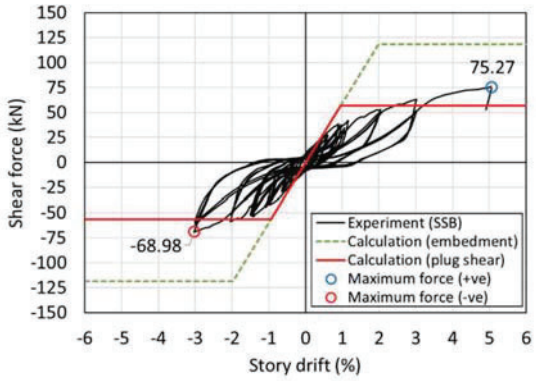

Figure 16: *Shear force-story drift curve for SSB wall specimen*

The shear force-story drift curve for the SSS specimen is shown in Figure 17. The maximum strength in the positive direction was 23% higher than that for the negative direction. Although the screw connection was designed to have a similar strength capacity to the bolt connection, the maximum strength of the SSS specimen was 32% smaller. The shear force-story drift curve for the SCB specimen is shown in Figure 18. The difference between maximum strength in the positive and negative direction was also within 8%. When compared to the single wall specimen (SSB), the maximum strength of the SCB specimen was only two times larger (198%). Therefore, each wall behaved as a separate wall and the proposed connections need to be improved to ensure the single-panel rocking behaviour.

The bilinear curves and the characteristic values (i.e., initial stiffness (K), yield strength (P_y), ultimate strength (P_u), and ductility (μ)) of the tested specimens were calculated based on the standard method described in the Japanese CLT Design Manual [11]. This method is based on the method proposed by Yasumura [14] for framed shear walls subjected to lateral load and is illustrated in Figure 19. The characteristic values of the tested specimens are summarised in Table 5. As a general tendency, for all the characteristic values, the single wall with screws connections specimen (SSS) had smaller values than the single wall with bolted connections specimen (SSB), as shown in Figure 20.a. The SSS specimen had a 60% smaller initial stiffness than the SSB specimen. When compared to the single wall specimen (SSB), the characteristic values of the coupled wall specimen (SCB) were almost two times larger on average. The initial stiffness of the SCB specimen was only 25% larger than the SSB specimen.

4.5.3 Performance of the proposed joint system

In this section, the performance of the proposed connection, as observed in the single wall specimen (SSB), is discussed. The contribution ratios of the different deformation components for the CLT wall panel at each peak drift in the positive direction are illustrated in Figure 21. In Figure 21, the contribution of the connection to the total deformation, and the bending and shear deformation of the wall panel are compared to the story drift. Deformation at the connection (rocking and sliding) was larger than the deformation of the CLT panel and was dominant from the small to ultimate story drift angle. Rocking deformation had the largest share with a 55.1% ratio on average, compared to the summation of the four components. The sliding deformation ratio was 32.5% on average. The CLT panel bending, and shear deformation ratio was 2.8% and 9.6%, respectively. It was found that the major component in the overall deformation of the wall is the rocking deformation, which represents the vertical deformation of the steel connection. This dominant rocking deformation was further investigated by looking into the relation between the moment at the bottom of the wall and the rocking angle of the wall, as shown in Figure 22.

In Figure 22, for experimental values, the rocking angle was taken as the value of the vertical LVDT sensors attached to the connection (δ_3 in Figure 12), and the flexural moment at the bottom of the wall ($M_{W\text{-}B}$) was calculated using the calculation method explained in section 4.4 (using Equation ((12)). To draw the calculation values curve, the rocking angle was calculated by the calculation method introduced in section 2 (using Equation (8)). Wall moment ($M_{W\text{-}B}$) was also calculated by the calculation method introduced in section 2. The calculated maximum moment was 16% smaller than the experimental result. The same tendency between calculation and experimental results was also found for the overall wall shear force-story drift. It was found that the introduced calculation method can be used to predict the structural behaviour of the proposed connection.

5 CONCLUSIONS

In this paper, a novel steel joint system for CLT-steel hybrid structures in seismic regions was proposed. The connections used in this joint system consist of steel bolts and a steel plate and works under bi-directional loading condition. One-bolt connection tests were conducted to investigate the effect of loading direction. Also, full-scale CLT wall-steel beam cyclic tests were conducted to investigate the structural performance of the hybrid structural system. The findings of this research are as follows:

1. Simple and easy-to-install bolted connection that can utilize the actual strength of CLT was developed.
2. Based on the one-bolt connection tests, it was found that maximum strength can be predicted, and the connection can be designed to have ductile embedment failure with the considerable selection of the embedment length over bolt diameter ratio (i.e., L_n/Φ larger than 3.2). Also, for CLT panels with a one-bolt connection, the effect of loading direction on the ultimate strength was not significant (within 16%)
3. For CLT walls tests, the wall with the proposed joint system showed higher average shear strength of 0.83 MPa, compared to 0.15 MPa of conventional tensile bolt connection. The wall also showed ductile behaviour and did not fail until a large story drift angle of 5% (the story drift angle at steel beam yielding). Regarding the coupled wall test, the two walls behaved as separate single walls and the strength was about twice the single wall. Further improvements are required to secure the single-panel rocking behaviour.
4. In the wall-beam system, the deformation of the proposed connection was dominant (i.e., rocking 55.1% and sliding 32.5% of the wall lateral deformation). The proposed calculation method can be used to predict the performance of the joint system.

For future consideration, improvements of the proposed connection to ensure CLT embedment failure is needed. Also, further considerations to improve the rocking behaviour of the coupled walls are desirable.

A NOVEL LIMITED-DAMAGE 3D-PRINTED INTERLOCKING INTER-MODULE CONNECTION SYSTEM FOR CROSS LAMNINATED TIMBER (CLT) VOLUMETRIC STRUCTURES

Zhengyao Li[1], Konstantinos Daniel Tsavdaridis[2]

ABSTRACT: With both the sustainability of timber and efficiency of modular construction, Cross Laminated Timber (CLT) volumetric construction is considered a potential solution to the severe environmental impact of modern construction. Conventional connection systems of CLT modular structures (angle bracket, hold-down) are mainly designed for panelised and framed construction. Due to their nature, they require careful design while numerous damages have been reported not only on their steel components but also timber fibres. The UK's funded project 3DMBC (https://3dmbc.com) was established to explore new ways of connecting CLT volumetric modules, ideally being damage-free and self-locking onsite during installation, aiming to improve the efficiency, adaptability and reusability of CLT volumetric construction. Damage avoidance philosophy (controlling deformation and damage away from timber and the embedded fasteners) was a key objective in the design of a three-dimensional connector system. A novel inter-locking system was recently proposed, tested experimentally and validated via numerical analysis. The proposed connection design also showcases a new concept of module assembly in CLT volumetric construction with higher efficiency, flexibility and adaptability, meanwhile demonstrates the potential in mitigating (permanent) damage of timber, thus increase service life and enable disassembly and reuse operations. The study shows that the screw-free assembly was provided along with adequate stiffness, strength and ductility by the new connections, and no damage was observed in timber after testing, proving the feasibility of the new connection design.

KEYWORDS: CLT Volumetric Construction, Timber Panel, Interlocking Connection, Damage-controlled Connection

1 INTRODUCTION

Volumetric construction is a modern method of construction (MMC) that is widely applied in buildings with high repeatability such as schools, offices, residential and hotels. Forming buildings with prefabricated flat modules that contain preassembled building accessories such as cladding, internal finishes and MEP services, this construction method is highly efficient with reduced waste production, workspace requirements and reliance on on-site manual work [1-2]. Concrete and steel volumetric construction are now rapidly growing in densely populated regions due to their great efficiency, while the potential of Cross Laminated Timber (CLT) in volumetric construction is also being explored for its additional material sustainability.

In volumetric construction, the connections that joint the adjacent modules (inter-module connections) provide load transferring path and define the overall structural performance, while the installation of them is a widely acknowledged problem due to the limited space (access) between modules for installing and dismantling connections. In CLT volumetric structures, where CLT panels are used as the primary structural elements to form the enclosed flat modules, the space for inter-module connection installation can be even more limited (Figure 1). As a recently developed construction technology, specific connection products have not yet been proposed for CLT volumetric structures. Therefore, flat modules could be left disconnected in low-rise CLT volumetric buildings. Alternatively, conventional timber connections angle brackets and hold-down plates are commonly employed, while the drawbacks are evident, such as the connection accessibility requirements, intensive labour force requirement for installation, insufficient stiffness and strength as well as the unpredictable and unfavourable brittle failure modes [3-5]. To promote the development of multi-storey CLT volumetric structures, the investigations on inter-module connections are crucial.

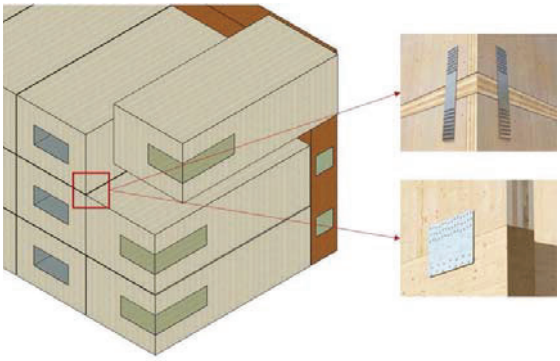

Figure 1: *Illustration of inter-module connection locations and the conventional hold-down (top) and bracket (bottom) that could be used in CLT volumetric structures*

A few bespoke connections (Figure 2) have been proposed recently for bespoke CLT volumetric projects to address the connection accessibility problem. These connections employ slot (groove) and ridge (tongue) designs that have matched shape, which can fit together without additional joining operations, such as adhesive or fasteners. In this way, the needs for access to install fasteners can be eliminated, and thus achieve a more efficient assembly and accurate positioning of modules. However, such connection designs require panel modifications for connection fitting, which may cause cross-sectional loss in structural elements and limit their applicability to other CLT volumetric structures [5]. A universal connection solution was still missing for the ease of design and construction for this structural system. Therefore, a novel interlocking connection system is developed within 3DMBC group, exploring convenient onsite joining methods with enhanced structural performance.

2 CONNECTION DESIGN

2.1 INTERLOCKING CONNECTION SYSTEM

The proposed interlocking connection system consists of a tensile and a shear connection (Figure 3) [8]. Both are strip-like devices that formed by repetitive 3D unit elements. Both shear and tensile connections include two parts, named male connectors and female connectors, which self-lock after assembly, prohibiting module movement on their primary and secondary working directions (Figure 3).

Connection strips are fastened to CLT flat modules in the factories to achieve precise position, proper tightening, as well as improved project efficiency. Utilising this interlocking technique, modules with pre-installed connections can be accurately assembled on-site by simply sliding or stacking them (Figure 3) without additional onsite fastening. The pre-installed sliding connection units (Figure 4) also act as guiding devices to help locate the modules into the right positions and avoid potential construction errors from manual operations advancing the overall construction management tasks. Different from the conventional point-to-point connections, continuous reinforcement is formed along the edges of modules after guided assembly, which is suitable to CLT volumetric structures, where translational forces are important in structural design. The tensile connections provide vertical constraints at the edge of the structure and help resist uplifting. The shear connections provide horizontal constraints at the middle of the structure to resist lateral movement from wind and seismic load (Figure 5).

https://doi.org/10.52202/069179-0163

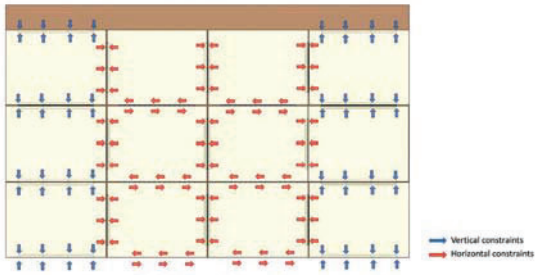

Figure 5: *Continuous reinforcement along CLT modules edges provided by assembled connections [8]*

2.2 CAPACITY DESIGN AND DAMAGE AVOIDANCE PHILOSOPHY

Beyond the advanced installing method, this connection system is also designed with the damage avoidance philosophy to limit the permanent damage in timber that is observed when using the conventional timber connections, hence enable reuse. In timber connection design, fastener deformation is treated as the primary source of ductility, and overstrength method (eq.1) is commonly applied to strengthen the brittle elements and ensure the activation of fastener deformation before the brittle failures happen in timber and metal plates (Figure 6), which is known as "strong plate-weak fastener" behaviour [9].

$$\gamma_{Rd} R_{d,ductile} \leq R_{d,brittle} \quad (1)$$

The application of this method can, however, be problematic due to the inherent defects of timber as natural material, the unclear understanding of the interaction between timber and deformed fasteners, and the insufficient accuracy of currently available analytical models [5]. As the overstrength factor (γ_{Rd}) is calculated by multiplying γ_m (partial factor of material properties), γ_{an} (ratio of estimated value to analytical value of the target strength) and γ_{sc} (scattering of the target strength), the above reasons can lead to unrealistic values of these factors, and then lead to inappropriate overstrength factor, especially when specific overstrength factors are not provided for timber structures in EC8 [10][11]. Such overstrength factor may lead to undesirable failure modes, for example timber splitting and metal plate fracture [12][13]. In addition, the deformed fasteners can crush the timber and create permanent cavities around timber fibres, which lead to degraded stiffness and strength [9], reducing structure's capacity in energy dissipation during seismic events as well as develop large residual displacements that reduce the structure's resistance to aftershocks [14-16]. Consequently, relying on fastener deformation for ductility is not ideal as it imposes difficulties to the design prediction and repair of timber connections (for reuse), and ultimately reduces seismic resistance.

Interlocking connection design benefits from utilising the metal connectors which are treated as the ductile elements (Figure 6). Shifting the ductility source from the timber-fastener interaction to the metal connector deformation (not the screws) can make connection properties dependent on the stable metal material properties, instead of the timber grain orientations and conditions, reducing the risk of brittle failures and providing controlled and easily predicted connection performance.

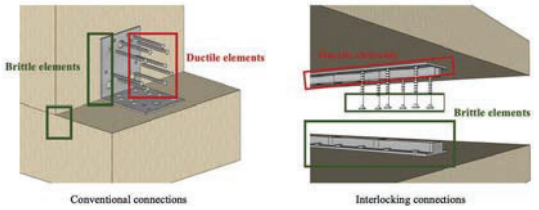

Figure 6: *Capacity design of conventional plate connections (left) and novel interlocking connections with damage avoidance philosophy (right)*

2.3 ADAPTABLE CLT VOLUMETRIC BUILDINGS

In addition, the special functionalities of this proposed connection system, such as the interlocking and damage avoidance effect, can be used for adaptable structures that possess the ability to address changes during construction and meet different functionality requirements during service life, such as partial disposal, change of use, re-usability and extension of buildings, for coping with future building obsolescence and redundancy [17]. The adaptability of such structures is attributed to the design of connections. The below criteria are recognised as crucial factors for developing adaptable connections [17][18]:

Demountability: Adaptable connections should be demountable to comply with the potential modifications in building design, and allow for easy dismantlement without demolition and damage of the structural members at the end-of-service life. The undamaged structural components or even the entire flat modules can be directly reused or recycle at their highest extent, improving the resources scarcity and environmental degradation brought by the building-related activities.

Standardisation: Adaptable connections should be standardised, hence allow for general application without modifications required, facilitating design simplifications.

Size, shape and position tolerance: Adaptable connections should be project-independent products that can fit with structural elements (here CLT panels and volumetrics) with varied dimensions at different positions within the structure. This refers to the connections that need no modification requirements for the fitting of connections.

Individual removability: The structural elements with adaptable connections should be removable without interfering with other elements, in response to external factors.

Direct usability: Adaptable connections should be operational immediately after installation without further modifications, such as fixing, adjusting and controlling to speed up the construction process, eliminate the onsite manual work and ensure safety.

https://doi.org/10.52202/069179-0163

Based on the above criteria, the proposed connections are highly adaptable, as they are demountable, standardised, flexible and can provide immediate reinforcement after self-locking.

3 NUMERICAL AND EXPERIMENTAL ANALYSIS

3.1 EXPERIMENT PREPARATION

To evaluate the realistic performance of the proposed connection design, monotonic and cyclic push-out and pull-out tests were performed on the connection specimens, using loading protocol as prescribed in EN12512 [19]. The unit elements of each connection were tested; first screwed to 5-ply GL24h CLT panels and then assembled together without any fastener (Figure 7). Six LBS7100 and four HBSP12120 from Rothoblaas were used in each of the tensile and shear unit connectors to achieve higher timber-fasteners connection capacity than the estimated interlocking connector capacity, ensuring the successful attainment of damage avoidance effect.

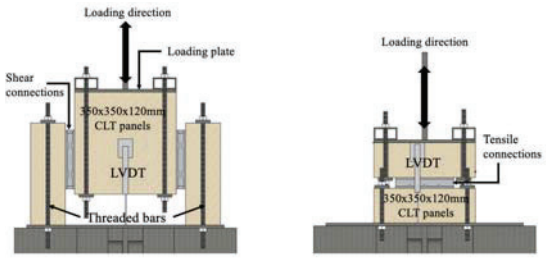

Figure 7: *Experimental set-ups of the push-out (left) and pull-out test (right) on shear and tensile connectors*

Due to the complex geometric design (cantilevering and curvy features) of interlocking connectors and the limited number of specimens needed for testing, 3D printing was used as the manufacturing method to produce the testing specimens using SS420/BR (Figure 8), considering its manufacruting freedom without requesting moulding [20]. All specimens were printed with satisfying accuracy, and both male and female connectors fitted well with 1mm printing tolerance. To determine the actual properties of connection material to be used in the numerical validation, coupons tests were conducted on the specimens from the undeformed female connectors, which confirmed the modulus of elasticity E=130GPa, yield strength σ_y =304MPa, ultimate strength σ_u=638MPa and ultimate strain of ε_u=5.9 % of the 3D printed steel.

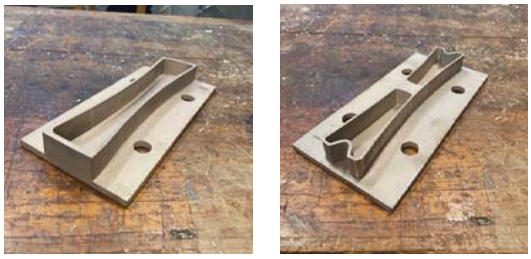

Figure 8: *3D printed specimens of shear (top) and tensile (bottom) connection units*

3.2 EXPERIMENTAL RESULTS

As demonstrated in Figures 5 and 6, the deformation of both connections was localised on part of the connections (the male connectors). After removing the screws, only slight wearing can be observed around the screw holes on the connector plates without visual deformation in the screws and timber, indicating the successful attainment of damage avoidance effect on the structural material.

The primary deformation mode in the shear connection was buckling of the middle of steel plate on both sides. Also, slight close-up at the end suckens can be observed (Figure 9). The primary deformation mode in the tensile connection was bending of the L-shaped elements in the male connector (Figure 10). The female connectors and screws of both connections remained mostly undeformed; only very slight open-up in the bearing walls and slight bending in the bottom plate in the tensile female connector were recorded at the end of testing. Thus, it can be concluded that the deformation of the interlocking connections was well controlled within both male connectors.

Figure 9: *The tested shear connection specimens and screw removal*

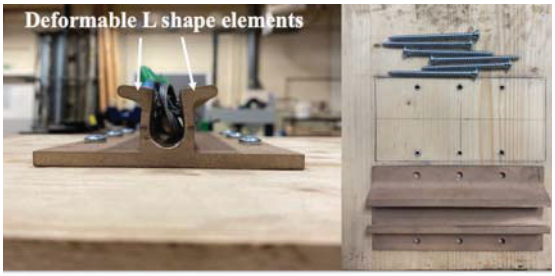

Figure 10: *The tested tensile connection specimens and screw removal*

https://doi.org/10.52202/069179-0163

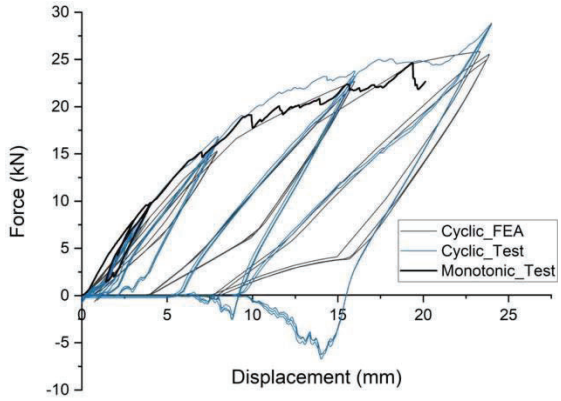

Figure 11: *Force-displacement curve of the tensile connections [8]*

Figure 11 demonstrates the cyclic performance of the tensile connections, and shows adequate strength, stiffness and ductility. The stiffness and maximum strength in the first cycle of each loading step during the cyclic test were well consistent with the monotonic tests, indicating that the plastic deformation in the steel male connector does not affect the maximum capacity in the subsequent loading. On the contrary, conventional timber connections normally demonstrate reduced maximum capacity in cyclic test in comparison to the monotonic test due to the damage of timber in the vicinity of deformed fasteners. However, the plastic deformation causing a gap between the male and female connectors, consequently sliding of the male connector with no reaction force can be identified at the initial phase of each loading cycle.

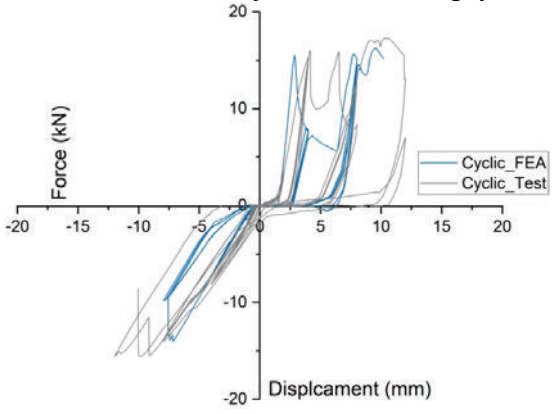

Figure 12: *Force-displacement curve of the shear connection [8]*

As depicted in Figure 12, the shear connections demonstrated higher stiffness but reduced ductility than the tensile connections in the cyclic testing. Three sudden resistance reductions can be identified at the displacement of 4mm, 6.5mm and -8mm, respectively, corresponding to the three buckling points observed in the failed shear specimens. After the buckling, the connection strength continued to develop in the deformed steel band and the end sunken in the male connector, leading to the plump hysteresis loop at large displacement until the breakage happened at the buckling point (Figure 9). Therefore, buckling at the middle of the deformable plate and bending at the sunken design at the end of the steel band are the two major deformation modes identified in the shear connections, and the buckling locations were relatively consistent among all the specimens.

3.3 NUMERICAL ANALYSIS

The numerical models of all experimental models were developed for validation (Figure 13). CLT panels were modelled with an orthotropic elastoplastic material; the properties are summarised in Table 1.

Table 1: *Material properties adopted for CLT panel model (spruce) [21]*

Elastic modulus (MPa)					
E_{11}		E_{22}		E_{33}	
11000		370		370	
Poisson's ratio					
ν_{12}		ν_{13}		ν_{23}	
0.48		0.48		0.22	
Shear modulus (MPa)					
G_{12}		G_{13}		G_{23}	
690		690		50	
Parallel-to-grain (MPa)		Perpendicular-to-grain (MPa)		Shear strength (MPa)	
f_{c11}	f_{t11}	f_{c22}	f_{t22}	f_v	$f_{v,roll}$
36	24	4.3	0.7	6.9	0.5

Grade-300PLUS steel (σ_y= 320MPa and σ_u=440MPa) and Grade 10.9 carbon steel (σ_y=σ_u=940.3MPa) [22] were used for steel fixture devices and screws, respectively, and the material properties of SS420/BR that determined from coupon test were used for the connectors. Different published modelling methods were employed to simulate the screw-timber interactions of screw working in different directions. To model the pull-out behaviours of LBS7100 of the interlocking tensile connectors that rely heavily on the threaded part of screws, an efficient approach presented in the literature was adopted [23] [24]. This method introduces a fictitious layer of 'soft material' that wraps the shank of screws as the simplified threaded part (Figure 13). The 'soft material' is assumed to be perfectly elastic with the same capacity as CLT (Table 1) except for the radial modules (E_{33}). A reduced value of 50MPa was used instead to simulate the weakened compressive capacity of timber around the threads. To model the bending capacity of HBSP12120, only the screws shank was modelled (Figure 13) [25], as it is the primary part that defines the bending behaviours of screws. For all other interfaces, the surface-to-surface discretisation method was adopted with the "Hard Contact" option in the normal direction, and the "penalty friction formulation" option in the tangential direction. The good agreement between the experimental results and numerical output in terms of the maximum strength, initial and reduced stiffness of each loading cycle, as well as the deformation modes, proves the

https://doi.org/10.52202/069179-0163

feasibility of the adopted modelling methods for both interlocking connections (Figure 11&12).

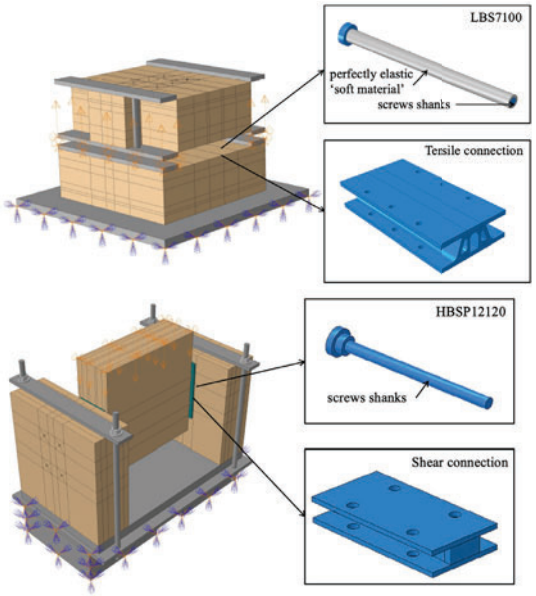

Figure 13: *FE models for tensile connection (top) and shear connection (bottom) validation*

After the validation, complimentary FE analyses were performed to further investigate the performance of the connectors with more common grade of steel S235 (E=210GPa, σ_y =235MPa and σ_u =360MPa) and better understand the deformation progression in the connectors, which are not visual during the testing due to the enclosed connection design.

Both connection models were tested numerically under primary and secondary directions (Figure 3), confirming the adequate stiffness and ductility in both translational directions. In the primary working direction, the damage avoidance effect was attained in both connections with most deformation being localised in male connectors. Negligible strain can be observed in the fasteners and timber. In the secondary working direction, both connections behaved more like conventional connections and all elements deformed including male connectors, female connectors and screws (Figure 14&15).

4 CONCLUSIONS

This research proposed a novel connection system for CLT volumetric construction, as part of the modern methods of construction (MMC), to enable safe and efficient assembly as well as fast erection and dismantling. Without the need of panel modifications, the interlocking connectors can be easily applied to different projects with varied mechanical performance requirements and modules' specifications by simply adjusting the connector strip length. The adoption of unit element design also allows for easy standardisation, as the connections can be directly applied in construction without changes in geometries. Therefore, the proposed connection system can improve the constructability, adaptability and reusability of CLT volumetric structures. The conducted experimental and numerical analyses proved that the proposed connections have adequate translational strength, stiffness and ductility in both primary and secondary directions. The application of plug-and-play connections can enable automation/robotic construction methodologies with accuracy and speed,

https://doi.org/10.52202/069179-0163

resulting to less resources consumption and waste production, thus reduced environmental impact and destruction to the surrounding area. Though construction operations need to be somewhat altered for the sliding operations, this interlocking connection system can be a promising solution to efficient and adaptable multi-storey CLT volumetric construction.

ACKNOWLEDGEMENTS

IMPACT OF MOISTURE CYCLING ON SCREW WITHDRAWAL CAPACITY OF TREATED AND UNTREATED RADIATA PINE

Luis Yermán[1], Zidi Yan[2], Wen Feng[3], Lisa-Mareike Ottenhaus[4]

ABSTRACT: The increased use of wood products for construction has intensified the need to understand how moisture affects the mechanical properties of timber connections. The withdrawal capacity of dowel-type fasteners, such as screws, needs to be measured, or estimated, for the design of timber systems having connections with axially loaded dowel-type fasteners. The influence of the moisture content changes on the timber is often examined, but its effect on the mechanical performance of connections is poorly considered, including the design codes. This work examined changes in the screw withdrawal capacity in light organic solvent preservative-treated and untreated Radiata pine with type 17 screws inserted perpendicular and parallel to the grain and subjected to repeated wetting and drying cycles. A comparison of the screw withdrawal capacities with those predicted from Australian and European codes was performed. The results presented here are part of a larger project that includes the study of embedment strength and lateral resistance in combination with different wood treatments and pine species.

KEYWORDS: Screw withdrawal capacity, Preservative treatment, Moisture content, Radiata pine

1 INTRODUCTION

Wood is a hygroscopic material that easily absorbs and desorbs moisture from the environment, producing swelling or shrinking. Dimensional changes induce stresses in the timber elements that can lead to cracks or failures [1]. Induced stress is even more important in timber connections, as the deformations and movement incompatibilities produced by differential moisture responses create even more stress [2]. For example, the screw withdrawal capacity (SWC) in timber can be affected by moisture/drying exposure conditions that eventually reduce fastener capacity and can also induce metallic corrosion [3].

Most timber buildings are designed to exclude moisture, but some elements may be subjected to wetting and must be supplementally protected with preservatives to provide acceptable service life. Many of these preservatives are water-based products that may accelerate fastener corrosion and eventually the loss of mechanical properties of the timber connection [4]. For this reason, most preservative suppliers recommend the use of either stainless steel or hot-dip-galvanized fasteners.

Despite the potential for preservative treatment to affect fastener performance, there is limited research on the impact of moisture content (MC) changes on treated timber connections. The increased use of wood products in construction has intensified the need to understand how moisture affects the mechanical properties of timber connections, as wetting of these elements can occur due to rain penetration, condensation [5], as well as bathroom or pipe leakages.

Design standards can be used to estimate the strength of a timber connection, and ultimately design safe structures. According to Eurocode 5 (EC5) [6], the withdrawal capacity of dowel-type fasteners is necessary for the design of connections with axially loaded dowel-type fasteners. Nevertheless, the influence of the MC on the mechanical performance of these connections is poorly considered. In the EC5, the design value (X_d) of a strength property of a timber connection is calculated by modifying the characteristic value (X_k) according to Equation 1:

$$X_d = X_k \frac{k_{mod}}{\gamma_M} \quad (1)$$

where k_{mod} accounts for the service class (a function of load duration and expected equilibrium moisture content of the material) and γ_M is the partial factor (a function of the type of material, e.g., solid timber, particleboard). The impact of the MC in the design is considered only through k_{mod} with discreet values ranging from 0.2 to 0.6 in 0.1 intervals. Other design standards, such as the Australian standard AS 1720.1-2010 (AS1720) [7] only consider moisture effects on member strength, but not on the connection strength.

Screws are one of the most used timber fasteners. Nevertheless, little research has been conducted on the effect of MC variations on SWC [8]. Apart from MC, the SWC depends on several factors including connection

https://doi.org/10.52202/069179-0164

geometry (e.g., diameter and penetration depth), tensile screw capacity (which in turn depends on the material and diameter), timber density, and the direction of loading with respect to the grain orientation for larger screws. While this creates an infinite array of possible tests, these can be simplified to several critical factors.

This work examined changes in the SWC in light organic solvent preservative (LOSP) treated and untreated Radiata pine with screws inserted perpendicular and parallel to the grain and subjected to repeated wetting and drying cycles. A comparison of the experimental withdrawal capacity with those predicted from the standards AS1720 [9] and EC5 [6] are presented and discussed. This work is part of a larger project that aims to assess the impact of moisture cycles on the withdrawal capacity, embedment strength and timber joints for a series of Australian timber species and preservative treatments.

2 EXPERIMENTAL

2.1. SPECIMEN CONFIGURATION

Defect-free 272 mm long Radiata pine (*Pinus insignis*) specimens were cut from 5 m long 45 x 90 mm boards with and without LOSP treatment.

LOSP-treated and untreated specimens were conditioned at a temperature of 25 °C and 65 % of relative humidity, using an environmental chamber (Labec F-HWS-250B). The samples were kept inside the chamber until constant mass to ensure moisture equilibrium.

Stainless steel screws with a 4.2 mm outer thread diameter (Table 1) were driven into a lead hole with a 2.94 mm diameter, to a penetration depth of 37.5 mm. Three screws were inserted perpendicular to the grain, and two parallel to the grain (Figure 1). The specimens were designed to meet the minimum requirements according to the testing standards AS 1649 [10] and ASTM D1761 [11]. The screws were weighed before being driven into the wood. After installing the screws, timber samples were checked to ensure that no cracks developed.

Table 1: *Wood and screw specifications for creating the test assemblies, and the number of specimens built for testing.*

Wood type	2	Radiata pine (LOSP treated and untreated)
Screw types	1	Type 17 (8g), SS 304, 4.2 x 50 mm
Screws per specimen	3 + 2 5	Side + end grain TOTAL
Test conditions	5	0, 2, 4, 8 and 12 moisture cycles
Repetitions per condition	15 10	Side grain End grain
TOTAL	**50** **250**	**Wood specimens** **Screws**

The moisture content of the conditioned LOSP-treated and untreated woods was determined using the oven-dry method from 20 smaller samples from the same boards. For the determination of the density, the dimensions (L, W, T) were measured at three different points, using a digital calliper, for each specimen and then averaged (Table 2).

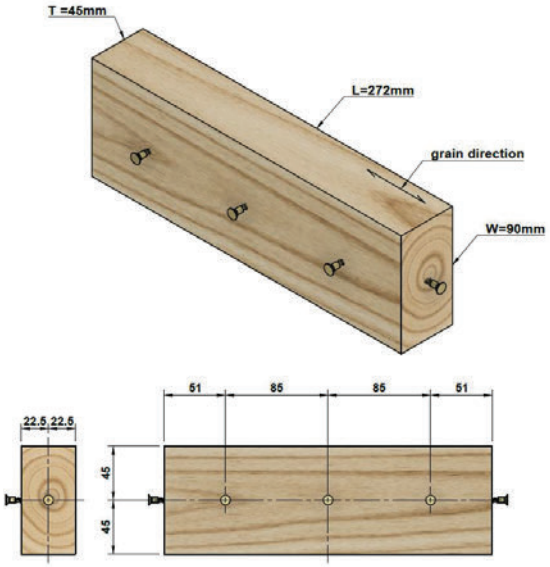

Figure 1: *Specimen dimensions and configuration showing the relative position of the screws and the grain direction. All distances are in mm (L = length, W = width, T = thickness).*

Table 2: *Wood types, mean density, and moisture content of the treated and untreated wood used in the experiments. Values in parenthesis are standard deviations.*

Wood type	*Mean density (kg/m3)*	*MC (%)*
Untreated	485 (49)	11.7 (0.8)
LOSP treated	465 (37)	12.9 (0.9)

2.2. MOISTURE CYCLES

One set of five specimens (controls) was immediately tested, while the remaining specimens were weighed to determine the initial weight and then soaked until their moisture contents had reached 50-60 wt% (between 4 and 6 days). The samples were then dried for 40-50 hours at 50 °C for a slow loss of moisture to a final MC between 10 and 15 wt% before being weighed again. At this point, the specimens were tested or subjected to another wet/dry cycle.

2.3. WITHDRAWAL TESTS

The effects of wetting and drying on withdrawal capacity were assessed after 0 (controls), 4, 8, 12 and 16 moisture cycles. Screw withdrawal tests were carried out according to the standard AS 1649 [10] using an Instron 3400 universal testing machine (Instron, Inc. Norwood, MA, USA). The speciemens were conditioned in the same environmental chamber and conditions mentioned before. The specimens were placed in a specially constructed assembly (Figures 2 and 3) and the screw was withdrawn

https://doi.org/10.52202/069179-0164

at a rate of 2.5 mm per minute. The load required to withdraw the screws was recorded as a function of time.

2.4. COMPARISON WITH DESIGN STANDARDS

The comparison of the experimental SWC with the estimated from the current Australian (AS1720 [9]) and European (EC5 [12]) codes was done based on the following ratio (Equation 2):

$$Ratio = \frac{SWCe}{SWCp} \quad (2)$$

where *SWCe* is the fifth percentile of the experimental SWC values from each series, and *SWCp* is the predicted SWC using Equations 3 and 4, corresponding to the AS1720 and EC5, respectively.

$$N_{k,j} = k_{13} l_p n Q_k \quad (3)$$

In Equation 3, $N_{k,j}$ is the *SWCp*, k_{13} is a modification factor (1.0 for screws on the face grain and 0.6 for screws in the end grain), l_p is the depth of the screw penetration (37.5 mm), n is the number of screws (1 screw), and Q_k is the characteristic capacity (56 N/mm).

$$F_{ax,\alpha,Rk} = \frac{n_{ef}\, f_{ax,k}\, d\, l_{ef}}{1.2cos^2\alpha + sin^2\alpha} \left(\frac{\rho_k}{\rho_a}\right)^{0.8} \quad (4)$$

In Equation 4, $F_{ax,\alpha,Rk}$ is the *SWCp*, n_{ef} is the number of effective screws (1 screw), d is the outer thread diameter of the screw (4.2 mm), l_{ef} is the penetration depth of the threaded part (35 mm), ρ_k is the characteristic density of the wood (considered as the fifth percentile of the density of the batch, in kg/m^3), and ρ_a is the associated density (considered as the 5th percentile of the densities of all the specimens, 418 kg/m^3), $f_{ax,k}$ is the characteristic withdrawal parameter, determined with the 5th percentile of the *SWCe* of the controls (specimens at week 0), and α is the load-grain angle, with screws driven into end grain α = 0º and screws driven into side grain α = 90º.

In practice, *SWCp* values are used to design timber structures. A safe prediction is considered when the ratio is above 1.

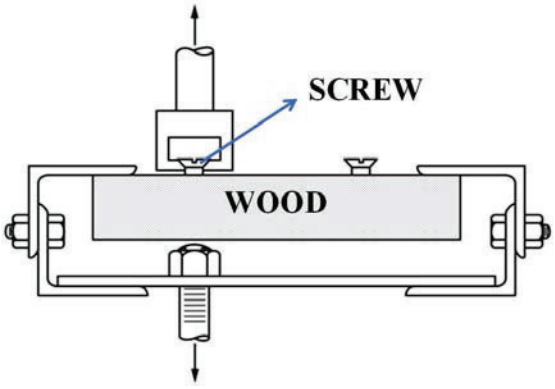

Figure 2: *Diagram of the screw withdrawal test assembly (adapted from* [11]*).*

2.5. STATISTICAL ANALYSIS

The data were subjected to an Analysis of Variance (α = 0.05) to determine the effects of the moisture cycles on the screw withdrawal capacity. Differences between means were examined using T-tests at a confidence interval of 95 %. Normal distribution was verified through Shapiro-Wilk tests.

Figure 3: *Screw withdrawal test setup, showing (a) grip and (b) test rig.*

3 RESULTS AND DISCUSSION

3.1. SCREW WITHDRAWAL TESTS

All withdrawal tests, regardless of load-grain angle, exhibited the same failure mode, as shown in Figure 4. The failure was characterized as a shear failure of the wood spile around the screw's thread.

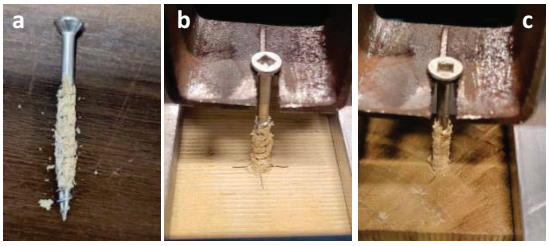

Figure 4: *Failure mode of the specimens, showing the wood spile around the screw's thread (a), the failure on a side-grain test (b) and the failure on an end-grain test (c).*

All load-displacement curves exhibited linear-elastic behaviour up to failure (Figure 5). Screws inserted in the side grain exhibited an initial linear phase, followed by limited 'yielding' (quasi-brittle behaviour) with a significant load drop of about 50 %, after which the load reached an almost constant region, until complete withdrawal from the timber. In contrast, screws inserted in the end grain showed a linear relationship until the maximum load, with a sharp and more significant load drop (about 70-80 %). Furthermore, the curves exhibited half-sine-wave-like shapes during the final withdrawal.

https://doi.org/10.52202/069179-0164

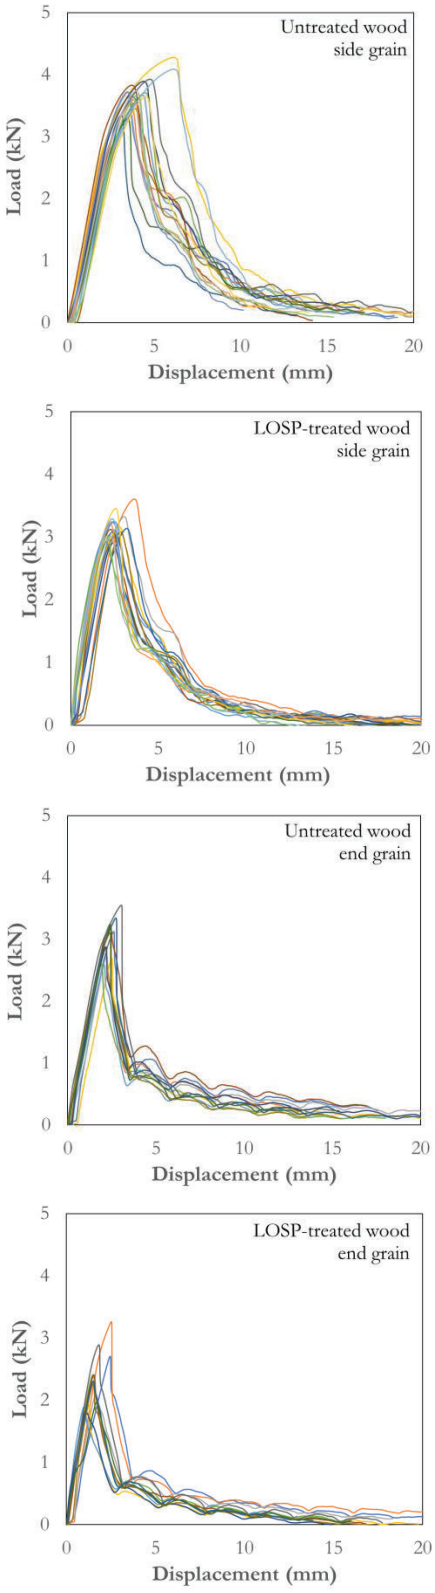

Figure 5: *Examples of load-displacement curves for specimens subjected to 8 moisture cycles.*

Gutknecht and MacDougall [13] observed similar behaviour for screws inserted in the end grain of Douglas fir and eastern white pine. Although they found two different failure modes, they describe this behaviour as a residual strength in the connection after the withdrawal limit is reached due to changes in the friction of the wood spile as it is pulled out. Interestingly, the authors also found that the distance between the minimums of these half-sinus waves coincides with the thread spacing of the screws. The same relationship was found here.

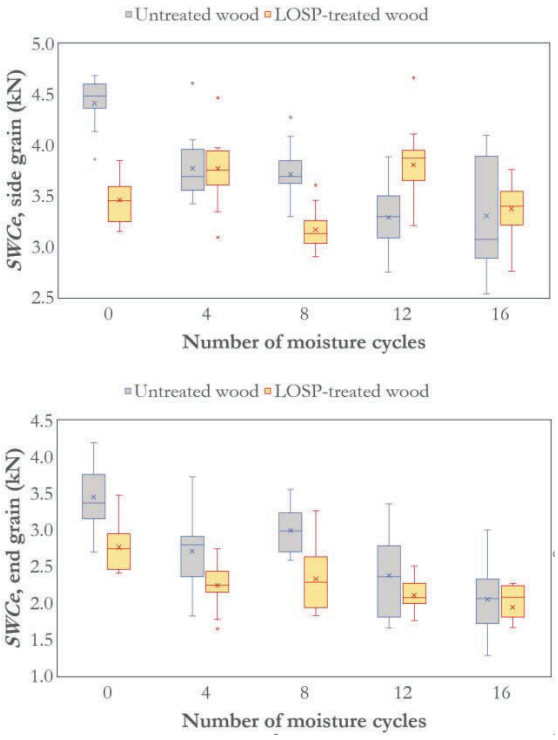

Figure 6: *Experimental withdrawal capacity for screws inserted in the side grain (top) and end grain (bottom) of LOSP-treated and untreated wood. The* X *and line represent the average and median values, respectively. The circles represent the outlier values.*

In terms of maximum withdrawal capacity, results showed that the initial (week 0) *SWCe* in LOSP-treated samples was lower than those in the untreated wood, for both side and end grain. Moreover, the impact of the moisture cycles showed a strong dependence on the timber faces the screws were driven into, only when LOSP-treated wood was tested. To analyse the significance of these differences, independent t-tests for the *SWCe* values in paired moisture cycles were performed (Table 3).

For screws driven in the side grain, the *SWCe* in untreated wood was reduced with increasing moisture cycles (26 % reduction after 16 moisture cycles), whereas the *SWCe* in LOSP-treated wood showed significant fluctuations. Meanwhile, for screws driven in the end grain of untreated

https://doi.org/10.52202/069179-0164

wood, the *SWCe* showed the same behaviour as the side grain, but with a drop of 42 % in this case. Nevertheless, the *SWCe* in LOPS-treated wood showed a 19 % loss after 4 moisture cycles, remaining statistically unchanged afterwards.

The moisture cycling had less effect on the *SWCe* of screws in LOSP-treated samples, possibly due to the protective effects of the residual solvent. LOSP-treated material typically contains up to 50 litres of residual solvent per m^3 of wood and can limit the initial moisture uptake around the connections, although it would eventually evaporate.

Table 3: *P-values results from the T-test performed (the null hypothesis is the SWCs are not significantly different) and the difference of the SWCe averages (Av. diff.) for paired moisture cycles. P-values below 0.05 reject the null hypothesis. Values in bold correspond to SWCe values that are not statistically different.*

Face	Wood	Moisture Cycles	p-value	Av. diff. (%)
Side	Untreated	0 - 4	< 0.001	-15
		4 - 8	**0.526**	**N/A**
		8 - 12	< 0.001	-11
		12 - 16	**0.919**	**N/A**
	LOSP-treated	0 - 4	0.006	+9
		4 - 8	< 0.001	-16
		8 - 12	< 0.001	+20
		12 - 16	< 0.001	-11
End	Untreated	0 - 4	0.002	-21
		4 - 8	**0.098**	**N/A**
		8 - 12	0.007	-21
		12 - 16	**0.160**	**N/A**
	LOSP-treated	0 - 4	< 0.001	-19
		4 - 8	**0.568**	**N/A**
		8 - 12	**0.127**	**N/A**
		12 - 16	**0.269**	**N/A**

3.2. COMPARISON TO DESIGN STANDARDS

The comparison of the 5th percentile of the *SWCe* values with those calculated from the standards AS1720 and EC5 are represented in Figure 7, as per Equation 2.

The results showed a significant overestimation of the *SWC* using the AS1720, with ratios closer to 2, or even above in some cases. This standard was developed about 15 years ago and lacks variables in the prediction. For example, the prediction from the AS1720 does not consider the actual density of the timber, but instead a characteristic density for groups of timber species.

This results in the same predicted value for that group of timber species which needs to be overestimated to compensate for the natural variability in the timber density. On the other hand, the EC5 showed ratios closer to the unit in every case, although in some cases the ratios were below 1. This highlights the importance of considering more specific system characteristics (e.g. wood density, nail diameter) for these predictions.

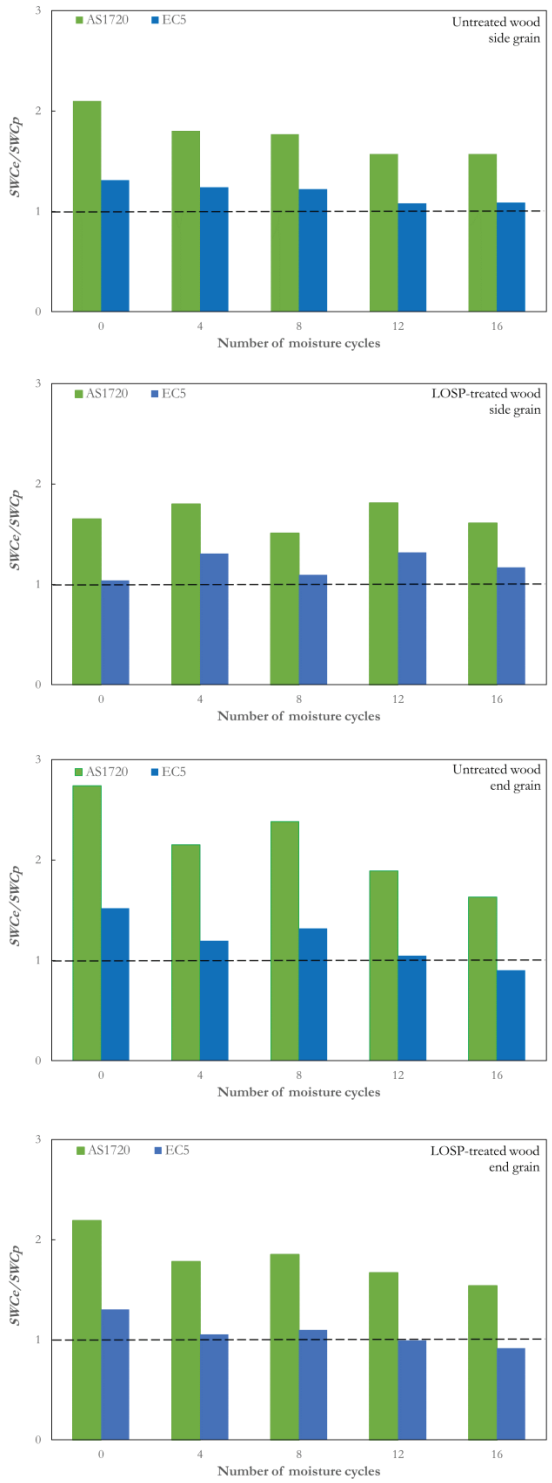

Figure 7: *Ratios of experimental and predicted SWCs for the different series tested (see Equation 2). The dashed line, at ratio =1, marks the limit where the predictions are safe.*

4 CONCLUSION

The main conclusions from this work are as follows:

- The withdrawal capacity for screws driven into the side and end grain of untreated wood after 16 moisture cycles was reduced by 26 and 42 %, respectively.
- The moisture cycling had less effect on the *SWCe* of screws in LOSP-treated samples. For screws driven into the side grain, the *SWCe* fluctuated, having an overall reduction of 2% after 16 moisture cycles. The *SWCe*, in the end, grain showed an initial loss of 19 % after 4 moisture cycles, remaining constant afterwards.
- The Australian standard AS1720 significantly overestimates the SWC value. This would lead to a misuse of resources and also to an over-design and overstrength of the timber connections, which in turn can trigger undesired brittle failures.
- Although in some cases the prediction from EC5 was not safe (ratios below 1), it showed a better prediction than the AS1720. This highlights the importance of considering more system characteristics for these predictions.

ANALYSIS AND DESIGN ASPECTS OF MOMENT-RESISTING, BEAM-TO-COLUMN, TIMBER CONNECTIONS WITH INCLINED THREADED RODS: FROM FASTENER LEVEL TO CONSTRUCTION LEVEL

Haris Stamatopoulos[1], Osama Abdelfattah Hegeir [2], Kjell Arne Malo [3]

ABSTRACT: Moment-resisting timber frames (MRTFs) can be an alternative load-carrying system for mid-rise buildings, compared to systems based on walls or diagonals. The response of MRTFs depends largely on their connections. This paper provides an overview of analysis and design aspects of connections for MRTFs based on inclined threaded rods. Simplified expressions are provided for the properties of such connections and for the properties of threaded rods. Finally, the effects of connection's stiffness variability are explored. It is shown that this variability can result in increased values of actions compared to the values obtained by use of mean connection stiffness.

KEYWORDS: Moment-resisting connections, Moment-resisting frames, Threaded rods, Stiffness variability

1 INTRODUCTION

Moment-resisting timber frames (MRTFs) can reduce the need for bracing by shear walls or diagonal elements and allow for greater architectural flexibility in mid-rise buildings. The response of MRTFs depends on the properties of their connections, especially with respect to the serviceability aspects, see e.g.[1]. Moreover, MRTFs are statically indeterminate structures and the magnitude and distribution of internal forces and moments at the Ultimate Limit State, depend on the stiffness of their connections. The variability of the connections' stiffness can also significantly influence the internal forces and moments as will be shown in Section 4.

A concept for a moment-resisting connection with inclined threaded rods is presented in Figure 1. The rods are inserted with an inclination in pre-drilled holes in the beam and the column and jointed by use of metallic coupling parts. In the prototype tests for this concept [2], beams and columns were made of glued-laminated timber (glulam) and purpose-made steel rings were used as the coupling parts, see Figure 1. To allow fastening of rods to the steel rings, threaded rods with metric thread at their end are used, as shown in Figure 1. The use of steel brackets or plates and friction bolts can be an alternative to steel rings, see for example [3].

As shown in Figure 1, the coupling parts are connected to the column by use of a pair of inclined threaded rods (rods c1-c2 at the top and rods c3-c4 at the bottom). Due to rod inclination and the presence of shear forces, a load situation consisting of both axial and lateral forces occurs in the rods. However, the rods will mainly experience axial forces since their axial stiffness is much greater than the lateral one. The transfer of forces in this configuration resembles the transfer of forces in a truss system where all members are axially loaded. Therefore, the lateral forces in the rods c1, c2, c3 and c4 may be neglected.

The rods in the beam are inserted at a small angle. Rods parallel to the grain are vulnerable to cracks since a single crack along the grain might lead to a considerable loss of strength if the crack occurs in the same plane as the rod. Therefore, the beam is connected to the coupling parts by use of threaded rods (b1 and b2) inserted at a small angle to the grain, i.e. 5°-10°, see Figure 1. Greater angle should be avoided as it would also result in high lateral forces in the threaded rods and therefore smaller stiffness.

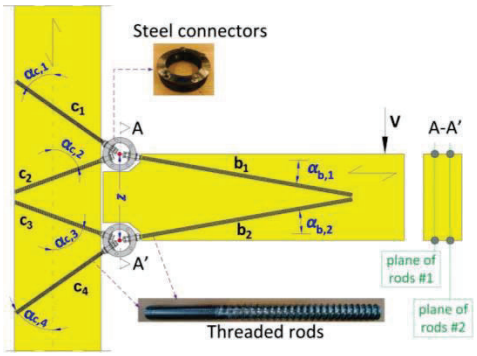

Figure 1: *Moment-resisting connection with inclined rods*

This paper consists of two parts:

- In the first part (Sections 2 and 3), analytical expressions are provided for the estimation of the properties of a connection as shown in Figure 1 and for the rods, based on recent publications;
- In the second part (Section 4) a preliminary study regarding the effects of connection stiffness variability on response of MRTFs is presented.

2 CONNECTION PROPERTIES

2.1 STIFFNESS

The connection in Figure 1 can be considered as a system of rotational springs in series consisting of: a) the connection of rods c_1-c_4 to the column with spring constant $K_{\theta,c}$, b) the connection of rods b_1-b_2 to the beam with spring constant $K_{\theta,b}$ and c) the connectors with spring constant $K_{\theta,con}$. Therefore, the rotational stiffness of the connection can be determined by Eq.(1). The geometry is given in Figure 2. In [4], Eqs.(2)-(3) were derived by use of the component method and validated by experimental results. The compliance S-terms (Eqs.(4)-(7)) are given as functions of the axial stiffness ($K_{ax,i}$) and lateral stiffness ($K_{v,i}$) of the rods and the rod-to-grain angles (Eq.(8)). In Figure 2 and Eqs.(2)-(3), the lever arm is assumed the same on the beam and the column side ($z_b = z_c = z$). However, Eqs.(2)-(3) can also be applied for different lever arms. Eqs.(2)-(3) depend also on the moment to shear ratio ($L_v = M/V$) which is not known - a priori - in the structural analysis and approximations are needed, see also Eqs.(9)-(12). Eqs.(1)-(8) apply per plane of rods.

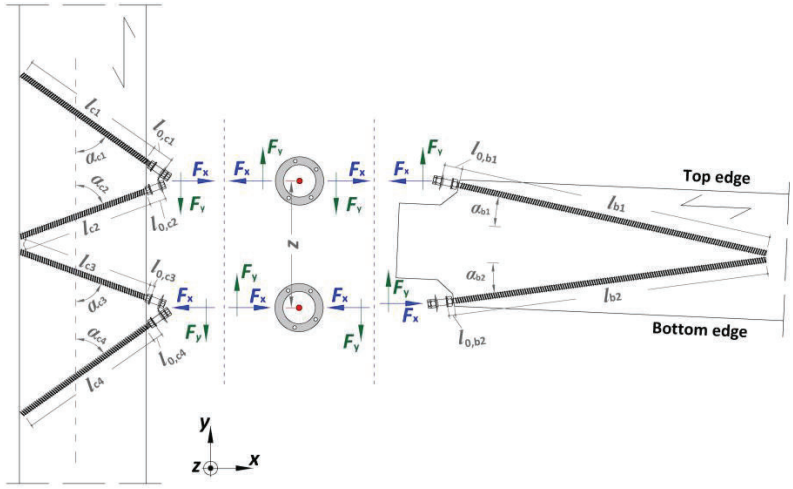

Figure 2: *Forces and geometry of a moment resisting connection with inclined threaded rods*

$$K_\theta = \left(1/K_{\theta,c} + 1/K_{\theta,b} + 1/K_{\theta,con}\right)^{-1} \tag{1}$$

$$K_{\theta,c} = \frac{z^2}{\left(S_{xx,c}{}^{(c1-c2)} + S_{xx,c}{}^{(c3-c4)}\right) + \left(S_{xy,c}{}^{(c3-c4)} - S_{xy,c}{}^{(c1-c2)}\right) \cdot z/(2 \cdot L_v)} \tag{2}$$

$$K_{\theta,b} = \frac{z^2}{\left(S_{xx,b1} + S_{xx,b2}\right) + \left(S_{xy,b2} - S_{xy,b1}\right) \cdot z/(2 \cdot L_v)} \tag{3}$$

$$S_{xx,c}{}^{(c1-c2)} = \frac{{c_{c1}}^2/K_{ax,c2} + {c_{c2}}^2/K_{ax,c1}}{(c_{c1} \cdot s_{c2} + c_{c2} \cdot s_{c1})^2} \; ; \; S_{xx,c}{}^{(c3-c4)} = \frac{{c_{c3}}^2/K_{ax,c4} + {c_{c4}}^2/K_{ax,c3}}{(c_{c3} \cdot s_{c4} + c_{c4} \cdot s_{c3})^2} \tag{4}$$

$$S_{xy,c}{}^{(c1-c2)} = \frac{c_{c1} \cdot s_{c1}/K_{ax,c2} - c_{c2} \cdot s_{c2}/K_{ax,c1}}{(c_{c1} \cdot s_{c2} + c_{c2} \cdot s_{c1})^2} \; ; \; S_{xy,c}{}^{(c3-c4)} = \frac{c_{c3} \cdot s_{c3}/K_{ax,c4} - c_{c4} \cdot s_{c4}/K_{ax,c3}}{(c_{c3} \cdot s_{c4} + c_{c4} \cdot s_{c3})^2} \tag{5}$$

$$S_{xx,b1} = {s_{b1}}^2/K_{v,b1} + {c_{b1}}^2/K_{ax,b1} \; ; \; S_{xx,b2} = {s_{b2}}^2/K_{v,b2} + {c_{b2}}^2/K_{ax,b2} \tag{6}$$

$$S_{xy,b1} = s_{b1} \cdot c_{b1} \cdot \left(1/K_{v,b1} - 1/K_{ax,b1}\right) \; ; \; S_{xy,b2} = s_{b2} \cdot c_{b2} \cdot \left(1/K_{ax,b2} - 1/K_{v,b2}\right) \tag{7}$$

$$c_i = \cos\alpha_i \; ; \; s_i = \sin\alpha_i \; ; \; L_v = M/V \tag{8}$$

Neglecting the shear term in Eqs.(2)-(3) results in the following crude approximations:

$$K_{\theta,c} \approx z^2/\left(S_{xx,c}{}^{(c1-c2)} + S_{xx,c}{}^{(c3-c4)}\right) \tag{9}$$

$$K_{\theta,b} \approx z^2/\left(S_{xx,b1} + S_{xx,b2}\right) \tag{10}$$

Assuming further that the rods are inserted at equal angles in the column ($\alpha_{c,1} = \alpha_{c,2} = \alpha_{c,3} = \alpha_{c,4} = \alpha_c$) and the beam ($\alpha_{b,1} = \alpha_{b,2} = \alpha_b$) and that they approximately have equal stiffness ($K_{ax,c1} = K_{ax,c2} = K_{ax,c3} = K_{ax,c4} = K_{ax,c}, K_{ax,b1} = K_{ax,b2} = K_{ax,b}, \quad K_{v,b1} = K_{v,b2} = K_{v,b}$), Eqs.(9)-(10) can be further simplified as follows:

https://doi.org/10.52202/069179-0165

$$K_{\theta,c} \approx z^2 \cdot K_{ax,c} \cdot {s_c}^2 \tag{11}$$

$$K_{\theta,b} \approx \frac{z^2 \cdot K_{ax,b}/2}{\left(K_{ax,b}/K_{v,b}\right) \cdot {s_b}^2 + {c_b}^2} \tag{12}$$

2.2 FORCES IN THE RODS

The forces in each rod can also be determined by use of the component method [4]. The rods on the column-side are mainly axially loaded and the forces are equal to:

$$\begin{Bmatrix} F_{ax,c1} \\ F_{ax,c2} \end{Bmatrix} = \frac{1}{n} \cdot \begin{Bmatrix} \dfrac{c_{c2} + s_{c2} \cdot z/(2 \cdot L_v)}{c_{c1} \cdot s_{c2} + c_{c2} \cdot s_{c1}} \\ \dfrac{c_{c1} - s_{c1} \cdot z/(2 \cdot L_v)}{c_{c1} \cdot s_{c2} + c_{c2} \cdot s_{c1}} \end{Bmatrix} \cdot \frac{M}{z} \tag{13}$$

$$\begin{Bmatrix} F_{ax,c3} \\ F_{ax,c4} \end{Bmatrix} = -\frac{1}{n} \cdot \begin{Bmatrix} \dfrac{c_{c4} - s_{c4} \cdot z/(2 \cdot L_v)}{c_{c3} \cdot s_{c4} + c_{c4} \cdot s_{c3}} \\ \dfrac{c_{c3} + s_{c3} \cdot z/(2 \cdot L_v)}{c_{c3} \cdot s_{c4} + c_{c4} \cdot s_{c3}} \end{Bmatrix} \cdot \frac{M}{z} \tag{14}$$

On the beam-side, the rods are subjected to combined axial and lateral loading [4]:

$$\begin{Bmatrix} F_{ax,b1} \\ F_{v,b1} \end{Bmatrix} = \frac{1}{n} \cdot \begin{Bmatrix} c_{b1} + s_{b1} \cdot z/(2 \cdot L_v) \\ -s_{b1} + c_{b1} \cdot z/(2 \cdot L_v) \end{Bmatrix} \cdot \frac{M}{z} \tag{15}$$

$$\begin{Bmatrix} F_{ax,b2} \\ F_{v,b2} \end{Bmatrix} = -\frac{1}{n} \cdot \begin{Bmatrix} c_{b2} + s_{b2} \cdot z/(2 \cdot L_v) \\ -s_{b2} + c_{b2} \cdot z/(2 \cdot L_v) \end{Bmatrix} \cdot \frac{M}{z} \tag{16}$$

Eqs.(13)-(16) can be used in the corresponding design checks for the rods, see also Section 3. The parameter n is the number of planes of rods.

2.3 PANEL ZONE

Horizontal forces result in high shear stresses in the panel zone of the column, i.e. the region between rods c1-c2 and c3-c4. Moreover, stresses perpendicular to grain occur around the threaded rods. The combination of tensile stresses perpendicular to grain and shear stresses is unfavourable due to their high degree of interaction [5] and may cause fracture in the panel zone, as shown in Figure 3. Thus, the panel zone must be designed with sufficient strength against combined shear and tension perpendicular to grain. If the rods are long and cross the entire height of the column they act as reinforcements [6], increasing the capacity of the panel zone.

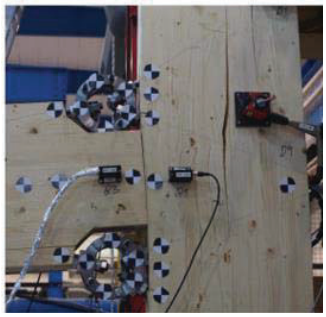

Figure 3: *Fracture in the panel zone due to combined shear and tension perpendicular to grain (Photo: [2])*

3 FASTENER PROPERTIES

The properties of threaded rods are necessary inputs for the properties of the entire connection. The axial stiffness of a threaded rod is given by:

$$K_{ax} = \frac{K_{ser,ax} \cdot K_{ax,l0}}{K_{ser,ax} + K_{ax,l0}} \tag{17}$$

where $K_{ser,ax}$ is the withdrawal stiffness and $K_{ax,l0}$ is the axial stiffness of the non-embedded part of the rod:

$$K_{ax,l0} = A_{net} \cdot E_s / l_0 \tag{18}$$

where $E_s = 210000$ N/mm^2 is the modulus of elasticity of steel, A_{net} is the net cross-sectional area and l_0 is the non-embedded length of the rod. Eq.(19) provides an approximation for $K_{ser,ax}$ (in N/mm) as function of the outer-thread diameter d (in mm), the rod-to-grain angle α, the mean density ρ_m (in kg/m^3) and the embedment length l (in mm). Eq.(19) was derived in [7] by use of non-linear regression on experimental results for threaded rods with diameters 16-20 mm embedded in softwood, see [8-10].

$$K_{ser,ax} \approx \frac{50000 \cdot \left(\frac{d}{20}\right)^2 \cdot \left(\frac{\rho_m}{470}\right)^2 \cdot k_{length,K}}{0.40 \cdot \cos^{2.3}\alpha + \sin^{2.3}\alpha} \tag{19}$$

$$k_{length,K} = \min\left[(l/300)^{3/4}, 1\right] \tag{20}$$

The stiffness of a laterally loaded threaded rod can be determined by Eq.(21). Eq.(21) is derived by modelling the rod as a beam on elastic foundation assuming that rotation is restrained at the loading point, see in detail [7]:

$$K_v = \frac{3 \cdot k_v \cdot l_{ch}}{{\lambda_0}^3 + 3 \cdot {\lambda_0}^2 + 3 \cdot \lambda_0 + 3} \tag{21}$$

$$\lambda_0 = l_0 / l_{ch} \;;\; l_{ch} = \sqrt[4]{4 \cdot E_s \cdot I_s / k_v} \tag{22}$$

The parameter $I_s \approx \pi \cdot {d_1}^4/64$ is the 2nd moment of area and d_1 is the core diameter of the rod. The parameter k_v is the foundation modulus (i.e. stiffness per unit length) of a laterally loaded rod. According to Eqs.(3),(6),(7) and (12) , the lateral stiffness of a rod is an input parameter for the rotational stiffness on the beam-side. There the rods are inserted at small angles to grain and therefore the lateral foundation modulus may be approximately taken as the foundation modulus perpendicular to the grain. Based on an experimental study of laterally loaded rods with $d = 22$ mm embedded in glulam made of pine and spruce [11] an approximate value of $k_v \approx 300$ N/mm^2 may be used.

A power criterion is often used - as an approximation - to determine the capacity of fasteners subjected to combined axial force (F_{ax}) and lateral force (F_v), i.e.:

$$\left(\frac{F_{ax}}{F_{ax,R}}\right)^q + \left(\frac{F_v}{F_{v,R}}\right)^q \leq 1 \tag{23}$$

In Eq.(23), $F_{ax,R}$ and $F_{v,R}$ are the axial and lateral capacity of a fastener respectively. According to EN 1995-1-1 [12], a quadratic failure criterion applies for screws, i.e. $q = 2$. The quadratic criterion has provided safe-sided predictions for long screws (i.e. with steel failure being

https://doi.org/10.52202/069179-0165

more critical than withdrawal) inserted perpendicular to grain [13] and for glued-in rods parallel to grain [14].
The rods on the beam side are subjected to both lateral and axial forces and therefore their capacity should be checked by use of a criterion that considers the interaction of forces, as the one given by Eq.(23). On the other hand, the rods in the column are mainly axially loaded (i.e. $F_{v,ci} \approx 0$) as explained in Section 1 and therefore in this case Eq.(23) reduces to: $|F_{ax,ci}| \leq F_{ax,R}$.

4 STIFFNESS VARIABILITY EFFECTS

MRTFs are statically indeterminate systems, and the distribution of the internal actions depends on the stiffness of their elements and connections. The internal forces and moments are typically determined by use of mean stiffness values in the structural analysis. However, the inherent variability of the connection stiffness can result in variations of internal forces and moments, compared to the expected values obtained by use of mean stiffness values. In this section, the effects of connection stiffness variability are explored by use of a simple beam model with semi-rigid end restrains (Section 4.1) and by linear-elastic Finite Element simulations of MRTFs with semi-rigid moment connections (Section 4.2).

4.1 BEAM MODEL

A beam with semi-rigid end restrains (Figure 4) subjected to uniformly distributed load q is used here -as a simple example- to study the effects of the connections' stiffness variability. The connections are represented by linear-elastic rotational springs with spring constants $K_{\theta,1}$ and $K_{\theta,2}$ which can be expressed in dimensionless form-by dividing by the beam stiffness-as follows:

$$k_1 = \frac{K_{\theta,1}}{(EI/L)} \; ; \; k_2 = \frac{K_{\theta,2}}{(EI/L)} \tag{24}$$

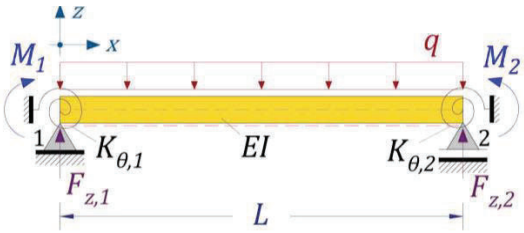

Figure 4: *Simply supported beam with semi-rigid end restrains*

The moments and the vertical forces at the beam ends can be expressed as functions of k_1 and k_2 as follows:

$$M_1 = -\frac{q \cdot L^2}{12} \cdot \frac{k_1 \cdot (k_2 + 6)}{k_1 \cdot k_2 + 4 \cdot (k_1 + k_2) + 12} \tag{25}$$

$$F_{z,1} = \frac{q \cdot L}{2} \cdot \frac{k_1 \cdot k_2 + 5 \cdot k_1 + 3 \cdot k_2 + 12}{k_1 \cdot k_2 + 4 \cdot (k_1 + k_2) + 12} \tag{26}$$

$$M_2 = -\frac{q \cdot L^2}{12} \cdot \frac{k_2 \cdot (k_1 + 6)}{k_1 \cdot k_2 + 4 \cdot (k_1 + k_2) + 12} \tag{27}$$

$$F_{z,2} = \frac{q \cdot L}{2} \cdot \frac{k_1 \cdot k_2 + 3 \cdot k_1 + 5 \cdot k_2 + 12}{k_1 \cdot k_2 + 4 \cdot (k_1 + k_2) + 12} \tag{28}$$

The maximum span moment can be simply written as function of the forces and moments:

$$M_{span} = M_1 + \frac{{F_{z,1}}^2}{2 \cdot q} = M_2 + \frac{{F_{z,2}}^2}{2 \cdot q} \tag{29}$$

By letting $k_1 = k_2 = k_{mean}$, the moments and the reactions at the supports become equal ($M_1 = M_2 = M_{end}$ and $F_{z,1} = F_{z,2} = F_z$):

$$M_{end}(k_1 = k_2 = k_{mean}) = -\frac{q \cdot L^2}{12} \cdot \frac{k_{mean}}{k_{mean} + 2} \tag{30}$$

$$F_z(k_1 = k_2 = k_{mean}) = \frac{q \cdot L}{2} \tag{31}$$

$$M_{span}(k_1 = k_2 = k_{mean}) = \frac{q \cdot L^2}{24} \cdot \frac{k_{mean} + 6}{k_{mean} + 2} \tag{32}$$

For each realization of the connections' stiffness, the ratios between the actual action divided by the corresponding values by use of mean stiffness values were calculated, as specified by Eqs.(33)-(37). These ratios express the deviation between a realization (numerator) and the corresponding value obtained by static analysis by use of mean stiffness (denominator) and they depend only on the normalized stiffness values given by Eq.(24).

$$n_{M,end,1} = \frac{|M_1(k_1, k_2)|}{|M_{end}(k_1 = k_2 = k_{mean})|} \tag{33}$$

$$n_{M,end,2} = \frac{|M_2(k_1, k_2)|}{|M_{end}(k_1 = k_2 = k_{mean})|} \tag{34}$$

$$n_{M,span} = \frac{M_{span}(k_1, k_2)}{M_{span}(k_1 = k_2 = k_{mean})} \tag{35}$$

$$n_{V,end,1} = \frac{F_{z,1}(k_1, k_2)}{F_z(k_1 = k_2 = k_{mean})} \tag{36}$$

$$n_{V,end,2} = \frac{F_{z,2}(k_1, k_2)}{F_z(k_1 = k_2 = k_{mean})} \tag{37}$$

In other words, the ratios by Eqs.(33)-(37) multiplied by the internal forces and moments by use of mean stiffness provide the actual internal forces and moments. Therefore, to get an indication of the unfavourable effect of stiffness variability on the internal forces and moments, it makes sense to consider an upper percentile value of these ratios, e.g. the 95th or 98th percentile. Thus, the variability of the ratios by Eqs.(33)-(37) is important.
To study the effects of stiffness variability, realizations of normalized stiffness values k_1 and k_2 were generated. Note that the variability of parameters k_1 and k_2 results from the variability of the properties of the connection (K_θ) and the material (E). Here, for simplicity k_1 and k_2 were assumed as the random variables instead of K_θ and E separately. Due to the lack of data with respect to the distribution of the connection stiffness K_θ, two different distributions were assumed: namely normal and

https://doi.org/10.52202/069179-0165

lognormal distribution. Figure 6 shows an example of the distribution of the ratio $n_{M,end}$ (Eq.(33) or Eq.(34)) assuming that k_1 and k_2 are either normally or lognormally distributed. The distribution of the output variable $n_{M,end}$ is fairly similar for both assumptions. This observation holds true for relatively small values of k_{mean} and $CoV(k)$ and for the other output variables ($n_{M,span}$ or $n_{V,end}$) with some small deviations.

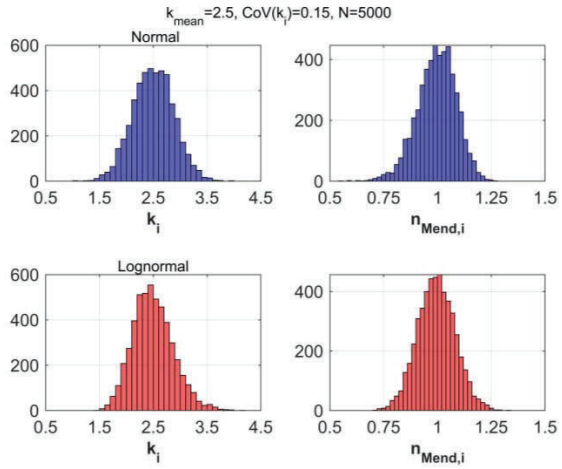

Figure 5: *Distribution of $n_{M,end}$ (right) for normal (up-left) and lognormal (bottom-left) distribution of k_1 and k_2 (example here for $k_{mean} = 2.5$ and $CoV(k) = 0.15$)*

Given that the distribution of the output variables (Eqs.(33)-(37)) is fairly similar for either normal or lognormal distribution of the input variables $k_1$and k_2, only results assuming normal distribution of $k_1$and k_2 are presented further. The mean value is denoted k_{mean} and the coefficient of variation is denoted $\mathrm{CoV}(k)$, thus:

$$k_1 = N\big(k_{mean}, \mathrm{CoV}(k)\big) \tag{38}$$

$$k_2 = N\big(k_{mean}, \mathrm{CoV}(k)\big) \tag{39}$$

Figure 6 shows the ratio $n_{M,end}$ according to Eq.(33) or Eq.(34) for varying values of k_{mean} based on 5000 realizations per k_{mean}-value. Figure 7 shows the corresponding results for $n_{M,span}$ (Eq.(35)) and Figure 8 for $n_{V,end}$ (Eq.(36) or Eq.(37)). All Figures are plotted for $\mathrm{CoV}(k) = 0.15$. Such coefficient of variation has been observed for the rotational stiffness of connections with glulam beams and columns and inclined threaded rods as shown in Figure 1 [15]; however the sample size was small and this number is only used as indicative.
The 95th and the 98th percentiles are also provided in the Figures together with the theoretical estimations that correspond to normal distribution: $X_{95\%} = X_{mean} \cdot (1 + 1.645 \cdot \mathrm{CoV}[X])$ and $X_{98\%} = X_{mean} \cdot (1 + 2.054 \cdot \mathrm{CoV}[X])$. As shown in the Figures, these estimations are in good agreement with the percentiles of each sample.

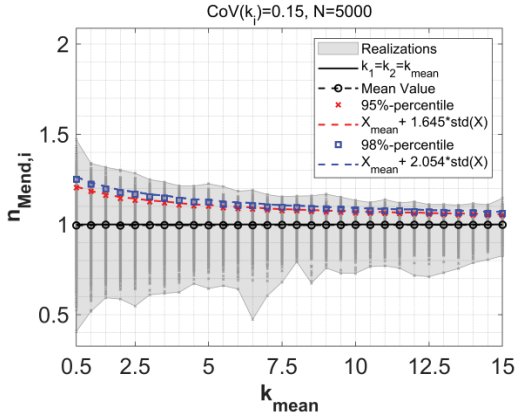

Figure 6: *Ratio $n_{M,end}$ for varying k_{mean} and $CoV(k_i) = 0.15$ (5000 realizations per k_{mean} value, assuming that k_1 and k_2 are normally distributed)*

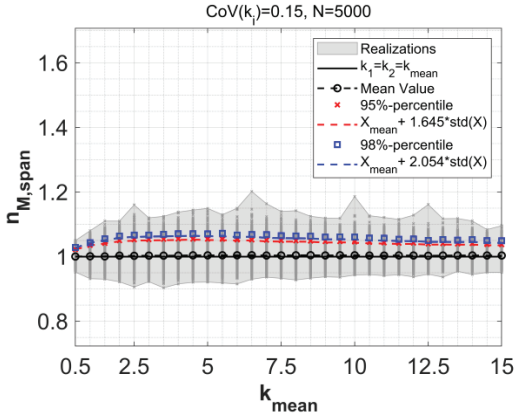

Figure 7: *Ratio $n_{M,span}$ for varying k_{mean} and $CoV(k_i) = 0.15$ (5000 realizations per k_{mean} value, assuming that k_1 and k_2 are normally distributed)*

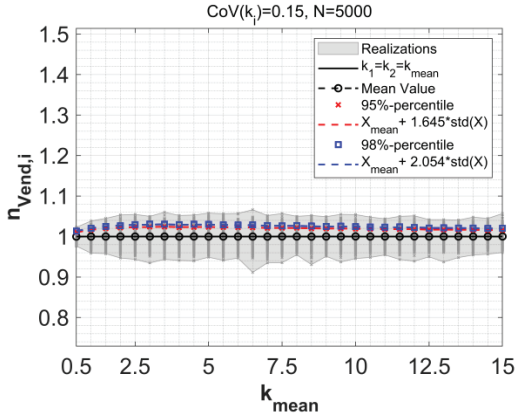

Figure 8: *Ratio $n_{V,end}$ for varying k_{mean} and $CoV(k_i) = 0.15$ (5000 realizations per k_{mean} value, assuming that k_1 and k_2 are normally distributed*

As shown in Figure 6, the end moments are significantly influenced by stiffness variability, especially for low k_{mean}-values. Low mean connection stiffness values result in greater variability of the end moments. Timber moment-resisting connections are typically semi-rigid with k_{mean}-values up to maximum 5-6 and thus such

variability of the end moments is to be expected. For increasing k_{mean}-values (i.e. quasi-rigid connections) the variability and the 95th/98th percentiles of the end moments reduce significantly. On the other hand, the variabilities and the 95th/98th percentiles of the span moment (Figure 7) and the shear forces (Figure 8) are fairly small and not sensitive to k_{mean}-values.

Tables 1-3 provide the coefficient of variation and the 95th/98th percentiles of the ratios $n_{M,end}$ (Eq.(33) or Eq.(34)), $n_{M,span}$ (Eq.(35)) and $n_{V,end}$ (Eq.(36) or Eq.(37)) for varying values of k_{mean} and $\mathrm{CoV}(k)$ based on 5000 realizations.

The 95th/98th percentiles of $n_{V,end}$ can be approximated by the following expressions:

$$n_{V,end,95\%} \approx 1 + (0.15 - e^{-5 \cdot k_{mean}}) \cdot \mathrm{CoV}(k) \quad (44)$$

$$n_{V,end,98\%} \approx 1 + (0.20 - e^{-5 \cdot k_{mean}}) \cdot \mathrm{CoV}(k) \quad (45)$$

The relative difference of the 95th/98th percentiles assuming lognormal distribution of the stiffness parameter k is within 6% or less compared to the values in Tables 1-3. This is also indicated by the distribution shape of the output variables, shown in Figure 5.

As shown in the values of Tables 1-3, the ratio $n_{M,end,i}$ (Table 1) is more affected by the variability of the stiffness parameter k. In other words, the end-moments are more sensitive to the stiffness variability compared to the span moment and the shear forces. As expected, the coefficient of variation of the stiffness parameter k results in higher variability of the output variables.

To facilitate comparison, we can consider a connection with $k_{mean} = 1.5$. For $\mathrm{CoV}(k) = 15\%$, the 98th percentile of the end moment, the span moment and the shear force are approx. 20%, 5% and 3% higher than the reference values respectively. The corresponding 98th percentile values for $\mathrm{CoV}(k) = 30\%$ are approx. 37%, 13% and 5%. Especially for the end moments, the 98th percentiles may reach values of the order of 20-40% higher than the reference value for reasonable input ($\mathrm{CoV}(k) \geq 15\%$ and $k_{mean} = 1 - 5$). Such effect should be considered in the design.

4.2 FINITE ELEMENT ANALYSIS OF MOMENT-RESISTING TIMBER FRAMES

The effects of connection stiffness variability are further studied in this Section by use of Finite Element (abbr. FE) analyses of planar MRTFs. The software SAP2000 was used for the structural analysis. An algorithm was developed to perform several analyses with varying properties.

The structural model for the analysis is presented in Figure 9. The frames consisted of glulam columns and beams with cross-sectional dimensions $b_c \times h_c$ and $b_b \times h_b$ respectively. The columns were continuous. The mean modulus of elasticity was $E_{0,\mathrm{mean}} = 13000$ N/mm^2 and the mean shear modulus was $G_{\mathrm{mean}} = 650$ N/mm^2. These values correspond to strength class GL30c [16]. The beams and the columns were modelled as linear elements and the material was modelled as linear-elastic. Shear deformations of timber were taken into account in the model. All frames consisted of 3 bays with 8.0m bay length between the center-lines of the columns. Frames with 4 and 8 storeys were studied. The height of each storey was h =3.0 m.

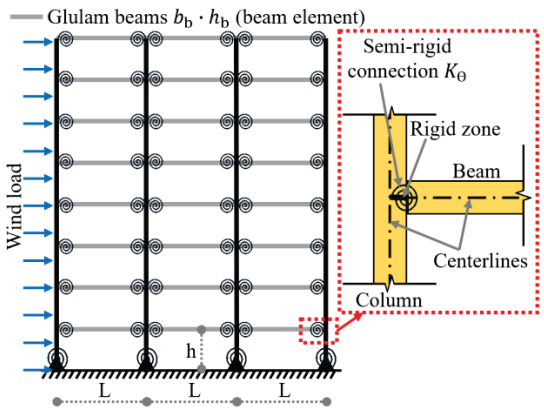

Figure 9: *Structural model for FE analyses*

https://doi.org/10.52202/069179-0165

The connections were modelled as linear-elastic rotational springs with spring constant K_θ (by use of the partial release command of SAP2000). With respect to the translational degrees of freedom, the connections were modelled as rigid. Since the columns were continuous, the connections were placed at the edge of the columns with a rigid offset of $h_c/2$ to the columns' centerline, see the detail in Figure 9. The supports of the frame were assumed rigid with respect to translations while the for the rotational degree of freedom a small rotational stiffness of 5000 kNm/rad was assumed.

Three actions were considered in the analysis: dead load ($G = 2.0$ kN/m^2), live load ($Q = 3.0$ kN/m^2) and the wind action W. The wind load was calculated according to EN 1991-1-4 [17] for a basic wind velocity $v_b = 26$ m/s and terrain category IV (urban environment). For the determination of loads on the frame and wind-induced accelerations it was assumed that the building consists of six frames equally spaced at a distance of 4.0 meters, resulting in a total width of 20 m.

To consider the connection stiffness variability, the stiffness of each beam-to-column connection was selected as a normally distributed random variable (see Eqs.(38)-(39)). Similar to the definition given by Eq.(24), the stiffness can be expressed in dimensionless form by dividing the rotational stiffness by the bending stiffness of the beams, i.e.: $k = K_\theta/(EI_b/L_b)$. Here, L_b is the net bay length. For each frame, analyses with mean dimensionless connection stiffness of $k_{mean} = 1.5$ and $k_{mean} = 2.5$ were performed. These values represent feasible connection stiffness for moment resisting connections with threaded rods (see Section 2). Moreover, they are sufficient, so that the frames fulfil the serviceability requirements with respect to wind-induced deformations and accelerations; see e.g. Figure 10 for accelerations. For each k_{mean}-value, two values of the coefficient of variation were considered: $\mathrm{CoV}(K_\theta) = 15\%$ and 25%.

As a crude simplification, the modulus of elasticity and the shear modulus of glulam were assumed constant and equal to their mean value, i.e. their variability was not taken into account in this analysis. All other parameters (e.g. loads, mass etc.) were also kept constant. Therefore, the results of these analyses should only be considered as indicative; however, they allow for comparison with the results provided in Section 4.1. In total, 8 frames were studied (2 number of storeys × 2 k_{mean}-values × 2 $\mathrm{CoV}(K_\theta)$ values). For each frame type, 3000 realizations were generated and solved by use of FE analysis (in total 24000 analyses were performed).

The following response quantities were quantified by FE analysis, for each frame:

- The internal actions were determined by use of linear-elastic analysis. The envelopes of the internal forces and moments were then determined for the fundamental Ultimate Limit State combinations according to EN1990 [18], with wind load (in both directions) being the leading variable action. The load safety factors were $\gamma_G = 1.2$ for the permanent load, $\gamma_Q = 1.5$ for the live load and $\gamma_W = 1.5$ for the wind load. The ratios between the envelope internal forces and moments for each realization divided by the corresponding values obtained by use of analysis with mean stiffness values were determined for each frame, as specified by Eqs.(33)-(37).
- The horizontal deflections were determined for the characteristic Serviceability Limit State combination according to EN1990 [18], with wind as the leading variable load. The maximum horizontal deflection is denoted Δ and the maximum inter-storey drift is denoted IDR_{max}.
- The fundamental eigenfrequency (f) was quantified by modal analysis. The quasi–permanent load ($G + 0.3 \cdot Q$), according to EN1990 [18] was used to determine the mass.
- The wind-induced accelerations (A) on the top-floor were determined by use of the approximate method given by EN1991-1-4 [17] (Annex B), A damping ratio of $\xi = 2.0$ % was assumed based on measurements of timber buildings [19]. The accelerations were compared to the requirements by ISO10137 [20]. To consider the smaller return period, the basic wind velocity was multiplied by $c_{prob} = 0.73$.

The results of the FE analyses are summarized in Table 4 (4 storey frames) and Table 5 (8 storey frames). The ratios $n_{M,end}, n_{M,span}, n_{V,end}$ (Eqs.(33)-(37)) were determined separately for each connection of the frame and the range is given in the Tables. As indicated by the small ranges the ratios for different connections are quite similar. The FE results can be summarized as follows:

- The end moments are -by far- the action that it is most sensitive to connection stiffness as indicated by the higher $n_{M,end}$-values. On the other hand, the span moments and the shear forces are not very sensitive to connection stiffness as indicated by the low values of $n_{M,span}$ and $n_{V,end}$.
- The ratios $n_{M,end}, n_{M,span}, n_{V,end}$ are quite similar for 4-storey and 8-storey frames. Moreover, they are in very good agreement with the results obtained by the simple beam model in Section 4.1 (Tables 1-3). In fact, the beam model results in slightly higher values of $n_{M,end}$. Therefore, the beam model can be used to provide safe-sided predictions.
- The effect of stiffness variability on deformations, eigenfrequency and top-floor accelerations is quite small as indicated by FE results. Figure 10 shows a plot of the fundamental eigenfrequencies and top floor accelerations for all realizations of MRTFs, compared to ISO10137 **[20]** requirements. As shown by the results, the response of all realizations is quite similar for each frame. Therefore, the effects of the variability of connection stiffness can be neglected in the serviceability limit state.

The aim of the present -preliminary- study was to highlight the effects of connections' stiffness variability. A more detailed reliability analysis considering the variability of the loads and the material stiffness can be used to better quantify the values of ratios $n_{M,end}, n_{M,span}$

https://doi.org/10.52202/069179-0165

and $n_{V,end}$. Moreover, the presented results come solely from linear-elastic analysis; i.e. possible redistribution of moments if the connections are ductile was not considered.

5 CONCLUSIONS AND FUTURE WORK

This paper provides an overview of analysis and design aspects of moment-resisting connections with inclined threaded rods. In the first part of the paper, a series of expressions that estimate the properties of such connections were provided based on recent publications. In the second part of the paper, a preliminary study on the effect of connections' stiffness variability on the structural response of timber frames was presented, based on a simple beam model and Finite Element simulations of planar frames. In common practice, structural analysis of timber structures is performed by use of mean stiffness values. However, in moment-resisting frames the magnitude and distribution of internal forces and moment is highly dependent on the stiffness of their connections. The results of this study have shown that the variability of connections' stiffness can result in great variability of the internal forces and moments. The end moments are more sensitive to this effect with 98th percentiles of the order of 20%-40% higher than the reference values obtained by analysis with mean stiffness values. Such increase should be considered in the design for the Ultimate Limit State. The Finite element results were in good agreement with the predictions obtained by use of a simple beam model

https://doi.org/10.52202/069179-0165

with rotational springs. When it comes to serviceability requirements, the FE models showed that the variability of connections' stiffness has small influence and may be neglected.

APPLICATION OF A TUBE CONNECTOR FOR CATENARY ACTION IN CLT FLOORS

Johannes A. J. Huber[1], Yunbo Huang[2], Sivert Knutsen[3], Alicja Przystup[4], Thomas Tannert[5], Sven Berg[6]

ABSTRACT: Multi-storey buildings require provisions to avoid disproportionate consequences after unexpected events, e.g. explosions or human error during design and construction. To prevent failure progression in the structure after an initial damage (loss of load-carrying elements), alternative load paths, like catenary action, should be provided. Catenary action supports the sagging structure after element loss by transferring the loads horizontally to the adjacent elements; this mechanism requires the connections to remain ductile under high load. Conventional dowel-type connectors in timber structures have limited potential to develop catenary action in beams or floors. A previously developed tube connector exhibited desirable behaviour to develop catenary action in cross-laminated timber floors; however, the tube exhibited and undesirable failure mode. In the present study, the behaviour of a newly designed variant of the tube connector was experimentally investigated under catenary action. The new connector design was tested in varying configurations, at both the component level and full-scale floor level, in Canada and Sweden. The results show that a more desirable behaviour of the adapted connector could be achieved compared to the previous design, with respect to catenary action.

1 INTRODUCTION

1.1 BACKGROUND

Multi-storey timber buildings can provide living space for many occupants. The more occupants, the more severe are the possible consequences if unforeseen events lead to a damage and a subsequent collapse. Disproportionately large collapses, in relation to their original cause, e.g. an explosion, a vehicle accident or human errors during design and/or construction, must be avoided. Often, a disproportionate collapse occurs because the progression of an initial component failure cannot be halted, which is then usually referred to as a progressive collapse. Some building codes, e.g. Eurocode 1 [1], require that a progressive collapse shall be avoided for buildings taller than four storeys or with a certain number of occupants.

A building can be designed to resist a progressive collapse by providing alternative load paths (ALPs) after certain components have failed. [2]. Examples of ALPs in floors after the loss of a support include compressive arching action for small deflections, and catenary action or membrane action for large deflections [3]. In catenary action, the beams or floors support the sagging structure by acting like a chain and transferring the loads mainly by in-plane tension to the surrounding undamaged structure.

1.2 FLOOR CONNECTORS AND CATENARY ACTION

In timber structures, catenary action can be developed in beams in post-and beam systems, or in cross-laminated timber (CLT) floor panels. Currently available dowel-type connectors do not allow for large deformations of beam or floors, e.g. tests of timber post-and-beam systems found that conventional connectors failed prematurely and could not develop catenary action; however, a double slotted-in steel plate connector, with elongated holes to allow joint rotation, was able to develop catenary action [4]. Support-removal tests in [5] on lap-jointed solid timber floors and walls in platform-type construction, including CLT floors, found that conventional screw connections were not able to develop catenary action.

In contrast, tube connectors [6] were able to support substantial catenary forces under large displacements in CLT floors [5]. In a numerical optimisation of the original design [7], the most influential parameters were found to be the tube diameter, the tube thickness, and the coupler diameter. The original tube design used a welded coupling nut on the inside of the tube; this was a weak spot where brittle rupture occurred, as shown in Figure 1.

***Figure 1**: Original tube connector with welded coupler*

In a numerical study [8], 3D finite element (FE) models were developed, and parameter variations were conducted reflecting a building situation to study both traditional screw connections and the tube connector in a support-removal scenario. The study found that catenary action was the dominant ALP and confirmed the suitability of the tube connector for catenary action.

1.3 OBJECTIVE

Given the simplicity of the tube connector regarding manufacturing and installation, and its suitability to develop catenary action under large floor rotations, it was deemed worthwhile to investigate further adaptations to improve its performance. The goal of the present study was to investigate the behaviour of a newly designed variant of the tube connector with a hammerhead under catenary action in CLT floors.

2 MATERIAL & METHODS

Tests were conducted at the Wood Innovation Research Lab in Prince George, Canada, and the lab of the Research Institutes of Sweden (RISE) in Skellefteå, Sweden.

2.1 MATERIALS

In Canada, 100 mm thick 5-ply CLT panels with 20 mm thick layers made of Norway Spruce (*Picea abies*) of strength class C24 [9] were used. The boards were edgewise bonded. All cutting and milling was done in the test lab. In Sweden, 200 mm deep 5-ply CLT panels with 40 mm thick layers of Norway Spruce of strength class C24 [9] were used. The edges of the boards were not glued. The panel geometry including the cut-outs for the tube was cut and milled at the manufacturing site.

The outer diameter of the tubes was 3'' (76,2 mm). The steel for the Canadian tubes was A/SA 106 Grade B (minimum yield strength 240 MPa) and for the Swedish tubes was S355 (minimum yield strength 355 MPa). In Canada, the length of the tube was 100 mm and the thickness was 3 mm, and in Sweden, the length was 140 mm and thicknesses of 4 mm and 5 mm. Two holes on opposing sides were cut at mid-length of the tube for passing through the rod. In Canada, two circular holes were cut, but in Sweden one of the holes was cut as an elongated slot to not restrict the rod movement in certain test variations.

Instead of the welded coupler used in [5], a conically shaped steel part with a cylindrical base was used, herein referred to as the *hammerhead*, and it was held in place by a standard nut. The hammerhead pushed onto the outside of the tube instead of pulling on the inside. In Canada, a hammerhead with an outer diameter (D_1) of was 1,5'' (38,1 mm) and a height (h) of 0,5'' (12,7 mm) was used, with the conical base facing away from the tube, see Figure 2b. The hammerhead was mild steel grade ASTM A36, while for the threaded 5/8" (19,9 mm) rod, grade ASTM A193 Grade B7 was used (minimum yield strength 720 MPa). In Sweden, a hammerhead with $D_1 = 50$ mm and $h = 20$ mm was used and it was positioned with the cylindrical base towards the tube, see Figure 2a. A standard M20 threaded rod with strength class 8.8 (minimum yield strength 640 MPa) was used together with a class 12.9 nut.

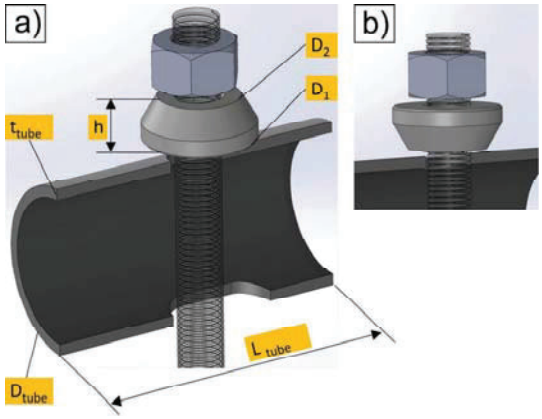

***Figure 2:** Tube connector with hammerhead; a) Swedish and b) Canadian version*

2.2 TUBE PRE-TESTS

Tensile tests on the tube connector, embedded in CLT, were performed by applying a displacement-controlled, quasi-static load along the axis of the rod. The insights gathered during the pre-tests were used for final adjustments of the connector designs to be used on tests in full floor elements.

For the Canadian tests, the CLT samples were 350 mm wide and 800 mm long, see Figure 3. The cut-out to embed the tubes was machined through the full depth of the panel and the part for embedding the rod was machined to a depth of 60 mm (3 layers). A symmetric loading setup with two tubes being tested simultaneously was chosen. The relative displacement between CLT panel and tube edge was measured by two linear variable differential transformers (LVDT) positioned on a thin metal plate locked by nuts to the end of the rod. The load was applied displacement-controlled at 10 mm/min.

https://doi.org/10.52202/069179-0166

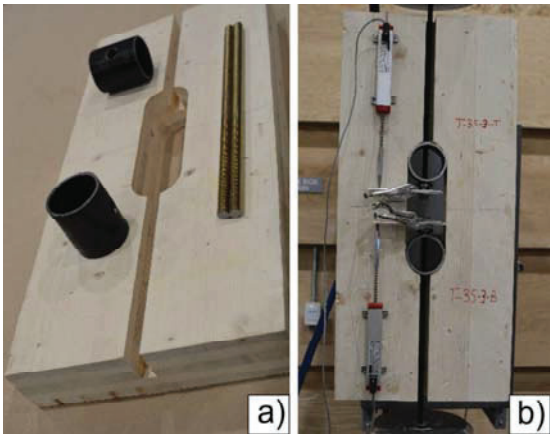

***Figure 3**: Canadian pre-tests of the tube connector*

For the Swedish pre-tests, the CLT samples were 400 mm wide and 600 mm long, see Figure 4. The circular part to embed the tube was machined to a depth of 170 mm and the part to embed the rod was machined to 130 mm depth, see Figure 4a. Only a single tube was used in each test repetition, while the rod was fixed at approximately half its length to a rigid steel frame. The other side of the CLT sample was fixed by nine fully-threaded self-tapping screws (STS) with diameter 13 mm and length 200 mm [10] to customised steel parts which provided a rotation-free connection to the pulling hydraulic cylinder, see Figure 4b. The STSs were inserted using a 45-degree angled washer of type VGU [10]. The displacement in the hydraulic cylinder was increased by 6 mm/min and the resulting load was recorded. The total displacement was measured at the edge of the panel facing the fixed point of the rod using a LVDT. Additionally, the relative displacement between the CLT panel and the customised steel parts was measured to control for slippage.

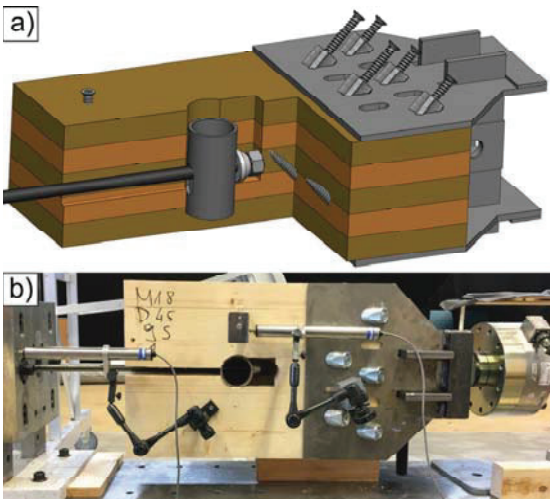

***Figure 4:** Swedish tube pre-test; a) tube placement and b) test setup*

2.3 FLOOR ELEMENT TESTS

To evaluate the performance of the tube connector under catenary action in the lengthwise direction of the floor panels, pushdown tests were conducted with full-length CLT panels over a removed wall support, as shown in Figure 5 for the Canadian tests.

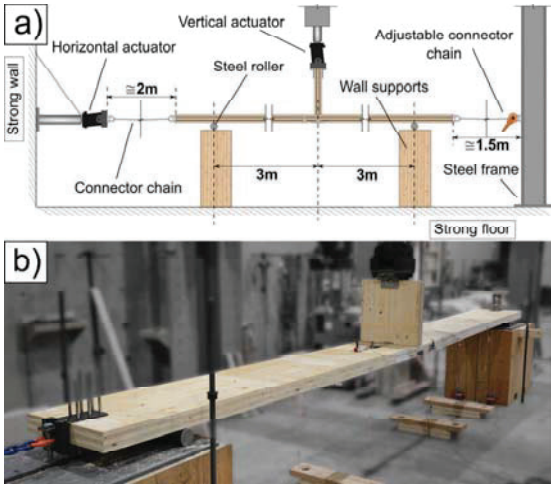

***Figure 5:** Canadian floor element tests; a) idealised and b) lab setup*

For the Canadian tests, a single span of 3 m was assumed, i.e. the nominal length between the supports in the tests was 6 m. The CLT panels were 600 mm wide and butt-jointed lengthwise (Figure 6). The tube connector was inserted in pre-milled cut-outs in the panels. The screws used for the butt connection were 140 mm SWG fully threaded STS [11] installed at 45° angle. To prevent the rod of the tube connector from rising above the surface of the CLT panels, the loading was applied via a CLT wall section on the centre of the joint. A steel stopper was manufactured to fit underneath the load application wall to prevent the rising rod from compromising the wall-to-floor contact. Since the pushdown actuator had a maximum stroke of 500 mm, the test was conducted in two stages to fully deform the tubes; firstly, a 600 mm tall wall section was used up to approximately 300 mm extension of the actuator, and after unloading and exchanging the wall with an 800 mm section, the loading was continued. The vertical supports were long steel rollers, and the horizontal displacement was fixed by running chains from strong wall to the sample on both sides. These were fixed onto steel C-clamps with 6 steel ¾" (19,1 mm) bolts. One of the chains ran to a horizontal actuator which allowed for pre-tensioning of the chains to take out slack while acting as a load cell. Thanks to this setup, compressive arching was omitted as only tensile forces could be transferred through the chain and the friction of the rollers was negligible.

https://doi.org/10.52202/069179-0166

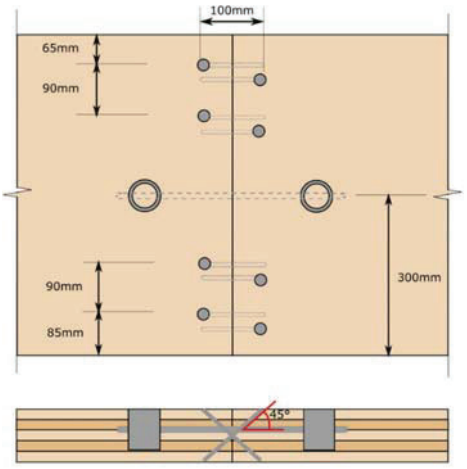

***Figure 6**: Butt joint and tube connector alignment in Canadian floor tests*

For the Swedish tests, the test setup was adapted for an inverted load application, see Figure 7, to allow the use of the full hydraulic cylinder stroke. The panels were flipped, and the tubes were thus inserted from below to connect the panels. The custom steel plate connectors from the pre-tests were slightly adapted and used for rigidly fixing the panels horizontally. Rotation was free at the ends which was achieved by a pinned connection between the end connection and the rigid frame. Effectively, the span was 200 mm larger due to the connector. An additional hydraulic cylinder with a load cell was attached to one of the end connections to measure the horizontal tie force and to apply a 0.5 kN pre-load on the tube connector to prevent it from slipping out of the cut-out.

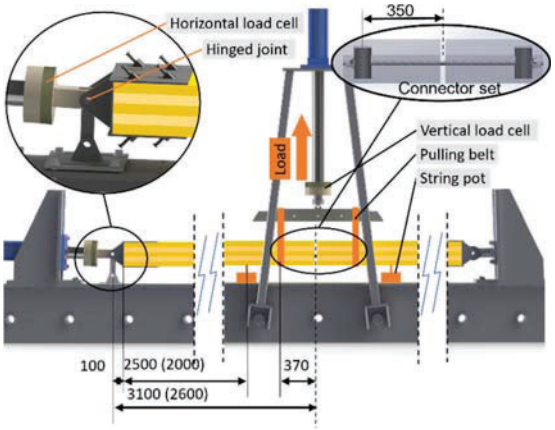

***Figure 7:** Swedish test setup for the floor element tests (mm)*

The panels used were machined symmetrically such that a cut-out for the tube was provided in both ends. After initial tests with a length of 3 m, 500 mm were cut off from the end used in the experiment and the remaining panel was reused at a length of 2.5 m, i.e. a length of 5 m between the supports. For the 2.5 m panels, the tube was inserted as indicated in Figure 4a, i.e. with the slot hole restricting the motion of the rod during rotation, and for the 3 m panels, the tube was inserted in a flipped orientation to allow rod movement during pushdown. For reference, floor elements without a tube connector, but with four angled double-threaded 8.2 mm × 280 mm STS [10] were tested.

The floor system was pushed down (i.e. pulled up) by applying a displacement-controlled quasi-static load via a spreader beam and straps, see Figure 7. The vertical pushdown force and the horizontal tie force were recorded. The pushdown displacement was recorded using string potentiometers. Since the horizontal fixture of the floor was unable to provide noticeable compliance, compressive arching action as in [8] was expected to occur between the panels. Since this resistance mechanism was not of interest for this study, and to single out the effects of catenary action, an initial 20 mm gap was provided between the panels. For the tests with STSs only, no initial gap was provided since a gap was expected to disproportionately affect the performance of the screw connection negatively.

3 RESULTS & DISCUSSION

3.1 PRE-TESTS

A typical development of the tube deformation during the Canadian pre-tests is shown in Figure 8 and the corresponding force-displacement curves in Figure 9. After an initial elastic phase (Figure 8a), tube yielding (8b) and hardening occurred until the ultimate load was reached (8c) and subsequent yielding led to softening (8d). The tubes predominantly engaged in a folding mechanism along a line along the tube length during yielding.

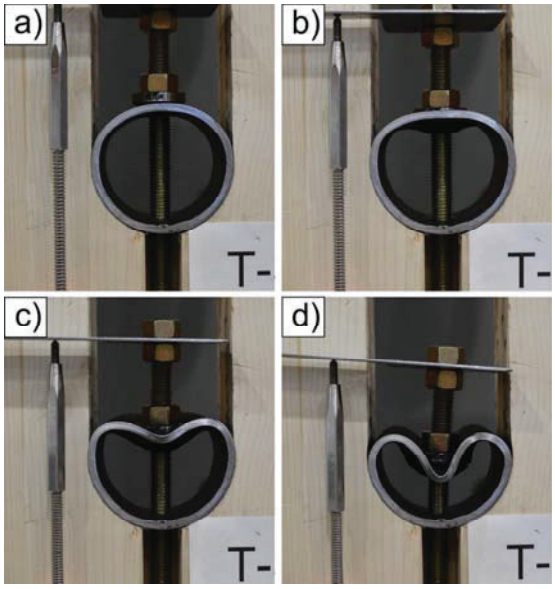

***Figure 8**: Pre-test of the Canadian tubes showing the tube deformation from unloaded to loaded state (a-d)*

https://doi.org/10.52202/069179-0166

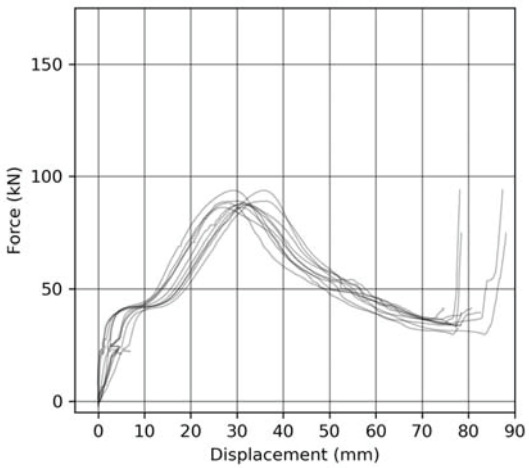

***Figure 9**: Force-displacement curves of 10 Canadian pre-tests.*

The Swedish pre-tests showed that the folding mechanism of the tubes during yielding was dominated by the more point-wise circular impression of the hammerhead (see Figure 10) than the Canadian tests due to the increased tube length. It was observed that the 5 mm tubes induced timber failure before the ultimate load of the tube could be reached. The 4 mm tubes reached their ultimate load consistently without timber failure if hammerheads with $D_1 = 50$ mm were used, see Figure 11. Additional tests with hammerheads of $D_1 = 45$ mm resulted in the hammerhead being pulled through the hole of the tube during yielding before tube folding was completed.

***Figure 10**: Deformed tube from the Swedish pre-tests*

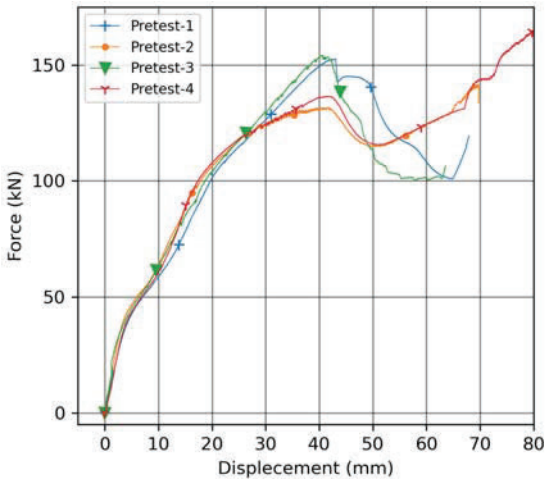

***Figure 11**: Force-displacement curves of the Swedish pre-tests for 4 mm tubes with hammerheads with 50 mm diameter.*

3.2 FLOOR ELEMENT TESTS

Figure 12 shows the pushdown and tie force curves of the Canadian floor element tests. The initial gradual increase in slope proves to be proportional to the geometrical deformation as expected of the steadily increasing catenary response with no compressive arching present. The failure of the butt joint is indicated by load plateau at approximately 350 mm pushdown, after which all load is transferred to the tube connector. Two clear peaks at approximately 10° and 13° floor rotation and subsequent load drops represent both tubes buckling at separate times.

The three-point testing may have affected the redistribution of forces in the connector as the metal stopper (Figure 13b) under the wall forced the deformation in the tubes on both sides to be in line with the panels. This setup might also have caused tube buckling to occur at corresponding lower pushdown distance than in the Swedish four-point tests (see below) because the displacement of the hammerhead was larger in order to conform with the enforced bent shape of the rod. The benefit of this wall configuration however is that the rod alignment remains normal to the tube walls, which could make the tube behaviour more predictable as it can be correlated more directly to the pure tension tests. This may furthermore reduce the risk of punching failure through the tube wall.

Despite the additionally provided actuator stroke, none of the specimen failed completely, after having deformed both tubes fully, see Figure 13c. Given the results of the Swedish tests (see below), it seems likely that the tube connectors in the Canadian tests reached their maximum load at the second buckle peak and that failure would occur not long after.

https://doi.org/10.52202/069179-0166

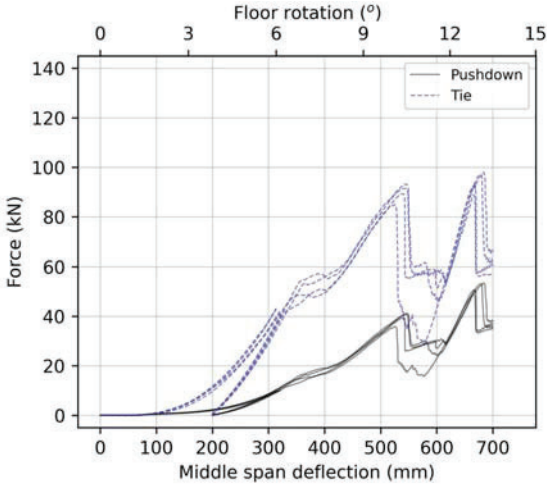

***Figure 12**: Force-displacement curves of the four Canadian floor element tests*

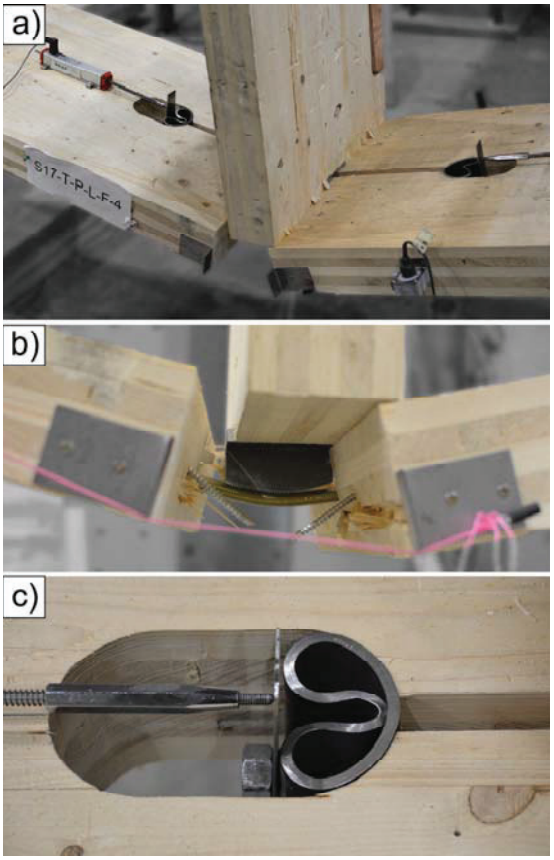

***Figure 13**: Canadian floor level tests during large floor rotations; a) wall section pushing on the floor panels, b) metal plate bending the rod of the tube connector and c) deformed tube connector*

The pushdown and tie force curves for the Swedish floor element tests with tube connectors in 3 m panels are shown in Figure 14 and for the 2.5 m panels in Figure 15.

After an initial dead phase caused by the gap between the panels, catenary action developed and could be sustained up to at least 10° of floor rotation. The dip in force at approximately 570 mm of pushdown deflection in Figure 14 was due to shear failure in the tube since the large rotation led to a load concentration at the hammerhead, see Figure 16a, which was aggravated by the slot hole. This effect was not as pronounced for the 2.5 m panels, because the flipped orientation of the slot kept a straighter pushing direction of the hammerhead onto the tube.

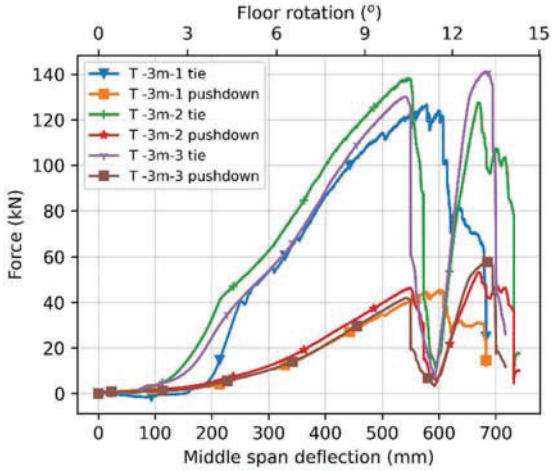

***Figure 14**: Force-displacement curves of the Swedish 3 m floor element tests with tube connectors*

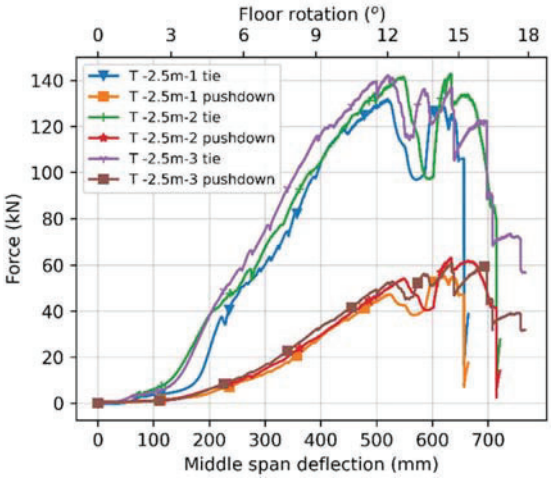

***Figure 15**: Force-displacement curves of the Swedish 2.5 m floor element tests with tube connectors*

https://doi.org/10.52202/069179-0166

***Figure 16**: Swedish floor element test; a) load concentration in the tubes and b) pushed-down floors*

Figure 17 shows the mean pushdown and tie curves of three Swedish floor element tests each with the screw connection. Since no gap existed between the panels, no dead phase occurred and instead, compressive arching action developed below 200 mm of pushdown deflection. Catenary action could not be sustained as the screws were bent and extracted from the CLT, see Figure 18.

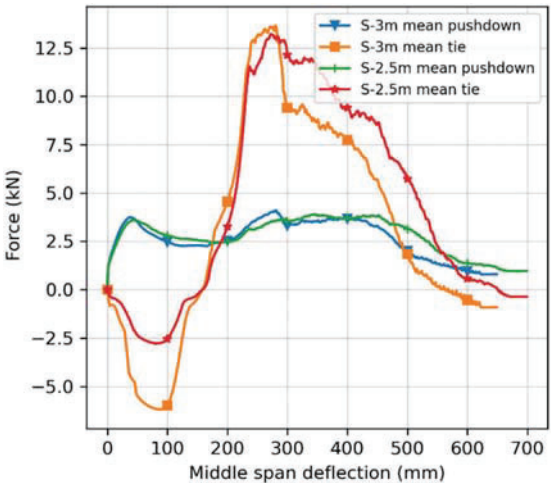

***Figure 17**: Force-displacement curves (means) of the Swedish floor element tests with screw connections*

***Figure 18**: Screw failure during pushdown in the Swedish tests*

3.3 COMPARISON TO PREVIOUS RESULTS

Previously conducted tests of the original tube connector design in [6] tested 3'' diameter tubes (variant T3) of 3 mm thickness in CLT in a similar loading configuration as the pre-tests in the present study. The used steel grade of the tubes had a yield strength of approximately 400 MPa. The results for the monotonic tests in [6] showed an ultimate load of approximately 50 kN at 24 mm displacement in the tube, which are both lower than the corresponding results in the present study. The development of the tube deformation and the characteristic shape of the load-displacement curves were similar in both studies.

The previous tests in [5] used the original tube connector design, as specified above, in similar pushdown tests as in the present study. Two connectors were used in CLT panels of a single span of approximately 2 m. The ultimate load of the tubes was not reached due to limited pushdown displacement and the maximum pushdown force for a single tube connector was approximately 15 kN at a floor rotation of approximately 7.2°. The models in [8] simulated larger pushdown displacements at slightly different boundary conditions for the tests in [5] and predicted an ultimate pushdown force of approximately 24 kN at a floor rotation of 12° for a single connector. The results of the present study indicate higher pushdown forces at corresponding floor rotations.

4 CONCLUSION

A new design of a tube connector for sustaining catenary action after a support removal in CLT was explored. Instead of using an internally welded coupler which may exhibit brittle weld failure, an external hammer pushed onto the tube and plastically deformed it during large joint rotations. The new connector design was tested in varying configurations, at both the component level and full-scale floor level, in Canada and Sweden.

The results indicate that the adapted tube connector could sustain higher catenary forces than the previous design at similar joint rotations. While variants with 4 mm tubes and slot holes which allow a changing direction of load application in the hammerhead could lead to abrupt load decreases due to shear failure, the new design did not exhibit a tendency for brittle failure. The conducted tests provided consistent results although slight variations existed in the material and test setups.

Compared to the initial design, a larger cut-out in the CLT was required to embed the connector. Nevertheless, the new design provides a more independent separation of the design components of the tube connector. The hammerhead geometry may further be adapted to produce a desired plastic deformation mode of the tube under load. With this design flexibility, alternative load paths in a damaged structure may be customised as desired.

EXPERIMENTAL VALIDATION OF PROPOSED CAPACITY-BASED DESIGN APPROACHES FOR MULTI-PANEL CLT SHEARWALLS

Mohammad Masroor[1], Ghasan Doudak[2], Daniele Casagrande[3]

ABSTRACT: Several research studies have proposed capacity-based design (CD) approaches for multi-story buildings containing cross-laminated timber (CLT) shearwalls. The current study contributes to the state of knowledge by evaluating experimental tests and numerical models on multi-panel CLT shearwalls in context of a proposed CD method available in the literature. The evaluation includes the yield hierarchy among energy dissipative elements and requirements to ensure sufficient energy dissipation is achieved in the shearwall. The results from the experimental tests on conventional connections used in CLT shearwalls are presented, as they are used as inputs in the numerical model and CD expressions. Reasonable correlation was found between the results obtained from experimental tests and numerical models. The walls' shear resistance obtained from the CD expressions represented a load level lower than the maximum resistance obtained from the experimental tests and numerical modes. This additional strength could be attributed to the contribution of angle brackets after the yielding of the hold-down, which is represented in the tests and numerical models but not in the CD equations. It was demonstrated that satisfying the proposed equations would lead to the desired lateral behaviour and energy dissipation in CLT shearwalls.

KEYWORDS: Cross-Laminated Timber (CLT); Capacity-based Design (CD); experimental tests; connections; seismic load

1 INTRODUCTION

The performance of cross-laminated timber (CLT) shearwalls subjected to seismic loads is mainly dominated by behaviour of the mechanical connections, which provide resistance and energy dissipation in the system, while the CLT panels can be reasonably assumed to behave like rigid bodies. Experimental tests have demonstrated that multi-panel CLT shearwalls possess better seismic performance than shearwalls consisting of a single panel, since joints connecting the panels together provide significant ductility (e.g., [1], [2]). This is also emphasized in the current version of the Canadian Engineering Design in Wood standard, CSA O86-19 [3], where panel-to-panel connections are defined as one of the main energy-dissipative elements in CLT shearwalls. A typical multi-panel CLT shearwall consists of panels attached together using panel-to-panel connections, and mechanical anchors, such as hold-down and angle brackets, which connect the wall to the foundation or floors, as shown in Figure 1.

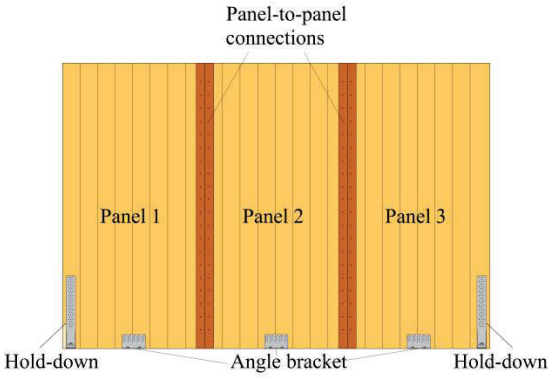

Figure 1: *Example of a multi-panel CLT shearwall*

Recent research has developed and proposed capacity-based design (CD) approaches for multi-story buildings containing CLT shearwalls, with the aim of preventing the occurrence of brittle failure and ensuring adequate energy dissipation under seismic loads. Gavric et al. [4] indicated dissipative connections, such as fasteners (nails and screws) used in panel-to-panel connections, hold-downs and angle brackets, in which plastic hinges are developed, and non-dissipating elements, such as CLT panels and brackets and anchoring bolts attached to the base. The

authors extended the proposal to multi-storey buildings, identifying panel-to-panel connections and hold-downs as dissipative connections, while requiring angle brackets to remain elastic. As a result of research efforts in Europe, a comprehensive CD approach was developed and proposed for inclusion in the next generation of Eurocode 8 [5]–[8]. Based on the proposal, CLT shearwall buildings can be classified into two levels of ductility, namely: medium ductility, which refers to buildings constructed from single panel or multi-panel CLT shearwalls that behave monolithically, and high ductility, which refers to multi-panel CLT shearwalls behaving in coupled-panel (CP) kinematic mode and where the panel-to-panel connections are designed to dissipate energy.

Casagrande et al. [9] proposed a CD approach for multi-panel CLT shearwalls using minimum potential energy method based on the developed analytical approach presented in [10]. Masroor et al. [11] extended the CD approach to include the bi-directional contribution of angle brackets, which was considered as a circular domain, as presented and investigated in [12]–[14]. A yield hierarchy was introduced for the dissipative connections, while ensuring that non-dissipative elements and those with limited-dissipative capability remain elastic. To achieve the proposed hierarchy and provide protection for non-dissipative elements, the concept of introducing over-strength factors were proposed and discussed.

The current study aims to validate the proposal developed in [11] by means of comparing the procedure to experimental test results and numerical models for multi-panel CLT shearwalls with conventional connections. The results of the experimental tests on connections are also presented, as they were used as inputs in the design equations and numerical models.

2 The CD design approach

2.1 General

This section reviews the CD approaches for multi-panel CLT shearwalls developed and reported in [11]. To ensure the proper sequence of the yield hierarchy, a CP kinematic mode is required, in which panel-to-panel connections yield before hold-downs. This behaviour implies that all panels have individual centers of rotation, which remain in contact with the ground. Figure 2 illustrates the investigated shearwall, consisting of m panels, subjected to gravity load, q, factored bending moment, M_f, and shear, V_f, at the base of the shearwall, and achieving CP kinematic behaviour. The figure also indicates the vertical (uplift) stiffnesses of the hold-down and shear stiffness in each panel-to-panel connection, $k_{h,z}$ and k_f, respectively, horizontal (shear) and vertical (uplift) stiffnesses of the angle bracket, $k_{a,x}$ and $k_{a,z}$, respectively, and the number of panel-to-panel connections and angle brackets used in each panel, n_f and n_a, respectively. The width and height of each panel are denoted as b and h, respectively.

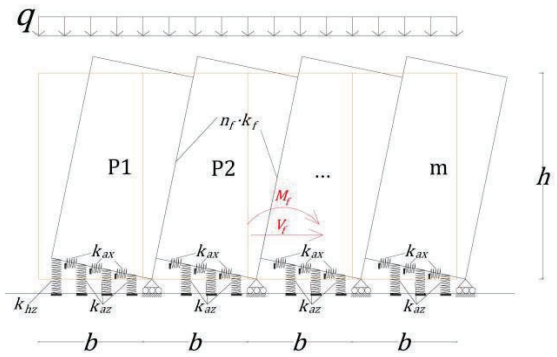

Figure 2: *The CP lateral behaviour of a multi-panel CLT shearwalls*

The proposal defines four categories of structural elements, as presented in Table 1: (1) Primary energy dissipative connections, which refers to panel-to-panel connections, considered to yield prior to other elements; (2) Other energy dissipative connections, which refers to hold-down connections, considered to yield after panel-to-panel connections; (3) Limited energy dissipative connections, which refers to angle brackets, considered elastic when panel-to-panel connections and hold-down have yielded; and (4) Non-energy dissipative elements, which refers to brittle structural elements such as CLT panels, which are expected to remain elastic until the energy dissipative connections reach a given load or displacement. Three over-strength factors were proposed to ensure such yield sequence is achieved and confirm that angle brackets and non-dissipative elements remain elastic. $\gamma_{r,h}$ is proposed to ensure that panel-to-panel connections yield prior to the hold-down, $\gamma_{r,a}$ ensures that angle brackets remain elastic when dissipative connections have yielded, and $\gamma_{r,ND}$ is meant to overprotect non-dissipative connections and ensure they remain elastic.

Table 1: *Proposed framework for the over-strength factors* [11]

Category	Element	Behaviour	Over-strength factor
Primary energy dissipative	Panel-to-panel connections	Yield	-
Other energy dissipative	Hold-down	Yield	$\gamma_{r,h}$
Limited energy dissipative	Angle brackets	Elastic	$\gamma_{r,a}$
Non-energy dissipative	E.g., CLT panels	Elastic	$\gamma_{r,ND}$

https://doi.org/10.52202/069179-0167

2.2 Capacity-based design requirements

The first step to establish requirements for the CD approach involves achieving CP kinematic mode. This is ensured by satisfying the requirement presented in Equation (1), which is a function of the connections' stiffness contributing to rocking behaviour, wall geometry, gravity load, and bending moment acting at the base of the shearwall.

$$\frac{k_{h,z}}{n_f \cdot k_f} \geq \frac{1-\frac{\widetilde{M}\cdot[3\cdot m-2]}{m^2}}{\left(1+\frac{\beta\cdot n_a}{2}\right)-\frac{\widetilde{M}\cdot\left\{m\cdot\left(1+\frac{\beta\cdot n_a}{2}\right)-2\cdot\left[1+\frac{n_a\cdot(2\cdot n_a+1)\cdot\beta\cdot m}{6\cdot(n_a+1)}\right]\right\}}{m^2}} \quad (1)$$

where, $\widetilde{M}$ and β are the dimensionless bending moment and vertical stiffness (uplift) ratio of mechanical anchors, presented in Equations (2) and (3), respectively.

$$\widetilde{M} = \frac{q\cdot m^2\cdot b^2}{2\cdot M_f} \quad (2)$$

$$\varphi = \frac{k_{a,z}}{k_{h,z}} \quad (3)$$

The requirement associated with the panel-to-panel connections yielding prior to the hold-down can be satisfied by ensuring the requirement outlined in Equation (4).

$$r_{h,z} \geq \gamma_{r,h} \cdot r_f \cdot \frac{k_{h,z}}{k_f} \quad (4)$$

where $r_{h,z}$ and r_f are the yield resistance of the hold-down in the vertical direction (uplift) and the yield resistance of one panel-to-panel connection, respectively.

The angle brackets are required to remain elastic when energy-dissipative connections have yielded, which ensures that sliding is minimised. This can be done by satisfying the requirement in Equation (5).

$$\left[\frac{\gamma_{r,a}\cdot n_a\cdot\beta\cdot r_{h,z}}{r_{a,z}\cdot(n_a+1)}\right]^2 + \left(\frac{C_h\cdot V_f}{r_{a,x}\cdot m\cdot n_a}\right)^2 < 1 \quad (5)$$

where, $r_{a,x}$ and $r_{a,z}$ are the yield resistance of one angle bracket in the horizontal (shear) and vertical (uplift) directions. V_f refers to applied shear acting at the base of the shearwall. C_h represents the ratio of the wall's bending moment resistance when hold-down yields to the bending moment acting at the base of the shearwall, and it can be obtained using Equation (6)

$$C_h = \frac{M^c_{r,h}}{M_f} \quad (6)$$

The wall's bending moment resistance when hold-down yields can also be calculated using Equation (7)

$$M^c_{r,h} = b \cdot \left\{r_{h,z} \cdot \frac{[1+n_a\cdot(2\cdot n_a+1)\cdot\beta\cdot m]}{6\cdot(n_a+1)} + r_f \cdot n_f \cdot (m-1) + \frac{q\cdot m\cdot b}{2}\right\} \quad (7)$$

The bending moment resistance of the shearwall, $M_{r,w}$, can be expressed as the wall's bending moment resistance when hold-down yields, $M^c_{r,h}$, which is required to be equal to or greater than the bending moment acting at the base of the shearwall due to the applied lateral loads.

$$M_{r,w} = M^c_{r,h} \geq M_f \quad (8)$$

Finally, the non-dissipative elements are required to be capacity-protected. For example, the resistance of the CLT panels, $V_{r,CLT}$ is required to be equal to or greater than the applied shear load at the base of the shearwall when hold-down yields, considering the appropriate over-strength factor, as shown in Equation (9)

$$V_{f,CLT} = \gamma_{r,ND} \cdot C_h \cdot V_f \leq V_{r,CLT} \quad (9)$$

3 EXPERIMENTAL TESTS RESULTS OF CONNECTIONS

The experimental tests were conducted on conventional connections used for CLT shearwalls. The average results of two tests on fully nailed WHT620 hold-downs [15] under uplift load and two tests on panel-to-panel connections consisting of partially threaded self-taping screws HBS 6x70 mm [16] are obtained from [17]. Figures 3 and 4 illustrate the load-displacement curves of the hold-down connections (HD-1 and HD-2) and panel-to-panel connections (PP-1 and PP-2), respectively. The average mechanical properties of each connection are presented in Table 2, based on the Equivalent Energy Elasto-Plastic (EEEP) curve, according to ASTM E2126-16 [18], including yield load, r_y, and corresponding displacement, d_y, elastic stiffness, k, and ultimate displacement, d_u.

Connection	r_y [kN]	d_y [mm]	k [kN/mm]	d_u [mm]
Hold-down	90.80	7.30	12.44	16.60
Panel-to-panel	4.60	5.50	0.84	41.60

The results of monotonic shear and uplift experimental tests on fully nailed TCN200 angle brackets without washers [19], are presented here in the following and shown in Figure 5. Two repeats were conducted for each loading. A displacement rate of 3 mm/min was selected, consistent with the rates used in tests on the hold-downs and panel-to-panel connections.

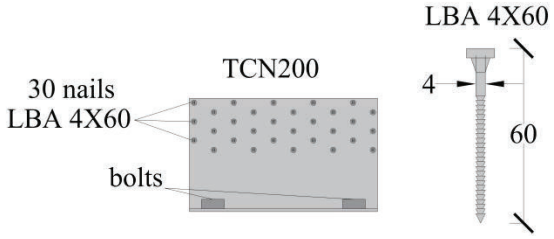

Figure 5: *Fully nailed TCN200 angle bracket*

Figures 6 and 7 illustrate the test setups for the angle bracket under monotonic uplift and shear loads, respectively. The CLT panels were composed of three layers, E1 grade, manufactured according to ANSI/APA (2020) [20]. Panel thickness was 105 mm (35-35-35), and the width of each board was 89 mm.

4 EVALUATION OF THE CD PROCEDURE FOR MULTI-PANEL CLT SHEARWALLS

Experimental tests were conducted on two CLT shearwalls (W-1 and W-2), with the configurations shown in Figure 10, to investigate the CD approach proposed in [11] and presented in section 2. Walls W-1 and W-2 were subjected to equivalent uniform gravity loads, q, of 1.45 kN/m and 6.67 kN/m, respectively. The shearwalls consisted of three panels with height and length of 2438 mm and 1219 mm, respectively. The walls were anchored to the steel base and to the CLT panel by means of fully nailed hold-down and angle brackets, (i.e., WHT620 and TCN200). Two hold-downs were used on each face of the wall, while two angle brackets were used in each panel attached only to one face. Panel-to-panel joints consisted of nine HBS 6x70 mm screws.

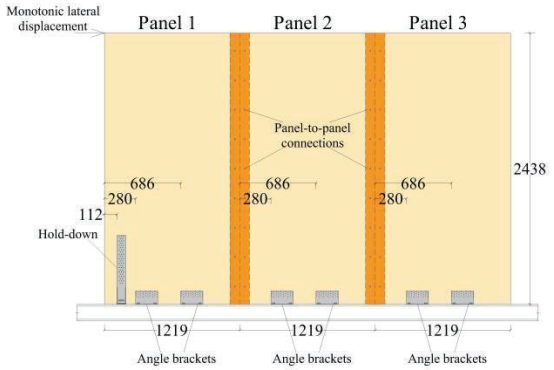

Figure 10: *Test set-up of CLT shearwalls*

Numerical models were developed using SAP2000 software [21], as illustrated in Figure 11. Multilinear link elements were used to model the connections based on the curves obtained from the connection tests. The interaction between uplift and shear in angle brackets were modelled using macro element, as presented in [22]. A concentrated lateral load, F, was applied at the top of the shear-wall consistently with the position of the loading actuator in the experimental tests, while the gravity loads were applied on top of the panels. Rigid gap elements acting only in compression were modelled at the bottom of the walls to simulate the contact between the steel base and the CLT panels. At the top and bottom of each panel, diaphragm constraints were applied. Orthotropic material properties were used for the CLT panels. The input values of $E_{eff,1}$, $E_{eff,2}$, and G_{eff} were equal to 4100 MPa, 7900 MPa, and 361 MPa, respectively [17].

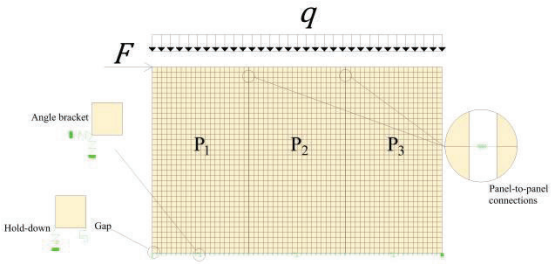

Figure 11: *SAP2000 numerical models of a three-panel CLT shearwalls*

Figure 12 demonstrates the load-displacement curves obtained from experimental tests and numerical models. Also presented in the figure is the wall's shear resistance at the point of hold-down yielding, obtained by dividing the wall's bending moment resistance when hold-down yields (Equation (7)) by the wall height, h. For both walls, reasonable matches can be observed between the results obtained from experimental tests and numerical models. The calculated shear resistance obtained from Equation (7) appears to be lower than the peak resistance obtained from the experimental tests and numerical models. This additional strength could be attributed to the contribution of angle brackets after the yielding of the hold-down, which is represented in the tests and numerical models but not in the CD equations.

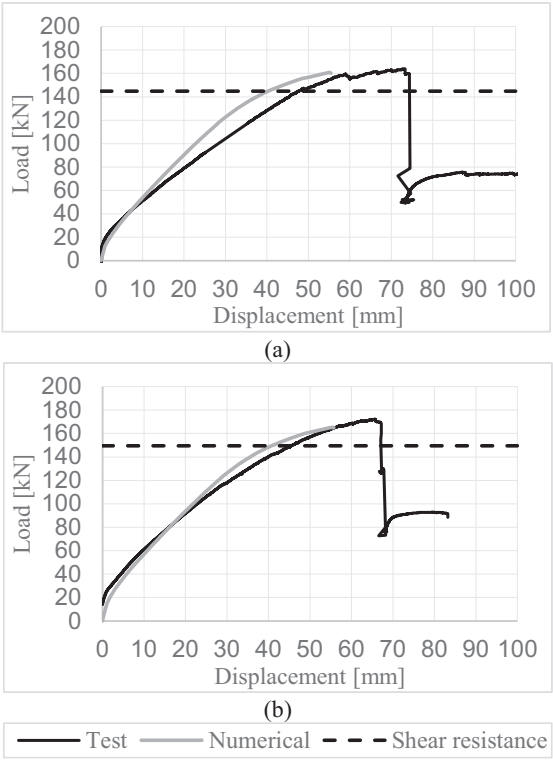

Figure 12: *Load-displacement curves of investigated CLT shearwalls: (a) wall W-1 and (b) wall W-2*

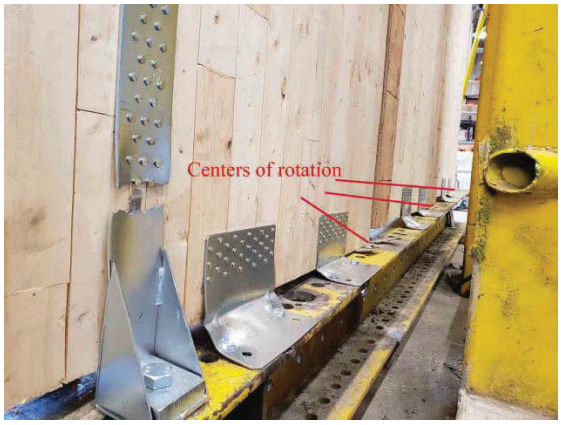
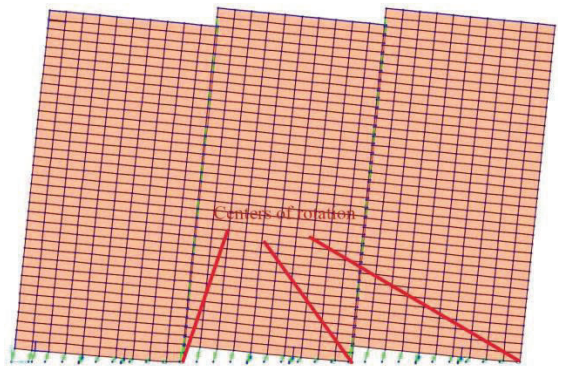
Evaluating the validity of the CD requirements, presented in Section 2.1, it can be noted that the CP kinematic mode was achieved in both experimental tests and numerical models, as shown in Figure 13(a) and (b), respectively. This satisfied the requirement outlined in Equation (1). The panel-to-panel connections yielded before hold-downs, which satisfied the requirement in Equation (4). The angle brackets remained elastic when hold-down yielded, satisfying the requirement in Equation (5), and the requirement related to the CLT panels remaining elastic was clearly also met.



(a)



(b)

Figure 12: *Load-displacement curves of investigated CLT shearwalls: (a) wall W-1 and (b) wall W-2*

Table 4 presents the results obtained from the CD expressions for each requirement, as outlined in Section 2.1. Due to the deterministic nature of these examples, overstrength factors of unity were employed for the hold-down, $\gamma_{r,h}$, and the angle brackets, $\gamma_{r,a}$. A value of 1.6 was set for non-dissipative elements, $\gamma_{r,ND}$, such as CLT panels, based on [4]. For each wall, the requirements outlined in Equations (1), (4), (5) and (9) were calculated with inputs obtained from table 2 and 3. As can be observed in the table, all requirements were satisfied for both walls. This demonstrates that satisfying the proposed equations could lead to the desired lateral behaviour in CLT shearwalls. It is also noteworthy to mention that calculating the shear resistance of CLT panels in order to compare it with the value obtained from Equation (9) is out of the scope of this research, however, observations from the experimental study clearly shows that the shear strength of the CLT panels far exceeded the shear forces induced by the lateral load.

Table 4: *CD requirements' values for walls W-1 and W-2*

Eq.	Values		Satisfied
	W-1	W-2	
(1)	3.28>0.85	$3.28 > 0.80$	Yes
(4)	181.60>135.81	181.60>135.81	Yes
(5)	0.65<1.00	0.66<1.00	Yes
(9)	231.62	239.24	-

5 CONCLUSIONS

The current study investigates the validity of a proposed capacity-based design procedure with the help of experimental tests and numerical models on multi-panel CLT shearwalls. The results of experimental tests of fully nailed TCN200 angle brackets without washers under uplift and shear loads were also presented. The mechanical properties of connections obtained from literature and those presented in the current study were used as inputs to the CD equations and numerical models. Experimental tests and numerical models from two CLT shearwalls comprised of the tested connections were evaluated. reasonable match was observed between the results obtained from experimental tests and numerical models, while wall shear resistance obtained from the capacity-based design equations was observed to be relatively lower. All the requirements from the capacity-based design approach were met in experimental tests, numerical modes and the results demonstrated that satisfying the proposed equations would lead to the desired lateral behaviour.

ACKNOWLEDGEMENT

The authors wish to acknowledge Rothoblaas Srl (Italy) and Nordic Structures (Canada) for providing the connections and CLT panels that were used in this study.

GLUED-IN ROD CLT CONNECTIONS WITH FLEXIBLE POLYMER ADHESIVE

Boris Azinović[1], Václav Sebera[2], Meta Kržan[1], Andreja Pondelak[1], Jaka Gašper Pečnik[3], Arkadiusz Kwiecień[4]

ABSTRACT: This paper explores the possibility of using flexible adhesives for glued-in rods in cross laminated timber (CLT). In the first series of tests, a rod glued in a CLT panel with flexible adhesive was investigated for its mechanical resistance. The connection was tested in pull-pull configuration using monotonic and cyclic, tensile-only loading. Different glued-in lengths were tested, for which the rod diameter and glue-line thickness were constant. The tests have shown that the adhesive can resist large elastic deformations, while it does not exhibit large energy dissipation capacity. Based on the test results the numerical analyses were performed to study the behaviour of the connection where other parameters were considered. Existing constitutive models available in Ansys software were used to simulate the specific mechanical behaviour of the connection under monotonic loading. The results of the FE model exposed an optimal glue-line thickness and glued-in length in relation to the engineering design parameters. The second series of tests were material emission tests, which were carried out in a Micro-Chamber (μ-CTE) with the intention to further explore the feasibility of such connections in terms of volatile organic compound (VOC) emissions.

KEYWORDS: CLT connections, glued-in rods, flexible adhesive, polyurethane, cyclic tests, environmental aspects

1 INTRODUCTION

The glued-in rod connections are commonly used also in structures and are constructed from: i. rod, ii. adhesive and iii. structural element (e.g. structural timber, CLT etc.). In most cases such connections consist of brittle adhesive with thin bondline and a steel threaded rod. This combination of materials usually leads to a brittle failure of the connection (see e.g. [1]), where the ductile response could be reached by yielding of the rod.

In this paper, the possibility to reach a more controlled response within the adhesive layer is explored. For this purpose, a thicker bondline and a flexible polyurethane adhesive were selected for investigation. Such "flexible" glued-in rods could be used at the connection between the panel and the wall at the top and/or bottom of the wall (e.g. as hold-down connections – HD). During the seismic loading the panels are exposed to rocking, which causes the rods to be pulled out of the panels. One possible improvement by using "flexible glued-in rods" would be an increase of deformation capacity in the elastic range. Furthermore, while pulling the rod, the energy could be dissipated through the shear deformation of the adhesive layer, making the connection more ductile in comparison with brittle adhesive connections.

The prospect of building larger and taller timber buildings creates new structural design challenges due to wind and seismic actions, such as higher demands on HDs in CLT shear wall buildings: strength to resist loads, lateral stiffness to minimize deflections and damage, as well as deformation compatibility to accommodate the desired system rocking behaviour during an earthquake [2]. While in the proposal for the new Eurocode 8, the plastic deformations in HD connections are allowed [3], [4], the Canadian standard CSA 086 interprets HDs as non-dissipative connections which shall be capacity protected by designing them to remain elastic under the force and displacement demands that are induced in them when the energy-dissipative connections reach the 95th percentile of their ultimate resistance [5]. Therefore, there is also a need to develop HD solutions with high load-bearing and deformation capacities while remaining elastic. In this respect, the flexible glued-in rods could possibly meet these requirements for CLT shear walls without yielding in the (steel) rod itself.

To account for high elasticity and load-bearing capacity, recently, a hyperelastic HD solution for CLT shear walls was developed [6]. These HDs include an elastomeric bearing layer and steel plates, which were fixed inside the CLT panel by steel rods. All steel and CLT members were designed to have no inelastic deformation for a given

target load and therefore the HD deformations result from the rubber layers' deformation. Additionally, the overstrength factor to design the rubber layer needs to prevent the brittle failure of the CLT panel [7]. Depending on the assembly of the hyperelastic HD, the mean load bearing capacity in the study ranged from 100-150 kN, while reaching the corresponding displacements from 3-12 mm [6].

The solution presented in this paper could offer an alternative solution to the hyperelastic HD, where instead of in the rubber layer, the elastic deformation occurs in the adhesive of the glued-in rod connection. This could be achieved in a single glued-in rod connection or a combination of several glued-in rods to increase the load bearing capacity. One of the possible benefits compared to the hyperelastic HD is to retain a visible outer layer of the CLT and protect the connection in case of fire load, since it is hidden within the inner CLT layers. The paper explores the mechanical resistance of such glued-in rod connections on monotonic and cyclic axial load, while also some information on the emission tests is provided.

2 EXPERIMENTS

2.1 TENSILE RESISTANCE

The pull-pull experiments were performed on Zwick Z2500Y testing machine at the Slovenian National Building and Civil Engineering Institute (ZAG). The specimens were cut out of a 5-layer CLT (layers: 33-20-34-20-33 mm, produced according to ETA-12/0281), where the dimensions of the CLT were cca. 25 cm × 100 cm × 14 cm. For inserting the threaded rods, holes of 28 mm diameter were drilled on the tested end and 24 mm at the supported end of the CLT prisms. The rods were oriented parallel to the grain of the laminations in the middle and outer CLT layers. The test setup of the "pull-pull" test is presented in Figure 1.

At the supported end of CLT, a large diameter rod (Φ20 mm) was inserted in the 300 mm deep hole. The rod was glued to the CLT with an epoxy adhesive (HILTI RE 500) of 4 mm thickness. This ensured a large rigidity and large resistance of the fixed support. Behaviour of the rigid supporting connection was not considered in this test, since it has a negligible effect At the tested end, considered for investigation, a threaded rod with smaller diameter (Φ12 mm) was glued in the holes of 28 mm diameter (specimens' description: dh28) with an elastic polyurethane adhesive PST of 8 mm thickness, where two glued-in lengths were tested: 160 mm and 320 mm (La160 and La320). The properties of the adhesive and the timber adhesive bondline were previously determined [8]. At least three samples with the same characteristics were tested for monotonic (M) as well as for cyclic (C) tests to verify the scattering of the results. The configuration of the tested specimens is shown in Table 1.

The glued-in rods were tested under monotonic and cyclic loading in the tensile direction only. The loading was applied to the samples using a constant displacement rate of 70 mm/min. The induced displacements approximately followed the ISO 16670 displacement protocol [10]. According to ISO protocol, the small-amplitude cycles with single repetition are followed by large-amplitude cycles with three repetitions until the failure occurs. The protocol was adapted, since the connection is asymmetric, and it does not deform significantly under compression. Therefore the displacement was induced only in tension and the displacement at failure was estimated as 20 mm, what corresponds to the shear deformation angle (shear strain) of the adhesive layer equal to 250%. The real relative displacement of the connection between the rod and the CLT panel was measured with an optical extensometer which is built into the Zwick test device. The displacement was measured near the tested surface at the distance of 18 cm (Figure 1). In addition, the behaviour of the connection at the tested end was recorded with a HD camera.

Table 1: *The configuration of tests*

Specimen	α [°]	l_a [mm]	Φ_a [mm]	$\Phi_{a,r}$ [mm]	t [mm]	n
La160/M/dh28	0	160	28	12	8	4
La160/C/dh28	0	160	28	12	8	3
La320/M/dh28	0	320	28	12	8	4
La320/C/dh28	0	320	28	12	8	3

α …rod to grain angle
l_a …glued-in length
Φ_a …diameter of the hole at the tested end
$\Phi_{a,r}$ …diameter of the rod at the tested end
t …thickness of the adhesive
n …number of samples
M, C …Monotonic or Cyclic tests

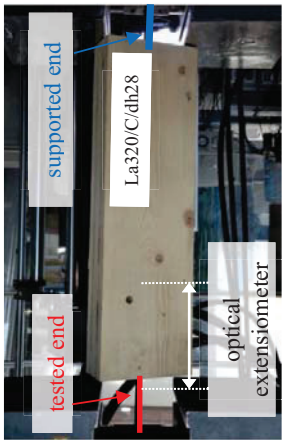

Figure 1: *Test set-up*

All deformations took place in an adhesive joint and the failure (rod pull-out) mainly occurred within the glue line (cohesive failure of the adhesive), see Figure 2. As expected, the behaviour of the connection during the monotonic loading was highly elastic, until maximum

https://doi.org/10.52202/069179-0168

load bearing capacity was reached (Figure 3). The connection resisted large deformations, while it did not prove to fail in ductile manner. The ductility values (D_f) of all tested connections were less than 1.5. The ductility value was calculated for monotonic tests as the quotient of the displacement at failure (u_f) and the displacement at the elastic load limit (u_y). The displacement u_f was determined at the 80% drop of the maximum force (F_{max}), where the displacement u_y was defined according to the method defined in EN 12512 [11].

The results (mean values with Coefficient of Variation – CoV) of monotonic loading showed elastic behaviour up to the displacement of 6.8 mm and 7.1 mm, giving ultimate shear strain of 85% and 89% (calculated for 8 mm adhesive thickness), for glued-in lengths of 160 mm and 320 mm respectively. Load-bearing capacity of the connection is approximately proportional to the glued-in length assuming all other properties are the same; mean value reaches 23.9 kN and 44.3 kN for glued-in length 160 and 320 mm respectively. Mean nominal shear strength values of the polyurethane PST adhesive (cohesive failure), calculated for the cylindrical area at the contact between the steel rod and adhesive ($\pi \times 12 \times La$) are 4.0 MPa and 3.7 MPa, respectively. Similarly, the mean stiffness values also increase by the glued-in length from 4.0 kN/mm to 6.5 kN/mm (Table 2).

Figure 2: *Rod pull-out*

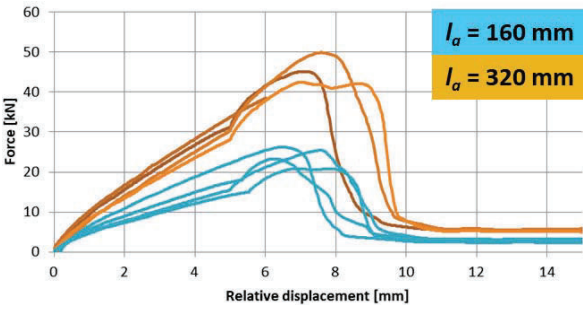

Figure 3: *Results of monotonic experiments for tested glued-in lengths 160 and 320 mm*

Table 2: *The mean results from the monotonic tests: load-bearing capacity (F_{max}), stiffness ($K_{0.1–0.4}$) and displacement at F_{max} (d_u)*

	La160/M/dh28			La320/M/dh28		
sp. no.	F_{max} [kN]	d_u [mm]	$K_{0.1–0.4}$ [kN/mm]	F_{max} [kN]	d_u [mm]	$K_{0.1–0.4}$ [kN/mm]
1	26.25	6.5	5.20	45.11	7.1	6.70
2	20.79	6.9	3.87	42.51	7.0	5.71
3	23.30	6.3	3.93	49.87	7.6	6.13
4	25.43	7.6	3.04	39.51	6.5	7.43
mn.	**23.94**	**6.8**	**4.01**	**44.25**	**7.1**	**6.49**
CoV	10.2%	8.4%	22.6%	10.0%	6.4%	11.4%

The cyclic response of the connections in terms of actuator force versus relative displacement of the joint is shown in Figure 4. The hysteretic curves for the connections with glued-in length of 160 and 320 mm showed a similar response, so only the hysteretic curves for glued-in length of 160 mm are shown, while Figure 5 shows hysteresis envelope curves for the tensile part of the cyclic test. The hysteretic curves show a typical hyperbolic strain hardening up to the maximum load capacity. This is followed by an exponential decrease in strength until failure (minimum residual load).

To characterize the performance of the connections during earthquake loading the amount of dissipated energy was evaluated in terms of equivalent viscous damping for the first cycle. The equivalent viscous damping coefficient (ξ) was evaluated from the hysteretic response as the ratio of dissipated energy (E_{DIS}) to potential energy (E_{INP}) as suggested by Chopra [12]:

$$\xi = \frac{E_{DIS}}{2\pi\, E_{INP}} \qquad (1)$$

The equivalent viscous damping coefficient was calculated for the first loading cycle and is provided in Table 3. The values for moderate amplitudes (up to the maximum load) ranged from 1% to 4.5% for glued-in length of 160 and 320 mm, respectively. The results indicate that the response is mainly elastic with little input energy dissipated.

2.2 EMISSIONS TESTS

The investigation of the connection feasibility in practise included emission tests on a CLT panel and on adhesive samples carried out in a Micro-Chamber (µ-CTE) at the Fraunhofer Institute for Wood Research WKI [13]. The purpose of the tests was to obtain general information about the emission strength of the samples and the spectrum of the emitted substances.

Sample preparation

The CLT was cut into small cubes (3 cm x 3 cm x 1 cm). The specimen contained one adhesive joint. The primer (ZP Primer) and adhesive (PS A + B) were applied in a small petri dish. The CLTs were conditioned for 15 minutes, the primer and adhesive for 30 minutes. The adhesive PS differs from the PST adhesive in terms of its mechanical response, but similarities in VOC spectra was assumed due to its source of origin.

Testing

CLT sampling was performed over 30 minutes, corresponding to a volume of about 3 litres. The primer and adhesive were tested for 10 minutes with a sampling volume of 1 litre. The difference in sampling volume was chosen because primer and adhesive are considered high emitting materials to avoid overloading the adsorbent tube. Adhesive and primer were tested in fresh – uncured state. A piece of the sample was mounted in the Micro-Chamber for emission testing (µ-CTE) in cell mode. The test was performed at 23 °C with dry synthetic air. The µ-CTE effluent was collected on a sorbent tube (Tenax TA) and analysed on a thermal desorption GC-MS system. Compounds were analysed using MS-Spectra libraries. Surface area for CLT was 27 cm^2 and the flow rate was 106.5 ml/min, while the surface area for primer and adhesive was 7 cm^2 and the flow rate was 112.8 ml/min.

Results

The Table 4 shows substances emitted from CLT, ZP Primer and adhesive PS A + B. In the case of the CLT panel, more than 30 substrates were detected with the highest concentrations of acetic acid, hexanal, formic acid, acetone, pentanal, pentanol, butanal, furaldehyde, and terpineol. Most of the substances emitted from CLT panels (organic acids, aldehydes and terpenoids) are substances characteristic of wood-based materials [14]. The highest concentrations emitted from the primer were 1-Methoxy-2-propyl acetate, Ethylbenzene and Xylene and formylmorpholine and Xylene in the case of adhesive (Table 4).

The µ-CTE emission tests were performed to obtain general information about the emitted substances from the CLT panel, the flexible adhesive, and the primer. The CLT emitted organic acids, aldehydes and terpenes, which are characteristic of wood-based materials. The primer (ZP) released a range of solvents, with 1-methoxy-2-propyl- acetate, xylene- isomers and C3-benzenes being the most abundant substances. Emissions from adhesive (PS A +B) were much lower, with N-formylmorpholine being released at higher concentrations. As mentioned above, the aim was to assess which volatile compounds were emitted by selected materials. The measurements were made on small samples (27 cm^2 or 7 cm^2) with different sampling volumes (one or three litres) and different result delivery (µg/h*m^2 or µg/h*g), so the measurements cannot be compared with each other.

3 NUMERICAL ANALYSIS

The numerical simulations using the finite element method consisted of three different analyses with the objectives: 1) to study whether it is possible to model a threaded rod without threads; 2) to simulate the real size problem and validate it through conducted experiments; and 3) to perform parametric studies for different glued-in lengths and adhesive thicknesses.

The finite element package Ansys [15] was used for all analyses. All solids were modelled using SOLID185 finite elements. All models were symmetrical, so only a quarter of the problem was modelled to reduce computational effort. Wood was modelled as a linear orthotropic material with the following properties: E_L = 14850, E_R = 352, E_T = 289, E_{LR} = 573, E_{RT} = 53, E_{LT} = 474 [MPa], μ_{LR} = 0.023, μ_{RT} = 0.557, μ_{LT} = 0.014 [-], where L, R, and T stand for longitudinal, radial and tangential anatomical directions, respectively. Steel rod was modelled as linear isotropic material with E = 200 GPa and µ = 0.3. The PST adhesive was modelled as hyperelastic material with Yeoh 3 parametric model given as c_{10} = 1.6641, c_{20} = -0.49288, c_{30} = 0.14807, $d_{1,2,3}$ = 0 that was curve-fitted to following experimental stress/strain data: 0/0.0173, 0.1/0.933, 0.2/1.541, 0.3/2.025, 0.4/2.392, 0.5/2.645, 0.6/2.838, 0.7/3.001 [MPa/-].

Boundary conditions (BC) consisted of: 1) fixing two sides of the block against movement; 2) symmetrical BC's were applied on two other sides; 3) pulling the rod in its axis by 6 mm in a monotonic way. At each step of the rod displacement, the force was read to generate force-displacement diagrams.

3.1 THREADING ANALYSIS

To determine if threading is important to be included in the analysis, the analysis was performed with and without threading. The model (Figure 6) was reduced to a length of 11 mm to reduce computational complexity, and a sensitivity study of mesh density was also performed.

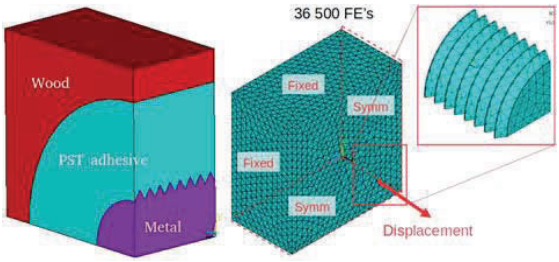

Figure 6: *Symmetrical geometry (left) and FE mesh and BC's (right) of model for thread analysis*

The model resulted in three data series as a function of mesh density (Figure 7). It is clear that the model with M11 thread (red line) behaves according to the same pattern as the models without thread with 10 and 12 mm diameter, and it is between them. This is an important finding because we can omit the thread in the full-scale models without losing the correct overall force-deflection response.

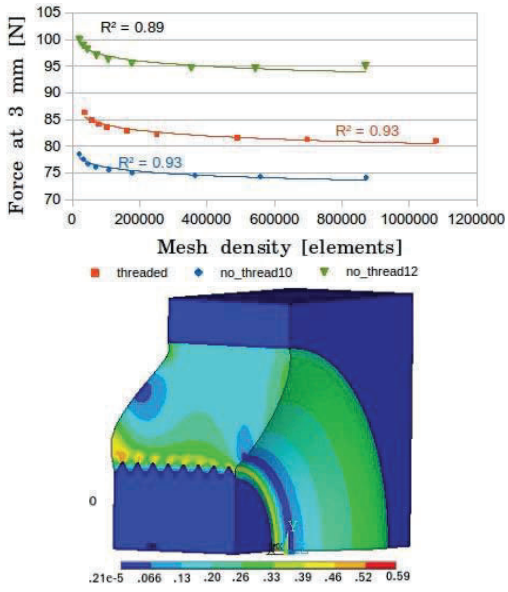

Figure 7: *Threaded vs. non-threaded models depending on mesh density (left) and von Mises Strain around threading*

Figure 7 (right) also shows that the highest strain occurs at the tips of the threads, which could indicate the position of failure initiation.

3.2 VALIDATION WITH EXPERIMENTS

A full-size 3D FE model was made in two lengths reflecting the physical experiments. The comparison of the FE models (blue and red lines) with the experiments (grey and black lines) is shown in Figure 8. The FE models of both lengths predict well the behaviour found in the experiments in terms of stiffness and hyperelastic progression of the force versus displacement. The FE models predict the behaviour up to a displacement of 6 mm, not taking into account the strength limit of the PST adhesive.

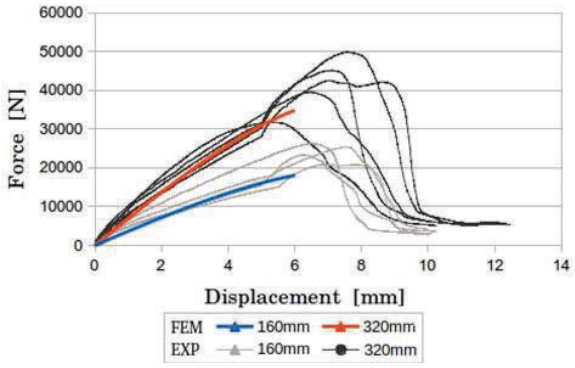

Figure 8: *Comparison of FE models (blue and red line) with experiments (grey and black lines) for both rod lengths*

3.3 PARAMETRIC STUDY

The parametric studies investigated the influence of the glued-in rod length and bondline thickness (Figure 9).

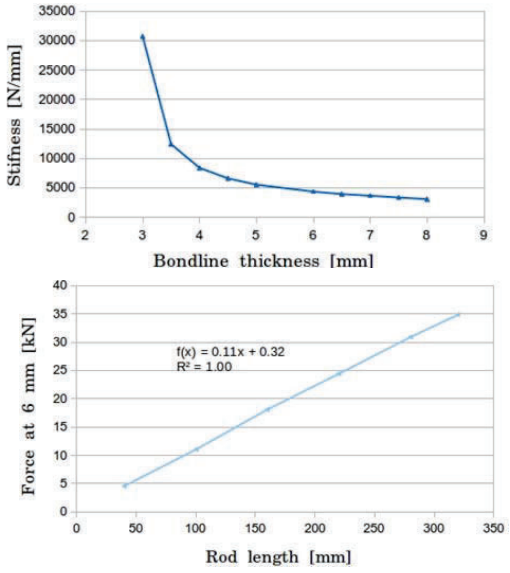

Figure 9: *Influence of bondline thickness on stiffness (top) and influence of glued-in rod length on force (bottom)*

https://doi.org/10.52202/069179-0168

These studies were performed on a full-size model (quarter-symmetrical) and did not include threads. The effect of rod length on force shows a linear trend. The effect of bondline thickness on connection stiffness, on the other hand, shows a hyperbolic trend with a decreasing tendency. Both parametric studies allow the glued-in rod connection with the CLT panel to be designed as required for the given conditions - for specific structural design. Future FE studies should focus on extending the hyperelasticity to include the range of plastic strains, so that the failure of the bonded PST connection can also be predicted, as this is the predominant failure observed in experiments.

4 CONCLUSIONS

Monotonic and cyclic tensile tests were performed on rods bonded with a flexible adhesive in CLT. The tests showed promising behaviour of such connections in terms of their elastic deformability under cyclic loading. On the other hand, a rather brittle failure with limited ductility occurred. Also, the energy dissipation capacity at larger amplitudes was not significant. The tests have also shown that the load-bearing resistance of the connection is proportional to the rod length.

To test the behaviour of the "flexible" glued-in rods when applied in CLT buildings, a series of numerical analyses were performed. First, the numerical model of the connection was calibrated based on the experimental results. The material model was able to simulate the linear part (stiffness) of the connection and provided a relatively good agreement with the experimental results. In the next phase, the model of the connection was used for the parametric study of the glued-in length and bondline thickness. The results showed that the effect of the rod length on the force exhibited a linear trend, while the bondline thickness showed a hyperbolic trend on connection stiffness with decreasing pattern. Both parametric studies demonstrate that the glued-in rod connections in CLT panels can be designed to meet the required boundary conditions in CLT walls.

Additionally, the Micro-Chamber emission tests were carried out in order to obtain general information about the emitted substances from the CLT panel, flexible adhesive and primer. The CLT panel showed the release of organic acids, aldehydes and terpenes characteristic for wood-based materials. The Primer (ZP) released a range of solvents with 1-methoxy-2-propyl-acetate, xylene-isomers and C3-benzenes as most abundant substances. Emissions of adhesive (PS A +B) were much lower with emission of N-formylmorpholine in higher concentrations.

The results of the study show a potential of using CLT wall system with “flexible” glued-in rods in seismic areas. However, future studies are necessary to investigate the long-term behaviour and performance of such connections at elevated temperatures. Also, an improvement of the performance in the nonlinear part of the connection would be essential for its actual applications.

EVALUATION OF BEARING STRENGTH PERFORMANCE OF STS CONNECTION ACCORDING TO BEARING SECTION ON LOADING DIRECTION

Keonho Kim[1], In-Hwan Lee[2], Gwang-Mo Kim[3]

ABSTRACT: Since self-tapping screws (STS) are widely used for structural cross-laminated timber(CLT) connections, the bearing performance according to the shape information of fasteners is required to design connections for CLT. In this study, to evaluate the bearing strength of STS connection using the lamina of domestic softwoods, the half-holed bearing test was conducted according to the bearing section on loading direction. The species of lamina were japanese larch, korean pine and japanese cedar. The specimen was prepared according to the thread part (thread + tip) and shank part (shank + shank cutter) of STS and three types of diameters (8, 10, 12 mm) in the bearing section (cross section, radial section, tangential section). The 5 % offset yield bearing load of cross section of japanese larch was the highest value according to the specific gravity of laminas. As the diameter of STS increased, the bearing load showed a tendency to decrease. Even STS with same diameter, the bearing strength of thread part was higher than shank part due to the difference of effective bearing area.

KEYWORDS: Self tapping screw, Bearing strength, Connection, Domestic softwood, Half-holed test

1 INTRODUCTION

The use of engineered wood, known as a carbon storage, has expanded the scale of wooden buildings. The cross laminated timber (CLT), which is generally used in high-rise wooden buildings, is one of the engineered woods and is widely used for shear walls and floors. The lateral resistance of a wooden structure is an important design value to secure its seismic performance. The strength performance of the CLT itself and the lateral strength performance of the connection are important factors for the lateral resistance capacity of the CLT structure. The self-tapping screw (STS) are mainly used for CLT connections. The lateral strength design of the connection can be predicted by the bending performance of the fastener and the bearing strength of members of connection by Korean Design Standard (KDS). In this study, to evaluate on the bearing strength performance of STS connection, the bearing test of CLT using the domestic species was conducted according to the shape of STS and loading direction to the grain.

2 EXPERIMENTAL

2.1 MATERIAL

As the lamina for the CLT, japanese larch (*Larix kaempferi* Carr.), korean pine (*Pinus koraiensis*) and japanese cedar (*Cryptomeria japonica*) were used, which are structural materials for softwoods in Korea (KS F 2020). The cross section of specimens was 50 × 50 mm. The fasteners used in the bearing strength test were the self-tapping screw (galvanized carbon steel) from Rothoblaas (Italia) shown in Figure 2. The type of STS ccording to the diameter is divided into 3 types (8, 10, 12 mm), and their length is 120 mm. The diameter (ds) of the shank was 5.8 mm, 7.0 mm and 8 mm, and the diameter (dc) of the shank cutter was 6.8 mm, 8.4 mm and 9 mm, which is larger than the diameter of the shank. The diameter of the thread is divided into an inner diameter (d2) and an outer diameter (d1).

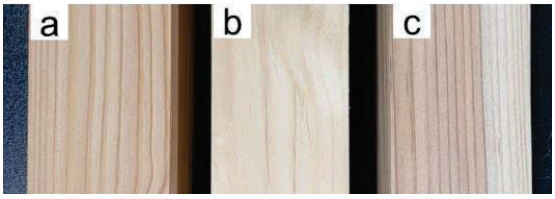

Figure 1: *Photographs of timber (a- Japanese larch, b- Korea pine, c- Japanese cedar)*

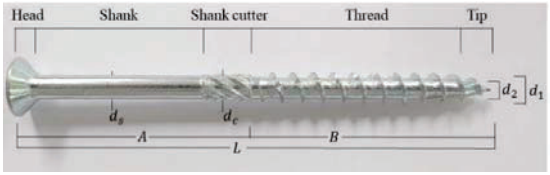

Figure 2: *Photographs and details of self-tapping screw*

The bearing strength test specimens is classified and manufactured according to the shape of STS fastener in bearing section. The bearing part of STS fastener was divided into T-series for bearing with the thread of STS and the S-series for bearing with a shank. The nomenclature of specimens was named according to the species and species cross-section, 8, 10, and 12 mm of the

STS standard diameter (d1), and the location of the bearing STS (thread part and sank part). The STS with a diameter of 12 mm was not tested due to the fact that the length of the shank was 40 mm shorter than the length of the specimen. A total of 450 specimens were produced, 10 specimens for each type.

2.2 METHODS

The half-holed bearing test of STS connections was conducted in accordance with KS F 2156. The bearing test specimens was drilled with the diameter of STS fastener. The T-series was tested by inserting it into the groove so that only the thread part, excluding the tip part, was in contact. S-series included both shank and shank cutter, and tested after inserting STS into the groove. A bearing load and an embedment were measured by the universal testing machine (Instron 5585) with the 30 ton load capacity. The loading speed was 0.5 mm/min.

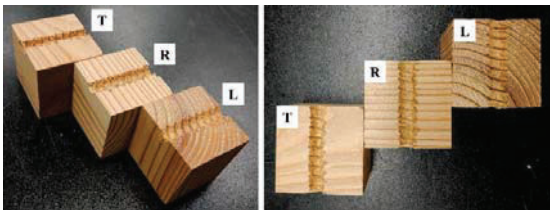

Figure 3: *Configuration of bearing test specimen (note : C, R and T means the cross, radial and tangential section of specimens respectively.)*

3 RESULTS AND DISCUSSION

3.1 5% OFFSET YIELD LOAD ACCORDING TO SPECIES AND BEARING SECTION

The maximum load of the specimens in longitudinal section is easy to measure because of the clear load drop, but the maximum load of the radial and tangential sections specimens is difficult to measure because the load drop is not clear. Therefore, the bearing strength was calculated jointly as the yield strength, and the results were compared and analyzed.

The yield strength was calculated by the 5% offset of the thread diameter of the STS fastener. The yield strength was calculated according to KS F 2156 (2017). First, the initial straight line of the load-deformation curve obtained in the experiment was shifted 5% of the STS diameter in parallel, as shown in Fig. 6. Then, the yield load way was calculated at the intersection of the moved straight line and the load-deformation curve.

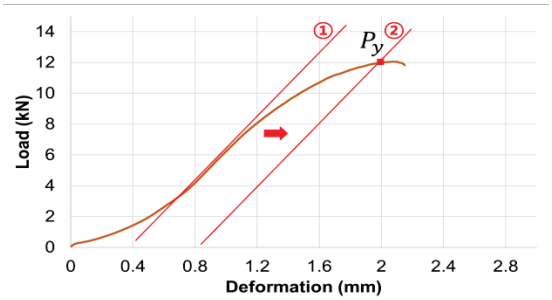

Figure 6*: Load-deformation curve at 5% offset yield load*

Figure 8 shows the average yield load of softwood with STS. The average yield load by tree species was calculated as 6.01 kN for Japanese larch, 5.47 kN for Korean pine, and 4.15 kN for Japanese cedar, with the yield load in the order of Japanese larch, Korean pine, and cedar. It appears that a higher specific gravity of the species resulted in a higher yield load.

The average yield load of the longitudinal section was the highest in all directions at 7.93 kN, the radial section was 3.69 kN, and the tangential section had the lowest yield load at 4.01 kN. The average coefficient of variation was 0.18, 0.14, and 0.18, respectively, and the reliability of the value was high.

For the longitudinal section, the loading direction and the grain direction are parallel, so it can be assumed that the resistance to the bearing load is large. This phenomenon shows a similar trend in structural glulam (Kim and Hong 2008). According to STS type, the average yield load tended to increase with increasing diameter, and the T-series had a higher average yield load than the S-series.

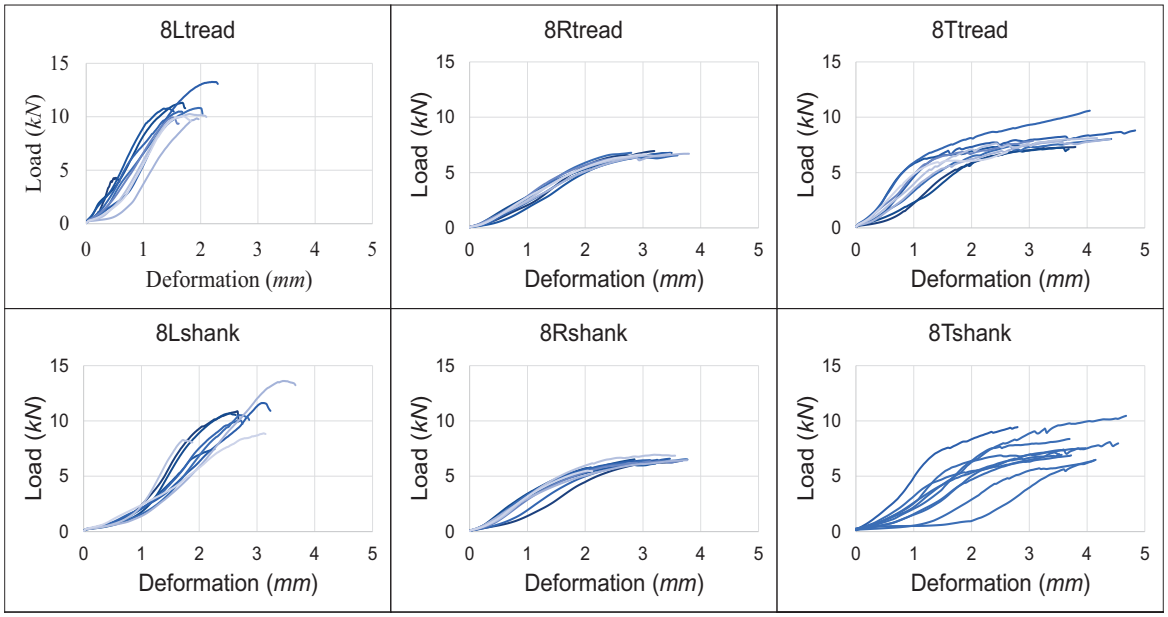

Figure 5: *Load—deformation curves of Japanese larch specimens with 8mm diameter of STS*

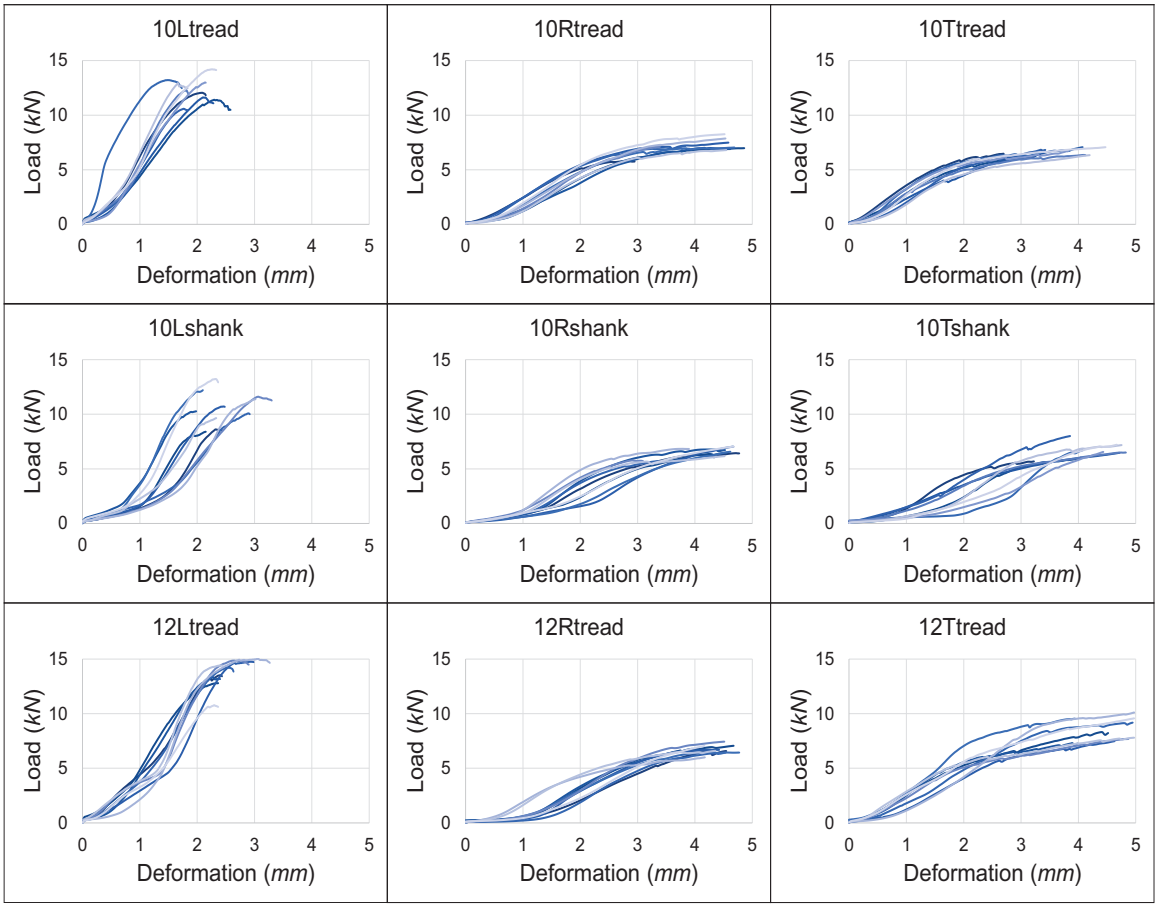

Figure 7: *Load—deformation curves of Japanese larch specimens with 10mm and 12mm diameter of STS*

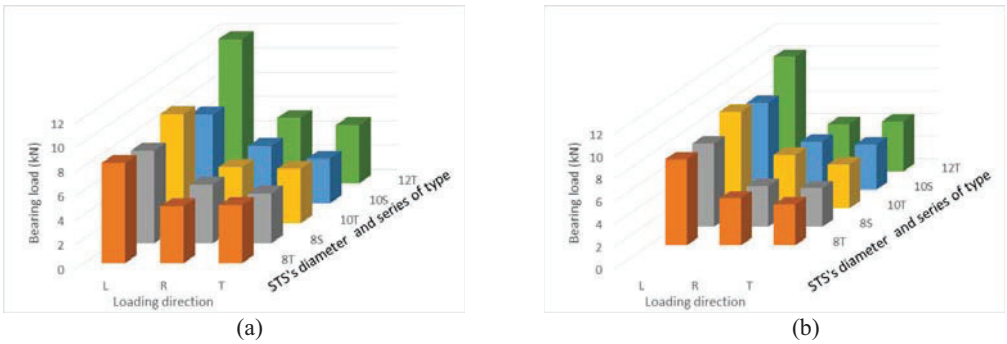
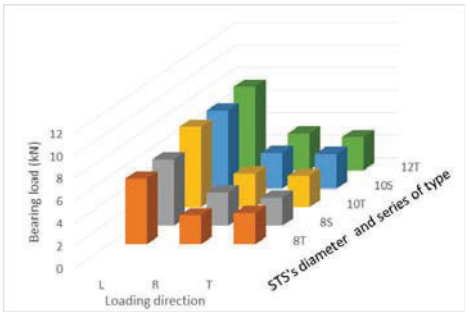


(a) (b)



(C)

Figure 8: *Relationship of 5% offset bearing load on loading direction and STS's diameter types(a-Japanese larch, b-Korean pine, c-Japanese cedar*

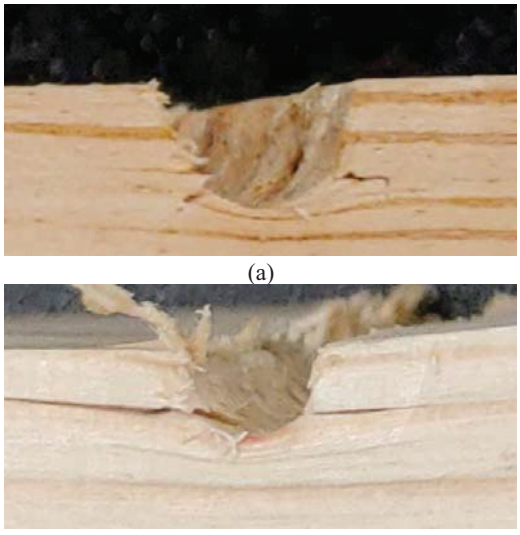
https://doi.org/10.52202/069179-0169

In case of the series of STS, the average yield load of the T-series specimens with 8mm STS was measured 0.87 ~ 1.17 times than the S-series. The average yield load of the T-series specimens with 10mm STS was measured 0.90 ~ 1.23 times than the S-series. It is considered to because the bearing area of the S-series is smaller than that of the T-series.

3.2 FAILURE MODE UNDER BEARING LOAD

Most of the failure modes of the specimens on the longitudinal section showed that the wood split slightly along the direction of the grain in parallel to the loading direction by STS.

In case of the specimens on radial and tangential secion, the failure mode of bearing area showed that the bearing load at the shank or thread part of STS were concentrated the wood in perpendicular to the grain, resulting in short cleavage. This is the same result as the failure mode for each direction of the pine wood in a previous study (Lee *et. al.* 2022).



(a)

(b)

Figure 9: *Failure mode of the radial specimens on T-series(a-Japanese larch, b-Korean pine)*

4 CONCLUSIONS

To evaluate the bearing strength performance of STS connection using domestic species, the bearing test on the loading direction to the grain was conducted. The conclusions can be drawn as follows :

1. The bearing load showed a proportional relationship with the specific gravity of the species and the STS diameter.

2. Since the effective bearing area of shank and thread parts of STS is different according to the shape's characteristics of STS, it is necessary to reflect this in the prediction formula of the bearing strength for the connection design.

INCLINED SCREW CONNECTIONS WITH INTERLAYERS: BEAM ON FOUNDATION NON-LINEAR MODELLING

Yuri De Santis[1], Angelo Aloisio[2], Dag Pasquale Pasca[3], Igor Gavrić[4], Iztok Šušteršič[5], Massimo Fragiacomo[6]

ABSTRACT: Self-tapping screws, thanks to the speed and ease of installation have become more and more popular in the last 25 years. Slip modulus and strength increase when the screw axis is inclined with respect to the normal to the sliding plane, however, in this configuration screw is subjected to axial and shear force, together with bending moment. Moreover, interlayers having poor mechanical properties are often inserted between main connected members to ensure human comfort in the buildings or because it is required by the structural system. The complex interaction between axial and transversal behaviour of inclined screws may not be fully considered by some of the simplified models in literature and codes, in this paper the behaviour of steel-to-timber connection is experimentally assessed and a finite element model of non-linear beam on foundation is validated. Experimental results are compared with the results of finite element analysis and the with Eurocode 5 model results.

KEYWORDS: Inclined screws, Load-bearing capacity, Timber-to-timber connection, Eurocode 5, Friction.

1 INTRODUCTION

Self-tapping screws are commonly used in timber-to-timber, timber-to-concrete, and timber-to-steel connections and are well suited for use in composite floors and beams. They can be easily inserted at an angle with respect to the normal to the sliding plane. In this configuration their axial resisting mechanisms can be exploited. Stiffness and strength of inclined screws can be 5 to 10 times the stiffness and strength of screws perpendicular to the sliding plane. While for screws perpendicular to the sliding plane the ultimate force is usually reached at the conventional displacement of 15 mm with a ductile behaviour, for inclined screws the failure displacement is between 1 mm and 5 mm depending mainly on the inclination angle of the screw and the connection fails mainly due to screw withdrawal or due to screw failure. However, when the screw is inclined, it is simultaneously subjected to axial force, shear force and bending moment. This strong coupling between the axial and the transversal behaviour of the screw makes difficult to predict the actual connection behaviour by means of simplified models.

The connection mechanical behaviour becomes even more difficult to model when an interlayer having structural or non-structural role is present. Often polyurethane interlayers are used for soundproofing and OSB interlayers are common in light-frame buildings.

The interlayer can be considered rigidly connected when it is glued to the main timber member. The interlayer is weakly connected when the secondary connection between the interlayer and the main timber member has negligible strength and stiffness compared to the main connection. It is the case of staples, nails and small diameter and length screws. Examples of interlayers not connected are soundproofing interlayers.

It is known that the interlayer affects the slip modulus of connections as highlighted in [1], however less studies have been conducted on the capacity of connections with interlayers.

Eurocode 5 design method for strength calculation of dowel type fastener connections is based on the Johansen's work [2]. According to European standards, the load-bearing capacity of a screw simultaneously subjected to shear and axial stress, as in the case of inclined screws connections, is given by a quadratic combination of the stress-strengths ratios for transversal and axial directions [3]. This design model might highly underestimate the strength of connections with inclined screws as highlighted by Tomasi et al. in [4].

Bejtka I. and Blaß H.J. in [5] extended the Johansen's yield theory accounting for the withdrawal behaviour of the screws. However, the complex interaction between axial and transversal stresses of inclined screws may not be fully considered in determining the plastic properties of the screws.

In recent years, several advanced three-dimensional numerical models have been proposed to study the behaviour of connections made of threaded fasteners embedded in timber. The complex screw-timber interaction, due to the presence of thread, has been modelled using various techniques ranging from the reproduction of the actual thread geometry [6] to the use of cohesive contact with damage evolution in conjunction with a fictitious material that wraps the screw and models a complex medium where steel and timber interact [7].
In order to avoid the detailed three-dimensional modelling of the screw using solid elements, some authors developed an approach based on beam to-solid coupling [8].
Also, empirical models for capturing load-slip behaviour joints with dowel-type fasteners were proposed [9, 10].
Another approach to the problem is represented by Beam-On-Foundation (BOF) modelling. According to this method, fasteners are numerically modelled as elastoplastic beams on a nonlinear foundation. BOF modelling has been used to reproduce the hysteretic behaviour and failure mechanisms of timber joints with dowel-type fasteners perpendicular to the sliding plane [11, 12].
In this paper, a BOF model capable of taking into account of the interaction between moment, shear and normal force which may lead to metal fastener yielding at loads below those predicted by the EYM is proposed. The model is able to reproduce the following mode of failure: timber crushing, screw withdrawal and screw yielding. The model also accounts for friction on the sliding plane and interlayer.
The outcomes of an experimental investigation conducted on various inclined screws timber-to-steel connection configurations with or without soundproofing and OSB interlayers are herein described and discussed. These results have been used to validate a finite element modelling approach suitable for describing the ultimate conditions.
The experimental results are also compared with the Eurocode 5 model results.

2 EXPERIMENTAL INVESTIGATION

The experimental campaign involves timber-to-steel connections with screw inclined at 45° inserted in glue laminated timber of strength class GL24h and UPN 100 steel profiles (Figure 1). The screws are self-tapping fully-threaded screws with a diameter of 9 mm and length of 240 mm or 140 mm. The characteristic ultimate stress of the screw is $f_{u,k}$ = 1000 N/mm^2. A special washer is used to restrain the screw head in the tight-fitting oval shape hole in the UPN 100 profile (Figure 2). Washers with an insertion angle α = 45◦ are common for inclined positioned screws in steel-to-timber joints. In this case the washer has the role of replacing the countersunk drill holes in the steel plate by more economically producible slots. However, due to their particular geometry, a part of the screw near the sliding plane is left free of bending. The soundproofing interlayers are made of polyurethane and are 6 mm thick and 100 mm wide whilst OSB interlayers are 22 mm thick.
Four different configurations have been considered:

- C-45-R: reference configuration
- C-45-S35: with soundproofing interlayer
- C-45-O: with OSB interlayer
- C-45-RL: reduced length of the screw

The materials and the geometries of the configurations are summarised in Table 1.

Table 1: *Configurations details*

Configuration	Interlayer	Thickness (mm)
C-45-R	-	-
C-45-S35	Polyurethane	6
C-45-O	OSB	22
C-45-RL	-	-

A detail of sliding plane between the UPN profile and the glulam member with a soundproofing intermediate layer is showed in Figure 1.

Figure 1: *Test setup detail: shear plane with soundproofing interlayer*

2.1 TEST METHODS

The typical test consisted in a standard symmetric push-out test. The specimen, consisting of 3 members and therefore 2 shear planes with a single screw per shear plane, is brought to failure by pushing the central member. The relative displacement between members has been measured through a LVDT (Linear Variable Differential Transformer). Due to the eccentricity between the load applied to the central member and the reaction that the test plane exerts on the lateral members, in the standard configuration for push-out tests the members tend to

https://doi.org/10.52202/069179-0170

separate during the test. For this reason, side members were clamped with support not able to induce pre-stress. No predrilling was applied.
The general principles for the determination of strength and deformation characteristics of joints made with mechanical fasteners are described in the European standard EN-26891 [13]. The procedure requires the knowledge of an estimated maximum load F_{est} to be determined on the basis of experience, calculation or preliminary tests, and should be adjusted if, during the execution of the tests, the mean value of the maximum load of the tests already carried out deviates by more than 20% from the estimated value.
The chosen loading procedure is divided into the following phases:

- force controlled loading from 0.0 F_{est} to 0.4 F_{est};
- force controlled holding at 0.4 F_{est} for 30 s;
- force controlled unloading from 0.4 F_{est} to 0.1 F_{est};
- force controlled holding at 0.1 F_{est} for 30 s;
- force controlled loading from 0.1 F_{est} to 0.7 F_{est};
- displacement controlled until failure or 15 mm.

The speed in the displacement-controlled phase has been set equal to 0.06 mm/s and the loading speed in all other phases has been calculated to achieve 15 mm of relative displacement in 12 min resulting in a loading speed comprised between 0.03 kN/s and 0.20 kN/s depending on the estimated maximum load.

Figure 2: *Washer for timber-to-steel connections*

2.2 RESULTS AND DISCUSSION

From the recorded measurements, the initial slip modulus, the slip modulus, the ultimate slip modulus and the maximum load have been determined.
To calculate the stiffness and ultimate displacement values net of displacement components related to local crushing at the member ends, the LVDT displacement measurements were used.
The initial slip modulus has been determined with the following definition:

$$k_i = \frac{0.4F_{max}}{\nu_{04}} \quad (1)$$

Where F_{max} is the maximum force measured up to a relative slip of 15 mm and ν_{04} is the relative slip in the first loading phase corresponding to the considered load.
The slip modulus has been determined with the following definition:

$$k_s = \frac{0.4F_{max} - 0.1F_{max}}{\nu_{04} - \nu_{01}} \quad (2)$$

Where ν_{04} and ν_{01} are the relative slip in the loading phase corresponding to the considered loads.

Figure 3: *Experimental failure modes: tensile-bending combined failure and withdrawal failure.*

The initial slip modulus and the slip modulus are summarized in Table 2. Significant reductions in slip modulus were observed for both the soundproofing interlayer and OSB interlayer.
The reference configuration C-45-R, the configuration with soundproofing interlayer C-45-S35 and the configuration with the OSB interlayer C-45-O showed a failure due to the screw failure (Figure 3) or due to screw withdrawal. The configuration with reduced length screws showed failure due to the screw withdrawal.
The average of the maximum load registered for each configuration are showed in the plot of Figure 5.
The insertion of the interlayer led to a reduction of 10% and 17% in strength in the cases of soundproofing interlayer and OSB respectively (Figure 5).
The configuration with screws with reduced length has 51% less strength than the reference connection (Figure 5).

Table 2: *Results in terms of stiffness referred to a single screw.*

Configuration	$k_{i,m}$ (kN/mm)	$k_{s,m}$ (kN/mm)
C-45-R	9,1	10,5
C-45-S35	9,1	8,1
C-45-O	4,6	5,8
C-45-RL	10,6	14,5

3 FINITE ELEMENT MODEL

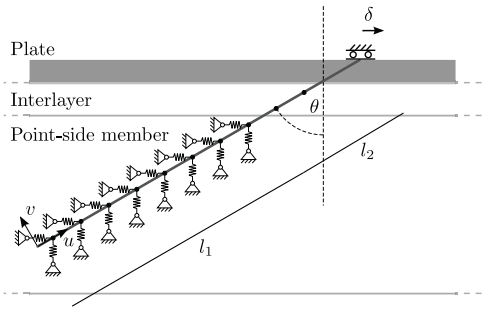

Figure 4: *Finite element model*

3.1 DESCRIPTION

The problem of the determination of the capacity of connections with inclined screws is reduced assuming a beam behaviour for the screw and describing its interaction with timber by 2-node connector elements (Figure 4).

Common screw types have negligible section variations over the screw length. Small section increments are usually made in areas without threads thus causing a partial compensation of the geometric properties. In determining the section properties, the circular section is assumed of diameter equal to 1.1 times the screw core diameter d_c as suggested for transversal capacity calculation in Eurocode 5 [3].

The beam elements used to model the screw are mono-dimensional and linear with section properties integrated during the analysis to account for the steel non-linear behaviour. An elastic-perfectly plastic isotropic behaviour is assumed for the screw steel. The Young's elasticity modulus is E_s = 210000 N/mm^2 and the mean yielding strength is f_y = 1200 N/mm^2. The reaching of high failure stress is granted by the cold forming during the production process.

The interaction between the screw and the surrounding timber along l_1 is modelled through a system of discrete connectors:

- A series of springs parallel to the sliding plane having elastic-perfectly plastic behaviour [14, 15];
- A series of springs perpendicular to the sliding plane having elastic-hardening behaviour and friction parallel to the sliding plane [14, 15];
- A rigid contact with damage between the common node between parallel and perpendicular springs and the node on the beam schematizing the screw (black dots in Figure 4).

The series of springs parallel and perpendicular are non-linear springs which schematize the embedment interaction in the grain direction and in the perpendicular to the grain direction.

Embedment is one of the fundamental load transfer mechanisms in a dowel-type connection. Due to the scale effect, the timber mechanical properties in embedment are significantly different from the mechanical properties that describe the macroscopic behaviour of a timber element. Therefore, proper tests had to be defined in order to provide suitable parameters for mechanical modelling. For a dowel-type fastener, the foundation modulus and the embedment strength can be experimentally determined via test according to EN 383.

In the model, the stiffness of each connector element parallel and perpendicular to the sliding plane has been assumed as:

$$\mathrm{K_{pa}} = \mathrm{k_h d l_m} \cos\theta \tag{3}$$

$$\mathrm{K_{pe}} = \beta \mathrm{k_h d l_m} \sin\theta \tag{4}$$

where $\mathrm{k_h}$ is the stiffness per unit of length of the beam and have been assumed as for the regression formula provided in [1] derived by interpolation of embedment test:

$$\mathrm{k_h} = (-147.8 + 30.9\rho^{0.46}\mathrm{d}^{-0.32})d \tag{5}$$

$\beta = 0.5$, ρ is the timber density, d is the screw thread outer diameter and $\mathrm{l_m}$ the length of the element between two connectors.

The yielding force of parallel to grain connector has been assumed as:

$$\mathrm{F_{y,pa}} = \mathrm{f_{h,0} d l_m} \cos\theta \tag{6}$$

$$\mathrm{F_{y,pe}} = \mathrm{f_{h,90} d l_m} \sin\theta \tag{7}$$

and the ultimate force in the direction perpendicular to the grain at a displacement equal to 2d has been assumed as:

$$\mathrm{F_{u,pe}} = \Omega \mathrm{F_{y,pe}} \tag{8}$$

where Ω has been assumed 1.72 as found by Schweigler et al. in [14, 15] where a strong hardening behaviour in the direction perpendicular to the grain is observed.

In connections with inclined screws in tension, a compression in the direction perpendicular to the sliding plane develops. This compression force generates a friction force parallel to the sliding surface. According to literature this contribution leads to an increase in slip

https://doi.org/10.52202/069179-0170

modulus and strength. To account for this effect connectors perpendicular to the sliding plane are defined as to develop a transversal force proportional to the axial force by means of the friction coefficient. The friction coefficient has been set to $\mu = 0.5$ for connections without interlayer or with OSB interlayer, while $\mu = 0.7$ has been chosen to reproduce the timber-polyurethane frictional behaviour.
The embedment strengths have been assumed as in the Eurocode 5 [3]:

$$f_{h,\alpha} = \frac{f_{h,0}}{k_{90,e} \sin^2 \alpha + \cos^2 \alpha} \quad (9)$$

where $f_{h,0}$:

$$f_{h,0} = 0.082(1 - 0.01 d_{ef}) \quad (10)$$

and where d_{ef} is the effective screw diameter and according to Eurocode 5 [3] can be assumed as 1.1 the screw core diameter d_c. α is the force to the grain angle and $k_{90,e}$ can be assumed as $1.35+0.015d_{ef}$.
The mechanical behaviour of axially loaded screws, and specifically the withdrawal behaviour depends on the interaction along the axial screw direction between the screw thread and the surrounding timber. The withdrawal failure has to be regarded as a local failure of the timber surrounding the screw.
The withdrawal behaviour is modelled through rigid-plastic connectors whose properties are defined according to the findings of Blaß et al. [16] and [17]. According to the formulation proposed by Blaß et al., the withdrawal failure stress can be estimated as follows:

$$f_{w,\alpha} = \frac{f_{w,0}}{k_{90,w} \sin^2 \alpha + \cos^2 \alpha} \quad (11)$$

where $f_{w,0}$:

$$f_{w,0} = 0.6 d^{-0.5} l_{ef}^{-0.1} \rho_m^{0.8} \quad (12)$$

and where d is the screw thread outer diameter, α is the force to the grain angle and $k_{90,w}$ is 1.2.
The associated withdrawal failure force per-connector is:

$$F_{u,E_{tr}} = f_{w,\alpha} \pi d l_m \quad (13)$$

A linear damage evolution with ultimate displacement of 4 mm is assumed to reproduce the withdrawal failure according to the findings of Bedon et al. [7] based on detailed three-dimensional finite element models and experimental outcomes of [17].
The connectors are restrained to external hinges capable of preventing translations only.
Along l_2, that is the length of the part of the screw embedded into the interlayer and the part of the screw free of bending near the sliding plane, no connectors has been considered. The part of the screw free of bending is the section comprised in the UPN web thickness. Therefore, the l_2 of the experimental case C-45-R is greater than zero, despite the absence of interlayer.
The translation perpendicular to the sliding plane and the rotation of the head-end of the screw are restrained to reproduce the clamping effect of the washer (Figure 2). At failure, contact between components is established and the washer behaves as a rotation restraint.
The relative displacement between the UPN profile and the timber members is reproduced by an imposed displacement applied to the screw head, parallel to the sliding plane (Figure 4). Therefore, a typical simulation consisted of a static incremental, displacement-controlled analysis.

3.2 VALIDATION

As highlighted in Figure 5 the finite element model tends to slightly underestimate the failure load, but it is overall quantitatively accurate. Percentage scatters are between -17% and -3%.

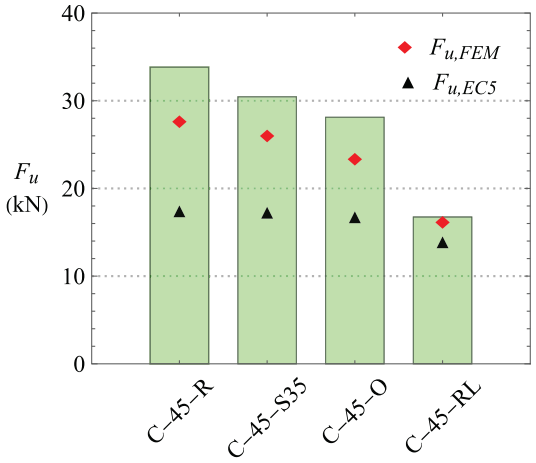

Figure 5: *Experimental (bars) and predicted failure loads with finite element model and Eurocode 5 model (markers).*

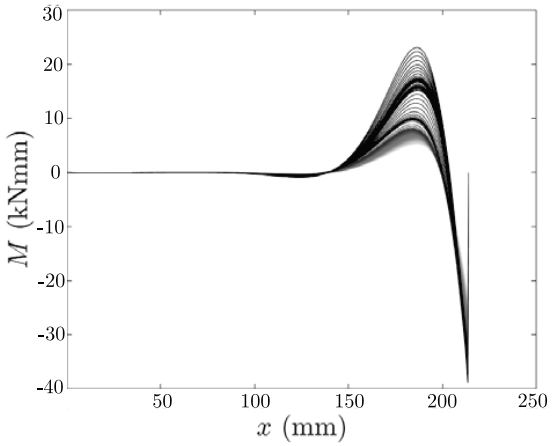

Figure 6: *Bending moment evolution in configuration C-45-R. Darker colour for higher connection slip.*

https://doi.org/10.52202/069179-0170

The plot in Figure 6 shows the bending moment diagram evolution for increasing applied displacement. When the maximum load is achieved, a plastic hinge forms in the head-end of the screw. The bending moment becomes null due to full plasticization of the section caused by the combination of axial force and bending moment.

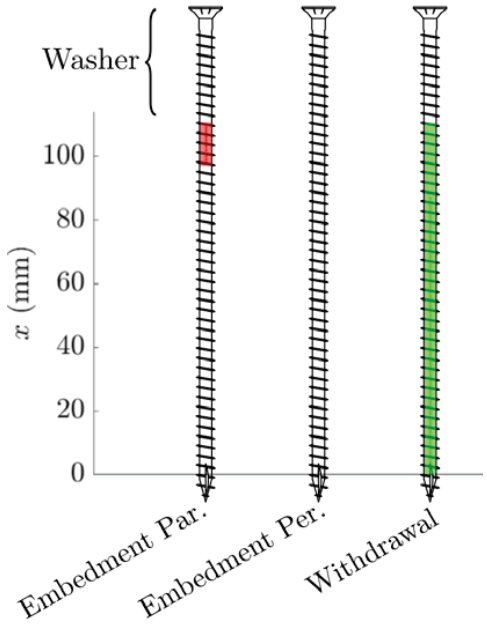

Figure 7: *Failure mode of configuration C-45-RL. Connectors in plastic range position.*

In Figure 7 the connector elements parallel to the sliding plane and the withdrawal connectors that reached plasticization at connection failure are highlighted. No connectors perpendicular to the sliding plane are found to be in plastic range at failure. For the reduced length configuration, a clear withdrawal failure is observed in the finite element model as well as in the experimental investigation. Embedment failure is confined to a zone of negligible extent.

3.3 PARAMETRIC STUDIES

The finite element model has been used to perform parametric studies. The influence of soundproofing interlayer is investigated ($\mu = 0.7$).

The first parametric study is conducted by varying l_2, the length of penetration of the screw into the interlayer plus the part of the screw free of bending, while maintaining the screw length constant (l = 200 mm and l = 100 mm). It can be observed from the plot in Figure 8 that the strength of the connection remains almost unvaried until l_2 reaches 20 mm and 10 mm in the case of 200 mm and 100 mm screw respectively. A small increase in strength is registered between the case of no-interlayer and interlayer length of penetration equal to 5 mm. This is due to the increased friction coefficient granted by the soundproofing interlayer. Moreover, the reduction in strength is more pronounced for shorter screw than for longer screw (-59% and -31% respectively).

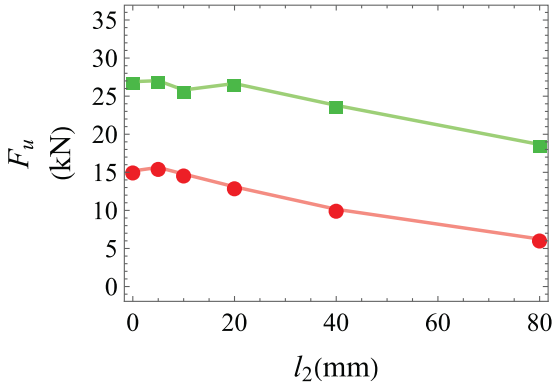

Figure 8: *Interlayer influence on FEM predicted strength for constant screw length: l = 200 mm (green) and l = 100 mm (red).*

The second parametric study is conducted varying the length l_2 while maintaining the screw length constant (l_1 = 200 mm and l_1 = 100 mm). It can be observed from the plot in Figure 9 that the strength of the connection remains almost constant. A small increase in the ultimate force can be observed for increasing l_2. This increase is caused by the increase of the friction component.

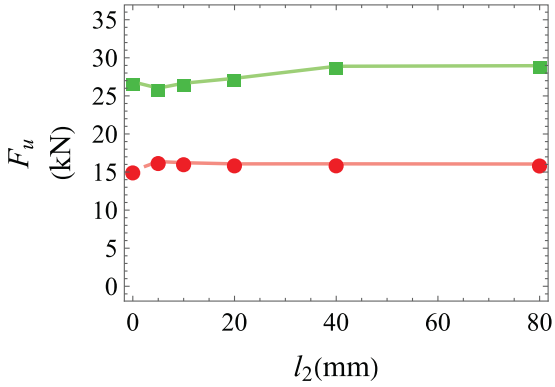

Figure 9: *Interlayer influence on FEM predicted strength for constant length of penetration into the main timber member: l_1 = 200 mm (green) and l_1 = 100 mm (red).*

4 EUROCODE 5 MODEL

The European Yield Model (EYM) is a commonly accepted procedure to calculate the capacity of laterally loaded connections with dowel type fasteners. The EYM is described in the Eurocode 5 [3] and it is based on the Johansen yield theory [2]. According to Johansen yield theory it is assumed that steel and timber exhibit a rigid-plastic behaviour. Different failure modes are identified depending on the degree of restraint that the steel plate has

https://doi.org/10.52202/069179-0170

on the fastener. According to Johansen theory [2] the transversal strength of dowel-type fastener connecting a thick plate to a timber member is given by:

$$R_{tr} = \min \begin{cases} f_h\, l_1\, d_{ef} \;\; Embedment \\ f_h l_1 d_{ef}\left(\sqrt{2 + \frac{M_y}{f_h d_{ef} l_1^2}} - 1\right) 1\ hin. \\ 2.3\sqrt{M_y f_h d_{ef}}\ 2\ hin. \end{cases} \quad (14)$$

In the EYM the rope effect can also be considered to account for the friction contribution induced by the force normal to the sliding plane generated by the deformation of the fastener.
Regarding the axial behaviour, two more failure mechanisms must be considered:

$$R_{ax} = \min \begin{cases} f_w l_1 d \min\left(\frac{d}{8}, 1\right) \;\; Withdrawal \\ f_u \pi \frac{d_{ef}^2}{4} \;\; Tensile \end{cases} \quad (15)$$

According to the current Eurocode 5 [3], a quadratic interaction between transversal and axial capacity should be considered irrespective to the combined failure modes:

$$\left(\frac{F_{tr}}{R_{tr}}\right)^2 + \left(\frac{F_{ax}}{R_{ax}}\right)^2 \leq 1 \quad (16)$$

4.1 RESULTS COMPARISON

Eurocode 5 model underestimates the capacity of all experimental configuration, despite the mean values of input parameters has been considered (Figure 5). EYM shows slightly more accurate in the configuration characterized by a lower penetration length. The scatters between EYM prediction and experimental results are between -48% and -16%.

5 CONCLUSIONS

The connection with inclined screws and interlayer exhibits a more pronounced reduction in stiffness (23% to 45%) than in strength (10% to 17%).
The quadratic combination approach prescribed by Eurocode 5 proved to be too conservative leading to an underestimation of the strength up to 48% while the proposed numerical model can predict the failure load considerably more accurately for the tested configurations (percentage scatters between 17% and -3%).
The proposed finite element model represents a valid alternative to complex three-dimensional models for the study of connections with inclined screws as it accurately describes the experimentally assessed behaviour in terms of both failure mode and failure loads. The reduced computational cost, which is associated with the reduced number of degrees of freedom, makes it suitable for carrying out comparisons and parametric analyses.
Sensitivity studies had demonstrated that the insertion of an interlayer can appreciably affect the failure load of the connection only if the sum of the length of penetration of the screw into the interlayer and the length of the screw free of bending is at least 1/10 of the screw length. Increasing the screw length to compensate for the loss of effective length into the timber member can completely compensate for the interlayer presence.

ACKNOWLEDGEMENT

This article is based upon work from COST Action Helen (CA20139), supported by COST (European Cooperation in Science and Technology).
The authors thank all the people involved in the execution of the experimental campaign.

A FRACTURE MECHANICAL AND ANISOTROPIC FEM MODEL OF THE "RECONWOOD JOINT" AND EXPERIMENTAL VERIFICATION

Jesper Kierkegaard Hansen[1], Mads Friborg Nielsen[2], Søren Gustenhoff Hansen[3], Anja Kunic[4], Roberto Naboni[5]

ABSTRACT: Contemporary capabilities in timber fabrication have encouraged the advancement of robotic manufacturing and assembly. In this paper, the *ReconWood joint*, a new type of reversible joint conceived for robotic timber assembly is investigated. The joint use CNC milled shear-keys to ensure enhanced shear capacity and more ductile behaviour over the conventional dowel-type connection. More specifically, we here establish a method for the modelling and structural analysis of such joint where the complex nature of timber is tackled by using material laws which are readily available in most commercial FE software. The paper presents a hybrid material model using the Hill Criterion in combination with fracture mechanics (CZM) to appropriately describe these behaviours. The material model is implemented in a three-dimensional FEM model to simulate the joint's mechanical behaviour, and a test series is presented to validate the modelling approach. The results show that the model is able to predict the mechanical response with great precision, both in relation to the stiffness, ultimate strength, and failure mode.

KEYWORDS: Timber joint, Solid 3D FEM, Experiments, Fracture mechanics, Anisotropy

1 INTRODUCTION

Timber is considered one of the most promising construction materials of the future due to its carbon sequestration capability, its relatively rapid circles of regrowth, and its re-use and adaptation potential while offering great mechanical performance and lightweightness [1].

The structural capacity of timber structures is often governed by the load-carrying capacity or deformations of the bolted joints. However, the past decade's development of contemporary fabrication technologies within timber engineering has led to the advancement of novel, refined, joint typologies. This paper presents a second generation of a shear-key-based bolted joint [2], specifically the *ReconWood joint,* a part of the *ReconWood construction system*. The construction system has been developed by the CREATE Group at the University of Southern Denmark (SDU CREATE), envisioning building components that are robotically assembled, dis-assembled and re-assembled, can be reconfigured into various structural and functional formations and are structurally optimised for re-use [3-5].

The *ReconWood joint* improves the stiffness and load-carrying capacity over conventional bolted joints [2]. To ensure its reusability within multiple structural configurations over time and provide a viable design and engineering tool for the reconfigurable wood architecture of the future, a reliable structural model that encompasses the complex nature of timber's strength and stiffness is crucial. As the capacity and stiffness of the joint are governed by very complex mechanisms and nonlinear material properties, a reliable model must be based on the finite element method, FEM. This paper aims to showcase a reliable model for structural analysis of the *ReconWood joint* using widely available commercial FEM software and perform an experimental verification.

This paper first introduces the *ReconWood joint* before presenting a detailed description of an appropriate material model for structural analysis of the joint. Hereafter, a *ReconWood joint* is analysed, first via FEM and afterwards experimentally. The results are compared before the paper rounds off with a conclusion.

2 THE *RECONWOOD JOINT*

The *ReconWood joint* is a part of the *ReconWood construction system* [3,4] conceived as a reusable and reconfigurable construction kit made out of discrete building blocks with reversible joints. The blocks and the joints are designed to facilitate robotic assembly and re-assembly of various structural formations as seen in Figure 1. [5]

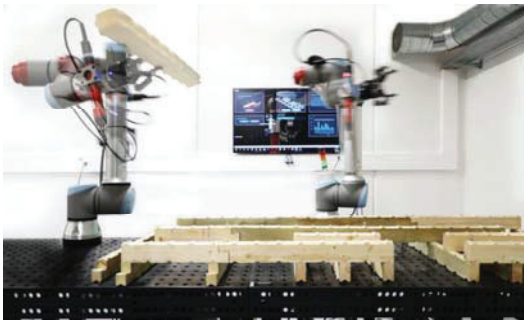

Figure 1: *Collaborative robot assembly of a ReconWood construction system*

The *ReconWood joints* are characterised by robotically milled cross-shaped male/female interlocking features, connected by a steel bolt with insert nut fasteners (Figure 2). The interlocking three-dimensional geometry of the joints assures precision and rigidity during the assembly process.

In the assembled structure, these joints ensure an increased stiffness and capacity when subjected to shear due to the shear key effect facilitated by the milled features [2], instead of activating dowel and rope actions as for the conventional bolted joints. The increased capacity results in a one-bolt joint which (*i*) eases the robotic assembly, and (*ii*) the edge distance does not govern the block dimensions. The increased stiffness of the joints is highly beneficial for the *ReconWood construction system* due to the large number of connections within such a structure, where the global stiffness is significantly affected by the joint stiffness.

3 MATERIAL MODEL FOR NUMERICAL ANALYSIS

The aim of the FEM model is to evaluate the stiffness, load-carrying capacity, and reusability of the *ReconWood joint*. To establish this, the material model must account for the complex mechanisms and nonlinear material properties of timber.

3.1 TIMBER'S MECHANICAL PROPERTIES

Timber is a complex anisotropic material due to its structure. Comprised of tube-shaped cells in a lignin matrix, the strength, stiffness, and post-peak behaviour of timber depend on the direction and the type of stress applied. [6]

The anisotropy of timber is often defined by a cylindrical coordinate system with three axes denoted longitudinal (L), radial (R), and tangential (T), see Figure 3. A common practice in timber engineering is a simplification of using the same mechanical properties for radial and tangential direction resulting in two distinctive directions: parallel-to and perpendicular-to the grain direction. [7,8]

https://doi.org/10.52202/069179-0171

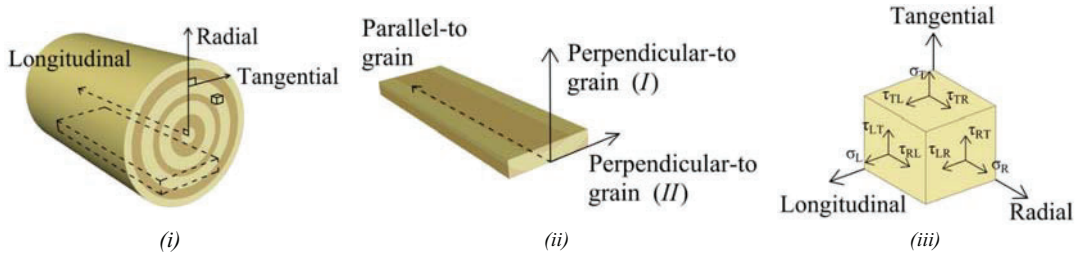

Figure 3: *Material directions of timber and 3D stress components.*

Typically, timber's properties are described for compression, tension, and shear, individually. When subjected to tension, timber can be described by linear elastic and brittle behaviour regardless of the grain orientation. However, the stiffness and strength are highly anisotropic parallel to the grain. In compression, timber has ductile behaviour with anisotropic post-peak behaviour in all directions. Compression parallel to grain direction is characterised by strain softening, while compression perpendicular to grain direction shows strain hardening. [6]

The six shear stress components, referring to the cylindric coordinate system (see Figure 3) are due to equilibrium pairwise equal ($\tau_{\mathrm{TL}} = \tau_{\mathrm{LT}}, \tau_{\mathrm{RL}} = \tau_{\mathrm{LR}}, \tau_{\mathrm{RT}} = \tau_{\mathrm{TR}}$). Each of the three pairs of stress components has an individual shear strength. The shear strength for the four parallel-to stress components ($\tau_{\mathrm{TL}}, \tau_{\mathrm{LT}}, \tau_{\mathrm{RL}}, \tau_{\mathrm{LR}}$) are almost identical and due to convenience, the lowest strength τ_{TL} is used. However, the strength for the perpendicular-to shear stress components, also known as rolling shear, is significantly lower[6,7]. The application of this is further discussed in Section 4.4.

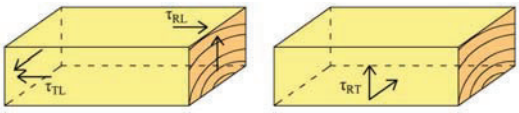

Figure 4: *Shear directions in timber*

This paper proposes a hybrid modelling approach as no available model exists that *(i)* addresses the anisotropic strength and stiffness of timber in combination with simultaneous brittle and ductile behaviour, and *(ii)* is readily implementable in commercial software. Therefore, the material model presented is divided in two - one for the brittle behaviour and one for the ductile behaviour.

3.2 MODELLING THE BRITTLE BEHAVIOUR

For the modelling of brittle failure within solid wood, three main approaches are found in the literature: *Cohesive Zone Model* (CZM) [10-12], *Continuum Damage Mechanics* (CDM) [8-9,13-14], and *lattice models* [15]. Both CZM and CDM are well-researched in the field of advanced numerical analysis of timber structures, while analysis with lattice models is mostly used in mesoscopic and microscopic fields of timber study.

While many studies have employed CDM to model the brittle behaviour of timber e.g. [8-9,13-14], the method has the disadvantage of not being able to show permanent deformations in the analysis as well as being mesh dependent with convergence problems when used in implicit code [7, 14]. As permanent deformations are essential for the analysis of the reusability of the joint, the material model presented has utilised fracture mechanics with cohesive zone modelling (CZM) to model the brittle behaviour of timber. Using CZM has the disadvantage of requiring predefined fracture surfaces, but as these fracture planes are predictable for the *ReconWood* joint, the method fits well.

Two different modes can initiate a fracture in a Cohesive Zone Model: tensile stresses acting perpendicular to the fracture plane (mode I); and tangential stresses acting parallel to the fracture plane (mode II) [16]. In this study the fracture has been restricted to mode II as only this type of failure is expected in the fracture plane. Despite it being possible to define both failure modes, including mixed-mode fracture, it is undesirable unless necessary as CZM requires substantial computational time.

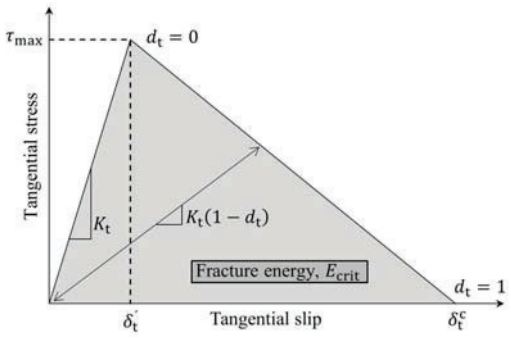

Figure 5: *Cohesive Zone Modelling, CZM, for mode II*

The progressive failure of a Cohesive Zone Model is expressed by a bilinear stress-slip law as shown in Figure 5. Damage is initiated at δ_t' ($d_t = 0$) and is completed at δ_t^c ($d_t = 1$) when the stress reaches zero value. Any further tangential slip occurs without any tangential stress.

https://doi.org/10.52202/069179-0171

3.3 MODELLING THE DUCTILE BEHAVIOUR

In the literature, the compressive behaviour of timber is often modelled as an anisotropic plastic behaviour using a single surface yield function, such as the *Hill Criterion* [10,17], the *Hoffman Criterion* [18], or the *Tsai-Wu Criterion* [19]. A popular alternative is to implement these yield functions as failure criteria within continuum damage mechanics (CDM) [8,9]. This enables the modelling of both strain hardening and softening by modifying the stiffness matrix. However, utilising CDM shows some drawbacks as mentioned in Section 3.2.

Both the Hoffman Criterion and the Tsai-Wu Criterion are modifications of the Hill Criterion introducing separate yield stresses for tension and compression. The Hoffmann Criterion obtains the capability of differentiating yield stresses in tension and compression by including terms that are linear on the stress. The Tsai-Wu Criterion extends this further by the addition of a parameter that accounts for interactions of normal stresses. [7,20] However, as each criterion expands in complexity, so does the application in commercial FE software. The *ReconWood joint* analysed in this paper is not expected to be subjected to noteworthy tensile stresses so applicability is prioritised and the Hill Criterion is utilised. The post-peak behaviour in compression is thus simplified to being ideally plastic, neglecting the direction-dependent hardening and softening.

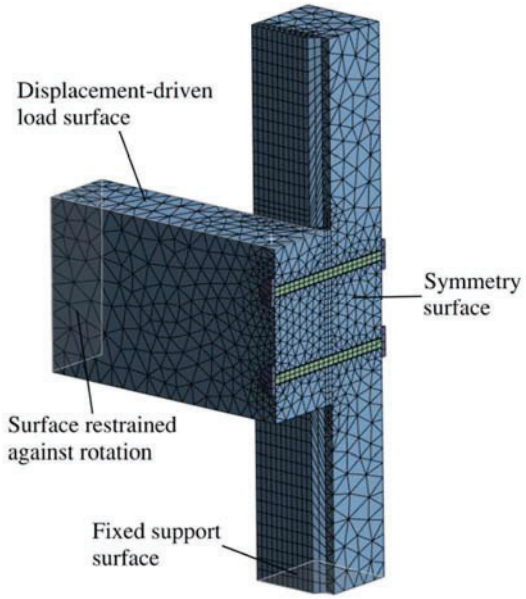

Figure 6: *FEM model with boundary conditions.*

4 FINITE ELEMENT MODEL

The aim of the FEM model is to predict the load-carrying capacity, stiffness, failure mechanism, and reusability of a *ReconWood joint*. The proposed material model is implemented in *Ansys Mechanical* for FEM analysis of the joint.

4.1 GEOMETRY

The joint in question connects two orthogonal timber blocks as used when constructing lattice structures such as that shown in Figure 2. The FEM model, Figure 6, comprises a horizontal timber block containing the male shear key part and a vertical timber block containing the female part. Dimensions of the horizontal block can be seen in Figure 7, while the vertical block is modelled as a perfect negative of the horizontal. The blocks are held together by M5 steel bolts.

4.2 BOUNDARY CONDITIONS, CONTACT DEFINITION, AND MESHING

The model is intended to represent a subpart of a larger lattice structure consisting of multiple *ReconWood joints.* When used in this manner the joints will solely transfer shear forces. Hence the FEM model is designed to investigate the joint in a state of pure shear. This is done by applying the boundary conditions shown in Figure 6.

Interaction between both the timber elements and the bolts and timber are defined by a frictional surface contact with a friction coefficient of 0.2.

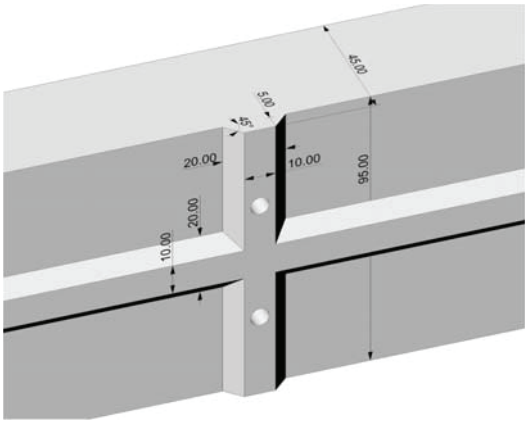

Figure 7: *Geometry of the shear key in the considered ReconWood joint*

The model is discretised with a combination of *tetrahedral* and *hex-dominant* meshes as seen in Figure 6. Generally, the parts are meshed with a size of 8 mm, while the contact surfaces are reduced to 4 mm with a fast transition. A mesh sensitivity study was carried out to balance accuracy and computing resources satisfactorily.

To decrease computational time, a vertical plane of symmetry is used.

4.3 IMPLEMENTING THE MATERIAL MODEL

The material model is implemented by utilising the built-in material laws provided by Ansys' *Engineering Data.* This is done in two steps. (*i*) The timber blocks are assigned a material defined by *Hill Yield Criterion;* (*ii*) CZM is included by defining a fracture surface on the back of the shear key as seen in Figure 8. This surface is assigned a *Fracture Energy Debonding* material for mode II debonding.

This two-step implementation enables a distinguishment between two possible failure modes and gives the option to evaluate the level of damage to the joint by analysing both the plastic strains from compression and the damage evolution on the CZM surface from shear.

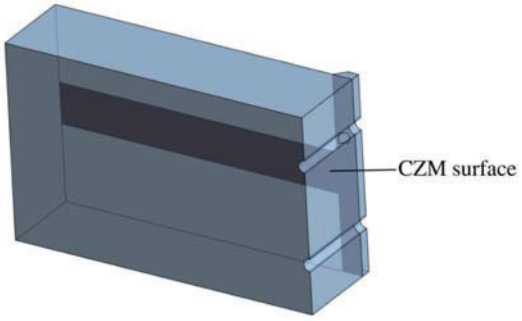

Figure 8: *Predefined fracture surface in FEM model*

4.4 MATERIAL PROPERTIES

The material properties of the timber blocks are based on the verification experiments presented in Section 5. Where applicable, the material properties are determined based on the procedure outlined in EN 384 [21] and JCSS Probabilistic Model Code Part 3 [22], while the remaining properties are based on values found in the literature. The bending strength, the bending modulus of elasticity, and the density are determined experimentally in accordance with EN 408 [23], whereupon these three properties are used to estimate the majority of the remaining properties.

The material properties used in the FEM model are given in Table 1 along with a reference to how the properties were determined. For properties determined using EN384 [21], mean reference properties are used as input in the formulas given in the standard. This is in accordance with the procedure presented in [7]. Using this method also proves to yield reasonable results by comparison with experimental data found in literature e.g. [24].

Neither EN 384 [21] nor JCSS Probabilistic Model Code Part 3 [22] give an estimate of the rolling shear strength, rolling shear modulus or Poisson's ratios. The rolling shear strength is highly discussed in the literature [7,25,26]. EN1995 [26] specifies the rolling shear strength to be approximately twice the tensile strength perpendicular to the fibre direction. This yields a mean strength of 1.2 MPa. This lies well inside the range of values that is normally suggested in other literature, therefore this value is used. Most literature suggests a rolling shear modulus of 50 MPa [7]. Hence, this is the value adopted for this model. The Poisson's ratios are often set in the range of 0.3-0.5 [7,8,27]. Values of $\nu_{LR} = 0.45$, $\nu_{LT} = 0.45$ $\nu_{RT} = 0.50$ are used in this analysis, as suggested in [8].

The bolts are assigned an isotropic linear-elastic material with Young's modulus = 210 GPa and Poisson's ratio = 0.3.

5 EXPERIMENTS

In order to verify the FEM model presented in Section 4, a test series with the same *ReconWood joint* was conducted. The test series consisted of three identical joints with the same material properties and geometry as implemented in the FEM model.

5.1 PRODUCTION OF THE TEST SPECIMENS

The specimens were fabricated using a KUKA KR240 R3330 industrial robot arm equipped with a 12 kW rotary spindle. The employed robot arm has an additional "absolute accuracy" feature, which assures precise

https://doi.org/10.52202/069179-0171

dimensions and geometry of the milled specimen, and therefore a desired tight fit of the male and female parts of the joints.

Three milling tools were exchanged during the fabrication process to produce the cross-shaped joints, utilising automatic tool change. Firstly, the 6 mm holes were drilled, generating some extra space around the M5 bolts. This was desired both for facilitating the automated robotic assembly process as well as for the performance of the joints. Secondly, a V-shaped tool with a 45° inclination blade was used to achieve the inclined sides of the cross geometry in a single cut, and finally, a flat end mill was to clear out the left material and even out all the horizontal sides of the joint.

5.2 TEST SETUP

The experiments were performed with a Zwick/Roell Z050 testing machine, applying a deformation-controlled load at 1.2 mm/min.

The test setup is shown in Figures 9 and 10. To obtain shear in an orthogonal joint, three timber elements were used. The vertical element of the joint was installed in a specially designed steel shoe and connected to the horizontal element by the *Reconwood joint* with M5 bolts. A vertical load-transferring element was likewise installed in a steel shoe and placed on top of the horizontal element. To ensure that the tests were performed in pure shear the load was applied on two knobs located directly in the joint's shear plane.

To eliminate the effects of bending and torsional moments in the joint, two bolts were used instead of one and the horizontal element was restrained against rotation by using two nail plates.

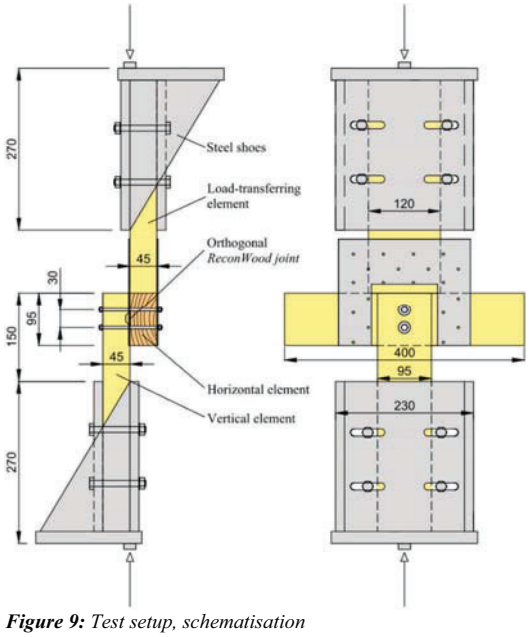

Figure 9: *Test setup, schematisation*

Figure 10: *Test setup, photo*

6 RESULTS AND COMPARISON

The FEM model is evaluated by comparison with the experimental findings, namely by: (*i*) the observed failure mechanism and (*ii*) the force-displacement response.

Additionally, the FEM model presents the option to analyse the reusability. As no evaluation of the reusability was done in the experiments, no comparison can be made. However, an assessment of the joint's reusability is made based on the FEM model and previous studies of the *Reconwood joint*.

6.1 FAILURE MECHANISM

Despite the similarity of the test specimens, two failure mechanisms are observed. The failure mechanisms are *FM1* - local compressive failure; *FM2* - shear cut-off. FM1 corresponds to a situation where the compressive strength is insufficient to carry the load without introducing irreversible deformations. FM2 corresponds to a situation where the shear strength of the keys is insufficient to carry the load, and thus the shear keys are (partly) cut off.

In the FEM model, the failure mechanism is evaluated based on the damage level at the fracture surface. FM1 is defined as the situation where the damage coefficient, d_t, has reached a value of 1 acc. Figure 5. All other situations are interpreted as FM2.

https://doi.org/10.52202/069179-0171

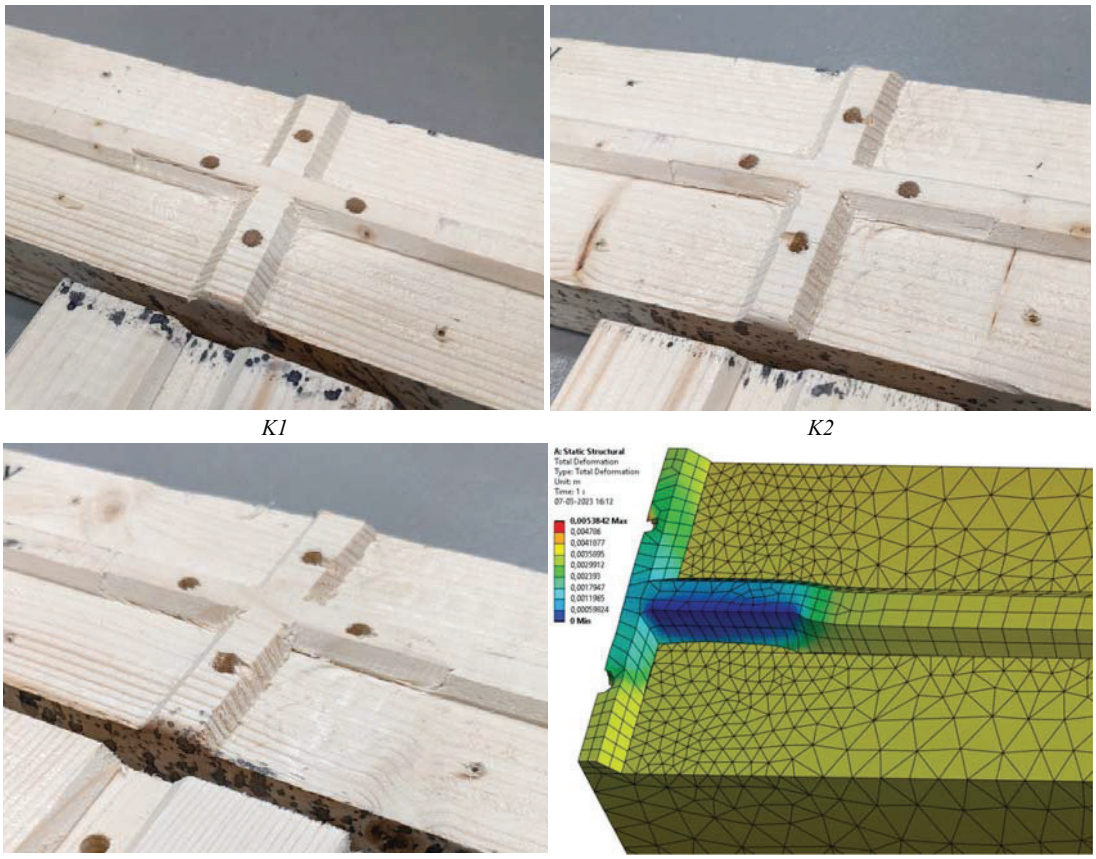

Figure 11: *Failure mechanisms found in the experimental testing and FE analysis*

For the tests, the failure mechanisms are evaluated qualitatively by visual inspection. The failure is classified as FM2 when apparent failure cracks are visible.

The observed failure mechanisms for both the FEM model and the experiments are listed in Table 2 and shown in Figure 11.

Test	FEM model	Experiments
K1		FM1/FM2
K2	FM2	FM2
K3		FM2

Table 2: *Failure mechanisms in FEM model and experiments*

6.2 FORCE-DISPLACEMENT RESPONSE

The force-displacement response curves of the numerical analysis along with the results from the experiments are shown in Figure 12. In this comparison, the weight of the test setup is included in the response of the experiments, which results in an initial load at $d = 0$ mm.

It is seen that the FEM model shows great accuracy in predicting the response of the *ReconWood joint*.

The force-displacement response curves in Figure 12 show that this type of timber joint displays a large degree of nonlinear behaviour when subjected to shear. This corresponds well with the findings in [2] which analysed an earlier generation of the *ReconWood joint*.

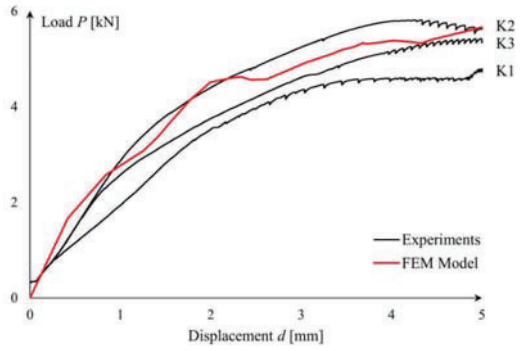

Figure 12: *Force-displacement response curves for the FEM model and the experiments*

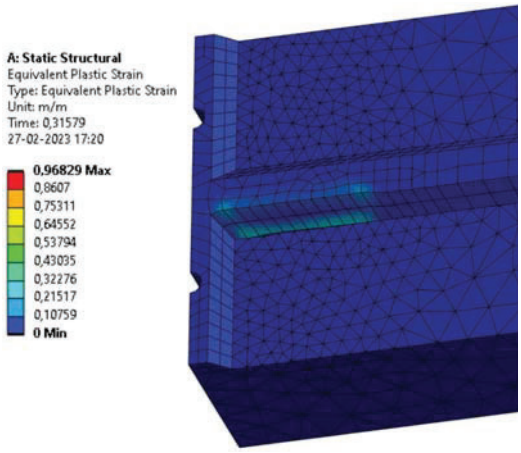

Figure 13: *Plastic strains at 3.4 kN load*

6.3 REUSABILITY

The FEM model presents the option to analyse the reusability in two ways: by permanent deformations of the timber material due to compression and by damage initiation and evolution of the CZM material due to shear.

A qualitative assessment of the reusability of the joint is presented. In Figure 13, the maximum plastic strains at 3.1 kN load are shown as the point of acceptable permanent deformations. Figure 14 shows the damage evolution of the CZM material at 4.4 kN and 5.0 kN, respectively showing the brittle failure from shear. It is seen that approximately no damage is seen at 4.4 kN before a fast escalation of damage. The threshold for reusability of the joint is set at 3.1 kN.

In earlier studies of the first generation of the *ReconWood joint,* a recommendation of 50%-60% of the ultimate capacity was proposed as a threshold for reusability [30]. By studying the FEM model it is found that this threshold gives a good indication of the reusability. The average ultimate capacity of the experiments was found to be 5.48 kN, setting the threshold for reusability at 57%.

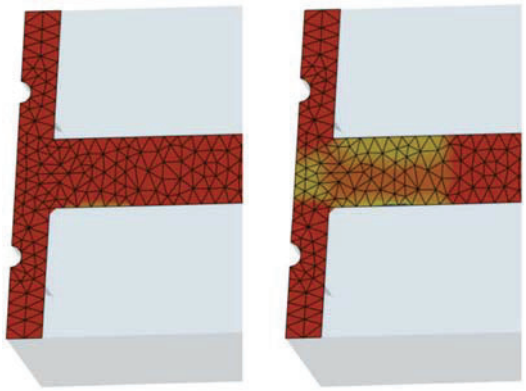

Figure 14: *Damage evolution on CZM material at (i) 4.4 kN and (ii) 5.0 kN load. Damage under* $d_t = 1$ *is marked in red; damage at* $d_t = 1$ *is marked in orange and yellow*

7 CONCLUSIONS

The present paper outlines a method for performing structural analysis of a complex timber joint using FEM along with an experimental verification. Focus has been given to developing a reliable model that can predict the mechanical response while being easily implementable in widely available FE software. This is achieved through a hybrid material model which combines two methods for capturing the complex anisotropy of timber. The ductile behaviour seen in compression is modelled as a single yield surface using the Hill Criterion, and the brittle behaviour from shear by fracture mechanics is modelled with Cohesive Zone Modelling (CZM).

The FEM model is able to predict the failure mechanism observed in the experiments satisfactorily, capturing the failure of the shear keys seen in experiments. Moreover, the model depicts the force-displacement response highly satisfactorily, capturing the stiffness degradation and nonlinear behaviour seen in experiments. The proposed model is highly implementable in conventional FEM software, which sets it apart from more advanced methods, making it accessible and useful for practical engineering applications. The simplicity in the material modelling ensures furthermore a low computational time which facilitates the modelling approach can be upscaled to an analysis of a larger structure with multiple joints.

The present study has been limited to one specific joint, and further experimental and analytical studies are necessary to investigate the applicability and validity of the proposed method to different joint configurations. Additionally, the reusability of the joints was not assessed during the tests; thus, a more comprehensive experimental program is required to expand the scope of the study and investigate the threshold for reusability of the proposed model.

NUMERICAL AND EXPERIMENTAL STUDY OF GLULAM BEAMS JOINTED WITH SLOTTED-IN STEEL PLATE CONNECTION

Sigurdur Ormarsson[1], Le Kuai[2], Musaab Ahmed Mahjoub[3], Simon Aicher[4]

ABSTRACT: The present work focuses on analysis of deformation and strength behaviour of slotted-in steel plate connections in glued laminated timber (GLT). In Eurocode 5 (EC5), the design of metal dowel-type timber joints is based on the yield theory presented by Johansen [1]. It consists of analytical expressions to calculate the lateral load-carrying capacity of single fastener joints that exhibit different (plastic) failure modes. When designing optimised multiple fastener connections that are exposed to dominating moment action, the calculation of fastener forces and their directions during progressive plasticization of the dowel group is difficult to perform manually. Therefore, a simple numerical model to simulate progressive elasto-plastic force development for every individual dowel is needed. This study presents new and simple models to analyse the bending deformations of glulam beams jointed with mechanical slotted-in steel plate connections. The proposed models were experimentally verified using results obtained from a joint project with the Material Testing Institute (MPA) at University of Stuttgart.

KEYWORDS: Jointed timber beams, steel-to-timber joints, failure modes, FE-modelling, experiments

1 INTRODUCTION

This investigation arises from the increased usage of large timber trusses jointed with slotted-in steel plate connections in bridges, long-span roofs, and high-rise buildings. For these types of structures, deformation and strength behaviour of the connections are often critical elements in the design, especially if exposed to significant in-plane moment action during varying environmental conditions. The load-carrying capacity calculations of single and double shear joints, according to EC5, are based on the Johansen theory in [1]. According to this theory the joints fail in several plastic failure modes depending on the thickness of the wood members. The shear load carrying capacity for these failure modes differs significantly in size, depending on various parameters such as wood thickness, embedding strengths, dowel diameter and yield moment of the dowel. The embedding strengths are also highly influenced by the angles between the fastener forces and fibre directions of the wood members. In design of multi-dowel connections exposed to significant moment action, a typical hand calculation of the fastener forces and their directions is too simple since the slip modulus does not consider the angle between the fastener force and the fibre direction. To study how fastener forces and their directions vary during progressive plasticization in different dowel groups, simple finite element models need to be developed. Some 3D numerical models to simulate the mechanical behaviour of multiple fastener connections have been published in recent decades, see e.g. [2–5]. These models allow for detailed analyses of the connections in terms of local slip deformations, dowel force distributions and timber failures. They are good for understanding and they can obtain results that are impossible to obtain from experiments. For example, they can show the difference in dowel force size and directions compared to the simple analytical approach used in EC5. As for disadvantage, these models are computationally costly and sometimes numerically unstable. However, the detailed results provided help us to limit the number of expensive experiments and develop more optimized and simpler analytical or numerical models. Some researchers have developed more efficient models to tackle the drawbacks of using 3D models. In [6], a two-dimensional finite element model was developed to simulate multi-dowel timber-to-timber moment-resisting connections. The timber was modelled as an elastic orthotropic material and each fastener was modelled with two nonlinear springs. A semi-analytical model based on kinematic compatibility and equilibrium considerations was presented in [7]. The disadvantage of this model is that it neglects the elastic timber deformations between the dowels. The beam on foundation modelling approach to calculate the slip displacements and load carrying capacity of the connection using nonlinear springs to simulate the embedment behaviour was also used in [8].

This study is based on the master thesis work presented in [9], where three simplified FE-models using structural elements were created to study the bending behaviour of jointed glulam beams using mechanical slotted-in steel plates. To verify the models, extensive experimental tests were performed at MPA, University of Stuttgart. The aim

of this work was to develop effective and flexible engineering models useful when designing jointed glulam beams.

2 MODELLING

To study the slotted-in steel plate connection behaviour in the studied glulam beams, three different finite element models were created. The first was a parameterized single-dowel model for double shear joints; the second was a simple beam model to simulate the global bending deformations and (ideal plastic) load carrying capacity of glulam beams jointed with a slotted-in steel plate. The connection was modelled with two nonlinear connector elements for each dowel group. The final model was a combined beam-shell model of the same glulam member using a few connector elements to simulate each dowel in the dowel groups. This work focuses on developing simple and efficient models by using effective structural elements (beams, shells, and spring-based connector elements) to simulate both global bending deformations and local dowel force distributions in glulam members jointed with slotted-in steel plate connections.

2.1 MODELING OF SINGLE DOWEL JOINTS

For single dowel (slotted-in steel plate) joints loaded to failure, EC5 shows three (plastic) failure modes for different thickness ranges. In Figure 1, these failure modes together with curves (based on Eq. 1) illustrate how the shear load carrying capacity of the joint varies with increasing wood thickness. According to EC5 the shear load carrying capacity of the (slotted-in steel plate) joint is the minimum value obtained from the three following expressions in Eq. (1), where t is the thickness

$$\begin{bmatrix} F_{v,\alpha,Rk,I} \\ F_{v,\alpha,Rk,II} \\ F_{v,\alpha,Rk,III} \end{bmatrix} = \begin{bmatrix} f_{h,\alpha,k} t d \\ f_{h,\alpha,k} d \left[\sqrt{(t+2e)^2 + t^2 + \frac{4M_{y,Rk}}{f_{h,\alpha,k} d}} - (t+2e) \right] \\ f_{h,\alpha,k} d \left[\sqrt{e^2 + \frac{4M_{y,Rk}}{f_{h,\alpha,k} d}} - e \right] \end{bmatrix} \quad (1)$$

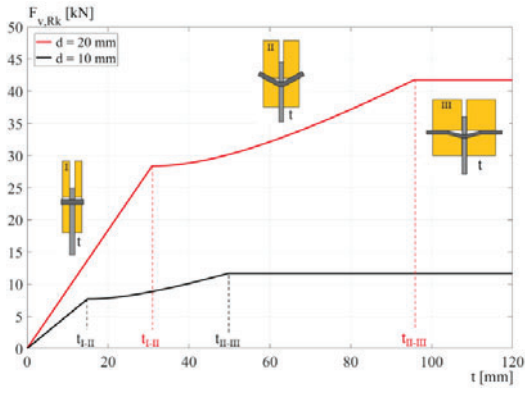

Figure 1: *Three failure modes for single dowel slotted-in steel plate joints together with two curves showing how the shear load carrying capacity varies with increasing wood thickness when* $\rho_k = 350\ [\frac{kg}{m^3}]$, $f_{u,k} = 400\ [MPa]$ *and* $\alpha = 0$.

of the wood members and d is the diameter of the dowel. The characteristic embedding strength of the wood material in the dowel force direction $f_{h,\alpha,k}$ and the characteristic yield moment of the steel fastener $M_{y,Rk}$ are given by

$$M_{y,Rk} = 0.3 f_{u,k} d^{2.6} \quad (2)$$

$$f_{h,\alpha,k} = \frac{0.082(1 - 0.01d)\rho_k}{k_{90} sin^2\alpha + cos^2\alpha} \quad (3)$$

$$k_{90} = 1.35 + 0.015d \quad (4)$$

where the characteristic wood density is ρ_k, the characteristic tensile strength of the steel material is $f_{u,k}$ and the angel between the fibre direction and the dowel force direction is α. The two limit-thicknesses t_{I-II}, and t_{II-III} shown in Figure 1 are given by

$$\begin{bmatrix} t_{I-II} \\ t_{II-III} \end{bmatrix} = \begin{bmatrix} \sqrt{e^2 + \frac{2M_{y,Rk}}{f_{h,\alpha,k} d}} - e \\ \sqrt{\frac{4M_{y,Rk}}{f_{h,\alpha,k} d}} + \sqrt{e^2 + \frac{4M_{y,Rk}}{f_{h,\alpha,k} d}} - e \end{bmatrix} \quad (5)$$

Failure mode *I* is a pure compressional failure of the wood material caused by a constant plastic embedment deformation over the cross-sectional thickness. This failure mode arises for small wood thicknesses ($t < t_{I-II}$), where the maximum moment in the dowel does not reach the yield moment of the dowel. Failure mode *II* is a mixed steel/wood failure caused by varying embedment deformation over the wood thickness. It occurs for larger wood thicknesses ($t_{I-II} \leq t < t_{II-III}$), when a yield hinge in the shear plane has developed together with plastic compressional failure of the wood material caused by combined translational and rotational embedment deformations. Failure mode *III* is also a mixed steel/wood failure caused by varying embedment deformation over a part of the wood thickness. This occurs for large thickness

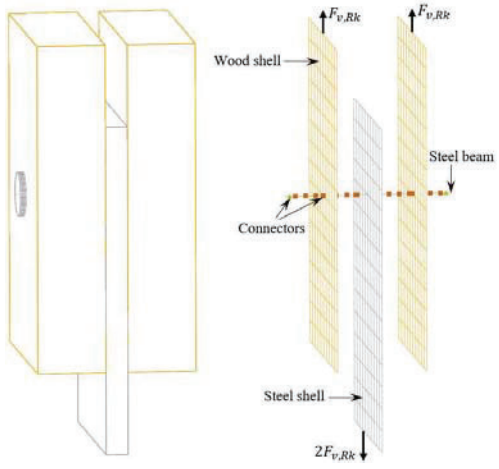

Figure 2: *Illustration of the beam and shell elements used to simulate the single dowel double shear joint.*

values ($t_{II-III} \leq t$), where the plastic clamping moment of the wood member is equal or larger than the yield moment of the dowel. Note that the expressions in Eq. (1) have no criterion concerning maximum embedment deformation related to the risk of crack initiation. The challenge here is to develop an effective FE-model (in a 3D-space) that can simulate both the different failure modes and realistic (slip-driven) elastic and plastic embedment deformations. To achieve model efficiency, the wood members and steel plate were modelled with shell elements and the fastener with beam elements; see Figure 2. Special nonlinear connector elements were also used to connect the different joint members. Both translational and rotational springs were used to model the constantly respective linearly varying elastic and plastic embedment deformations over the wood thickness. This allows us to simulate both the generation of yield hinges in the steel dowel (beam elements) and plastic embedding failure in the wood material (connector elements). The static dowel models for the three different failure modes are shown in Figure 3. The two yellow springs (translational and rotational) in Figure 3 show the two wood-to-dowel connectors used to simulate the embedment deformation of the wood. The yellow strokes parallel to the dowels represent the mechanical contacts

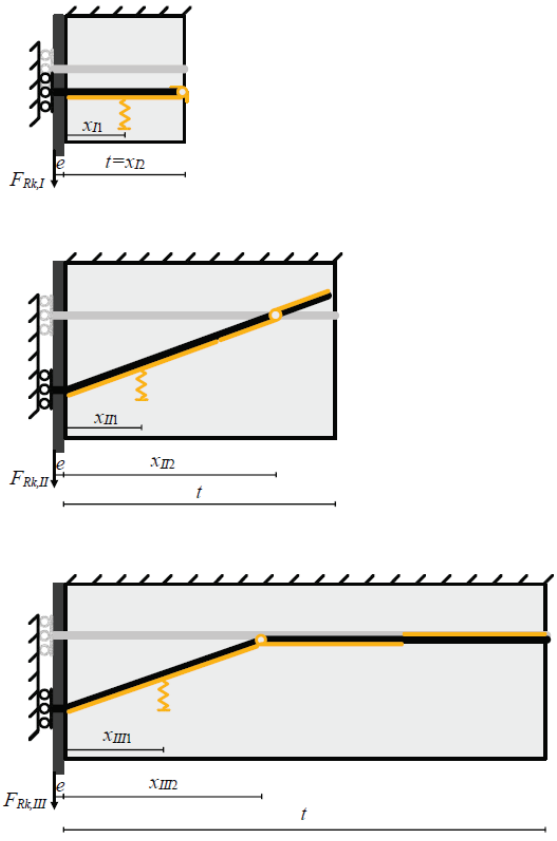

Figure 3: *Static beam-connector models used for the dowels at failure (i.e., failure modes I, II and III).*

between the wood and the dowels. Therefore, the three translational springs represent springs distributed along the lengths ($2x_{I1}$, $2x_{II1}$ and $2x_{III1}$). The translational and rotational spring stiffnesses ($k_{Iu}, k_{IIu}, k_{IIIu}$) and ($k_{I\theta}$, $k_{II\theta}$, $k_{III\theta}$) as well as the yield force ($P_{Iy,w}, P_{IIy,w}$, $P_{IIIy,w}$) and clamping moments ($M_{Iy,w}$, $M_{IIy,w}$, $M_{IIIy,w}$) for the different failure modes are calculated as

$$\begin{bmatrix} k_{Iu} \\ k_{I\theta} \\ k_{IIu} \\ k_{II\theta} \\ k_{IIIu} \\ k_{III\theta} \end{bmatrix} = \begin{bmatrix} \frac{E_{\alpha,k} x_{I1} d}{l_{\alpha,t,I}} \\ 0 \\ \frac{2E_{\alpha,k} x_{II1} d}{l_{\alpha,t,II}} \\ \frac{2E_{\alpha,k} x_{II1} d}{l_{\alpha,t,II}} (t - x_{II2})^2 \\ \frac{2E_{\alpha,k} x_{III1} d}{l_{\alpha,t,III}} \\ \frac{2E_{\alpha,k} x_{III1} d}{l_{\alpha,t,III}} \left(\frac{3(t - x_{III2})}{4}\right)^2 \end{bmatrix} \tag{6}$$

$$\begin{bmatrix} P_{Iy,w} \\ M_{Iy,w} \\ P_{IIy,w} \\ M_{IIy,w} \\ P_{IIIy,w} \\ M_{IIIy,w} \end{bmatrix} = \begin{bmatrix} 2f_{h,\alpha,k} d x_{I1} \\ 0 \\ 2f_{h,\alpha,k} d x_{II1} \\ f_{h,\alpha,k} d (t - x_{II2})^2 \\ 2f_{h,\alpha,k} d x_{III1} \\ f_{h,\alpha,k} d \left(\frac{(t - x_{III2})}{2}\right)^2 \end{bmatrix} \tag{7}$$

where $E_{\alpha,k}$ is the effective modulus of elasticity in the dowel force direction and ($l_{\alpha,t,I}$, $l_{\alpha,t,II}$, $l_{\alpha,t,III}$) are the effective lengths for the embedment deformations in the dowel force direction. Finally, the lengths shown in Figure 3 are defined as

$$\begin{bmatrix} x_{I1} \\ x_{I2} \\ x_{II1} \\ x_{II2} \\ x_{III1} \\ x_{III2} \end{bmatrix} = \begin{bmatrix} \frac{1}{2}t \\ t \\ \frac{\sqrt{(t+2e)^2 + t^2 + \frac{4M_{yRk}}{f_{h,\alpha,k} d}} - t - 2e}{2} \\ \frac{1}{2}\sqrt{(t+2e)^2 + t^2 + \frac{4M_{yRk}}{f_{h,\alpha,k} d}} - e \\ \frac{1}{2}\left(\sqrt{e^2 + \frac{4M_{yRk}}{f_{h,\alpha,k} d}} - e\right) \\ \sqrt{e^2 + \frac{4M_{yRk}}{f_{h,\alpha,k} d}} - e \end{bmatrix} \tag{8}$$

2.2 A BEAM MODEL USING TWO CONNECTORS FOR EACH DOWEL GROUP

Deflection of mechanically jointed timber beams is difficult to calculate manually, especially if the beams are unsymmetric and the connections are exposed to both

https://doi.org/10.52202/069179-0172

shear and moment action. To simulate bending of a jointed glulam with a slotted-in steel plate connection, a simple beam model in a 3D-space was created. To reduce the model size, the mechanical connections between the steel plate and wooden members were modelled with two nonlinear connector elements for each dowel group. The model geometry and locations of beams, connectors and coupling constraints for cross sections are shown in Figure 4.

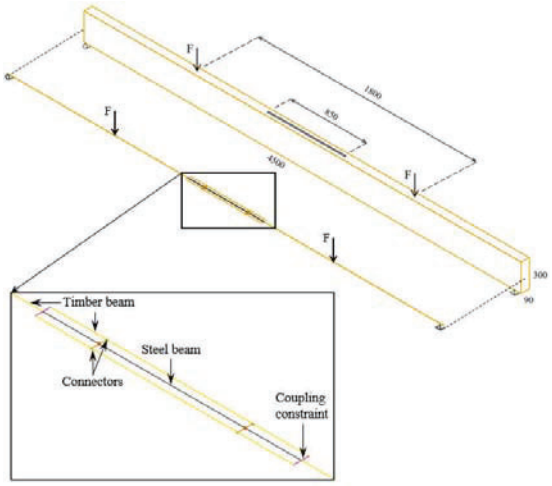

Figure 4: *A beam model of the jointed glulam which also visualizes a 3D-sketch of the beam and a close-up picture showing the most important elements in the connection part.*

Figure 4 shows how beam elements are used for the wooden members and the steel plate. To ensure that each half of the glulam will work as a single member, the two wood beams beside the steel plate are coupled (with a kinematic constraint) to the end-beams. For each shear plane between the steel plate and the wood members the joint behaviour of each dowel group was modelled with only one nonlinear connector. The connectors are placed in the centre of gravity of the dowel group and consist of three uncoupled springs to model the relative in-plane slip deformations caused by normal, shear and moment action in the joint. The stiffness values of the springs are calculated according to Eq. (9), where $E_{m,0}$, $E_{m,90}$ and $E_{m,\alpha i}$ are the mean modulus of elasticity for varying dowel force directions, l_0, l_{90} and $l_{\alpha i}$ are effective lengths for the local embedding deformation, r_i is the radii from the centre of gravity of the dowel group to the different dowels and n is number of dowels in each dowel group. To model the (ideal plastic) dowel group failure at the ultimate load, a failure moment for the rotational spring

$$\begin{bmatrix} k_N \\ k_V \\ k_M \end{bmatrix} = \begin{bmatrix} n\dfrac{E_{m,0}td}{l_0} \\ n\dfrac{E_{m,90}td}{l_{90}} \\ td\displaystyle\sum_{i=1}^{n}\dfrac{E_{m,\alpha i}}{l_{\alpha i}}r_i^2 \end{bmatrix} \quad (9)$$

was defined based on the experimental results in [10], briefly described in Section 3. This model is parametrized, i.e., it can easily be used to study how different joint configurations will influence the bending deformations of the mechanically jointed glulam beams.

2.3 A BEAM-SHELL MODEL USING A FEW CONNECTORS FOR EACH DOWEL

To simulate global bending deformations, failure modes and progressive development of the elasto-plastic force distributions in all dowels, a combined beam-shell model was created, see Figure 5.

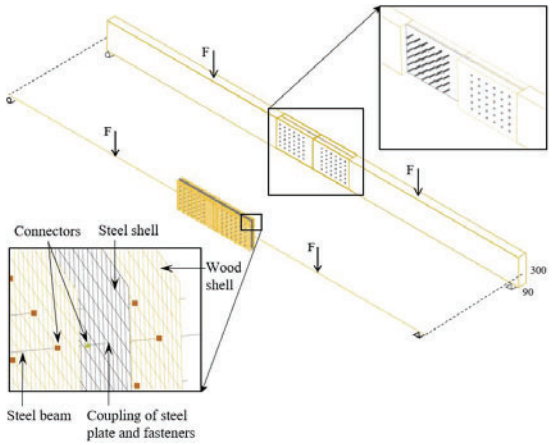

Figure 5: *A beam-shell model of the jointed glulam which also visualises a 3D-sketch of the beam and two close-up pictures showing a dowel group and the most important elements in the connection part.*

For the connection part, the wooden side members and the steel plate are modelled with shell elements, while all the steel dowels are modelled with small beam elements. The two wood shells are coupled (with kinematic constraints) to the beam elements used to model the remaining part of the glulam. The beams for the steel dowels are used as fastener elements between the steel plate and the wooden side members. Interaction between these beams and the steel and wood shells are modelled with nonlinear connector elements. Both elastic and plastic properties of the connectors are defined as for the single joint model.

3 EXPERIMENTAL STUDY

To verify the numerical model, several full-sized glulam beams with a mid-span slotted-in steel plate connection were tested in four-point bending until failure. The tests were performed at an ambient climate, with a temperature range of 20-25 °C. In total, six beams with cross-sectional dimensions of 90x300 mm were tested. Each specimen was constructed of eight stress graded wood lamellae from Norway spruce. The beams were divided into two groups, A with 10 mm dowels and B with 20 mm dowels. Beam assembly resulted in three density classes (DL, DM and DH) for each group. The average moduli of elasticity were 14.3, 15.1 and 15.7 GPa for group A and 14.2, 15.1

https://doi.org/10.52202/069179-0172

and 16.1 GPa for group B. The beams were cut into two equal parts and then re-jointed with a mechanical slotted-in steel plate connection, as shown in Figure 6.

Figure 6: *Glulam beams jointed with mechanical slotted-in steel plate connections.*

The dowel length was 100 mm, and the total number of dowels were 72 for group A and 24 for group B; see the detailed drawings of the connections in Figure 7. The dowel groups are quite different, but the rotational stiffness of group A is only 22% larger than of group B. Throughout the entire experiment, the force-displacement relationship was measured for the maximum mid-span deflection. Figure 8 shows this relationship for all the tested beams. The test results show almost similar linear relationships all the way up to the first crack initiation, when the force significantly drops followed by a jagged curve that on average is quite horizontal under a certain increase of the deflection.

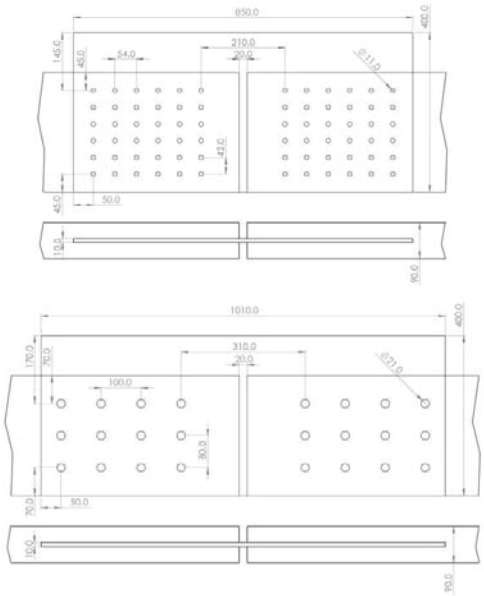

Figure 7: *Connection drawings showing the most important geometrical measures for dowel groups A and B.*

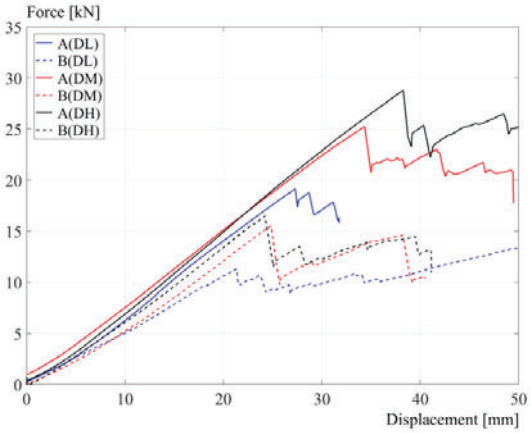

Figure 8: *Experimentally obtained force-displacement relationship for all the beams studied.*

Most of the connection failures show cracks that propagated between the bottom dowels and occasionally between the top dowels. Figure 9 shows two pictures of typical failure appearances for dowel groups A and B.

4 RESULTS AND DISCUSSION

Simulation results are here presented and discussed to show certain outputs from the models.

4.1 SINGLE DOWEL MODEL

The single dowel model was used to simulate deformations and dowel forces in slotted-in steel plate joints of different thicknesses. Figure 10 shows simulated failure modes of three different single dowel joints together with simulated and manually calculated curves that show how the shear load carrying capacity of the joint varies with increasing wood thickness.

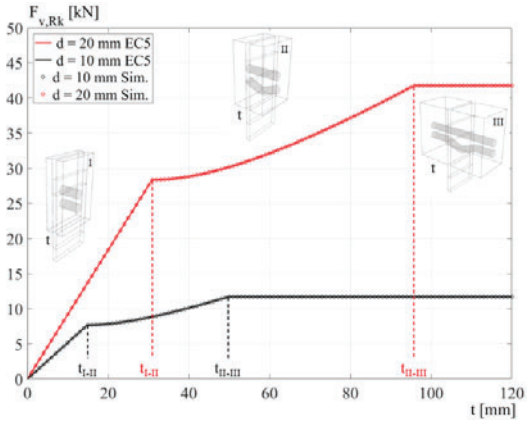

Figure 10: *Comparison of simulated and manually calculated curves showing variation in shear load carrying capacity with increasing wood thickness together with simulated failure modes of the joints.*

Figure 10 shows exact match between simulated and manually calculated load carrying capacity curves as the expected failure modes develop. However, to obtain good results, properly defining the location of the connectors and how to calculate the clamping moment of the dowels are essential. This also allowed us to consider the eccentricity of the fastener forces in the shear joint.

4.2 A BEAM MODEL USING TWO CONNECTORS FOR EACH DOWEL GROUP

This simple model was used to simulate the global bending deformations and (ideal plastic) load carrying capacity of the two tested beam types A and B. The beams had the same geometry, though they had different dowel groups; see Figure 7. The material data used in the model was mainly obtained from the test results. To illustrate some of the model outputs, Figure 11 shows typical bending deformation of beam A together with a close-up figure of the connection part. For a load of $F = 15$ kN, the maximum deflection became $u_{max} = 20.8$ mm. A similar deflection value for beam B is approximately 4% larger than for beam A. The connection of beam A thus reduces the bending stiffness by 19.2% compared with a continuous beam of the same dimensions. This could also be seen as 16.7% reduction of the cross-sectional height in the connection area.

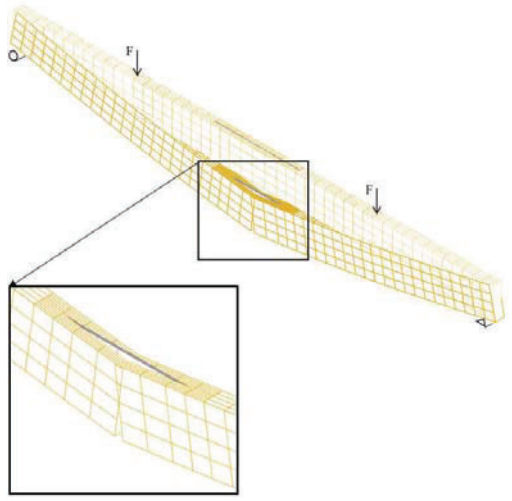

Figure 11: *Magnified bending deformation of the glulam beam A for F = 25 kN.*

The experimental results in Section 3 show a linear relationship between the external load and the deflection all the way up to failure. A typical failure occurs when cracking propagates between the bottom dowels. When cracking starts, the force drops slightly and then maintains a constant or slightly decreasing value under a certain increase of deflection. These test results were used to calibrate the model regarding stiffness and yield moment of the rotational spring. Figure 12 shows the simulated results with the experimentally obtained curves for the three glulam beams of type A. To illustrate the flexibility of the model, Figure 13 shows the bending deformation of the unsymmetric glulam beam jointed with a similar connection that is subjected to both shear and moment loading. The close-up figure in Figure 13 shows clearly the unsymmetric deformation in the connection due to the varying moment and shear forces over the length of the connection.

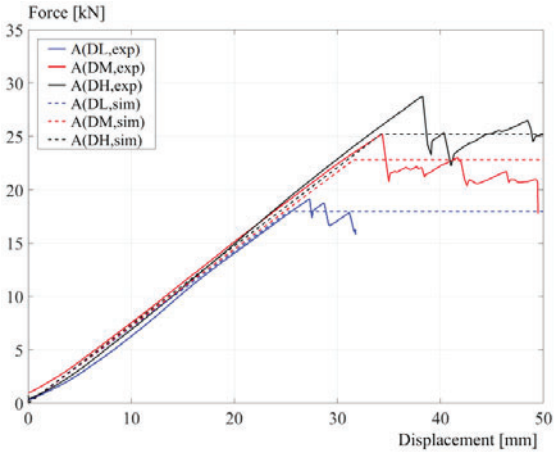

Figure 12: *Simulated and experimentally obtained force-displacement curves for the three beams of type A.*

https://doi.org/10.52202/069179-0172

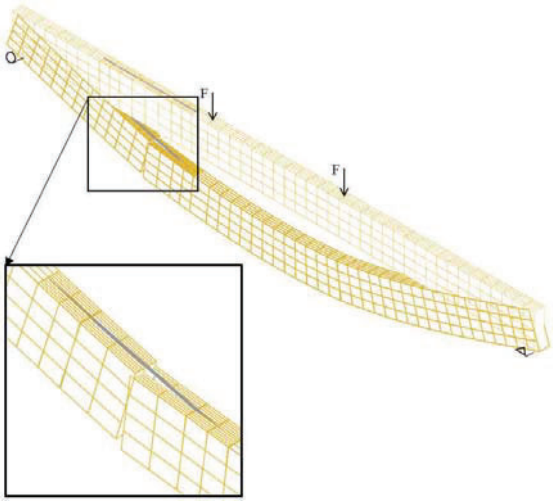

Figure 13: *Magnified bending deformation of an unsymmetric glulam beam with a mechanical connection exposed to both shear and moment action.*

4.3 BEAM-SHELL MODEL WITH A FEW CONNECTORS FOR EACH FASTENER

This model was used to simulate the experimental beams A and B to study how bending deformation and fastener force distribution develop in multiple fastener connections during progressive plasticization of the dowels.

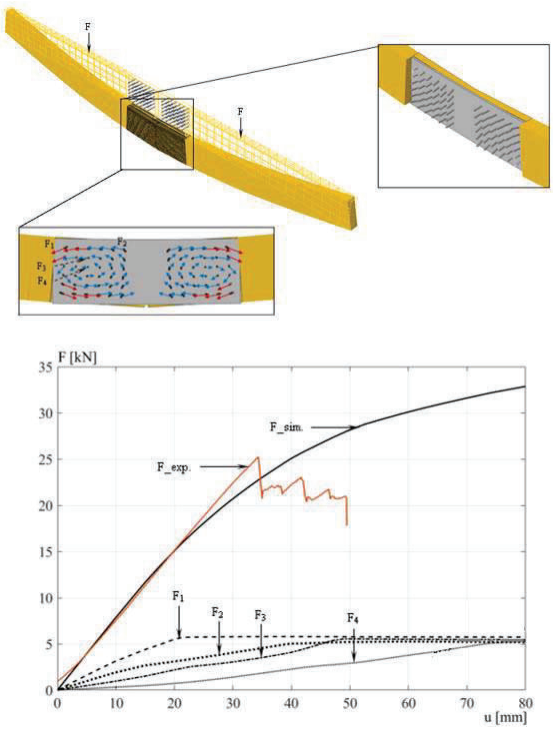

Figure 14: *Simulated bending deformation and fastener force vectors at F = 22 kN as well as simulated and experimentally obtained force-deflection relationships.*

Figures 14*(a)* and 15*(a)* show simulated bending deformations and fastener force distributions when the beams are loaded with F = 22 kN. The bending of the beams is quite similar, though beam B is slightly more curved. The fastener force distribution in beam A shows several plasticized dowels (red arrows), whereas beam B shows none (only blue arrows). The largest forces arose at the corners of the dowel groups, and their directions deviated somewhat from those used in manual calculations. Figures 14*(b)* and 15*(b)* show that the numerical force-deflection curve for beam A fit well with the test results up to a certain force value. However, the conformity was not as good for beam B. To better illustrate the dowel plasticization, the subfigure 14(*b)* also shows elasto-plastic shear force development of some selected fasteners in the dowel groups. The results show clearly how these dowels progressively plasticize during increased loading. The numerical modelling of these beams is based on stiffness data from the experimental study.

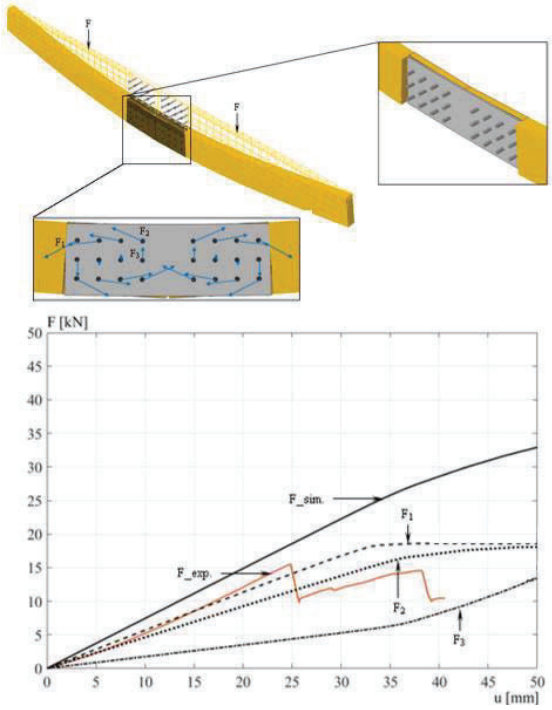

Figure 15: *Simulated bending deformation and fastener force vectors at F = 22 kN as well as simulated and experimentally obtained force-deflection relationships.*

5 CONCLUSION

This work focuses on simple and effective modelling of mechanically jointed glulam beams with slotted-in steel plate connections. The simulation models use beam, shell, and connector elements together with analytical expressions and failure modes from EC5. The single dowel model can simulate both elastic and plastic embedment behaviour of the joints in the form of

https://doi.org/10.52202/069179-0172

deformations and different failure modes. As well, the model was directly implemented when simulating multiple fastener connections where progressive plasticization of the dowel groups was studied during increased loading. Based on the experimental verification, it can be concluded that this model is useful to simulate bending behaviour and failure modes of mechanically jointed timber beams in a constant climate condition. Most numerical results agreed well with the experimental findings up to a certain level of deformation. All experimental results confirmed that these types of connections have low plastic utilization of the dowels, and instead failed in relativity brittle cracking of the wood material. An interesting fact is that beams A have slightly higher bending stiffness but almost double the load carrying capacity of beams B. This indicates that the dowels diameter has a significant impact on the load carrying capacity of jointed glulam beams exposed to dominating moment loading. Based on the experimental observation, a simple beam model was created and used to simulate both global bending deformations and (ideal plastic) load carrying capacity of the two tested glulam beams. It also turned out that the elastic load carrying capacity (with only plasticization in the corner dowels) according to manual EC5 calculations was ca 17% lower than the experimental failure value for beam A(DL) and ca 60% higher for beam B(DL).

A major advantage of the models presented are their short computational time compared to 3D models. It is concluded that these models are useful to simulate bending deformations, fastener forces and failure modes of mechanically jointed timber beams. As well, they have good potential for further development regarding large deformations to simulate rope effect in bolts and screws and moisture related dowel forces.

PERFORMANCE OF GLUED-IN RODS IN GLULAM AND MPP IN TENSION AND COMPRESSION

Alexander Salenikovich[1], Étienne Lapointe[2], Bruno Zumbrunn-Maurer[3], Thomas Brotschi[4], Anthonie Kramer[5]

ABSTRACT: This paper is focused on evaluation of the performance of glued-in rods (GIR) in Douglas-fir glulam timber and Mass Ply Panels (MPP) produced in the USA for structural applications. One of the objectives of the study was to compare the performance of GIR joints with and without recess of the bond length in tension and compression. High-strength steel threaded rods of 15.9 mm in diameter were bonded into wood members of 70 mm × 70 mm in cross-section in three configurations. In one configuration, the bond length was 20 times the stress diameter (d_s) of the rod. In another configuration, the embedded length of the rod included a machined portion (constriction zone) near the end of the wood member, which created a recess (not bonded length) of 4d, while the bond length remained the same (20d_s). In the third configuration, the bond length was 24d_s without a recess. Test results clearly demonstrated the benefits of a recess in GIR joints to increase the structural efficiency of timber connections. No GIR buckling was observed in compression tests.

KEYWORDS: Bonded-in threaded rods, GSA Technology, Mass Ply Panel (MPP), splitting, stiffness of GIR joints

1 INTRODUCTION

With growing demand in multistorey mass timber construction, there is a critical need in efficient, reliable, fire-resistant, and aesthetically pleasing connections. Joints with glued-in rods (GIR), if properly designed and executed, meet these requirements. Glued connections are strong and rigid, but due to inherent weaknesses of wood in shear and low splitting resistance, they may provoke undesirable premature brittle wood failures leading to a catastrophic collapse if not taken into account in design. It is desirable to optimize the joints to achieve an equivalent strength and stiffness with the wood structural elements while minimizing the risk of brittle wood failures [1].

Connections with GIR connections have been successfully applied in large-span timber structures in Russia since the 1980s [2], which resulted in the design provisions for GIR [3]. During the last decade, several adhesives for use with GIR systems in timber structures have been developed and approved in Europe [4],[5],[6],[7],[8],[9],[10]. Common rules for the assessment of GIR have been adopted in EU in 2019 [11]. Testing requirements for GIR in glued structural timber products have been adopted in 2021 [12]. Basic provisions for design of GIR for timber connections are now given in EOTA TR 070 [13], and considered in the Eurocode 5 draft [14]. Nowadays, developers seek approval of GIR technologies in North America.

One of the main objectives of this project was to facilitate the development of acceptance criteria for factory installed glued-in rods in wood structural elements to be evaluated for the use in mass timber construction in North America [15]. In addition, the test program was undertaken to compare the performance of GIR in static tension and compression and to demonstrate the advantages of the special rod design used in the GSA Technology.

2 METHODOLOGY

The experimental study was conducted on high-strength steel threaded rods of the class B7 [16] of 15.9 mm (d = 5/8 in.) in diameter bonded at the ends of wood members using the GSA adhesive, a two-component epoxy resin. The high-strength steel was used to minimize the chance of the rod yielding and to force the failure of the bond line or of the wood. The wood members were Douglas-fir glulam timber (GLM) and Mass Ply Panel (MPP) [17] of 70 mm × 70 mm in cross-section. In the first configuration (Series "20d"), the bond length was 267 mm, approximately 20 times the stress diameter (d_s) of the rod. In the second configuration (Series "20d-c"), the embedded length of the rod included a machined portion (constriction zone) near the end of the wood member, which created an additional recess (not bonded length) of 51 mm (14+51 ≈ 4d), while the bond length remained the same (≈ 20d_s). This configuration was representative of the GSA Technology [4]. In the third

configuration (Series "24d"), the bond length was 317 mm (≈ 24d_s) without a recess. Five specimens were fabricated and tested for each configuration and wood material. The dimensions of steel rods are illustrated in Figure 1. The definitions of the variables are depicted in Figure 3. The values of the variables in each test series are summarized in Table 1.

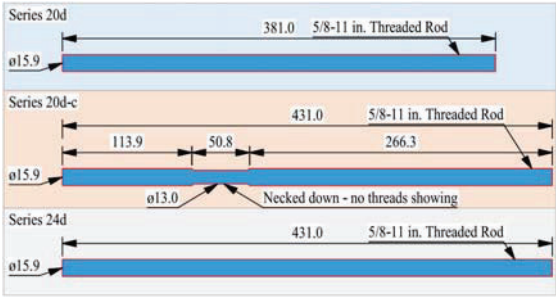

Figure 1: *Dimensions of steel rods*

At first, the specimens were tested in tension by static loading using self-centering pinned fixtures in accordance with ISO 6891 [18] loading procedure until failure at one end. The speed of testing was chosen so to achieve failure within (5 ± 2) minutes. The slip of the joints was measured using three laser-displacement sensors at each end (see Figure 2). The reference plates were glued at the ends of the wood member and the mounting platform for the laser sensors was attached to the ends of the rods with nuts and Belleville washers. The distance between the member end and the mounting platform of the laser sensors was 46 mm in the tension and 26 mm in the compression setup. After the tensile test, the wood member was cut in half, and the surviving joint was tested in compression with a ramp load at the same speed. The load was applied until failure or until the load head reached 15 mm displacement. The maximum load, the slip, the elastic stiffness (slip modulus), and the failure mode were determined for each test. The specific gravity and moisture content of wood members were measured in accordance with ASTM D2395 [19] using full cross-section samples cut near mid-length of each specimen.

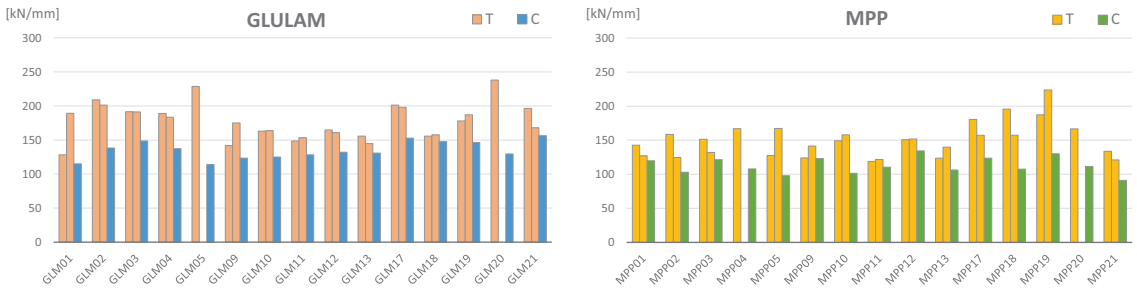

Figure 5: *Slip modulus*

3 RESULTS AND DISCUSSION

A total of sixty tests have been performed in this campaign. Load-slip graphs for each specimen are depicted in Figure 4. For the tensile tests, only the graphs of the failed end are shown. Based on the load-slip data, the slip modulus (k_s) was calculated in the range between 7 kN and 14 kN, which represented 10% and 40% of F_{est} = 70kN. For the tensile tests, the slip modulus was determined for both ends. The values of k_s for each specimen are illustrated in Figure 5.

https://doi.org/10.52202/069179-0173

The statistics for each test series, including the maximum load (F_{max}), the slip modulus (k_s), and predominant failure modes are shown in Table 2 for glulam and in Table 3 for MPP. The mean values and CoV in parentheses are shown for F_{max} and k_s. The moisture content at test and the specific gravity (oven dry mass / oven dry volume) of the specimens are given in Table 4. Typical failure modes of GIR in glulam and in MPP are illustrated, respectively, in Figures 6 and 7, where the top row shows the failures in tension and the bottom shows the failures in compression.

Table 2: *Summary of test results for GIR in DF glulam*

Series	Load direction	F_{max} [kN]	k_s [kN/mm]	Predominant failure mode
20d	Tension	86.4 (8.4%)	190 (14%)	Splitting
	Compression	110 (7.2%)	131 (12%)	Splitting
20d-c	Tension	96.3 (2.9%)	157 (6.6%)	Pull out
	Compression	108 (7.4%)	128 (2.9%)	Push in
24d	Tension	83.7 (13%)	187 (14%)	Splitting
	Compression	109 (8.9%)	146 (7.1%)	Splitting

Table 3: *Summary of test results for GIR in MPP*

Series	Load direction	F_{max} [kN]	k_s [kN/mm]	Predominant failure mode
20d	Tension	60.8 (18%)	144 (12%)	Splitting
	Compression	86.3 (7.0%)	110 (9.5%)	Splitting
20d-c	Tension	67.8 (11%)	138 (11%)	Splitting
	Compression	105 (4.5%)	115 (12%)	Splitting
24d	Tension	68.7 (4.9%)	169 (19%)	Splitting
	Compression	96.7 (29%)	115 (12%)	Splitting

Table 4: *Moisture content and specific gravity (mean and SD)*

Series	Glulam		MPP	
	MC	SG	MC	SG
20d	13.2% (0.6%)	0.519 (0.049)	9.0% (0.5%)	0.531 (0.020)
20d-c	13.1% (0.5%)	0.504 (0.021)	9.4% (0.4%)	0.549 (0.012)
24d	12.8% (0.3%)	0.528 (0.018)	8.6% (0.5%)	0.511 (0.017)

From the test results on GIR in glulam (Series GLM), the following observations were made. The GSA GIR joints (Series 20d-c) showed the highest strength, with the least variability and, most importantly, predominantly favourable failure modes – pull out in tension and push in – in compression. The strength of joints appeared to be independent of the specific gravity of wood. The GIR joints without the constriction zone were somewhat stiffer, but they were weaker and all, but one specimen, failed by wood splitting when loaded in tension. When loaded in compression, all GIR joints in glulam showed a higher resistance than in tension; the maximum load and the variability were independent on the configuration. No buckling of rods was observed, although the maximum loads approached or exceeded the minimum specified yield load of steel.

GIR joints in MPP failed by splitting in 100% of the tests, which led to a lower resistance than expected. The resistance and the stiffness of these joints in tension and in compression were lower than in glulam.

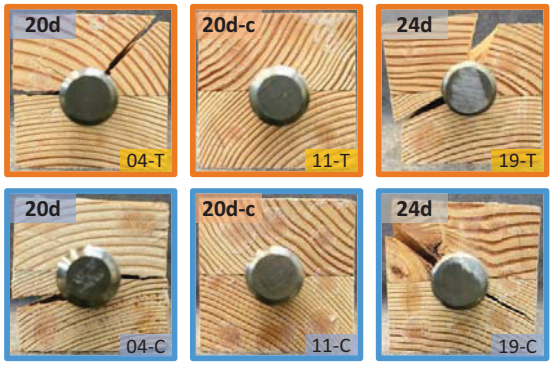

Figure 6: *Typical failure modes of GIR in glulam*

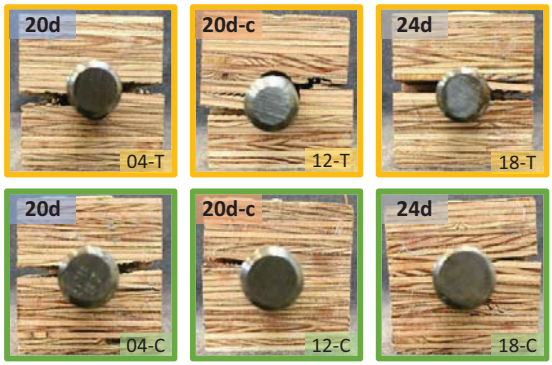

Figure 7: *Typical failure modes of GIR in MPP*

After the tests, each specimen was cut open along the rod to inspect the quality of the manufacturing and further investigate the failure modes and potential reasons for the splitting. It was established that in many cases rods were installed with an inclination of the axis up to 1.6° from the axis of the wood member. Not optimal drilling technology (Auger Bit) is considered as a reason for this misalignment of some predrilled holes in the wood member. Examples are shown in Figure 8. The deviations of the axis were especially frequent in the MPP specimens. These deviations resulted in the eccentricity of the load application, which may have exacerbated the propensity of wood for splitting. However, the investigation showed that the GIR with the largest inclination between the two rods in the specimen did not always fail first in the tension test.

4 CONCLUSIONS

The presented test campaign served for the development and validation of the first edition of the acceptance criteria ICC-ES AC526 for factory installed glued-in rods in wood structural elements for the use in mass timber construction in North America [15]. The developed test procedure and setup with three displacement sensors allowed evaluating the strength and stiffness of GIR in mass timber with high precision. The static test results clearly demonstrated the benefits of recessing the effective bond length in GIR joints to increase the structural efficiency of timber connections. It was demonstrated that resistance in compression was not compromised, and the GIR joints reached the maximum loads without lateral buckling of the rods. It was also observed that the deviation of the rod from the axis of the wood member during fabrication exacerbates the propensity of wood for splitting. Lastly, it was evident that the tested MPP specimens were undersized and were susceptible to splitting; therefore, aiming for a similar resistance per rod, GIR joints in MPP would require larger spacing and edge distances in real structural applications.

ACKNOWLEDGEMENT

Jean Ouellet and Félix Pedneault, technicians at the Renewable Materials Research Centre (CRMR) at Laval University, developed the test setup. Étienne Lapointe conducted the tests at FPInnovations laboratory in Québec City.

QUASI-STATIC CYCLIC TESTS OF NOVEL HIGH-PERFORMANCE SHEAR-CONNECTORS FOR MASS-TIMBER PANELS

Blériot V. Feujofack K.[1], Cristiano Loss[2]

ABSTRACT: In this work, the results from quasi-static cyclic tests on a novel hybrid steel-grout shear connector for cross-laminated timber (CLT) panels is presented. These tests are part of a set of experimental, analytical, and numerical studies aiming at developing a reliable and resilient hold-down connection for CLT panels in mass-timber construction. The cyclic tests have been done based on monotonic-test results, and all cyclic loading was done below the yield point of each connector. From cyclic-test results, mechanical characteristics, namely, the secant loading stiffness and the residual slip were evaluated and are discussed in this paper. Furthermore, analyses using a Gaussian process regression machine learning algorithm were conducted in order to predict the mechanical characteristics of connectors in function of a vast number of inputs, including geometrical properties of connectors, mechanical properties of each material used, and physical parameters such as the position of lumber laminates in the CLT. It was shown that the steel rod diameter, the grout diameter, and the curing time of the grout are the most influencing parameters regarding the secant loading stiffness of connectors. As for the residual slip, it was found that the grout diameter, the steel rod grade, and the position of face-laminate joints in the CLT are the most influencing parameters. In overall, the results of this work contribute to an improved understanding of the connection under development and confirms the resilience of individual connectors under cyclic loads.

KEYWORDS: CLT, Hybrid steel-grout connector, Quasi-static cyclic, Hysteresis, Secant loading stiffness, Residual slip, Gaussian process regression algorithm, machine learning

1 INTRODUCTION

Mass timber construction is increasingly growing attention among architects, engineers, and other practitioners. Factors such as ease of hybridization, high sustainability potential, along with the better performance of mass timber products under fire motivate building regulators to relax timber buildings' height limitations around the world. For instance, timber buildings can now reach up to 25 m in Australia; 12 stories in Canada; and 18 stories in the USA [1]. Although the development of novel mass-timber products and hybrid timber-based systems can result in high-performance solutions for tall buildings, the structural efficiency of those buildings heavily depends on the connection technologies employed. Various connection technologies have to be reinvented in order to suit the needs of mass-timber construction, among which dowelled hold-downs connections. Research has already been initiated for such connection technologies [2]. The few solutions proposed remain very embryonic, and the observed performance are not always satisfactory, as brittle failure in wood is engaged before developing yielding in the connectors. Therefore, the need for reliable, resilient, and high-performance dowel-type connection technologies for mass timber components is becoming increasingly critical. In this work, the results of quasi-static cyclic tests on a novel hybrid steel-grout shear connector for cross-laminated timber (CLT) panels are presented. Precisely, this work is part of a research program aiming at developing a reliable and resilient hold-down connection for CLT panels in mass timber construction.

2 METHODS

2.1 Description of the hybrid connector

The hybrid shear connector developed and tested in this work consists of a threaded steel rod embedded into cross-laminated timber (CLT) through a thick layer of epoxy-based grout mixture. With specific reference to Figure 1, each connector unit includes:

- A steel threaded rod, which ensures the transfer of shear forces from side members to the connector and conversely. In this study, three steel rod diameters were used and tested, namely 20 mm, 24 mm, and 30 mm. Additionally, two steel rod grades were accounted for, namely 4.8 strength class and 8.8 strength class.

• An intermediary thick layer of epoxy-based grout, which enables to embed the threaded rod into the CLT panel (wood). More importantly, this intermediary layer of epoxy-based grout enables to reduce stress and strain on wood, delaying crushing and failure in wood to a great extent. In the current study, the diameter of the grout was varied in function of the diameter of steel threaded rods. The grout-to-rod diameter ratio was set to 2, 3, and 4.

• A CLT block, into which the steel rod and the grout layer are embedded. A 3-ply CLT with fixed thickness of 105 mm was studied. Two CLT grades were used, namely machine graded CLT (E), and visually graded CLT (V). In addition, the CLT block size was varied from 280 mm to 340 mm, to 420 mm, in function of the diameter of steel threaded rods used.

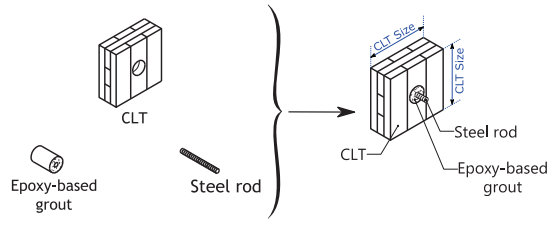

Figure 1: *Individual components (left); the hybrid steel-grout connector (right) for CLT panels*

Shulman and Loss [3], [4] conducted an extensive experimental campaign on this connector and provided insights on the actual structural performance of such connectors under monotonic loading.

2.2 Rationale for conduction of cyclic testing

The shear connector presented in this work is expected to be wood-damage-free and de-constructable. For such goals to be attained, it is important for the connector to remain elastic throughout the building lifespan. For static loading, the connector has been proven to display a high slip modulus and a clearly identifiable yield point [5]. However, repeated cyclic loads can lead to permanent deformation into the connector, even for small load amplitudes. Given that buildings are often subjected to recurrent cyclic loading such as regular winds or gusts, and sometimes earthquakes, it is important to determine the behaviour of the connector under repeated cyclic loading.

In the aim of determining the mechanical properties of the connector when subjected to cyclic loads, load-controlled quasi-static cyclic non-reversed tests were conducted on connectors. The tests were non-reversed, because in the scenario where connectors are used in hold-down connections, each connector is loaded in one direction only: the full reverse of loads does not occur for individual connectors. Three replicates of all the variants tested by Shulman and Loss [3], [4] were fabricated under the same condition and stored for at least seven days, before proceeding to testing. The testing campaign was set to evaluate to what extent cyclic loading, below the connector's yield strength, negatively impacts the connector strength, stiffness, and overall integrity.

2.3 Testing program

2.3.1 Design of experiments

The size of specimens and testing method were set based on monotonic-test results conducted in early 2021 by Shulman and Loss [3], [4]. Cyclic tests were load-controlled, and the amplitude of cycling was kept below the yield point for each connector. As shown in Figure 2, experimental variables include the grade of the CLT panel, the diameter of the steel threaded rod, the strength class of the steel threaded rod, and the ratio between the grout diameter and the steel rod diameter. The combination of all experimental variables yielded a total of 30 connector variants. Each test was replicated thrice, leading to a total of 90 tests for this study.

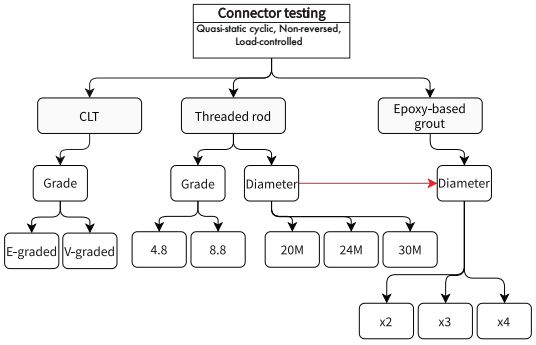

Figure 2: *Experimental variables and their associated levels*

2.3.2 Loading protocol for cyclic testing

The loading protocol was crafted from European [6] and American [7] standards. For each connector variant, the reference maximum load ($\boldsymbol{F_{max-cyclic}}$) was set as the average yield load ($F_{y,mean}$) obtained from monotonic tests by S. Shulman and C. Loss [3], [4]. Then, cyclic loads were applied on connectors by steps, at 5%, 20%, 40%, 60%, 80%, 90%, and 100% of $F_{y,mean}$. Figure 3 shows a graphic of that loading protocol. Specifically, only one cycle was applied at the first load step. For each subsequent load step, five non-reversed loading cycles were applied. The loading speed was set at one cycle per two minutes, for a total of 62 minutes per test. Figure 3 presents the loading protocol of the connector variant 280–E–20M–4.8–2d. Table 1 shows the characteristics of this connector variant such as the CLT block size and grade, the steel rod diameter and grade and the grout diameter; each load step, as well as number of cycles per steps are also provided.

https://doi.org/10.52202/069179-0174

***Table 1**: Loading protocol sample*

Specimen: 280 – E – 20M – 4.8 – 2d				
CLT size	CLT grade	Rod diameter (d)	Steel class (rod)	Grout diameter
280 mm	E	20M	4.8	2d

$$F_{max-cyclic} = F_y = 74.58\ kN$$

Loading schedule					
Steps	Number of cycles	Load percentage (%)	Actual load (kN)	Loading speed (kN/min)	Total time (min)
1	1	5	3.73	3.73	2
2	5	20	14.92	14.92	10

6	5	90	67.13	67.13	10
7	5	100	74.58	74.58	10
Total					62

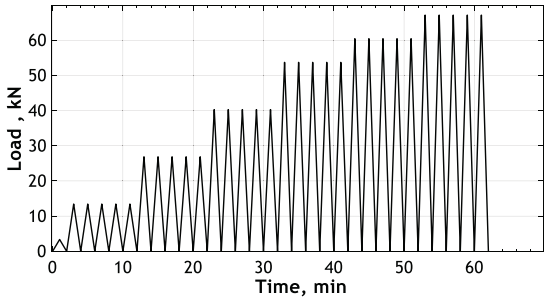

***Figure 3:** Graphic representation of the loading protocol*

All tests were conducted in the Timber Structural and Mechanical Lab at the University of British Columbia, using a custom-made test apparatus, as shown in Figure 4. Throughout the tests, the load was measured and recorded using the built-in load cell of the MTS machine. The slip of the connector was measured with two linear voltage displacement transducers and recorded using a standard data acquisition system. The load and slip data were acquired with a frequency of 4 Hz. Furthermore, physical and environmental variables such as moisture content of the CLT were duly recorded during the tests. In addition to the geometry and mechanical properties of the steel threaded rod, the layer of epoxy-based grout, and the CLT block, parameters such as the number of knots in the loaded end of the CLT and the position of the connector with respect to edge joints in the CLT face lamellae (Figure 5) were recorded as covariate for the predictive models to be developed. The parameter d_1 represents the horizontal eccentricity: it was measured as the perpendicular distance between the vertical axis of the steel threaded rod and the closest face lamination (major) joint of the CLT block. As for d_2, it represents the vertical eccentricity: it is the perpendicular distance between the horizontal axis of the steel threaded rod and the closest lower internal-laminate (minor) joint.

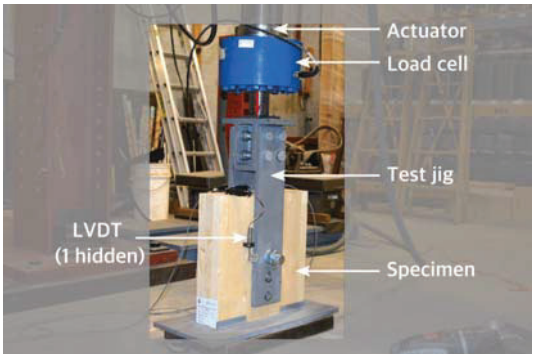

***Figure 4:** Experimental test apparatus*

***Figure 5:** Characterization of the location of the connector in the CLT panel, and defects in the panel*

2.4 Evaluation of structural performance parameters

Based on the experimental tests conducted, a set of parameters have been selected to characterize the structural performance of connectors, namely, the secant loading stiffness (k_{sl}), and the residual slip of the connector and the end of the cycling process ($\delta_{res-slip}$). These structural performance parameters are represented in an idealized hysteresis plot in Figure 6.

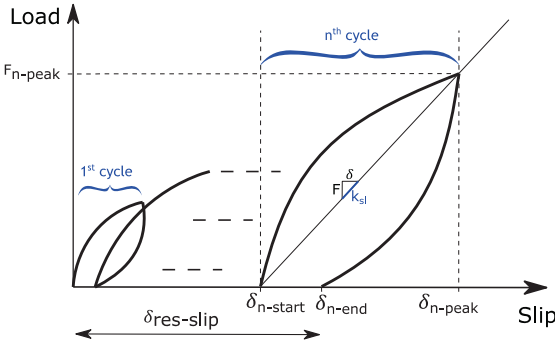

***Figure 6:** Idealised hysteresis curves of the connector and identification of performance parameters.*

https://doi.org/10.52202/069179-0174

With specific reference to Figure 6, the secant loading stiffness for a given cycle n was determined using equation 1 [8], [9].

$$k_{sl} = \frac{F_{n-peak} - F_{n-start}}{\delta_{n-peak} - \delta_{n-start}} \quad (1)$$

Where $\delta_{n-start}$ and δ_{n-peak} correspond to the recorded connector slip at the starting and ending of the load cycle n, respectively. $F_{n-start}$ and F_{n-peak} correspond to the recorded load at the starting and ending of the load cycle n, respectively. In this study, the final value of k_{sl} considered was obtained by averaging the secant loading stiffness of the last five cycles of each test-run. For what ensues, k_{sl} will be referred to as loading stiffness.

2.5 Machine learning regression analyses

Machine learning methods are increasingly used in predicting the mechanical parameters of materials based on experimental data sets. A Gaussian process is a generalization of the Gaussian probability distribution and can be used as basis for sophisticated machine learning algorithms for classification and regression. In machine learning, Gaussian process regression (GPR) was developed out of neural networks research and is a Bayesian method for data regression or classification. Gaussian process models have become very popular for solving non-linear regression problems. They are known to be expressive, interpretable, avoid over-fitting, and to yield a high predictive performance in many thorough empirical comparisons [10], [11]. In this study, a GPR algorithm was used to perform a regression analysis on inputs and output results obtained from cyclic tests on hybrid connectors. Figure 7 features a schematic of the Gaussian process regression network. Squares represent observed variables and circles represent unknowns. x is a general input (predictor) variable, y is target output, and w are weights functions. Often a bias weight or offset is included to avoid over fitting. This noise assumption together with the model directly gives rise to the likelihood, the probability density of the observations given the parameters, which is factored over cases in the training set. Because of the marginalization property of GPR addition of further inputs, x, latent variables, f, and unobserved targets, $y*$, does not change the distribution of any other variables.

In the Bayesian formalism there is a need to specify a prior over the parameters, expressing the beliefs about the prior parameters before looking at the observations. In GPR, a zero mean Gaussian prior is used. Also, a shape of the function is set for the prior; in the case of this work, and exponential shape was used. Inference in the Bayesian linear model is based on the posterior distribution over the weights. The posterior combines the likelihood and the prior and captures everything known about the parameters. To make predictions for a test case, all possible parameter predictive distribution values are averaged and weighted by their posterior probability. Thus, the predictive distribution is given by averaging the output of all possible models regarding the Gaussian posterior. An inherent advantage of GPR processes is that the predicted output is a distribution, and not a number.

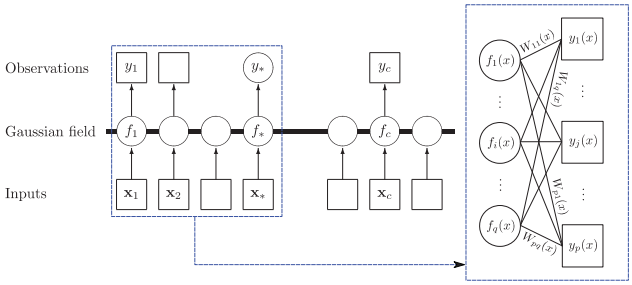

Figure 7: *The Gaussian process regression network. Adapted from [10], [12]*

In this work, the GPR was conducted under the software MATLAB, using the Regression Learner application. Two models were developed: one for the secant loading stiffness, and the other for the residual slip of the connector. The models were trained with normalized input parameters, as presented in Table 2.

Table 2*: Normalization of input parameters for the GPR learning algorithm*

	Actual values	**Normalized values**
	variables	
CLT size (mm)	280, 340, 480	280, 340, 480
CLT grade	E, V	0, 1
Steel rod grade (strength class)	4.8, 8.8	0, 1

vertical eccentricity, d_2 (mm)		
Curing time for the grout (days)		

3 RESULTS

In this section, the mechanical characteristics evaluated based on the experiments are presented first; then, outputs from the Gaussian process regression ensue.

3.1 Cyclic performance of the connector

3.1.1 Secant loading stiffness and residual slip of the connectors

The box plots in Figure 8 provide a visualization of statistical information for two output data under consideration, namely the average secant loading stiffness at the last cycle of loading and the residual slip of the connector. The bottom and top of each box are the 25th and 75th percentiles of the data, respectively. Each box covers the interquartile interval, where 50% of the data is

found. The horizontal line in the middle of each box is the sample median. The thinner lines extending above and below each box represents whiskers, which go from the end of the interquartile range to the furthest observation within the whisker length [13]. This variation of the box and whisker plot restricts the length of the whiskers to a maximum of 1.5 times the interquartile range [14]. Data points that are outside this interval are represented as red points on the graph and considered potential outliers.

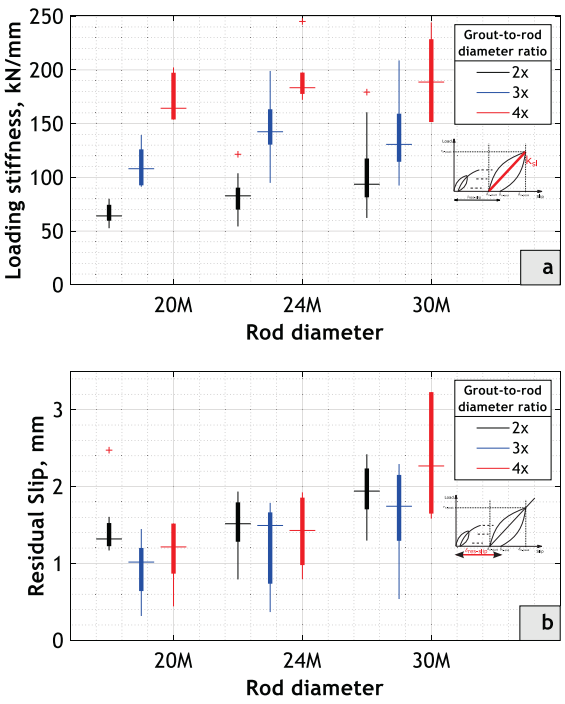

Figure 8: *Box plots of performance parameters. (a) loading stiffness, (b) residual slip. In black – grout to rod diameter ratio is 2; blue - grout to rod diameter ratio is 3; red - grout to rod diameter ratio is 4.*

A general trend is that the variability in loading stiffness increases with the grout diameter. The loading stiffness itself increases with both the rod diameter and grout diameter. As for the residual slip, once again, it is observed that the variability grows with the gout diameter. The effects of the rod and grout diameter on the residual slip are, however, less pronounced.

3.1.2 Hysteresis of connectors

The typical hysteresis of the connector is shown in Figure 9. This hysteresis corresponds to the connector tested with the loading diagram presented in Table 1 and Figure 3. In this plot, the load slip curves from monotonic tests are presented (Shulman and Loss [3], [4]). The hysteresis is represented by bold black, red, and blue lines. A switch in color in the hysteresis means a change of loading step. It was observed that the connector conserves it stiffness during cyclic loading (Figure 9). Additionally, the residual slip was observed to remain in moderate ranges. The premise that the hysteresis of the hybrid connector is contained within the monotonic load-slip curve is also validated. There appears to be a larger loop at the first cycle of the fourth load step: this was observed for all the connector variants tested. Lastly, a slight pinching is observed at the last load step. All tested connectors displayed a similar hysteresis pattern, with an observed residual slip between 40% and 60% of the maximum slip reached during the testing.

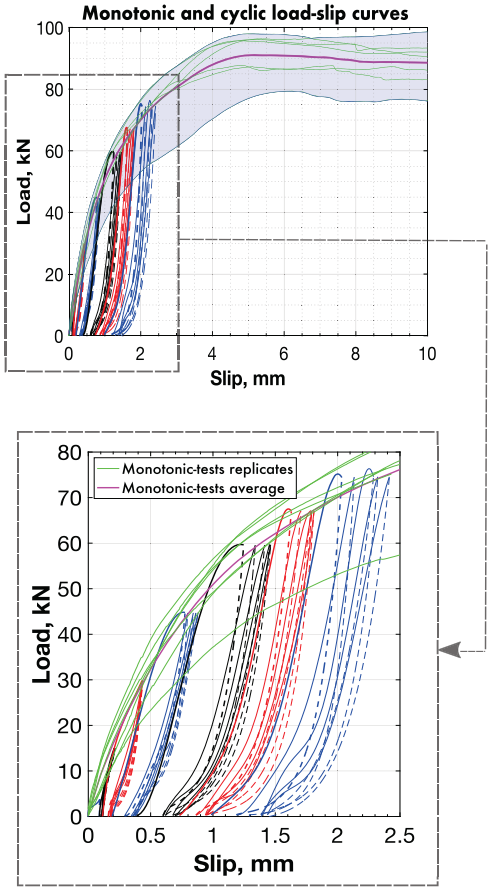

Figure 9: *Hysteresis of a specific tested connector arrangement (280–E–20M–4.8–2d)*

3.2 Gaussian process regression

Gaussian process regression (GPR) machine learning algorithm was used to develop predictive models for the secant loading stiffness and the residual slip of the connectors.

3.2.1 Variables importance scores

First, an F-test was used to determine the importance of each feature variable on the outputs. Figure 10 shows the feature importance scores.

https://doi.org/10.52202/069179-0174

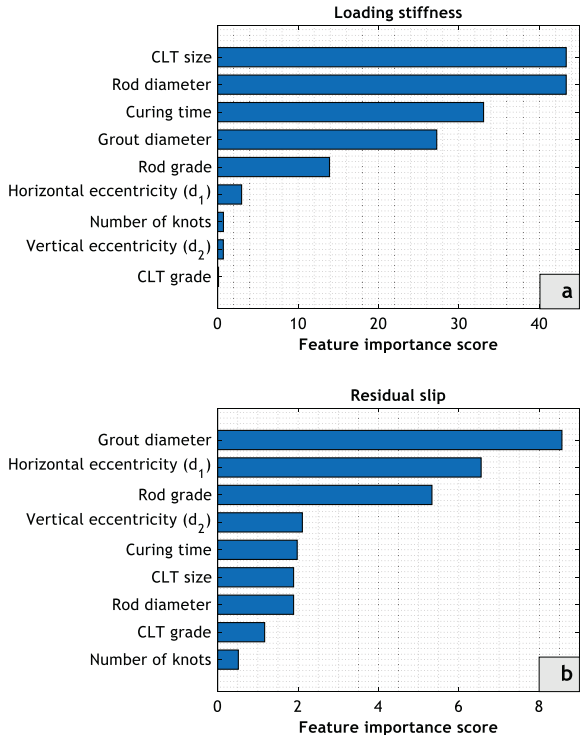

Figure 10: *Feature importance score obtained through the F-Test algorithm. (a) loading stiffness, (b) residual slip.*

It can be observed that the CLT size and the rod diameter have an equal importance score as far as the loading stiffness is concerned (Figure 10.a). This is because these two variables are perfectly correlated. 20M, 24M, and 30M rods were used on 280 mm, 340 mm, and 420 mm CLT blocks respectively. Because of this correlation, only the rod diameter was used for subsequent analyses. The curing time of the epoxy-based grout is third in the ranking of importance factors. Conversely, the CLT grade, the vertical eccentricity, and the number of knots in the face laminations of CLT were found to have very little effect on the secant loading stiffness of connectors.

As for the residual slip, it is observed that the grout diameter, the horizontal eccentricity, d_1, and the steel rod grade are the most significant parameters, with importance scores above 8, 6, and 5, respectively (Figure 10.b). The number of knots and CLT grade were found to have little effect on the residual slip of connectors

3.2.2 Training of GPR models

The GPR was executed twice: once for the secant loading stiffness, and the second time, the residual slip, leading to two trained models. In order to minimize the overfitting, 75% of the ninety data sets were randomly selected and used to train each model. Each model was then validated using the 25% remaining data. The root mean-square error as well as other parameters describing the performance of the algorithm are presented in Table 3. The scatter plots for predicted vs experimental data are presented in Figure 11.

Table 3: *Performance of the GPR learning algorithm*

	Secant Loading stiffness [kN/mm]	**Residual slip [mm]**
RMSE - *Validation*	26.007	0.5734
R-squared	0.70	0.57
Training time (obs/sec)	5700	6800
Prediction speed (sec)	3.353	2.2493

As can be seen from Table 3, the model for the secant loading stiffness presents a good validation root mean square error (RMSE), with a determination coefficient R-squared of 0.7 (this can be observed on Figure 11.a). The prediction speed for the 25% validation data was observed to be below the 3.50s.

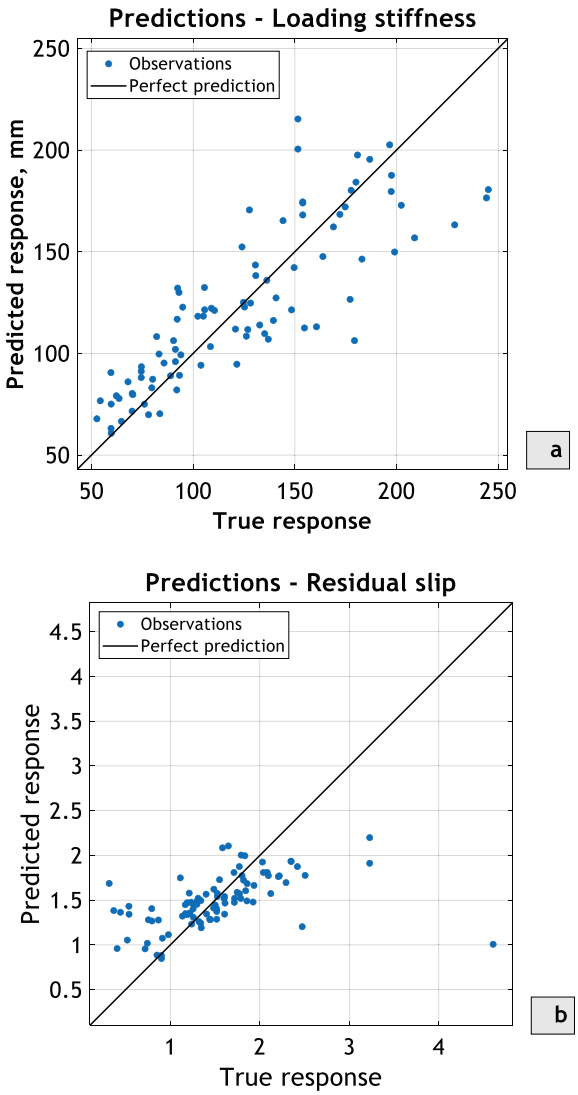

Figure 11: *Scatter plots of the predicted vs experimental data. (a) secant loading stiffness, (b) residual slip.*

The residual slip on the other hand was a little more complex to predict. The coefficient of determination for this model was obtained to be only 0.57 (this can be observed on Figure 11.b, with a few outliers on the lower

right corner of the plot). This can be due to the fact that other non-controlled variables may have a significant effect on the slip of connectors. For instance, the friction between the test apparatus and the specimens was not measured. In addition, the testing apparatus may have not stayed perfectly vertical all along the cycling process (Figure 4). In overall, the prediction speed was higher for the residual slip, with a prediction time of 2.25 s.

3.2.3 Response surface representations of trained GPR models

Using the developed models from the GPR learning algorithm, response surfaces were plotted in order to assess the overall effects of the most significant variables on the outputs.

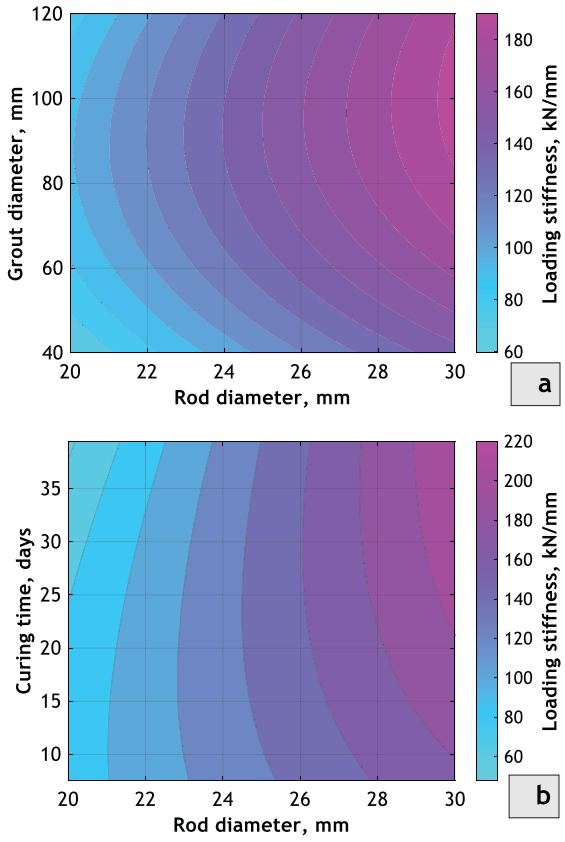

Figure 12: *Response surface of the predicted secant loading stiffness (units in kN/mm). (a) secant loading stiffness vs rod diameter & grout diameter, (b) secant loading stiffness vs rod diameter & curing time.*

First, the secant loading stiffness model was plotted, with variable parameters including diameters of rods and grout. With reference to Figure 12.a, it can be observed that the secant stiffness model captures the effects of the rod and grout diameters. Besides, it is shown that the grout diameter gradually has less impact on the secant loading stiffness as the rod diameter reaches larger values. In Figure 12.b, plots were drawn using the rod diameter and the curing time of the grout as variables. As a result, it can be seen that the curing time of the grout has larger effect on the secant loading stiffness as the rod diameter reaches extreme upper values.

Similarly, the residual slip was plotted, with variable parameters including the grout diameter and the horizontal eccentricity, d_1 (Figure 13.a). The residual slip appears to be lower with lower grout diameters. However, the value of horizontal eccentricity that minimizes the residual slip appears to be between 20 mm and 50 mm, and this value increases with the grout diameter. Results based on the grout diameter and the steel rod grade as variables are plotted in Figure 13.b. From these latter, it can be seen that there is a linear relation between inputs and outputs. The residual slip is minimized as the grout diameter decreases and the steel rod grade is kept at 1 (corresponding to 8.8 strength class).

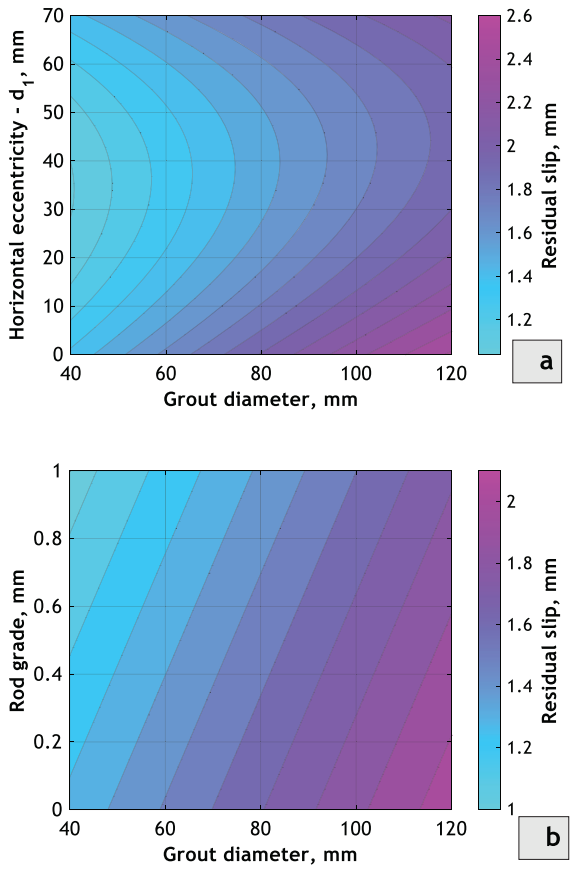

Figure 13: *Response surface of the predicted residual slip (units in mm). (a) residual slip vs & grout diameter & horizontal eccentricity, (b) residual slip vs grout diameter & steel rod grade.*

4 CONCLUSION

This work focused on the performance of a novel high-performance shear connector for mass-timber panels under quasi-static cyclic loading. In addition to assessing the experimental results, two models were developed using a Gaussian process regression machine learning

https://doi.org/10.52202/069179-0174

algorithm to determine the final secant loading stiffness and the residual slip of the connector. Based on the tests performed and analyses conducted, the following conclusions are at the forefront:

- The connector maintains its initial stiffness throughout the cyclic loading history
- The connector displays a relative residual deformation in the order of 50% at the end of the test.
- The most significant parameters influencing the secant loading stiffness are the rod diameter, curing time of the grout, and grout diameter. Whereas the most significant parameters for the residual slip are the grout diameter, the horizontal eccentricity and the steel rod grade.
- The Gaussian process regression algorithm yielded acceptable models for the prediction of the secant loading stiffness and the residual slip, with an r-squared value of 0.70 for the secant loading stiffness and 0.57 for the total residual slip.
- In overall, the results of this work contribute to an improved understanding of the connection under development and confirms the resilience of individual connectors under cyclic loads.

JOINT PERFORMANCE TESTING OF A CLAMPED JOINT FOR TIMBER STRUCTURES AND APPLICATION TO STRUCTURAL DESIGN

Yoshisato Esaka[1], Tatsuki Ishizaki[2], Tsubasa Seguchi[3], Tokuma Azemi[4]

ABSTRACT: The authors developed a clamped joint system, which they called *Tsunagi-clamp*, to assemble and reassemble timber structures easily without complex wood manufacturing. The purpose of this study is to make clear the performance of joints using *Tsunagi-clamp* and effective method of reinforcement, as well as to predict the horizontal resistance performance of a timber cubic frame structure that used this claimed joint system, in which the analysis was performed on the stiffness of the clamped joints during application. By testing the clamped joints under torsion loading and moment loading, it was confirmed that the stiffness of damaged joints reinforced with screw or wood putty were larger than that of undamaged joint. The assumed deformation by analyzing the cubic frame model, in which the stiffness of the joints deformed 1/100 radians, closely fitted the results of the horizontal resistance test. This result suggests that it is possible to verify the performance of other structures with *Tsunagi-clamp* by using the same analyzing method.

KEYWORDS: Clamped joint, Joint performance, Temporary structure, Structural design

1 INTRODUCTION

From a carbon emission point of view, the demand for medium to large-scale timber buildings is increasing. However, the specialization of the forest industry makes timber distribution complex, especially in Japan. This circumstance disturbs not only normal market principles but also the normal circulation of forests. The authors propose that providing consumers with the opportunity to directly construct human-scale timber buildings will help promote its widespread use. This goal is achieved by suggesting various structures that can be built, transformed, disassembled, and easily relocated. The authors call this structure *Tsunagi*, which means "connect" and "connecting wood" in Japanese.

The authors developed a simple clamped joint system, known as *Tsunagi-clamp*, so to assemble and reassemble the structures easily without complex wood manufacturing.

Figure 1: *Example of transforming "Tsunagi"*

The purpose of this study is to evaluate the performance of joints using *Tsunagi-clamp* and the horizontal resistance performance of a timber cubic frame structure using this clamped joint system and to apply the clamps to structural design.

2 DETAIL OF CLAMPED JOINT

Tsunagi-clamp has been developed based on scaffolding clamps [1], connecting orthogonal members as shown in Figure 2. This clamp is able to clasp a 45 mm squared cross-sectional timber by fastening the bolt at the tip of the clamp as shown in Figure 3.

Figure 2: *Detail of Tsunagi-clamp*

Figure 3: *How to use Tsunagi-clamp.*

One of the characteristic features of *Tsunagi-clamp* is the jagged teeth shape plate. Even if the timber shrinks upon

[1] Yoshisato Esaka, NIKKEN SEKKEI LTD, Structural Engineer, Japan, esakay@nikken.jp
[2] Tatsuki Ishizaki, NIKKEN SEKKEI LTD, Structural Engineer, Japan, ishizaki.tatsuki@nikken.jp

[4] Tokuma Azemi, NIKKEN SEKKEI LTD, Structural Engineer, Japan, azemi.tokuma@nikken.jp

https://doi.org/10.52202/069179-0175

drying, the clamp can grab the timber firmly using these jagged plates.

There are 5 holes in each plate to reinforce the joint by screws and to connect other components to the clamp. For example, braces can add to *Tsunagi* easily by connecting the eye bolts, or it becomes possible to fix the structure by grabbing poles by connecting to the scaffolding clamp as shown in Figure 4.

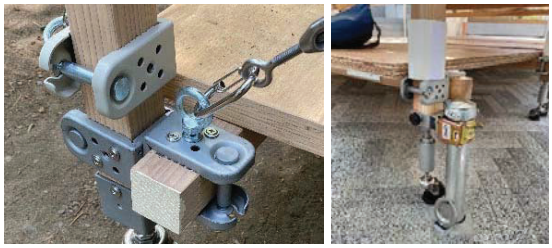

Figure 4: *Example of connecting Tsunagi-clamp and eye bolt or scaffolding clamp*

3 CLAMPED JOINT TESTING

To evaluate the performance of clamped joints, three types of tests were conducted. In all tests, the timber cross-sectional dimension was 45 mm squared, and the timber species was the Japanese Cedar (*Cryptomeria japonica*) with a Young's Modulus of 6000 N/mm^2.

3.1 Torsion tests

The torsion test used a T-shaped joint consisting of two 300 mm long members, connected by *Tsunagi-clamps*. There were five types of specimens as shown in Table 1.

To test the effect of the damage to the area of timber grabbed by the clamp, specimens T3 to T5 were cut down 2 mm in depth before the test. Specimen T2 and specimen T4 were reinforced by four screws, and specimen T5 was reinforced by filling the trimmed area with wood putty (main component was lacquer resin).

Figure 5 shows details of the experimental setup. Static monotonic loading was applied to the vertical member. Vertical force, vertical displacement, slip displacement, and angle of rotation of the vertical member were measured.

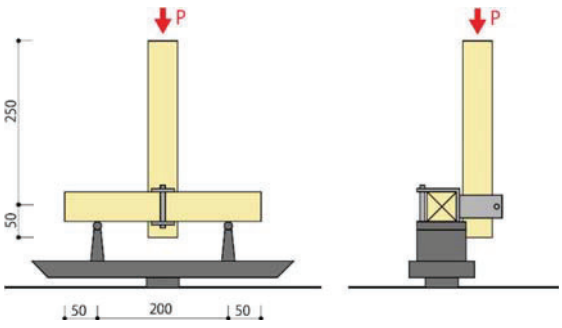

Figure 5: *Test setup of clamped joint torsion tests (units in mm)*

Table 1: *Specimens of the torsion tests*

Testing type	No.	Surface of timber	Reinforcement	Number of specimens
Torsion tests	T1	normal	—	3
	T2	normal	screw	3
	T3	damaged	—	3
	T4	damaged	screw	3
	T5	damaged	putty	3

By adding the vertical force, the nails of *Tsunagi-clump* caved into the horizontal members as shown in Figure 6. These fractures were less detected in Specimen T2 and T4.

Figure 7 shows the relationship between the vertical load and the vertical deformation of the specimens. In each graph, the line of average initial stiffness of T1 was drawn, which was calculated as the slope of the line from the point of $0.1 \times P_{max}$ to that of $0.4 \times P_{max}$, a method based on the structure design guide for framed wall construction houses [2]. This calculation method of initial stiffness was defined as Case 1 in this paper. The average initial stiffness of T4 was 2 times larger and and that of T5 was 4 times larger than that of specimen T1. These results suggest that both ways of reinforcement were effective even if the surface of the timber was damaged.

Figure 6: *Fracture of timber in the area grabbed by timber*

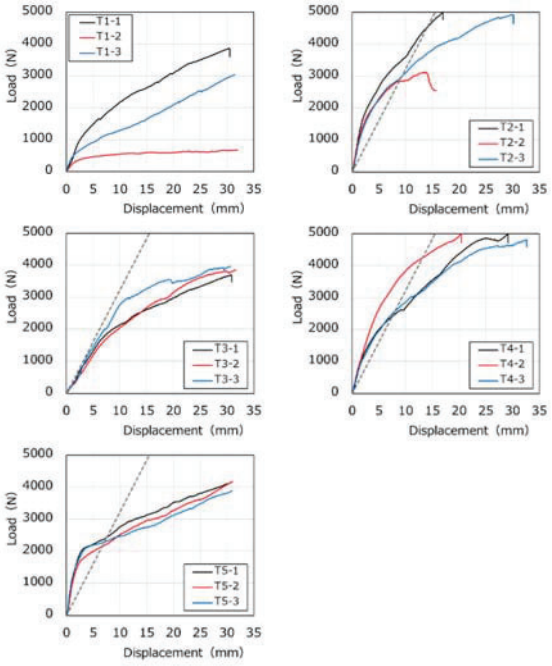

Figure 7: *Load (N) vs. vertical displacement (mm)*

https://doi.org/10.52202/069179-0175

It can be seen that by comparing T4 and T5, the stiffness of the reinforced specimen by screw became smaller gradually, but that by putty had a clear yield point. From this difference, it was assumed that the performance of wood putty method decreased above the initial deformation area.

Vertical displacement was divided into 2 types of displacements, rotate displacement ($= \delta_r$) and slip displacement ($= \delta_s$), both shown in Figure 8 and calculated by Equations (1) and (2). In the initial deformation area, the summation of δ_r and δ_s was closely equivalent to the measured vertical deformation ($= \delta_v$) shown in Figure 9

$$\delta_r = l_1 \times \theta_a \quad (1)$$

$$\delta_s = \delta_{ms} - l_2 \times (\theta_a - \theta_b) \quad (2)$$

Where δ_{ms}= measured slip displacement.

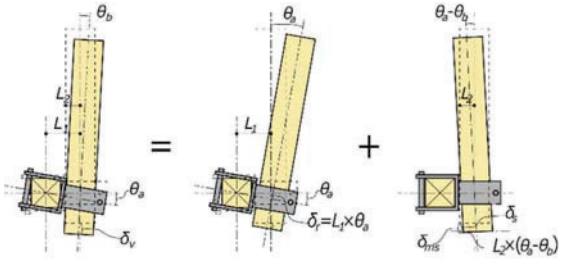

Figure 8: *Model of the deformation in the torsion test*

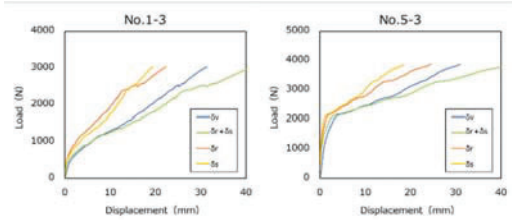

Figure 9: *Load vs. displacement (mm)*

The average stiffness K_r and K_s, calculated by δ_r and δ_s, are shown in Figure 10. In addition to Case 1, the slope of the line, from the starting point to point $\theta_a = \frac{1}{100}$ radians, was calculated as Case 2.

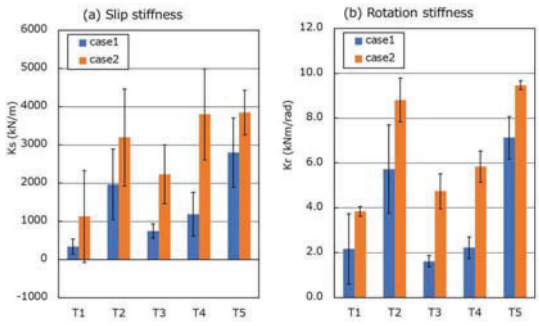

Figure 10: *Average slip stiffness and rotation stiffness.*

The stiffness in Case 1 were smaller than that of Case 2. In Case 1, the average stiffness while slip displacement occurred for T4 was about 1.6 times larger than T3 and T5 was 3.5 times larger than T3. When rotation displacement occurred in Case 1, the average stiffness of T4 was 1.4 times larger than T3 and T5 was 4.4 times larger than T3. From these results, it was assumed that putty was a more effective reinforcement than screws in both displacement cases.

3.2 Moment tests

The specimens for the moment tests consisted of two units of L-shaped joints, arranged to avoid any torsion effects. The lengths of the timber were 300 mm for monotonic loading tests and 450 mm for cyclic loading tests. The 5 types of specimens are shown in Table 2. The condition of the timber surfaces and reinforcement were similar to that of torsion tests, M3 to M5 were damaged and M2 and M4 were reinforced by screws, and M5 was reinforced by wood putty. Monotonic loading was applied to specimens M2 and M5, and cyclic loading was applied to specimens M1, M3, and M4).

Figure 11 shows the details of the test setup. Static monotonic loading was applied to both units. Vertical force, vertical displacement, and rotation angle between each member were measured.

Table 2: *Specimens of the moment tests*

Testing type	No.	Surface of timber	Reinforcement	Number of specimens
Moment tests	M1*	normal	—	6
	M2	normal	screw	3
	M3*	damaged	—	6
	M4*	damaged	screw	6
	M5	damaged	putty	3

*3 speciments were applied cyclic loading

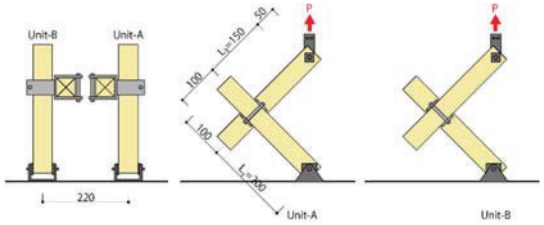

Figure 11: *Test setup of the clamped joint moment tests (mm)*

To analyze the relationship between the moment and angle of rotation, the moment of each unit was calculated by Equations (3) and (4).

$$M = PL \quad (3)$$

$$L = \frac{l_3 l_4 \sin\left(\frac{\pi}{2} + \theta\right)}{\sqrt{l_3^2 + l_4^2 - 2 l_3 l_4 \cos\left(\frac{\pi}{2} + \theta\right)}} \quad (4)$$

Figure 12 shows the relationship between the vertical load and the vertical deformation, and Figure 13 shows the comparison of the average rotational stiffness for the two cases. The initial stiffness of specimen M3 was 25% smaller than the average stiffness of specimen M1. The initial stiffness of specimen M4 was closely equal to that of specimen M3, and M5 was 35% larger than specimen

https://doi.org/10.52202/069179-0175

M1. These results suggested that putty was a more effective reinforcement than screws, similar to the results for torsion loading.

On the other hand, it was assumed that both screw and putty cannot prevent fracture by moment strength effectively since the maximum moment was about 230 Nm for all specimen cases.

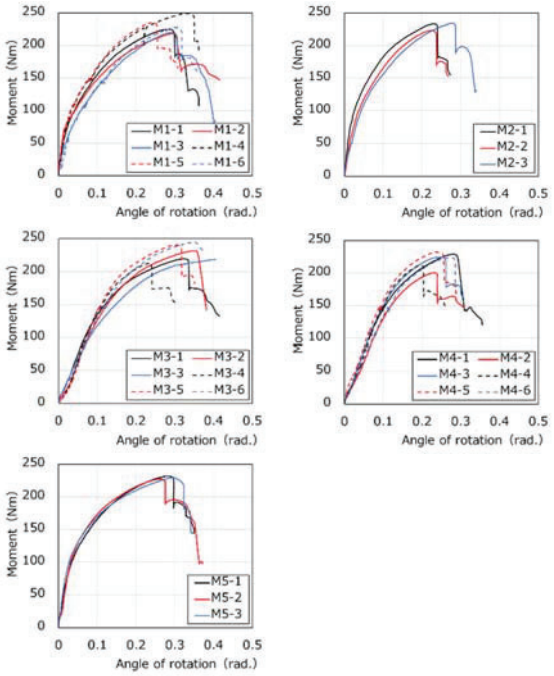

Figure 12: *Moment (Nm) vs. angle of rotation (rad)*

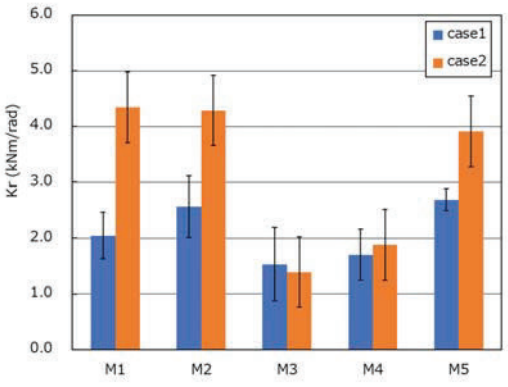

Figure 13: *Average rotational stiffness (kNm/rad)*

3.3 Long-term loading tests

To analyze the behavior of clamped joints under described two types of loading conditions, Long-term loading tests had been conducted for 300 days long. There were 3 types of specimens in each type of loading as shown in Table 3. Specimen LT2 and LT3 were conducted in outdoor conditions. The surface of LT3 was reinforced by filling the trimmed area with wood putty. Specimen LM2 was tested under the same condition as LT2, and LM3 was the same as LT3.

Figure 14 and Figure 15 show the details of the test setup. Static loading was applied to each specimen by hanging mass blocks. Vertical displacement and rotation angle between each member were measured.

Table 3: *Specimens of long-term tests*

Testing type	No.	Surface of timber	Reinforcement	Location	Number of specimen	Loading (N)
Tosion test	LT-1	normal	-	indoor	1	1,000
	LT-2	normal	-	outdoor	1	1,000
	LT-3	damaged	putty	outdoor	1	1,000
Moment test	LM-1	normal	-	indoor	1	100
	LM-2	normal	-	outdoor	1	100
	LM-3	damaged	putty	outdoor	1	100

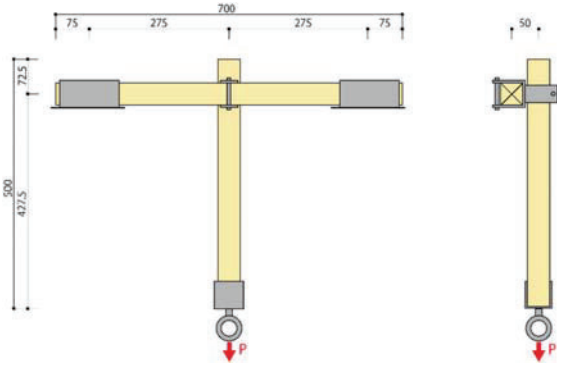

Figure 14: *Test setup of long-term torsion tests (mm)*

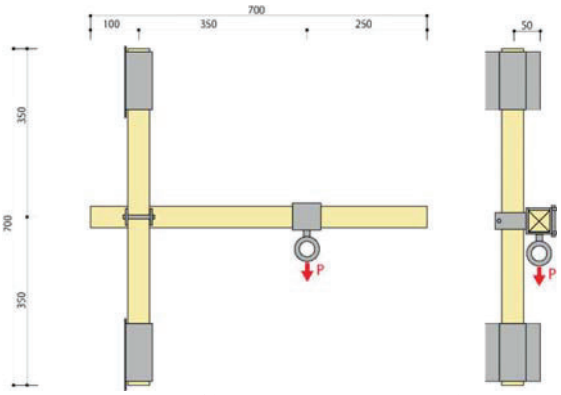

Figure 15: *Test setup of long-term moment tests (mm)*

Figure 16 shows the relationship between the time and angle of rotation. In both tests, the angle of rotation of LT1 increased slower than LT2 and LT3. In the torsion test, the angle of rotation of LT2 was 2 times larger than LT1, and LT3 was 5 times larger than LT1. In the moment test, the angle of rotation of LT2 and LT3 were 2.5 times larger than LT1. The results suggest that under outdoor conditions, filled putty tend to lose the performance of reinforcement, especially for the torsion loading condition.

Table 4 shows the creep coefficient in one week and one month, analyzed with power-law creep [3]. For the moment test, the coefficient ranged from 2.5 to 3.5 regardless of condition. On the other hand, for the torsion test, the factor ranged from 2.3 to 4.4 during normal surface conditions and ranged from 4.7 to 9.3 during wood putty reinforcement. These results suggested that reinforcement by wood putty were not suitable for outdoor usage.

https://doi.org/10.52202/069179-0175

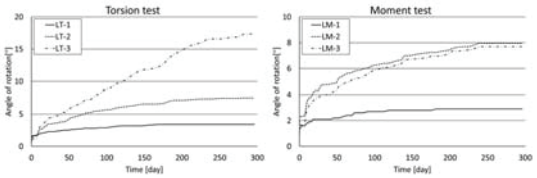

Figure 16: *Angle of rotation (°) vs. Time (day)*

Table 4: *Increasing coefficent of deformation*

	LT-1	LM-1	LT-2	LM-2	LT-3	LM-3
a week	2.32	2.50	3.06	2.32	4.66	2.62
a month	2.72	2.86	4.41	2.91	9.32	3.51

4 ANALYSIS OF CUBIC FRAME STRUCTURE

To confirm the horizontal resistance performance of *Tsunagi* with *Tsunagi-clamp*, an analysis of the cubic frame structure was performed. The model of the cubic frame structure is shown in Figure 19. The model had dimensions of 2.8 m × 2.8 m× 2.1 m and was designed to be used as a medical booth, as shown in Figure 18.

Figure 18: *Modeling of Tsunagi used as a medical booth*

Each lumber was replaced with beam elements (drawn as red lines in Figure 19), each joint was replaced with elastic springs (drawn as black short lines in Figure 19), and the stiffness of clamp joints are listed on Table 5. These stiffnesses of y and z direction were the slip stiffness of T1 shown in Figure 10, these of rotation x direction was the rotational stiffness of T1 shown in Figure 10 and these of rotation y and z direction were the rotational stiffness of M1 shown in Figure 13. These stiffnesses of x direction were set by other joint tests.

The boundary conditions were the 8 pin supports at the base of the columns on both the left and right sides of the booth and the 5 roller supports at the base of columns on both the front and back sides of the booth as shown in Figure 19. Monotonic loadings were applied horizontally at Points A and B.

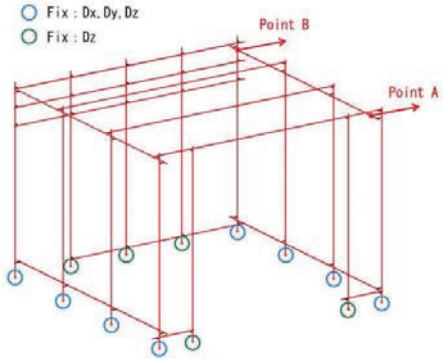

Figure 19: *Model of the cubic frame structure*

Table 5: *Stiffness of the clamp joints*

	Direction (kN/m)		Rotation (kNm/rad)		
Case1	x	420	x	2.2		y	340	y	2.0	
	z	340	z	2.0	
Case2	x	420	x	3.8	
	y	1100	y	4.3	
	z	1100	z	4.3	

5 CUBIC FRAME STRUCTURE TESTING

To confirm the horizontal resistance performance of the cubic frame structure, the authors conducted a full-scale horizontal load experiment as shown in Figure 20. The composition of the frame structure was the same as the analysis model. In order to replicate the boundary conditions used in the analysis, the bottom of each vertical member was fixed by setting the weights.

Monotonic loading of 100 N each was applied step by step to the top of the structure in the horizontal direction. Horizontal force and horizontal displacement at the top of the structure were measured.

The displacements of the frame structure by experiment and by analysis in former section are shown in Figure 21. Due to the difference in the number of joints, displacement at point A was bigger than that at point B. The displacement by case 1 analysis was smaller than the displacement by the experiment in the initial displacement area. But the results of case 2 analysis were closely matched the experimental results in the initial displacement area. Since *Tsunagi* was generally used only when the interlaminar deformation angle was under 1/100 radians, it was assumed more appropriate to use the

https://doi.org/10.52202/069179-0175

stiffness of case 2 in the analysis of *Tsunagi*. In addition, these results support this analysis method can adopt to other types of *Tsunagi* consisted with timber and clamped joint.

Figure 20: *Exsample of specimen of the horizontal loading tests*

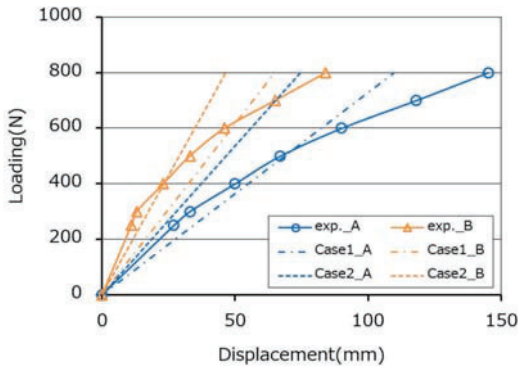

Figure 21: *Displacement of frame structure by analysis and by experiment*

6 EXAMPLE OF STRUCTURE WITH CLAMPED JOINT

The authors used *Tsunagi-clamp* to build cubic frame structures at KITAYA PARK, Shibuya. The overall structure consisted of three cubic structures and the dimensions each structure was 0.9 m × 1.8 m× 1.95 m. Each structure consisted of 13 timbers members and 22 *Tsunagi-clamps* and was built by 2 people in about an hour. To move them easily, these structures had wheels at the bottom of each vertical member. By changing the combination of each structure, the overall structure can be adapted for various usage as shown in Figure 22.

In this park, there is a building that used removable timber for exterior materials. It is envisioned that these *Tsunagi* could be built as temporary tents for emergency support by using this exterior timber in case of disaster.

7 SUMMARY AND CONCLUSION

By testing the clamped joints with *Tsunagi-clamp* in two types of loading conditions, the performance of this joint was analysed. It was confirmed that the reinforcements with screws or putty were effective for the improvement of the stiffness of joints even the surface of timber was damaged. On the other hand, considering long-term use, reinforcement with putty is not effective enough to prevent an increase in joint deformation.

The deformation by analysis of the cubic frame model with the stiffness of clamped joint tests in Case 2 was almost equivalent to that of the horizontal loading test. By analyzing with that stiffness, this clamped joint system can be applied to structural design and the prediction of other types of structure with this joint system are possible.

The authors have designed and constructed a structure as *Tsunagi* and plan to continue this activity to promote wood utilization.

EXPERIMENTAL STUDY ON CONTROL PARAMETERS FOR AUTOMATED APPLICATION AND IN- SITU PERFORMANCE ASSESSMENT OF JOINTS WITH SELF-TAPPING TIMBER SCREWS

Alexandra Eckert[1], Reinhard Brandner[2], David Glasner[3]

ABSTRACT: The paper in hand presents findings from experimental insertion tests with the purpose of establishing and quantifying necessary parameters for an automated application of the investigated self-tapping timber screws. The effects of input parameters such as contact force and revolutions per minute are examined and control parameters such as insertion moment and insertion length are recorded continuously. The biting-behaviour of screws is highly influenced by the contact force and the material parameters such as screw-diameter, screw-tip as well as the density and growth characteristics of the timber. With continuous control of insertion length and insertion moment a tight fit of the screw can be ensured, without damaging the screw or the surrounding timber. Given automatically applied screws with continuous recording of insertion moment and insertion length, the insertion energy can be calculated easily. As an in-situ performance assessment of automatically applied screws the hypothesis of estimating withdrawal characteristics on the basis of insertion energy is made. To validate this hypothesis, given experimental data of combined insertion and withdrawal tests is re-evaluated. A remarkable potential of predicting withdrawal properties with the insertion energy is found. This allows to thoroughly re-consider the design-to-execution process and the implementation of a research informed design process.

KEYWORDS: Automated application, insertion tests, withdrawal tests, self-tapping screws, in-situ performance assessment, research informed design

1 INTRODUCTION

The following studies were obtained as parts of the FFG BRIDGE project "CLT_joint" (project no. 883672), with the aim of developing an efficient, systematized and quality-assured connection solution for solid timber constructions with cross laminated timber (CLT). The solution is envisaged as a combination of timber-connection (application on CLT-components with self-tapping screws in course of joinery in the factory) and assembly-joint (joining of CLT-components on site). Due to the dominating quasi-brittle properties of timber components, it is intended that the timber-connection is designed with a sufficient over-strength to achieve the required ductility and energy dissipation specifically in the assembly-joint. Considering the prefabrication of the timber-connection this solution promises shorter assembly times and higher reliability and thus enhanced quality and cost-effectiveness in comparison to the current state of manually and completely on-site applied fasteners.

Known and already established, industrially implemented possibilities for an automated application of fasteners (e.g. automotive or aviation industry) motivate the integration of such processes supplemented by continuous quality control measures also within the timber industry, e.g. during the joinery of the CLT-elements. Required process steps for such, in the prefabrication integrated, application-units include separation, feeding and positioning, as well as the insertion of the screws and metal fittings. Common existing application units are limited to screws with small dimensions and correspondingly low max. insertion moments and primarily vertical insertion. For the expected screw dimensions used in timber construction (nominal diameter $d = 6$ to 12 mm, lengths up to 500 mm), the required flexibility to apply such screws at different angles (in and out of plane), together with higher insertion moments must be considered and necessary parameters for a controlled insertion need to be established.

Regarding performance-assessment, the hypothesis is made that the individual information on the insertion-energy, which can be calculated very easily assuming a continuous control of the insertion moment and insertion length, is more suitable for estimating the withdrawal capacity and the slip modulus than the information on the individual maximum insertion moment or the global product density (please note: density is currently the only timber-specific property for estimating the stiffnesses and strengths of fasteners anchored in timber in the course of the design). The background for the made hypothesis is that by recording the insertion energy, the interaction

between the material and the fastener, influenced by local growth characteristics such as knots, is considered along the entire screw channel, whereas the single knowledge of the maximum insertion moment, although also considered as individual property, only represents a punctual information. The idea to estimate the withdrawal properties of self-tapping screws based on the insertion energy came up in frame of a previous research project, see [1]. A similar approach was already successfully applied for screws inserted in bones; see [2].

2 INSERTION TESTS

2.1 GENERAL INFORMATION

With the purpose of establishing and quantifying necessary control parameters, insertion tests were carried out. Special attention was set on the two critical phases of an automated insertion process: the biting of the screw-tip and the tightening of the screw-head.

2.2 MATERIALS AND METHODS

2.2.1 Materials and test overview

Insertion tests were carried out with self-tapping screws with countersunk heads, varying nominal diameters d = {8; 10; 12} mm, total lengths l = {180; 300; 400} mm and screw-tips {C; D; F; H}, see Figure 1 and Table 1.

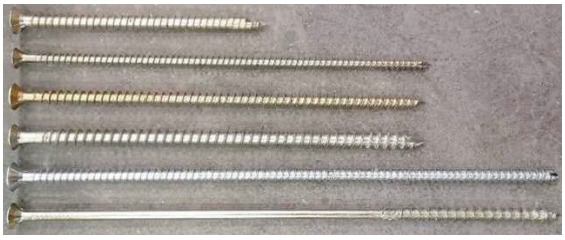

Figure 1: *Investigated self-tapping screws – from top to bottom: 10/180 mm with tip H, 8, 10, 12/300 mm with tip C, 10/400 mm with tip D and 10/400/120 mm with tip F.*

The screws were inserted in the middle layer of five-layer CLT-elements (layup 40 | 20 | 40 | 20 | 40 mm) made of Norway spruce (*Picea abies*). The angle between the axis of the screw and the fiber-orientation of the middle layer (short: load-grain angle α) varied between α = {0; 45; 90} °, see Table 1. In order to adequately represent the characteristics of timber used in construction practice, screws were also applied in finger joints, knots and other typical growth and product characteristics.

Table 1: *Matrix of investigated parameters, such as: screw-tip, nominal screw diameter d, screw length l and load-grain angle α.*

screw-tip	d [mm]			l [mm]	α [°]		
type H	–	10	–	180	0	45	90
type C	8	10	12	300	–	–	90
type D	–	10	–	400	0	45	90
type F	–	10	–	–	0	45	90

Twelve series (three series per screw-tip) with 20 replications each and thus a total of 240 screws were tested. The fully-threaded screws where inserted completely; partially-threaded screws with tip F were only tested in respect to their biting behaviour.

2.2.2 Test configuration

The insertion tests were carried out as illustrated in Figure 2. An electric drive on a fixed support drives the screw while a standard pneumatic cylinder applies pressure between the timber specimen on the moving support and the screw. Both, revolutions per minute (RPM) of the electric drive and contact pressure of the standard pneumatic cylinder, are controlled manually. A cable extensometer between the fixed and the moving support is measuring the displacement. The insertion moment is recorded by a torque transducer, which is placed between the screw and the electric drive. In order to measure the screw force (force between wood specimen and screw head while tightening the screw) a load cell is placed between two steel plates in front of the timber specimen, mirroring a steel-timber joint with outer steel plate. The inserted length of the screws is reduced by 80 mm (height of the load cell plus thickness of steel plates). During insertion testing the parameters time (t), insertion length (l_i)*, insertion moment (M), rotation angle (φ) and screw force (F) were recorded continuously (measurement rate 5 Hz).

* possible small angular deviations might cause differences between insertion length and measured displacement; these are neglected

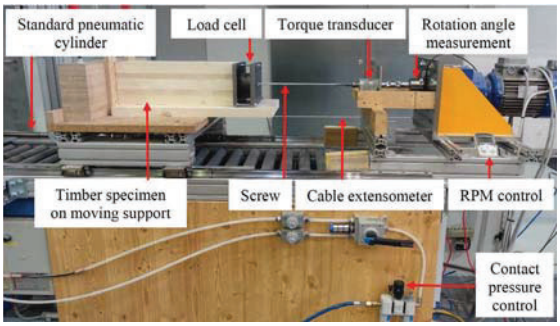

Figure 2: *Test setup and measuring devices of insertion tests.*

2.2.3 Input parameters

To determine optimal conditions for rapid biting of the screw, the effects of input parameters, such as revolutions per minute (RPM) and contact force (CF) between the wood specimen and the application device were investigated. The input parameters RPM and CF were chosen with {50; 100} Hz and by setting the contact pressure to {0.5*; 1.0; 2.0; 4.0; 6.0} bar, respectively. After a small test series and by using the load cell, the according results of the CF are {0.11; 0.14; 0.29; 0.61; 0.95} kN. These results are lower than the calculated force of the standard pneumatic cylinder (contact pressure times cylinder area), which attributes to frictional loss.

* due to inaccuracy of the pressure-control in the lower range the value 0.5 is assumed to be approx. 0.7 bar (corresponds with resulting CF)

https://doi.org/10.52202/069179-0176

2.2.4 Test procedure

The recording of said parameters started after placing the screw tip through the load cell onto the timber specimen. CP and RPM started simultaneously. While the set CP was reached immediately, the acceleration of RPM took a view seconds to reach its set value.

Special attention was set on the critical phase of the insertion: the biting of the screw-tip. In case of no biting after 20 revolutions, the biting process was considered as failed and the CP was raised until biting occurred which enabled the continuation of the insertion test. After reaching a specific insertion length during the insertion (depending on the pitch of the screw and the set RPM), the RPM was decelerated to 5 Hz for better observation of the other critical phase: the tightening of the screw. The testing finished after failure due to torsion of the screw or overturning of the screw.

2.2.5 Evaluation of biting behaviour

To evaluate the biting behavior, the continuous recording of insertion length (l_i), rotation angle (φ) and insertion moment (M) was examined. The biting behaviour was assesed with the amount of revolutions until the screw-tip bite. The evaluation is limited to 20 revolutions, because during testing at this point the biting was classified as failed. When biting occurred the gradient of the insertion length-revolution graph corresponded with the respective pitch (p) of the screw and the insertion moment increased, as exemplarily illustrated in Figure 3.

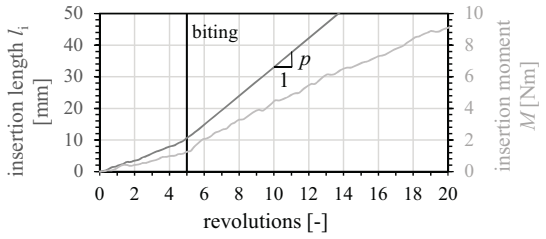

Figure 3: *Example of biting evaluation on insertion length (l_i) and insertion moment (M) plotted over revolutions.*

2.3 RESULTS AND DISCUSSIONS

2.3.1 Density and moisture content

There is only a slight variability in the density between the series and the ranges are quite comparable. The average density ($\rho_{12,mean}$) is 461 kg/m³ with a range from 408 to 515 kg/m³ (CV = 4.7 %). The average wood moisture content is 11.7 %. Further details can be found in the accompanying test report, see [3].

2.3.2 Biting behaviour

To investigate the influence of parameters on the biting behaviour, different sets of test data with equal boundary conditions are compared. Figure 4 shows different load-grain angles and contact forces with equal boundary conditions d = 10 mm and screw tips H, D and F. Wood specimens with knots or other growth or product characteristics are excluded in this diagram to concentrate on the influence of α. The results only differ noticeably in the low CF-range for α = 0°. In the higher range of CF, the influence of the load-grain angle seems to diminish.

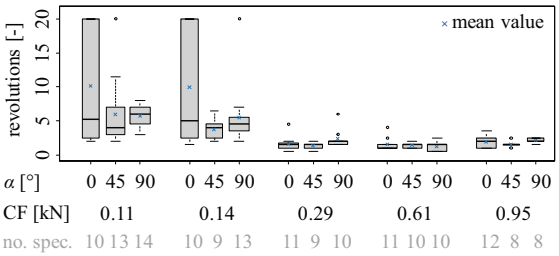

Figure 4: *Biting behaviour vs. load-grain angle α and contact force CF (please note: statistical values of groups exceeding the evaluation-limit of 20 revolutions represent lower estimates).*

In Figure 5 the biting behaviour is shown for different screw diameters and contact forces with equal boundary conditions α = 90° and screw-tip C. In this diagram data from screw insertion in knots and other growth and product characteristics are included. The influence of the screw diameter on the biting-behaviour is evident, but an overall more perceivable effect is again reached by the CF. Setting the CF to approx. 0.3 kN already achieved successful biting for those tested boundary conditions.

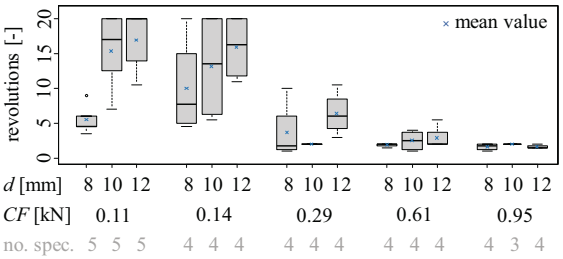

Figure 5: *Biting behaviour vs. diameters d and contact force.*

The required CF for a rapid biting in knots is shown in Figure 6, representing the collected data of screw tips inserted in knots with d = 10 mm regardless of the type of the screw tip {H; C; D; F} and α = {0; 45; 90}°.

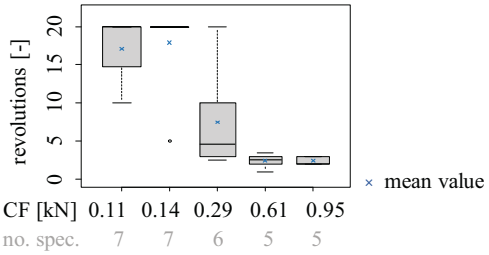

Figure 6: *Biting behaviour of screws applied in knots.*

Regarding RPM no influence on the biting behaviour can be detected due to the fact that the biting often took place

https://doi.org/10.52202/069179-0176

before the set RPM was reached. Yet the observation was made, that in cases of no biting after 20 revolutions where the RPM had reached its set value, the CF needed to be increased even higher at RPM = 100 Hz than at 50 Hz to achieve biting.

2.3.3 Tightening – insertion moment

Beside the biting of the screw, the tightening of the screw represents another critical phase within an automated insertion process. Figure 7 plots the insertion moment of screws with different diameters (d) and the following boundary conditions: $\alpha = 90$ °, $l_i = 220$ mm and screw tip C. The lower box-plots represent the distribution of the max. insertion moment measured from the screw-tip to the beginning of the screw-head and the highest plots represent the max. insertion moment measured from contact of the screw head with the sinking until failure. The full dots in between represent the characteristic values of the torque resistance ($f_{tor,k}$) for each screw diameter according to the European Technical Assessments (ETAs) of these screws. The insertion moment increases with increasing screw diameter, considering the data until head and incl. head.
The max. insertion moment incl. head exceeds the torque resistance by a significant margin. Although the actual resistance of the tested screws is probably higher than the characteristic value, the amount of deviation is most likely a result of the interaction between screw head and steel plate (please note: screws compared in Figure 7 have the same underhead milling ribs).

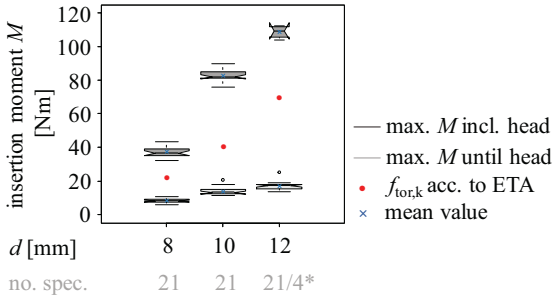

Figure 7: *Diameter vs. max. insertion moment until the beginning of the screw head and max. insertion moment incl. embedment and tightening of the screw head in the sinking of the steel plate (* only 4/21 screws with d = 12 mm failed by torque as the screw drive reached their max. capacity before).*

Figure 8 plots the insertion moment of screws with different insertion lengths and the following boundary conditions: $d = 10$ mm and $\alpha = 90$ °. Whereas screws with $l_i = 100$ and 220 mm had similar underhead milling ribs, screws with $l_i = 320$ mm had a smooth underhead surface. The max. insertion moment until head (lower boxplots) increases with increasing insertion length.
The results of the max. insertion moment incl. head (higher boxplots) of screws with milling ribs ($l_i = 100$ and 220 mm) also increase with increasing insertion length. Between the heads of these screws and the sinkings a high interaction was observed in form of abrasion of the sinking, which is attributed to friction and milling. The investigated screws with a smooth underhead surface ($l_i = 320$ mm) are not reflecting the same effect. This is most likely due to the lower interaction between the head and the sinking which in this case can be attributed solely to friction. Nonetheless, their data incl. head exceeds $f_{tor,k}$ according to the ETA (full dot) by a significant margin.
Screws with insertion lengths $l_i = \{220; 320\}$ mm failed due to torsion of the screw. The screws with the lowest insertion length failed due to overturning of the screw. In combination with a relatively high $f_{tor,k}$ this leads to an overlap of the data incl. head and $f_{tor,k}$ (please note that 10 d represents a low insertion length in timber constructions where high load bearing screwed joints are often designed for screw tension failure).
Speaking for the critical phase of screw tightening, for screws designed for tension failure (where the possibility of overturning principally can be neglected) higher tightening moments are possible and also often required compared to standard screw torsion tests.

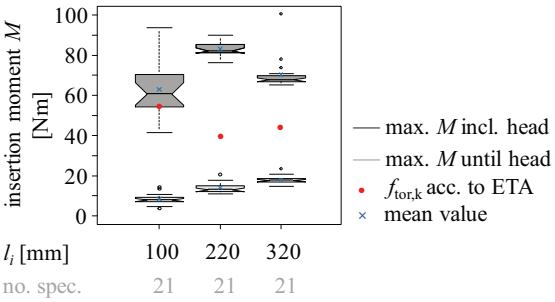

Figure 8: *Insertion length vs. max. insertion moment until the beginning of the screw head and max. insertion moment incl. embedment and tightening of the screw head in the sinking of the steel plate.*

2.3.4 Further results

The insertion energy was calculated with the pitch of the screw and the insertion moment in combination with the insertion length according to Equation (1) in Chapter 3.2. Results show an increase in insertion energy with increasing nominal screw diameter. The same effect is observed, when analysing the maximum screw force of the tested diameters.
The insertion energy and the maximum screw force also increase with increasing insertion lengths, although this effect is limited by the screw capacity itself; the tensile strength ($f_{tens,k}$).
When analysing the influence of input parameters CF and RPM on the maximum insertion moment, the insertion energy and the screw force, no correlation can be determined. For further details see [3].

3 PERFORMANCE-ASSESSMENT AND OPTIONS FOR RESEARCH INFORMED DESIGN (RID)

3.1 SETTING UP THE HYPOTHESIS AND GENERAL COMMENTS

In the following, the hypothesis is analysed, that the total insertion energy, determined along the total insertion length, serves as a better, more reliable predictor for the withdrawal properties (strength and slip modulus) than the maximum insertion moment, as one punctual characteristic, and the density, whether it is available as local or global (product) characteristic.

The background to this consideration is simply the fact, that the total insertion energy, as integral of the measured insertion energy along the insertion length, takes local irregularities into account, such as knots, checks and reaction wood. The prerequisite for this is a quasi-continuous recording and data processing of insertion moment and insertion length together with parameters of thread geometry, as it would be possible during an automated and controlled application of screws. Saying that, the insertion energy provides additional information on screw application but cannot substitute others, e.g. the insertion moment, which still needs to be controlled to prevent overturning and torque failure of the screw.

The following sections analyse the hypothesis in detail. As this is done as a second, widely independent part of the overall paper, the principle structure of a research paper is widely repeated.

3.2 MATERIALS AND METHODS

In total 284 data sets from twelve series, each with 20 to 24 specimens, from insertion tests without predrilling acc. to [5] and withdrawal tests acc. to [6] conducted on the same specimens are used. The tests, made in Norway spruce (*Picea abies*), comprised three different density classes {A; B; C}, two different screw types {RF; P1}, each with a nominal diameter d = 8 mm, and two different load-grain angles $\alpha = \{0°; 90°\}$. Series of the same density class were organised as matched samples, i.e. as series with similar density distributions. To test solely the thread, all screws were screwed through the specimens with a nominal thickness in loading direction of 50 mm, so that the tip and compressor left the opposite side. This boundary condition should be kept in mind as it represents a rather uncommon practical condition. The specimens were conditioned at 20 °C and 65 % rel. humidity before testing. Details on the determination of the moisture content u [%], the local density ρ_{12} [kg/m³], the insertion moment M [Nm], the withdrawal strength f_{ax} [MPa] and the slip modulus K_{ser} [kN/mm] are provided in [3] and [4]. The insertion tests were re-evaluated to determine not only the maximum insertion moment but also the insertion energy W [Nm] calculated acc. to Equation (1):

$$W = \frac{2\pi}{p} \int M \, \partial l_i \qquad (1)$$

where l_i is the insertion length [mm] and p the pitch of the screw [mm].

Three different conditions were investigated for the completion of the summation: (1) the final insertion length, (2) the point of the maximum insertion moment, and (3) 50 mm insertion length. In the following, the insertion energy acc. to (3) is used as it is the most representative for practical applications; it is also rather close to (2); see [3].

3.3 RESULTS AND DISCUSSIONS

3.3.1 General statistics and regression analyses

Table 2 summarizes the main statistics per test series for the most important properties. Statistics for the moisture content are provided in [3] (average moisture contents per series within 12.5 and 13.2 %).

The average densities confirm the successful creation of matched samples within each density class and clearly different densities between the classes. The total bandwidth of 330 to 620 kg/m³ covers a typical range for Norway spruce. The maximum insertion moments for P1 are on average slightly higher than for RF. The difference between both screw types is even higher for the slip modulus, irrespective of the load-grain angle. In contrast, the withdrawal strengths are similar at 90° and slightly lower for P1 at 0°, due to the thicker core of P1; see [7]. Compared to P1, for RF the average values for the insertion energy are in trend clearly higher in case of $\alpha = 0°$ and slightly lower in case of $\alpha = 90°$. The coefficients of variation (CV) for the insertion energy are widely within 15 and 20 % and similar as for M; see [3].

***Table 2**: Main statistics of analysed series of insertion and withdrawal tests.*

Series	n [–]	$\rho_{12,mean}$ [kg/m³]	$f_{ax,mean}$ [MPa]	$K_{ser,mean}$ [kN/mm]	M_{mean} [Nm]	W_{mean} [Nm] | CV [%]

For the statistical analyses of the relationships between the withdrawal properties $\boldsymbol{Y} = \{f_{ax}; K_{ser}\}$ and the indicating properties $\boldsymbol{X} = \{\rho_{12}; W\}$ power regression models are applied which consequence from assumed lognormal variables; see Equation (2):

$$Y_j = \beta_0 X_j^{\beta_1} \varepsilon_j \quad \Leftrightarrow \quad \ln(Y_j) = \ln(\beta_0) + \beta_1 \ln(X_j) + \varepsilon_j \qquad (2)$$

where $\{\beta_0; \beta_1\}$ are the regression coefficients and ε is the standard error. Regression models are calculated for each

https://doi.org/10.52202/069179-0176

screw type {RF; P1} and load-grain angle α = {0°; 90°} whereby the density groups {A; B; C} are combined. The outcomes for the estimated regression coefficients, standard errors (s_e) and adjusted coefficients of determination (r^2_{adj}) are summarized in Table 3.

***Table 3**: Regression coefficients and main statistics of power regression models per screw type and load-grain angle.*

Group	Model	$\hat{\beta}_0$	$\hat{\beta}_1$	s_e	r^2_{adj}
RF0	$f_{ax} \sim \rho_{12}$	0.062	0.724	0.225	0.23
	$f_{ax} \sim W$	0.138	0.686	0.176	0.53
	$K_{ser} \sim \rho_{12}$	49.77	0.990	0.179	0.48
	$K_{ser} \sim W$	366.9	0.763	0.133	0.71
RF90	$f_{ax} \sim \rho_{12}$	0.005	1.164	0.071	0.88
	$f_{ax} \sim W$	0.216	0.631	0.081	0.84
	$K_{ser} \sim \rho_{12}$	5.885	1.275	0.123	0.74
	$K_{ser} \sim W$	365.7	0.685	0.133	0.70
P10	$f_{ax} \sim \rho_{12}$	0.063	0.702	0.225	0.21
	$f_{ax} \sim W$	0.140	0.673	0.172	0.54
	$K_{ser} \sim \rho_{12}$	194.6	0.793	0.216	0.27
	$K_{ser} \sim W$	837.1	0.653	0.178	0.50
P190	$f_{ax} \sim \rho_{12}$	0.004	1.200	0.093	0.82
	$f_{ax} \sim W$	0.112	0.750	0.080	0.87
	$K_{ser} \sim \rho_{12}$	2.557	1.441	0.138	0.75
	$K_{ser} \sim W$	145.8	0.883	0.135	0.76

These power regression analyses are illustrated exemplarily for the screw type RF and α = 0° in Figure 9 and Figure 11 and for α = 90° in Figure 10 and Figure 12.

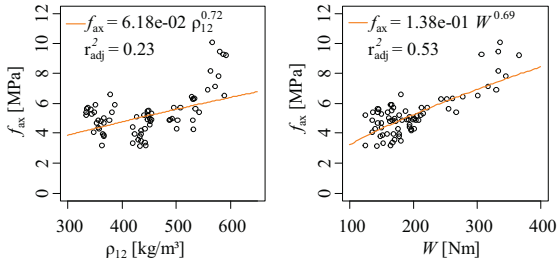

***Figure 9:** Power regression analysis for f_{ax} vs. ρ_{12} (left) and f_{ax} vs. W (right) exemplarily for RF and α = 0°.*

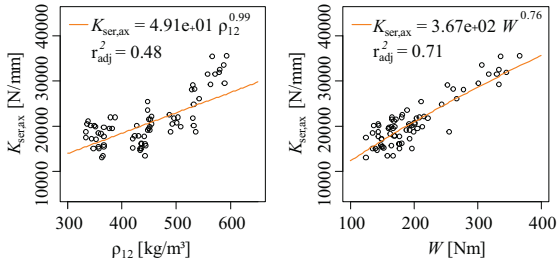

***Figure 10:** Power regression analysis for $K_{ser,ax}$ vs. ρ_{12} (left) and $K_{ser,ax}$ vs. W (right) exemplarily for RF and α = 0°.*

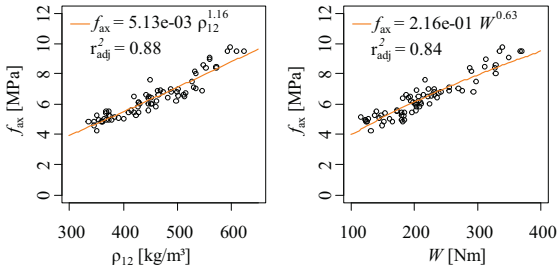

***Figure 11:** Power regression analysis for f_{ax} vs. ρ_{12} (left) and f_{ax} vs. W (right) exemplarily for RF and α = 90°.*

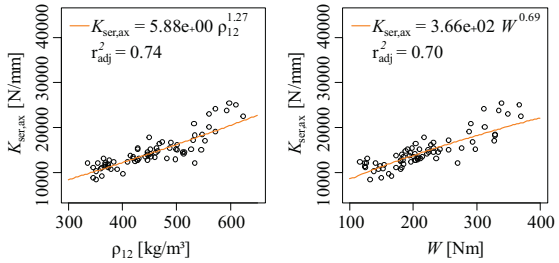

***Figure 12:** Power regression analysis for $K_{ser,ax}$ vs. ρ_{12} (left) and $K_{ser,ax}$ vs. W (right) exemplarily for RF and α = 90°.*

With ρ_{12} as indicating property, the regression coefficients for α = {0°; 90°} are clearly different whereas in case of W the coefficients are rather close. The values for r^2_{adj} confirm previous findings of the very limited capability of ρ_{12} to predict withdrawal properties at α = 0°; see [8] and [9]. This circumstance is usually of less importance as the reference properties normally refer to α = 90° and properties at deviating conditions are adapted accordingly by means of corresponding relationships. W is rather able to reliably predict the withdrawal properties which is clearly demonstrated by overall higher degrees of determination. The total insertion energy also adapts more individually to the insertion conditions which is also visible in Figure 9 to Figure 12 where for the same withdrawal data the ratio $\rho_{12,max}$ / $\rho_{12,min}$ is approximately two whereas it is four for W_{max} / W_{min}. To conclude: based on this analysis there is a clear indication that the total insertion energy serves overall as better and more reliable predictor of the withdrawal strength and slip modulus than the local density.

In order to benefit accordingly from this finding, the acquisition of the data required for this in the course of an automated, controlled screw application process is indispensable. It should be mentioned that the insertion energy is influenced by certain screw features (e.g. cutters and compactors, tip geometry, slide coating, screw length in the case of partially-threaded screws, etc.) which do not (or only to a minor extent) affect f_{ax}. As a result, more general models to describe f_{ax} by means of the insertion energy might need to consider these parameters and thus the individual screw type. In the following it is assumed that this will take place.

3.3.2 Analysis of the current design process and the potential benefits of the new findings

Within the current design process and with focus on the resistance part, the engineer doing the design usually follows design standards and applies characteristic properties, which are tabulated in referenced product standards or can be easily calculated from standardized relationships. The standardized characteristic properties and relationships need to account for all the uncertainties associated with the assumed product, strength class, production, producer and execution; see e.g. [10]. As long as the structure is not realised, these uncertainties belong to the aleatoric part; only the timber product and the nominal strength class are determined by the designer who assumes that it will also be executed that way. By erecting the structure, the aleatoric part becomes epistemic; the properties are fixed but usually still remain unknown.

In the current design of joints in timber, the properties of fasteners determined from their interaction with timber are only related to one timber property, the characteristic (5 %-quantile) of the density of the specific timber product and the nominal strength class. This value has to be distinguished from the local density which is usually determined in tests and used as indicating property in regression analyses to derive the before mentioned standardized relationships. The product density itself is usually not representative for the individual fastener properties as homogenisation effects, caused by the composition of products out of components (e.g. glulam composed of laminations) are considered in setting the characteristic values, whereas fasteners often penetrate only one or a limited number of components and therefore do not realize the same homogenisation effects ([11], [12]).

An automated controlled screw application system combined with the possibility to receive direct information on the local insertion properties, a set of models for a reliable estimation of the individual fastener withdrawal properties and newly created opportunities to adapt the joint execution, e.g. by adaptation of the insertion length, the number of fasteners within a joint and/or the spacing between joints in discretely equipped connection lines, provides a set of new possibilities to thoroughly re-consider the design-to-execution process by implementing research informed design (RID; see [13]). In doing so, a number of uncertainties inherently associated with the current design process would be eliminated. Designers could compensate this by setting higher characteristic properties, referring to higher quantile values, and/or by lower partial safety factors. During the automated screw and joint application, the fulfilment of the requirements set by the designer is individually controlled and adapted if necessary. This way, the determined but in current design-to-execution processes usually remaining unknown properties become known to a significant extend. Thereby, the model uncertainties associated with the estimated withdrawal properties and all uncertainties associated with the execution and quality assurance process, including the uncertainty associated with the measurement itself, shall be considered, e.g. by using lower quantile values of the estimates. For example, under the made assumption of lognormal variables the regression models in Table 3, which lead to average estimates for Y_j given a specific value of X_j, could be easily transformed to calculate quantile values, e.g. acc. to Equation (3):

$$y_{p,j} = \exp\left(\left(\ln(\beta_0) + \beta_1 \ln\left(X_j\right)\right) + z_p \sigma_{\ln(Y_j)}\right) \qquad (3)$$

where $y_{p,j}$ is the p-quantile value of Y for the j-th screw, z_p is the p-quantile value of the standard normal distribution and $\sigma_{\ln(Y_j)}$ is the standard deviation of Y for the j-th screw in the logarithmic domain.

The benefit of this approach is exemplarily demonstrated for the series C_RF90. The reason for selecting this series is its representativeness in respect to CV[f_{ax}] = 14.6 % and CV[ρ_{12}] = 7.0 %; see e.g. [7], [8], [14]. Please note: this demonstration is not intended to validate any of previously presented models. To ensure equal conditions for the following comparisons, all statistics and models are taken directly from series C_RF90.

The characteristic values for the density and the withdrawal strength, as 5 %-quantiles of assumed lognormal variables, are $\rho_{12,05}$ = 484 kg/m³ and $f_{ax,05}$ = 6.1 MPa, respectively. Following the current version of prEN 1995-1-1 [15] and [14], the characteristic withdrawal strength for a material featuring a similar characteristic density as series C_RF90 would be $f_{ax,k}$ = 5.9 MPa. By considering that $f_{ax,k}$ acc. to [15] has to account for all the additional uncertainties related to product, batch and many more (see e.g. [10]), the values appear as too close in this case.

The power regression model $f_{ax} \sim W$ for series C_RF90 reads $f_{ax,j} = 0.1075 \cdot W_j^{0.7583}$, with $r^2 = 0.89$, so 89 % of the variance in f_{ax} can be explained by the regression model; thus, only 11 % uncertainty remain in the individually estimated $f_{ax,j}$. To be in line with current design procedures, by means of Equation (3) 5 %-quantile values $f_{ax,j,05}$ are calculated for each individually estimated $f_{ax,j} \mid W_j$. The average value of these 5 %-quantiles is $f_{ax,j,05,mean}$ = 6.63 MPa. By considering the individual potentials, in comparison to $f_{ax,05}$ for series C_RF90 and $f_{ax,k}$ acc. to [15], the characteristic value is on average 9 % and 13 % higher, respectively. The bandwidth of the ratio $f_{ax,j,05,est} / f_{ax,j,test}$ is 0.77 to 0.92, the average value 0.85, which means that the applied approach is conservative; theoretically the capacity of 1 / 24 specimens could be overestimated.

Acc. to the load and resistance factor design (LRFD) approach, as implemented in the Eurocode, the reduced uncertainty not only consequence in higher characteristic values but also in lower partial safety factors γ_M. Acc. to [16], for simple cases and lognormal variables the design value can be calculated acc. to Equation (4):

$$y_d = \mu_Y \exp\left(-\frac{1}{2}\ln(1 + CV_Y^2) - \alpha_s \beta \sqrt{\ln(1 + CV_Y^2)}\right) \qquad (4)$$

https://doi.org/10.52202/069179-0176

where α_s is the sensitivity factor and β the target reliability index. In the following a 50-year reference period with $\alpha_s = 0.8$ and $\beta = 3.8$ for buildings in consequence class CC2 are applied. Acc. to [15] the reference partial safety factor for connections is $\gamma_M = 1.30$. Considering the significantly reduced uncertainty associated with the individually estimated withdrawal strengths $f_{ax,j}$, the partial safety factor can be adapted accordingly by reformulating Equation (4). In this special and simplified case $\gamma_M = 1.05$ would be sufficient to reach the same reliability (please note: $\gamma_M = 1.30$ is already higher than required for the reference case with CV[f_{ax}] = 15 %).
Although this demonstration example is rather simplified and could be also further elaborated by means of a Baysian approach, it clearly shows the advantages of RID in the sense of applying regression equations with high prediction quality for an individual estimation of withdrawal properties by means of in-situ acquisition of indicating properties. The reduced uncertainty allows to apply higher characteristic values and lower partial safety factors. Apart from that, knowing more about the individual screw properties in combination with a controlled screw application also raises the knowledge on the group behaviour. This enables to increase the effective number of screws accountable in the design, i.e. to apply a higher n_{ef}.

4 CONCLUSIONS

Within this contribution the potentials of an automated and controlled screw application are exemplarily analysed. The first part discusses the basic setting, parameters and requirements to secure a controlled automated screw application for the investigated screws. The second part outlines the power of the insertion energy as indicator for the withdrawal properties and demonstrates exemplarily the advantages of an individual estimation of the screw properties instead of using characteristic values of the population as common in the current design. In the following, the main conclusions of both parts are given.

4.1 AUTOMATED APPLICATION – CONTROL PARAMETERS

The automated application process is divided into its phases: (feeding and) positioning, biting, insertion and tightening (see Figure 13).
In the following paragraphs the established control parameters and their influences are summarized for each application phase. Furthermore, quantified suggestions for an automated application of the investigated self-tapping screws with countersunk heads connecting steel components with timber specimens of a typical density according to Norway spruce, diameters of $d = \{8; 10; 12\}$ mm and insertion lengths designed for screw tension failure, are made.

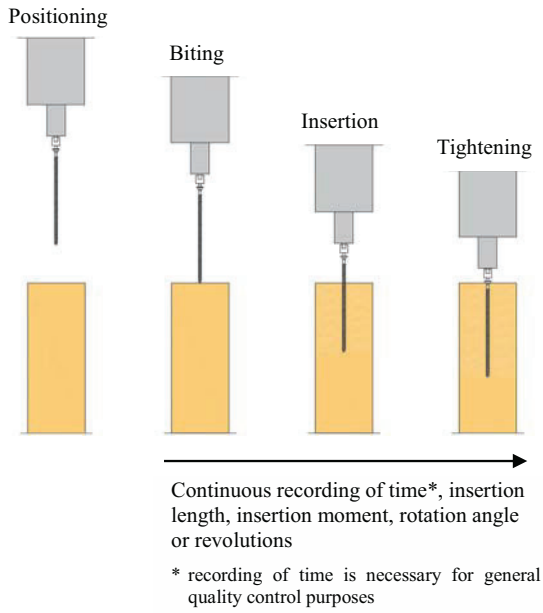

Figure 13: *Principle phases of an automated screw application process.*

- For feeding and positioning information on the screw (type, diameter, length and head), the screw drive, the application angles (in and out of plane) and position on the timber specimen are necessary.
- Strong influences on the biting behavior can be traced back on the contact pressure, the screw characteristics (diameter, tip-type) and on the local properties of the anchoring timber (e.g. density, growth characteristics). Overall, the load-grain angle α was found to have only a minor influence, althought the test results show that biting of screws inserted in grain ($\alpha = 0°$) is slightly more difficult than at $\alpha = 45°$ or 90°. Knowledge of the above mentioned boundary conditions is necessary to define a sufficient contact pressure. In general, a higher contact force is required for larger screw diameters and/or higher densities (including growth characteristics). Within the tested boundary conditions a contact force between 0.5 and 1.0 kN is suggested for rapid biting. The upper limit is set to prevent bending of the screw and damage of the timber specimen in the area of the tip. It is suggested to set the RPM to approx. 20 Hz for rapid biting of the screw.
- As for the insertion of the thread, control of the insertion length and the insertion moment is necessary to prevent failure due to torsion. RPM can be accelerated after biting. To prevent the screw from overturning a limitation of the insertion moment of 70 % of the respective torque resistance is advised.
  Before the tightening of the screw the RPM has to be decelerated in time at a certain insertion length, depending on the pitch of the screw, the RPM during insertion and the deceleration rate of the RPM. Furthermore, angular deviations of the screw must be

taken in account when setting the insertion length for deceleration.

- It is advised to decelerate the RPM asymptotically to 5 Hz (or less) to tighten the screw in a controlled manner, as the insertion moment increases very rapidly when the screw head contacts the sinking. To achieve a tight fit of the screw without failure, limiting the tightening torque with 80-90 % of the torque resistance (depending on underhead features) is advised.

4.2 IN-SITU PERFORMANCE ASSESSMENT – INSERTION ENERGY

- The insertion energy, which can be measured continuously in the course of a controlled automated screw application, has been identified as an extremely powerful predictor for the withdrawal properties of the investigated screw types.
- The high degrees of determination of presented power regression models $f_{ax} \sim W$ and $K_{ser} \sim W$ based on the investigated data sets demonstrate exemplarily the possibility for a significant reduction of the uncertainty in individually estimated withdrawal properties. As consequence, on average higher characteristic withdrawal properties and overall lower partial safety factors for the controlled failure modes could be applied.
- Overall better controlled and research informed executed joints might also be designed for higher capacities which is in addition supported by a higher accountable effective number of fasteners (n_{ef}) for the controlled failure modes. In order to react appropriately on differences between designed and in-situ estimated withdrawal properties, opportunities to adapt the joint execution are required, e.g. by adaptation of the insertion length, the number of fasteners within a joint and/or the spacing between joints in discretely equipped connection lines. This together provides a set of new possibilities to thoroughly re-consider the design-to-execution process by implementing research informed design (RID).
- This new process would have positive effects not only on the overall efficiency of prefabricated timber constructions but in particular on the over-strength-design for the brittle failing connection components since the existing potential could be better exploited. The resulting lower ratio between the properties of ductile and brittle failure mechanisms consequently would yield an economically more viable solution in particular for the design in case of characteristic load scenarios.
- Nevertheless, it needs to be considered that the investigations on the total insertion energy to date are limited to Norway spruce, screw types {RF; P1}, nominal screw diameter $d = 8$ mm, insertion length 50 mm, self-tapping insertion, load-grain angles $\alpha = \{0°; 90°\}$ and screwing through the specimen. Additional investigations are needed to further validate the applicability of the presented approach, in particular under variation of the nominal screw diameter, insertion length, additional load-grain angles and without screwing through the specimen. In addition, certain parameters need to be considered which have an effect on the insertion energy but not on the withdrawal properties. Consequently, structural reliability investigations need to be intensified for a fundamental quantification of expectable gains.

INFLUENCE OF LOW CURING TEMPERATURES ON THE STRENGTH DEVELOPMENT OF END-GRAIN BONDED TIMBER

Dio Lins[1], Steffen Franke[2]

ABSTRACT: The end-grain bonding of timber components with the Timber Structures 3.0 technology (TS3) is an emerging construction method in timber engineering for which various research projects are being conducted. For onsite applications, among other things, it is being investigated how low temperatures during the curing process affect the bonding. The current research results show that low curing temperatures have a negative impact on the mechanical properties of the bond. However, it also shows that low temperatures have a different effect on the pure casting resin strength (cohesion) than on the bonding strength (adhesion). It has turned out that the pure casting resin is neither the decisive factor for the tensile strength of the end-grain bonding nor for the curing time. Based on these findings, compensation measures for bonding at low temperatures can be determined and further research can be carried out.

KEYWORDS: Cross Laminated Timber, end-grain bonded timber, tensile strength, temperature effect

1 INTRODUCTION

With the TS3 technology, timber components are bonded together at the end-grain surfaces in a statically load-bearing manner. In particular, this offers the possibility of creating biaxial load-bearing flat slabs made of Cross Laminated Timber (CLT) in any geometry and size. For this purpose, CLT elements with pre-treated side surfaces are mounted next to each other with a 4 mm gap between. This gap is then filled with a casting resin so that a bonding takes place without lateral pressure necessary. A two-component polyurethane casting resin is used, like that used for bonding steel rods into load-bearing timber components.

However, in order to establish this technology internationally and thus create a high-quality climate-neutral substitute for reinforced concrete slabs, the required processing or curing temperature of at least 17 °C according to the approval for bonded-in steel rods in load-bearing timber components [1] is currently still a challenge for construction site application. The reason for this is that this temperature is hardly or only rarely reached during the colder season in parts of the European sales market, especially in Scandinavia, which has a high affinity for timber constructions, but also in the Baltic States and Central Europe. Therefore, practicable solutions must be found to extend the applicability geographically without being limited to the summer season. For bonded-in steel rods, there have already been studies on the temperature dependence of the bonding and experiments on bonding at low temperatures have been carried out, for example using inductive heating (see [2]). The experiments described in this paper also address the question of temperature influence to be able to embed the TS3 technology as soon as possible in quality assuring design standards, as for universal finger joints [3].

2 MATERIAL AND METHODS

2.1 GENERAL

The curing process depends not only on the curing temperature but also on the curing time [1]. According to the approval, this is 14 days at 17 °C until the final strength is reached [1]. To determine whether the specified final strength is only achieved after a longer curing time at lower curing temperatures, or whether this remains significantly lower, the curing process is investigated experimentally as a function of the two parameters temperature and time.

In order to determine the curing characteristics of the casting resin, test specimens are cast at about 20 °C and then allowed to cure at different (lower) temperatures (20 °C, 15 °C, 10 °C, 5 °C, 0 °C) and tensile tests are carried out at different times. These tensile tests take place on the 1. / 2. / 3. / 6. / 10. / 15. / 20. / 30. day after casting. In addition, it is checked whether and, if so, to what extent post-curing takes place during post-storage at 20 °C. For this purpose, after 20 days of curing at low temperature, test specimens are subsequently stored at 20 °C for a further 7 or 14 days (see Figure 1) and then subjected to a tensile test.

According to the manufacturer's data, the tensile strength of the pure casting resin is approx. 45 N/mm^2, which is significantly higher than the previously determined strength of bonded timber (end-grain bonding).

https://doi.org/10.52202/069179-0177

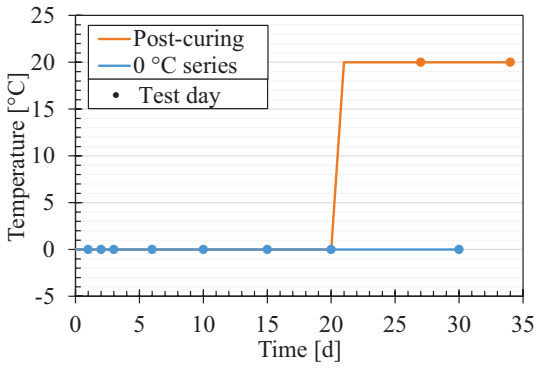

Figure 1: *Exemplary representation of the curing temperature for the 0 °C series incl. post-curing*

Furthermore, low curing temperatures may have a different effect on the curing characteristics of the bonding strength, than of the pure casting resin. Therefore, timber bonding specimens are additionally tested. The development of hardness for similarly stored casting resin samples was also investigated to derive a possible correlation between hardness and strength. This correlation could be used to introduce an additional option for quality monitoring. In this way, the simple and quick handling of the hardness test can be conducted on the construction site and thus conclusions can be drawn about possible curing deficits.

2.2 DETERMINATION OF THE CASTING RESIN STRENGTH

The casting resin strength is tested according to SN EN ISO 527 (Plastics - Determination of tensile properties) [4]. To produce the test specimens, TS3's own 2K-PUR casting resin "TS3 PTS CR192" is poured into a template to obtain the geometry according to Figure 3. This template is fixed in a casting device (see Figure 2). Immediately after casting, the test specimens together with the casting device are stored in a climate chamber at the respective low temperature. On the first test day, all test specimens of a series are taken out of the template and

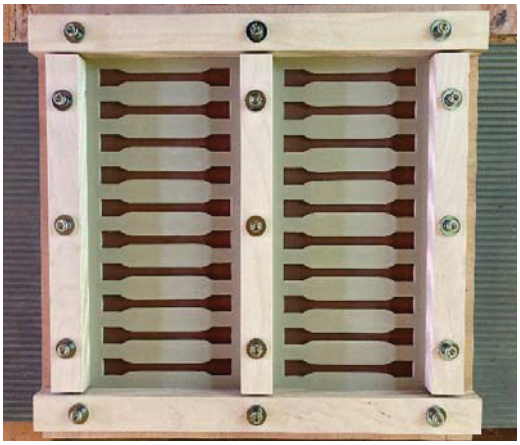

Figure 2: *Casting device*

	Specimen type	1A	1B
l_3	Overall length[a]	170	≥150
l_1	Length of narrow parallel-sided portion	80 ± 2	60,0 ± 0,5
r	Radius	24 ± 1	60 ± 0,5
l_2	Distance between broad parallel-sided portions [b]	109,3 ± 3,2	108 ± 1,6
b_2	Width at ends	20,0 ± 0,2	
b_1	Width at narrow portion	10,0 ± 0,2	
h	Preferred thickness	4,0 ± 0,2	
L_0	Gauge length (preferred)	75,0 ± 0,5	50,0 ± 0,5
	Gauge length (acceptable if required for quality control or when specified)	50,0 ± 0,5	
L	Initial distance between grips	115 ± 1	115 ± 1

[a] The recommended overall length of 170 mm of the type 1A is consistent with ISO 294-1 and ISO 10724-1. For some materials, the length of the tabs may need to be extended (e.g. l_3 = 200 mm) to prevent breakage or slippage in the jaws of the testing machine.

[b] $l_2 = l_1 + [4r(b_2 - b_1) - (b_2 - b_1)^2]^{1/2}$, resulting from l_1, r, b_1 and b_2, but within the indicated tolerances.

Figure 3: *SN EN ISO 527-2:2012: Dimensions of type 1A and 1B test specimens [4]*

the thickness is calibrated on a wide belt sander (grit 100) to the specified 4 mm ± 0.2 mm (see Figure 3). Subsequently, the test specimens are again stored at the respective low temperature and removed from the climate chamber at the planned times and subjected to a tensile test. The tensile test also takes place according to EN ISO 527 and is displacement-controlled with a test speed of 2 mm/min. The test is carried out in a constant climate of 20 °C and 65 % r. h. Since the casting resin is a homogeneous material after mixing the two components and thus a low scatter is to be expected, only three test specimens are tested per test day and temperature.

2.3 DETERMINATION OF THE BONDING STRENGTH

The bonding strength of the end-grain bonding at low temperatures is determined following the TS3 approval tests of the MPA University of Stuttgart [5]. These in turn were carried out in close accordance with DIN EN 301 [6] and DIN EN 302-1 [7]. Just like the tensile tests of the pure casting resin, the timber bonding test specimens are also tested at 20 °C and 65 % r. h. with a displacement-controlled test speed of 2 mm/min.

To be able to consider the temperature influence in isolation, all other parameters are excluded as possible influencing factors on the tensile strength as far as possible. For this purpose, spruce timber with a low scattering gross density of 350 kg/m^3 ± 25 kg/m^3 is defined for all test specimens. Secondly, the wood moisture content should be 12 % in all test series. For this purpose, the relative humidity is adjusted according to the respective temperature in such a way that a compensation wood moisture content according to Keylwerth and Noak [8] of 12 % is achieved. For monitoring purposes, the

https://doi.org/10.52202/069179-0177

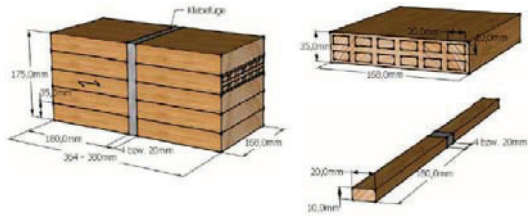

Figure 4: *Schematic representation of the axial composite tensile test specimen [5]*

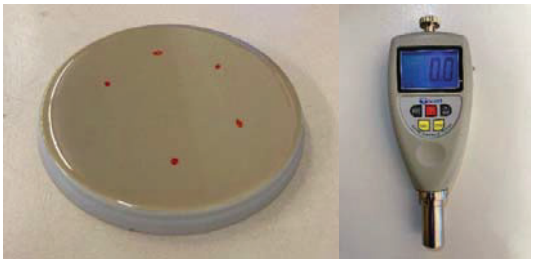
temperature, the relative humidity as well as the wood moisture content are recorded during the entire test. The wood moisture content is measured in two separate ways on reference test specimens, which are also located in the climate chamber. On the one hand, the wood moisture content is continuously recorded using the resistance method, and on the other hand, several test specimens are weighed regularly, and oven dried at the end of the test series to determine the wood moisture content at the respective measurement times. Since wood defects, such as knots in particular, have a great influence on the tensile strength of the small, end-grain bonded test specimens, these are also excluded in order to be able to determine the temperature influence as accurately as possible.

To produce the timber bonding test specimens, glulam elements are first made from board lamellas, see Figure 4, left. These are then cast together on the end-grain surface according to the TS3 technology and stored in a climate chamber at the intended temperature. Analogous to the determination of the casting resin strength, the glulam elements are cut apart after the first day, so that the test specimens are produced with the dimensions 10 mm x 20 mm, see Figure 4. These are then stored again in the climate chamber and tested on the corresponding days. The aim of this complex test specimen production is to eliminate possible edge influences such as bubble formation or incomplete casting, because although these are negligible on the component scale, they can result in significant deviations in the small test specimen geometry. Since the timber and thus the bonding test specimens, despite the homogenisation approaches mentioned above, give rise to the assumption of greater scattering compared to the casting resin, five test specimens are tested per test day and temperature.



(a) Test specimen *(b) Durometer*

Figure 5: *Test specimen (a) and measuring device (b) for determining the casting resin hardness*

2.4 DETERMINATION OF THE CASTING RESIN HARDNESS

The hardness is determined according to EN ISO 868 [9]. According to the standard, the Shore-D hardness of the "TS3 PTS CR192" casting resin is tested with a corresponding durometer (see Figure 5). The test specimens are small round plates (see Figure 5), which are cast in corresponding templates and then stored with the tensile test specimens in the climate chamber. Five hardness measurements are conducted on different samples for each test day and temperature.

3 RESULTS

3.1 GENERAL

In Figure 7 to Figure 9, the mean value curves of the three measured variables (casting resin strength, bonding strength, casting resin hardness) including standard deviation are plotted against time and compared with each other for the different curing temperatures. This is shown individually for each measurand. In addition, a comparison of the curves of the three measured variables is shown as an example for 10 °C curing temperature in order to recognise the correlation between the casting resin hardness and strength. Furthermore, a proposal is made for a design concept that considers the influence of low curing temperatures on the tensile strength of end-grain bonded timber components.

3.2 CASTING RESIN STRENGTH

Figure 7 shows the development of the tensile strength of the casting resin at the five different curing temperatures. It can be seen that lower curing temperatures result in significantly lower initial strengths. It can also be seen that the strength development is completed more quickly at higher temperatures than at lower ones. It can also be seen that the post-curing effect has a greater impact at lower curing temperatures and is no longer noticeable at 15 °C. The difference between the final strengths after post-curing is exceedingly small and the overall scatter is relatively low, as expected.

3.3 BONDING STRENGTH

Since knots were removed from the composite test specimens to isolate the influence of temperature, the absolute strength values are not directly representative for

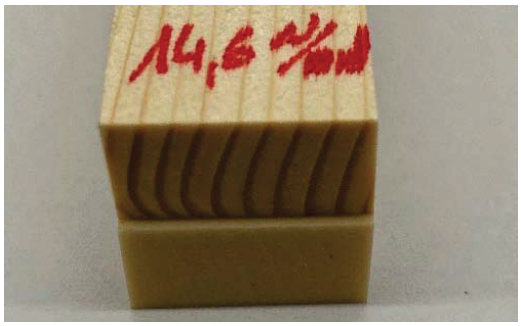


Figure 6*: Fracture pattern of timber bonding test specimen*

https://doi.org/10.52202/069179-0177

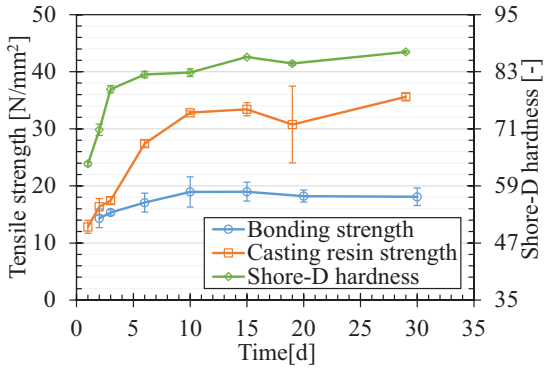

Figure 10: *Comparison of the casting resin strength, the bonding strength, and the casting resin hardness at 10 °C (mean values)*

design; however, the temperature comparison provides an elevated level of information. Figure 8 shows, analogous to Figure 7, the development of the tensile strength of the timber bonding specimens at the different curing temperatures. Here, too, lower temperatures during curing result in lower initial strengths. However, regardless of the curing temperature, the final strength is reached earlier than with the pure casting resin, i.e., at the latest approx. 6 days after casting. Furthermore, there is no further increase in strength during post-curing, so that low curing temperatures also result in lower final strengths. It is also clear that the scatter in the bonding strength is, as expected, higher than with the pure casting resin. Furthermore, it is noticeable that in most cases the fracture appears to occur exactly in the area between the pre-treatment and the casting resin (see Figure 6).

3.4 CASTING RESIN HARDNESS

Figure 9 shows the development of the casting resin hardness at the different curing temperatures. As in the two previous diagrams, it can be seen that a lower curing temperature results in a significantly lower initial hardness. Analogous to the casting resin strength, it can also be seen with the casting resin hardness that curing proceeds more slowly at lower temperatures, since the final hardness is reached significantly later than at higher temperatures. As with the casting resin strength, the post-hardening effect is also greater at lower temperatures than at higher temperatures. Here, however, this effect is no longer significant at 10 °C. Accordingly, the final hardness after post-curing is at a similar level despite the different curing temperatures, but with greater differences than for the casting resin strength. The scatter of the casting resin hardness is also very low, analogous to the casting resin strength.

3.5 COMPARISON CASTING RESIN STRENGTH – BONDING STRENGTH – CASTING RESIN HARDNESS

The comparison between the casting resin strength, the bonding strength, and the casting resin hardness in Figure 10, shown exemplarily for 10 °C curing temperature and without the post-curing, shows that the three measured variables basically correlate with each other over the period of 30 days. However, this fundamental correlation is not very surprising, as all the measured variables mentioned inevitably increase due to the chemical reaction after casting. However, a closer look at the graphs reveals that the casting resin strength and hardness in particular show approximately parallel curves. This can also be confirmed by the correlation coefficient according to Pearson [10] of 0.91 (r above 0.8: "high to perfect correlation"). Compared to the bonding strength, the

https://doi.org/10.52202/069179-0177

deviations of the curves are significantly greater since the bonding strength increases less strongly between initial and final values and also reaches its final values considerably faster.

3.6 DESIGN CONCEPT

In the following, based on the findings on the curing characteristics of the bonding strength, a proposal for a design concept is developed which considers the temperature influence on the tensile strength of the TS3 joint. For this purpose, the results of the timber bonding series are first presented in a different form. The final tensile strengths of the individual series, i.e., the respective values from the 10th day after casting, are summarised and evaluated for each series. The mean value is formed, and the standard deviation is calculated. Then the tensile strength is plotted against temperature instead of time (see Figure 11). As already described in chapter "3.3 BONDING STRENGTH" it can be seen that the tensile strength also increases with increasing curing temperature. However, this relationship is not linear. The additionally drawn green dotted trend line corresponds to a third-degree polynomial.

The design concept is conceived based on DIN EN 1995-1-1 [11] so that it can be integrated as well as possible into the existing standardisation. Accordingly, the design value of the tensile strength of timber in fibre direction is calculated as in equation (1):

$$f_{t,0,d} = k_{mod} * \frac{f_{t,0,k}}{\gamma_M} \quad (1)$$

The following condition must then be fulfilled for the dimensioning (equation (2)):

$$\sigma_{t,0,d} \leq f_{t,0,d} \quad (2)$$

To take into account the temperature influence on the tensile strength of the TS3 joint, a coefficient k_t is proposed, which is included in the design specification as follows (equation (3)):

$$\sigma_{t,0,d} \leq k_t * f_{t,0,d} \quad (3)$$

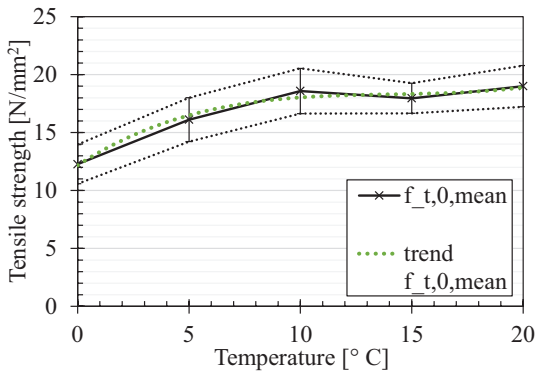

Figure 11: *Temperature comparison of the bonding strength (mean values)*

This coefficient must be dimensionless, lie between 0 and 1 and describe the temperature range between 0 °C and 20 °C to which its application is initially restricted. For the dimensionless determination of the coefficient k_t the ultimate tensile strengths of the different temperatures are normalised so that the tensile strength at 20 °C corresponds to 100 %, i.e., 1.0 (see Figure 12).

In contrast to the cubic trend line in Figure 11, the following bilinear approach for k_t (equation (4) and (5)) is chosen for simpler calculation in engineering practice (see Figure 12):

$$0\,°C \leq t < 10\,°C\colon\ k_t = 0.65 + 0.033 * t \quad (4)$$

$$10\,°C \leq t < 20\,°C\colon\ k_t = 0.98 + 0.002 * t \quad (5)$$

The concept presented is only a first proposal for the consideration of the temperature influence on the tensile strength of the TS3 joint in the design. Apart from the fact that the concept in its described form is on the unsafe side in the range of 15 °C, the introduced coefficient refers to the mean values of very small samples where timber features such as knots were sorted out. For the actual applicability, it is indispensable to generate a representative sample length with a commercially available timber sorting as a basis for the coefficient k_t and to define the ratios of the characteristic tensile strengths as a basis.

4 DISCUSSION AND CONCLUSION

The test results presented provide important findings for TS3 bonding at curing temperatures below the 17 °C specified by the manufacturer. The investigated properties (casting resin strength, bonding strength, casting resin hardness) initially show lower values at lower curing temperatures. However, the curing characteristics of the bonding strength and the casting resin strength differ significantly in some cases. Worth mentioning here is the fact that the final strengths of the timber bonding specimens are achieved significantly faster than those of the pure casting resin, regardless of the temperature. In addition, in contrast to the casting resin strength, there is no discernible post-curing effect in the timber bonding specimens, which means that the final strengths after post-

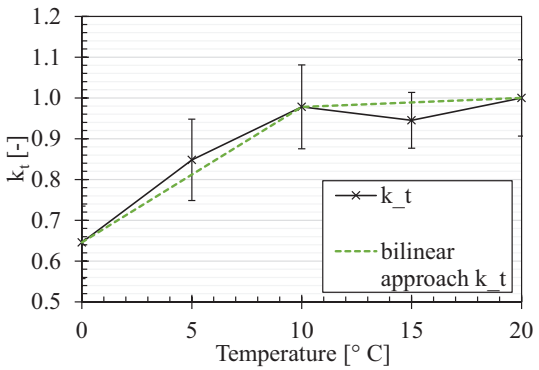

Figure 12: *Coefficient k_t*

https://doi.org/10.52202/069179-0177

curing of the timber bonding specimens differ significantly as a function of temperature, whereas they are at a similar level with the pure casting resin. These observations can be justified based on the bond fracture pattern: Since the fracture apparently occurs in the area between the pre-treatment and the casting resin, it can be assumed that the adhesion between the pre-treatment and the casting resin is the decisive factor for the bonding strength and reaches its final strength approx. 6 days after casting. The further curing of the casting resin therefore no longer has any influence. The following conclusions can be drawn from this:

- An extension of the curing time does not result in a higher bonding strength.

- Possible additional measures for tempering the TS3 joint are only required over a relatively brief period of time.

Furthermore, the assumption that there is a strong correlation between casting resin strength and hardness has been confirmed. This can be used to enable additional quality monitoring by means of on-site hardness tests. However, this can only be used to monitor the properties of the pure casting resin and thus detect possible negative influences (mixing ratio, curing temperature). However, it is not possible to draw a direct conclusion on the bonding strength without further ado, as the timber results in further influencing factors (wood moisture content, raw density, knottiness) that cannot be recorded by the curing characteristics of the pure casting resin.

5 OUTLOOK

To validate the previous findings on the curing characteristics of the bonding strength as a function of temperature, further test series are being carried out. For this purpose, a larger number of samples with larger timber cross-sections are evaluated, which already have the respective low temperature when casting, in order to represent the "worst case" that can occur on the construction site. The timber used corresponds to a commercially available sorting to be able to generate representative absolute tensile strength values. In addition to the distribution function, both the mean values and the characteristic values of the respective tensile strength must be determined. In particular, this is intended to further elaborate the design concept, because up to now this has been based on the mean values of relatively small samples. To be able to actually apply the concept in practice, it must refer to the characteristic values of representative samples. Furthermore, within the framework of these test series, random samples of the fracture patterns are analysed microscopically. In addition, the possibility of casting the resin at a temperature of 35 °C to obtain higher tensile strengths is being investigated.

Another approach to be able to conduct the end-grain bonding in the future even at low outside temperatures without loss of strength is the local tempering of the casting resin joint during the curing time with a heating wire. This possibility is also currently being researched at BFH so that it can be used as soon as possible.

ACKNOWLEDGEMENT

The project is a collaboration of Timber Structures 3.0 AG, Schilliger Holz AG, Henkel & Cie. AG, ETH Zürich and BFH. Gratefully acknowledged by the authors is the intense cooperation among the partners of this project, as well as Innosuisse, which is funding the ongoing project to a greater part.

EXPERIMENTAL CHARACTERIZATION OF THE MULTI-DIRECTIONAL BEHAVIOUR OF ANGLE BRACKETS AND HOLD-DOWNS

Riccardo Fanti[1], Andrea Polastri[2], Daniele Casagrande[3], Ernesto Callegari[4], Alvise Ramazzini[5], Luca Sestigiani[6], Peter Lang[7]

ABSTRACT: The multi-directional mechanical behaviour of angle brackets and hold-downs (i.e. NINO and WKR) is investigated in this study by means of monotonic tests in tensile (F1), in-plane shear (F2/3) and out-of-plane (F4) load configurations. The values of resistance and stiffness for each angle bracket were determined. For WKR hold-downs the load acting on anchor bolt were measured through a load cell. The analyses of results showed that the tested connectors are characterized by significant strength and stiffness for different load configurations, as reported in other experimental campaign for similar connectors where the multi-directional behaviour was investigated.

KEYWORDS: angle bracket, hold down, CLT connections, multi-directional behaviour, monotonic tests.

1 INTRODUCTION

The mechanical behaviour of Cross Laminated Timber (CLT) and Light-Frame Timber (LTF) shearwalls is typically governed by the connections used to either connect the timber elements each other or anchor the wall to either the foundation or the floor below [1,2]. Hold-downs are usually placed on the two vertical edges of the shearwalls in order to limit the rigid body rotation of the wall while angle brackets are uniformly distributed along the entire length of the shearwall to limit sliding. Angle brackets and hold-downs are typically composed with cold-formed steel plate (2-3mm thick) connected to timber elements by means of nails or screws and to the foundation with a threated steel bar. A uni-directional behaviour of hold-down and angle brackets is typically assumed by the designers [3], so that hold-downs are designed to resist a tensile-vertical load (uplift), due to the rocking, while angle-brackets are primarily designed to resist the shear-horizontal actions: interaction between tensile (F1) and in-plane shear (F2/3) loads is neglected.

Recent experimental campaigns show both traditional [4,5,6] and innovative [7] typologies of angle brackets can be characterized by significant strength and stiffness along multiple directions. The results at connection level are confirmed in shearwalls experimental tests where panels were anchored to the foundation through traditional [8] and innovative [9] angle brackets without using any hold-downs. As a result, the bi-directional behaviour of such types of connectors cannot be neglected in design calculations and experimental testing should be conducted by considering multiple direction load configurations. This paper presents the results obtained from an experimental campaign conducted with the aim to characterize the multi-directional behaviour of the new Rothoblass NINO angle bracket (Figure 1a) and WKR hold-down (Figure 1b). The influence on the mechanical behaviour due to different load configurations, fastener patterns, eccentricity between the fasteners in vertical and horizontal flanges, application of washer and geometry of steel plates were analysed. For tested WKR hold-downs, the load acting on the steel bar used to anchor the hold-down to the foundation was measured in order to determine the load amplification factor on the steel bar.

2. MATERIALS AND METHODS

Rothoblaas NINO angle brackets and WKR hold-downs are obtained from a S235 or S250GD steel plate with different thickness (t) depending on the model. The geometry of each connector (Figure 2) is reported in Table 1. The number and the diameter (d) of holes in vertical flange (Side A) and horizontal flange (Side B) are specified. Holes with d equal to 5mm were used for nails

while holes with d equal to 10mm and 14mm were used for screws and bolts, respectively. According to ETA-22/0089 [10], in timber-to-foundation (T-F) connection, NINO15080 and NINO100200 can be installed with specific 6mm thick and 8mm thick washer, respectively.

a. b.

Figure 2: *Geometry of: a. NINO and b. WKR.*

In timber-to-timber (T-T) connections NINO angle brackets can be installed in two different configurations: with or without screws VGS 9x140mm in the horizontal flange (screwed with an inclination of 15° close to the bend line as for TTV angle bracket [7] in addition to the 4x60mm ring shank nails. The tension loads are transferred from the threaded shank of these screws into the CLT floor panel, avoiding large deformations of horizontal flange. WKR hold-downs have to be anchored in T-T and T-F connection through screw (HBS, TBS or VGS) and M12 threaded rod (in horizontal plate), respectively. Both NINO and WKR connector can be installed with different fasteners patterns in vertical and horizontal flanges, according to [10].

All three different NINO angle brackets were tested along F1, F2/3 and out-of-plane compression (F4) load directions, see Table 2. The WKR hold-downs were conversely tested along F1 and F4 configurations, see Table 3. In some cases of T-F connection an interlayer was interposed to simulate the mortar layer or the concrete curb under the wall panel. The WKR285 was also tested with 10mm gap under the horizontal flange in order to characterized the behaviour of hold-down for particular applications, when there is no contact between the base of connection and the foundation/floor panel.

Sixty-nine monotonic tests were carried out (three tests for each angle bracket or hold-downs for different fasteners patterns and load configuration). Tests were performed according to EN26891:1991 [11]. The load rate was not greater than 0,2 mm/s and the maximum load was reached in 300 ± 120 s in all tests.

In T-T and T-F connections loaded in F1 direction one NINO angle bracket was fastened at each side of CLT wall panel (two angle brackets on each panel) in symmetric configuration and the specimens were tested as shown in Figure 3a and Figure 3b, respectively, while in the specimens loaded in F2/3 direction two NINO angle brackets were fastened at each side of CLT wall panel (four angle brackets on each panel) in symmetric configuration as shown in Figure 3c and Figure 3d, respectively. In T-T connections along F4 direction one NINO100100 angle bracket was fastened at each end of CLT panel, (two angle brackets on each panel), as shown in Figure 3e. For all load directions tested, NINO angle bracket's horizontal flange in T-T connection was nailed (or nailed and screwed) to the CLT floor panel while in T-F connection was bolted to the steel setup.

3-layer 100 (33-34-33) mm thick CLT panel and 5-layer 140 (30-30-20-30-30) mm thick CLT panel are used in NINO angle brackets experimental tests to represent wall and floor panel, respectively, while a 80mmx160mm C24 solid wood stud is used in WKR hold-downs experimental tests to represent external vertical element of a timber frame.

The vertical flange (Side A) of each connector is fastened to the CLT panel or to the solid wood stud through Rothoblaas LBA 4x60mm ring shank nails (ETA-22/0002 [12]); horizontal flange (Side B) of each connector is fastened to either the CLT panel (T-T configuration) or to the steel base (T-F configuration) by means of Rothoblaas LBA 4x60mm ring shank nails [12] and Rothoblaas VGS 9x140mm screws (ETA-11/0030 [13]) or M12 8.8 steel bolts.

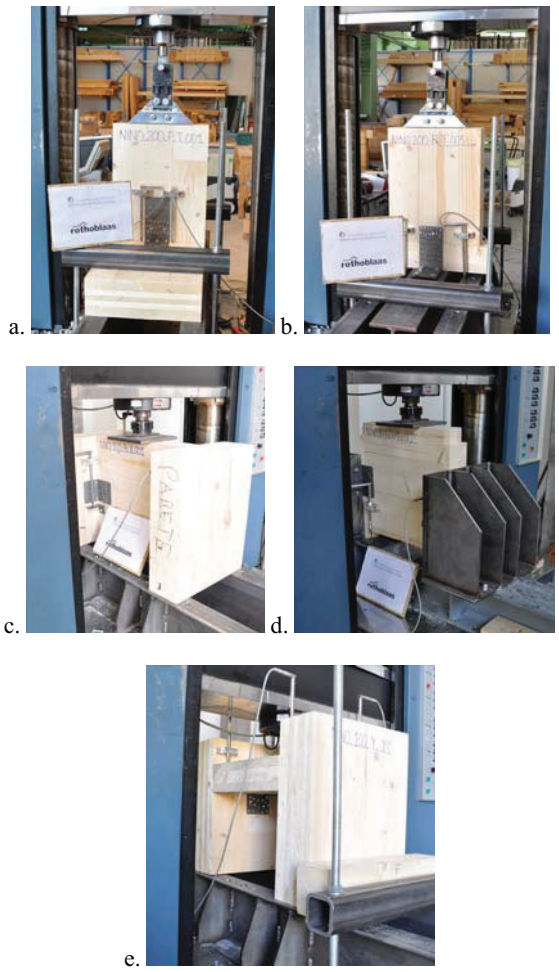

Figure 3: *Setup for: tensile force F1 (a. T-T, b. T-F), shear force F2/3 (c. T-T, d. T-F) and out-of-plane force F4 (e. T-T).*

In WKR hold-down connections loaded in F1 direction (except WKR530) one WKR hold-down was fastened at each side of solid wood vertical stud element in symmetric configuration (two hold-downs on each stud) and tested as shown in Figure 4a (WKR can be noted in the bottom part of the picture). The WKR530 hold-down was bolted directly to the testing machine through M5 bolts and the load was applied directly to the steel plate, as shown in Figure 4b. The vertical flange was nailed to the solid wood stud through twenty-two 4x60mm ring shank nails. In both cases the horizontal flange of hold-down was bolted to the load cell in order to measure the load acting on bolt. Along F4 direction two WKR095 hold-downs were fastened at each end of CLT panel, (four hold-downs on each panel), as shown in Figure 4c.

For each connector the maximum load F_m and corresponding displacement v_m, the load at 15mm F_{15}, the displacements $v_{0,1Fm}$ and $v_{0,4Fm}$ at $0,1F_m$ and $0,4F_m$ were determined from the load-displacement curves. The tri-linear relationship is determined from the mean force-displacement curve obtained from the three tests in each configuration. The value of yielding load F_y, yielding displacement v_y, ultimate load F_u and ultimate displacement v_u are calculated according to EN12512:2005 [14].

For WKR hold-downs tested in F1 configuration, the load acting on each M12 bolt F_{bolt} that anchored the WKR to the foundation was measured through a load cell. The amplification coefficient k_t, defined as the ratio between the tensile load on the anchoring bolt F_{bolt} and the hold-down F_{WKR}, was calculated according to Equation 1. F_{WKR} for WKR530 is equal to the force F_{app}, measured by the testing machine, while for other WKR hold-downs tested in symmetric configuration F_{WKR} is equal to $F_{app}/2$.

$$k_t = F_{bolt}/F_{WKR} \quad (1)$$

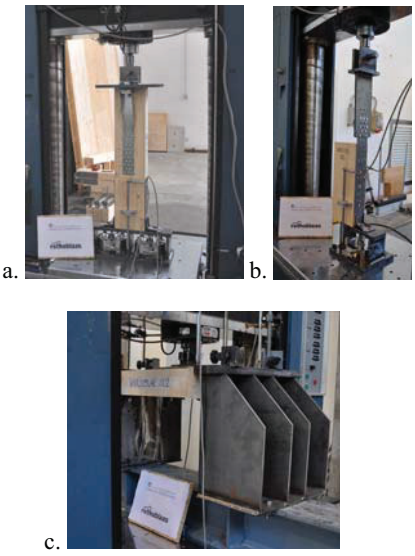

Figure 4: *Setup: a. F1 symmetric, b. F1 WKR530, c. F4.*

3 RESULTS AND DISCUSSION

The results of the experimental campaign on NINO angle brackets and WKR hold-downs are presented in this section. The force-displacement curves, failure modes (Figure 5 and Figure 6 for NINO and WKR connectors, respectively) and tri-linear relationships are reported and discussed.

https://doi.org/10.52202/069179-0178

3.1 NINO ANGLE BRACKETS

Force displacement curves for F1 and F2/3 load directions are reported in Figure 7 (T-F), Figure 8 (T-T) and Figure 9 (T-F), Figure 10 (T-T), respectively.

As shown in Figure 7, in case of T-F connection for F1 load direction, NINO angle brackets equipped with NINO washer showed higher stiffness and strength and a different failure mode compared to the angle brackets without washer: for angle brackets without washer, the failure mode is associated to the pull-through of bolts heads (Figure 5a) in the horizontal flange with large deformation of the steel plate, at the opposite in the angle brackets equipped with washer a ductile failure of nails was observed (Figure 5b).

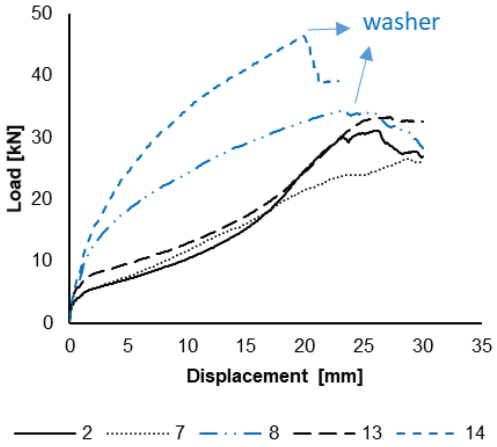

Figure 7: *NINO angle brackets for T-F connection (F1)*

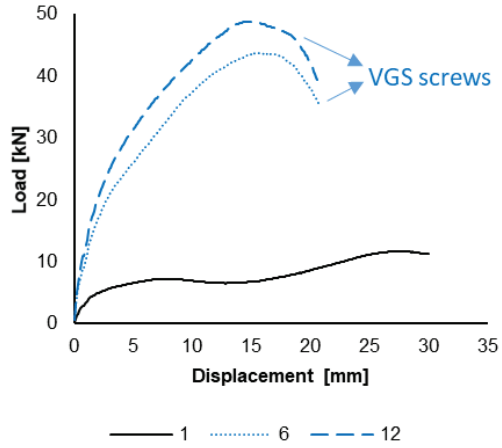

Figure 8: *NINO angle brackets for T-T connection (F1)*

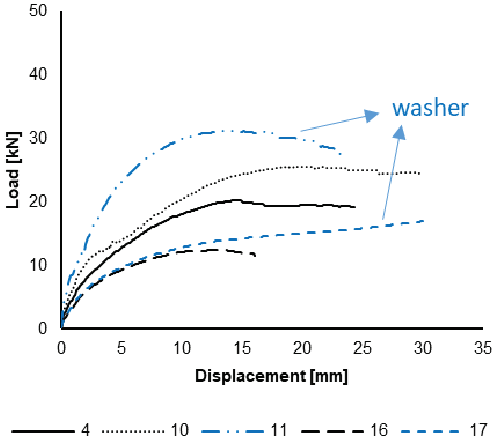

Figure 9: *NINO angle brackets for T-F connection (F2/3)*

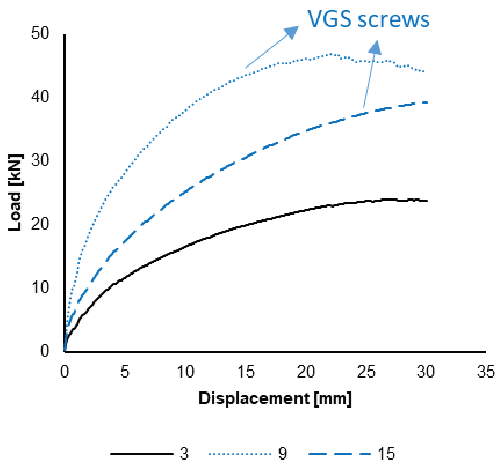

Figure 10: *NINO angle brackets for T-T connection (F2/3)*

As shown in Figure 8, in case of T-T connection for F1 load direction, the NINO angle brackets with VGS screws exhibit a completely different behaviour compared to the NINO without screws when subjected to a F1 load direction. Fully threaded screws installed adjacently to the bend line reduce the eccentricity between the fasteners in the two flanges and significantly increase the strength and stiffness of connections. In NINO angle brackets without VGS screws failure occurs due to the withdrawal of nails in horizontal plate (Figure 5c) while pull-through of screws heads (Figure 5d) or nails shear failure was observed in other cases (depending on the number of nails in vertical flange).

Table 4: *NINO tri-linear curves.*

	5	5,2	5,1	24,2	30,0	44,7	-	-
NINO 150 80	6	6,9	4,2	31,8	16,1	43,6	20,8	34,9
	7	1,5	14,6	23,1	28,7	26,5	30,0	26,0
	8	5,8	2,7	17,7	23,3	34,4	30,0	28,1
	9	8,2	3,1	28,7	22,6	46,9	30,0	43,9
	10	4,3	3,3	16,4	20,8	25,6	30,0	24,6
	11	5,2	4,3	24,9	13,4	31,2	23,3	26,9
NINO 100 200	12	8,6	3,5	34,0	14,8	48,8	20,6	39,0
	13	4,3	3,5	17,1	27,2	33,2	30,0	32,6
	14	5,9	4,9	31,8	19,9	46,4	22,8	39,1
	15	3,7	6,6	26,8	30,0	39,2	-	-
	16	2,7	3,1	9,2	13,1	12,4	16,0	11,5
	17	2,7	3,3	10,0	30,0	16,9	-	-

As for the load direction F1, the angle brackets were tested in F2/3 in different configurations: with and without washer and VSG screws in T-F (Figure 9) and T-T (Figure 10) configurations, respectively. Application of NINO washer or VGS screws allowed to increase the strength and stiffness also in F2/3 load direction, avoiding undesirable failure modes related to large deformations like buckling (Figure 5e) that occurred in some tested NINO angle brackets.

The NINO1001000 angle bracket was also tested in F4 load direction. It was observed remarkable values of strength and stiffness for out-of-plane compression, comparable to the highest values observed in other directions. The connection failed due to the compression perpendicular to the grain (Figure 5f). The tri-linear force-displacement curves parameters were reported in Table 4. The results confirm the marked multi-directional behaviour of NINO angle brackets.

3.2 WKR HOLD-DOWNS

A comparison in terms of force-displacement relationship in F1 load direction is reported in Figure 11 for different WKR hold-downs. The tri-linear force-displacement curve parameters were reported in Table 5.

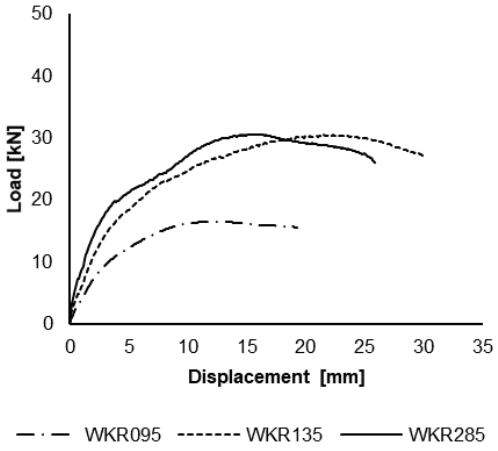

Figure 11: *WKR hold-downs for T-F connection (F1)*

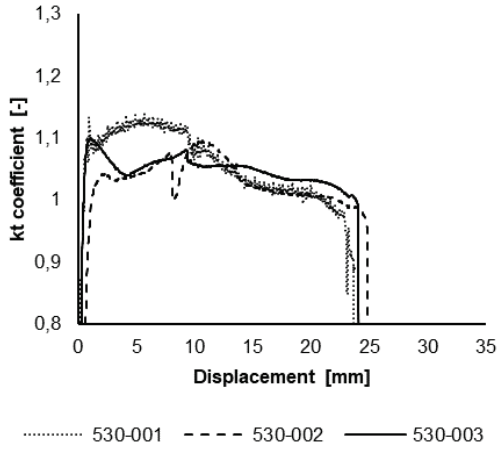

Figure 12*: Coefficient kt for WKR530 hold-down specimens*

In WKR095 hold-downs a shear failure of nails (Figure 6a) was observed while other hold-downs failed due the

https://doi.org/10.52202/069179-0178

pull-through of bolt head (Figure 6b) in the horizontal flange for a value of the load approximately equal to 30 kN (the geometry of the horizontal flange is the same for all WKR hold-downs): for each WKR size greater than WKR095 the pull-through failure was reached (the shear resistance of nails is greater compared to that of the horizontal steel flange).

For all the WKR specimens in F1 load direction the value of k_t factor was calculated for each hold-down and the maximum values are reported in Table 5. In Figure 12 the values of k_t factors calculated according to Eq.1 for the three tested specimens of WKR530 were showed. The values of k_t coefficient never exceed 1,13, for all specimens. The observed values indicate a slightly difference between the load applied to the hold-down and the load acting on anchor bolt. Moreover, the load amplification on anchor system results lower than that obtained from the formulation proposed in several European Technical Assessment [12] (approximately equal to 1,40). As reported in Table 5, the values of coefficient k_t for WKR285 with 10mm of gap are close to one, that means no amplification of load on anchor system are observed for the hold-downs installed with gap. The WKR095 hold-down was also tested in F4 load direction in order to characterized the out-of-plane behaviour: tests showed good results in terms of strength and stiffness (see Table 5).

Table 5: *WKR tri-linear curves.*

WKR 530	23	-	-	-	16,0	30,5	-	-	1,13

4 CONCLUSIONS

The mechanical behaviour of NINO angle brackets and WKR hold-downs was investigated by means of monotonic experimental tests. Several setup configurations were specifically developed in order to test the connectors in different load directions. The main novelties of NINO angle brackets are the use of fully threaded screws and washer in horizontal flange in T-T and T-F connections, respectively. The two devices were never used before for small size angle brackets and significantly increase the strength and stiffness in F1 and F2/3 load direction of connectors. F4 tests confirmed a remarkable multi-directional behaviour for all the tested specimens of NINO angle brackets. WKR hold-downs were studied taking into account the possibility to install the connector with a gap between the horizontal flange and the foundation/floor panel. Proper investigations were conducted in order to measure and calculate the coefficient k_t. Tests showed similar results for installation with or without gap for WKR285 hold-down. The amplification of loads on anchor bolts was measured through load cells and can be taken into account by the designers through the coefficient k_t, which results always lower than 1,13. The tests highlight that the value of this coefficient is close to the unit and is smaller than the value obtained from analytical calculation, reducing the design tensile load on anchor system. No amplification was registered on anchor bolts of WKR285 with gap.

ASSESSMENT OF COMBINED EFFECTS OF AXIAL AND LATERAL LOADING OF GLUED-IN ROD CONNECTIONS IN LVL

Daniel Fawcett[1], Eleni Toumpanaki[2]

ABSTRACT: Glued-in rod connections for timber offer improved strength, stiffness, aesthetics and fire performance compared to bolts and dowels. Extensive investigations have been done into the pull-out capacity of rods under pure axial load, however the capacity and stiffness of laterally loaded rods, particularly when combined with axial loading, is under-researched, with further investigation being crucial as nearly all connections are subject to this combination. The provision of an unbonded length has been shown to increase pull-out capacity, but its effect on laterally loaded rods has not been investigated. Investigations also often use softwoods over hardwoods. As a result, design codes lack informed guidance for laterally loaded rods and underestimate the capacity of rods in hardwood. In this study, 15 Beech LVL specimens with steel rods glued in with epoxy adhesive were subjected to varying ratios of axial to lateral load, to study the combined effects. The introduction of lateral load had no effect on axial capacity with a governing failure mode of rod yielding. The lateral capacity exceeded the design code prediction by 92%, and alternative parameters and equations were presented and discussed for more accurate estimation.

KEYWORDS: Glued-in rods, timber, LVL, Eurocode 5, moment rotation, epoxy

1 INTRODUCTION

1.1 GENERAL OVERVIEW OF GLUED-IN RODS

Glued-in rods (GiRs) offer a desirable alternative to bolts and dowels for timber connections [1]. By inserting rods into pre-drilled holes in timber and filling the surrounding void with adhesive to bond them together [2], a very strong and stiff connection is achieved. Multiple rods glued-in at a distance apart provide efficient moment resistance due to the couple of axial forces created [3]. Greater aesthetic appearance and fire resistance is achieved with the timber cover provided, obscuring the rods [4], whereas conventional connections are often exposed or covered with limited wood sheathing.

It is common for steel to be used as the rod material due to its strength and, crucially, ductility. Carbon and glass FRPs [5] and basalt FRP [6] are sometimes used, though despite being very strong and stiff, they lack high ductility.

The adhesives that have been studied for glued-in rods are epoxy, polyurethane and fibre-reinforced phenol-resorcinol, in descending order of strength (determined by the GIROD project in the late 90s [4]). The first two are used most frequently [2].

There are numerous potential modes of failure with this connection type, including longitudinal shear failure in the adhesive, timber-adhesive interface, steel-adhesive interface or in the timber surrounding the adhesive; timber splitting due to short rod-edge or rod-rod distances (particularly with lateral rod loading); or tensile yield failure of the rod or the timber cross-section [2]. The ductile failure mode of steel rod yielding is always preferred over the other brittle failure modes [7]. As a result, all relevant failure modes should be assessed during design, and rod yielding must be the critical one. This requires a detailed understanding of all the failure modes, and how variation of the multitude of parameters involved, including the effect of lateral loading, affects the failure load for each mode.

1.2 RESEARCH INTO GLUED-IN RODS

Many studies have focused just on the 'pull-out' capacity of glued-in rods by conduction of tests with the pull-pull test setup (rods glued into both ends of a timber element gripped and pulled apart), as studies can be easily compared if they follow the same experimental programme [8]. Softwoods are often the timber type used for tests, meaning that the current design equations,

https://doi.org/10.52202/069179-0179

informed by such tests, often under-predict the pull-out strength of rods glued into hardwoods [9]. In addition, comparatively little research has been done on laterally loaded glued-in rods, let alone combined axial and lateral action. Further research in this area is important as nearly all connections are subject to both axial and lateral force.
The provision of an unbonded length close to the loaded end of the rod has been shown to increase the axial pull-out capacity by shifting the longitudinal shear stress distribution in the timber-adhesive interface away from the end grain, where there would otherwise be a local concentration, decreasing the likelihood of timber splitting [2]. Franke et al. [7] showed that an unbonded length of 2d prevented timber splitting and reduced experimental scatter, and a greater unbonded length of 5d markedly increased the pull-out capacity on top of this.
The recently published EN 17334:2021 [10] provides specific guidance for glued-in rod connections regarding universal testing, design, and manufacturing of glued-in rods. Design guidelines for glued-in rods are included in Annex A of [10], which specifies that lateral rod capacity should be estimated using equations for dowel-type fasteners from EC5 [11], which do not have a glue-line. The presence of glue-line can affect the embedment strength of the rods and there is limited research addressing this aspect.
Due the current lack of design standards for glued-in rods in EC5 [11], there is still much hesitation in the construction industry over use of glued-in rod connections: a survey [12] found that of the 56 European scientists, timber industrialists and structural designers who took part, 9% use glued-in rods frequently, 68% have never or very rarely used them, 60% are not confident in using them, and 89% are not satisfied with current standards. The second generation of EC5 to be released in 2025 will include design guidelines for bonded-in rods.

1.3 EXISTING STUDIES ON COMBINED AXIAL & LATERAL LOADING

There are limited studies investigating the interaction of axial and lateral rod force in glued-in rods, and these have addressed the brittle failure modes (shear failure in the timber or adhesive, or interfacial shear failure). Aicher and Simon [3] performed tests in spruce glulam GL30h with steel rods of class 8.8 and 16 mm nominal diameter, glued-in with 2 mm thick epoxy resin and parallel to grain. Pull-out tests assessed the axial rod capacities, shear tests assessed the lateral capacities, and cantilever tests assessed the combined axial and lateral interaction, with two different beam lengths tested for different ratios of axial to lateral force. The results, shown in Figure 1, strongly support an elliptic relationship which is given by the current governing equation (Equation (8) in this paper). This study also confirmed that providing greater edge distance between the top rod and top of the timber beam results in a significant increase in the lateral capacity, which is currently not accounted for in design code: rather a minimum edge distance of 4*d* (from the centre of the rod of diameter *d*) is specified.

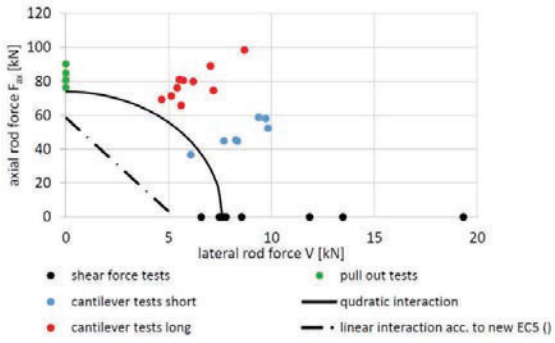

Figure 1: *The plotted ultimate rod axial and lateral loads compared to trend lines for Aicher's and Simon's study [3].*

This minimum edge distance was used for some specimens and the results were close to the EC5 [11] prediction.
Walker and Xiao [13] performed tests with a different setup, whereby rods were glued-in at differing angles to the timber surface but still parallel to grain, as indicated by Figure 2, and pulled out with force normal to the timber surface, inducing a lateral force component in the rotated section of the rod. The timber was LVL, and the bent rods were class 8.8 steel of 12 mm nominal diameter, bonded with 4 mm glue-line thickness. Contrary to the previous study, this yielded a decreasing linear interaction between the axial and lateral rod force, as depicted in Figure 3. Reasons could include the different test method or the different materials.

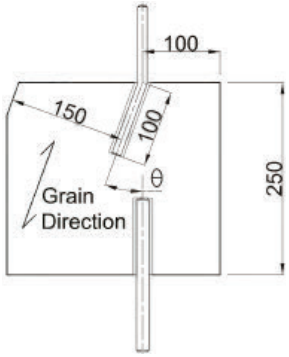

Figure 2: *The setup of Walker's and Xiao's study [13].*

2 DESIGN EQUATIONS & CRITICISMS

2.1 AXIAL CAPACITY

EN 17334 A.2.4 [10] specifies the axial capacity of glued-in steel rods as given by Equation (1):

$$F_{ax,Rd} = min\begin{cases} f_{y,d}A_{ef} \\ \pi d l_a f_{vr,d} \end{cases} \quad (1)$$

where $F_{ax,Rd}$ is the rod axial capacity (N), $f_{y,d}$ is the design yield strength of the steel rod (N/mm^2), A_{ef} is the effective stress area of the rod (mm^2, equal to the nominal stress area $A_{s,nom}$ specified in [14]), d is the nominal rod diameter (mm), l_a is the bond length (mm), and $f_{vr,d}$ is the design adhesive bond strength (N/mm^2). The two expressions are for the rod yield and adhesive ('pull-out') capacity respectively. Equation (1) is widely used and included in other design codes. However, it does not account for the fact that increasing bond length provides diminishing (not linear) returns for increased capacity, which has been shown by many studies [2].

2.2 LATERAL CAPACITY

For calculation of rod lateral capacity, EN 17334 A.3.1 and A.3.2 [10] specify referral to sections 8.2 and 8.5 of EC5 [11] respectively, which give design equations for the lateral capacity of metal dowel-type fasteners. The lateral capacity of a metal dowel-type fastener (or in this case the glued-in rod) connected to a thin plate in single shear is given by Equation (2):

$$F_{v,Rk} = min\begin{cases} 0.4 f_{h,k} t_1 d & (a) \\ 1.15\sqrt{2M_{y,Rk} f_{h,k} d} + \dfrac{F_{ax,Rk}}{4} & (b) \end{cases} \quad (2)$$

where $F_{v,Rk}$ is the characteristic fastener (rod) lateral capacity (N), $f_{h,k}$ is the characteristic timber embedment strength (N/mm^2), t_1 is equal to the bond length l_a (mm) for glued-in rods, d is the nominal fastener (rod) diameter (mm), $M_{y,Rk}$ is the characteristic fastener (rod) yield moment (Nmm), and $F_{ax,Rk}$ is the fastener (rod) axial capacity (N). Alternatively, the lateral capacity for connections to a thick plate in single shear is given by Equation (3):

$$F_{v,Rk} = min\begin{cases} f_{h,k} t_1 d & (c) \\ f_{h,k} t_1 d\left(\sqrt{2 + \dfrac{4M_{y,Rk}}{f_{h,k} d t_1^2}} - 1\right) + \dfrac{F_{ax,Rk}}{4} & (d) \\ 2.3\sqrt{M_{y,Rk} f_{h,k} d} + \dfrac{F_{ax,Rk}}{4} & (e) \end{cases} \quad (3)$$

Each expression within Equations (2) and (3) is for a different failure mode, with Figure 4 illustrating them. The first terms are the capacities according to Johansen yield theory, and the second term $F_{ax,Rk}/4$ included in some of the expressions is an estimation of the beneficial contribution from the rope effect. EC5 [11] section 8.2.2(2) specifies different limits for the contribution of this effect, as a percentage of the Johansen part, for different fastener types. A 25% limit for bolts was applied for estimated lateral rod capacities in this study, and the appropriateness of this value for glued-in rods was discussed upon analysis of the experimental results.

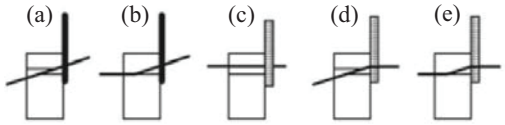

Figure 4: *Depicted failure modes from Equations (2) and (3), in the same order the expressions are in (from Figure 8.3 of EN 1995-1-1:2004).*

The embedment strength parallel to grain is given by equation 8.32 in section 8.5.1.1 of EC5 [11]. EN 17334 A.3.4 and A.3.5 [10] combined specify a factor of 0.125 on this to give the embedment strength perpendicular to grain, $f_{h,90,k}$, given in Equation (4), which is applicable for laterally loaded rods glued-in parallel to grain:

$$f_{h,90,k} = 0.125 \cdot 0.082(1 - 0.01d)\rho_k \quad (4)$$

where ρ_k is the characteristic timber density (kg/m^3). Equation (4) doesn't account for the use of an EWP (e.g. glulam or LVL) over sawn timber, or for the presence of adhesive. The embedment strength of the adhesive and timber in combination and the glue-line thickness are not considered. An effective density equal to the geometric mean of the timber and adhesive densities, given in Equation (5), could be used in place of ρ_k in Equation (4) to calculate the embedment strength required for Equations (2) or (3):

$$\rho_{ef} = \sqrt{\rho_{timber} \cdot \rho_{adhesive}} \quad (5)$$

Furthermore, none of the previous discussion accounts for the presence of an unbonded zone. The absence of adhesive near the shear plane results in a gap around the rod, causing the rod to bend and embed directly into the above timber, affecting the failure mode and capacity. Moreover, the bearing zone is lower than the theoretical one including part of the unbonded length due to the local restrictive effect of the fully bonded length (see Figure 5).

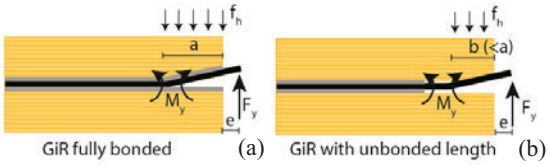

Figure 5: *Embedment stresses in (a) a fully bonded glued-in rod and in (b) a glued-in rod with an unbonded length.*

Riberholt [15] proposed equations to estimate the timber embedment strength and lateral capacity for laterally loaded glued-in bolts, with consideration of the bolt and

hole diameters (the maximum of which is d (mm)), bolt yield moment M_y (Nmm), embedment strength f_h (N/mm^2) and eccentricity, e, of the applied lateral load with respect to the timber loaded face (mm) where there is absence of bearing stresses. The maximum lateral force F (N) acting at distance e is given by Equation (6):

$$F = \left(\sqrt{e^2 + \frac{2M_y}{df_h}} - e \right) df_h \tag{6}$$

with embedment strength f_h given by Equation (7):

$$f_h = (2.3 + 750d^{-1.5})\rho \tag{7}$$

where ρ is the relative timber density (dimensionless, normalised by ρ_{water} = 1000 kg/m^3). Equation (6) accounts for both bolt (rod) yielding and embedment failure. It may appear sensible at first to assign the unbonded length as the load eccentricity, e, as the rod is not supported over this length. However, it will likely not take much rod deformation until the rod contacts with the timber at the end of the unbonded zone, i.e. yield failure in the rod won't yet have occurred. This contact then means more support to resist rod yielding due to bending, and likely embedment failure here instead of at the end of the bonded zone, not predicted by Equations (6) and (7). Furthermore, the equations do not account for thick glue-lines and are derived for glulam, whereas LVL is likely to have greater embedment strength (discussed later). Clearly a new and more comprehensive set of equations is needed. Nevertheless, Equations (6) and (7) were also used to give a prediction of the lateral load capacity.

2.3 AXIAL & LATERAL COMBINED CAPACITY

EN 17334 A.4 [10] recommends an elliptic relationship between the axial and lateral rod forces, given in Equation (8), to be satisfied:

$$\left(\frac{F_{lat,Ed}}{F_{lat,Rd}}\right)^2 + \left(\frac{F_{ax,Ed}}{F_{ax,Rd}}\right)^2 \leq 1 \tag{8}$$

This equation is found in other design codes such as DIN EN 1995-1-1/NA [16], in addition to a linear version (the quotient terms not squared) given in the Final draft *Connections* SC5.T5 to the new DIN EN 1995-1-1:2020 [3]. The results of Aicher and Simon [3] support the elliptic relationship, whereas the results of Walker and Xiao [13] support the linear relationship.

2.4 ROTATIONAL STIFFNESS

There are no standards for the estimation of the rotational stiffness of timber connections [17], but such calculations are important for serviceability checks. As such, analytical models are proposed in literature, and they are verified with experiments. This study makes use of the proposal by [18]: a component method for moment-resisting glued-in steel rod connections in glulam, analogous to that used for steel moment connections. It is recommended to refer to their paper for the full set of equations involved and the supporting diagrams, though an equation of interest is the stiffness of the timber compression zone k_c (N/mm), given by Equation (9):

$$k_c = \frac{E_{w,0}\sqrt{A_c}}{4} \tag{9}$$

where $E_{w,0}$ is the timber elastic modulus parallel to grain (N/mm^2) and A_c is the area of timber in compression (mm^2). Equation (9), as derived from equation 17 in [18], has been modified here so that it is applicable to the specimens in this study, due to differences in the type of support. Note how there is no inclusion of the timber beam length: this is discussed in section 4.4.

To calculate the rod axial stiffness, required for the above model, Xu et al. [1] proposes using the axial rigidity E_sA_s (N) divided by the bond length l_a (mm), but with the addition of a coefficient 0.3 to account for mechanical interlocking and the bond stress distribution along the bonded length, hence providing an effective stiffness. This coefficient value was determined by comparison between FE analysis and an experiment on the same specimen. Deviations due different materials (e.g., glulam versus LVL) and adhesive types may lie between studies. The steel rod stiffness k_s (N/mm) is hence given by Equation (10):

$$k_s = \frac{E_sA_s}{0.3l_a} \tag{10}$$

2.5 OUTLINE OF THIS STUDY

The purpose of this study was to investigate the effects of combined axial and lateral force in the axial withdrawal capacity of glued-in rods in LVL. The study addresses the ductile failure mode for glued-in rods (rod steel yielding) as opposed to the brittle failure modes that have been investigated in other studies. This is because the steel yielding failure mode is the expected design failure mode, to increase ductility and energy dissipation, and favour load re-distribution and non-catastrophic sudden failures. For the evaluation of the axial and lateral load capacities, pull-pull and shear tests were conducted respectively. The combined effects of axial and lateral loading were investigated with cantilever tests of varying length, similar to the test methodology in [3]. The EN 17334 [10] design rules were adhered to, and its design capacity equations were used as the baseline comparison for the results of the study. A fixed unbonded length was provided for all specimens to investigate the resulting effect on the rod capacities when compared to predictions. The axial and rotational stiffnesses of the connections were also measured experimentally and compared to predictions using the analytical models discussed in previous section. Characteristic values (rather than design values) were used.

https://doi.org/10.52202/069179-0179

3 EXPERIMENT PROGRAMME

3.1 MATERIALS

Steel rods with a metric thread, a nominal diameter of 12 mm and of property class 8.8 were used, hence they had characteristic yield strength $f_{y,k}$ = 640 N/mm^2, tensile strength $f_{u,k}$ = 800 N/mm^2 and nominal stress area $A_{s,nom}$ = 84.3 mm^2 [14]. The yield and tensile strengths of the three steel rods were verified by tensile tests. The results were a mean 0.2% proof stress of 613.0 N/mm^2 (standard deviation 14.3 N/mm^2) and a mean tensile strength of 783.0 N/mm^2 (standard deviation 9.2 N/mm^2), respectively 4.2% and 2.1% lower than the respective characteristic strengths. The experimental values were used in the design equations for rod capacities rather than the characteristic strengths given in [14]. An elastic modulus of 200 kN/mm^2 was assumed for the rods. The timber was Beech LVL (BauBuche GL70). An average moisture content of 13.5% was recorded after testing with a Protimeter Surveymaster Moisture Meter using the non-invasive method. Tests on the same timber in [19] yielded a flexural elastic modulus of 15.7 kN/mm^2 and a compressive yield stress of 43 N/mm^2. The adhesive used was a 2-component thixotropic epoxy adhesive (Rotafix Timberset Adhesive), especially suited to bonding metal to timber, with a bond strength of 6-10 N/mm^2 according to the manufacturer, with >6 N/mm^2 specified for UK structural softwoods and >9 N/mm^2 for Jarrah hardwood [20].

3.2 SPECIMEN GEOMETRIES & SETUPS

The specimen geometries and test arrangements are summarised in Figure 6, with the actual specimens shown in Figure 7. The nomenclature adopted is S for shear tests, A for axial pull-pull tests and C for cantilever tests with 1, 2 and 3 referring to a specimen length of 500, 750 and 1000 mm respectively. Three specimens were tested for each test configuration, hence a total of 15. The bond length was fixed at 240 mm, with an unbonded length of 50 mm (the maximum according to [10]) provided for all specimens by wrapping duct tape around the rods in this region to stop adhesive flow encroaching in the unbonded length during manufacturing of the specimens. The rod hole diameters were 16 mm, yielding a 2 mm glue-line thickness. The adhesive was applied by injection and exit through 2 respective pre-drilled holes of 8 mm diameter perpendicular to the rod hole, with the rods inserted beforehand and aligned with acrylic rings. This method of adhesive application ensures minimal skew in rod alignment and good filling of voids with adhesive, providing some quality assurance [2]. Rod lengths, separations and edge distances all complied with rules in [10], such as the minimum top rod edge distance of 4*d* provided for all tests (except the axial tests which had greater edge distance).

3.3 AXIAL (PULL-PULL) TESTS

The axial specimens were subjected to 'pull-pull' tests to study axial behaviour without the influence of lateral load. The test setup is shown in Figure 8(a). The axial

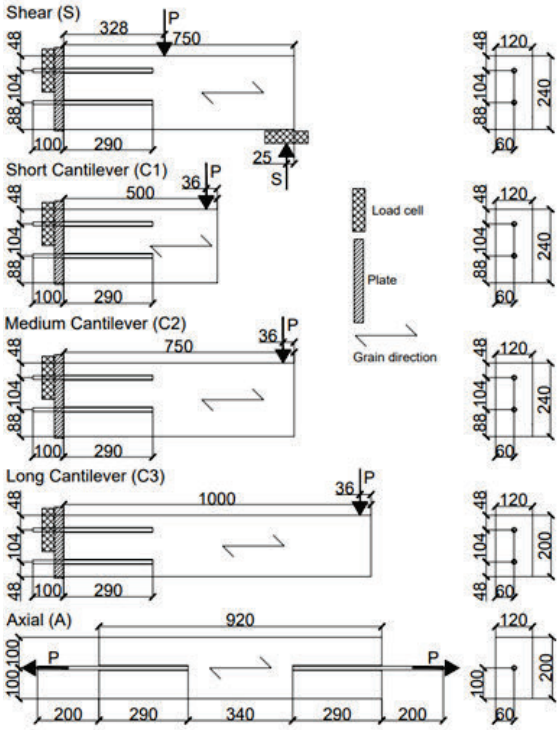

Figure 6: *Summary of the specimen geometries and test setups.*

Figure 7: *Specimens following the application of the adhesive.*

displacement of the rods was tracked by 2 LVDTs on either side (for the mean average). The test was conducted at a displacement control mode of 1 mm/min.

3.4 CANTILEVER TESTS

The setup for the cantilever tests is shown in Figure 8(b). The large supporting plate was 30 mm thick (>d hence thick according to [11]). No separation was provided between the timber face and supporting plate for these tests, to mimic the realistic situation of a timber beam connected to a steel connector plate. As a result, a compressive distribution was to be introduced into the timber. Analytical equations derived in [21] were used to

estimate the position of the neutral axis of bending, which was found to be below the bottom rod for all cantilever specimens. As a result, the bottom rod was predicted to also experience tension, though much less than the top rod. For the cantilever (and shear) tests, a pancake load cell tracked the tension force in the top rod (the expected failure region). Even distribution of lateral force between the rods was assumed, as verified with a FE model in the linear elastic range, so the individual lateral rod forces were taken to be half of the total (equal to the specimen weight plus the applied load *P*).

Axial displacements of the rods were again tracked by 2 LVDTs either side of each rod (for the mean average). The load, *P,* was applied at 3-7 mm/min downward displacement (the longer the cantilever the higher the displacement rate).

Figure 8: *(a) The axial, (b) cantilever and (c) shear test setups.*

3.5 SHEAR TESTS

The setup for the shear tests is shown in Figure 8(c). The shear test setup involved a slight adaptation to the cantilever test setup, with a support provided under the (previously) free end (of which the load taken, *S*, was tracked with a pancake load cell), and with load *P* applied just beyond the end of the bond zone of the rods: a compromise between applying load close to the support to minimise moment hence axial rod load in that region (as these tests are an investigation of the lateral capacity), and applying load away from the end of the rods to avoid interfering with their failure. Separation was provided between the timber and supporting plate with washers in these tests to eliminate steel-timber friction, for accurate tracking of the total lateral rod loads, equal to the specimen weight plus the applied load, *P,* minus the support load, *S*. The load, *P,* was applied at 2 mm/min downward displacement.

4 RESULTS AND DISCUSSION

4.1 AXIAL & CANTILEVER SPECIMEN RESULTS (AXIAL CAPACITY & STIFFNESS)

The results for the rod forces and slippages are summarised in Table 1. Only results for the top rods are shown as failure always occurred here. Note that the 'failure' yield point is top rod yielding for the A and C1-3 specimens, and first crack for the S specimens; and the 'ultimate' load point is the maximum top rod load reached for the A and C1-3 specimens, and the first significant split for the S specimens. One of the C1 specimens failed prematurely (short of top rod yielding) due to a connection issue, hence data from this test was only used for rotational stiffness assessment. One test from the C2 and C3 group stopped prematurely at the ultimate load due to a hydraulics issue.

Examples of the observed failures are shown in Figure 9. The failure mode for all tests, except the shear tests, was yielding of the steel rods at 51.7 kN according to the experimental yield strength value. The predicted failure loads according to Equation (1) range from 54.3-90.5 kN (for adhesive bond strength 6-10 N/mm^2, see section 3) with the lowest value corresponding to steel yielding based on the nominal yield strength. Most specimens reached ultimate load followed by fracture, with a mean ultimate load reached at 64.2 kN for the axial and cantilever specimen top rods (4.7% lower than the nominal value of 67.4 kN). The yield (and consequently fracture) points often occurred in the unbonded zone within the timber. The mean ultimate load value suggests an adhesive bond strength of >7.1 N/mm^2, as no signs of failure of the adhesive were observed.

The LVDT data confirmed tension in the bottom rods for the cantilever tests, with its value estimated by subtracting the measured top rod force from the timber compressive force, which was estimated with Euler-Bernoulli theory. The timber compression was very large, commonly reaching around 112 kN for the C1 and C2 tests, and the resulting extreme fibre compressive stress reached around 35 N/mm^2, below the compressive yield stress of 43 N/mm^2 [19].

Table 1: *Mean average values for load and slip at failure for top rods, and axial stiffness (outliers excluded; bracketed values are ultimate; non-bracketed values are at yield or first crack for S specimens)*

Specimen	Axial Load (kN)	Lateral Load (kN)	Axial Slip (mm)	Axial Stiffness (kN/mm)
S	14.1 (14.6)	18.4 (18.7)	-	-
C1	51.7 (62.5)	14.4 (18.6)	1.1	13.4 (17.3)
C2	51.7 (64.5)	9.0 (12.2)	1.2	12.8 (17.4)
C3	51.7 (64.2)	4.4 (6.1)	1.1	8.4 (11.7)
A	51.7 (65.1)	0.0 (0.0)	0.7	-

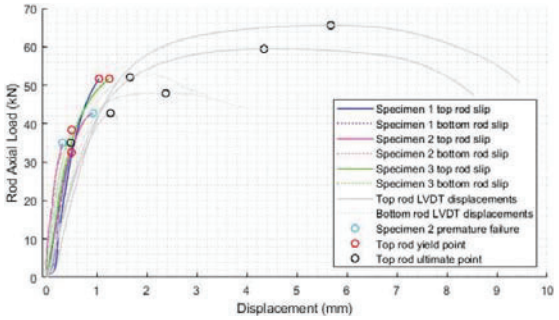

Figure 11: *Top and bottom rod axial force-slip and full axial force-displacement curves for the short cantilever (C1) tests.*

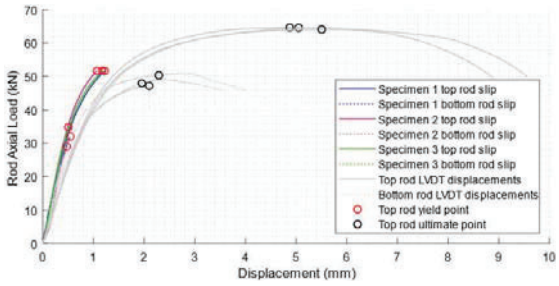

Figure 12: *Top and bottom rod axial force-slip and full axial force-displacement curves for the medium cantilever (C2) tests.*

The axial stiffnesses of the top rods were calculated using the linear elastic range of the load-slip relationship, assumed to be between 10-40% of the ultimate rod load, with the values given in Table 1, as well as the slippage values at yield failure. The cantilever specimen top rod stiffnesses (which were very similar despite differing lateral load) were an average of 43% lower than the axial specimen rod stiffnesses (79.0 kN/mm compared to 138.6 kN/mm), indicating that a small addition of lateral load due to cantilever action markedly decreases the axial stiffness, though internal timber strain differences due

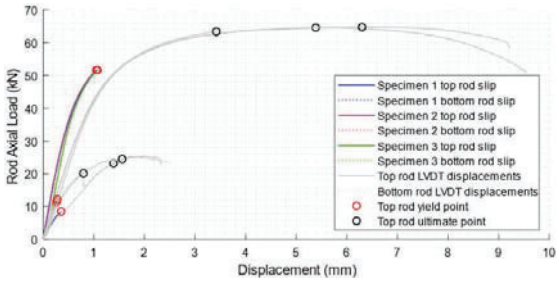

Figure 13: *Top and bottom rod axial force-slip and full axial force-displacement curves for the long cantilever (C3) tests.*

to different rod edge distances and timber areas could also contribute to this.

An interesting observation is how the total lateral forces in the short cantilever tests were only slightly less than those in the shear tests, but no signs of splitting or embedment failure were observed. A reason could be the yielding of the top rod combined with increased embedment stresses leading to load redistribution to the bottom rod, causing neither to quite reach the lateral load capacity. Another likely reason could be a vertical frictional resistance introduced due to the timber-steel contact which, if accounted for (assuming a friction coefficient of 0.2 [22]), is found to be dominant, given the large timber compression force. However, this friction force is expected to be limited given the small hole clearance in the steel plate, and the main bearing action between the rods and the plate. The friction force was not included in the results due to its uncertain value and variation, but its presence can represent a real scenario of a moment resisting connection.

4.2 SHEAR SPECIMEN RESULTS (LATERAL CAPACITY)

The shear specimens failed by splitting of the LVL in lamination plane interfaces around the top rod, as shown in Figure 9 (c). Embedment failure was observed at the end of the unbonded zone as predicted, due to the upward rod deformation which the zone allowed for. The rod deformations and embedment failures were greater in the bottom rods, though this could be due to a transfer of much of the lateral load to the bottom rod upon splitting failure around the top rod, rather than an uneven force distribution between the rods throughout the test within the linear elastic range.

Calculations using the measured *P* and *S* forces confirmed an increasing sagging moment at the rod support for the duration of all 3 shear tests, likely as this end displaced downwards due to rod deformation and embedment failure, but the other end was vertically restrained due to the rigid vertical support provided by the pancake load cell. Such behaviour is expected with plastic hinge formation at the rod support. The top rods experienced axial tension of 23-34% of the yield load, as measured by the pancake load cell, with loads shown in Figure 14. A likely reason could be a significant axial force due to the rope effect, evidenced by the large deformation of the rods observed, causing them to be 'pulled through' the plate.

https://doi.org/10.52202/069179-0179

Such a force would significantly exceed the 25% limit prescribed for the contribution to the lateral capacity of bolts, used to estimate the rod lateral capacities in this study, indicating that a higher limit (the determination of which requires further investigation) may be more suitable for glued-in rods.

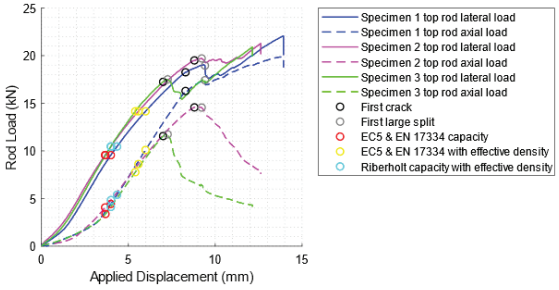

Figure 14: *Graph of top rod loads against the vertical displacement at the point of load application for the shear (S) tests, with predicted and observed failure loads indicated.*

Table 1 includes the lateral force values at failure, with a mean of 18.4 kN observed. Referring back to section 2.2, use of EC5 [11] equations yield an embedment strength of 6.1 N/mm^2 (Equation (4)), and hence a lateral capacity of 9.6 kN according to the failure mode (c) of Equation (3) (as the plate used was thick), which is 92% less than the observed lateral capacity. This disparity is attributed to the use of LVL causing an under-prediction of the embedment strength, and the provision of an unbonded length, which shifts the lateral force distribution away from the timber surface, hence increasing the resistance to splitting. Equation (4) does not account for use of an EWP over sawn timber, with LVL being particularly neglected due to the thinner laminations (as opposed to glulam). Schweigler et al. [23] found an embedment strength of 27.5 N/mm^2 for dowels in LVL (of the same 12mm diameter of the rods used in this study), which is 351% greater than the EC5 [11] predicted value; similarly, Bader et al. [24] found 24.9 N/mm^2. Using $f_{h,k}$ = 27.5 N/mm^2 for Equation (3) yields a much greater capacity of 19.5 kN (again from the bottom expression), which is close to the observed capacity, but does not account for the presence of the adhesive or unbonded length. Alternatively, using an effective density according to Equation (5), with ρ_{timber} = 680 kg/m^3 for GL70 BauBuche LVL [25], and $\rho_{adhesive}$ = 3125 kg/m^3 [20], ρ_{ef} = 1458 kg/m^3 is yielded, hence an increased embedment strength of 13.2 N/mm^2 and an increased capacity of 14.1 kN. Riberholt's [15] proposal yields a lateral capacity of 2.6 kN if Equation (7) is adopted in Equation (6) based on the timber density. This results in a vast underprediction. If the effective density, $\rho_{ef,}$ (converted to relative for Equation (7)) is adopted, this yields a high embedment strength of 29.7 N/mm^2, thus a lateral capacity of 10.5 kN. This is slightly greater than the EC5 [11] and EN 17334 [10] prediction, but it is still only 57% of the experimental lateral capacity. In the previous calculations, e is set to equal 0, such that the embedment strength at the end of the bond zone is estimated. It should be noted that Equations (6) and (7) were derived from fully bonded rods and some deviations are expected due to the non-uniform embedment stresses when an unbonded length is provided.

4.3 COMBINED AXIAL & LATERAL FORCE INTERACTION

Figure 15 shows the experimental data of axial and lateral loads for all specimens (top rods only), compared to the elliptic design capacity relationships (Equation (8)) using the various lateral capacities discussed previously. For the Riberholt capacity using Equation (6), only the effective density was considered. It is evident that there is no relationship between axial load capacities and lateral loads when rod yielding is the dominant failure mode, as the elliptic trend is not followed (as opposed to pull-out failure, for which Aicher and Simon [3] confirmed suitability of the elliptic relationship). This is particularly evident for the short cantilever tests, where the failure loads far exceed the EC5 [11] and EN 17334 [10] design capacity line. The experimental lateral load capacities (from the shear tests) agreed well with the EN 17334 [10] design prediction when a higher embedment strength of 27.5 N/mm^2 was used. The effect of lateral loads in ductile failure modes of glued-in rods should be directly addressed in the current design guidelines.

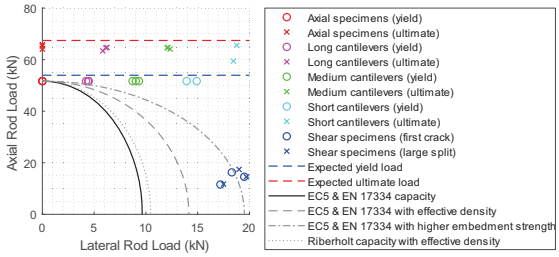

Figure 15: *Graph of axial load against lateral load for the failure and ultimate points for all specimens, with prescribed and suggested elliptic trend lines for load limits also plotted.*

4.4 MOMENT-ROTATION RESULTS

The cantilever specimen support moment and rotation results are summarised in Table 2, in addition to theoretical stiffnesses calculated using the model discussed in section 2.4. The support rotations were derived from the LVDT data for the top rod (combined rod strain and slip) and the predicted strain of the extreme timber compression fibre. In the calculations the weight of the beam was also considered. The moment-rotation relationships are plotted in Figure 16, along with the theoretical predictions. The rotational stiffnesses were calculated using the linear range of the moment-rotation relationships, ranging from 10-40% of the ultimate moment. The mean experimental rotational stiffness of the C1 specimens was 10.7% higher than that of the C2 specimens despite the same predicted stiffness, attributed potentially to an influence of the beam length that is not accounted for by the analytical model used (the C1 specimen length being 33.3% shorter than the C2 length),

https://doi.org/10.52202/069179-0179

though this difference could be insignificant considering experimental scatter.

Table 2: *Mean average values for support moment and rotation at failure (bracketed values are ultimate; non-bracketed values are at yield); and rotational stiffnesses.*

Spec-imen	Support Moment (kNm)	Support Rotation (mrad)	Experiment Rotational Stiffness (kNm/rad)	Theoretical Rotational Stiffness (kNm/rad)
C1	13.4 (17.3)	9.56	1870	1980
C2	12.8 (17.4)	9.55	1690	1980
C3	8.4 (11.7)	11.15	950	1120

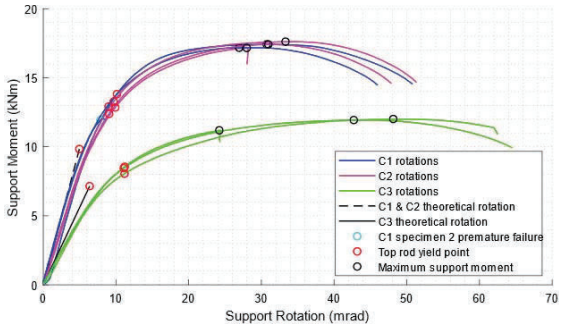

Figure 16: *Moment-rotation curves for the cantilever specimens, with theoretical rotations also plotted.*

The experimental rotational stiffnesses are always lower than the theoretical ones: for a two-tailed t-test with 5% significance, the results for the C1 tests are not statistically significant, but the results for the C2 and C3 tests are. A higher coefficient on the bond length for a greater effective stiffness length (as opposed to 0.3 as discussed in section 3.4) may be more appropriate, given that different timber and adhesive is used here than in [1], where glulam and a different epoxy adhesive were investigated. A coefficient of 0.9 is found to result in a similar axial stiffness to those observed in the cantilever tests. It is also observed that top rod yielding occurs at greater support moment and rotation than predicted.

5 CONCLUSIONS

The application of lateral load to the rods had no effect on their axial capacities with a governing failure mode of rod yielding: this should be addressed in the design guidelines. The lateral capacities of the shear specimens exceeded the design code prediction by 92%, and the use of an effective density accounting for the presence of adhesive in calculation of the embedment strength was shown to give a better prediction. The use of a higher embedment strength for LVL found from literature (27.5 N/mm^2 as opposed to just 6.1 N/mm^2 as predicted by EC5 [11], which is a staggering 351% lower) was shown to predict the lateral capacity very accurately, but it did not account for the adhesive or unbonded length. An unexpectedly significant axial force due to the rope effect was observed for the shear specimens, exceeding the 25% design limit, hence a higher limit for glued-in rods may be appropriate. Axial rod stiffnesses decreased by 43% with a small addition of lateral load due to cantilever action, with the quantity of load not having a notable further effect. Cantilever rotational stiffness was always slightly lower than the theoretical prediction, and a lower stiffness was observed for longer beams but of the same cross-section, which the analytical model used did not account for.

It is of interest to investigate the effect of lateral load on the axial load capacities of steel rods glued into LVL for the brittle failure modes, and understand in depth the lateral load distribution between rods when yielding or first failure occurs in the top rod. A comparison between fully bonded glued-in rods and glued-in rods with an unbonded length will shed more light on the effect of the unbonded length in the embedment stress distribution of GiRs when subjected to lateral loads. This can lead to updates regarding design equations for the lateral load capacity of of GiRs with the presence of a glue-line and an unbonded length.

ACKNOWLEDGEMENT

Acknowledgement is given to Joshua Mudie who sourced the LVL for their project [19] and who's supervisor, James Norman, gave permission for the use of the left-over LVL for this project; and to the staff at the University of Bristol's Mechanical Workshop and Heavy & Light Structures Lab for their assistance with the manufacture and testing (respectively) of the specimens.

SOLUTIONS FOR EDGE CONNECTIONS TO BUILD TWO-WAY SPANNING CROSS LAMINATED TIMBER SLABS

Thomas Stieb[1], Bernhard Maurer[2], Maximilian Bestler[3], Philipp Dietsch[4], Roland Maderebner[5]

ABSTRACT: Two-way spanning slabs made of cross laminated timber (CLT) require a rigid connection of the single elements. In particular for point-supported flat slabs this connection is necessary to enable spans that exceed the transport-related width of the single CLT-elements. The paper shows solutions how this connection could be designed and realized. In addition to the load-bearing capacity, especially the rotational stiffness is a crucial factor for the edge connection. A certain stiffness is needed to meet the requirements of a floor in terms of serviceability. To determine the load-bearing capacity and stiffness, four-point bending tests were performed on different types of possible edge connection solutions. The investigations revealed two connection types that meet the specified criteria without on-site gluing. One approach consists of a timber-concrete-composite system. Here, reinforcing bars are glued into the narrow surface of the CLT-element and the gap between the adjacent CLT-elements is then casted on-site. A second, completely dry application is to use a system connector with serrated steel plates. This serration ensures the force transmission between the CLT-elements by the connector. In addition to the results of these two types, also further options for the edge connection are presented.

KEYWORDS: Cross laminated timber, two-way spanning slab, flat slab, joints, edge connection, rotational stiffness

1 INTRODUCTION

The Unit of Timber Engineering at the University of Innsbruck has been intensively investigating point-supported flat slabs within the last few years [1-3]. This construction method has its architectonical charm, because it avoids walls and joists, enabling a much more flexible floor plan and increasing the effective living space. An essential structural characteristic of this construction method is the biaxial load carrying capacity of the flat slab. Cross laminated timber (CLT) could be a very suitable material for point supported flat slabs due to its bonded, crosswise layers. However, if the column grid of the floor exceeds the transport and production related maximum width and length of the CLT panels (width: 2.5 – 3.5 m, length ≤ 22 m), a supporting system with joists is still used by the designers most of the time, see Figure 1. The CLT is thereby only loaded in one direction. Nevertheless, the aim is to build flat slabs with a column grid of 5.0 to 7.0 m without any joists to compete with conventional concrete construction. This poses two major challenges from a structural point of view. One of them is the high load concentration in the area of the point support. This topic is treated very comprehensively in the works of [4-6], for example. Secondly, due to the limited width and length, the panels need to be connected on the construction site, so that a flat slab made of CLT can perform a biaxial load-bearing behaviour at all. This joint has to transfer mainly bending moments and shear forces. It should be easy to assemble, as rigid as possible and show ductile failure for reasons of robustness. This paper focuses on the edge connection of such CLT panels. Beginning with an overview of existing solutions for the joint, alternative approaches are shown and new systems are presented. For point supported flat slabs, requirements for the edge connection are defined and the experimental results for selected solutions are analysed in this respect. The findings about structural behaviour of CLT edge connections is not restricted to the use in a flat slab. The connection can also be applied for line supported CLT slabs in order to improve the system's stiffness (e.g. for a better dynamic behaviour), also rigid edge connections can increase the advantageous load-bearing behaviour of CLT near openings, see Figure 2.

2 SOLUTIONS FOR THE DESIGN OF THE CLT EDGE CONNECTION

2.1 OVERVIEW OF STATE OF KNOWLEDGE

For the construction of edge connections which enable the transmission of bending moments in addition to shear forces, approaches with splice plates are frequently found in the literature. The plates are usually made of wood-based panels. These are connected to the CLT either by means of screw press gluing [7] or by inclined screws [8]. The force transmission between the two elements takes place via the loading of either the screws or the adhesive joint and the plates. Tests on these types of connections have also been carried out at the University of Innsbruck [9]. A similar approach to enable a rigid connection in the secondary load-bearing direction of the CLT is presented in [10]. Here, the screw press gluing plates made of laminated veneer lumber (LVL) are additionally milled in with finger-joint like profiles.

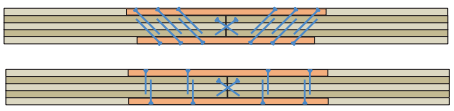

Figure 3: *Solutions with wood-based panels and inclined screws or screw press gluing*

In [11] a special two-component polyurethane adhesive is used for butt gluing of the full narrow surface of the CLT. The approach of glued-in perforated steel plates presented in [12] may also be used for the edge connection. A similar solution is also presented in [5], where sandblasted steel plates are applied. Apart from connections based mainly on adhesives, [2] presented a concept of a dovetail joint combined with a synthetic reaction resin. This solution adds a form closure to the chemical bonding.

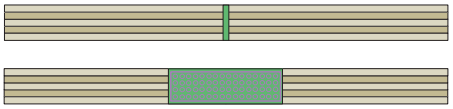

Figure 4: *Solutions with adhesives (butt gluing and glued-in-perforated steel plates)*

These investigations in the literature show a wide variety of solutions with different quality in terms of rigidity and load-carrying capacity. A comparison between different studies is difficult, because the authors didn´t use the same raw material or test setups.

2.2 CONCEPTS WITH CONVENTIONAL MATERIALS

In the work of [13], several solutions for the edge connection were investigated with tests in the laboratory using the same general conditions in each series (CLT dimensions and quality as well as the test setup). Therefore, four-point bending tests were carried out in order to determine the rotational stiffness and load carrying capacity of the edge connection. One solution was similar to the method presented in [8]. However, steel plates are used and fully threaded screws with angled washers were arranged inclined in the tension and compression zone of the edge connection. [13] used for another series self-tapping screws within a planar scarf joint. They should enable the transmission of bending moments and reinforce the CLT panel at once.
A further concept involves a butt joint where a post-tensioning system is installed to compress the joint and therefore enable the application of bending moments before a gap on the tension side of the element occurs.

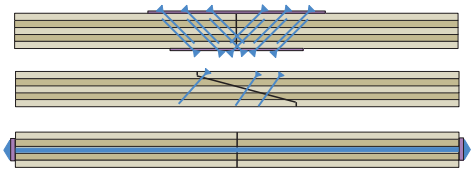

Figure 5: *"Dry" solutions with conventional construction materials*

Another approach in [13] was the use of glued-in reinforcing bars for realising the joint by a timber concrete composite (TCC) system. Here, a lap splice of the reinforcement was created between the two narrow surfaces. The resulting gap is further reinforced acc. to EN 1992-1-1 and then casted with standard concrete. A comparable method was suggested in [14] for the construction of two-way spanning TCC slabs.

Figure 6: *Timber concrete composite solution [13]*

https://doi.org/10.52202/069179-0180

The results from [13] give the opportunity to compare several construction types in terms of the rotational stiffness of the joint solutions and also the load-carrying capacities. Hence, the next chapters will refer to this work more often.

2.3 CONCEPT WITH SERRATED STEEL PLATES

The Unit of Timber Engineering at the University of Innsbruck is currently developing a new connector for edge connections, which is based on steel plates with micro-teeth [15]. The principle function of this system is illustrated in Figure 7. With the help of pre-tensioned threaded rods, wedges are used to press micro teeth of steel plates into the milled slot surfaces of the CLT. The force is transmitted via the connectors steel plates and the interlocking between the CLT panel and the numerous small teeth.

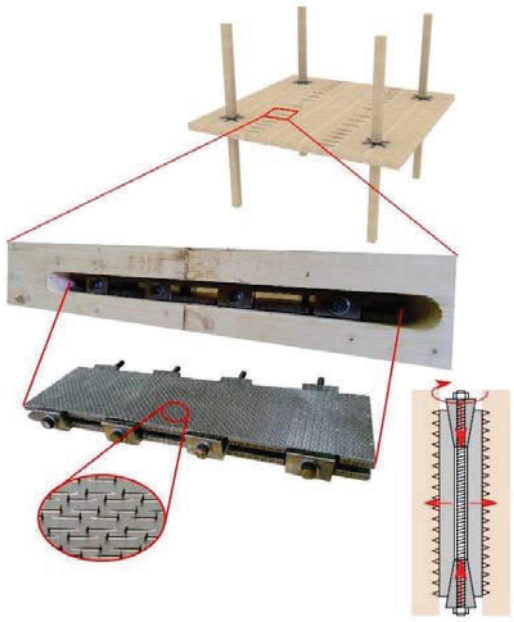

Figure 7: *System connector with serrated steel plates – operating principle [16]*

The major advantage using this type of connection is the mechanical interlocking between the serrations and the timber. As shown later, high stiffnesses with ductile failure can be achieved with this method. Due to the small teeth, the insertion resistance can be reduced compared to punched metal plate fasteners. The pre-tensioning of the threaded rods is intended to ensure the permanent insertion of the teeth over time.

3 INFLUENCE ON VIBRATIONS AND BENDING MOMENTS

Connections are often simplified as rigid or hinged. This section will show how important it is to take the real stiffness into account when designing point supported flat slabs. The focus is on the impact of the stiffness of the edge connections on the vibrational behaviour and the bending moments, even though the impact on deflections, the fire safety, the load carrying capacity or the robustness of the total structure are important aspects, too.

The edge connection between two CLT elements can be simplified to a rotational spring stiffness k_φ (see Figure 8). It´s actually obvious, that this spring has to be rigid and strong enough to prevent the formation of a kinematic chain in point supported flat slabs.

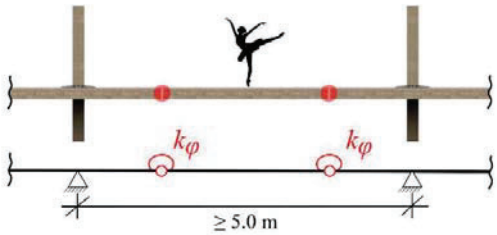

Figure 8: *Panel joints in point supported flat slab*

Within a parameter study of a simple floor system, the effect of the rotational stiffness of the edge connection is shown. The spans of a slab system with 3 x 3 fields are varied between spans of 5.0 and 7.0 m for different CLT element thicknesses (see Table 1). Figure 9 illustrates the model which was used for the parameter study. In general, this construction method requires the use of CLT with a layer structure that generates a balanced bending stiffness ratio ($EI_{ef,x}$ / $EI_{ef,y}$) between the main and secondary load-bearing direction, as shown in Table 1.

Table 1: *CLT used for the parameter study*

CLT depth	Layer	$EI_{ef,y}$ / $EI_{ef,x}$	Layup
200 mm	7	0.838	20-40-20-40-20-40-20
240 mm	9	0.946	20-40-20-20-40-20-20-40-20
280 mm	9	1.079	20-40-20-40-40-40-20-40-20
320 mm	9	0.910	20-40-40-40-40-40-40-40-20

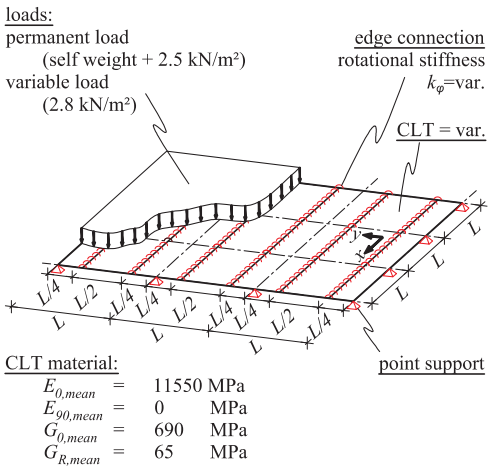

Figure 9: *Parameter study of a point supported flat slab*

https://doi.org/10.52202/069179-0180

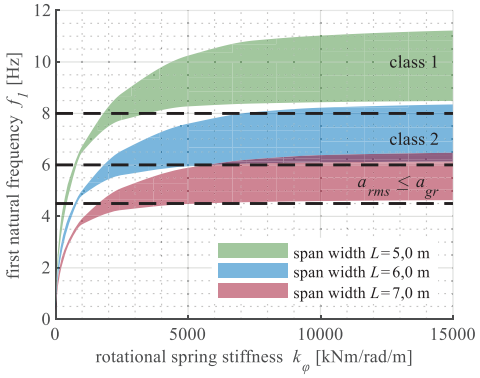

Figure 10: *Influence of rotational spring stiffness on first natural frequency (classification acc. frequency criterion in Eurocode 5)*

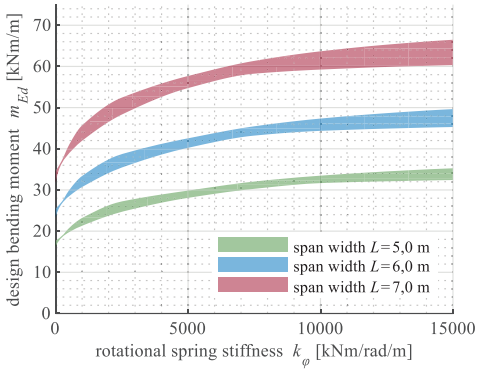

Figure 11: *Influence of rotational spring stiffness on maximum design moment*

The rotational stiffness of the edge connection significantly influences the floor's vibration behaviour. This is shown in Figure 10 by the relation of the first natural frequency of the slab and the rotational stiffness considered. However, it can also be seen that this influence is decreasing as the rigidity is increasing. This influence can also be observed for the maximum bending moment occurring in the edge connection. In the slab considered, this maximum moment occurs in the outmost connection of the end spans.

An important finding of this study is that completely rigid connections are not necessary for the application of the edge connection in point-supported flat slabs. Since connections with stiffness above 5000 kNm/rad/m only improve the investigated system to a minor extent.

4 DETERMINATION OF STIFFNESS AND LOAD CARRYING CAPACITY

The parameter study underlined the relevance of the bending load bearing capacity of the connection as well as the corresponding rotational spring stiffness.

4.1 EXPERIMENTAL APPROACH

Four-point bending tests can be carried out according to the specifications given in [17] in order to gather findings about stiffness and load-carrying capacity of different types of edge connections. By comparing the stiffness of the joined panel with a continuous one, the rotational spring stiffness of the connection can be determined from this test. This was already shown by [5] and described with Equation (1). Where a is the distance from the load to the bearing, l the static length of the specimen, F the full load of the hydraulic cylinder. The displacements w_{ref} and w_{con} are described in Figure 5. At best, the stiffness of a continuous panel is first determined non-destructively. Then the panel is cut, reconnected and finally tested again. However, the stiffness of the continuous CLT panel can be determined analytically too. An advantage of this approach is in general, that the rotation don´t have to be measured.

$$K_\varphi = \frac{a\,l}{8 \cdot \left(\frac{w_{con}}{F_{con}} - \frac{w_{ref}}{F_{ref}}\right)} \tag{1}$$

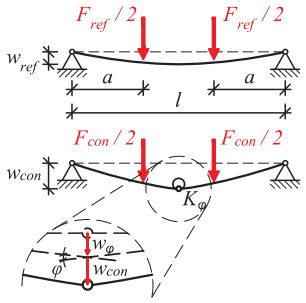

Figure 12: *determination of rotational stiffness of the edge connection*

4.2 INVESTIGATED SOLUTIONS

Seven different solutions of the edge connection were investigated by four-point bending tests. The detailed description can be found in Table 2 and in Figures 13 to 19. Series A, B, C, D, F and G were taken from [13].

Table 2: *Investigated solutions (n – number of tests, l & a acc. to Figure 12)*

Series	Solution	n [-]	l [m]	a [m]
A	butt joint	2	4.80	1.60
B	glued-in steel plates	3	4.80	1.60
C	inclined screws	3	4.80	1.60
D	scarf joint	3	4.50	1.50
E	post-tension system	3	4.75	1.58
F	TCC-system	3	4.80	1.60
G	system connector	3	4.20	1.40

For the tests, 240 mm thick, CLT elements with 7 layers were chosen with a layup of 30-40-30-40-30-40-30. Series A was also used as a reference test to determine the stiffness of a continuous panel. A two-component epoxy resin was used as adhesive. The same resin was used in Series B to glue in the perforated steel plates. The screws

https://doi.org/10.52202/069179-0180

applied in the test complied with the European Technical Approval (ETA) [18]. For Series F, the used concrete quality was C30/37 with reinforcement steel B550. The post-tension system applied in Series E may be taken from ETA [19].

5 RESULTS AND DISCUSSION

The main results of the investigations can be found in Table 3. In addition to the load bearing capacity, an overview of the rotational spring stiffnesses for each series is given. Due to the small number of tests, characteristic values are not stated.

Table 3: *Main results of the experimental study*

Series	F_{max} [kN]	m_{mean} [kNm/m]	$k_{\varphi,mean}$ [kNm/rad/m]
A	44.4 83.4	51.1	∞
B	169.3 167.3 164.4	133.6	∞
C	88.4 79.5 99.1	71.2	2170
D	64.9 73.6 64.3	50.7	2760
E	51.3 50.2 49.1	56.7	3840
F	39.8 46.9 47.5	35.8	14120
G	66.0 75.0 46.1	42.4	6170[1)]

[1)] Only tests 2 and 3 were considered. No global displacement transducers were used in test 1. For all 3 tests the same two system connectors were used.

Series A using the butt joint provided a reference stiffness of a continuous panel to determine the rotational stiffness of the remaining series. The specimens failed in a brittle manner on very different load levels.

https://doi.org/10.52202/069179-0180

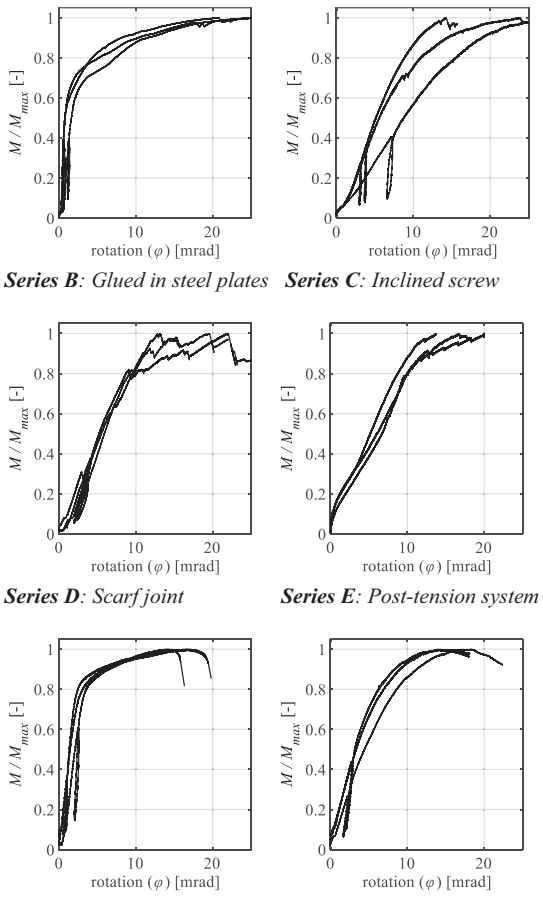

Figure 20: *Moment-rotation diagrams of experimental study*

The series with the glued-in perforated steel plates (Series B) failed in a much more ductile way. Here, very high load-bearing capacities were observed. The load-bearing capacity of the joint may be aligned to the load of the edge connection via the spacing of the glued-in plates. The failure of the test specimens was announced by an opening of the gap between the panels. This is due to yielding of the steel plates in this area. However, there was no difference in the initial stiffness between the reference tests (Series A) and the glued-in perforated steel plates. Therefore, both solutions may be classified as rotationally stiff connections. As presented in Figure 10 an absolutely rotationally stiff connection is not necessary for the use of an edge connection in a point supported flat slab.

The Series C using inclined fully threaded screws resulted in a clearly lower rotational spring stiffness. The initial spring stiffness is only about 2200 kNm/rad/m, although there is a clear increase in stiffness while unloading and reloading the specimens. The tests revealed tensile failure as well as withdrawal failure of the screws. The equivalent rotational spring stiffness of the planar scarf joint (Series D) is only insignificantly higher at around 2800 kNm/rad/m. The specimens failed in a more brittle manner than the series with inclined screws (Series C). Although screws perpendicular to grain were installed to avoid this failure, when reaching the load-bearing capacity, a failure combination of rolling shear and tension perpendicular to grain occurred. A corresponding image of the resulting cracks is presented in Figure 21.

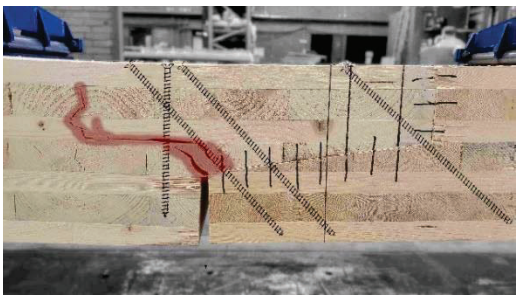

Figure 21: *Failure of Series D - scarf joint (cracks coloured)*

The results of the rotational stiffness for the Series E using the post-tensioning system are also within this range. A stiffness of approx. 3800 kNm/rad/m is obtained here. The load was stopped when a clear decrease of the system stiffness occurred.

For the application in point supported flat slabs, the solutions for the edge connection of Series C, D and E do not meet the requirements stated in section 3. This is mainly caused by the insufficient rotational spring stiffness. However, Figure 22 shows the application of such a stiffness for a flat slab supported on all four sides. The numerical solution for the first natural frequency of a continuous slab corresponds well to the analytical solution according to [20].
Considering the individual CLT elements with a hinged connection reduces the eigenfrequency of the system significantly. Here, even the use of small spring stiffnesses can contribute to a system improvement.

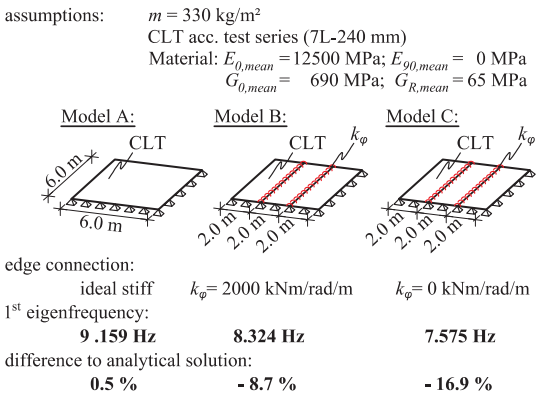

Figure 22: *Influence of rotational spring stiffness on the first natural frequency for a flat slab supported on all four sides*

A much higher rotational spring stiffness was reached in Series F, using the TCC system. On average, a value of about 14100 kNm/rad/m could be achieved. In these tests the glued-in rebars started yielding before failure. This failure was announced by an opening of the gap between the concrete and the CLT panel.

https://doi.org/10.52202/069179-0180

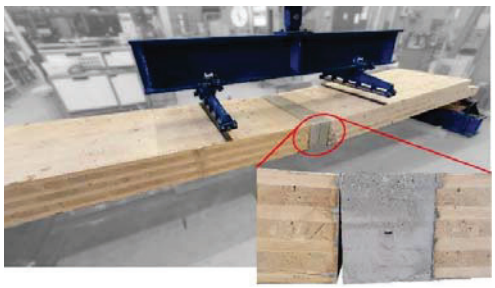

Figure 23: *Failed specimen of Series F - TCC system - opened gap between CLT and concrete*

The force occurring in the rebar may be determined with a similar analytical model as for concrete constructions. However, for CLT the compressed zone should be only assumed at the stiffer longitudinal layers. The stress in the reinforcement may then be calculated over the height of the compressed zone (x) and the inner lever arm (z).

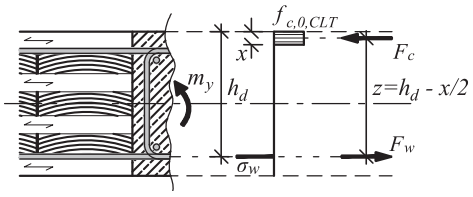

Figure 24: *Analytical model for Series F – TCC system*

$$x = h_d - \sqrt{\frac{f_{c,0,CLT} \cdot h_d^2 - 2 \cdot m_y}{f_{c,0,CLT}}} \qquad (2)$$

$$F_w = \frac{m_y}{z}$$

This analytical model already represents the tests quite well. The results of this model are shown in Figure 25 by comparison with the experimental results once for reaching the yield stress (f_y = 550 MPa) in the rebar as well as the tensile strength (F_{tens} = 33.3 kN acc. to tensile tests).

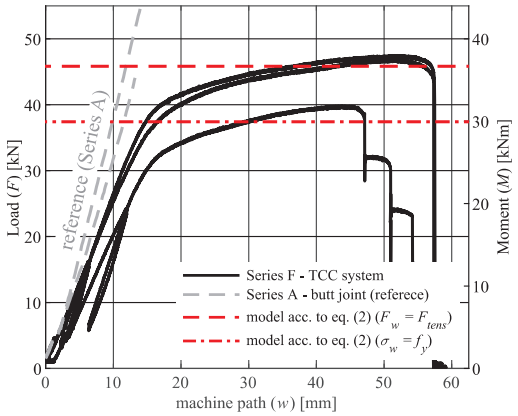

Figure 25: *Results Series F - TCC-system comparison with analytical model acc. to Equation (2)*

Notably, one of the tests showed a significantly lower load-bearing capacity. A possible explanation is that the gluing of one rebar was inaccurate there. To avoid the risks of non-properly fabricated gluing, in the next step the rebars were replaced by fully threaded screws. The force is again transmitted via a lap splice of the screws in the concrete. For this system, comprehensive investigations have been carried out which led to the ETA [21] and will be published in more detail in the future [22].

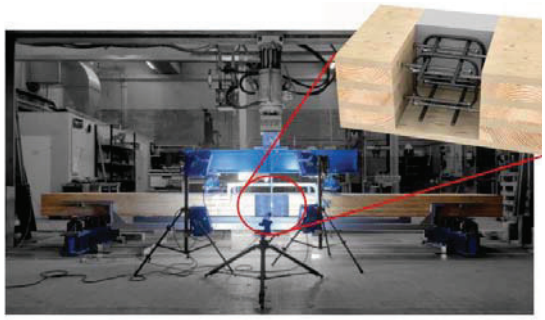

Figure 26: *Ongoing investigations on a TCC-system with self-tapping fully threaded screws [22]*

A completely "dry" solution for the edge connection was carried out using the system connector shown in Figure 7. This connector enables a significant reduction in construction time, for instance by eliminating curing times. With an average of approximately 6200 kNm/rad/m, this system also achieves a rather high rotational spring stiffness.

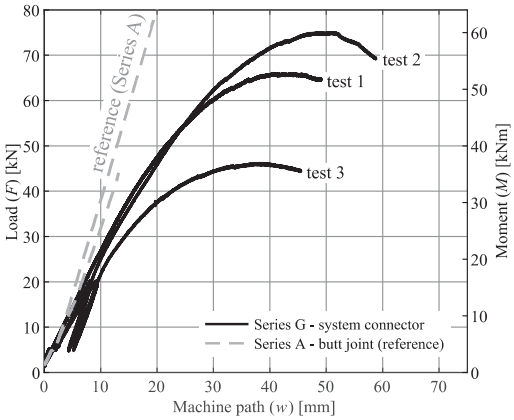

Figure 27: *Result Series G - system connector in four-point bending tests*

These were tests with first prototypes of the connector. There was only one set of two connectors available. So, these two connectors were used three times in a row. While the initial stiffness remained relatively constant, the load bearing capacity decreased significantly in the third test. This may be due to the reuse of the connectors. However, ductile failure behaviour was always observed.

https://doi.org/10.52202/069179-0180

6 CONCLUSIONS AND OUTLOOK

The edge connection between two elements in cross laminated timber slabs has a major influence on the behaviour of the entire system. In an experimental study, solutions for this joint were investigated with regard to the application in point-supported flat slabs. Based on a parameter study, the rotational spring stiffness of the connection is determined as an essential parameter for the suitability. Four-point bending tests are an appropriate test for determining the load-carrying capacity as well as the rotational spring stiffness. It showed that some of the solutions may be more appropriate to improve other slab systems than point supported flat slabs.

Two connection types were identified that meet the mechanical requirements for edge connections used in point supported flat slabs without any on-site gluing. One is the TCC system with glued-in rebars and the other the use of a system connector with micro-teeth. Both connection types are characterised by a distinct ductile failure behaviour and can easily be adapted to the load by variation of the spacing between the fasteners. However, questions regarding the long-term behaviour and the performance of the connection under biaxial loading still remain for both connection types.

The results presented for the TCC system were the initial impulse for further studies. A system where self-tapping, fully threaded screws are used instead of glued-in rebars is the subject of ongoing research.

A major benefit of the system connector compared to the remaining connection types is the quick assembly and the lack of any curing time. The possibilities of using micro-teeth as a new type of joining technique in timber constructions reach far beyond the application at the panel joint. Hence, the University of Innsbruck is currently carrying out extensive research on this topic.

EXPERIMENTAL AND ANALYTICAL ANALYSIS OF TIMBER CONNECTIONS WITH INTERPOSED ACOUSTIC RESILIENT STRIP

Luca Pozza[1], Giulia D'Amato[2], Paola Brugnara[3], Ernesto Callegari[3], Luca Sestigiani[3]

ABSTRACT: The load-carrying capacity and stiffness of timber-to-timber or steel-to-timber connections with an interlayer is a topic of great interest, as it is increasingly required to acoustically insulate, by means of resilient strip, the connections used to assemble timber buildings. The effects of the interposed resilient strip on the stiffness and load-carrying capacity of connections have not yet been studied effectively from experimental and theoretical point of view. This paper reports the main outcomes of an ongoing research, supported by Rotho Blaas S.r.l. company, aimed at the characterization of timber connections with interposed an acoustic resilient strip for flanking noise reduction. The research is developed on two levels: experimental and analytical. An experimental campaign conducted on steel-to-timber nailed connections was carried out and analysed. Experimental results were used to validate analytical models available in literature and specialized to account for the effect of acoustic interlayer on both elastic behaviour and failure mechanism.

KEYWORDS: Acoustic layer, Load-carrying capacity, Resilient soundproofing, Sound insulation, Timber joints

1 INTRODUCTION

Timber structures are particularly sensitive to low frequencies and require appropriate sound insulation strategies to comply with critical acoustic performance levels. This problem is significant in light structures such as traditional ceilings or frame walls because of reduced mass and acoustic damping. Cross Laminated Timber (CLT) structures are more soundproof performing thanks to their massiveness and the continuity of the panels. However, the structural connections can cause acoustic bridges which negatively affect the acoustic performance of the system [1]. A valid constructive strategy to limit the acoustic transmission through the connections consists in the insertion of resilient strips between the connected elements (Figure 1).

The effects of the interposed resilient strip on the stiffness and load-carrying capacity of connection have not yet been studied adequately from experimental and theoretical point of view. Calculation is therefore approximatively based on the models developed for standard connections without considering accurately the effects of the interposed layer or gap.

In this work results of an experimental campaign are used to assess the effects of an interposed resilient strip on the mechanical behaviour of timber-to-steel nailed connections. Experimental results are finally used to validate robust analytical models, available in literature and developed for different applications [2-3], to account for the effect of resilient strip on the mechanical response of timber connections.

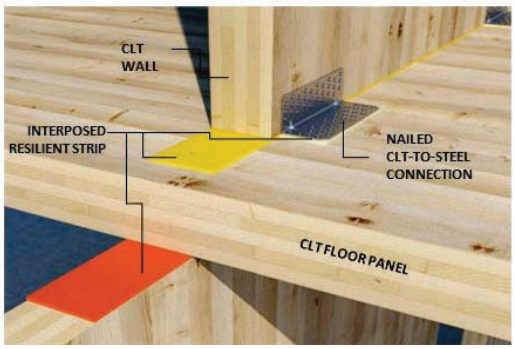

Figure 1: *Example of wall-to-floor CLT joint with interposed acoustic layer.*

2 EXPERIMENTAL CAMPAIGN

The experimental campaign was aimed to investigate the effects of the interposition of a resilient acoustic strip on the mechanical response of a timber-to-steel nailed connections. Four types of timber-to-steel connection were tested varying: the type of timber elements (GluLam or CLT) and the gap between the timber elements (in contact or with 6mm thick resilient acoustic strip). The tested nails are "LBA" type according to ETA-22/0002 [4] while the resilient acoustic strip is "XYLOFON 35" type according to ETA-23/0061 [5]. The experimental program, carried out according to EN 1380 [6] provisions, is summarized in Table 1.

Table 1: *Detail of the experimental campaign*

Sample ID	*Timber element*	*Interposed strip*	*N. of test*
GL-NX	GluLam	*none*	3
GL-X35	GluLam	*Xylofon 35*	3
CLT-NX	CLT	*none*	3
CLT-X35	CLT	*Xylofon 35*	3

The tested sample is geometrically represented in Figure 2 and is composed by the following components:

(a) timber element (GluLam or CLT). The rectangular cross section dimension is 120x80mm while the length is 200mm;
(b) couple of U-shaped 4mm thick steel profiles;
(c) 2 x 5 nails LBA type with a diameter of 4mm and length of 60mm;
(d) 6mm thick XYLOFON 35 resilient acoustic strip (only for X35 configuration).

As prescribed by EN 1380 [6], the timber specimens were conditioned at (20 ± 2)°C temperature and (65 ± 5)% relative humidity for 15 days before performing the tests. The resulting mean density of the samples was equal to 458kg/m^3 for GluLam specimens and to 472 kg/m^3 for CLT specimens.

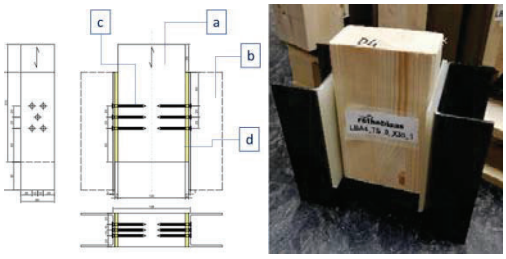

Figure 2: *Geometry of the tested samples*

The samples were tested using a universal testing machine in displacement control. The upper face of the timber element was loaded while the U-shaped steel profiles contrasted against the basement. The nailed connections were therefore monotonically loaded parallel to grain direction. Figure 3 reports a photo of the adopted setup.

During the test the applied force and the timber-to-steel relative displacement were recorded.

Figure 3: *View of the experimental setup.*

3 EXPERIMENTAL RESULTS

This section reports the test results in terms of load-displacement curves and observed failure modes.

It is worth noting that the experimental capacity curve of a steel-to-timber connection generally does not show a well-defined yielding limit [7-10]. Two different criteria can then be adopted for the definition of the yielding condition starting from experimental results [11]: the first one is based on EN 12512 [12] provisions, while the second one is based on an energetic approach (the so-called Equivalent Energy Hardening method [13]).

For traditional steel-to-timber connections, the well know Method "b" of EN 12512 is typically adopted since load-displacement curves are not characterized by a marked variation of the gradient at the level of yielding condition. In this work, in order to better capture the features of the experimental curves, an alternative approach for the definition of the yielding point was adopted referring to the Equivalent Energy Hardening method [12]: the slope of the second branch of the bi-linear curve is defined by forcing the passage through the peak force point and the equivalence of strain energy between the experimental envelope curve and the piecewise linear approximation. In the following, Method "b" of EN 12512 will be labelled as EN12512-b, whereas the Equivalent Energy Hardening method as EEH. Experimental load-displacement curves superimposed to the mean tri-linear backbone curve obtained according to the EN12512-b and EEH methods are reported in Figure 4 and Figure 5 respectively.

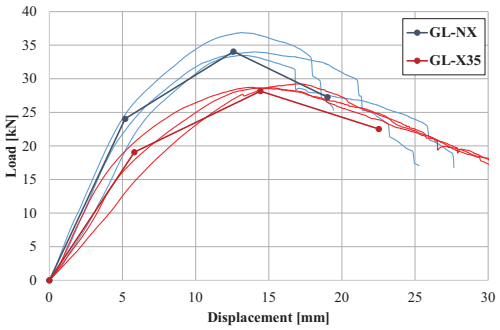
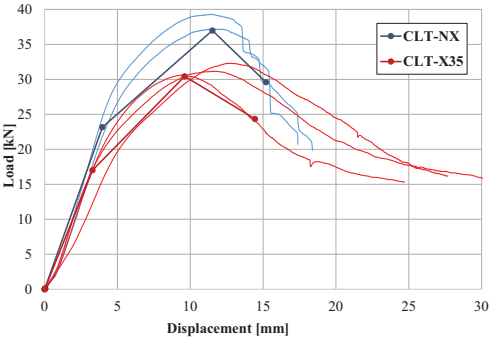
b)

Figure 4: *Experimental load displacement curves superimposed on mean trilinear backbone curve obtained applying the EN12512-b method: a) GluLam and b) CLT configurations.*

https://doi.org/10.52202/069179-0181



a)



b)

Figure 5: *Experimental load displacement curves superimposed on mean trilinear backbone curve obtained applying the EEH method: a) GluLam and b) CLT configurations.*

The failure mode observed at the end of all experimental tests principally involved the nails used to connect the steel plate to the timber element. Two plastic hinges can be typically recognized in the nails, one under the cap and another one in the shank (about 20–25 mm below the cap). In addition, localized crushing of wood around the nail shank, oriented in the axial load direction, can be observed, see Figure 6-a. For large displacement, the failure of the head of the nails occurred, see Figure 6-b.

a)

b)

Figure 6: *Samples GL-X35_02 at the end of test: a) local crashing of the timber along the grain direction and b) failure of the head of nails.*

The detailed analyses of the experimental results conducted according to method EN12512-b and EEH are reported in Table 2 and Table 3 respectively. More specifically, the tables report: the yielding and peak point parameters; the elastic and post elastic stiffnesses. Analyses were performed separately for each sample and then the averaged values were computed in order to perform a direct comparison between the configuration without and with interlayer.

Table 2: *Analyses of experimental results according to EN12512b method. Label "A" stands for averaged values.*

Data reported in Table 2 and Table 3 are plotted in the graph of Figure 7-9 and Figure 10-12 for GluLam and CLT specimens respectively.

Analysing the results, it is possible to observe that the interposition of a resilient layer strongly affects the global response of the connection. In detail obtained results demonstrate that, regardless of the linearization criterion used, the interposed resilient layer induces:

i) a negligible effect on the yielding and peak displacements and therefore on the ductility values;

ii) a reduction of the yielding force of about 20% for GluLam samples and of about 25% for CLT samples and a reduction of the peak force of about 15% for both Glulam and CLT samples;

iii) a reduction of the elastic stiffness of about 28% for GluLam samples and of about 17% for CLT samples;

vi) a negligible effect on post elastic and ultimate stiffness.

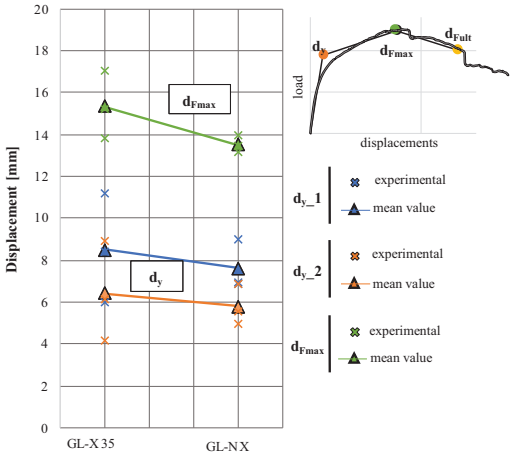

Figure 7: *Effects of interposition of a resilient acoustic strip on the yielding and peak displacement of GluLam samples.*

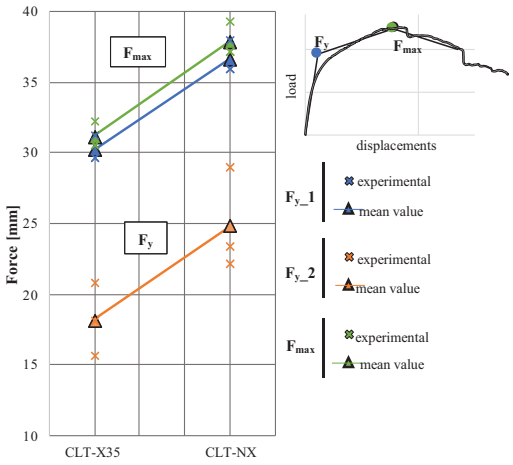

Figure 11: *Effects of interposition of a resilient acoustic strip on the yielding and peak force of CLT samples.*

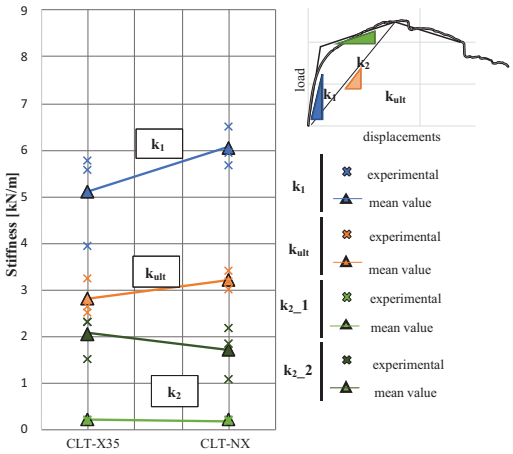

Figure 12: *Effects of interposition of a resilient acoustic strip on the elastic and post-elastic stiffness of CLT samples.*

It is worth noting that the above-described effects of the interlayer on the strength and stiffness of the nailed steel-to-timber connection is relative to the case of an infinitely stiff metal plate.

In the case of connections typically used to transfer shear forces in real GluLam or CLT structures, the geometry of the brackets is three-dimensional with a consequent significant deformative contribution of the steel plates.

When the bracket is used with an acoustic interlayer, the strength and stiffens reduction of the nailing system might not be significant as recorded in the tests exposed in this work as the deformability of the bracket itself could prevail (see for example [13]).

4 ANALYTICAL MODELS

The general formulations proposed in Johansen's theory and reported in the codes [15-16] or product technical sheet [4] are not applicable in the case of an interposed layer in the shear plane. Alternative methods accounting for the gap due to the interlayer are therefore necessary to define the strength and stiffness of the connection.

In this work, two different literature models were analysed and applied to account for the effects of an acoustic interlayer on the behaviour of a timber-to-steel connection.

The first model is based on the universally recognized Johansen theory as specified by Blass et al. [2] to account for the effects of an interlayer on the load-carrying capacity of the timber connection. This model was firstly developed to account for the effects of a OSB panel interposed into single shear timber-to-timber and timber-to-steel joint considering also the interlocking effect due to the stapled OSB-stud connection. This method provides the estimation of the connection strength while does not deal with the aspects related to connection stiffness.

An alternative model, developed for timber-to-concrete connection of composite floor beam, is the one proposed by Gelfi et al. [3]. This model assimilates the connector to a beam on an elastic support considering the connector free to deform in the interlayer. Hence, the effect of the interlayer is accounted both in terms of elastic stiffness and load-carrying capacity.

Despite the different basic formulations, for both models the key parameter governing the effect of the interlayer on the stiffness and strength is the ratio between the thickness of the interlayer and the diameter of the connector.

For the sake of brevity, only the results obtained with the two considered models are reported below; for the complete formulations, see the cited literature.

The geometric parameters of the specimens and the average density values were considered in the calculations. The cases without interlayer were considered as limit condition of zero gap.

The results obtained with the two models are reported in Table 4 and Table 5 for the strength and stiffens respectively.

Table 4: *Strength estimation obtained with the Blaas and Gelfi-Giurinai analytical models. Analytical values include the rope-effect contribution according to ETA-22/0002 [4].*

	F_{y_Enb} [kN]	F_{y_EEH} [kN]	F_{max} [kN]	F_{v_Blass} [kN]	$F_{v_Gelfi-Giuriani}$ [kN]
GL-NX	33.51	25.24	34.79	28.66	28.66
CLT-NX	36.66	24.87	37.88	28.92	28.92
GL-X35	27.55	20.28	28.89	24.00	22.48
CLT-X35	30.23	18.22	31.16	24.1	22.6

Table 5: *Stiffness estimation obtained with the EC5 and Gelfi-Giuriani models.*

	$K_{1_exp.}$ [kN/m]	$K_{ser\ (EC5)}$ [kN/m]	$K_{1_Gelfi-Giuriani}$ [kN/m]
GL-NX	6.06	9.9	5.67
CLT-NX	4.47	10.36	5.79
GL-X35	5.12	-	4.31
CLT-X35	3.43	-	4.4

Results shows that both the analytical models capture the strength reduction due to the interlayer. Analytical

strength values are in the range F_{y_EEH} and F_{max} providing a good estimation of the expected load bearing capacity.
As far as stiffness is concerned, it can be observed that the Gelfi-Giuriani model is able to capture, with excellent approximation, the stiffness reduction due to the interlayer.

5 CONCLUSIONS

Results obtained in this work demonstrate that the mechanical behaviour of a nailed timber-to-steel connections is strongly affected by the interposition of a resilient acoustic strip. Experimental tests conducted on different connection configurations highlight a quite relevant stiffness reduction due to the resilient strip interposition. Otherwise, the strength seems less affected by the presence of the interlayer. Failure modes are not affected by the presence of the interlayer.
Analytical models provide an accurate estimation of the stiffens and strength reduction due to the interposition of resilient strip even if, as far as strength is concerned, they seem to be calibrated on the yield condition and not on the peak force.
Finally, in the case of tri-dimensional bracket used with an acoustic interlayer, the strength and stiffens reduction of the nailing system might not be significant as recorded in this work as the deformability of the bracket itself could prevail.
An extension of the experimental campaign is ongoing with the aim of characterizing the effects of the interposition of an interlayer for the different types of connection typically used in Glulam and CLT structures.

ACKNOWLEDGEMENTS

The Authors would like to thank the company Rotho Blaas S.r.l for the support in the experimental campaign.

ON-SITE GLUING AND WEATHER EFFECTS ON TALL WOODEN WIND TURBINE TOWERS

Viktor Norbäck[1], Pierre Landel[2], Erik Dölerud[3], Anders Wickström[4]

ABSTRACT: Modvion develops modular wind turbine towers made of wood. The application requires strong and stiff connections and to achieve the desired performance, a hybrid connection with perforated steel plates slotted into LVL modules is used. The parts will be glued together on site, using a polyurethane adhesive (PUR), providing high strength and stiffness to the connection. This paper presents a preliminary screening on how temperature and relative humidity of the surrounding air during assembly and curing will influence the strength of the bond glued on-site. Static tests were performed on the hybrid connections which were glued and cured in different climates. Tests were also performed at different hardening times to evaluate strength growth in the studied climates. The test results show that at cold temperatures of 9 °C to 12 °C there is a breakpoint where the rate of strength growth starts to decline. The experiments show also that the relative humidity may influence the final strength of the bond. However, the low number of tested specimens brings uncertainties to this observation. High temperatures up to 27 ºC and dry climates down to 20% RH did not impact the strength of the tested hybrid connections.

KEYWORDS: Hybrid connection, Polyurethane adhesive, On-site gluing, LVL, Glued-in plates connection type

1 INTRODUCTION

The Swedish company Modvion AB is developing modular wind turbine towers made of wood [1]. To be competitive, the production method must be both fast and reliable, following specific standards [2]. To achieve this a recently developed joining technique is used, where the LVL wall-modules are assembled on-site, combining adhesive and perforated steel plates. Thin plates made of high-strength steel are inserted into slots in the wall-modules and bonded using a two-component polyurethane (PUR) adhesive. The method results in strong and stiff connections with glue-dowels through the holes of the plate. This hybrid type of glued-in plate joints has been used in different timber building applications to elegantly assemble CLT, LVL, and GLT elements. Research and development works have been performed in central Europe [3] and in Germany, where the commercial and certified HSK-system from the company TiComTec is available [4]. This technology is similar to glued-in rods in glued structural timber products, which adhesively bond steel rods and timber members. Standardized testing methods and requirements for glued-in rods are defined in the European standard EN 17334:2021 [5]. Some experimental studies on the gluing procedures of glued-in rod joints have shown important outcomes concerning the mechanical effects of elevated moisture contents [6] and temperatures [7].

Connections with glued-in plates provide a strong and stiff joint compared to more traditional mechanical connections for timber structures, e.g., screws and dowels. It can be applied with high precision and keeps the steel elements encapsulated in the timber structure, which protects the steel and allows for additional architectural possibilities. However, the mechanical properties of glues are affected by the temperature and relative humidity of the surrounding air when gluing. As a result, the application process of adhesives for structural timber products is recommended for controlled conditions that are mostly offered in factories. Gluing processes applied on building sites, with uncontrolled and variable weather conditions, are not common.

To be competitive the assembly of tall modular wind turbine towers must be fast without compromising the safety of the workers. To maximize the efficiency of assembly, it is important to have better knowledge on the strength growth of the glued hybrid joints and how it is affected by the temperature and the moisture content of the surrounding air.

This study focuses on how the strength and the rate of strength growth of the hybrid joints used in Modvion's towers vary depending on weather conditions during gluing and curing. Temperature, humidity and curing time are investigated experimentally to determine the impact on the capacity of the joints at different curing times. This screening is aimed to identify suitable weather conditions

when assembling the tower and which environmental parameters require further investigation to ensure that the joints perform as desired.

Uni-axial, destructive compression tests were performed on small-scale hybrid joint test specimens. Tests were performed in a reference climate of 20 ºC and 65% RH, which is to resemble good weather conditions. The same test procedure was performed on test specimens, glued and cured in different extreme climates. The studied climates are high and low temperatures and high and low relative humidity.

2 TEST PROCEDURE

Small-scale tests of the hybrid joint were performed at RISE's lab in Borås by Viktor Norbäck and Pierre Landel. The procedure involves destructive compression tests on specimens glued and cured in climates with different temperatures and relative humidity.

2.1 TESTED MATERIAL

The test specimens were assembled from an LVL block with a cut slot in which the steel plate was later slotted. A two-component PUR adhesive was used to glue the two parts together. The glue used was Loctite PURBOND CR821, manufactured by Henkel. Both the timber blocks and the steel plates are shown in Figure 1 with a pen for size reference.

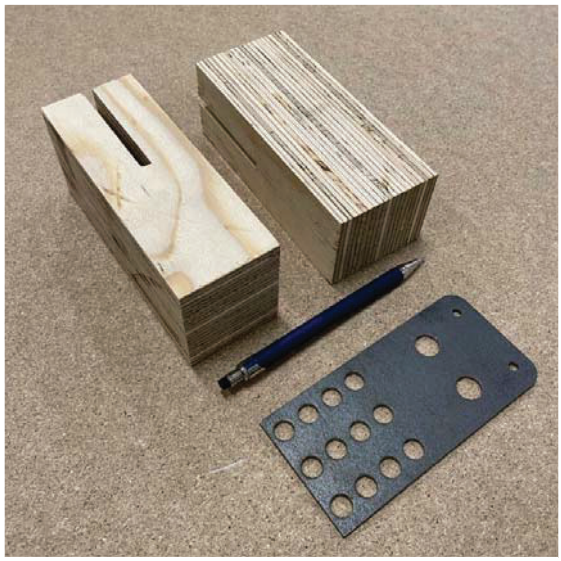

Figure 1: *Test specimen parts. LVL blocks with a cut slit from two different sides and the perforated steel plate. The pen acts as size reference.*

The perforated steel plates were 3 mm thick and had 16 holes. On the side that was slotted into the LVL block, there were 12 holes of diameter 10 mm. It was in these holes where the glue was cast, forming glue dowels connecting the steel plate to the timber part. On the other side of the plate, there were two pairs of holes of diameter 5 and 13 mm. These holes were not used in the compression tests and are meant for another series of tests where the fatigue strength of the hybrid joints is investigated [8]. The perforated steel plate and its holes were cut with a laser cutter with a tolerance of 0.03 mm. Figure 2 shows a blueprint of the perforated steel plates.

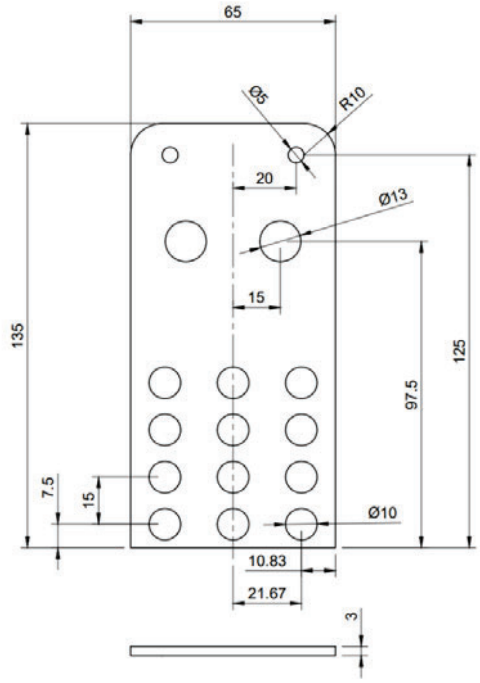

Figure 2: *Blueprint of the perforated steel plate which is slotted into the LVL blocks.*

The LVL blocks were cut from a larger LVL plate manufactured my Metsä wood. The plate consisted of a cross-layup with 21 veneers and a total thickness of 65 mm. The lay-up sequence was [2L/T/7L/T/7L/T/2L] where L denotes longitudinal veneers and T denotes transversal veneers. The direction of the longitudinal and transversal veneers in relation to the LVL block as well as the dimensions of the blocks are shown in Figure 3. Prior to testing, the components and the glue were conditioned until equilibrium in a constant climate of 20ºC and 60% RH.

https://doi.org/10.52202/069179-0182

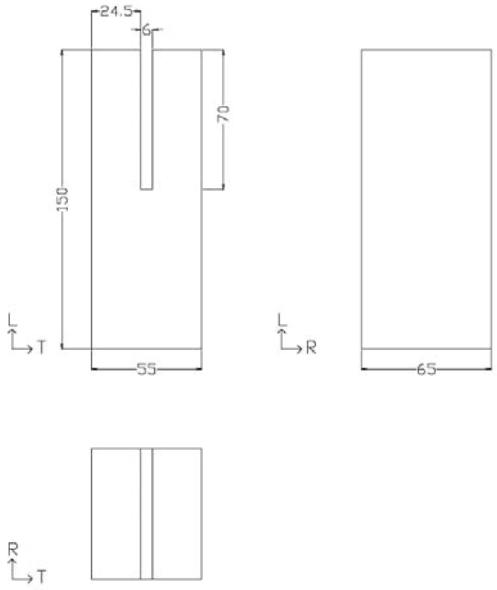

Figure 3: *Blueprint of the LVL blocks with a cut slot.*

2.2 TEST PROCEDURE

From the conditioned climate of 20°C and 60% RH, the specimens were moved and conditioned in a new climate for 48 hours. When two days had passed, the steel and the timber were glued together using the two-component PUR adhesive, which reaches full strength after 7 days and 75% after 2 days according to the manufacturer Henkel [9]. When gluing, 3D-printed plastic holders were clamped onto the timber blocks as shown in Figure 4. In the holders, there was a slot where the steel plate was inserted to be kept in the correct position when gluing. Before inserting the steel plate, a soft foam material was inserted at the bottom of the slot in the timber block to avoid glue from hardening beneath the steel plate. The foam material's stiffness was much lower compared to

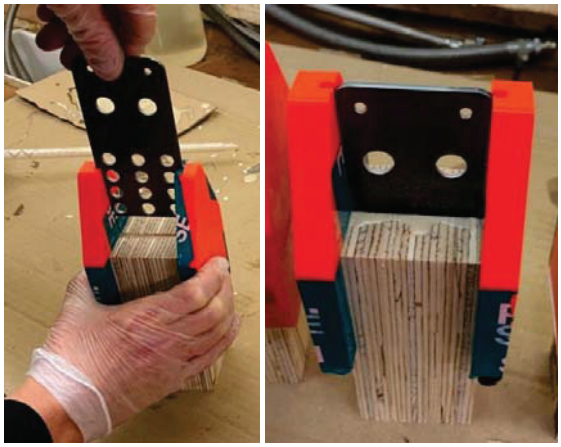

Figure 4: *The perforated steel plates slotted into the slit in the LVL using plastic holders.*

steel and timber. Thereafter, the slot in the LVL block was partly filled with adhesive, leaving room for the steel plate.

Immediately after applying the glue and inserting the steel plates the test specimens were put back in the same climate as before assembly to harden for a certain time. The number of tests in different climates and at different curing times are shown in Table 1. Note that the curing climate is a target climate. There is a variability of up to 0.1°C and 1.2% RH from the target climate.

Table 1. *The number of tests in different climates and for different curing times. Before curing the parts were conditioned for 2 days in the corresponding climate.*

Curing climate	Number of tests	Curing time
20°C 65% RH	1	3.17 h
	1	4.25 h
	1	5.17 h
	1	18.55 h
	1	1 day
	1	3 days
	1	4 days
	1	5 days
12°C 60% RH	3	1 day
	3	5 days
9.1°C 60% RH	3	1 day
	3	5 days
20°C 25% RH	3	1 day
	3	5 days
20°C 95% RH	3	1 day
	3	5 days
27°C 60% RH	3	1 day
	3	5 days

After a certain time, which varies for different test series, the specimens were loaded until failure in a hydraulic press. Two different hydraulic presses were used, both manufactured by Instron, one model 1253 and the other model Satec. 11 tests were performed with model 1253 and 27 tests with model Satec. Two machines were used due to logistic reasons. The setup for both machines was the same; a steel adapter was pushed onto the perforated

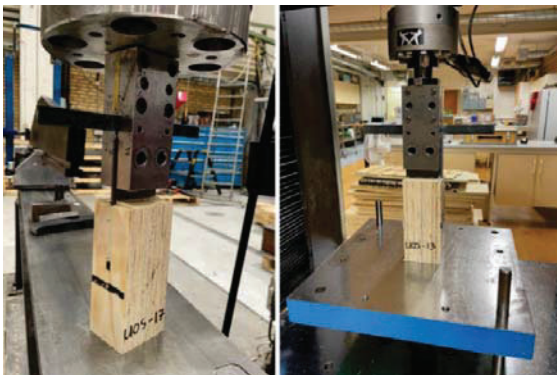

Figure 5: *Compression test setup in both machines. To the left: Instron model Satec. To the right: Instron model 1253.*

steel plate from above, compressing the specimen against

a fixed surface beneath it. The tests were deformation controlled with a constant deformation increment over time. Figure 5 and Figure 6 show examples of the test setup for both hydraulic presses. The foam material was considered to not take any significant loads because of its low stiffness in comparison to steel and LVL.

3 RESULTS, ANALYSIS, AND DISCUSSION

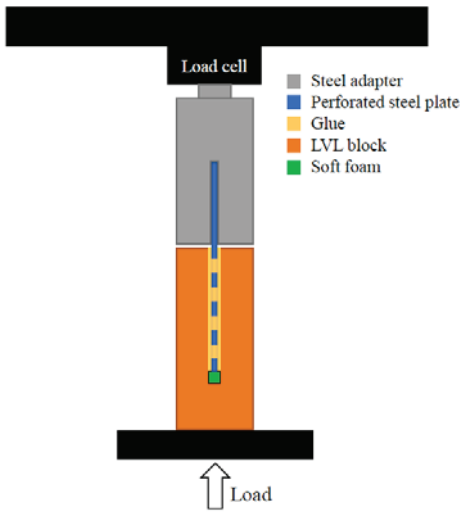

Figure 6: *Principal image of the test setup and the different materials.*

Figure 7 shows a scatter plot including all tested specimens with maximum load in kilonewtons on the vertical axis and curing time in hours on the horizontal axis. The circular data points correspond to the test series studying hardening time in the reference climate of 20°C and 65% RH. The triangular data points correspond to the different assembly and hardening climates at times 27 and 120 hours.

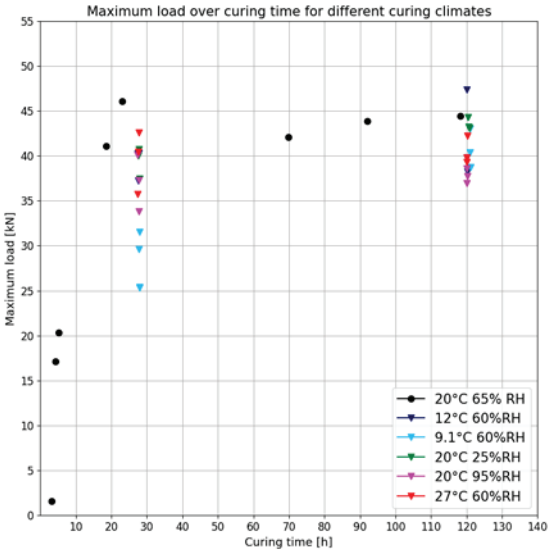

Figure 7: *Maximum load over curing time for different curing climates. On the horizontal axis: Curing time in hours. On the vertical axis: Maximum load in kilonewtons.*

From interpretation of the scatter plot, the strength of the joint starts to build up somewhere between three and four hours at the reference climate. The specimen tested after 3.17 hours demonstrated close to no strength and the specimens tested after 4.25 and 5.17 hours show a strength closer to 20 kN. In addition, for the specimen tested after 3.17 hours the glue was still more or less liquid. To investigate the strength growth of that particular test specimen, the steel plate was slotted back into the LVL block to be tested again after another hour of curing. This time the capacity was much higher similar to the other specimens tested after four to six hours and that had a strength of around 20 kN. The results from the two loadings of the same test specimen are presented in Table 2.

Table 2: *Test results for the same specimen first loaded after 3.17 hours and then loaded once more after a total curing time of 4.50 hours.*

Curing climate	Curing time	Maximum load
20°C 65% RH	3.17 h	1.55 kN
	4.50 h	18.71 kN

During the first day, the strength increased at a high rate up to a level that corresponds to the strength of specimens cured for three, four and five days. This indicates that full strength is reached after the first day of curing in the reference climate. For test specimens cured in other climates, the same trend was observed. Thus, no significant strength growth was noticed after the first day of hardening. However, the specimens cured at 9.1°C and 60% RH were an exception, with lower strength after one day of curing compared to the other specimens cured in other climates. This shows that low temperatures of 9.1°C will influence the curing time of the hybrid joints. The specimens cured at 12°C showed no trend of slower curing time, which suggests a breakpoint for the strength growth between 9.1°C and 12°C at 60% RH.

After 5 days, the specimens cured at 9.1°C and 60% RH had strength in the same range as the other curing climates. This is an indication that the final strength is unaffected by temperatures down to 9.1°C.

Humid climates of 95% RH did not affect the strength growth but may influence the final strength of the specimen. All three specimens tested at 20°C and 95% RH had lower strength compared to the other specimens. However, the number of data points in each climate is low which brings uncertainties as to whether this assumption would be valid if more tests were made in the same climate.

https://doi.org/10.52202/069179-0182

The static loading tests in compression showed two different types of failures. The displacement-to-loading diagrams from the tests exhibit either a brittle failure (Figure 8) or a ductile failure (Figure 9).

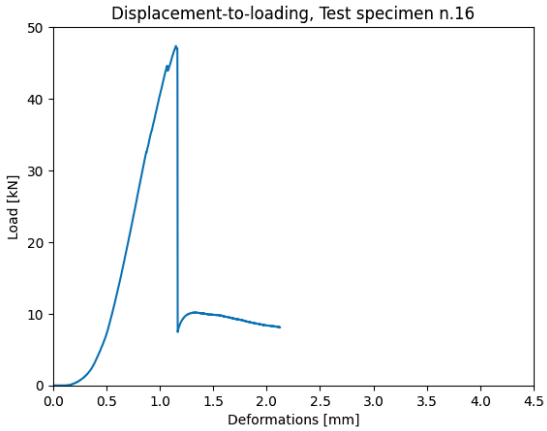

Figure 8: *Displacement-to-loading diagram for a specimen exhibiting a brittle failure.*

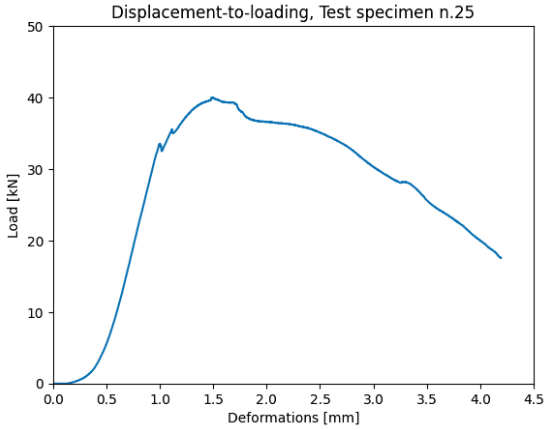

Figure 9: *Displacement-to-loading diagram for a specimen exhibiting a ductile failure.*

After testing, the samples were cut and split to inspect the quality of the gluing inside the joints and possibly reject the samples with lack of glue. Further analysis of the correlation between the failure modes and types would require a larger number of test replicates. Figure 9 and Figure 10 shows pictures of different tested samples and the types of failure modes.

The manufacturing process of gluing the test specimens resulted in specimens of varying quality, according to the testing operators own reflections. This may influence the results, e.g., some specimens had excess glue on top of the timber block and some had a string of glue between the steel plate and the soft foam. The extra glue can influence the joints' ability to transfer loads between the steel plate and the timber part and thus, increase the strength of the test specimen.
In contrast, some specimens had a lack of glue when hardened due to leakage inside or outside the timber

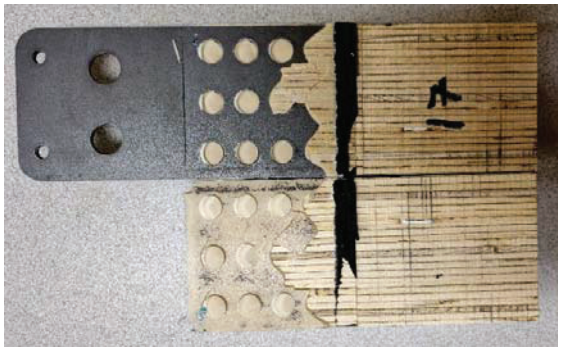

Figure 10: *Combined failure in the glue dowels, the steel-to-glue interface and in the wood-to-glue interface.*

Figure 11: *Failure solely in the glue dowels and in the steel-to-wood interface.*

block. This resulted in a gap at the top of the timber slot of a few millimetres which can lead to lower strength.

Two test machines were used, Instron model Satec and Instron 1253. From the calibration of the machines there is an error of 190 N for model Satec and 330 N for model 1253 for loads in the magnitude of the tests. The measurement uncertainties from the load cells are considered negligible in relation to the spread of quality from assembling the connections in combination with the spread of the material properties of timber.

4 CONCLUSIONS

In this preliminary study, the influences of curing time, ambient temperature and relative humidity when gluing an innovative hybrid connection type are investigated. The experimental results contribute to identifying the critical ambient parameters of such connections glued on-site. Moreover, they bring new knowledge on how to increase the construction speed of larger timber structures without jeopardizing the construction workers' safety or the structural properties of modular towers.

From the results presented in this paper the following conclusions are made:

- High temperatures up to 27 °C and a low relative humidity down to 25% do not influence the strength growth nor the final strength of the tested specimens.
- Strength growth is initially slow when the glue is more liquid. After 3-4.5 hours the curing starts

https://doi.org/10.52202/069179-0182

and strength grows more rapidly, reaching close to full strength after 24 hours of curing.

- Low temperatures down to 9.1°C of the materials and the surrounding air will slow down the rate of strength growth. It does not impact the final strength of the joints.
- There is a possibility that high moisture content in the materials and the surrounding air will influence the final strength of the joint. More test data are recommended to support this outcome.

ACKNOWLEDGEMENT

This project is funded by Energimyndigheten (Swedish Energy Agency) through SWPTC (Swedish Wind Power Technology Centre at Chalmers University). SWPTC aims to develop the Swedish wind turbine industry and promote its expansion.

INFLUENCE OF DENSITY AND PREDRILL IN THE EMBEDMENT STRENGTH OF TWO HARDWOOD SPECIES

Gonzalo Cabrera[1], Gonzalo Moltini[2], Vanesa Baño*[3]

ABSTRACT: The embedment strength is a key parameter in the design of timber connections with metal fasteners. It can be determined by the equations given by Eurocode 5 from the density value. Since those equations were mainly developed for softwood species, the objective of this work is to evaluate the influence of the density in the embedment strength of two high- and low-density hardwood species (beech – *Fagus sylvatica*- and poplar – *Populus x euroamericana*- , respectively) in the parallel- and perpendicular-to-grain direction. Four different experimental test configurations were carried out according to EN 383 for each species using a 5-mm nominal diameter and considering the influence of predrilling in the wood specimens. Results showed a good correlation between density and embedment strength for all the test types. In addition, predrilling showed no significant influence on the value of embedment strength, contrary to what is considered in the equations provided by the current version of the structural design codes. Both, current and new equations proposed by the new draft of Eurocode underestimate the values of embedment strength in both species, thus being on the safe side for the structural design of connections.

KEYWORDS: Embedment strength, density, predrilling, hardwood species, beech, poplar.

1 INTRODUCTION

Timber has been consolidated as a common material in short and large-span ceilings and roofs, and the current tendency is leaning toward mid- and high-rise buildings, where cross-laminated timber panels (CLT) become a key product in the design. In a bibliometric analysis of the research trends related to CLT between 2006 and 2018, the seismic performance of the structures and behaviour of connections resulted in the most relevant topics [1]. In structural design, the good execution and design of connections are vital for adequate behavior and stability of the structure.

Design codes of timber connections are based on the "European Yield Model" proposed by Johansen, whose equations for defining the strength capacity and stiffness of connections depend on the embedment strength of the wood and the yield moment of the fastener. Eurocode 5 [2], currently under review, regulates timber structural design in Europe; however, the Spanish Building Technical Code -CTE- [3] is mandatory in Spain for building design. The CTE got the connections design equations from EC5, but without taking into consideration the rope effect ($F_{ax,Rk}$). In both cases, the equations to determine embedment strength are based on experimental results and fit mostly for softwood species [4,5].

Several authors have studied the embedment strength in solid timber and Engineered Wood Products (EWPs) of softwood and/or hardwood species in different directions with respect to the grain and with different types and geometries of connectors, although most of the studies involve nails, bolts, or dowels, and not screws. For designing connections with smooth shank screws with a diameter greater than 6 mm, EC5 and CTE refer to bolts' equations. Otherwise, the requirements for nails apply. In the latest consolidated draft of Eurocode 5 (prEC5) [6] new equations are included for the specific case of screws in solid structural timber and to cover connections in other EWPs.

The current equations provided by the design codes to determine timber embedment strength are derived from two studies, Whale and Smith [7] and Ehlbeck and Werner [8], which included tests in both softwood and hardwood species. Nonetheless, the number of tests performed in softwood species was considerably higher than in hardwood ones. More studies were performed in the coming years, and some of them such as Sawata and Yasamura [9], Sandhaas et al. [10], and Yurrita et al. [5]found results not aligned with the equations proposed by previous works. In addition, Hubner [11], Sosa Zitto et al. [12], and Franke and Magniere [4], reached the conclusion that the current equations should be reviewed when considering hardwood species, and some of them proposed modifications to the equations based on their results. Since timber´s physical and mechanical properties depend not only on species but also on origin, it becomes necessary to know these parameters for the hardwood species from Spain.

https://doi.org/10.52202/069179-0183

The experimental methods that are more extensively used to determine the embedment strength are the ones from the European standard EN 383:2007[13], the American standard ASTM D 5764-97a [14], and the International Standard ISO 10984-2:2009 [15]. These methods have differences from each other, regarding test method, test setup, sample sizes, loading procedures, and evaluation methods. The most important difference is the determination of the maximum load, F_{max}, which leads to different results depending on the method and, therefore, to the difficulty of comparison.

Hardwood species currently visually- [16,17] or machine-graded [18] in Spain for structural use are southern blue gum (*Eucalyptus globulus*), shining gum (*Eucalyptus nitens*), and sweet chestnut (*Castanea sativa*). Since there are not yet harmonized European standards for the manufacturing of EWPs from hardwood species, some Spanish timber industries have obtained the European Technical Assessment (ETA) to commercialize specific certified products, such as glulam beams from oak by Grupo Gámiz and sweet chestnut by Sierolam, or Parallel Strand Lumber (PSL) from poplar by Tabsal.

The increasing demand for wood is leading the industry to look for alternative species for structural uses, both fast-growing with lower mechanical properties, such as poplar, and slow-growing with higher mechanical properties, such as beech. The rotation of poplar varies between 9 years in the south of Spain and up to 18 years in the north, depending not only on the origin but also on the subspecies and hybrid, and in 2016 the cuts represented 1.6% of the total cuts and 3.1% of hardwoods in Spain [19]. Characteristic values of the structural properties of the 18-year-old *Populus x euroamericana, hybrid I-214*, from the North of Spain were $f_{m,k} = 36.5$ N/mm^2, $E_{0,m} = 7746$ N/mm^2, and $\rho_k = 338$ kg/m^3 [20], which fit with the strength class C14 of EN 338:2016 [21]. The values of modulus of elasticity increased to 8800 N/mm^2 for the same hybrid from Central Spain (Guadalajara) [19] and to 9907 N/mm^2 for Portuguese poplar (*Populus alba* and *Populus nigra*) [22], showing in all the cases structural properties like softwood species. Until 2003, poplar was included in the Spanish timber grading standard [16], but it was removed due to the lack of updated data on new species and hybrids. The rotation of beech varies between 90 and 100 years old approximately [23], and occupies 2% of the total forest extension in Spain [24]. Sawmills classify solid wood in two qualities based on the wood color, first quality with white color destined for aesthetic, and second quality with red color and not industrial uses. In other countries of Europe, it is of interest for structural use due to its high mechanical properties [25–27], which reach the strength class D40 ($f_{m,k} = 40$ N/mm^2, $E_{0,m} = 13$ kN/mm^2, $\rho_k = 550$ kg/m^3) in Germany, Switzerland, and Austria [28,29] and D50 ($f_{m,k} = 50$ N/mm^2, $E_{0,m} = 14$ kN/mm^2, $\rho_k = 620$ kg/m^3) in France [27].

Previous experimental studies in these species [30], using 9 mm diameter screws and 12 mm diameter bolts (Fig. 1), showed that current equations of EC5 overestimated perpendicular to grain embedment strength. However, the equation proposed in prEC5 for screws fitted best perpendicular-to-grain embedment strength and underestimated the parallel-to-grain one.

This work aims to study the influence of the density in the embedment strength of poplar and beech from Spain in the parallel- and perpendicular-to-grain direction using a 5 mm diameter screw and considering the influence of predrilling.

2 EXPERIMENTAL CAMPAIGN

An experimental campaign was carried out to determine the embedment strength of two different low- and high-density hardwood species from Spain, poplar, and beech, in two different directions with respect to grain, parallel and perpendicular, using the following screw provided by Rothoblaas®: 5 mm diameter and 50 mm long screw (LBS550), Fig. 1. Specimens of poplar were between 12 and 15 years old, graded as ME-1 according to UNE 56.544:2003, and beech was around 90 years old classified as first quality according to the aesthetic criteria of the sawmill. Specimens were obtained from different boards and then conditioned until constant mass under conditions of relative humidity (65 ± 5) % and temperature (20 ± 2) °C, in a humidity chamber Memmert HCP240, before and after placing the fasteners (Fig. 2).

Figure 1: *5 mm ø screw, 9 mm ø screw, and 12 mm ø bolt provided by Rothoblaas®*

Figure 2: *Conditioning of the test specimens*

Four different test types were carried out for each species, following the specifications of EN 383:2007 [13], as summarized in Table 1, depending on the grain direction, and the predrilling of the wood. Since both CTE and EC5 propose a different formulation of the timber embedment

https://doi.org/10.52202/069179-0183

strength for each case (Eq. 1 and 2), specimens with and without a predrilled hole were tested.

Without predrilled hole:

$$f_{h,k} = 0.082\ \rho_k\ d - 0.3\ (N/mm^2) \quad (1)$$

With predrilled hole:

$$f_{h,k} = 0.082\ (1 - 0.01\ d)\ \rho_k\ (N/mm^2) \quad (2)$$

where, $f_{h,k}$ is the characteristic timber embedment strength, ρ_k is the characteristic timber density (kg/m³), and d is the nail (or screw) diameter (mm).

Table 1: *Test types per species*

	Test	N	Mean MC (%)	ϕ (mm)	Pre-drill	Cross-section (mm³)	Grain direct.
Poplar	T1	9	12.0 (5%)	5	No	17 × 50	∥
	T2	10	12.0 (5%)	5	No	17 × 50	⊥
	T3	10	11.8 (5%)	5	3 mm	17 × 50	∥
	T4	10	11.6 (5%)	5	3 mm	17 × 50	⊥
Beech	T1	7	12.5 (5%)	5	No	17 × 50	∥
	T2	10	12.1 (7%)	5	No	17 × 50	⊥
	T3	9	12.1 (5%)	5	3 mm	17 × 50	∥
	T4	9	12.2 (5%)	5	3 mm	17 × 50	⊥

* Note: MC is the moisture content and the coefficient of variation, CoV, is presented between ( ), and ϕ is the diameter of the screw.

2.1 METHODOLOGY

The specimens were tested in compression through a loading steel device, as shown in Figure 3. Figures 4 and 5 show the experimental tests in parallel- and perpendicular-to-grain compression in poplar and beech, respectively. The loading procedure was defined in terms of the maximum estimated load $F_{max,est}$ for each test. It consisted of two cycles: a preload cycle up to $0{,}4F_{max,est}$, and a final loading until failure. The loading procedure is presented in Figure 6. After testing, a slice of the specimen was extracted to determine its density and moisture content according to EN 13183-1:2002 [31]. Density was later adjusted to a reference moisture content of 12 %.

3 RESULTS AND DISCUSSION

3.1 LOAD-DISPLACEMENT CURVES

Load-displacement curves of both species tested in the parallel- and perpendicular-to-grain direction, with and without predrilling, are shown in Figures 7-10.

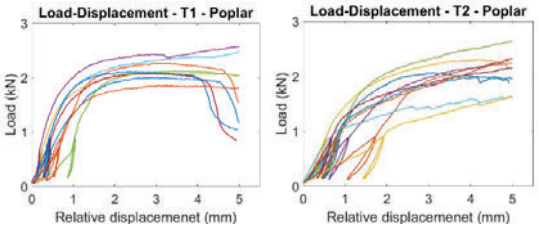

Figure 7: *Load–displacement curves of poplar without predrilling*

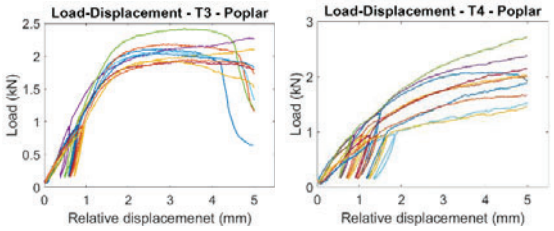

Figure 8: *Load–displacement curves of poplar with predrilling*

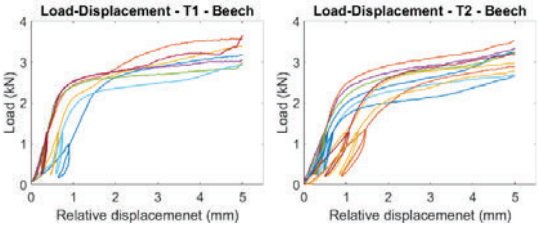

Figure 9: *Load–displacement curves of beech without predrilling*

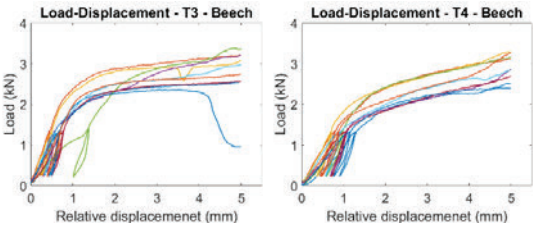

Figure 10: *Load–displacement curves of poplar with predrilling*

As expected, and observed previously by Cabrera et al. [30], beech presents higher values of embedment strength than poplar, and a difference in behavior is observed when comparing parallel- with perpendicular-to-grain tests. A plateau in the diagram is observed after the yield point in the parallel-to-grain tests, while the load increases with relative displacement in the perpendicular-to-grain tests, showing a hardening behavior of wood, but lower than that observed for greater fastener diameters.

Figures 11 and 12 show the comparison of the load–displacement diagrams of tests with and without predrilled holes within the same species. Load–displacement diagram of a particular test specimen representative of the mean behavior of the sample was selected in each case. Through this comparison, it can be directly observed that there are no important differences in behavior due to the execution of the predrilled hole. The shape of the curves in general terms are similar within the same test type for each species.

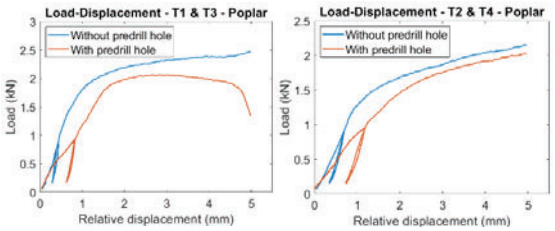

Figure 11: *Load-displacement diagram of poplar with and without predrilling in parallel and perpendicular to the grain tests*

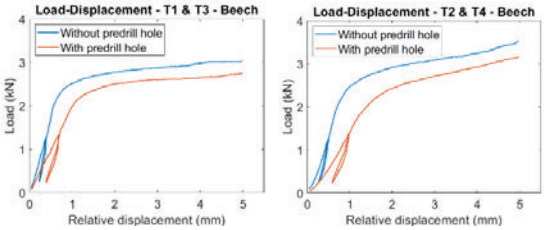

Figure 12: *Load-displacement diagram of beech with and without predrilling in parallel and perpendicular to the grain tests.*

3.2 EMBEDMENT STRENGTH

The embedment strength f_h was determined according to Equation (3), and characteristic values were obtained according to EN 14358:2016 [32] assuming a lognormal distribution.

$$f_h = \frac{F_{max}}{dt} \tag{3}$$

where F_{max} is the maximum load; d is the effective diameter of the screw, taken as 1.1 times the thread root diameter, which resulted in 3.3 mm for LBS550 screws; and t is the thickness of the test specimen.

Results from Cabrera et al. [30] showed that the method provided by EN 383 for the determination of embedment strength could overestimate that value for the perpendicular-to-grain direction. So, the embedment strength obtained from EN 383 was compared with that obtained from ASTM D 5764-97a and EN 408:2010 [33] according to the following criteria:

https://doi.org/10.52202/069179-0183

(i) F_{max} corresponding to a relative displacement of the fastener of 5 mm, or the maximum force in case it was reached at a lower deformation, as specified in EN 383.
(ii) F_{max} as the yield point defined in the load-deformation diagram by a straight line parallel to the elastic slope offset by deformation of 5% of the fastener diameter, as it is defined in ASTM D 5764-97a.
(iii) F_{max} determined according to the method defined in the EN 408 for the perpendicular-to-grain compression strength, like that described in (ii) but with a straight line offset by 0.01 h_t, where h_t is the loaded length, i.e., the distance below the fastener.
Results of mean and characteristic values of embedment strength -obtained from EN 383- and density, with their coefficient of variation, are presented in Table 2 for both species.

Table 2: *Results of the experimental tests according to EN 383*

	Poplar				Beech			
Test	$f_{h,m}$ (N/mm^2)	$f_{h,k}$ (N/mm^2)	ρ_m (kg/m^3)	ρ_k (kg/m^3)	$f_{h,m}$ (N/mm^2)	$f_{h,k}$ (N/mm^2)	ρ_m (kg/m^3)	ρ_k (kg/m^3)
T1	38.3 (11%)	30.6	414 (18%)	253	57.8 (9%)	46.9	670 (11%)	503
T2	37.6 (15%)	26.9	419 (19%)	252	54.6 (9%)	44.9	645 (7%)	549
T3	37.1 (8%)	31.6	424 (21%)	241	52.1 (12%)	39.8	692 (12%)	519
T4	35.1 (20%)	23.0	420 (21%)	239	51.8 (11%)	40.6	685 (10%)	542

Note: The value between brackets shows the coefficient of variation (%); ρ_k is the density adjusted to 12% of moisture content according to EN 384

Figures 13 and 14 show the characteristic values of the embedment strength depending on the standard method for both species and the four test types.
In poplar, experimental values obtained through the three different methods are more even between each other for the two parallel-to-grain tests performed than for the perpendicular-to-grain ones (Fig. 13). Values of perpendicular-to-grain embedment strength evaluated according to EN 383 standard were higher compared with those of the other two methods, especially in tests without predrilling (T2). In addition, perpendicular-to-grain embedment strength is rather lower than parallel-to-grain one, contrary to what the standard states according to its equations.

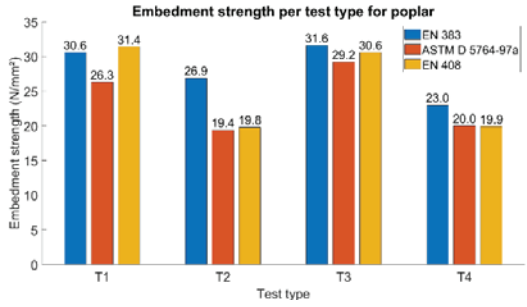

Figure 13: *Experimental characteristic values of embedment strength depending on the standard and test type in poplar.*

In beech (Fig. 14), higher values of embedment strength are obtained according to the EN 383 method for both with and without predrilling and parallel- and perpendicular-to-grain tests, with significant differences with respect to the other methods according to an ANOVA analysis. The small diameter of the screw and the cross-section of the wood specimen could lead to evaluate the embedment strength before the yield point of the load-displacement diagram for the ASTM and EN 408 methods, which could result in an underestimation of the embedment strength parallel to the grain.

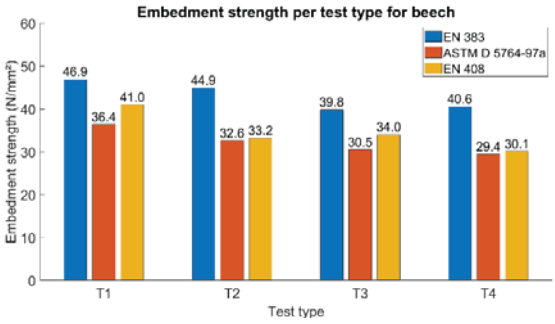

Figure 14: *Experimental characteristic values of embedment strength depending on the standard and test type in beech.*

3.3 FAILURE MODE

Most of the specimens from T1 to T4 tests showed a failure mode that combines the timber embedment with plastic deformation of the screw (Fig. 15), which differs from the failure mode of the fasteners with greater diameter, in which the plastic deformation of the fastener did not occur [30]. As in the case of the greater diameter of fasteners, a combination of embedment and splitting was observed in the perpendicular-to-grain tests especially performed in poplar.

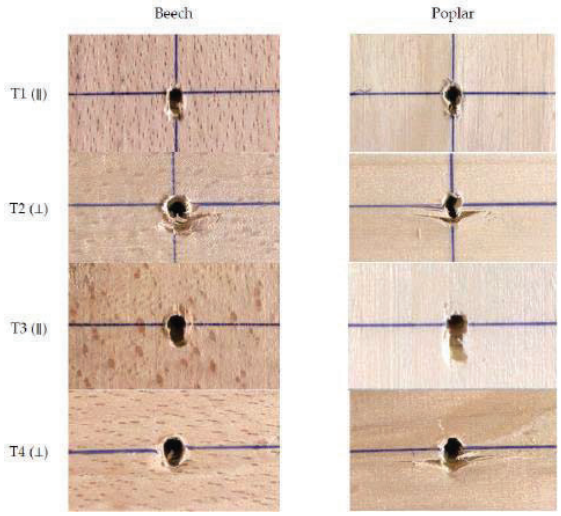

Figure 15: *Failure modes*

3.4 COMPARISON WITH THE THEORETICAL VALUES OF THE DESIGN CODES

For comparing experimental values with theoretical ones, the experimental values obtained according to the method of the EN 383 standard will be considered because of the two main reasons that follow. The first is that experimental values of embedment strength obtained according to the methods of ASTM D 5764-97a and EN 408 tend to underestimate embedment strength since as it was mentioned before, the small diameter of the fastener and geometry of test specimens lead to obtaining a failure point located before the yielding phase of the load-displacement diagram, which does not make any sense. The second reason is that the correlation obtained between density and embedment strength according to the methods of ASTM D 5764-97a and EN 408 was much lower than the one obtained with the results of the EN 383 standard.
Thus, the experimental values of the embedment strength obtained from EN 383 were compared with those obtained from the equations provided by the EC5 and prEC5. The equations that are applicable for each studied case depend on the existence or not of a predrilled hole as a determining factor in the embedment strength according to EC5, but not according to prEC5, which proposes only one equation for both cases, but considers the influence of the angle between the fastener axis and the grain direction, as shown in Table 3. Neither EC5 nor prEC5 considers load-to-grain angle as a determining factor for obtaining embedment strength.
Results are shown in Figures 16 and 17 and the ratios between theoretical values obtained from EC5 and prEC5 and the experimental values are presented in Table 4. It is not clear that a predrilled hole in the wood improves the embedment strength, as EC5 considers, resulting in an underestimation of embedment strength for the studied cases T1 and T2.

Table 3: *Equations provided by EC5 and prEC5 to determine the embedment strength of small-diameter screws.*

Test		Equation of EC5	Equation of prEC5
Nails without predrilling (EC5) Screws (prEC5)	T1 (∥) T2 (⊥)	$f_{h,k} = 0.082\rho_k d^{-0.3}$	$f_{h,k} = \frac{0.019\rho_k^{1.24} d^{-0.3}}{2.5\cos^2\varepsilon + \sin^2\varepsilon}$
Nails without predrilling (EC5) Screws (prEC5)	T3 (∥) T4 (⊥)	$f_{h,k} = 0.082(1 - 0.01d)\rho_k$	

ε is the angle between the fastener axis and the grain direction. $\varepsilon = 90°$ for all tests.

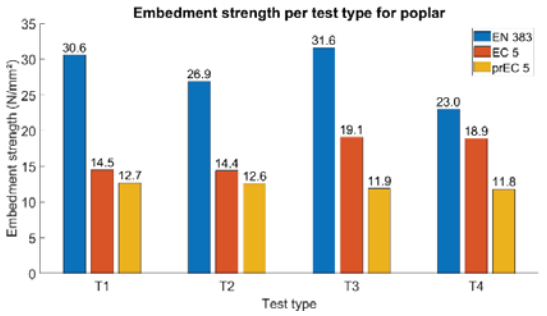

Figure 16: *Experimental vs. theoretical characteristic embedment strength in poplar*

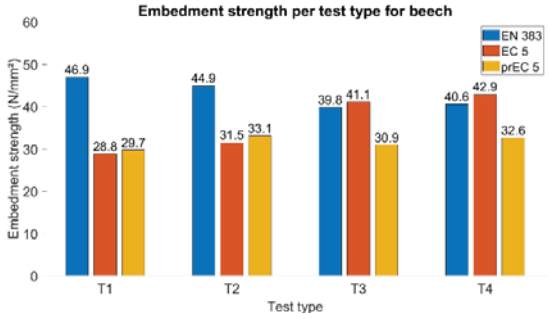

Figure 17: *Experimental vs. theoretical characteristic embedment strength in beech*

Table 4: *Ratios between theoretical and experimental values of embedment strength*

Test	Poplar		Beech	
	$\frac{f_{h,k_EC5}}{f_{h,k_exp}}$ (N/mm²)	$\frac{f_{h,k_prEC5}}{f_{h,k_exp}}$ (N/mm²)	$\frac{f_{h,k_EC5}}{f_{h,k_exp}}$ (N/mm²)	$\frac{f_{h,k_prEC5}}{f_{h,k_exp}}$ (N/mm²)
T1	0.47	0.41	0.61	0.63
T2	0.54	0.47	0.70	0.74
T3	0.60	0.38	1.03	0.78
T4	0.83	0.51	1.06	0.80

Results show that the execution of a predrill in the wood does not have a significant influence on the embedment strength for screws of 5 mm of diameter for both species according to an ANOVA analysis with a confidence level of 95%, which was also stated by Sosa Zitto et al. [12]and differs from the current EC5 approach. In addition, the equations provided by the EC5 underestimate the

https://doi.org/10.52202/069179-0183

experimental values for both parallel- and perpendicular-to-grain embedment strength of poplar. When it comes to beech, it is observed that EC5 equations predict appropriately the embedment strength in wood specimens with predrilling and underestimate embedment strength for the cases without predrilling. In terms of structural design, equations could lead to oversizing, but in any case are on the safe side.

New equations proposed by prEC5 showed similar values to those obtained from EC5 without predrilling, which implies that they also underestimate the embedment strength for both species with small-diameter screws.

In addition, no significant influence of the load-to-grain direction was observed for all the studied cases according to an ANOVA analysis with a confidence level of 95%, which goes along with the fact that the formulations proposed are independent of the load-to-grain angle.

3.5 CORRELATION BETWEEN DENSITY AND EMBEDMENT STRENGTH

The correlation between experimental embedment strength and density adjusted to 12% of MC was studied for both species and the different tests performed. Results are presented in Figures 17 and 18.

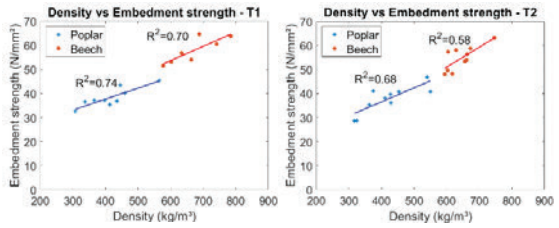

Figure 17: *Correlation between density (ρ_{12}) and embedment strength ($f_{h,exp}$) for wood specimens without predrilling.*

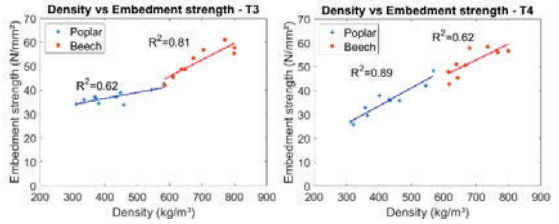

Figure 18: *Correlation between density (ρ_{12}) and embedment strength ($f_{h,exp}$) for wood specimens with predrilling.*

The correlation coefficient between density and embedment strength was higher than 0.62 for all the cases, except for beech without predrilling compression perpendicular to the grain (R^2=0.58) which indicates that density is a good predictor of embedment strength for these species.

4 CONCLUSIONS

Beech showed higher values of embedment strength than poplar for all the cases studied. Embedment failure was observed in parallel-to-grain tests, while a combined failure of embedment and splitting took place in some of the perpendicular-to-grain tests, especially in poplar.

When testing nails or screws with small diameters, the method provided by ASTM D 5764-97a or the one proposed based on EN 408, could lead to underestimation of embedment strength, thus being not appropriate.

Results showed that there is no significant influence of the predrilled hole in the embedment strength of the species studied with the small-diameter screw tested, contrary to what EC5 considers, thus penalizing embedment strength for the case without predrilled holes. New equations provided by prEC5 showed similar values to those obtained from EC5 without predrilling, therefore, a better prediction of embedment strength is obtained in the cases studied if the equation for nails with predrilled holes of EC5 is used in every case.

In addition, results also showed that there is no significant influence of the load-to-grain direction in the embedment strength for the studied cases, a fact that is aligned with the current proposal of EC5.

Density becomes a good predictor of embedment strength for these species and screws studied.

STRUCTURAL PERFORMANCE OF HIGH CAPACITY GLULAM MOMENT CONNECTIONS

Ryan Guay [1], Christopher Pitt [2], Reid B. Zimmerman [3], Ignace Mugabo [4], Peter Dusicka [5]

ABSTRACT: Moment connections in glulam members are desirable over simple connections to increase load-carrying capacity and reduce deflections for the same glulam cross section. However, moment connections in glulam members often result in a large tension-compression couple. To achieve high tension capacity, a large number of fasteners acting in dowel shear are often utilized. Brittle failure modes such as block shear and group tear-out can dominate such connections.

This study evaluates the structural performance of high capacity glulam moment and tension connections in two configurations based on the results of physical testing: (1) Steel plates installed with 90-degree screws on both of the outer, side faces of a glulam member, and (2) two steel plates nested into a glulam member and installed with self-drilling dowels. Calculation-based results and physical load test results are compared. The results from this study show that block shear capacity estimations as adopted in design standards may be unconservative for high capacity moment or tension connections. A potential modification through perpendicular-to-grain reinforcing screws to help mitigate the block shear failure is presented. Further research on high capacity moment and tension connections is needed to provide better agreement between design versus actual capacity, especially for block shear type failure modes.

KEYWORDS: Glulam Connections, Self-Drilling Dowels, Wood Screws, Block Shear Failure, Reinforcing Screws

1 INTRODUCTION

Glulam connections commonly used in buildings in North America are configured as simple shear connections with negligible capacity to resist bending moments. Glulam moment connections are uncommon, particularly in cases where high capacities are required. In order to achieve the long-span glulam beams, cantilevers, and wood-steel hybrid structure desired for the new Portland International Airport Terminal Core Redevelopment (TCORE) roof located in Portland, Oregon, USA, high capacity moment connections were developed for deep glulam beams. This paper evaluates dowel-type glulam moment connections using a multi-scale approach and a comparison between test and analytical results. The paper also presents a solution for mitigating premature block shear failures in such connections.

1.1 Background for timber connection testing

The Port of Portland's TCORE project is a roughly $2 billion terminal redevelopment project, including an approximately 300 m x 120 m mass timber hybrid roof with approximately 6 m wide x 2 m deep paired steel plate girder sections spaced at 30 m. Approximately 170 mm wide x 2 m deep x 24 m long Douglas-fir glulam beams span perpendicular to the steel plate girders at 3 m spacing. The roof structure is seismically isolated with curved surface slider (friction pendulum) isolators located at the top of the Y-column connections to the bottom of the steel plate girders [1]. This requires that the glulam beams transmit seismic loading from the roof diaphragm above to the isolation plane below through strong-axis bending. Additionally, glulam beams support roof edge cantilevers of over 10 m and are optimized by functioning as continuous beams with moment connections to the plate girders. Due to the large demands and unique nature of these connections, an effort was made early in design to perform physical load testing of various connection configurations to develop a thorough understanding of their capacities and failure mechanisms.

Allowing for expansion and shrinkage in the glulam beams due to variations in moisture content (MC) during construction and service was a critical consideration. Excessive moisture content change and/or excessive restraint introduced by the dowel-connected steel plate connections could have resulted in wood splitting, compromising the capacity of the connection. Design to prevent splitting pursued limiting the perpendicular-to-

grain distance between outer rows of fasteners connecting steel and glulam to a maximum of 150 mm, and separating the beam end tension/compression connections so they can each move independently in the vertical (perpendicular to grain) direction with the glulam beam end. Due to the critical nature of these connections, moisture cycling was performed on selected specimen followed by load testing, to verify that no significant reduction in capacity occurred due to moisture cycling.

1.2 Brief introduction to general testing approach

To develop the proposed connection configurations, the roof structure was analysed to determine the various levels of tension/compression demand required near the top and bottom of glulam beams to provide bending moment resistance at the beam ends. A data binning approach was used to group various levels of glulam demands to minimize the number of different connections required on the project, while also achieving efficiency in the design. Beam vertical shear demands are resisted by direct bearing of bottom of glulam beams on steel plate girder, not through dowel fasteners.

Analyses determined that (3) connection capacity levels were needed to efficiently meet the loading requirements for this project. Two proposed connection configuration options were explored. Both connection configurations were tested at all capacity levels, equalling (6) connection types, with (2) additional sub-types tested, for a total of (8) unique tested configurations.

Both beam bending specimen tests and smaller axial tension specimen tests were performed on the connection types, with the connections tested at full scale in both cases. The as-constructed connections in the TCORE roof are shown in photo 1 below.

Photo 1: As constructed glulam beam end moment connections

2 MATERIALS, METHODS, AND DATA PROCESSING

2.1 Description of timber connections

Two connection configuration design concepts were included in the testing program for the glulam beam end top/bottom moment connections; one consisted of a connection composed of exposed 6 mm thick steel side plates with 6 mm x 90 mm wood screws installed each side, loaded in single shear. The other consisted of a connection composed of a pair of 6 mm thick steel plates slotted into and concealed within the width of the glulam beam, with 6 mm diameter self-drilling dowels (SDDs) installed through the glulam thickness and both steel plates, loaded on 4-shear planes. See figure 1 below for a graphical representation of the two concepts, along with the various sizes for the connection test configurations and fastener quantity. The left side of figure 1 indicates the external steel side plates with screws connection; the right side of figure 1 indicates the internal steel plates with self-drilling dowels connection.

All glulam specimens were made of Douglas-Fir (*Pseudotsuga menziesii*) timber with a 16.5 MPa tension lam bending stress grade. Specimens were kept at moisture content of 12% +/- 4% during fabrication and load testing of the connections. Four specimens were moisture cycled prior to load testing to study the effects that weather exposure and drying may have on the capacity of the connections. The steel side and thru-plates consisted of 6 mm thick ASTM A572 Grade 50 steel.

The larger type C3 and C6 connection test specimens differed from the connections used in the project in that the test specimens had a single large plate, whereas the project connections used two separate plates to prevent restraint during moisture shrinkage/expansion.

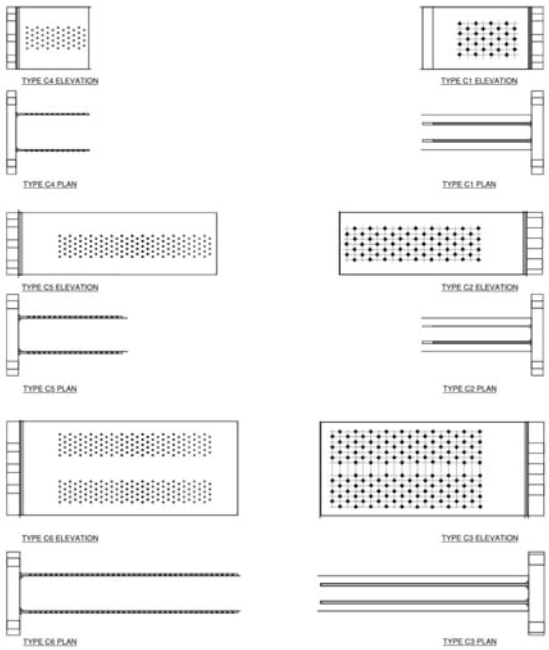

Figure 1: Summary of Connection Types Tested

2.2 Methods of testing

KPFF worked directly with Portland State University to utilize the infrastructure Testing and Applied Research

https://doi.org/10.52202/069179-0184

(iSTAR) Laboratory to perform the specimen load testing, which included both axial tension connection tests and beam bending tests. The specimens were fabricated off site by the same wood subcontractor as would be fabricating the project connections and shipped to the iSTAR Laboratory. A minimum of (8) connection tests were performed for each of the connection types. This number of tests was selected to balance cost/time of testing with the need to collect an adequate data set for performing limited statistical analysis.

Moisture content (MC) cycling testing followed by load testing on an additional (4) axial tension specimens was also performed. MC cycling was conducted in an environmental chamber at Oregon State University after which specimens were shipped to the iSTAR Laboratory for identical load testing to non-MC cycled specimens.

2.2.1 Physical Testing

A total of (28) axial tension specimen tests were performed, (12) tests using the 6 mm SDDs and (16) with the 6 mm x 90 mm wood screws. Following the completion of the axial tension specimen tests, (12) full scale bending specimen tests were performed, (6) using the 6 mm SDDs and (6) with the 6 mm x 90 mm wood screws. Douglas-fir glulam beams were used with the fasteners installed in laminations of equal or lower grade from those present at end connection locations in the project final condition. Steel test rig frames were fabricated to enable hydraulic jacks to apply loading to the specimens, with pressure/load and movements continuously monitored. The tension specimen tests were subjected to direct, concentric axial tension by pulling the two ends of the glulam specimen apart. The beam bending test specimens were subjected to shear and flexure by securing one end of the beam to the stationary test rig with a vertical shear bearing and horizontal compression connection bucket at the top and horizontal tension connection at the bottom, with a vertical upward load applied to the far end of the beam to induce shear and bending proportional with the actual roof demands. The beam bending specimens were each tested twice, with a tension connection installed at diagonally opposite corners to allow them to be flipped and rotated for testing after failure of the initially tested connection.

The connections were instrumented by the iSTAR Laboratory staff with load cells and deformation sensors. Deformation sensors measured deformation across the connection, rather than the entire specimen, directly. As a backup to the load cells for measuring force, pressure sensors for the hydraulic jacks were also present.

The axial tension specimen tests were performed first, which helped direct the path for the remaining tests by revealing which failure mechanisms should be more closely investigated. The axial tension specimen tests were quasi-statically loaded up to the approximate allowable stress design (ASD/service level) loads estimated from preliminary roof structure analyses, the load was held for 10 minutes, and then the connections were quasi-statically loaded to failure. The loading to failure procedure was based on ASTM D1761-12 [2], which is typically used for determining the lateral load resistance for wood screws in the U.S. For each of the axial tension specimen tests, the same connection configuration was installed on each end of the glulam. The measured capacity of whichever end connection failed first was conservatively used as the capacity for both end connections and treated as two equal data points in the data analysis.

The beam bending specimen tests were loaded in a similar manner to the axial tension specimen tests with the exception of one full beam specimen that was loaded and held for a full 24 hour period at the ASD/service load. The objective of this test was to determine if any additional creep occurred during the hold period. See figure 2 for the test setup for representative specimens.

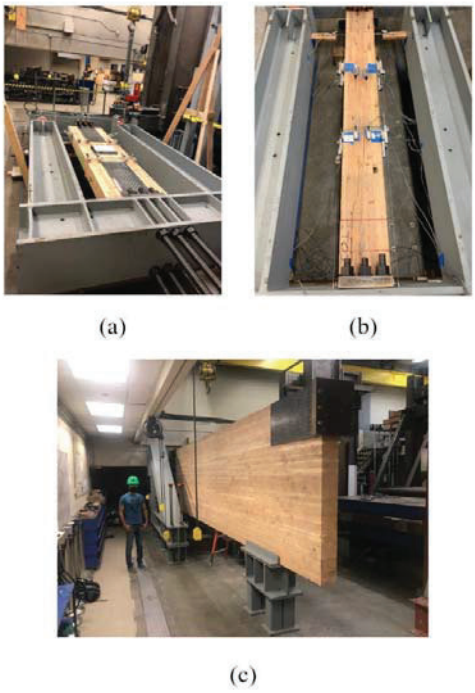

Figure 2: Connection testing setup (a) tension specimen with external steel plates and wood screws, (b) tension specimen with internal steel plates and self-drilling dowels, and (c) bending specimen.

2.2.2 Moisture Testing

To determine whether the proposed connection types were sensitive to wetting/drying (and associated wood shrinkage/expansion) after installation, moisture content (MC) cycling was applied to (4) axial tension test specimens prior to load testing. This was considered important because, in the actual project, the glulam beams would be exposed to weather during some phases of

https://doi.org/10.52202/069179-0184

construction despite best efforts to minimize such exposure through a detailed weather protection plan. For this testing, the connections were installed in glulam beams with industry standard 15%-16% MC, which aligned with the maximum MC allowed by project specifications. Pinned moisture monitors were installed to approximately 75 mm depth to measure internal MC before the glulam beam test specimens were placed in an environmental chamber at Oregon State University. Within the chamber, the temperature and humidity were controlled to cause expedited MC variations. The specimens were periodically sprayed with water for several days under low temperature and high humidity conditions until they increased to 22-27% MC (an increase of 6-12% MC). Then the chamber was set to higher temperature and low relative humidity to induce rapid drying. These conditions were maintained for over 4 weeks until the specimens reduced to 8-13% MC (a decrease of up to 16% MC from peak after wetting). See figure 3.

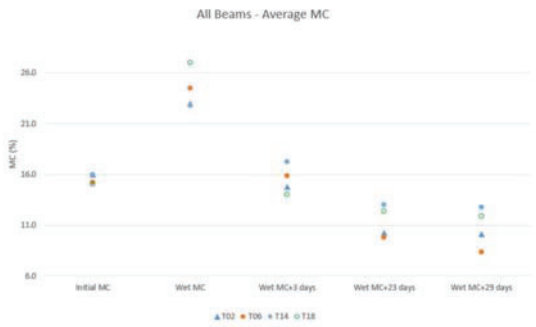

Figure 3: Moisture content (MC) cycling data of glulam specimens

Project specifications included requirements for moisture control and monitoring, which were calibrated to the MC testing performed. These included a maximum MC at time of connection installation, periodic monitoring of glulam beam MC after installation, and a maximum MC allowed at any point in construction. This ensured that the maximum variations in MC for in-situ project conditions were within those evaluated by testing. Final long-term minimum MC in the occupied building is estimated as 8% MC or above based on conservative assumptions of service temperature and relative humidity inside the conditioned building.

2.3 Statistical analysis of test results

To establish design capacities of the load tested connections, KPFF worked with the permitting authority for the project (The City of Portland, Oregon, Bureau of Development Services). Statistical analysis of the load test results following ASTM D2915-17 [3] established a nominal capacity for design on the basis that the physical testing methods for the connections were aligned with those of ASTM D1761-12 [2] and ASTM D5764-97a [4]. These latter ASTM standards are both typically used for testing of mechanical fasteners and dowel-bearing strength in wood products in the U.S.

With the data that was collected from the tests, a 75% confidence level, one-sided tolerance limit, and population content of 95% were chosen (indicating that 95% of the population lies above the tolerance limit, 75% of the time through sampling). This confidence level, tolerance limit, and population content are the traditional approach for establishing structural capacities of wood products in the U.S. (i.e., 5% exclusion of lower capacities).

See Section 3.1 for a summary of the results. A graphical representation of the design capacity compared with the test data for each of the different types of connections is shown in figure 6.

2.4 NDS and Eurocode Calculations

In advance of performing the physical tests, calculations were made utilizing fastener manufacturer listed capacities, the design provisions of Appendix E of the American Wood Council's National Design Specification (NDS) for Wood Construction [5], and Annex A of Eurocode 5 [6] to determine expected design capacities. For block shear calculations (named as group tear-out in the NDS), the NDS equations consider the sum of the resistance from both the shear and tension portions of a potential failure perimeter. In contrast, Eurocode only takes the larger of the shear or tension portion capacity. See figure 4. This represents a fundamental difference in philosophy between the NDS and Eurocode. Where the NDS appears to assume load-sharing between the shear and tension portions of a block shear perimeter up to ultimate failure, Eurocode appears to assume that failure will occur on either the shear or tension portion but not both simultaneously. In other words, Eurocode appears to consider the differing deformations at failure between the shear and tensions portions whereas the NDS either neglects this or assumes some ductility in the portion which reaches capacity first.

Figure 4 below excerpts the relevant equations from NDS and Eurocode for comparison. See Section 3.2 for a comparison of load test results to calculations from both codes.

https://doi.org/10.52202/069179-0184

E.4 Group Tear-Out Capacity

The adjusted tear-out capacity of a group of "n" rows of fasteners can be estimated as:

$$Z_{GT}' = \frac{Z_{RT-1}'}{2} + \frac{Z_{RT-n}'}{2} + F_t' A_{group-net} \qquad \text{(E.4-1)}$$

where:

Z_{GT}' = adjusted group tear-out capacity

Z_{RT-1}' = adjusted row tear-out capacity of row 1 of fasteners bounding the critical group area

Z_{RT-n}' = adjusted row tear-out capacity of row n of fasteners bounding the critical group area

$A_{group-net}$ = critical group net section area between row 1 and row n

(a)

Annex A (Informative): Block shear and plug shear failure at multiple dowel-type steel-to-timber connections

(1) For steel-to-timber connections comprising multiple dowel-type fasteners subjected to a force component parallel to grain near the end of the timber member, the characteristic load-carrying capacity of fracture along the perimeter of the fastener area, as shown in Figure A.1 (block shear failure) and Figure A.2 (plug shear failure), should be taken as:

$$F_{Bs,Rk} = \max \begin{cases} 1{,}5\, A_{net,t} f_{t,0,k} \\ 0{,}7\, A_{net,v} f_{v,k} \end{cases} \qquad \text{(A.1}$$

with

$$A_{net,t} = L_{net,t}\, t_1 \qquad \text{(A.2}$$

$$A_{net,v} = \begin{cases} L_{net,v}\, t_1 & \text{failure modes (c,f, j/l, k, m)} \\ \frac{L_{net,v}}{2}\left(L_{net,t} + 2t_{el}\right) & \text{all other failure modes} \end{cases} \qquad \text{(A.3}$$

3 RESULTS AND DISCUSSION

3.1 Summary of Results

The axial tension specimen test results for the smaller side-plated wood screw connections (type C4 per figure 1) aligned quite closely with calculated connection capacities based on the manufacturer published values, with load-displacement data indicating that ductile screw flexure was the dominant failure mode in those connections. However, the initial axial tension specimen tests for the medium and large connections (types C2, C3, C5, and C6 per figure 1) demonstrated block shear failures in the glulam beams at load levels significantly below calculations based on manufacturer published fastener shear capacity. After review of preliminary results, groups of (2) 10 mm diameter perpendicular-to-grain reinforcing screws were added at 150 mm spacing along the length of the larger side plate connections (C5 and C6) through the glulam beam, with the spacing of the wood screws in the side plates re-spaced to provide a 50 mm gap at reinforcing screw pair location. These reinforcing screws extended a minimum of 75 mm past rows of connection wood screws, as shown in figure 5 below, to increase resistance to glulam splitting and block shear.

Subsequent tests of reinforced connection types C5 and C6 achieved significantly higher capacities more in-line with the capacities needed for the design and estimated by calculations. See figure 5 showing load vs deformation for the reinforced vs unreinforced connections. It was not feasible to add reinforcing screws for the specimens with the double plates slotted into the glulams (C2 and C3) due to inadequate width of the roughly 50 mm wide glulam sections each side of the plates.

Upon completion of physical load testing, the data was compiled and analysed, and the project team selected the double side plate connections with wood screws for use on the project due to their higher capacity, improved constructability, and lower cost. The test failure loads and calculated nominal design capacity for these connections is shown in figure 6. For design, the LRFD resistance factor of 0.65 was applied to these nominal capacities per NDS [5], and compared against factored loads from ASCE 7-16 [7]. The capacity for the wood portion of the wood connections was based upon the statistical analysis completed per ASTM D2915-17 [3], with the following equation: Avg Load – (Std. Dev. x K). The K factor is based on the one-sided tolerance limit for a normal distribution (with a 75% confidence level and a population content of 95%) which varies depending on the number of tests completed. This is the standard procedure

https://doi.org/10.52202/069179-0184

used for statistical analysis of wood connections in the US. Specimen failure loads and calculated nominal capacities for the connection types used in the project (types C4, C5 & C6) are illustrated in figure 6.

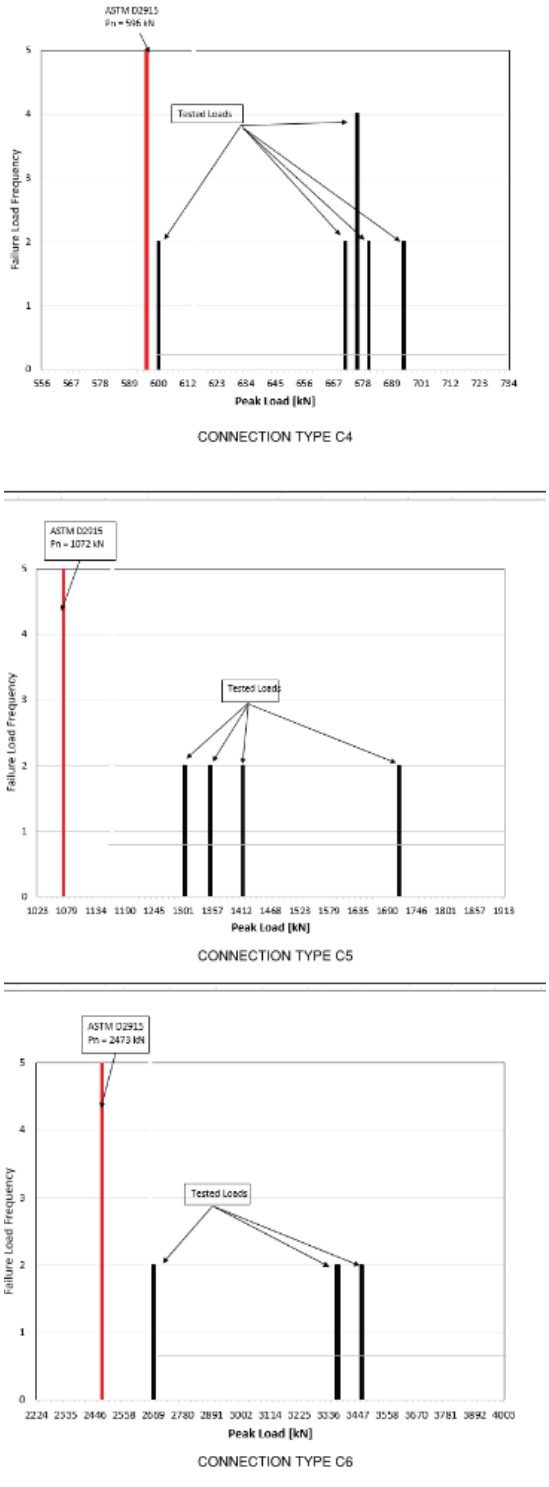

Figure 6: ASTM D2915-17 [3] test data and capacities

The failure loads indicated on figure 6 represent two data points since each tension specimen included two connections, one on each end. It should be noted that two vertical bars representing two specimens with very similar failure loads sometimes appear as a single, wider bar in figure 6. The majority of the tested failure loads are significantly larger than the nominal design capacity per ASTM D2915-17 [3]. However, for connection type C4 and C6, one outlier occurred with a failure load that was closer to the calculated nominal capacity.

The connection testing proved to be valuable in that it proved the connections could safely be used with a justifiable design capacity, with appropriate reinforcing. Additionally, for the actual project design conditions, where possible, the design was optimized such that bending of ductile steel plates in the connection assembly would be the controlling capacity, effectively limiting the load applied to the wood fasteners, to further ensure good behaviour in the event of an unforeseen overload.

3.2 Comparison of Test Data with NDS and Eurocode

For the smallest connection types, the failure mode appeared to be NDS [5] Mode IV fastener yielding, and the test results closely matched the calculated values utilizing the NDS equations (test values were approximately 10-20% higher than calculated values using NDS equations). The capacities utilizing the NDS equations were calibrated to the nominal LRFD capacity using a K_f of 3.32 and a λ of 1.0 (for short term, 10 min loading). None of the smallest connection types exhibited block shear or splitting failures, thus no reinforcing screws were added to the connections.

For the mid-size connection types utilizing the double plates slotted into the glulam with SDDs, the NDS greatly overpredicted the capacity of the connection, whereas Eurocode [6] only slightly overpredicted the capacity. The failure modes in these connection types were predominantly wood block-shear failures. If the Eurocode equation is used and only the shear portion is considered, the calculation closely predicts the tested values (less than 5% difference). However, if the tension portion of the equation is also considered, which in the mid-size connections results in a larger calculated capacity, the calculation moderately overpredicts the tested values (approximately 30%). The NDS equations overpredicted the capacity by approximately 80%. The initial mid-size connections utilizing the double side plates with wood screws similarly initially underperformed relative to calculated capacities, but after adding fully threaded reinforcing screws, the tested capacity more closely matched the calculated capacity.

For the largest connections utilizing the double plates slotted into the glulam with SDDs, the tested capacities were very closely predicted by both the NDS equations and the Eurocode equations. However, due to one outlier (that was significantly stronger than expected), the

https://doi.org/10.52202/069179-0184

capacity using the statistical analysis per ASTM D2915-17 [3] resulted in a capacity 30% lower than the equations predicted due to the increase in standard deviation. For the large connections using the double side plates and wood screws, with reinforcing screws, test capacities exceeded the capacity predicted by both the NDS and the Eurocode calculations. However, one outlier (which was significantly lower than the others), resulted in the capacity using the statistical analysis per ASTM D2915-17 being nearly equal to the code equation predictions.

See figure 7 below for a comparison of the calculated capacities and test values of specimen types.

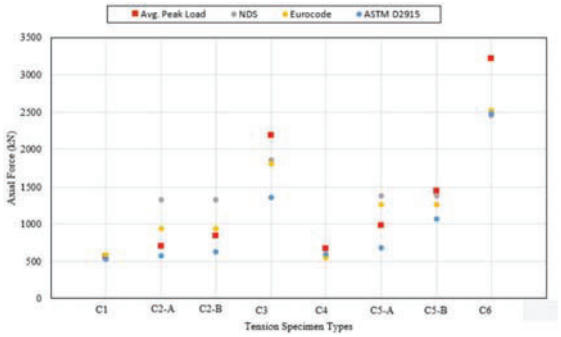

Figure 7: Comparison of calculated versus tested capacities. Connection type C2-A and C2-B indicate connection type C2 with different distances from the last row of fasteners to the end of the glulam. Connection type C5-A and C5-B are both connection type C5 (with C5-A having no reinforcing screws and C5-B with reinforcing screws)

3.3 Discussion

3.3.1. Effect of reinforcing screws

Reinforcing screws passing through the connection area perpendicular to grain significantly improved the performance of the mid-size and larger connections by resisting block shear/splitting across the glulam wood grain. In the cases of the mid-size side plate connection, the capacity of the connections improved by approximately 50% after adding the reinforcing screws.

3.3.2. Effect of moisture testing

See Section 2.2.2 for additional discussion on the specific moisture testing and cycling that was performed. The failure modes and capacities for moisture-cycled specimens were determined to not be statistically different from non-moisture-cycled specimens. As discussed in Section 1.1, the connection geometry was developed per the NDS [5] recommendation of 150 mm maximum dimension of outer rows of fasteners perpendicular to grain to prevent perpendicular to grain splitting due to shrinkage restraint. Tests of the moisture cycled specimens showed no indication of a reduction in capacity with the tested configurations, indicating the NDS recommendations appear to be appropriate for the MC variations considered.

4 CONCLUSIONS

4.1 Summary

Load testing of the initial design of the medium- and large-size connections exhibited brittle block shear/group tear-out failure modes which were not adequately predicted by calculations using the National Design Specification (NDS) for Wood Construction [5]. Calculations using Eurocode 5 [6] provided better predictions. This is a result of the NDS equations considering the sum of the resistance from both the shear and tension portions of a potential failure perimeter whereas the Eurocode equations only taking the larger of the shear or tension portion capacity.

The addition of reinforcing screws perpendicular to grain prevented block shear/group tear-out failure modes and allowed the medium- and large-size connections to realize the ultimate capacity and ductility of the dowel-type fasteners. That ultimate capacity of reinforced connections was reasonably well predicted by NDS equations.

Moisture cycling of connection specimens prior to load testing did not discernibly change the failure modes or capacities compared to connection specimens which were load tested without prior moisture cycling. This may support the conclusion that NDS recommendations for limiting the maximum distance perpendicular to grain between outer rows of fasteners in a given connection are sufficient for the moisture content variations considered in this research. Furthermore, moisture cycle testing on connection specimens provided specific criteria for moisture content management and control of the project connections throughout construction.

Successful physical testing of the glulam moment connections for the TCORE project made possible the long spans/cantilever conditions and resulting large axial tension/compression force couple demands. Although calculation-based approaches were available in the U.S. codes and standards, load testing was pursued by the project team to provide greater assurance and economy of the design. It also resulted in streamlined jurisdictional approval of these connections. As of the end of 2022, all connections had been installed in the over 400 glulam beams present in the roof, and the majority of the roof structure had been erected over the terminal.

4.2 Impact on Future Research and Codes

Based on the results of the connection load testing for this project, it is suggested that a thorough literature review be performed to specifically investigate block shear/group tear-out failure modes, particularly in large connection geometries. If the available literature is lacking or inconclusive, additional load testing may be necessary to determine the capacity of these failure modes. Ultimately, the available literature and any supplemental testing could inform changes to the block shear/group tear-out equations in the NDS [5] and Eurocode [6], especially if,

as identified in this research, the existing equations are not conservative. Finally, in this research, reinforcing screws installed perpendicular to grain were shown to prevent the development of block shear/group tear-out failure modes. However, little to no guidance exists in NDS or Eurocode for the appropriate design (e.g., diameter, length and spacing) of such reinforcing screws.

ACKNOWLEDGEMENT

The authors would like to thank the many individuals at ZGF Architecture (Architect of Record), Swinerton Mass Timber (mass timber subcontractor), and the Port of Portland (owner) who contributed to the glulam connection testing and the TCORE project in general. The authors would also like to thank the laboratory staff at the iSTAR Laboratory at Portland State University and at the environmental chamber at Oregon State University. Finally, the authors would like to acknowledge the significant, sometimes herculean, contributions of our colleagues at KPFF in making this research and project a success.

THE IMPACTS OF SCREW TIP, INCLINATION ANGLES AND NUMBER OF PENETRATION LAYERS ON SCREW WITHDRAWAL CAPACITY IN AUSTRALIAN MACHINE GRADED PINE

Zidi Yan[1], Lisa-Mareike Ottenhaus[2], Jingyuan Lin[2], Robert Jockwer[3], Andreas Ringhofer[4]

ABSTRACT: Connections play an important role in timber structures as they govern the overall stiffness, load-carrying capacity, and most of the ductility in a timber structure. Due to the high axial load-carrying capacity and ease of installation, self-tapping screws are nowadays one of the most widely used fasteners in timber construction. However, variations in national standards, regulations, or even timber species might lead to incorrect predictions for the screw's load-carrying capacity. The current Australian Timber Standard AS 1720.1-2010 has some fundamental limitations since it was primarily derived from old North American research and supplemented in the 1970s with empirical data on Australian hardwoods and a few softwoods. Modern European fasteners are increasingly employed in the Australian building industry, making it critical to examine their performance consistency in the context of Australian timber products. This research work, therefore, aimed to a) evaluate the interactions of numbers of penetration layers, screw tip, and screw characteristic withdrawal strength, b) evaluate the influence of inclination angles on characteristic withdrawal strength, and c) compare experimental results with existing models and provide recommendations.

KEYWORDS: axially loaded self-tapping screws, withdrawal strength, sawn timber

1 INTRODUCTION

McLain stated that 'a structure is a constructed assembly of joints separated by members' [1] and this is especially accurate to describe timber structures. Connections govern the overall structural performance, such as stiffness, strength, and most of the ductility in a timber structure. Due to their high axial performance, flexible geometry, cost efficiency, and quick installation, self-tapping timber screws are nowadays one of the most popular fasteners in global timber construction.

In recent years, European connectors and fasteners are increasingly employed in the Australian market due to the rapid development of the Australian timber building industry and the lack of local suppliers and experiences. In such a case, a performance solution allows the engineer to use the manufacturer's technical approval. However, an inappropriate capacity estimation can cause overstrength and brittle failure of European fasteners in Australian timber species [2,3]. Since the Australian timber standard (AS 1720.1 [4]) was originally derived from North American research and supplemented by Australian empirical data in the 1970s, it is lacking consistent analytical equations to adapt to various modern screws. It is, therefore, of great importance to carefully assess the suitability and performance consistency of European screws in the context of the Australian market.

Withdrawal strength is one of the most critical parameters that govern the performance of axially and laterally loaded screws (i.e., the rope effect that was introduced in Eurocode 5). The geometry of the screw (e.g., diameter, thread, tip), the number of penetrated layers/studs, and screw thread-to-grain angle affect the withdrawal resistance of screws. These potential influences are rarely considered in most of the existing design codes in Australia.

1.1 SCREW PENETRATED LAYERS

Light timber framing is commonly constructed with double studs in Australia, and fasteners penetrate both timber members (i.e., without glue) in most cases. AS 1720.1 [4] does not specify a minimum/maximum penetration length in the second member for withdrawal, yet it stipulates l_{ef} >17d for laterally loaded connections. Hence, the conservativeness of AS 1720.1 needs to be re-evaluated regarding the minimum effective screw penetration length in one or two non-glued timber layers. Moreover, Ringhofer et al. [5–7] studied the influence of the number of penetration layers on screw withdrawal parameter in cross-laminated and glue-laminated timber. They suggested system factors, $k_{sys,}$ for up to 10-layer laminated timber products. As part of this study, the feasibility of applying k_{sys} to non-glued double-layered Australian sawn timber was evaluated.

1.2 SCREW THREAD-TO-GRAIN ANGLE

As inclined screws provide greater strength under lateral loading than orthogonal screws, they are now widely used in timber construction [8]. Pirnbacher et al. [9] adapted Hankinson's relation and developed a modified model to fit the screw thread-to-grain angles (α) between 0° and 72.5°. In contrast, Ringhofer et al. [6] propose a bilinear model to predict the relationship between screw thread-

to-grain angle and withdrawal performance. According to their research, the withdrawal performance of the screw did not change for $\alpha > 30°$ [6,10]. This study compared the inclined screw withdrawal performance in Australian sawn timber with previous studies.

1.3 SCREW EFFECTIVE LENGTH

Eurocode 5 [11] states that the effective penetration length of the screw (l_{ef}) is limited to the threaded part. However, it is unclear whether the tip should be considered since modern screws commonly have fully threaded tips. The Canadian standard CSA O86 [12] requires l_{ef} to be the threaded length minus the tip length (typically equal to one nominal thread diameter, d). In contrast, AS 1720.1 [4] does not consider the potential influence of the tip and states that l_{ef} is equal to the entire length of a fastener's penetration, which includes the unthreaded shank and tip. Nevertheless, European scientists conventionally agreed that the screw tip should be deducted from the profiled length [13], and a length correction factor should be applied. From this, several questions arise: (1) Defining the length of the tip - should it be the exact length of the tip or include a certain length of regular thread? (2) While some European literature and experimental tests concluded that the tip length should be equal to $1.11d$ [13] or $1.17d$ [9], it is still uncertain whether this applies to Australian timber species due to their relatively higher density compared to European species.

Consequently, this work examined the interactions of numbers of penetration layers, screw thread-to-grain angle, screw tip, and screw characteristic withdrawal strength; evaluated the influence of inclination angles on characteristic withdrawal strength; compared and verified existing models and provided recommendations.

2 MATERIAL AND METHODS

2.1 SPECIMEN CONFIGURATION

This study was separated into three phases: (1) examine the effects of the penetrated layers (single or double stud); (2) assess the effects of different screw-to-grain angles, and (3) evaluate the contribution of screw tip during withdrawal.

2.1.1 TIMBER SAMPLES

Machine grade pine (MGP) specimens with orthogonal or inclined screws were tested according to the Australian Standard AS 1649 [14]. Clear 170 mm long specimens were cut from 3 m long 45×90 mm MGP10 boards. Timber densities were measured according to the weight and dimensions of each specimen. Timber densities were assumed as normal distributed, and the characteristic timber densities, ρ_k were calculated based on EN 14358:2016 [15]. Knotty specimens were removed to obtain more consistent results [5–7]. It is worth mentioning that AS1720.1 gives a mean density $\rho_m = 500$ kg/m^3 for MGP10, however, the timber density is not directly related to connection strength prediction which is based on joint groups that depend on species. Thus, a regression prediction model established by Pirnbacher et al [5] was also compared and verified in this study for the mean value of the screw withdrawal strength.

2.1.2 SCREW SAMPLES

A total of 330 8×120 mm Schmid Rapid screws (ETA-12/0373 [10]) were tested in single stud, double stud, and different inclination angles. All screws were manually installed in the timber specimens using a cordless handheld drill. To ensure the accuracy of inclination angles, a screw installation guide was used. The edge and end spacing of each test were checked according to the requirements of the ETA-12/0373 [10], Australian Standard AS 1649 [14] and EN 1382 [16].

In this study, the effects of the screw penetrated layers (Phase 1) were tested by inserting screws in both single and double layers of 45×90 mm MGP10 boards. The effects of the screw tip and penetrated layers (Phase 2) were examined by installing screw with the tip inside and outside timber specimens, respectively (Table 1). Axial withdrawal tests for inclined screws were carried out, and three load-to-grain angles were tested (Phase 3). In specimen designations, the first letter relates to layers (S = single, D = double) and the second letter relates to the tip position (W = within, O = outside). L is the nominal thread length that penetrated the timber specimen, and n is the replication of each test. The number (i.e., 90, 75, 60, 45 and 30°) attached to the letters indicates the inclination angle of the screws. A schematic diagram of all test series is shown in Figure 1.

2.2 WITHDRAWAL TESTS

Withdrawal tests were carried out according to AS 1649 (with the addition of inclined screw tests) using an Instron universal testing machine with a test rig that was specially made for inclined screw withdrawal (Figure 2). The screws were withdrawn at a constant rate of 2.5 mm/min. The moisture content was determined according to AS 1080.1 [17] (oven drying at 103°C) immediately after withdrawal testing as 12.9±1.1%.

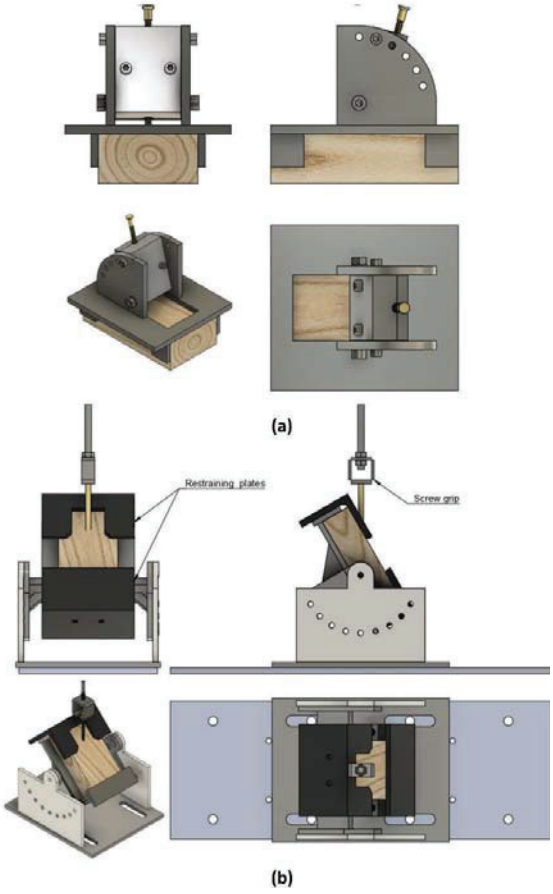

Figure 2*: (a) Screw installation guide and (b) withdrawal test setup.*

2.3 STATISTICAL DATA ANALYSIS

The statistical analysis of the test data was performed using SPSS. The Shapiro-Wilk test, Levene's test, ANOVA, student's T-test, and post-hoc test were used as statistical analysis methods in this study.

3 THEORY

The experimentally determined screw withdrawal parameter $f_{ax,exp}$ was modified from EN1382:2016 [16] as

$$f_{ax,exp} = \frac{F_{ax,exp}}{l_{ef} \cdot d} \quad (1)$$

where $F_{ax,exp}$ is the maximum force recorded from the individual screw withdrawal tests, and l_{ef} is the effective penetration length of the screw, where the penetration length is reduced by the tip length, l_{tp}. In ETA-12/0373 [10] l_{tp} is 11.0 mm for 8×120 mm Schmid Rapid screws. The experimentally determined screw withdrawal parameters were assumed as lognormal distributed, and the characteristic withdrawal parameter, $f_{ax,k,exp}$ was calculated according to EN 14358:2016 [15].

The screw's characteristic withdrawal parameter, $f_{ax,k,ETA}$ given in Schmid's ETA-12/0373 [10] is 13.1 N/mm^2. An equation that considers timber density, species, material, and screw installation angle is proposed by ETA-12/0373 [10] and calculated as

$$f_{ax,k,pre} = \cdot f_{ax,k,ETA} \cdot k_{ax} \cdot k_{sys} \cdot \left(\frac{\rho_k}{\rho_{k,ref}}\right)^{k_\rho} \quad (2)$$

where k_{ax} is the angle factor (k_{ax} = 1 for 30°≤ α ≤ 90°), k_{sys} is the system factor (k_{sys} = 1 for solid timber, however, k_{sys} =1.06 was additionally considered and assumed for DWT and DOT series for this research only), k_ρ is the density factor (k_ρ = 1.1 for softwood and 15°≤ α ≤ 90°), and $\rho_{k,ref}$ is the reference characteristic density ($\rho_{k,ref}$ = 350 kg/m^3). It is important to note that all factors were determined based on the previous study by Ringhofer et al. [5–7].

Apart from the characteristic value, a regression model established by Pirnbacher et al. [9] for predicting mean orthogonal screw withdrawal parameter, $f_{ax,mean,pre}$ is adapted as:

$$f_{ax,mean,pre} = (0.01353 \cdot \rho_m - 0.68679 \cdot d^{0.572} + 2.18888) \cdot \pi \quad (3)$$

Eq (3) was first derived by Pirnbacher et al. [9] after conducting a series of screw withdrawal tests for d = 6 to 12 mm and timber density ρ = 300 to 600 kg/m^3. This Equation was then further verified by Ringhofer et al [5] using screw diameters ranging from 6 to 12 mm and timber density ranging from 375 to 475 kg/m^3. The premise of this equation considered the effective length of screw penetration equals to $l_{ef} = L - 1.17d$.

4 RESULTS AND DISCUSSION

Test results are summarised and compared graphically in notched boxplots and in the following tables. All outliers presented in boxplots were removed from the statistical analysis and were considered as extreme values. Table 2 lists the mean density, ρ_m, coefficient of variation (COV), characteristic density, ρ_k and the number of timber

samples for each test series, n. SWT90 and SOT90 were carried out as the control group since $f_{ax,k,exp}$ were in good agreement with the prediction value $f_{ax,k,ETA}$. All screws failed in screw axial withdrawal and no other failure modes were observed during the tests. It is worth mentioning that after conducting the ANOVA and post-hoc tests, the mean densities of all tested samples presented statistically non-significant differences to each other. Thus, in most instances, the mean withdrawal parameter, $f_{ax,m}$ can be directly compared after applying the student t-test to access the influence parameters.

Table 2: *Sample densities and number of samples*

Test series	Test name	ρ_m [kg/m^3]	COV [%]	ρ_k [kg/m^3]	n [-]

	SOT45	425.7	8.0	361.7	30

4.1 Phase 1 – Screw penetrated layers

The effective penetration length, l_{ef} for Phase 1, was considered as L - l_{tp}. In Figure 3, $f_{ax,mean,pre}$ values were calculated according to ρ_m from Table 2. Considering the sample size, the experimental results agreed well with the predictions by Eq (2) and (3) and were only slightly non-conservative for SOT and DOT series.

After conducting the statistical analysis, the mean withdrawal parameter between SWT90 and DWT90 groups showed a non-significant difference, thus, this finding indicates that the multiple penetration layers did not influence screw withdrawal strength when the full length of the screw tip was deducted. In the DOT series, L in the second timber layer is 4.4d, indicating that a penetration length of 4.4d can still provide conservative withdrawal strength. The notched boxplot in Figure 3 shows that the difference between the SOT90 and DOT90 median values is about 1. The notch areas for SOT90 and DOT90 do not overlap, and a p-value < 0.05 indicates that the median and mean values differ significantly. The screw withdrawal parameter was thereby reduced by multiple studs when the screw tip stuck out of the timber specimen, and no glue was applied to the middle of the double boards. This finding was contrary to previous results by Ringhofer et al. [5]. In Table 3, the experimental results for SWT and DWT series are slightly higher than the prediction value. It is suggested to quantify the contribution of the screw tip in future studies. As of this section, it is concluded that the screw tip has a slightly positive effect on the withdrawal parameter, and therefore the accuracy of the deduction length should be re-verified.

4.2 Phase 2 – Screw inclination angles

SWT and SOT inclined screw withdrawal tests are summarised and compared in Table 4, Figure 4, Table 5, and Figure 5. As previously mentioned in Section 4.1, the effective penetration length for Phase 2 was also calculated as $l_{ef} = L - l_{tp}$.

The results for both SWT and SOT were generally consistent with the previous literature by Ringhofer et al. [6], in which the f_{ax} exhibited a bilinear behaviour (i.e., screw withdrawal strength is constant for $\alpha > 30°$ then a gradual decrease can be observed). Based on statistical analysis, no significant f_{ax} deviations were detected for α = 45, 60 and 75°.

In the SWT series, the screw withdrawal strength gradually increased with decreasing inclination angle (α from 90° to 45°). The boxplots in Figure 4 also suggest that the median values did not show statistical differences for $\alpha > 30°$. However, for $\alpha = 30°$, the ETA prediction equation overpredicted the withdrawal strength, and a dramatic decrease was observed. The strength reduction

https://doi.org/10.52202/069179-0185

for $\alpha = 30°$ might be explained by the orientation of the screw axis approaching the fibre grain direction.
Due to the limitation of the test rig, SOT30 was not conducted. Thus, only 90° to 45° screw withdrawal tests were achieved and evaluated. Future research should confirm whether the strength reduction observed for SWT30 applies to SOT30. In general, Eq. (2) works conservatively in the SOT series and the screw withdrawal strength increased when α decreased to 75°. Since the notched area for SOT90 and SOT75 were not overlapped, the result indicates that the medians differ significantly.

$f_{ax,k,exp}/f_{ax,k,pre}$	[-]	1.00	1.13	1.17	1.08

4.3 Phase 3 – Screw tip lengths

Figure 6 illustrates the ratio between $f_{ax,k,exp}$ and $f_{ax,k,ETA,}$ and confirms the conservativeness of selected calculation methods for l_{ef} (i.e., (a) $l_{ef} = L$, (b) $l_{ef} = L - 1.11d$, (c) $l_{ef} = L - 1.17d$ and (d) $l_{ef} = L - l_{tp}$). Table 6 lists the results from the student t-tests. Since no differences were observed for timber mean densities after statistical analysis, $f_{ax,m}$ was chosen to be compared directly. The SOT series was considered as the control group in this test campaign. From Table 6, student t-test p-values indicate that the tip length, l_{tp} should not be considered in the full threaded length, except when $\alpha = 45°$ and $L = 8d$. This finding was consistent with the results of a previous study by Pirnbacher et al. [5] in which the tip effect decreased with increasing penetration length.
As stated in Eurocode 5 [11] and ETA-12/0373 [10], l_{ef} must include l_{tp}. As shown in Figure 6, however, the results indicate that $f_{ax,k,pre}$ was overestimated for $l_{ef} = L$. This suggests that the screw tip should not be treated as a fully threaded element, and a length correction parameter should be considered.
Following the statistical analysis, p-values in Table 6 indicate the tip length should be fully subtracted from the penetration length, i.e., $l_{ef} = L - l_{tp}$ when $\alpha \geq 75°$ with $l_{tp} = 1.38d$. However, when $45° > \alpha > 75°$, $l_{tp} = 1.11d$ seems more appropriate for Australian timber species.
Generally, $l_{tp} = 1.17d$ [9] versus $l_{tp} = 1.38d$ only resulted in minor differences in withdrawal strength (i.e., the purple-square, green-cross, and blue-circle lines are positioned closely together) with little feasibility at different inclination angles.

5 CONCLUSION

This paper presented an experimental study on the effects of screw tip, inclination angles, and the number of penetration layers on screw withdrawal capacity of Australian machine graded pine. A total number of 330 Schmid screws according to ETA-12/0373 [10] were tested in double or single layers of Australian MGP10 board with inclination angles of 90, 75, 60, 45 and 30 degrees.

Overall, the key findings are:

- When the screw is installed perpendicular to the grain, prediction models based on previous literature and manufacturers' ETA are appropriate for Australian MGP10 and generally give conservative results. However, the tip length should not be fully considered in the screw effective penetration length, l_{ef}, and the ETA model should be re-evaluated when the thread-to-grain angle, α, is equal to 30°.
- Consistent with previous research, the thread-to-grain angle is negatively correlated with axial withdrawal strength in the range between $90° \geq \alpha > 30°$.
- The inclination angle factor k_{ax} in ETA-12/0373 [10] should be re-evaluated for $\alpha = 30°$ in Australian timber species. A deduction factor/equation should be further studied and applied to k_{ax}. To optimise k_{ax}, a regression model is recommended to consider all configurations.
- The tip length, l_{tp} (1.11d) suggested by Pirnbacher et al. [9] is generally conservative and acceptable except when $\alpha > 75°$. In contrast, l_{tp} (1.38d) is generally more versatile as it can be easily adapted for all inclination angles. However, to further evaluate this finding, more experimental tests should be conducted.
- Further research is suggested to develop a more versatile length correction factor. The length correction factor (length of screw tip, l_{tp}) should be optimised and verified using a regression model.
- Using screws in double timber layers (without adhesive) reduced the screw withdrawal parameter, likely due to insufficient local stiffness on layered timber. If no adhesive is applied between layered timber, the k_{sys} factor could likely be conservatively ignored for sawn timber. More experimental tests are suggested to determine the reduction factor.
- Further regression model analysis should be established to obtain an optimized analytical equation for the interactions of the screw tip, numbers of penetration layers, and screw characteristic withdrawal strength in Australian timber species.

In conclusion, the results of this study provide some insights into the withdrawal capacity of modern European screws in Australian machine graded pine. The study highlights the need for further research in this field, particularly in relation to the development of more accurate predictive models for Australian timber products.

ACKNOWLEDGEMENT

This research was jointly funded by the Faculty of Engineering, Architecture, and Information Technology and the School of Civil Engineering of the University of Queensland. Schmid Schrauben Hainfeld GmbH is gratefully acknowledged for providing the screws.

DESIGNING AND TESTING OF A WOOD-ONLY TIMBER FRAME CONNECTION INSPIRED BY THE GROWTH FORMATION OF TREES' STEM-BRANCH JUNCTION

Firas Hawasly[1], Naoyuki Matsumoto[2], Mikio Koshihara[3], and Koji Adachi[4]

ABSTRACT: This paper presents the design approach and testing of a new column-beam connection utilising wood as the sole structural material for application in multi-storey timber frames. This connection was inspired by the all-wood natural formation of trees' stem branch junction model. The growth model features were explored and approached in a simplified application of glued-laminated column-beam members joined through a conical mortise-tenon interface with bent laminated veneer plies flowing seamlessly across the connection. The tested connection was compared to steel-added conventional joint systems resulting in a comparable bending performance with desirable ductile behaviour and presenting the inclusion of seamless bent timber members as a possible reinforcement against bending for timber connections.

1 INTRODUCTION

The current application of steel and concrete in rigid frame structures is an appealing canvas for architectural applications, providing flexibility, uniformity, and safety; it is an evolved form of the long and rich history of timber framing, overcoming the span limitations and the inherent material combustibility.

The reappreciated potentiality of wood as a construction material following the shortages of iron through the world wars, combined with the awareness of the environmental impact of the construction field, facilitated an expedited shift in timber engineering research [1, 2] to maximise the utilisation of timber products in structural applications. However, and to a certain extent, it was applied by simply substituting the less sustainably sourced and widely utilised concrete and steel members with timber, using the same structural vocabulary, theory, and detailing, and expecting structural behaviour similar to that of the designed and manufactured materials.

In contrast, trees grow wood through 'Morphogenesis' [3], a form generation, adaptive growth process where the material properties are manipulated whilst waste and energy are optimised to ensure maximum functionality and efficiency and create a fully localised functional and structural system. Nevertheless, the adaptive growth processes of a tree, being complicated and ingenious natural systems (e.g., deviation of grain patterns, shedding of branches, encasing of knots), are, however, considered defects when the wood is used as a structural material. The techniques used in modern timber engineering depend on segregating these tree-specific, homogeneous structural tissues. Contrary to the early building traditions, wood was fitted to the desired location based on its form in the tree and guaranteed structural performance, e.g., shipbuilding.

The limitations imposed by the structural capabilities of the segregated, reused, linear, natural material and the limitation in the sourcing processes introduced a myriad of engineered timber products with enhanced structural properties; and have constantly been challenged by the feasibility of achieving an efficient joining system. As a result, a broad spectrum of innovative connections for timber was developed utilising processes and materials foreign to the organic wood. They fulfilled the sought structural requirements while gradually shifting the naturally grown material into a normalised product to suit our growing understanding of timber structures away from the systems and analytical tools initially developed for the designed concrete and steel materials.

While sharing a similar morphology to a timber frame connection, the trees' stem-branch junctions are inherently moment resistant; these cantilevered protrusions resist moments generated at their junctions by self-weight and wind loads [4]. This growth formation is nature's manifestation of wood as a constructional material, an intricately generated form that contributes to the tailored structural behaviour in resisting bending, shear, and fatigue induced by static and dynamic loads. Hence, investigating and mimicking its distinct and specific growth processes is sought to introduce a further befitting constructional language of timber at frame connections.

In this paper, biomimetic investigations of load paths and fibre assemblies of stem-branch junctions in trees inspired an approach towards a wood-only utilisation of a structural entity capable of transferring bending loads safely within a timber frame joint.

2 GROWTH FORMATIONS AT TREE BRANCH JUNCTIONS

The secondary growth of trees occurs at the vascular cambium, a thin, active layer of cells that forms a continuous sheath beneath the plant's surface. It increases the thickness of the plant seasonally in concentric layers by division outwards and inwards, creating phloem and xylem tissues, respectively. Xylem tissues, which make the whole woody material from longitudinal tube-like fibrous cells, are responsible for the tree's stability and the transfer of sap in one direction between the roots and leaves; given the energy and waste optimisation, there is no functional requirement, nor structural, for the fibres to flow from the branch up the stem or to other branches.
A single growth layer in a branch can be modelled as a unidirectional, fibrous, double-bent surface; hence, the growth model of a tree is interpreted as a stack of concentric, fibrous, unidirectional, double-bent surfaces. (Figure 1-1). Geometrically, the interface between the surfaces of the stem and the branch is conical and, depending on the branch's growth vigour, is partially or fully encased within the flow of the stem's fibres [5].
At the ridge point, the branch's fibres exhibit a sharp turn with small radii whilst maintaining their conductive functionality and gradually easing towards the junction's lower section in alignment with the stem. Similarly, the upper stem's fibres flow around the branch collar and exhibit similar radii above the branch ridge. Trees utilise the unidirectional flow of the branching fibres to create tissues with interlocking geometric assemblies at the top portion of the branch's collar to prevent failure and damage. These tissues are stiffer and mechanically superior to normal wood, albeit with constricted conductive functionality as a "structural trade-off" to support this critical location.[5, 6]. Furthermore, the naturally optimised form of the stem combined with the residual tensile stresses of its natural growth (preloading) significantly improve the tree's strength [7] and, consequently, the transfer of loads across the junction. [8]
In this paper, the explored growth model features of a branch junction are:

- the uninterrupted, seamless flow of fibres across the junction,
- the complicated compressed fibre formations within the conical interface of the junction, and
- the variable mechanical properties of localised wood cell types across the junction.

2.1 Hypothetical growth model

As the flow of forces in biological materials is governed by the direction of the fibres [9], trees transfer gravity and wind loads along the fibres from the leaves to the roots; additionally, the tree acquires an adequate resistance of uplift loads through the geometric fibres' assembly across the junction.
However, the frame structural connections demand substantial horizontal resistance. Hence, a hypothetical growth model was developed, assuming trees were designed to resist uplift and gravity loads equally by alternating the fibres' flow direction every other growing season, resulting in an equal cross-sectional area of the stem below and above the branching point. (Figure 1-2) (Contrary to Leonardo da Vinci's rule stating that the sum of the cross-sectional area of fibres above the branching point is equal to that below it)However, although this loading pattern contradicts the wood's natural growth and function, it is expected to provide the sought performance in resisting loads in both directions.

2.2 Simplification process

The current limitations in wood sourcing and machining technologies hinder the ability to produce a double-bent unidirectional surface similar to the interpreted model of a growth layer from wooden veneer material, especially with the localisation of different cell types (reaction, opposite and normal wood). Therefore, to utilise simple

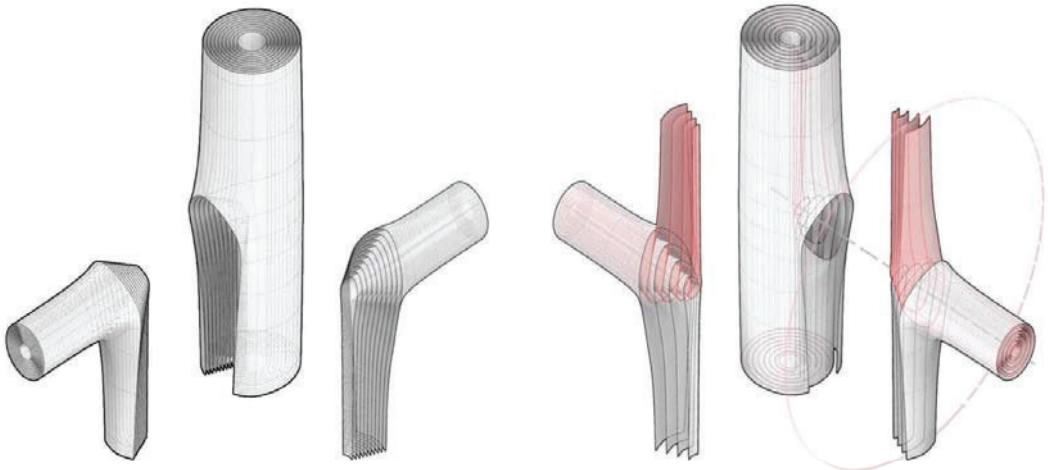

Figure 1: *Interpreted and hypothetical growth models of Stem-branch junction; (left) a detached branch showing the conical interface of the successive growth layers; (right) a detached view of the hypothesized branch through flipping every other growth*

https://doi.org/10.52202/069179-0186

techniques and available wood products, the proposed approach oversimplified the hypothetical growth model into two applicable connection patterns:
- Bent fibre continuity as a stack of one-way bent veneers in a T-formation, where the fibres are seamlessly flowing from the stem to one half of the branch (Figure 1-2), and
- Concentric fibre connectivity as a stack of concentric tubular veneers, where the fibres of corresponding tubes are butt-jointed, resulting in a stepped conical mortise-tenon integration (Figure 1-3).

3 MATERIALS AND METHODS

The approached connection combines both simplified interpretations of the hypothetical model, utilising the conical interface of a glued, stepped mortise-tenon beam integration within the column (Figure 1-6), with a set of symmetrical bent plies flowing seamlessly from the beam across the interface and into both directions of the column (Figure 1-5).
For this application, the dimensions were based on a selected prototype of a generic medium-sized office building with a simple and flexible structural system developed by 'KI' "www.ki-ki.info" (a Japanese timber structural study group and database) to promote and provide technical information for one-way timber frame structures using standardised glued-laminated timber sections for columns and beams at 600x210mm E65-F225 JAS (Japanese Agricultural Standards) in Japanese Cedar (*Cryptomeria japonica)*. In addition, two steel-added

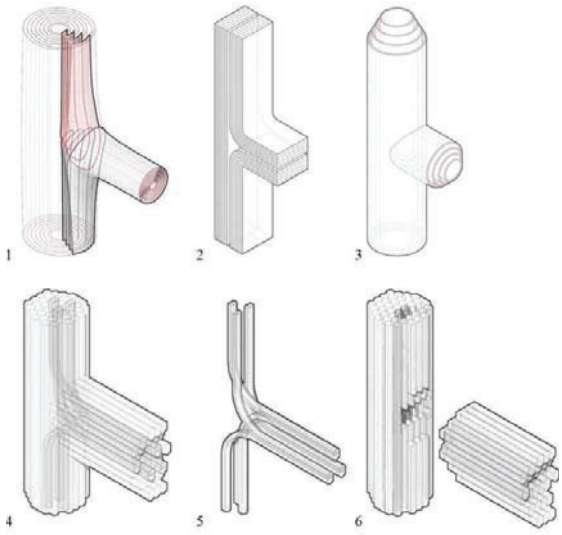

Figure 2: *Simplification and proposed connection typology; 1. hypothetical branch model; 2. bent fibre continuity; 3. concentric fibre connectivity; 4. connection morphology; 5. seamless bent plies; and 6. conical interface*

conventional joint systems were experimentally and numerically tested for this prototype in Japanese Cedar at half width (600x105mm), namely the glued-in rod (GIR) [10] and the lag-screw bolts (LSB) [11].

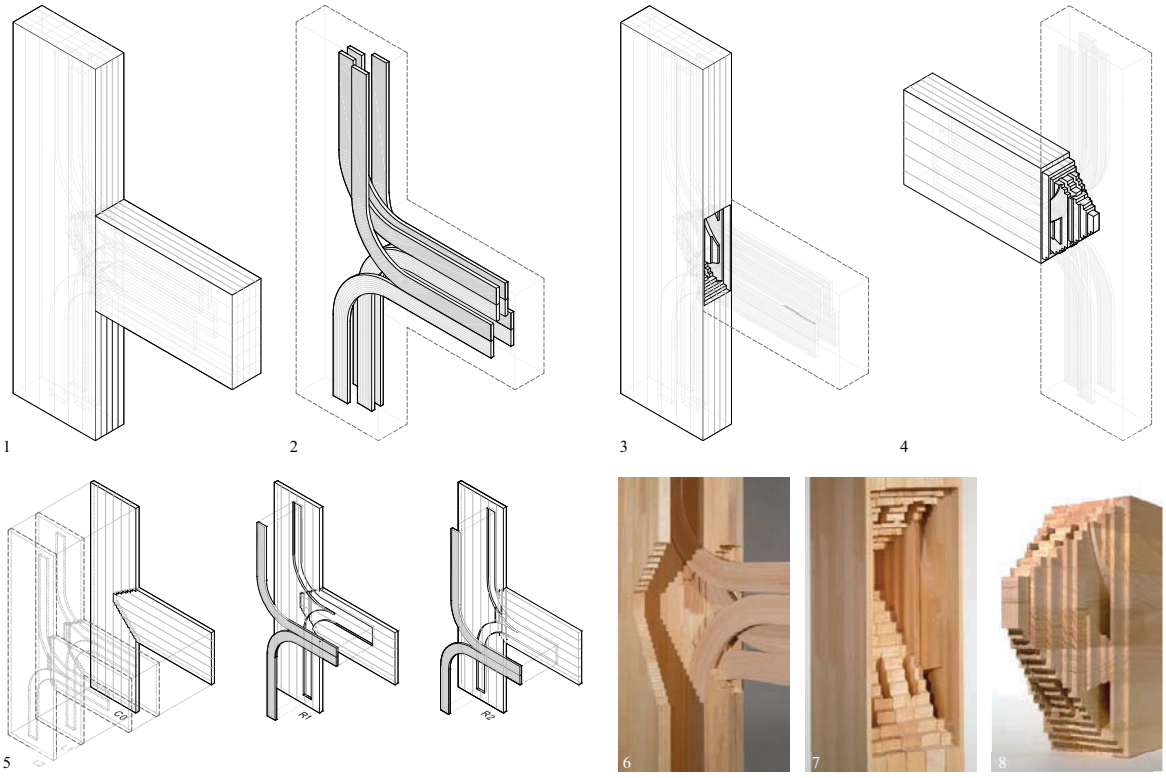

Figure 3: *The proposed connection (1); exploded isometric view of the constituting elements: bent plies (2), column (3), and beam(4); placement of the bent plies within the carved channels in the glue-laminated column-beam lamellae (5), a dry fit of the Pine column with the bent plies in their corresponding channels (6); and the conical interface in the column (7) and the beam (8)*

https://doi.org/10.52202/069179-0186

3.1 DESIGN DEVELOPMENT

Given the symmetrical and volumetric features of the multi-member integration, the size of the tested connection was opted to maintain the original proportions at half scale (300x105mm). Through the lamination process of the five laminated column-beam pairs, eight bent plies were fitted within corresponding channels placed symmetrically along the horizontal and vertical axes of the pair C0 (which contains no channels), flowing seamlessly from the beam and into both directions of the column. (Figure 3). The column-beam members were manufactured in Japanese Cedar (*Cryptomeria japonica)* and Merkusii Pine (*Pinus merkusii*), whereas the included seamless plies were manufactured from bent-laminated veneers in Beech (*Fagus crenata*).

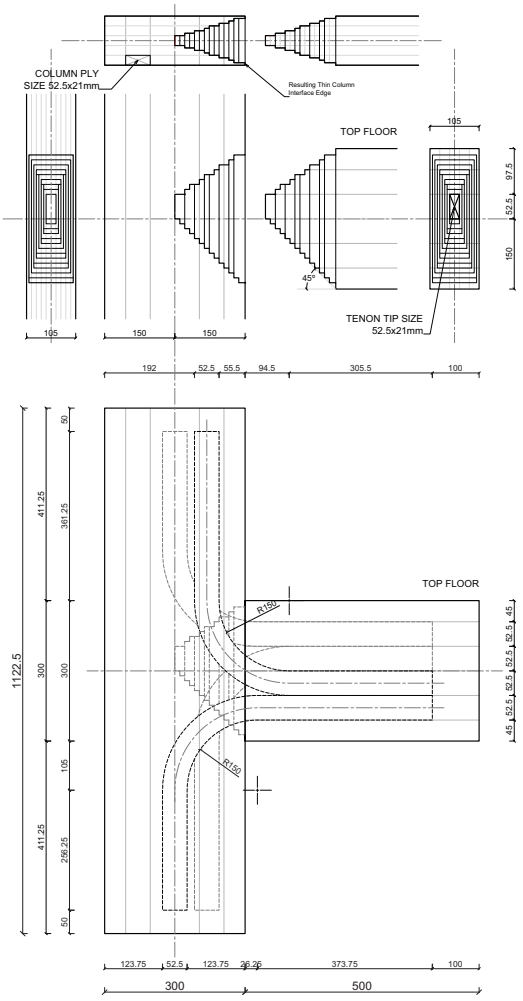

Figure 4: *Sizing of the conical interface without channels (above) and the column-beam assembly with the placement of the included bent plies (bottom) (units in mm)*

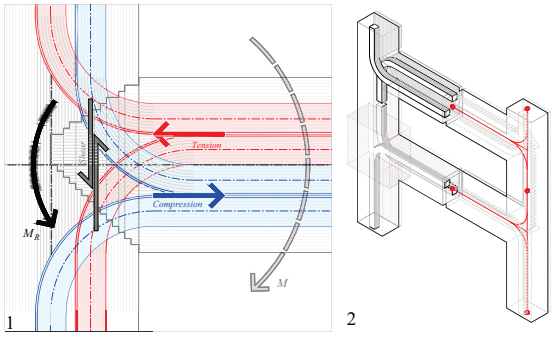

Figure 5: *The schematic structural dynamics of the proposed connection in response to an applied bending moment (1) in the proposed pinned portal frame system typology (2)*

The detailed sizing of the connection was based on a 10.5mm module per half the thickness of a single laminated column-beam pair at 300x21mm; the boards were made from edge-glueing six 52.5x21mm plies and were cut to a finished length of 1122.5mm and 650mm, for the column and beam, respectively.

The conical interface initiated above the column-beam axes' intersection with a single ply (at 52.5x21mm) and stepped towards the entire cross-section of the beam on a 10.5mm cubic grid. (Figure 4 - the asymmetrical interface mimics the shifted axis of the branch integration, a geometric growth feature of the flow of fibres)

Both sides of the column-beam members were processed with a CNC machine to shape the conical interface and carve the 52.5x10.5mm channels for the bent plies. The 90º fit at the edges of the conical interface and channels were processed with relief cuts at the inner corners using a Ø6mm bit. (Refer to Figure 9-left)

The bent plies were made from 90x1x1200mm Beech veneers, and they were bent-laminated with an inner radius of 150mm to a 54mm nominal thickness with aqueous polymer isocyanate adhesive (Koyo-Bond KR-134 at 150gm-2 spread) in block forms and cured under a press at 0.65MPa for 4 hours. Next, eight plies were rip-cut on a bandsaw at 10.5mm width and re-fitted to the desired channel (due to glue-bending spring-back) with ±1.5mm tolerance on a CN machine to a final section of 52.5x10.5mm; and a 3mm radius fillet was added to the edges facing the channels for glue distribution. Finally, the assembly of the connection members in Cedar and Pine was performed using resorcinol formaldehyde resin (Dianol 33N at 150gm-2 spread) and cured under a press at 1.0MPa for 6 hours. Moreover, a column-beam assembly without the channels for the included Beech plies was manufactured in Cedar and Pine to isolate the reinforcement effect of including the bent plies on the bending performance.

3.2 PROPOSED STRUCTURAL DYNAMICS

The modern applications of timber frame joints utilise adding foreign elements (to wood) at joint locations to provide the required resistance against specific loads. (primarily steel, e.g., plates and pins for shear, bolts and tie-rods for tension, and lags and threaded rods for bending) In contrast, the developed system approaches the features of the all-wood natural formation at branch locations through the above-mentioned simplified models in response to the hypothesised loading conditions.

Like the conical branch integration within the stem, the column-beam conical interface distributes shear loads evenly across its faces and reduces concentrated embedment damages. At the same time, the axial transfer

https://doi.org/10.52202/069179-0186

of compressive and tensile loads through the seamless bent plies reinforces the bending and shear performances due to their integration within the conical interface. as illustrated in (Figure 5-1).
Furthermore, the members are manufactured from species with different initial properties that, combined with the resulting multi-directional fibre assemblies, contribute to the approached distribution of mechanical properties; however, unlike trees, it is non-homogenous.
The proposed typology of the structural system utilises a one-way pinned-portal frame, similar to the monopodial nature of trees. [4, 12] (Figure 5-2)

4 TEST SETUPS AND RESULTS

The tests in this study focused on the static bending performance of the used materials and components.

4.1 THREE-POINT BENDING TEST

The bending performance of the Cedar, Pine, and laminated Beech plies was evaluated with a three-point bending test spanning 350mm. Table 1 lists the averaged dimensions, moduli of elasticity and rupture, with the initial stiffness derived from the tests and the initial modulus of elasticity acquired through a stress wave velocity measurement (utilising a *Fakopp* microsecond timer).

4.2 BENDING TEST OF BENT PLIES

The bending performance of six bent-ply specimens was tested in the setup displayed in Figure 6. The plies were laid horizontally and through-pinned on equal distances from the arched portion to the test base at one end and to an actuator at the other; given their slender sections, Teflon sheets separated the plies from the sandwiching steel plates with rollers to suppress the out-of-plane deformations.
Four specimens were loaded cyclically in the push (close) and the pull (open) directions, and two were loaded monotonously in either direction. The setup mimics the loading condition of the plies within the column-beam members in push (close) and pull (open) strokes. The cyclic deformation values were 1, 2, 3.5, 5, 7.5, 10, 15, and 20mm with 5mm increments till failure at a rate of 1mm per minute, corresponding to 750, 375, 200, 150, 100, 75, and 50 rad^{-1} of deformation angle as derived by equation (1):

$$\Theta = 2\,tan^{-1}\left[d \,/\, 2a\sqrt{2} - d\right] \qquad (1)$$

Where Θ is the deformation angle, d *is* the linear displacement between pins, and a is the 45º projection of the distance between the pins (refer to Figure 6).
Table 2 lists the averaged initial stiffness K_0, the maximum load P_{max} in the push (close) and the pull (open) directions, and the resulting bending moment mid-span of the arched section [$M_{max}=P_{max}\,(H + h/2)$], with the corresponding linear displacement d_{max} and the deformation angle Θ_{max}.
As illustrated in the load-displacement curves of four samples loaded till failure in the push (close) and pull (open) cycles (Figure 7), the bent plies exhibited higher ductility in the cyclic push direction and failed with

gradual crack development, while they failed in brittle behaviour when loaded in the pull direction.
The concentrated axial forces in the pull (open) cycles initiated failures near the centroidal axis with fibrous fracture patterns; these cracks gradually grew through the glue lines towards the pins, whereas the concentrated compressive forces excreted by the push (close) cycles were translated to fibre kinks on the concave side and tensile fracture on the concave side with out-of-plane deformations (twisting). However, the bent plies included in the full joint assembly will be glued within carved channels, effectively acting as a clamping feature and minimising the lateral deformation while maximising the tensile and shear strengths of the laminated material.

4.3 BENDING TEST OF THE COLUMN-BEAM ASSEMBLIES

The bending performance of the column-beam members with the included bent plies and without the channels for the bent plies (only the conical interface) was evaluated under a cyclic displacement-based loading protocol with values derived from the total frame drift. Table 3 lists the variations of the ten tested connections regarding the column-face support, the inclusion of bent plies, and material, in addition to an assembly in Cedar with a modified conical interface as a characteristic value. [CBRc with rigid column-face support had the central pair C0 of the column-beam lamella flipped, providing a larger glueing surface area and an extended tenon - Figure 9]
The loading was applied once per cycle till failure through an actuator pinned to a steel plate fixed at the upper side (top floor) of the vertical beam; the column face was laid on the test base with rigid or pin supports at its face and rigid supports at the ends, as shown in Figure 8. The different face support conditions were tested to investigate the performance of the second half of the column, given the placement of the bent plies along its centroidal axis.
Additionally, two horizontal supports with spherical rollers were added near the centre of the beam's surface to suppress out-of-plane deformations.
The cyclic angular deformation values in the push and pull directions were 300, 200, 150, 75, 50, 30, and 20 rad^{-1} at a rate of 1mm per minute. The loading was maintained until the load was reduced to 70% of the maximum load or till failure. The moment-rotation angle envelopes of the cyclic hysteresis loops in the push (compression) and pull (tension) directions for the Pine and Cedar variations are illustrated in Figure 10 and Figure 11, respectively. The data and derived evaluation items from the performed tests are listed in Table 3.

4.4 SIMPLIFIED ANALYTICAL MODEL

The comprising members of the connection, i.e., the eight bent plies and the five pairs of column-beam lamellae, were approximated analytically as a combination of individual models of beam-elements (Figure 13), simulating the support and loading conditions of the rigidly supported connection assemblies of PBR and CBR using Midas-iGen. (a general-purpose structural analysis and optimal design system)

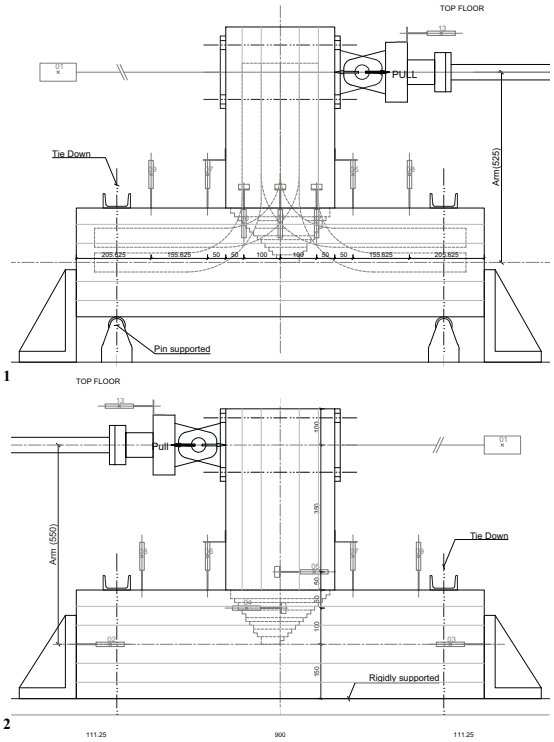

Figure 8: *Column-beam assemblies test setups. 1. Front side of the pin-supported full connection, and 2. Back sided of the rigidly supported column-beam assembly. Both setups share the same placement of transducers (1~13) (units in mm)*

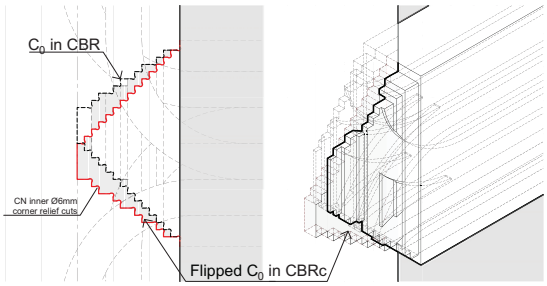

Figure 9 *Details of the flipped C0 in the conical interface of CBRc; hatched areas represent the added gluing surface of the extended tenon (left: illustrates the CN Ø6mm relief cuts)*

The arched portion of the bent ply was modelled in five rigidly connected linear beam-elements (Figure 12-1) with isotropic material properties derived from the three-point bending tests. Each segment had an elastic performance with a plastic hinge (equal to the material's yield strength P_y) near its rigid connections. The simulation followed the bent plies bending tests in support and loading conditions (results are illustrated in Figure 7, noting that the included bent plies were loaded within the plastic region in the column-beam assemblies)
Similarly, the centre-lines of the column-beam members were modelled as two linear beam-elements joined with a rotational spring (Figure 12-2). The spring properties were derived from the sole performance of the conical interface in the column-beam assembly without the bent plies PWR and CWR.

https://doi.org/10.52202/069179-0186

The conical integration of the beam within the column changes in size across its section, where the central lamina (C0) has the maximum integration. Ideally, the rotational spring should be weighted according to its integration when included in the model of each lamina; however, for simplification, the spring capacity was divided equally across the five laminae, given that the whole connection's analytical result is the sum of its members.

On the other hand, the linear segments of the bent plies were rigidly connected to the nearest column-beam element with thin and stiff links at 30mm intervals, whereas the segmented arched portion was connected to the column and beam elements. (Figure 12-3)

Accordingly, and given the connection's symmetry (where L1|R1 and L2|R2 are mirrored copies), the simplified analytical model of the connection in the push direction is the sum of $[C0_{push}+2L1_{push}+2L1_{pull}]$

The analytical models' performance of the column-beam assembly (without the channels for the bent plies) and the whole connection are illustrated in Pine and Cedar in Figure 10 and Figure 11, respectively.

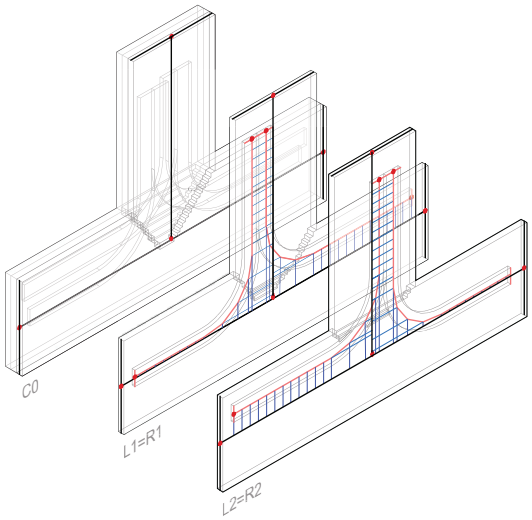

Figure 13: *Beam element models of the whole connection as the sum of the performance of the individual laminae models* $[C0_{push}+ 2L1_{push} + 2L1_{pull}]$

5 DISCUSSION

In all tested variations, early cracks were observed at the finger-joined plies of the glue-laminated boards at the thin edge of the column interface. Additionally, dissecting the connection's conical interface showed that the butt-jointed glue faces perpendicular to the loading plane were weakened by the CN machining corner relief cuts (Figure 14); moreover, the failure of the included bent plies was limited to splitting failure at the centroidal axis.

In the column-beam assemblies (without the bent plies, CWR and PWR), the distributed shear loads across the faces of the conical interface reduced the embedment of the tenon; however, the separation at the relief cuts and the conical geometrical slope caused the beam to pull out due to the cyclic loading, at which the connection was secured by the shear performance of the glue in the stepped surfaces parallel to the loading plane. (Figure 14)

Compared to the sole performance of the conical interface in PWR, including the bent plies in the Pine variations, PBR and PBP achieved a 114% and 68% increase in the maximum moment and a 14% and 42% decrease in the initial stiffness, respectively.

Similarly, the Cedar variations CBR and CBP achieved a 56% and 65% increase in the maximum moment and a 24% and 28% decrease in the initial stiffness compared to CWR, respectively.

However, CBRc with the modified conical interface exhibited the best performance, increasing the maximum moment by 102%, 23%, and 18% and the initial stiffness by 4%, 27%, and 31% compared to CWR, CBR, and CBP, respectively. Since the middle lamella of the conical interface (C0) does not contain any channels and is immediately glued to neighbouring bent plies, flipping its direction in BRc created an extended tenon. It increased the total glueing surface area by 20%, reinforcing the initial stiffness and moment capacity of the whole assembly while reducing the ductility factor; nonetheless, it failed in a similar pattern.

Furthermore, the bent plies acted as shear keys due to their integration within the asymmetrical conical interface, reduced the initial stiffness, prevented the beam from pulling out, and concentrated splintering and interlaminar failures along the vicinity of the conical interface and transverse tensile failure at the central region of the column along their linear axes (Figure 15).

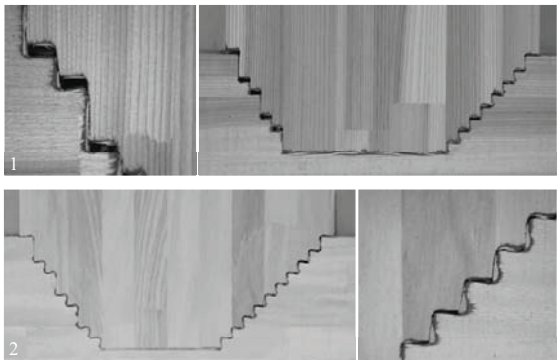

Figure 14: *Pull-out and relief cut separation in a dissected conical-interface in Cedar (1) and Pine (2)*

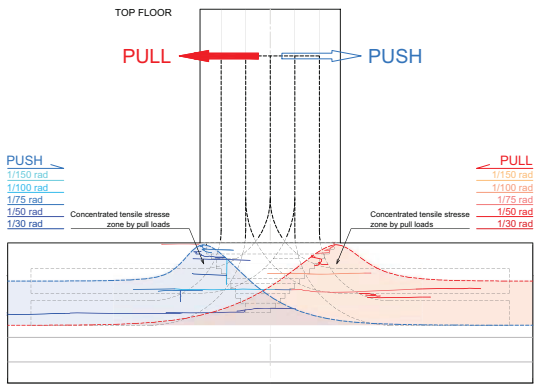

Figure 15: *Zone of the concentrated tensile stresses due to the included bent plies (cracks shown are from a CBR variation)*

https://doi.org/10.52202/069179-0186

However, due to the termination of the beam and bent plies integrations at the column's axis, the lower half was not fully incorporated in resisting the increased tensile stresses of the combined performance of the included bent plies and their captive channels. As a result, the performance of the pinned and rigidly supported connections was comparable in the Cedar variations; however, it was pronounced in the Pine variations (due to its higher MoE); additionally, vertical cracks in the PBP's beam were observed.

5.1 COMPARISON WITH STEEL-ADDED CONNECTIONS

Based on the calculation methods provided for the glued-in rod (GIR) [10, 13] and the lag-screw bolt (LSB) [11] at 105x600mm, the initial stiffness and ultimate loads were derived for a 105x300mm GLT section. Table 4 lists the ultimate moment and the initial stiffness of the compared connections. Figure 16 illustrates the equivalent energy elastic-plastic (EEEP) bilinear models averaged in the push and pull directions, the moment-rotation angle envelopes of tested variations, and the projected performance of GIR and LSB.

Accordingly, CBRc achieved a similar moment capacity to GIR with a reduced initial stiffness and an increased ductility (given the brittle failure pattern of GIR); on the other hand, it exceeded LSB's initial stiffness with a reduced moment capacity. Additionally, it has a joint efficiency of 30%, a practical value for a moment resisting joints in timber structures [14], calculated by Equation(2):

$$\alpha = M_{max}/F_b \times Z \quad (\times 100\%) \qquad (2)$$

Where α, joint efficiency; Mmax, maximum moment; Fb, bending strength of the glue-laminated member (= 27.5 N.mm^{-2} based on the "Japanese Agricultural Standard for Glued laminated timber 2007"); and Z, section modulus of the glulam member at 105x300mm.

5.2 PARAMETRIC INVESTIGATION

Further investigation in the material combinations was analysed in Cedar in CWR and CBR variations with enhanced material properties as parameters, as follows:

- Column-beam materials: modulus of elasticity *MoE.*
- Conical interface: rotational spring capacity in stiffness *K*, maximum load P_{max}, and yielding load P_y.
- Bent plies: modulus of elasticity *MoE* and yielding load P_y at the hinges.

Table 5 lists the analysed parametric variations, and Table 6 lists the correlations of the maximum moment and stiffness in the parametric and tested variations.

The enhanced material and rotational spring in the column-beam assembly without the bent plies in C2B0R achieved a similar maximum moment and a 57% increase in stiffness in CBRc, whereas C2B1R doubled the initial stiffness and maximum moment in CBR. On the other hand, the enhanced bent plies in C1B2R approached the effect of the elongated conical interface in CBRc, which complies with the tested impact of the bent plies on the shear performance of the conical interface.

Table 5: *Analysed parametric variations*

		Beech (Bent Plies) B0	B1 *1 x MoE, Py*	B2 *2 x MoE, Py*

https://doi.org/10.52202/069179-0186

6 CONCLUSION

Given that the proposed structural system was based on and limited by the dimensions of the case study and the currently available simple manufacturing technologies, the performance achieved by the bio-inspired, only-wood connection competed with the conventional steel-added joints and presented the utilisation of bent timber members within the frame joints as a possible application for reinforcement against bending moments, inviting further explorations and inspirations from tree structures. The parametric analysis (approximated from the material perspective) provided insights into the different material effects; however, further investigations into the adhesive properties and the geometric design in terms of configuration, size and dimensions are equally important. Furthermore, the proposed system had a long and complicated manufacturing process in controlled factory conditions compared to the simple in-situ application of the steel-added joint systems. Hence, further developments and simplifications for integrating and manufacturing these approaches are required, especially considering the design and assembly of multi-directional seamless members within two-way frame systems.

Although this research presented a valid proposal for the application of wood connections in timber frames in light of its performance in static bending and judging by the failure patterns, it can be argued whether the only-wood applications are supposed to seek a rigid performance comparable or similar to the steel-added ones. Regarding the projected shortcomings and limitations of the wood material in the current structural and constructional applications compared to its superiority and suitability in its natural formation, addressing the concept of damping in timber frames instead of rigidity is expected to provide further insights into timber structures towards a befitting constructional language in structural applications.

EXPERIMENTAL STUDY OF A TYPICAL EXTERNAL WALL-FLOOR-WALL CONNECTION IN A CLT PLATFORM TYPE CONSTRUCTION

Luka Vojnovic[1], Eleni Toumpanaki[2], James Norman[3]

ABSTRACT: This paper presents experimental studies of a typical external wall-to-floor-to-wall connection in a cross laminated timber (CLT) platform type construction in context of disproportionate collapse resistance. The studied connection mimics the finite element models developed by other authors in the international timber robustness research community. The assembled specimens were tested with aim of staying in the linear elastic range and understand how the rate of loading affects CLT and its connections. This study presents data of the observed behaviour of CLT, steel brackets and screws subjected to different rates of loading. Obtained results and observations will inform future testing programmes and experimental analyses whereby aim is to test the specimens beyond the linear elastic range and to failure.

KEYWORDS: CLT buildings, disproportionate collapse, experimental analyses, rate of loading, wall-to-floor-to-wall

1 INTRODUCTION

Cross laminated timber (CLT) is a relatively new construction material and both CLT balloon type and platform type [1, 2] construction methods have been increasingly popular in the building industry in the past three decades to build multi-storey buildings.

Some of the reasons are the advantages of using CLT over traditional materials such as concrete, steel and even timber used in timber frame construction method. For example, CLT panels of various sizes are manufactured and cut with high accuracy off-site in a factory. Assembly of CLT structure on site is usually shorter compared with building with concrete and/or steel, depending on the project size and complexity, requiring less person hours and produces less waste [3]. CLT structures could be lighter than steel and are lighter than equivalent concrete structures thus require less concrete for foundation. CLT has high strength to weight ratio compared to steel, concrete and masonry. In addition, CLT offers good quality and healthy living spaces and has a pleasant feel, should it be exposed inside of a building.

Many schools, hospitals and other commercial buildings have been built with CLT. Furthermore, the shortage in residential sector still exist and a portion of residential buildings could be built with the CLT. The United Nations (UN) projections are that quite a significant number of residential units will be required in the near future, a 2.3 billion new urban dwellers by 2050 – and entail the production of an enormous volume of housing and infrastructure [4].

Along with many other already available and newly emerging engineering solutions, using CLT to build some of the buildings could contribute to a more sustainable construction industry and to reaching the net zero commitment.

As any other building and structure, multi-storey buildings designed as a CLT platform type construction ought to be sufficiently robust to overcome any loads which may result in disproportionate collapse.

Experimental study presented in this paper considered the external wall-to-floor-to-wall (WFW) CLT connection which can be found in a multi-storey platform type building. Widely used construction practices for connecting CLT WFW were researched and a typical connection detail with a single bracket and floor-to-wall screw system was used to assemble the testing specimens.

The effect of different rates of loading (ROL) on the WFW connection and stiffness in the linear elastic range were studied which should inform future testing whereby specimens will be tested beyond linear elastic range including until failure.

Design for disproportionate collapse resistance requires consideration of stiffness and rotational capacity of structure's details, such as vertical and horizontal element connections and fixings. Sufficient tie forces should be present to develop catenary action in beams and membrane action in floors when an alternative load path is being developed at the time of sudden loss of a key structural element. Should stiffness be too high the catenary and/or membrane action cannot develop.

2 LITERATURE REVIEW

Current UK based legislation, codes and guidelines account for disproportionate collapse resistance in a prescriptive manner by relying on expertise acquired through previous research and construction practices mainly based on concrete and steel structures.

The UK Building Regulations have changed since Ronan Point disproportionate and progressive collapse incident occurred in 1968, whereby now the Approved Document, Part A defines disproportionate collapse as: "The building shall be constructed so that in the event of an accident the building will not suffer collapse to an extent disproportionate to the cause." [5]. It is worth noting that disproportionate collapse can lead to progressive collapse and progressive collapse can be disproportionate.

Design codes reference the term robustness which shall account for design to resist disproportionate collapse [6]. For the case of mid-rise timber structures, design to avoid disproportionate collapse is often left solely to engineering judgement [7] although guidance such as Practical guide to structural robustness and disproportionate collapse in buildings is available [8]. One strategy is that each element of a structure shall develop a resistance mechanism – an alternative load path to ensure sufficient robustness against accidental loading cases applied to a structure in the design process.

A thorough review of international research on structural robustness and disproportionate collapse up to 2011 has been undertaken by Arup and published by the UK's Department for communities and local government [9]. It can be highlighted that limitations such as lack of guidance on CLT and behaviour of walls with openings are identified. These can be attributed to lack of disproportionate collapse resistance and robustness of CLT specific research at the time. Nevertheless, Recommendation 19 proposes to undertake a review of the robustness of timber construction and connection including research is urgently undertaken to investigate methods by which effective horizontal tying can be achieved in timber.

Byfield et al. [10] review of progressive collapse research and regulations highlighted guidelines, procedures and methods which are mostly grounded in concrete and steel. Nevertheless, Byfield et al.'s [10] comment that despite tying force method is easiest to implement, it does not require additional structural analysis. Furthermore, constraint of the alternative load path method is being underlined whereby requirement that only one key element at a time is to be removed to check the ability of the structure to redistribute loads without leading to a disproportionate collapse.

Experimental testing to mimic key element removal is related to rate of loading and load removal. Gerhards' [11] study reports observations from a large number and broad range of timber products subjected to different load durations and rates of loading. Gerhards concluded that both do affect timber products. ROL affects ultimate stresses namely tension and compression perpendicular to the grain. Furthermore, further research is suggested too.

More recent reviews of timber robustness were undertaken by Huber et al. [12], Voulpiotis et al. [13] and Cost Action FP1004 [14]. Currently active are CA20139 [15] and CEN/TC250 N3288 [16]. Latest research for example by Bita et al. [7,17], Huber et al. [18, 19], Przystup et al. [20] offers insights to their vast experimental studies for mostly floor-to-floor CLT connections to better understand development of catenary action and horizontal tie forces. These studies are also complemented with numerical finite element modelling.

Akter et al. [2] and Huber et al. [18, 19] study WFW CLT connection in a platform type construction. They undertook multiparametric finite elements analyses of numerical models exploring joint stiffness and Akter et al. [2] studied the impact of wall height, floor length and wall and floor thickness on joint stiffness. Their model predicted a stronger influence of the wall thickness over the floor thickness on the floor connection's rotational stiffness [2]. It is worth noting that floor to wall connection is usually modelled with conservative assumption that the rotational stiffness is negligible due to hinged connection in structural model and calculation [2].

Bruehl et al. [21] studied moment-rotation behaviour in a semi-rigid GL24h timber doweled joint and its ductility to determine the joint stiffness. Evidently the main principle is that should joint be too stiff without any rotational capacity then the timber element would fail in a brittle manner next to the joint without any benefit.

Furthermore, insurance specialists in the UK are currently preparing a framework document which should result in reviewing models to progress and account for new materials and construction methods, such as CLT. Therefore, understanding the risks and mitigation measures when using CLT is important and would support assessing the relevant insurance metrics so that the premiums would be commensurate with risks and therefore making CLT structures more feasible to insure for all involved stakeholders [22].

Authors are not aware of a CLT specific report that would highlight failure of CLT identifying disproportionate collapse and investigation of root causes. Nevertheless, failure of balcony due to moisture was highlighted in oral presentation by the author Nocetti [23] at Rothoschool event in London in 2019.

More timber expertise generally and CLT specifically is required, through research and experimental analyses. These should include studying different typologies and connections between structural timber elements. Inherent material properties of timber prevent formation of plastic hinges hence indicate brittle failure. Research of dynamic response to adverse loading, rate of load within instantaneous load duration capturing joint's stiffness and its ability to plastically deform is required. This research responds to calls by the international robustness community for more experimental studies [2, 10, 11, 13].

3 THE EXPERIMENTAL PROGRAMME

Rate of loading (ROL) within instantaneous load duration on CLT is relatively unknown variable and this is an exploratory study to understand better the impact of changing ROL to inform future testing of the WFW connection. Furthermore, consideration to observe any available rotational stiffness and how it is affected by the ROL in the considered WFW CLT connection.

A series of non-destructive experiments have been performed with intention to stay inside the linear elastic range. Specimen arrangement was focused on the WFW connection level and considered the effect of ROL on the WFW setup at the WFW connection level arrangement. A typical multi-storey platform type CLT building, which would be a class 2B was considered in this study [5, 8]. Three approaches are suggested as levels of robustness commensurate with routine risks, i.e. provision of vertical and horizontal ties, alternative load path(s) to be available upon removal of elements, which is adopted for disproportionate collapse resistance, and specific load resistance method (the provision of key elements) [8].

This paper highlights experimental programme of a WFW connection adopting testing methodologies previously prepared and used as comparison whilst developing finite element modelling. The latter were developed by Akter et al. [2], Huber et al. [10] and Bita et al. [11, 13].

Furthermore, this experimental programme is part of a wider research programme which will study disproportionate collapse resistance of CLT buildings at connection and system level.

3.1 TESTING SET UP ARRANGEMENT

The testing arrangement in this research programme as shown in Figure 1 comprises vertical metal block (1) holding the hydraulic actuators (2 and 3), the horizontal metal blocks (1T and 1B) and metal brackets (4T and 4B).

The hydraulic actuator (2) was connected to a manually operated hydraulic single-acting cylinder-pump and a stop valve (not shown in the drawing).

The hydraulic actuator (3) used in testing had a 25 kN load capacity and piston rod with 260 mm (+/-130 mm) stroke length capabilities.

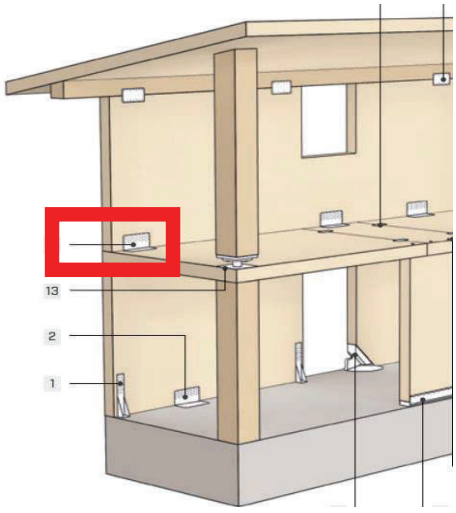

Figure 2: *The WFW connection addressed in the testing [24]*

The testing set up was arranged to mimic a cut at connection as shown in Figure 2, comprising ground floor wall, first floor panel and the first floor wall. Similar experimental arrangement was used elsewhere [2, 18].

The hydraulic actuator (3) was articulated at its rear. At its front a ball-and-cup arrangement was created. The ball part is attached at the end of the load cell which is screwed at the tip of the actuator's piston rod. The ball part is aligned and positioned at the centre of the cup part, which is attached to the floor element of the CLT specimen allowing the hydraulic actuator's piston rod to progress horizontally and upwards when the CLT floor element starts to rotate when subjected to the applied load.

Instrumentation used in this experimental programme were Linear Variable Displacement Transducers (LVDTs) and load cells (LCs) to detect displacements and loads as displayed in Figure 1.

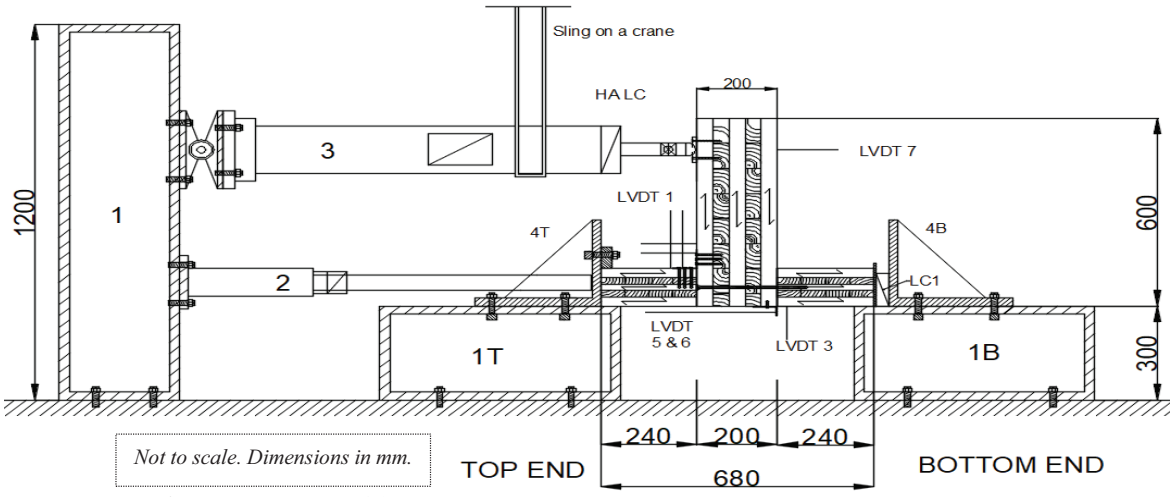

Figure 1: *Near side (NS) cross-section of the testing set up*

https://doi.org/10.52202/069179-0187

3.2 MATERIALS AND TESTING SPECIMENS

Materials used in testing were a combination of widely available commercial products and also generic products to consider their behaviour beyond a single manufacturer.

Self-tapping screws were obtained by Reisser and Spax, mechanical fixings (brackets) and fasteners (screws) were supplied by Rothoblaas and CLT was supplied by StoraEnso, both industry partners to this research.

Generic product, angle brackets made of mild steel were produced at University of Bristol. Rothoblaas brackets are made of zinc plated carbon steel. Rothoblaas screws are made of galvanized carbon steel and fully threaded [24]. Reisser screws are made of carbon steel rod according to EN10268 [25] and are fully threaded. Spax screws are made of carbon steel and are partially threaded [26, 27]. Dimensions are tabulated in Table 1.

Table 1: *List of material variables used in the testing, where A indicates type of timber, B type of bracket, WS wall screw and FWS floor-to-wall screw*

Item	Description
A1	CLT 5ply floor, 200 mm thick
A2	CLT 5ply wall, 120 mm thick
B1	Generic, 200x60x60x2 mm thick
B2	Rothoblaas, Nino15080, 2.5mm thick
WS1	Reisser, R2 Pan, 5.0x60 mm
WS2	Rothoblaas, LBS560, 5.0x60 mm
FWS1	Spax, wirox, 6.0x280 mm
FWS2	Rothoblaas, HBS6280, 6.0x280 mm

The specimens were assembled in combination of either:

UoB = 1x A1 + 2x A2 + 1x B1 + 60x WS1 + 1x FWS1
or
RO = 1x A1 + 2x A2 + 1x B2 + 36x WS2 + 1x FWS2

Where UoB means specimen with generic bracket (B1) and RO means specimen with Rothoblaas bracket (B2).

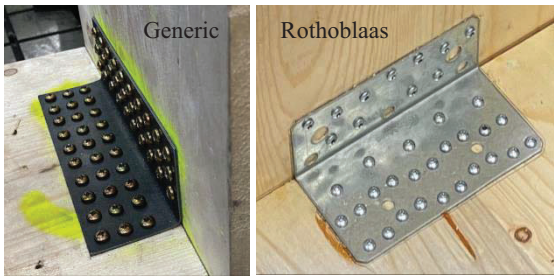

Figure 3: *Generic and Rothoblaas bracket used in testing (figures are not to scale)*

CLT was supplied and delivered cut-to-measure, then assembled in the laboratory to widely accepted and currently used CLT construction practice as per manufacturer's recommendations and as referenced in Swedish Wood CLT Handbook [24-28]. CLT elements and assembled specimens were kept dry at all times.

The humidity and temperature of the air in the large storage space was monitored over several weeks. Average temperature being 21.0°C and relative humidity 37.41%. The moisture content of the CLT was measured with a handheld moisture meter.

Testing specimen arrangement at connection level as shown in Figure 3 shows a typical connection in a multi-storey platform type CLT building. It comprises two wall elements and one floor element, each made of a C24, 5-ply CLT panel, connected with mechanical fixings tabulated in Table 1.

The floor and the bottom wall are fixed with a floor-to-wall screw while the top wall and the floor are connected with an angle bracket which is fixed with a number of self-tapping screws to both the top wall and the floor element.

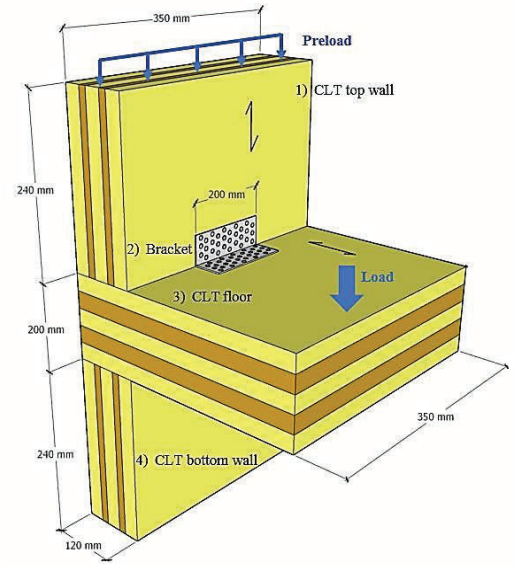

Figure 4: *Schematic of WFW testing specimen (not to scale)*

3.3 TESTING REGIME

Testing programme commenced with numerous preliminary trials to verify appropriateness and workability of the testing set up arrangement and instrumentation set up.

As supply of the CLT was limited, it was appropriate for the preliminary trials to be conducted using timber frame like specimens composed of C24 timber studs and oriented strand board (OSB) panels, fixed with self-tapping screws.

Following the preliminary trials the main experiments were performed with CLT specimens as displayed in Figure 5.

They were placed on the horizontal metal blocks in-between the metal brackets and preloaded with gravity loads of 18 kN induced by the hydraulic actuator (2).

https://doi.org/10.52202/069179-0187

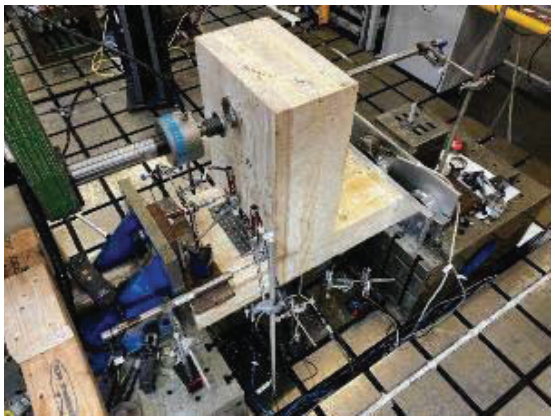

Figure 5: *Example of CLT specimen and the testing set up*

Gravity loads were combined as an accidental loading combination, based on an 8-storey CLT residential building with 6 m spans and 1.5 kN/m^2 live loading as per [29].

Then the metal brackets were bolted and fixed to hold the specimen in position which was restrained and rigidly fixed to mimic real conditions of fixing.

The hydraulic actuator loading operation comprised hold stage, load stage and load release stage.

The load from the hydraulic actuator was applied to the floor element at a predefined rate as tabulated in Table 2, to understand the impact of the ROL application.

ROL was one variable considered in this set of experiments. The load was removed immediately after reaching the predefined displacement.

Table 2: *Loading cases used in the testing, where C indicates the rate of loading (ROL)*

Item	Loading case	Abbreviation
C1	ROL = 6 mm/min	ROL6
C2	ROL = 600 mm/min	ROL600
C3	ROL = 3,600 mm/min	ROL3.6k
C4	ROL = 6,000 mm/min	ROL6k

C1 represents quasi-static load while C2, C3 and C4 represent an accidental loading to account for a scenario of disproportionate collapse modelled by a removal of a key element. In this testing this would be an internal wall in the ground floor.

Displacement controlled loading was used in all loading cases. Data collection frequency when using load scenario C1 and C2 was 1 kHz while using load scenario C3 and C4 it was set to 5 kHz.

4 RESULTS AND OBSERVATIONS

4.1 RESULTS

The results and observations of experiments are presented with series of graphs and tables below. Results obtained at C4 are not representative since they appear to be beyond the linear elastic state yet are still presented. The studied WFW connection is identified as a semi-rigid connection.

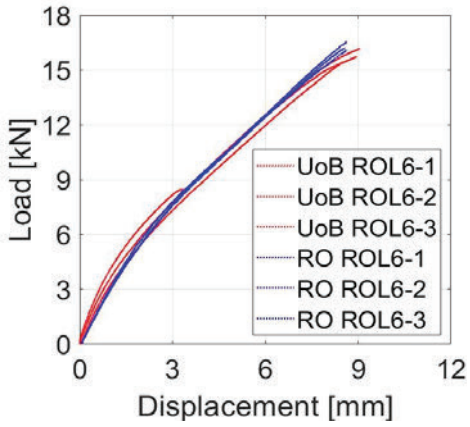

Figure 6: *Load – displacement for ROL 6 mm/min*

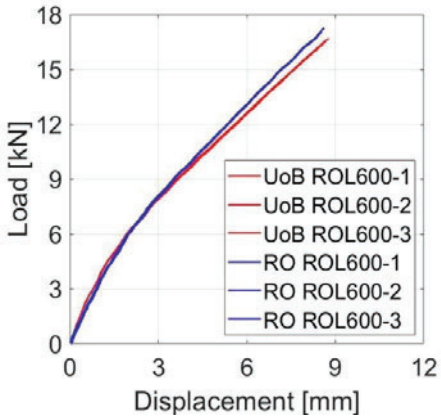

Figure 7: *Load – displacement for ROL 600 mm/min*

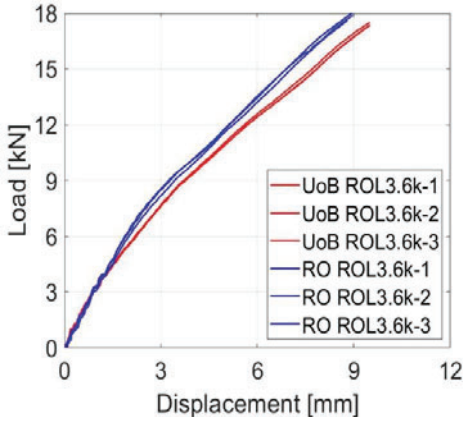

Figure 8: *Load – displacement for ROL 3,600 mm/min*

https://doi.org/10.52202/069179-0187

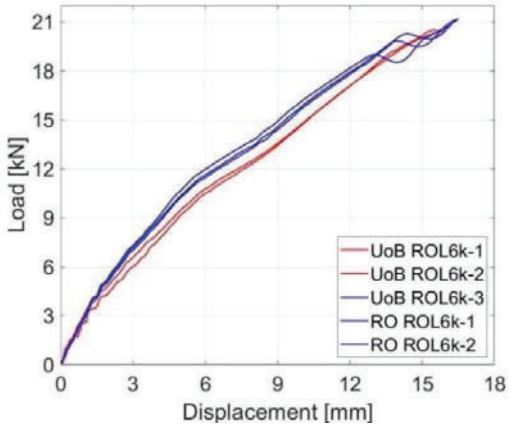

Figure 9: *Load – displacement for ROL 6,000 mm/min*

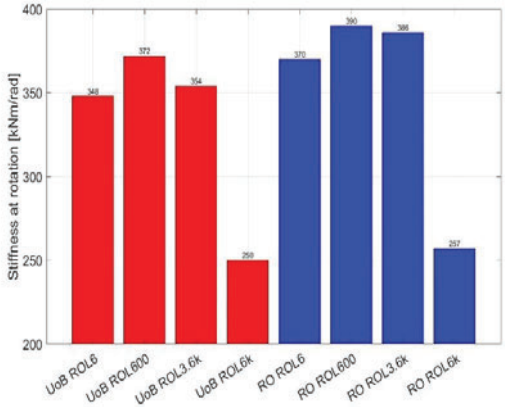

Figure 10: *Stiffnesses at rotation for rates of loads C1-C4*

Stiffness at rotation is calculated using engineering mechanics equations.

$$M = F \times L \quad (1)$$

$$\varphi = tan^{-1}(\frac{u}{L}) \quad (2)$$

$$K = (\frac{M}{\varphi}) \quad (3)$$

Where,

M = moment [kNm], F = force [kN], L = length from point of loading to wall is constant 440 mm (0.44 m),
u = displacement of app. 9 mm (0.09 m) for C1-C3 and app.16 mm (0.016 m) for ROL C4,
φ = rotation and is constant 0.02 rad and 0.036 rad,
K = rotational stiffness [kNm/rad].

Table 3 below tabulates the stiffness values for at the achieved rotations. Moreover, there is certain stiffness available in contrast to analytical approach of having hinged floor-to-wall joint where rotation is not considered.

Table 3: *Stiffness values for tests with generic bracket B1 UoB*

ROL	F	M	K
UoB ROL6	15.809	6.956	348
UoB ROL600	16.519	7.268	372
UoB ROL3.6k	17.431	7.670	354
UoB ROL6k	20.487	9.014	242

Table 4: *Stiffness values for tests with Rothoblaas bracket B2 RO*

ROL	F	M	K
RO ROL6	16.313	7.178	370
RO ROL600	17.177	7.558	390
RO ROL3.6k	17.924	7.886	386
RO ROL6k	21.054	9.264	246

Experimental values do not directly correlate to the models presented by Akter et al. [2] due to differences, such as wall and floor dimensions, fastener type, load on walls and the displacement induced, which resulted in a greater rotation of 0.05 rad.

4.2 OBSERVATIONS

General visual observation is that specimens do globally stay intact after being subjected to C1-C3. C4 however caused specimens to locally reach beyond elastic range. The plastic deformation is attributed to the increased displacement to achieve C4, which was governed by the software and hardware of the hydraulic actuator (3). In order to achieve C4 the displacement had to be greater than displacement at ROL C1-C3.

4.2.1 CLT

Most evident and immediately visible deformation was deflection of the floor, however no damage was identified visually as expected since the testing was planned to remain in the linear elastic range. Displacements of top and bottom walls, the lift and the drop under different ROLs are tabulated in Table 5 and Table 6 below.

Table 5: *Mean values of top wall vertical displacement (lift) LVDT1, where B1 indicates generic bracket (UoB) and B2 Rothoblaas (RO) bracket*

ROL	Mean (UoB)	Mean (RO)
C1	0.400	0.381
C2	0.484	0.423
C3	0.572	0.485
C4	0.722	0.690

Table 6: *Mean values of bottom wall displacement (drop) LVDT3*

ROL	Mean (UoB)	Mean (RO)
C1	3.870	3.926
C2	3.711	3.977
C3	4.107	4.169
C4	7.646	7.951

The bottom wall drops under the subjected loads. This results in opening between the floor element and the bottom wall as displayed in Figure 11. Consequently at C4 the strength perpendicular to the grain in the outer lamellas of the floor element was overreached and local crushing of the CLT occurred, because displacement was greater than in C1-C3. Figure 12 and Figure 13 display local crushing to the CLT.

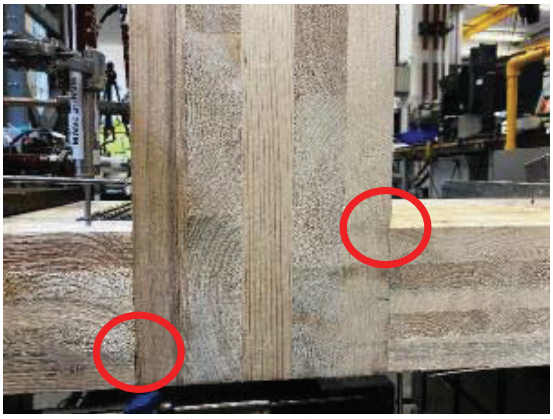

Figure 12: *Localised crushing to floor at both walls (specimen with generic bracket B1 UoB at C4)*

Figure 13: *Localised crushing to floor at the bottom wall (specimen with Rothoblaas bracket B2 RO at C4)*

4.2.2 Screws and brackets

No measurement on screws was undertaken but upon removal of the screws after the test no permanent deformation was observed.

No permanent deformation was anticipated and observed in metal brackets for ROL C1-C4, however generic bracket B1 plastically deformed under C4 as displayed in Figure 14.

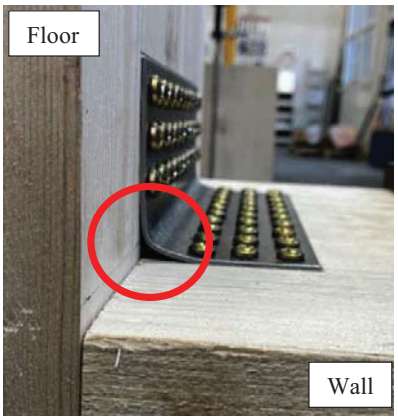

Figure 14: *Plastically deformed generic bracket (B1 UoB) when subjected to C4 and associated displacement*

5 CONCLUSIONS

Experimental studies of a typical wall-to-floor-to-wall (WFW) connection that can be found in a multi-storey building built in the platform type CLT construction were performed. Aim was to keep the specimens in the linear elastic range and to study how various rates of loading (ROLs) affect the CLT WFW connection.

Four different ROLs were used on two varied specimens. Most of the inherent material properties of timber, except the behaviour in compression, require designing in elastic range. When ROL C4 and associated displacement were applied to the specimens plastic deformation was confirmed as visible local crushing of outer lamellas of the floor element when in contact to the wall upon loading due to overreaching compressive strength perpendicular to the grain. Increase in stiffness at the achieved rotations might not be attributed to the ROL but to statistical error.

The outcomes of the performed tests will help with future testing scenarios where specimens will be tested beyond the elastic range and to failure and inform the development of future large scale system level study of the disproportionate collapse resistance of CLT platform type buildings. These are currently based on concrete and steel structures whereas slightly different behaviour is anticipated by CLT.

AN EXPERIMENTAL STUDY ON SHEAR PERFORMANCE OF CLT DOWEL JOINTS WITH SHEAR PLATES

Tsuyoshi Akutagawa[1], Hiroya Hanaoka[2], Masamichi Sasatani[3],

ABSTRACT: Cross Laminated Timber (CLT) is often used in mid and high rise timber buildings, and there has been much research into its joints. In this paper, a dowel-type joint with a steel plate and shear plate between two CLTs are proposed, and experiments are carried out to gain knowledge of the shear capacity and stiffness of the joint. The variables in the experiment were the composition of a CLT, shear plate way of insertion, and end distances. The experimental results and Johansen's theory were used to study the stress transfer mechanism and to obtain equations for estimating the stiffness and shear capacity of the joints. The experimental results confirm the superiority of shear plates in terms of shear capacity and other factors.

KEYWORDS: Cross Laminated Timber, Shear plate, drift pins, Shear performance of dowel joint

1 INTRODUCTION

Due to global environmental issues, there is an active movement to develop timber architectures, and Cross Laminated Timber (CLT) is often used, especially in mid and high rise timber architectures. In this case, the performance of the building hinges on the performance of its joints, given the high rigidity of CLT panels. Various techniques are employed to enhance joint strength, including augmenting the diameter or quantity of connectors. In this study, our emphasis was on the use of shear plates as a means of enhancing the performance of single joints.

Shear plates are one type of joint employed in timber architectures, but not enough knowledge is available on combining them with CLT. A design of shear plate connections in CLT is beyond scope of NDS and AIJ [1-2].

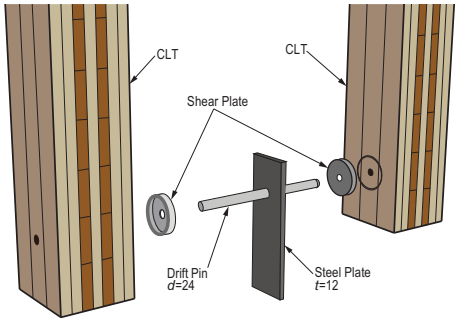

Figure1: *Image of the joint.*

In this study, we conducted experiments on joints that combined drift pins and shear plates, as shown in Fig. 1, and confirmed their shear capacity and stiffness properties. In addition, experimental results and Johansen's theory were used to estimate the load-bearing capacity using a simple equation.

2 TENSILE TESTING OF JOINTS

2.1 EXPERIMENT OVERVIEW

A list of specimens is in Table 1 and experimental variables are shown in Fig. 2.

Experimental variables were a composition of CLT (JAS standard grades: S90-5-7, S90-5-5, S60-3-4, and S60-3-3), way of insertion of shear plates, and end distance. The diameter of drift pins (d = 24 mm) and outer diameter of shear plates (D = 110 mm) used to join specimens were standardized for all variables. By CLT composition, four lengths were used, 417 mm, 297 mm, 237 mm, and 177 mm. Steel plates used for the joints were 12 mm thick, and holes for drift pins (φ=25 mm) were provided with a clearance of 1 mm. Between two CLTs, a plywood plate of a thickness equal to a steel plate was inserted.

A specimen is shown in Fig. 3.

Loading conditions were static monotonic loading and an application rate of 0.05 mm/sec. Displacement transducers were used to measure relative vertical displacement between each CLTs and steel plate at four locations, and mean values were used to evaluate results. An experiment was terminated when a load was reduced to 80% of a maximum load (Pmax) or when a displacement exceeded 25 mm.

2.2 CATEGORIES OF FAILURE

The typical failure modes of CLTs identified at the end of experiments are shown in Fig. 5, the typical drift pin deformation states are shown in Fig. 6, and the categories of failure modes for all variables are shown in Table 2.

In both variables, out-of-plane deformation occurred in the two CLTs due to bending deformation of the drift pins because the CLTs were not constrained to open in the out-of-plane direction.

Four failure modes were observed at the end of experiments when specimens were disassembled as follows.

Mode [a]: embedded drift pin deformation only.

Mode [b]: Shear failure at the end of CLTs.

Mode [c]: Tensile failure of the orthotropic layers and shear failure to laminate surfaces.

Mode[d]: Tensile fracture near a finger joint of laminae on steel plate side.

A Comparison of the failure status of each variable confirms that the insertion of shear plates suppresses the deformation of a drift pin and that the thinner the CLT, the more likely it is to fail in the orthogonal layers.

Mode [a] failure was observed only in the Type-(iii) specimens. Failure of mode [b] was observed in Type-(i) and (ii) but not in Type-(iii). Modes [c] and [d] were observed at J3 and J4, possibly due to the thin CLT thickness, which resulted in large out-of-plane deformations. In particular, mode [d] could be attributed to the stress concentration at the bottom of the shear plate when the CLT was deformed out-of-plane and to the smaller edge distance due to the insertion of a shear plate.

2.3 EVALUATION OF JOINT TESTS

A typical load(P)-displacement(δ) curve is shown in Fig. 7, a yield load evaluation method is shown in Fig. 8, bearing capacity and stiffness for each variable are shown in Table 3, and a comparison of experimental results is shown in Fig. 9.

All variables showed initial slip (δ=1mm) for a clearance with a steel plate. After that, stiffness began to decrease when displacement was about 3 mm. Type-(iii) specimens showed increased displacement at a nearly constant load without significantly decreasing load. Type-(i) and Type-(ii) specimens continued to increase in load at about 50-60% of their initial stiffness after the stiffness drop was observed, and the load dropped abruptly at maximum load.

Table 3: *Results of tensile test of joints*

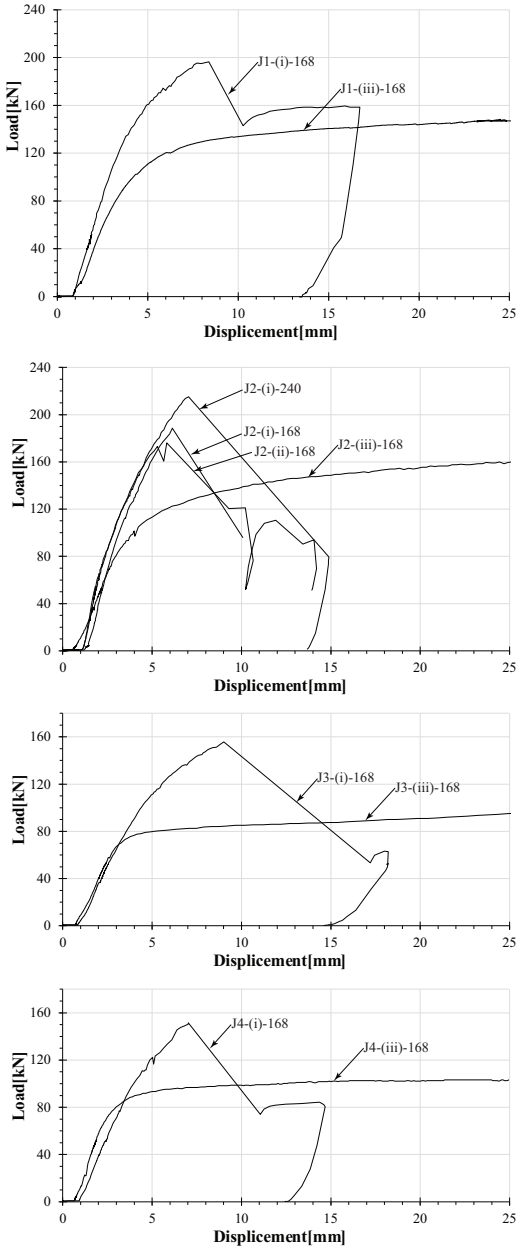

Figure7: *Relations between load and displacement*

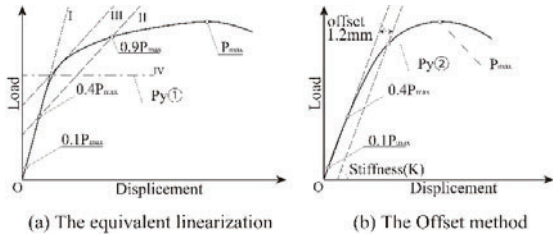

Figure8: *Yield load evaluation method*

Obtained stiffness and strength values are compared. For the maximum load, specimens of Type-(i) and (ii) were increased by 20-50% when compared to Type-(i). There

https://doi.org/10.52202/069179-0188

was no apparent difference in bearing capacity between Type-(i) and (ii), suggesting that the contribution of lumber inside a shear plate to the maximum load is small. No apparent increase or decrease in the stiffness was observed with a way insertion of a shear plate. It was considered that the clearance of holes for shear plate joints meant that a shear plate did not contribute to the stiffness. Yield loads differed significantly depending on the evaluation method. When the offset method(Py②) was used for evaluation, a 25-40% increase was observed for Type-(i) versus Type-(iii), and a 20% increase was observed for e=240mm versus e=168mm for the edge clearance distance e=240mm. On the other hand, when the equivalent linearization method[1] (Py①) was used for evaluation, the increase in bearing capacity was not as significant as the offset method. Depending on the variables, Type-(iii) showed higher results than Type-(i).

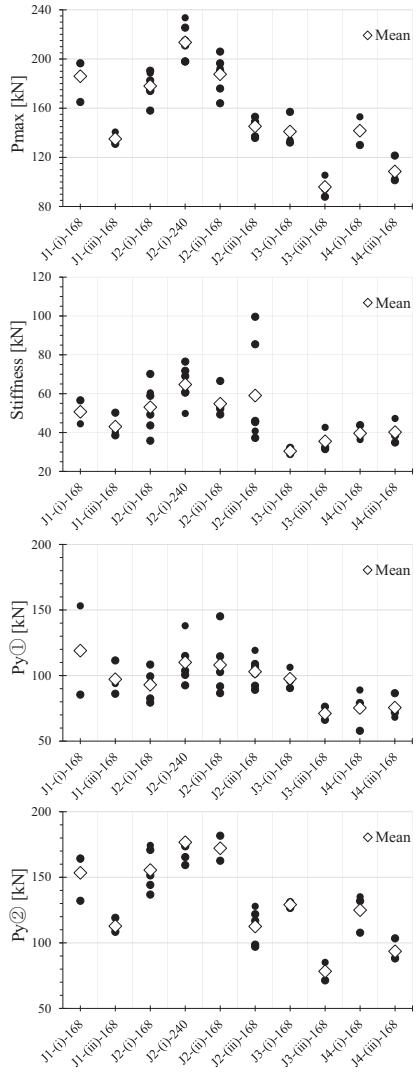

Figure9: *comparison of various property values.*

3 ESTIMATION OF LOAD CARRYING CAPACITY

3.1 EMBEDDING STRENGTH

Before estimating a joint's bearing capacity, an experiment was conducted to confirm CLTs' embedding strength (Fe). Experimental variables are shown in Table 4 and experimental results and specimen densities are shown in Table 5.

This study employed mean values of embedding strength to estimate yield capacities.

CLTs used in experiments were cut from the same panels as those used in Chapter 2, and four variables (S90-5-7, S90-5-5, S60-3-4, and S60-3-3) were conducted. The Dowel diameter (d) used for force application was 24 mm, and embedding strength was checked using the offset method (offset value was 1.2 mm) [3].

In this study, mean values of embedding strength were employed to estimate yield capacities.

Table 4: *Experimental variables (embedding test)*

Specimen	Grade	Composition	Thicness t [mm]	Specimen size
A-1	S90	5-7 (Cypress)	210	A-2		5-5 (Cypress)	150	
A-3	S60	3-4 (Cedar)	120	
A-4		3-3 (Cedar)	90	

Table 5: *Results of embedding test*

Specimen	Number Carried out	Density Mean [g/cm^3]	Embedding Stress [N/mm^2]
A-1	6	0.476	34.68
A-2	6	0.485	30.04
A-3	6	0.438	22.17
A-4	6	0.36	18.27

3.2 CALCULATION MODEL

Although previous studies have proposed evaluation formulas that consider the ratio of bearing strength for each lamina [4-6], in this study, the yield load was evaluated using equation (1) to simplify the formulas.

$$P_y = C \cdot d \cdot l \cdot F_e \quad (1)$$

Where *Py*: yield strength (kN), *C*: coefficient of joints type, *d*: pin diameter (mm), *l*: effective length of drift pin (mm), and *Fe*: embedding strength of lumber (N/mm2).

C in equation (1) assumes the case of a joint with a steel plate inserted. The equations for calculating *C* in 3 failure modes shown in Fig. 10 are below. The following minimum values are used in equation (1).

https://doi.org/10.52202/069179-0188

$$Mode1: C = 1.0 \tag{2}$$

$$Mode2: C = \sqrt{2 + \frac{8}{3}\gamma\left(\frac{d}{l}\right)^2} - 1 \tag{3}$$

$$Mode3: C = \frac{d}{l}\sqrt{\frac{8}{3}\gamma} \tag{4}$$

Where γ: ratio of material strength (F) of the drift pin to the reference bearing strength of the main material (F/Fe).

For joints with shear plates, *C* is similarly calculated for three failure modes. An assumed stress state is shown in Figure 10. In this case, the stress transmitted through a shear plate ($Fe \cdot D$) is not considered because this stress has a smaller shear span ratio than other stresses. The following equations express formulas for the forces and moments applied to the drift pins in each mode.

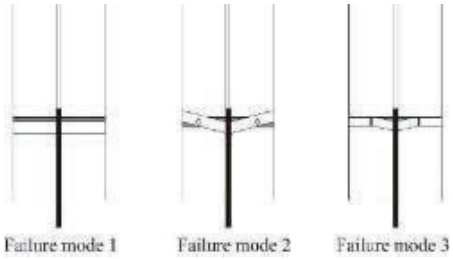

Figure10: *Failure modes.*

$Mode1$

$$\frac{P_y}{2} - F_e \cdot D \cdot h - F_e \cdot d \cdot \frac{l}{2} = 0 \tag{5}$$

$Mode2$:

$$\begin{cases} \dfrac{P_y}{2} - F_e \cdot D \cdot h - F_e \cdot d \cdot (x-h) + F_e \cdot d \cdot \left(\dfrac{l}{2} - x\right) = 0 \\ M_y - F_e \cdot d \cdot \dfrac{(x^2 - h^2)}{2} + F_e \cdot d \cdot \dfrac{\left(\left(\frac{l}{2}\right)^2 - x^2\right)}{2} = 0 \end{cases} \tag{6}$$

$Mode3$:

$$\begin{cases} \dfrac{P_y}{2} - F_e \cdot D \cdot h - F_e \cdot d \cdot (x-h) + F_e \cdot d \cdot \left(\dfrac{l}{2} - x\right) = 0 \\ M_y - F_e \cdot d \cdot \dfrac{(x^2 - h^2)}{2} + F_e \cdot d \cdot \dfrac{\left(\left(\frac{l}{2}\right)^2 - x^2\right)}{2} = 0 \end{cases} \tag{7}$$

Solving each simultaneous equation yields *C* for a joint with a shear plate, expressed by the following equation.

$Mode1$:

$$C = 1 - \alpha + \alpha\beta \tag{8}$$

$Mode2$:

$$C = \sqrt{2(\alpha^2 + 1) + \frac{8}{3}\gamma\left(\frac{d}{l}\right)^2} - 1 - \alpha + \alpha\beta \tag{9}$$

$Mode3$:

$$C = \sqrt{\alpha^2 + \frac{8}{3}\gamma\left(\frac{d}{l}\right)^2} - \alpha + \alpha\beta \tag{10}$$

Where *D* = outer diameter of shear plates (mm), h = depth of shear plate (mm), *My* = plastic moment of drift pin ($F \cdot d^3/6$ (N/mm)), α = ($2h/l$), β = (D/d), *x* = variable representing drift pin rotation center or plastic hinge position (mm).

For the embedded strength (Fe) in Equations (1), (2) through (4) and (8) through (10), the diameter of drift pins and shear plates were not distinguished, and the results in Section 3.1 were used to examine the applicability of a yield load. The calculation model for Type-(ii) was performed without distinction within this study since no difference in bearing capacity due to different ways of insertion was experimentally observed.

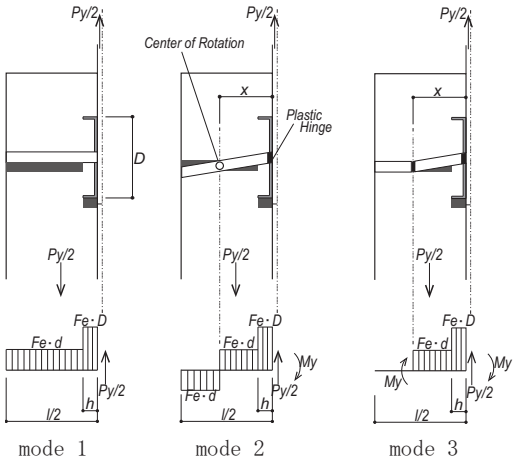

Figure11: *stress condition of joints with shear plates.*

3.3 ESTIMATED FAILURE MODE AND LOAD CAPACITY

Results of the calculation of *C* and estimated failure modes for each variable are shown in Table 6, and a comparison of calculation values and two experimentally obtained yield loads (Py① and Py②) is shown in Table 7. Colorized areas in Table 6 are the minimum values of *C*.

https://doi.org/10.52202/069179-0188

The deformation state of drift pins was generally similar to failure modes assumed from the calculated *C*. On the other hand, specimens Type-(i) and (ii) showed a sudden drop in load due to shear failure at the edge of CLT. A detailed study including shear failure is considered necessary in the following study.

Comparing two experimentally obtained yield loads with calculated values, evaluations using an equivalent linear replacement method tended to be slightly lower than calculated. Conversely, using the offset method, evaluation tends to be larger than calculated values. In addition to the fact that the embedding strength of each lamina was not considered to simplify this calculation, it is necessary to further examine experimental evaluation methods to improve calculation accuracy.

4 CONCLUSIONS

The following conclusions can be drawn from this study.

(1) Four types of wood fracture properties and three types of drift pin deformation states were identified. Shear failure at the CLT edge is more pronounced when shear plates are used.
(2) The deformation state of the drift pins indicates that yielding is dominated by the drift pins and the penetration stress.
(3) The use of shear plates is expected to increase the maximum load by 20-50%. On the other hand, the contribution to stiffness was not so great.
(4) The calculation of the joint type of coefficient C used in the proposed equation showed that the failure conditions of the drift pins in the experiment and the assumed yielding mode were in general agreement.

In the future, more detailed studies will be required, such as evaluation methods of the experiments and consideration of the embedded strength of each lamina that constitutes the CLT.

EXPERIMENTAL AND NUMERICAL INVESTIGATION OF CROSS-LAMINATED TIMBER JOINTS WITH MULTIPLE GLUED-IN RODS

Younes Shirmohammadli[1], Ashkan Hashemi[2], Reza Masoudnia[3], Pierre Quenneville[4]

ABSTRACT: Glued-in rod connections are highly efficient joints in timber structures, with many advantages, including high strength and stiffness, good fire performance, and architectural design advantages. They have been used for many years, mainly for glulam members and, to a limited degree for laminated veneer lumber (LVL) members in new timber structures or reinforcing existing timber buildings. This research covers glued-in rods in Cross-Laminated Timber (CLT) panels to address the growing interest in constructing mid-to high-rise buildings, where hybrid structural systems are frequently used. Therefore, a combined experimental and numerical investigation has been designed to apply such connections in CLT, and full-scale monotonic and cyclic tests have been performed. For the experimental tests, the specimens vary in embedment length and the location of the rods. Moreover, numerical simulations and parametric studies of glued-in rod connections in CLT have been performed to further extend the scope of the study and make conclusions. The simulations are based on a 3D finite element analysis, using a cohesive surface model for the interaction between the epoxy adhesives and the inner surface of the holes. The parametric studies investigated the influence of the anchorage length, the rod diameter, and the rod-to-grain angle on the load-bearing capacity and stiffness of the glued-in rod connections in CLT. The results of this study demonstrates a high potential of these connections in CLT construction with savings on space and cost when compared to conventional timber connections.

1 INTRODUCTION

In timber structures, connections can take up to 70% of the design effort, and the capacity of the structures is generally governed by the strength and stiffness of the connections and joints [1]. Glued-in rods are high-capacity hybrid connections that are largely used for new timber structures and reinforcement of existing timber buildings. They present high strength and stiffness, good resistance against corrosion and fire, present ductile performance, and provide aesthetic benefits [2]. The efficient design and construction of such high-strength connections often determine the level of success of timber structures compared to concrete and steel.

Glued-in rods have been used in New Zealand and other countries for over thirty years for glulam and LVL members, and well-designed timber structures with appropriate materials have shown good structural performance [3]. With the advent of CLT construction, glued-in rod connections demonstrated the potential to be widely implemented. Because the arrangement of layers and manufacturing process of CLT is different from other engineered wood products, the stress distribution and strength of connections in these products can also be different, which requires more detailed studies [4]. Moreover, depending on the CLT member size and structural design, the rods need to be located on the parallel, perpendicular, or on the boundary of two cross-wised layers.

Most of the studies regarding glued-in rods are focused on the single rod investigation, while in real applications, glued-in rods are used in groups. Plastic deformation of connections is frequently used in timber constructions to achieve ductility. Therefore, the behaviour of those crucial connections in terms of ductility and energy dissipation under cyclic loads must be thoroughly understood.

This research looks into monotonic loading and numerical modeling of glued-in rods embedded in various configurations on the edge of CLT panels. Moreover, the cyclic loading performance of glued-in rods is also investigated. The results of the cyclic loading will illustrate the effect of loading on the stiffness and strength of glued-in rod connections to be designed for high seismic regions.

2 Materials and Methods

CLT panels made of New Zealand-grown Radiata pine bonded with one-component polyurethane adhesive were used as the timber part of the connection. The CLT panels consisted of MSG8-grade laminations for longitudinal

layers and MSG6-grade laminations for transverse layers. In the experimental tests, for CLT specimens with rods embedded perpendicular to the lamination and rods on the boundary of two cross-wised layers, 5-layer CLT panels were used, while for the rods embedded parallel to the grain, 7-layer CLT panels were used, so the outer layers of the CLT specimens were lengthwise for all of the specimens. The panels were cut into specimens with 240 mm width to provide a 3.5*d* edge distance and a 3*d* rod distance. Four M24 threaded rods (8.8 grade) were placed in holes with 30 mm diameter in the parallel, perpendicular, and on the boundary of two cross-wised layers of the CLT panels at two different embedment lengths (250 and 350mm). The dimensions of the CLT specimens holding the glued-in rods are shown in Figure 1.

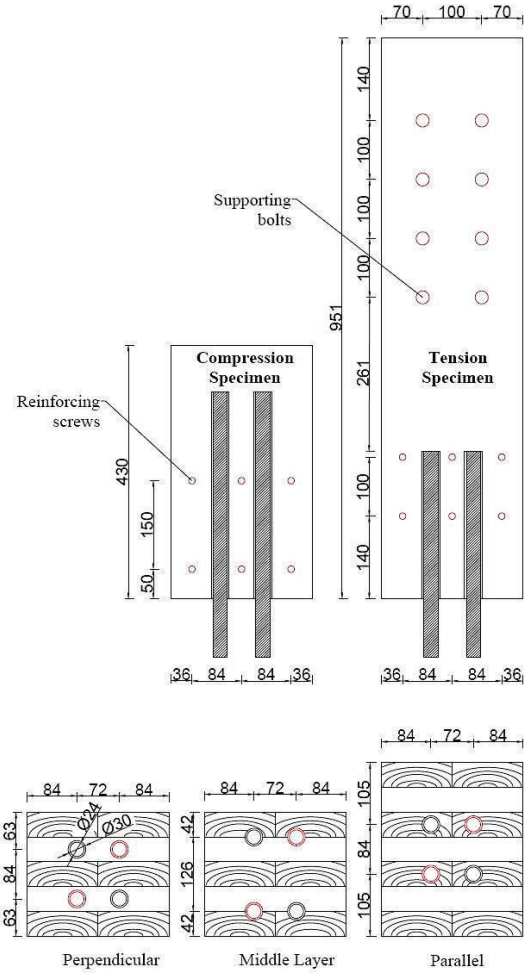

Figure 1. Dimensions of CLT specimens containing rods on the cross section. Rods drawn in red on the cross sections represent two diagonally tested rods.

The epoxy adhesive was injected into the bleeding holes located along each rod's length on the surface of CLT. The adhesive injected from one end of the rod's length travelled the length of the rod and exited from the other end after filling the gap by preventing the air bubble trap.

The properties of the applied epoxy adhesive are provided in Table 1.

Table 1. Typical properties of the cured epoxy adhesive.

	Typical cured properties			
Adhesive	Tensile strength (MPa)	Compressive strength (MPa)	Flexural strength (MPa)	Maximum operating temp (°C)
Epoxy	200-300	300-400	350-450	65-75

2.1 Experimental Tests

For the monotonic and cyclic tests, two diagonal rods were tested. The specimens containing rods with 250 mm embedment length were tested in tension, while specimens with 350 mm embedment length were tested in compression for both monotonic and cyclic tests. The 1000 kN Avery machine at the University of Auckland test hall was used for the monotonic loading, and a 500 kN MTS was used for the cyclic loading of the glued-in rod connections. The test setup of the cyclic tests is shown in Figure 2.

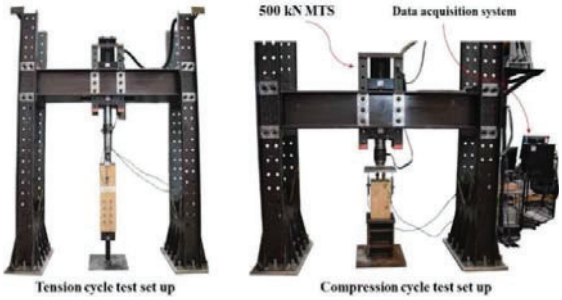

Figure 2. Cyclic loading test set-up.

For the tension tests, the CLT specimens were fixed using two knife plates inserted into the pre-cut slots in the transverse layers of CLT and held by eight M20 bolts. At the other end, a pulling steel member was designed and used to pull out two diagonal glued-in rods at the same time. Figure 3 shows the components of the CLT specimen with rods embedded perpendicular to the lamination to be tested in tension. The monotonic loading was applied at a constant displacement rate of 2 mm/min throughout the loading process. The average displacement/slip of the rods was measured using two LVDTs.

https://doi.org/10.52202/069179-0189

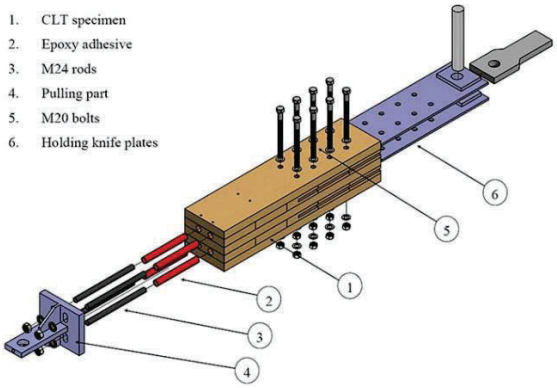

Figure 3. Exploded view of 5-layer CLT specimen with rods embedded perpendicular to the grain.

A loading procedure from BS EN 12512:2001 [7] was modified for cyclic loading. Due to the stiffness of the glued-in rod connections with failure occurring within 1-2 mm displacement of the rods, the rods were loaded in a force-control manner at a rate of 5 kN/s. The force reference for the cyclic loading was determined from the monotonic loading. For testing under cyclic loads, CLT specimens with 250 mm embedded length rods were subjected to tension-only cycles, while specimens with 350 mm embedment length rods were subjected to compression-only cycles. The specimens were put through a tension/compression load in the first cycle that applied 25% of the maximum load. Then, the load was released until zero force. The initial cycle was repeated in the second cycle, but this time 50% of the force was applied. In the third round, three cycles are completed at 75% of the maximum load. For the CLT specimens containing rods with 250 mm embedment length, the load was then increased until failure occurred, and for the specimens containing rods with 350 mm embedment length, three more cycles at the maximum load were established. Glued-in rods with embedment lengths of 250 mm were tested until they failed on the last cycle. However, specimens with embedment length of 350 mm did not fail within the standard range by the machine capacity. The loading cycles of specimens with 250 and 350 mm embedment lengths are shown in Figure 4.

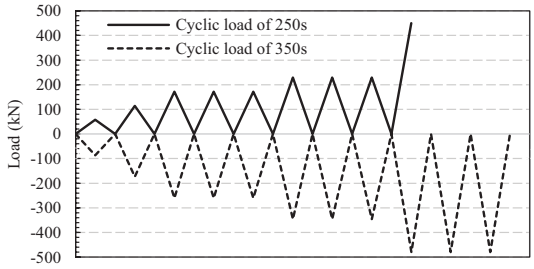

Figure 4. Cyclic loading protocols.

2.2 Numerical Modeling

The numerical analysis is performed using the Abaqus software package (finite element analysis software) [8] to investigate the effect of the rod diameter and embedment length on the pull-out strength and to study the stress distribution along the rods. The 3D model of the CLT panel was designed with cross-wised laminations with orthotropic properties (E_1= 10400 MPa, E_2-E_3= 347 MPa, ν_{12}= ν_{13}= ν_{23}= 0.2, G_{12}=G_{13}= 692, and G_{23}= 69) and tied interaction between the laminations and no edge bonding as in the tested CLT panel. While the properties of the rods (E=210000 MPa and ν=0.3) and epoxy adhesive (E= 2193 MPa and ν= 0.3) were defined as an isotropic material. The interaction between the rod's surface and the inner surface of the epoxy adhesive is defined as a 'tie' since in the experimental tests, no failure was observed (due to the excellent interaction of the threads of the rods and epoxy adhesive). The experimental test data was used to validate the numerical models. The load was applied to the rods with a displacement-based approach, and a rigid body was defined at the end of the CLT specimen and fixed as a boundary condition in the Z-direction to measure the reaction force. The numerical model of the glued-in rod connection is shown in Figure 5.

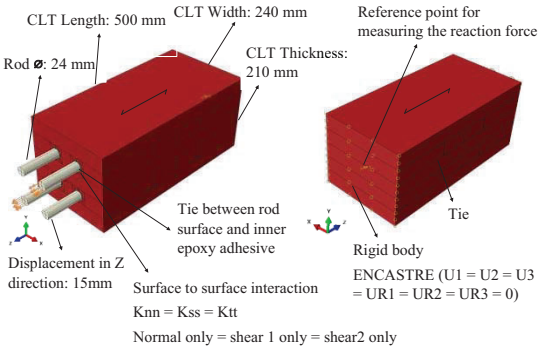

Figure 5. FE modeling of the glued-in rods connection with rods located on the perpendicular layers of CLT.

For each rod to grain configuration, different interaction properties are defined between the outer surface of the epoxy adhesive and the inner surface of the hole, which are shown in Table 2.

Table 2. Interaction properties of embedded rods regarding the rod to lamination angle.

Rod to grain orientation	*Knn* (N/mm^3)	*Kss* (N/mm^3)	*Ktt* (N/mm^3)	*Normal (MPa)*	*Shear-1 (MPa)*	*Shear-2 (MPa)*

3 RESULTS AND DISCUSSIONS

3.1 Experimental tests

3.1.1 Monotonic loading

The average pull-out strength of glued-in rods with 250 mm embedment length is shown in Figure 6. For the rods embedded on the perpendicular, parallel, and boundary of

https://doi.org/10.52202/069179-0189

two cross-wised layers, the average pull-out strength of glued-in rods with 250 mm embedment length was 343 kN, 333 kN, and 305 kN, respectively. The shorter distance between the rods and the CLT surface led to a lower pull-out strength of the rods embedded on the boundary of two cross-wised layers. As a result, the stress reached the surface of the CLT specimen and formed a premature crack, subsequently leading to a lower pull-out strength. The glued-in rods with 350 mm embedment length at the perpendicular, parallel, and boundary of two cross-wised layers had average compression strengths of 506, 493, and 482 kN, respectively. The connection strength also decreased as a result of the lower surface distance of the rods embedded on the boundary of two cross-wised layers. The average compression strength of rods with 350 mm of embedment is displayed in Figure 6.

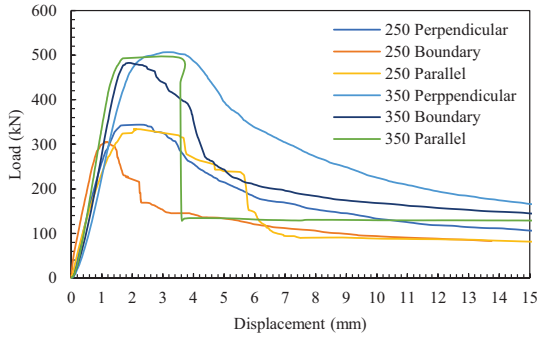

Figure 6. Average values for strength of glued-in rods with 250 and 350 mm embedment length.

The yielding of the steel rods in glued-in rod connections is intended to produce a ductile failure mode. To obtain the tolerance threshold of brittle failure and other types of failures of the connection components, this research was set up so that the steel rods' strength was greater than that of the other connection components. Given the characteristics of CLT, the specimen's failure mode can be influenced by its specifications, including laminations dimension, laminations grade, bonding, etc. For instance, not edge-bonded laminations, weak finger joints, and knots can initiate the failure and reduce the strength of the connection. Common failure modes of CLT specimens with rods embedment at the edge of CLT is shown in Figure 7.

Various potential failures have been reported in the literature for rods embedded perpendicular to the lamination. Most common failure types for rods implanted perpendicular to the grain is the separation of the entire transverse layer or rolling shear [5, 6]. Rolling shear failure in the transverse layers was the observed mode of failure for the rods embedded perpendicular to the lamination, as illustrated in Figure 7a. This is due to the lower tangential and radial strength of the wood. When glued-in rods are used as a connection, the failure in thetransverse layer caused by rolling shear revealed the need for reinforcing the CLT. Rolling shear still seems inevitable despite increasing the edge distance, and it is unaffected by the geometrical characteristics of the connection. This progressive rolling shear failure resulted in a smooth force-displacement curve. However, when the rods were put perpendicular to the grain, the stress did not reach the surface of the CLT. The epoxy adhesive was also crushed along the length of the rods.

The parallel to the grain rods were pulled out in the shape of plugs that held parallel lamination segments, as seen in Figure 7b. Therefore, whether it happened close to the wood-adhesive contact or by removing a block of wood, block shear of wood caused the connections to fail and resulted in a sharp strength reduction. The surface and edge of CLT specimens for the rods embedded parallel to the grain showed no signs of damage. The amount of plugged-out wood close to the rods could potentially be impacted by the non-edge bonded laminations. Similar plug-out failures have been recorded for rods inserted parallel to the lamination in the literature [9].

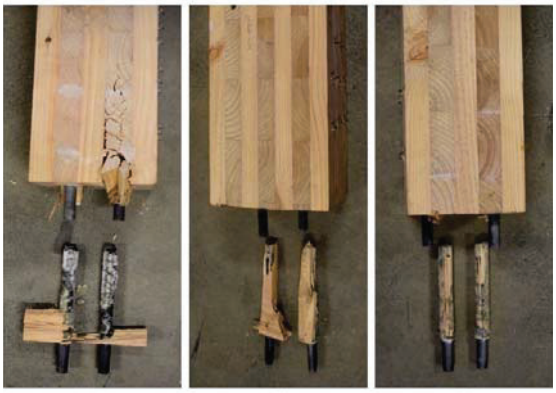

Figure 7. Failure modes on the edge of CLT specimens under tension test, (a) rods perpendicular to the lamination, (b) rods parallel to the lamination, and (c) rods embedded on the boundary of two cross-wised layers.

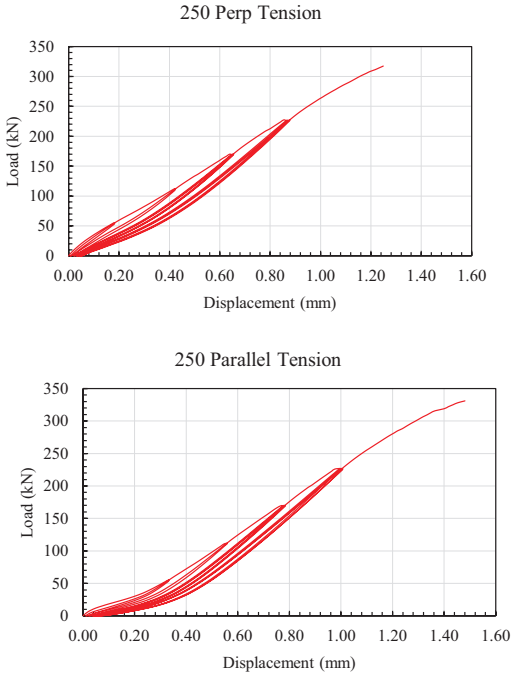
Rods inserted in the boundary of two cross-wised layers were entirely pulled out in the shape of a cylinder gripping the epoxy that had wood fibres on its surface, as shown in Figure 7c. Moreover, Figure 8 illustrates the influence of the rod's close proximity to the CLT surface by showing the failure mode of rods embedded on the boundary of two cross-wised layers while stress reaching the specimen's surfaces for both tension and compression specimens. When two lengthwise laminations that are not edge-bonded are situated close to the rod's length, this issue gets worse. Regarding the crack spreading to the CLT's surface, the edges of the specimens revealed no signs of damage. This crack formation has also been noticed in glulam specimens with glued-in rods due to the close edge distance, reaching the specimens' surface along the embedment length [10].

https://doi.org/10.52202/069179-0189

Figure 8. Surface crack of specimens containing rods on the boundary of two cross-wised layers.

3.1.2 Cyclic loading

Figure 9 provides an overview of the hysteresis response of the cyclic tests conducted on the glued-in rods embedded in CLT. All curves for the specimens with a 250 mm embedment length displayed a nearly linear trend at cycles until failure. Glued-in rods with 250 mm embedment length that were located perpendicular, parallel, and on the boundary of two cross-wised layers failed at 331, 317, and 297 kN, respectively. The connections for the rods with 350 mm embedment length demonstrated stiff and elastic performance, but there was a slight plastic deformation at each cycle in the last three cycles of the tests.



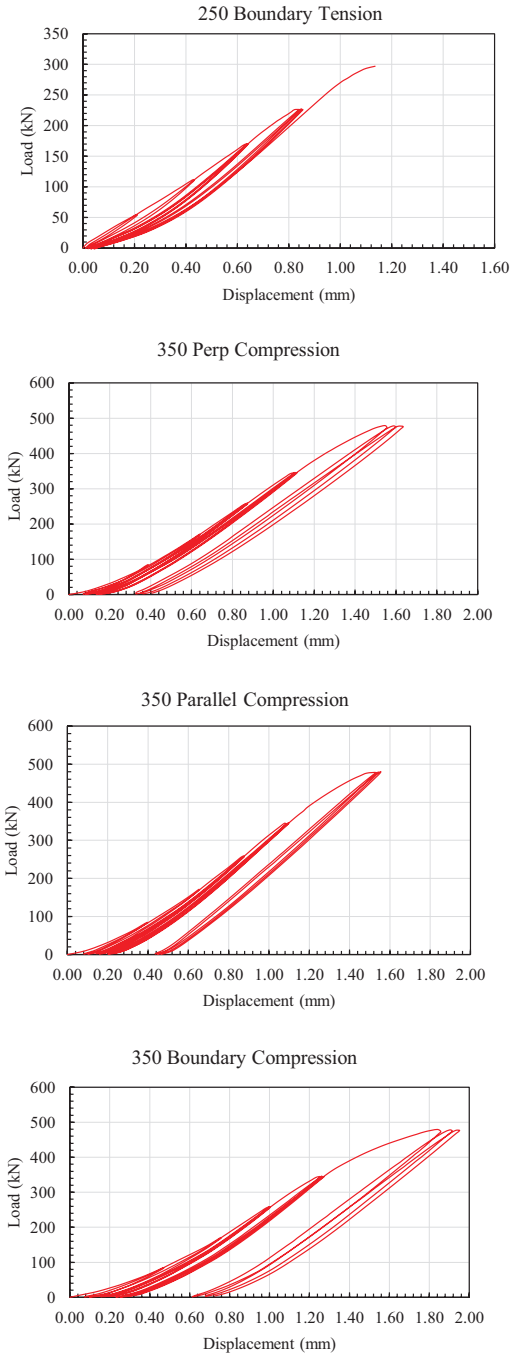


Figure 9. Hysteresis loops of glued-in rods under cyclic loading.

In contrast to glued-in rods with 250 mm embedment length, specimens with 350 mm anchorage length did not fail during the final cyclic tests. The specimens with 250 mm embedment length showed failure modes similar to monotonic tests.

https://doi.org/10.52202/069179-0189

3.2 Numerical modeling

3.2.1 Numerical modeling validation

Experimental tests were used to validate the numerical models. For every embedded rod that was parallel, perpendicular, or in the boundary of two cross-wised layers, high-precision validations were prepared. Maximum failure load, connections stiffness, and failure mode were the three characteristics used to evaluate the accuracy of the numerical modeling validations.

Table 3 compares the maximum loads of numerical models with the outcomes of experimental tests. The numerical models of rods with 250 mm embedment length at different locations were able to predict the pull-out strength with an average of 2% difference.

When the numerical models had been validated for rods with an embedment length of 250 mm, the prediction accuracy of the models was evaluated using experimental test results for rods with an embedment length of 350 mm. For the rods with 350 mm length which were modelled in tension, the numerical models estimated the pull-out strength of the rods with an average of 4% difference. The numerical models predicted the strength of glued-in rods with an overall P_{Test}/P_{FE} of 0.992 and a standard deviation of 0.028, as shown in Table 3. The higher discrepancy between the numerical modeling and experimental tests of rods with 350 mm embedment length was because rods were tested experimentally in compression while they were analysed in tension for the numerical modeling.

Table 3 Comparison of maximum strength of rods between experimental tests (P_{TEST}) and numerical modeling (P_{FE})

Rod to grain orientation	Embedment length (mm)	P_{Test}	P_{FE}	P_{Test}/P_{FE}
	L_a	(kN)	(kN)	
Perpendicular	250	344.0	346.7	0.99
Perpendicular	350	506.6	525.8	0.96
Boundary	250	305.2	310.0	0.98
Boundary	350	482.5	464.1	1.04
Parallel	250	333.9	331.8	1.01
Parallel	350	493.0	510.3	0.97
Average				0.992
Standard Deviation				0.028

The stiffness of the connections was also used to validate the numerical models. Figure 10 exhibits the strong conformity in stiffness between the numerical simulation and experimental tests of the M24 rods embedded perpendicular to the lamination of CLT and the experimental tests. Regarding the specified interaction properties in the numerical models, after following the stiffness and reaching the maximum load, it loses strength, although for the experimental tests, a gradual force reduction was obtained.

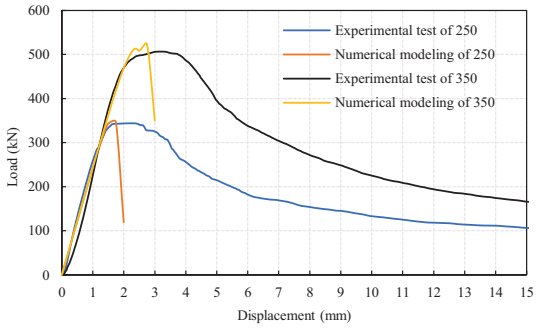

Figure 10. The force vs. displacement curves of numerical modeling and experimental tests for rods with 24 mm diameter and 250 mm anchorage length embedded perpendicular to the lamination.

In the experimental tests of rods embedded on the boundary of two-cross-wised layers, a crack appeared along the length of the rods on the surface of the CLT specimens. The numerical modeling of rods embedded on the boundary of two cross-wised layers revealed the same stress distribution that reached the surface of the CLT specimens, as shown in Figure 11.

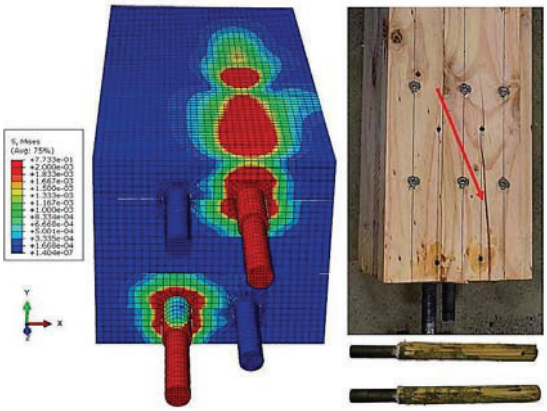

Figure 11. Numerical modeling and experimentally tested specimens of rods embedded on the boundary of two cross-wised layers.

Moreover, experimental tests of the rods embedded perpendicular to the lamination demonstrated rolling shear failure in the transverse layers. The stress distribution and displacement indicated by the numerical modeling of rods embedded perpendicular to the grain were predicted to reach the edge of the CLT specimen and cause rolling shear, as illustrated in Figure 12.

https://doi.org/10.52202/069179-0189

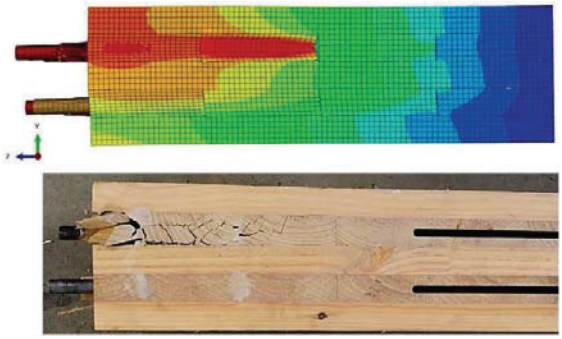

Figure 12. Numerical modeling and experimentally tested specimens of rods embedded perpendicular to the laminations.

3.2.2 Parametric investigation

The parametric study of two rods embedded perpendicular to the laminations and tested diagonally revealed that the pull-out strength increased with increasing the rod diameter and embedment length, as shown in Figure 13. Two rods with 30 mm diameter and embedment lengths of 450 mm reached a pull-out strength of 961 kN.

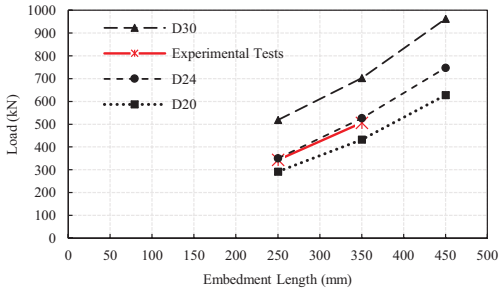

Figure 13. Numerical modeling and experimental test results of rods embedded perpendicular to the grain.

The pull-out strength of the numerical model of the two diagonal rods embedded parallel to the grain increased as the rod diameter, and embedment length increased. The pull-out strength of the rods reached 836 kN for two rods with 30 mm diameter and an embedment length of 450 mm, as shown in Figure 14.

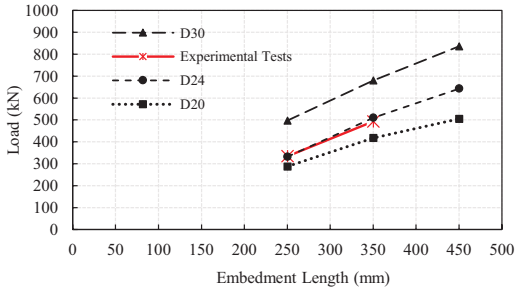

Figure 14. Numerical modeling and experimental test results of rods embedded parallel to the grain.

The pull-out strength of rods with 20- and 24-mm diameters embedded on the boundary of two cross-wised layers showed an increasing trend by increasing the rod diameter and embedment length. On the other hand, when the rod diameter was increased to 30 mm, they did not demonstrate a noticeably higher pull-out strength (as illustrated in Figure 15). This could be as a result of the rods being closer to the surface, which has been demonstrated to develop an early crack failure in experimental tests and numerical models.

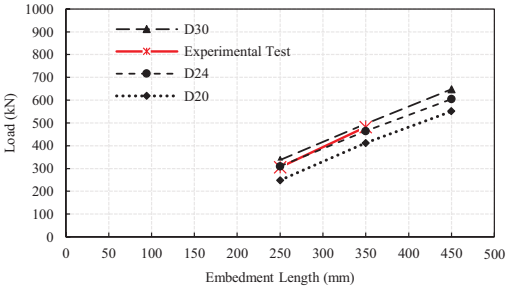

Figure 15. Numerical modeling and experimental test results of 5-layer CLT with rods embedded on the boundary of two cross-wised layers.

Using a new set of numerical models with a 7-layer CLT with rods on the boundary of two cross-wised layers, it was possible to overcome the stress distribution that reached the surface of CLTs, as illustrated in Figure 16. In this numerical model, the rod distance from the surface was extended to 84 mm while keeping the edge distance and rod distance at 84 mm and 72 mm, respectively. The interaction characteristics of this model were obtained from the characteristics of a 5-layer CLT with rods embedded on the boundary of two cross-wised layers.

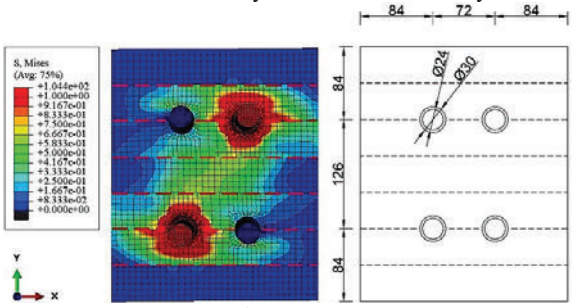

Figure 16. Numerical modeling of a 7-layer CLT containing rods embedded on the boundary of two cross-wised layers.

The numerical modeling of a 7-layer CLT with rods on the boundary of two cross-wised layers showed a proportional increase in the pull-out strength of rods with increasing the rod diameter and embedment length, as shown in Figure 17. By increasing the rod diameter from 24 to 30 mm when embedded on the boundary of two-cross-wised layers of a 5-layer CLT, the capacity of the connections increased by 9%, whereas for rods embedded on the boundary of a 7-layer CLT, the strength of the rods increased by 50%. The pull-out strength of rods with a diameter of 30 mm and embedment length of 450 mm was 738 kN. This occurrence demonstrated the negative impact of the rods' short surface distances for 5-layer CLTs. The pull-out strength of glued-in rods embedded

https://doi.org/10.52202/069179-0189

on the boundary of two cross-wised layers is lower compared to rods embedded perpendicular and parallel to the grain, even when the surface distance between the rods increased. This is because the surface cracking affected the rods' initial contact characteristics, and in practice, it is anticipated that the rods embedded on the boundary of two cross-wised layers of a 7-layer CLT to exhibit higher pull-out strength.

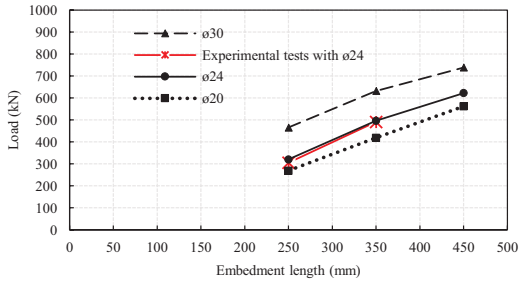

Figure 17. Numerical modeling and experimental test results of 7-layer CLT containing rods on the boundary of two-cross-wised layers.

4 CONCLUSIONS

High-capacity connections are required in designing high-rise buildings, and glued-in rods are one of the solutions to achieve this goal. Current full-scale monotonic and cyclic experimental tests are providing valuable results on the pull-out strength and seismic performance of CLT connections with multiple glued-in rods. The effect of the rods location regarding the laminations orientation is investigated, and stress distribution along the rods at various rod to lamination angles is provided.

According to the results of the experimental tests, the rod's failure mode and failure load were greatly influenced by the rod to lamination angle. Rods embedded perpendicular to the lamination led to the transverse layers rolling shear failure and crushed epoxy adhesive with a smooth force vs. displacement curve with maximum strength among tested configurations. If glued-in rods are used in CLT connections, it is recommended to embed them perpendicular to the grain. Due to the plug-out failure mode, rods embedded parallel to the grain demonstrated lower strength and a sharp strength reduction. Rods embedded on the boundary of two cross-wised layers demonstrated the lowest strength due to their closer distance to the surface of CLT, and rods containing epoxy adhesive were pulled out in a cylindrical shape. The results of the monotonic tests demonstrated that glued-in rod connections could only act ductile and fail when appropriately designed. Moreover, according to the cyclic loadings, glued-in rod connections maintain their elastic properties up until failure. The results of this investigation showed that glued-in rod connection technique could provide a solid connection for CLT construction. But it should be remembered that this investigation only looked at a certain kind of wood, adhesive, and rod. The increased list of parameters needs to be supplemented by more studies, such as using different glued-in rod connection details (rod sizes, adhesive types, spacings, and edge distance). In order to better understand the behaviour of glued-in rod connections, a wide range of test data with multiple failure mechanisms needs to be generated. Overall, this study demonstrated the high potential for this type of connection in CLT construction and showed that with glued-in rod connections, high capacities could be achieved.

ACKNOWLEDGEMENT

BEAM-ON-ELASTIC FOUNDATION MODEL OF MECHANICAL PROPERTIES OF RING NAILS AND HEAVY-DUTY SCREWS

Petr Sejkot[1], Asif Iqbal[2]

ABSTRACT: Beam-on-foundation modelling shows huge potential to substitute the limit analysis and empirical stiffness formulas used to calculate the load bearing capacity of timber connections with dowel-type fasteners like nails and screws. It takes into the account the non-linear behaviour of fastener's shank subjected to bending as well as the elastic-plastic behaviour of contact between the fastener and surrounding wood. Its another advantage is the capability to calculate both capacity and stiffness of complex connections commonly used in cross-laminated timber structures. This paper describes numerical models of axially and laterally loaded fasteners in wood. Results from modelling are thereafter compared to the experimentally obtained data.

KEYWORDS: Timber connections, heavy-duty screws, threaded nails, numerical simulation, Python scripting.

1 INTRODUCTION

During the late twentieth century, the limit analysis proposed by Johansen [1] replaced the empirical formulas used to determine the load bearing capacity of dowel-type timber connections. However, Johansen's simple design equations are becoming insufficient to cope with present-day challenges, which are e.g. related to the design of high-rise wooden buildings [2]. Former developments in computational mechanics made it possible to develop both simple [3,4] and advanced [5-9] numerical methods which take into the account the nonlinear phenomena. These approaches have remained unused in practical design due to their complex implementation and their high running time, at the time of their invention, while nowadays computational resources would allow fast and efficient numerical methods-based design. The aim of this paper is to test the applicability of these numerical methods to calculate the capacity and stiffness of various fasteners like ring nails and screws in steel-to-CLT connections.

2 EXPERIMENTAL TESTING

Mechanical properties of four types of fasteners (listed in Table 1) in CLT panels were the scope of the experimental testing.

Table 1: *Overview of used fasteners in connections.*

Fastener	Length	Shank diameter
CNA4-60	60 mm	4.0 mm
SDS10212	63.5 mm (2.5 in)	4.1 mm
SDS25112	38.1 mm (1.5 in)	4.7 mm
SDS25300	76.2 mm (3.0 in)	4.7 mm

For each fastener, two types of test-setups were assembled: to test fastener in the axial direction for withdrawal (Figure 1) and to test fastener in the lateral direction for shear (Figure 2). During each test, load magnitude applied to the fastener's head was recorded. Displacement from its original position was measured only at the fastener's head and its magnitude was related to the adjacent surface of the CLT panel. In addition, observed failure modes were noted down for each tested specimen.

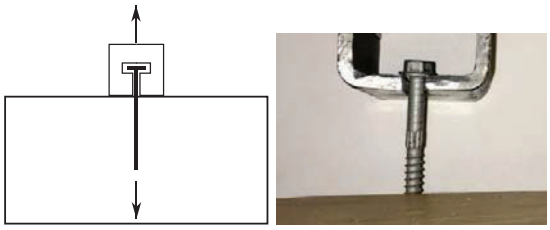

Figure 1: *Illustration of the experimental setup of axially loaded fasteners: schematic (left) and during tests (right).*

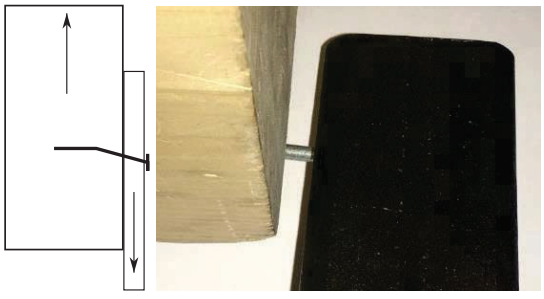

Figure 2: *Illustration of the experimental setups of laterally loaded fastener: schematic (left) and during tests (right).*

The aim of the experimental testing was to find the stiffness and load bearing capacity in order to compare it to the results from the simultaneously made numerical simulations.

3 NUMERICAL SIMULATIONS

The numerical models assembled in the Abaqus® software consist of beam elements representing fasteners, surrounding timber volume serving as a foundation and a number of nonlinear spring elements connecting nodes of beam elements to nodes of the surrounding volume made of timber. These nonlinear springs act both, in the axial and in the lateral direction of the fastener. Both the axial and the lateral properties are discretized according to the experimentally based data from the fastener withdrawal and shear tests. A similar approach has been previously successfully used by Izzi in [8] and Gikonyo in [10].

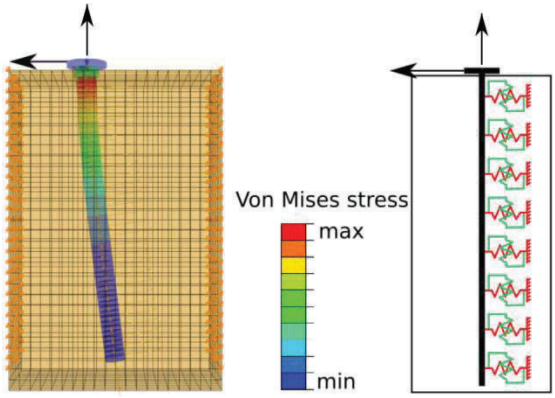

Figure 3: *Illustration of numerical model of single fastener used to simulate both test (lateral shear and axial withdrawal).*

The model presented in Figure 3 shows the single fastener after the simulation of the shear test (in the lateral direction of the fastener). The visualisation of the numerical simulation results shows von Mises stress over the shank of the fastener. The symbolic sketch outlines the way how the nonlinear spring connectors connect timber mesh to the shank of the fastener. The use of the sufficient number of spring element prevents the overloading of nodes of the mesh. The influence of the timber grain direction to the simulation results is neglected since the wood material model has unified properties in radial and tangential direction.

4 RESULTS AND DISCUSSION

The presented meshes obtained by the numerical models in Abaqus (figures 4 a nd 5) illustrate that 2 mm distance between the nonlinear springs placed at the shank of the fastener is a good compromise between the detailed model and reasonable computational cost.

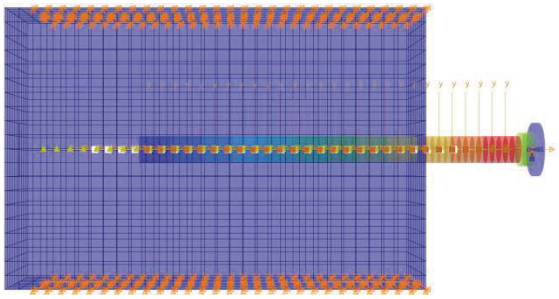

Figure 4: *Von Mises stress from numerical simulation of withdrawal of the CNA 4.0x60 nail from CLT.*

Since the withdrawal stiffness of the nonlinear springs used in the model is just the division of the overall axial stiffness of the fastener, the maximum of von Mises stress occurs at the location of the first spring (see Figure 4). This might be changed in order to get the result of the simulation closer to the real behaviour when the pulled-out fastener loses the contact with the surrounding timber.

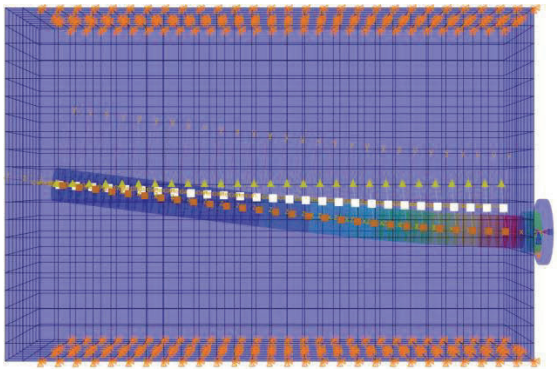

Figure 5: *Von Mises stress from numerical simulation of lateral shear slip of the CNA 4.0x60 nail in CLT.*

The stiffness of the nonlinear spring acting in the lateral direction of the shank of the fastener represents the embedment stiffness of the CLT material. The transfer of load between the fastener and the timber material is simplified by assigning the steel material properties to the parts of the mesh in the close vicinity (not exceeding the diameter of the fastener) of the beam representing the shank of the fastener. The important parameter influencing the behaviour of the model is the bending stiffness of the nail shank.
The following presented load-displacement curves for the individual fasteners in CLT bring a direct comparison between the experimentally and numerically obtained results as well as between the nails and screws.

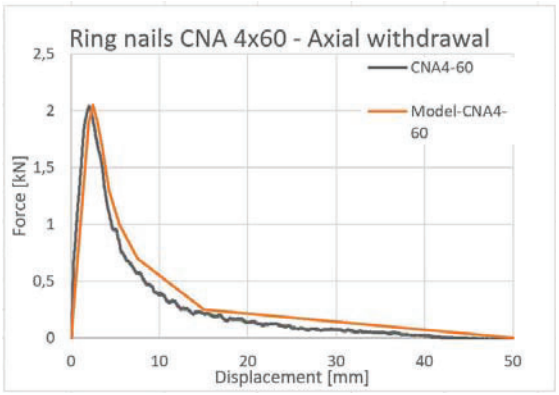

Figure 6: *Results of numerical simulation of CNA 4.0x60 NAIL in CLT connection compared to the numerical simulation.*

One representative specimen from the tested annular ring nails was chosen to be compared to the mechanical parameters used in the model (see Figure 6). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 2333 N/mm. The rest of the curve is defined by nonlinear plasticity.

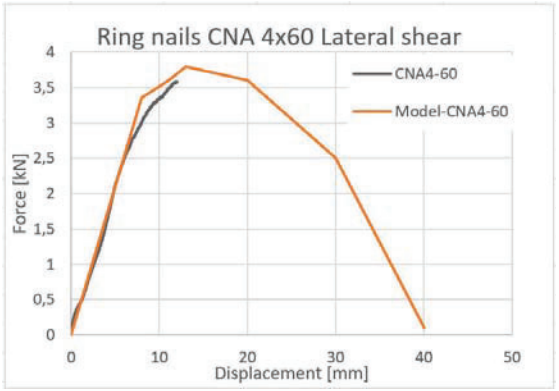

Figure 7: *Results of numerical simulation of CNA 4.0x60 NAIL in CLT connection compared to the numerical simulation.*

One representative specimen from the tested annular ring nails was chosen to be compared to the mechanical parameters used in the model (Figure 7). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 1014 N/mm. The rest of the curve is defined by nonlinear plasticity. The part of the curve which was not found by the test was extrapolated by using the knowledge of the behaviour of similar nails in a similar material.

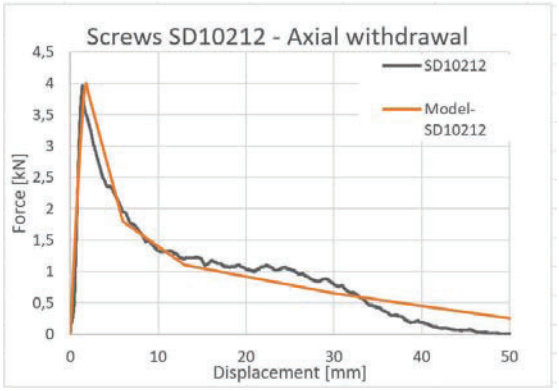

Figure 8: *Results of numerical simulation of SD10212 screw in CLT connection compared to the numerical simulation.*

One representative specimen from the tested screws was chosen to be compared to the mechanical parameters used in the model (see Figure 8). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 2750 N/mm. The rest of the curve is defined by nonlinear plasticity.

Figure 9: *Results of numerical simulation of SD10212 screw in CLT connection compared to the numerical simulation.*

One representative specimen from the tested screws was chosen to be compared to the mechanical parameters used in the model (see Figure 9). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 1000 N/mm. The rest of the curve is defined by nonlinear plasticity. The part of the curve which was not found by the test was extrapolated by using the knowledge of the behaviour of similar nails in a similar material.

https://doi.org/10.52202/069179-0190

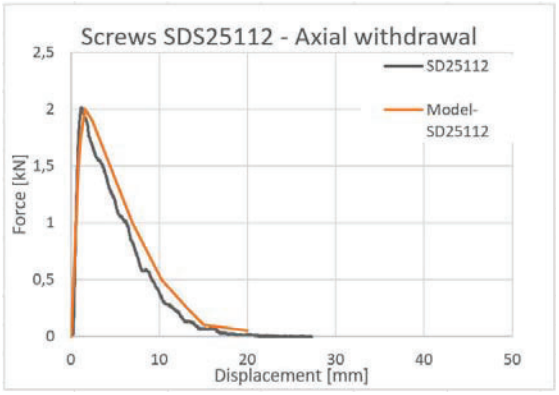

Figure 10: *Results of numerical simulation of SDS25112 screw in CLT connection compared to the numerical simulation.*

One representative specimen from the tested screws was chosen to be compared to the mechanical parameters used in the model (see Figure 10). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 2000 N/mm. The rest of the curve is defined by nonlinear plasticity.

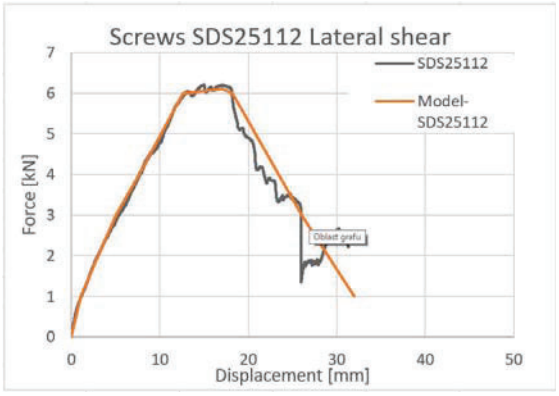

Figure 11: *Results of numerical simulation of SDS25112 screw in CLT connection compared to the numerical simulation.*

One representative specimen from the tested screws was chosen to be compared to the mechanical parameters used in the model (see Figure 11). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 2000 N/mm. The rest of the curve is defined by nonlinear plasticity.

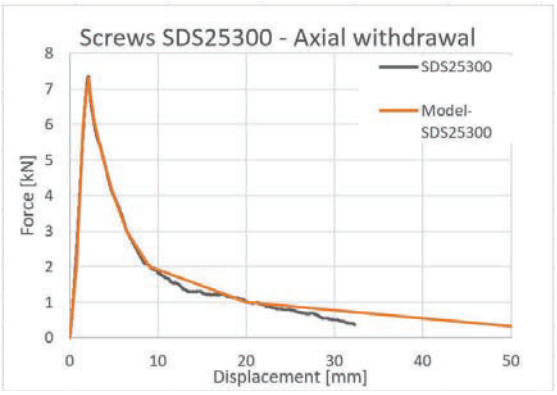

Figure 12: *Results of numerical simulation of SDS25300 screw in CLT connection compared to the numerical simulation.*

One representative specimen from the tested screws was chosen to be compared to the mechanical parameters used in the model (see Figure 12). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 8000 N/mm. The rest of the curve is defined by nonlinear plasticity.

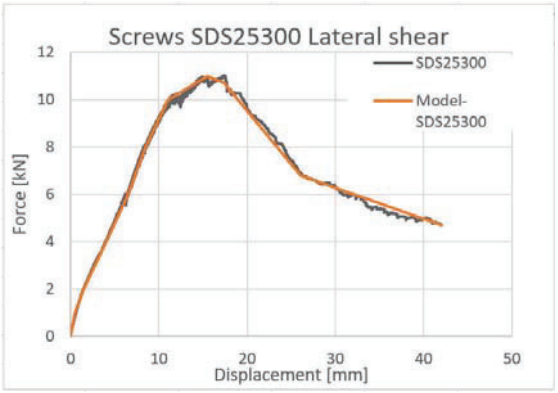

Figure 13: *Results of numerical simulation of SDS25300 screw in CLT connection compared to the numerical simulation.*

One representative specimen from the tested screws was chosen to be compared to the mechanical parameters used in the model (see Figure 13). It is the one which is closest to the mean behaviour of the tested sample. The spring model of the nail uses the elastic stiffness equal to 2000 N/mm. The rest of the curve is defined by nonlinear plasticity.
In addition, the overall comparison of tested fasteners is presented in following two figures.

https://doi.org/10.52202/069179-0190

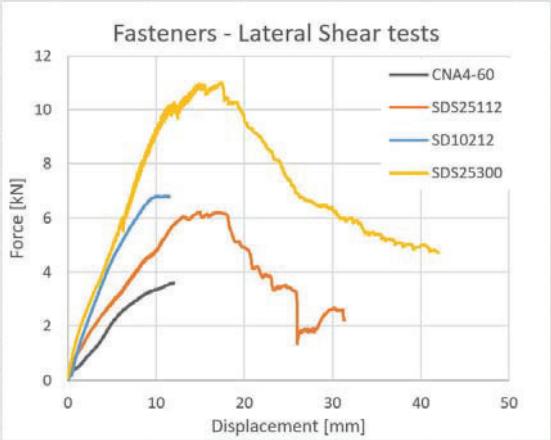

Figure 15: *Representative mechanical behaviour of three types of screws and one type of nail subjected to lateral shear test.*

5 CONCLUSIONS

The modelling approach by beam elements whose nodes are attached to the nodes in the volume of timber by nonlinear springs is relatively lightweight compared to the modelling approach using volume elements and friction for modelling fasteners in wood material. On the other hand, the approach with springs distributed over the shank of the fasteners has an advantage to the single-spring modelling approach of whole fasteners, because using the appropriate number of nonlinear springs allow to allocate the damage of the timber material to the top part of the fastener's shank whereas the properties of connectors placed deep in the timber volume may rest unaffected. Another advantage is a better simulation of coupling since the springs which are close to surface can resist to the shear and the rest of the springs can resist to the withdrawal.

Using multiple connectors over the shank of the screw also allows to simulate relatively easily a complex phenomenon of the cyclic mechanical loading of the fasteners. In this case, damage of wood material close to the surface of the CLT panels occurs, which affects both the axial and lateral resistance.

Another useful application of the proposed model of the presented fasteners can be the case when the connection is subjected to the combination of the axial and lateral loading (as shown in Figure 16). This has not been tested yet. Therefore, it is a scope of the further research to subject the screws and nails to this type of loading and compare the experimental results to the data obtained by numerical simulations.

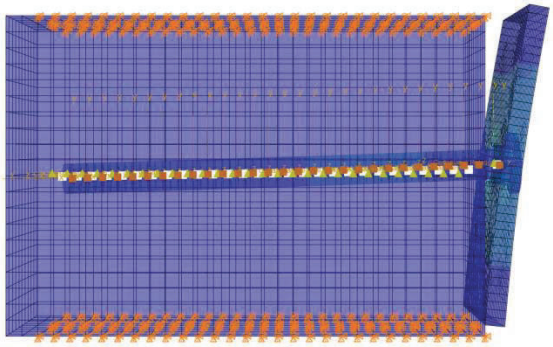

Figure 16: *Von Mises stress from numerical simulation of CNA 4.0x60 nail in CLT subjected to the combination of lateral (shear) and axial (withdrawal) load.*

The combination of the axial and lateral loading is a typical for connections of CLT elements by angle brackets (see Figure 17). It is a topic of an ongoing research to apply the fastener model in a simulation of mechanical loading of a more complex connection and compare the experimental results to the data obtained by numerical simulations (see Figure 18).

DUCTILITY OF WOOD CONNECTIONS WITH SDS SCREWS OR RING NAILS AND ANGLE BRACKETS

Petr Sejkot[1], Asif Iqbal[2]

ABSTRACT: Mechanical connections in wood structures typically consist of structural members connected with combination of cold-formed thin-walled steel angle brackets and fasteners in forms of nails or screws. Design of these steel connectors is typically based on short-term monotonic load bearing capacities. Observations from experimental testing indicate that their failure modes and resistance to a cyclic loading should be checked carefully to prevent the thread of sudden collapse of structures using these connections. This paper presents the experimental results of connections of CLT elements connected together by angle brackets and subjected to the external cyclic loading. Special focus is made on connections using heavy duty screws as fasteners. Results of experimental testing are compared to results of testing of similar connections using ring nails as fasteners. In addition, numerical simulations are made with aim to predict the failure modes and the load bearing capacities of experimentally tested connections.

KEYWORDS: Timber connections, angle brackets, screws, numerical simulation, full-scale tests, Python scripting.

1 INTRODUCTION

Since its invention in Europe, cross-laminated timber (CLT) has become a widely used construction material which has started to attract the global attention [1]. Due to the brittle nature of wood, CLT structures rely on metal connections to achieve required ductility and energy dissipation [2]. When designed properly with steel connectors and CLT elements, the structure can exhibit superior seismic performance by leveraging the high strength-to-weight ratio of wood members and the high ductility of steel components [3]. A good understanding of connections in CLT structures is needed to better predict the performance of the structures and avoid unexpected failures, e.g., caused by the out-of-plane movements under wind and seismic loads [4]. Some scholars [5-10] already used advanced modelling techniques in Abaqus® to predict the performance of structures connected by the steel components, ring nails or screws. Therefore, it is the aim of this paper to continue developing similar numerical models and try to use them to predict the performance of the experimentally tested connections of CLT structures.

2 EXPERIMENTAL TESTING

A number of CLT connections made of steel angle bracket connectors and screws has been extensively tested. Three test setups were made to achieve mechanical loading of the connections in pull-out, shear, and rocking (see Figure 1). Applied force as well as displacement at chosen locations of tested connections was recorded too. In each test-setup, various connections differing by used type of Simpson Strong-Tie® angle brackets (HGA10KT, ABR9020, ABR105) were used. As fasteners, Simpson Strong-Tie® heavy duty SDS screws were used.

Figure 1: *Experimental setup of CLT connection made of ABR9020 bracket and SDS screws subjected to rocking.*

These test-setups are identical to those previously used in [11]. However, the type of used fasteners varies between these two studies. Therefore, the influence of using screws instead of ring nails on the obtained mechanical properties of the tested connections, could be compared. The special attention was paid on load bearing capacity, measured

[1] Petr Sejkot, Czech Technical University in Prague, Klokner Institute, Czech Republic, petr.sejkot@cvut.cz
[2] Asif Iqbal, University of Northern British Columbia, Canada, Asif.Iqbal@unbc.ca

https://doi.org/10.52202/069179-0191

deformations (at the location of the red dot in figures 4-6), ductility and energy dissipations.

Table 1: *Overview of used fasteners in connections.*

Connector	Screw/Nail Type
HGA10KT	SDS25112 + SDS25300
HGA10KT	CNA4-60
ABR 105	SD10212
ABR 105	CNA4-60
ABR 9020	SD10212
ABR 9020	CNA4-60

CNA4-60 is an angular ring shank nail with 60 mm in length and 4.0 mm in diameter.

SD10212 is a screw with 63.5 mm (2.5 inch) in length, 25.4 mm (1.0 inch) long threaded part with 4.10 mm (0.161 inch) shank size.

SDS25112 is a screw with 38.1 mm (1.5 inch) in length, 25.4 mm (1.0 inch) long threaded part with 6.35 mm (0.25 inch) of outer diameter and 4.70 mm (0,185 inch) inner diameter.

SDS25300 is a screw with 76.2 mm (3.0 inch) in length, 50.8 mm (2.0 inch) long threaded part with 6.35 mm (0.25 inch) of outer diameter and 4.70 mm (0,185 inch) inner diameter.

All four types of listed fasteners were tested both in the axial (withdrawal) direction, as shown in Figure 2 and lateral (shear) direction (as shown in Figure 3). These experimentally obtained mechanical properties (force to displacement curves) of the fasteners were used later during the numerical modelling.

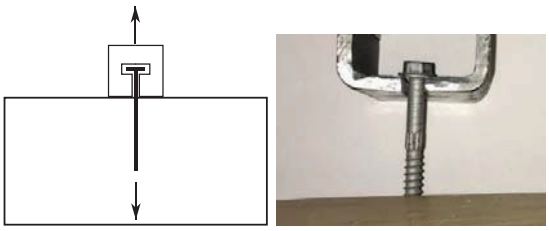

Figure 2: *Experimental setup of axially loaded fastener: schematic (left) and during tests (right).*

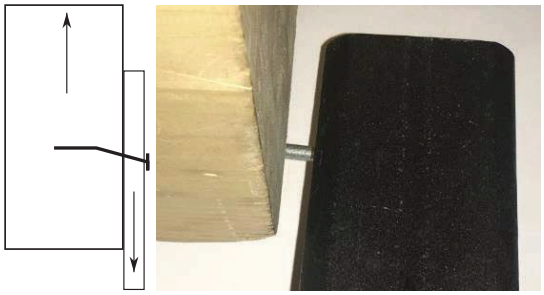

Figure 3: *Experimental setup of laterally loaded fastener: schematic (left) and during tests (right).*

The rocking test-setup consists of two CLT blocks (200x135x300 mm^3) fixed to the floor and one CLT block (105x300x150 mm^3) placed between them. A 3 mm gap between the blocks is designed to avoid friction between the CLT members. The load is applied at the top of the intermediate CLT panel at a distance of 205 mm from the shear plane, as shown in Figure 4. This eccentricity was chosen to ensure large bending load on the connection together with limited shear force action in relation to its shear load carrying capacity. A loading protocol with the maximal magnitude of displacement equal to 50 mm was used.

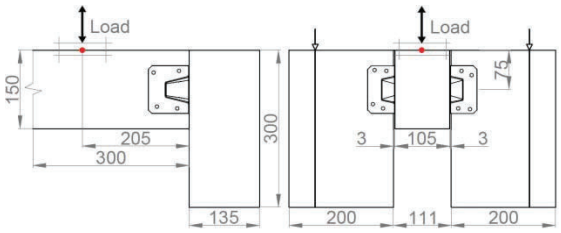

Figure 4: *Side and front view of the experimental setup of HGA10KT brackets for rocking test.*

The shear test setup consists of two CLT blocks (200x135x300 mm^3) fixed to the floor and one CLT block between them (105x320x300 mm^3). A 3 mm gap between the blocks is designed to avoid friction when the external load is applied.
The load is applied at the top of the intermediate CLT panel to act in the shear plane of the connection as shown in Figure 5. A loading protocol was used with a maximum displacement of 35 mm.

https://doi.org/10.52202/069179-0191

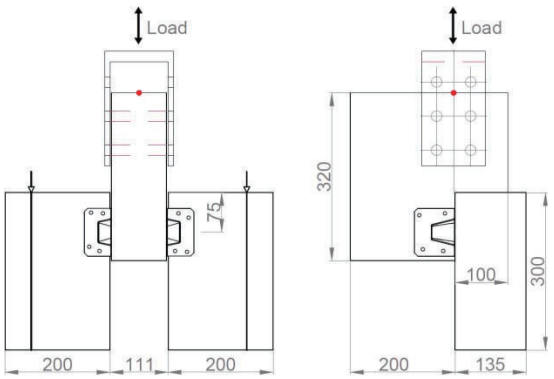

Figure 5: *Front and side view of the experimental setup of HGA10KT brackets for shear test.*

Pull-out test setup was made of one horizontal CLT block (105x150x600 mm^3) fixed to the floor and one vertical CLT block (105x320x150 mm^3). The load is applied at the top of the vertical CLT block as shown in Figure 6. A loading protocol was used with a maximum displacement of 50 mm.

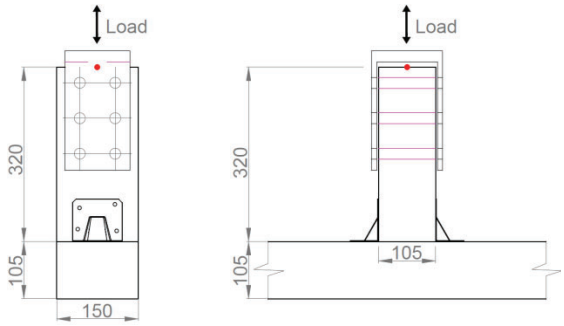

Figure 6: *Front and side view of the experimental setup HGA10KT brackets for pull-out test.*

3 NUMERICAL SIMULATIONS

Realistic numerical models (Figure 7) were assembled in the Abaqus® software, by using the same scripts as were used in [11]. Timber beams, where no contact occurred between the angle brackets and the wood, were simulated with beam elements. Some parts of the timber beams in close vicinity of angle brackets were simulated with shell elements. Shell elements were also used for the angle brackets. The Abaqus® wire elements connecting one point of mesh of beam part and one point of mesh in angle bracket part with assigned "uniaxial behaviour" represented each fastener in the model. This approach was chosen because it allows to define the re-loading path of the wires simulating fasteners in the Abaqus® software.

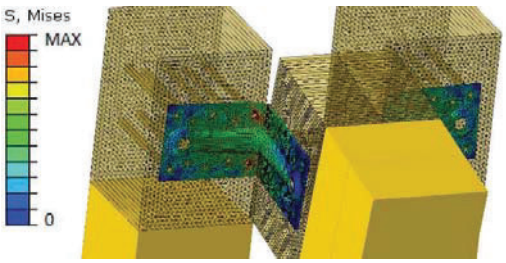

Figure 7: *Numerical simulation of CLT connection made of ABR9020 bracket and SDS screws subjected to rocking.*

Parametric modelling with Python scripting was used to create the model geometry and properties of the connections. This approach allows fast modification of beam dimensions, fastener properties and type of angle brackets, needed to cover a large number of possible combinations of possibly used angle brackets and fasteners. In addition, it allows to define the "uniaxial behaviour" directly to Abaqus® keywords.

4 RESULTS AND DISCUSSION

The presented load-displacement curves for both individual fastener joints and angle bracket connections bring a direct comparison between the nails and screws as well as between the experimentally and numerically obtained results.

4.1 FASTENERS

The presented force to displacement curves in Figure 8 show that the 60 mm long ring nails have very similar withdrawal resistance as only 38.1 mm long screws. In addition, screws are stiffer but less ductile. Other two tested screws (76.2 and 63.5 milometers long) have the same initial stiffness like the 38.1 mm long ones but they vary significantly in their strength.

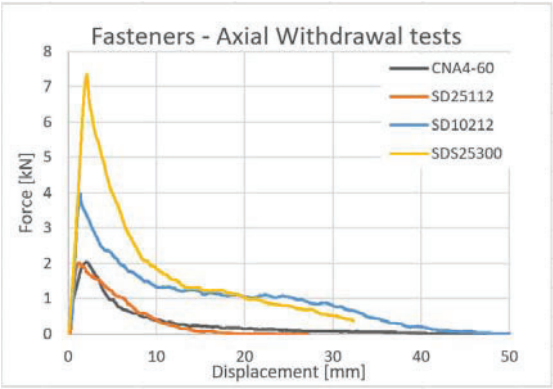

Figure 8: *Representative mechanical behaviour of three types of screws and one type of nail subjected to the withdrawal test.*

https://doi.org/10.52202/069179-0191

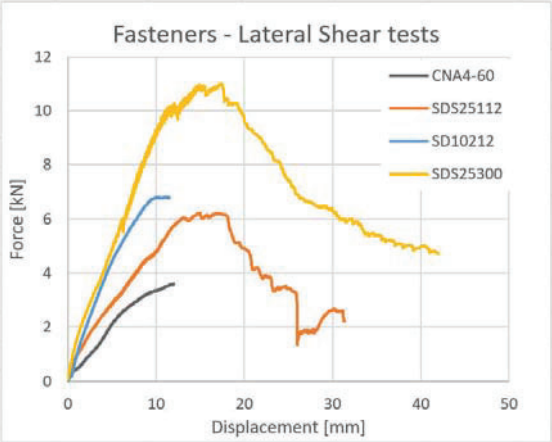

Figure 9: *Representative mechanical behaviour of three types of screws and one type of nail subjected to lateral shear test.*

The presented force to displacement curves in Figure 9 show that ring nails are both less stiff and weaker in term of the lateral resistance. 38.1 mm long screws have similar lateral resistance as 63.5 mm long screws because the shorter ones have thicker shank compared to the longer ones (4.1 mm compared to 4.7 mm). As expected, the longest screws with the thickest shank are both the stiffest and strongest.

4.2 CLT CONNECTIONS

The presented force to displacement curves in Figure 10 show that bigger angle brackets have higher load bearing capacity. In addition, connections with screws (dashed lines) have higher capacity than the similar ones with ring nails (full lines). The same colour is used for the same types of connectors (HGA10KT - blue, ABR9020 - orange, ABR105 - green) which were used in the tested CLT connections.

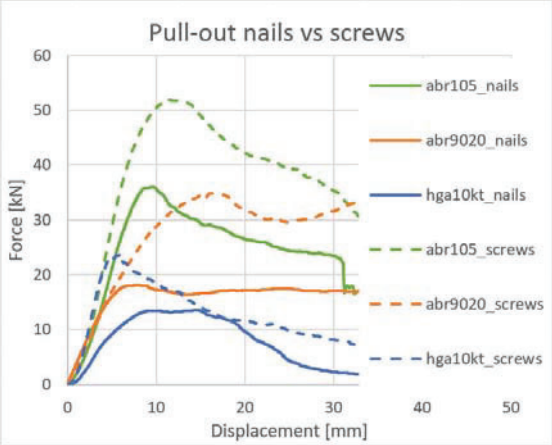

Figure 10: *Representative mechanical behaviour of three types of connections with nails and screws subjected to pull-out.*

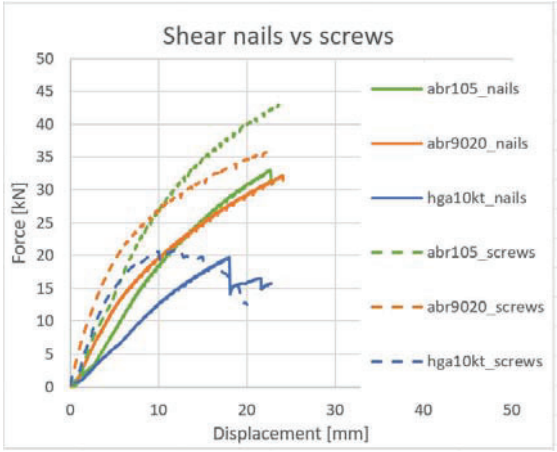

Figure 11: *Representative mechanical behaviour of three types of connections with nails and screws subjected to shear.*

The presented force to displacement curves in Figure 11 show that the size of the bracket does not have as significant influence on the load bearing capacity in shear as in case of the pull-out. Connections with screws (dashed lines) are generally stiffer than those with ring nails (full lines) but they do not have significantly higher capacity than the similar ones with ring nails. This indicates that not only fastener type contributes to the overall stiffness of the tested connections.

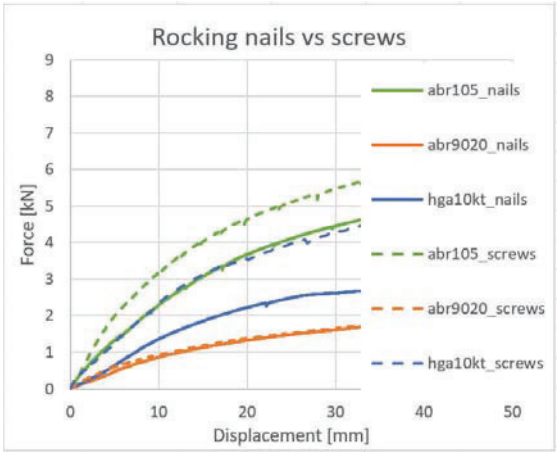

Figure 12: *Representative mechanical behaviour of three types of connections with nails and screws subjected to rocking.*

The presented force to displacement curves in Figure 12 show that the connections with the smallest bracket (HGA10kt) is stronger and stiffer that the medium size one (ABR9020). This might be caused by the influence of its relatively massive rib (compared to the one at the bigger angle bracket) on its stiffness. There is also no significant difference in stiffness nor capacity related to the used type of the fastener in case of the connection with ABR9020 bracket. Other two types of the brackets are stiffer and stronger with screws than with nails.

https://doi.org/10.52202/069179-0191

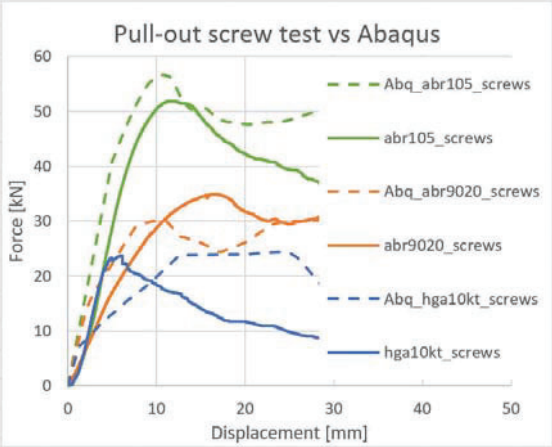

Figure 13: *Representative mechanical behaviour of three types of connections with screws subjected to pull-out compared to the results from simulations assembled in Abaqus (FEA).*

The presented force to displacement curves in Figure 13 show that there is the best agreement in case of the connection with the biggest (ABR105) angle bracket. The other simulations were relatively successful in predicting the stiffness of the connections in case of relatively small deformations and also in predicting of the load bearing capacities of the connections.

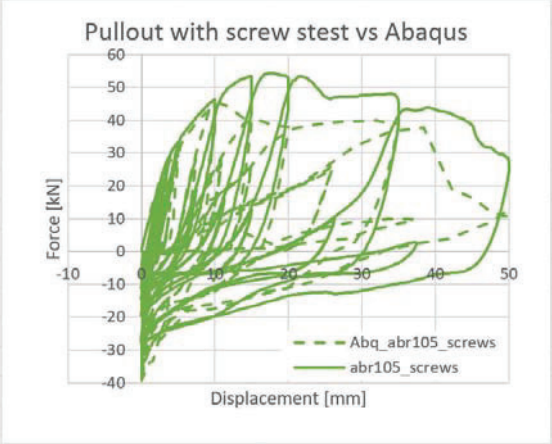

Figure 14: *Representative cyclic mechanical response of connection with angle bracket ABR105 and screws compared to the results from simulations assembled in Abaqus subjected to pull-out.*

The presented force to displacement curves Figure 14 shows the result of the most successful simulation of the mechanical response of the connection using ABR105 angle brackets and screws to the cyclic loading. There is better agreement between the numerical model and the results from the tests in case of the loading and unloading parts of the diagrams than in case of the re-loading ones.

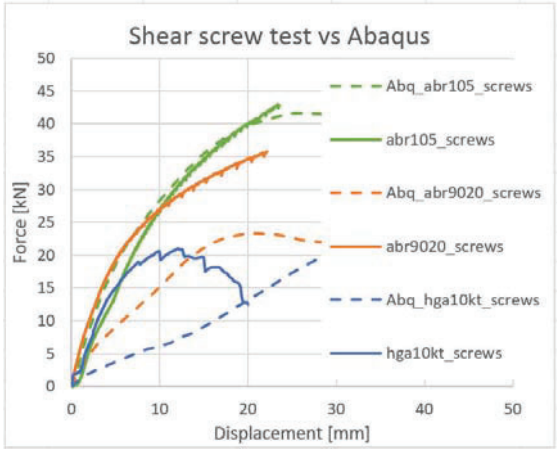

Figure 15: *Representative mechanical behaviour of three types of connections with screws subjected to shear compared to the results from simulations assembled in Abaqus (FEA).*

The presented force to displacement curves in Figure 15 show that there is the best agreement in case of the connection with the biggest (ABR105) angle bracket. The other simulations were relatively poor in predicting the mechanical behaviour of the tested connections.

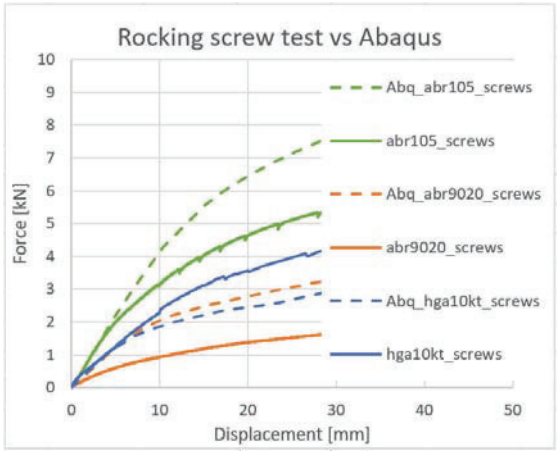

Figure 16: *Representative mechanical behaviour of three types of connections with screws subjected to shear compared to the results from simulations assembled in Abaqus (FEA).*

The presented force to displacement curves in Figure 16 show that there is the best agreement in case of the connection with the biggest (ABR105) angle bracket. However, all the simulations were relatively poor in predicting the mechanical behaviour of the tested connections.

5 CONCLUSIONS

Generally speaking, using screws instead of nails in studied connections lead to stiffer and stronger connections. On the other hand, using too strong screws

https://doi.org/10.52202/069179-0191

may lead to a brittle failure of the connections subjected to the external loading.

The relatively simple numerical models which were quite successful in predicting the deformed shape and the load to displacement curves of the experimentally tested connections of all three studied types of angle brackets and setups, i.e.: pull-out, shear and rocking with ring nails were not so successful in case of screws. This might be caused by failure modes which include cracking the timber during testing, particularly in pull-out (Figure 17) and shear (Figure 18).

Figure 17: *Test specimen with HGA10kt angle bracket and screws after pull-out test.*

Figure 18: Test specimen with HGA10kt angle bracket and screws after shear test

Another factor which seems to be relatively important and is not included in the numerical model is the friction between the steel plate of the angle bracket and the surface of the timber. Therefore, it is the scope of the further research to develop the numerical model further to be able to predict the mechanical response of all the tested connections more accurately.

EXPERIMENTAL INVESTIGATIONS ON TIMBER STEP JOINTS DETERMINING THE INFLUENCE OF INTENTIONALLY PLACED INACCURACIES ON THE LOAD-BEARING BEHAVIOUR

Matthias Braun[1], Benjamin Kromoser[2]

ABSTRACT: Various circumstances can lead to inaccuracies in timber step joints. Deviations from the desired geometry can be found for example due to inaccuracies within production or changes in the ambient humidity. The predominant question when considering step joints is, to what extent the load-bearing behaviour is influenced by these inaccuracies. To answer this question, the influence of purposefully placed inaccuracies on the load-bearing behaviour was investigated. The determined stiffnesses of the joint design with the intentionally placed inaccuracies were subsequently used within a numerical investigation in order to assess the influence on the deflection of an entire truss system.

1 INTRODUCTION

Large-scale prefabrication of components up to entire building sections plays an increasingly important role in the current timber construction industry. This manufacturing approach considerably reduces the on-site construction time. In order to ensure an efficient process on the construction site, a high fitting and dimensional accuracy of the elements is essential. Various methods exist for the connection of the truss components, with the most common being slotted-in steel plates in combination with steel dowels or glued-in threaded rods. In addition to these, carpentry joints can be used as a more environmentally friendly alternative. Step joints are, for example, often used in carpenter-based timber constructions or can be found in historical roof structures. They are characterised by their ability to reliably transfer compressive forces from one component to the next at different angles (between 30 and 60°) via contact surfaces [1,2]. When using timber as a building material, however, inaccuracies can occur for various reasons. Whereas in the past the carpenter's craftmanship was decisive for the production of a precisely fitting joint, nowadays, with modern CNC systems, work preparation including modelling, the creation of machining data and the conscientious work of the machinist play the most important role. Due to the permissible tolerances (-2 to +4 mm for cross-sectional dimension of > 100 and < 300 mm) according to ÖNORM EN 336:2013 11 15 [3], deviations in the cross-sectional dimensions between design and execution may occur when structural timber is used. This deviation from the nominal geometry requires a well-considered positioning of the components in the joinery process in order to ensure the best possible fitting accuracy of the connection. This is illustrated in Figure 1 in case of a double-step joint, with the inaccuracies cumulating when the positioning of the joint member is not considered during production.

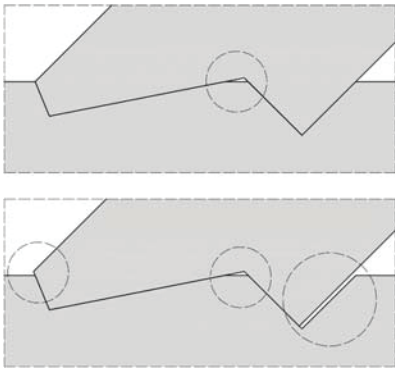

Figure 1: *Influence of the positioning of the joint's components in the joinery process on inaccuracies in case of deviation between nominal and actual cross sections using the example of the double step joint. Expected cross-sectional dimensions 120/120 mm, real cross-sectional dimensions 118/118 mm. Top: favourable positioning, bottom: unfavourable positioning.*

Apart from the dimensional inaccuracies due to the permissible tolerances, adjustments in the moisture content often lead to changes in geometry, which also result in gaps in the joints due to the different degrees of tangential and radial (regarding the annual rings) shrinkage. In order to prevent inaccuracies due to swelling and shrinkage, Blaß et al. [4] recommends that the moisture content of the components during the joining process corresponds to that in the final state.

Connections with mechanical fasteners, such as slotted-in plates and dowels show a slip at the beginning of the

https://doi.org/10.52202/069179-0192

force-displacement curve due to the required hole clearance, with the standardised calculation approach for the stiffness found in [5]. According to Seim [6], the slip at the beginning is also usually seen in carpentry joints resulting from inaccuracies, elastic and plastic deformations under load as well as creep and shrinkage deformations. The schematic load-bearing behaviour of a resilient joint is depicted in Figure 2. Initially, the joint cannot transmit any load until it transforms into a perfect fitting connection. After overcoming the initial phase, a linear-elastic behaviour is observed, defined by the stiffness C in N/mm, followed by the non-linear range with decreasing stiffness.

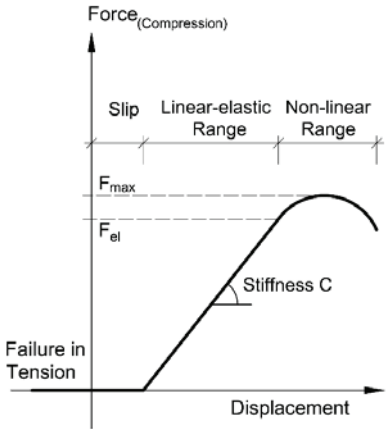

Figure 2: *Schematic force-displacement behaviour of timber step joint with diminished stiffness following [6].*

When modelling timber step joints, it should be noted that only compressive forces can be transmitted. directly under tension as timber steps are not able to transfer any tensile loads. Seim [6] states that the value for the step joints stiffness C defined at 20-25 kN/mm and the simplification of the force-displacement relationship, by disregarding slip and assuming linear-elastic behaviour until failure (see Figure 2), provide sufficiently accurate results for an implementation in practice. This statement will be assessed within this paper.

Numerous publications deal with the load-bearing behaviour of carpentry joints [7–10]. Villar-Garcia et al. [11] suggest adding a gap in the front notch of a double-step joint to improve the load-bearing behaviour. In order to achieve an efficient load transfer when using step joints, a high fitting accuracy is generally assumed as a predisposition, an assumption that has however not yet been quantified in detail. This paper therefore deals with experimental investigations of timber joints with intentionally placed gaps in step joints to determine the influence of inaccuracies on the load-bearing behaviour. The results of the experimental investigations are discussed based on recalculations of realistic truss structures.

2 Experimental Investigations

The load-bearing behaviour of traditional and newly developed step joints with a perfect fit was investigated and compared in a previous publication of the authors [2]. The most relevant geometries for practical application, as depicted in Figure 3, were selected from [2] for the investigations presented within this paper and in [12] in order to determine the influence of inaccuracies on the load-bearing behaviour. Configuration A represents a classic carpentry joint, the double-step joint. For Configuration B a third step was added to the double step joint. Geometry C is a multi-step joint with increasing cutting depth t_v from the front to the rear notch resulting in multiple shear planes. A multi-step joint with seven steps and a single shear plane was also considered within Configuration D. The reference configurations were designed and fabricated with an ideal fit between the joint members to ensure comparability with their related inaccurate versions.

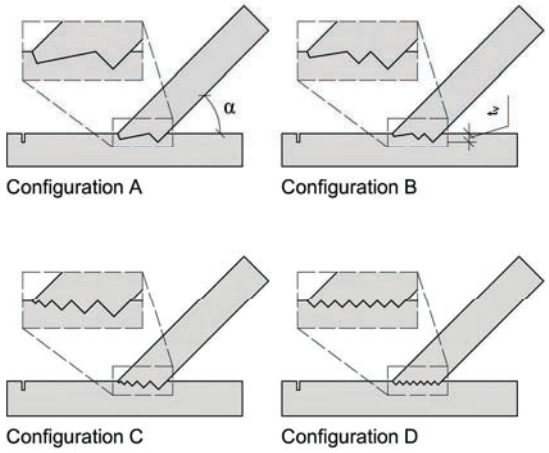

Figure 3: *Illustration of the reference configurations with a perfect fit based on the findings of [2].*

2.1 Test Specimens and Inaccuracy Placement

The investigated configurations, including the placement of the gaps, are pictured in Figure 4. While five different placements of inaccuracies were investigated for Configuration A, only one or two different variations of Configurations B, C and D were assessed. As was the case for the reference configurations and described in more detail in [2,12] the specimens were made from glue laminated timber made from spruce (GL24h) with an intended cross section of 120/120 mm (the actual cross section being 118 L3s configuration (39 l-40 w-39 l) according to ÖNorm EN 14080:2013 [13]) with the joining interfaces milled using the industrial robot at the BOKU robot laboratory [14]. All test specimens were stored in the same environment to ensure comparability of the results. The moisture content was determined using a GANN Hydromette BL H40/HT70 and lied in the required range of 12%.

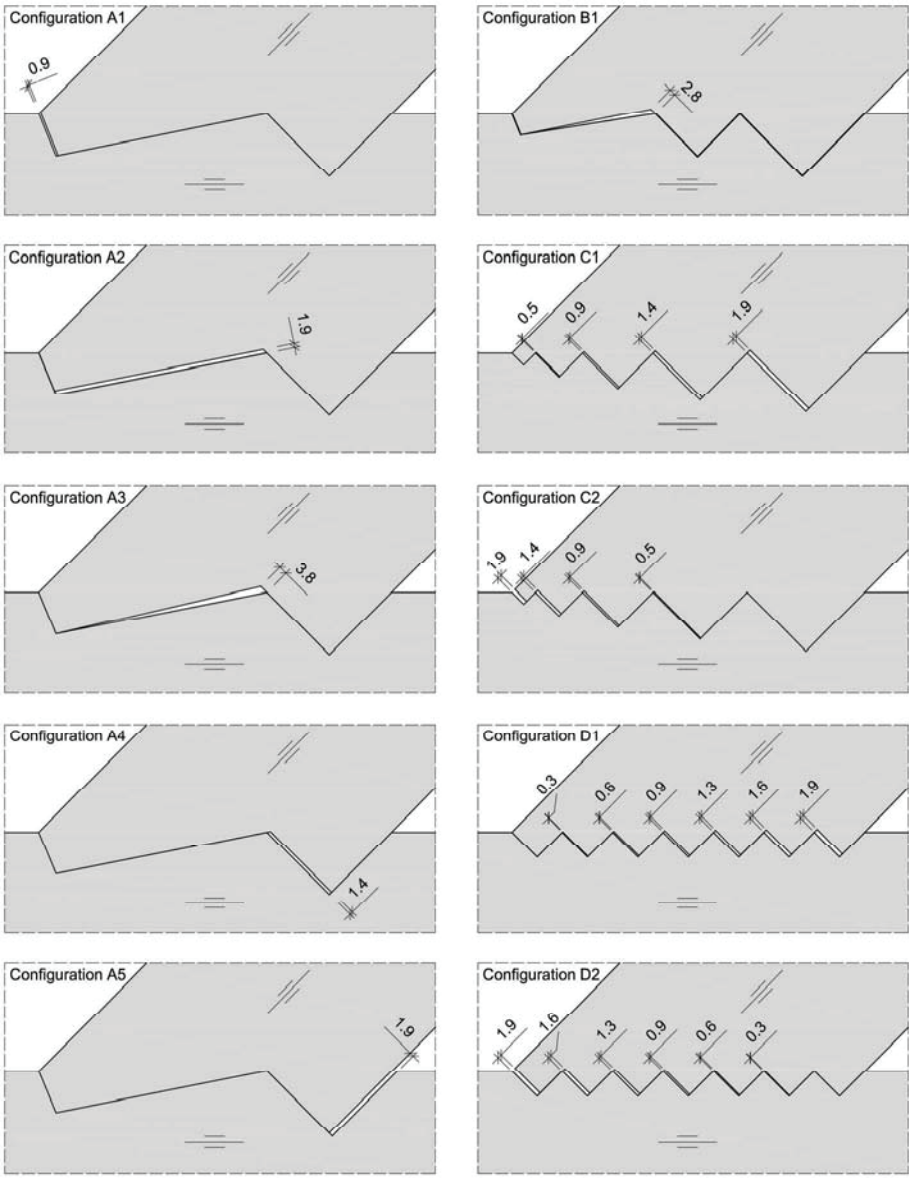

Figure 4*: *Placement of the internally manufactured gaps in the geometries selected from [2] [mm]. ***Configuration A1*: *Inaccuracy at the front of the front notch; ***Configuration A2****: *Inaccuracy at the back of the front notch; ***Configuration A3****: *Inclined inaccuracy at the back of the front notch; ***Configuration A4****: *Inaccuracy at the front of the second step; ***Configuration A5****: *Inaccuracy at the back of the second step ; ***Configuration B1***: *Inclined inaccuracy at the back of the front notch; ***Configuration C1****: *Increasing gap sizes from the front to the rear notch; ***Configuration C2****: *Decreasing gap sizes from the front to the rear notch; ***Configuration D1****: *Increasing gap size from the front to the rear notch; ***Configuration D2****: *Decreasing gap size from the front to the rear notch. [12]*

2.2 Test Setup

The test setup, described in more detail in [2,12], consisted of three steel profiles, welded together at an angle of 45°, as presented in Figure 5, allowing a vertical load application to the specimens. The length of the fore wood was set to 315 mm to achieve compression instead of brittle failure due to shearing of the tie-end.

The load, measured by a load cell, was applied using a servo-hydraulic testing machine in a monotonic, displacement-controlled manner with 1mm/min. During the tests the deformations on the surface of the specimens were recorded using digital image correlation (DIC). In postprocessing a virtual inspect extensometer, as depicted in Figure 5**Fehler! Verweisquelle konnte nicht gefunden werden.**, was used to determine the deformations between two reference points. By linking the measurement data of the load cell to the evaluated changes in length, the load-bearing behaviour was

https://doi.org/10.52202/069179-0192

visualised by means of the subsequently presented force-deformation diagrams.

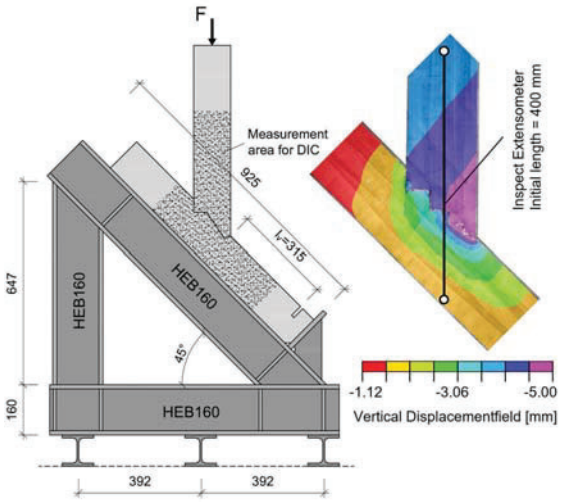

Figure 5: *Test setup including a visualisation of the virtual inspect extensometer in postprocessing. [12]*

2.3 Results and Discussion

The results of the experimental investigation of the in total 42 specimens, which were all carried out until failure, are presented in detail in [12] and illustrated in Figure 6. Within this paper the results are briefly discussed with a focus set on the stiffness C of the investigated joints. Within [12] the stiffness C is referred to as k_{lin}, which is calculated within the linear-elastic range. Apart from the mean values (MV) out of three specimens of the resulting stiffness C, Table 1 lists the mean ultimate load F_{max} for all configurations.

Table 1: *Mean stiffness C and ultimate load F_{max} values with the results of the reference geometries highlighted in bold and the lowest stiffnesses of each configuration underlined. [12]*

Configuration	F_{max} [kN]	C [kN/mm]
A1_MV	175.30	90.4
A2_MV	154.37	89.1
A3_MV	148.27	96.7
A4_MV	143.40	62.2
A5_MV	133.16	74.6
A6_MV	**165.40**	**87.0**
B1_MV	151.39	92.5
B2_MV	**171.26**	**93.9**
C1_MV	160.36	70.2
C2_MV	164.36	62.7
C3_MV	**175.30**	**93.8**
D1_MV	157.16	57.7
D2_MV	160.45	53.5
D3_MV	**176.83**	**107.5**

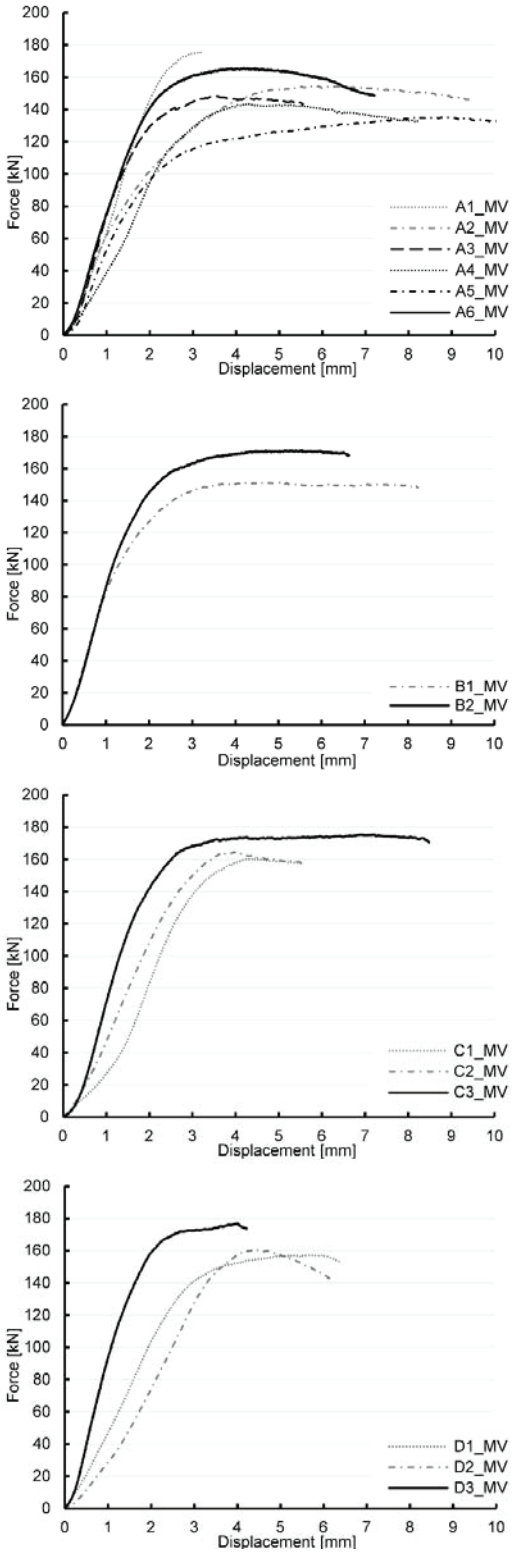

Figure 6: *Force-displacement diagrams of the mean values MV (consisting of three specimens per configuration, except for Configuration B1 with two specimens due to technical problems in postprocessing) of the individual configurations, the solid line represents the reference geometry. [12]*

The results show that, apart from Configuration B1, the intentionally manufactured gaps lead to a significantly lower stiffness C. Even though Configuration C2 shows smaller displacements, the ultimate stiffness C is lower than that of Configuration C1 and is therefore considered within the further investigations.

It could be shown that in all cases inaccuracies reduce the range of the linear-elastic phase, which starts at the end of the initial non-linear phase and ends with the beginning of failure and is characterised by a decrease in stiffness. A detailed description how these points are determined can be found [2,12]. As the linear-elastic range is reduced, the serviceability of a timber structure is negatively influenced for individual configurations if a load level above the linear-elastic range is reached in the static proof in the ULS. In only one out of ten configurations, the load-bearing capacity was increased compared to the reference geometry without gaps. Figure 7 illustrates the individual ranges according to Figure 2 and shows that the reference configurations (highlighted in bold) provide the widest range of the linear-elastic phase.

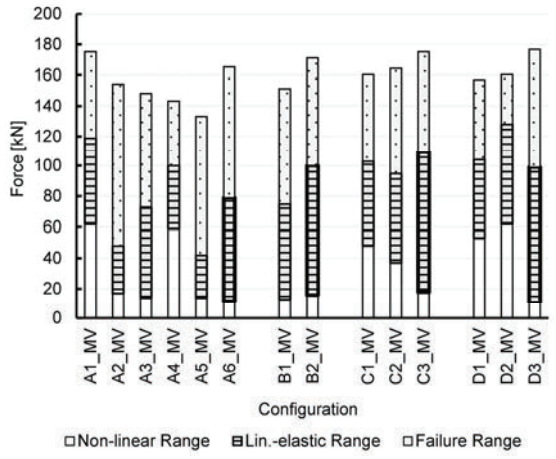

Figure 7: *Observed ranges of the mean values MV of the individual configurations. [12]*

In postprocessing, no damage was detected on the surface of the specimens at the end of the linear phase as determined in [12], so that a hypothesis of a local compression failure of the fibres leading to the stiffness decrease was made. The stiffness C of a single-step joint investigated in [2] was calculated to be 24.84 kN/mm according to [15], lying within the previously mentioned specified range of 20-25 kN/mm according to [6]. The results of the experimental investigations, however, show a stiffness C in the linear-elastic range of 53.5-107.5 kN/mm, as listed in Table 1. Even though the slip and initial non-linear range is not considered in the stiffness according to [6,15] it is still significantly lower than the determined values. This shows that the assumption of a purely linear-elastic response of a step joint with the stiffness according to [6] lying in a rage of 20-25 kN/mm should be seen as rather conservative with the authors advising to at least consider the initial non-linear range in a bi-linear approach.

In regard to the failure modes, a detailed discussion can be found in [12], where the DIC measurements and the thorough documentation of all surfaces allowed for a definition of seven predominant failure modes. Summarising the results, no general valid statement can be made on the relation of the force at the onset of the individual failure modes and the end of the linear-elastic range with the intentionally placed gaps not resulting in the avoidance of specific failure modes.

3 Practical Application

A typical application of step joints is the connection of the compression struts to the chords in trusses. In order to investigate the influence of the previously determined stiffness decreases within the joint areas caused by the inaccuracies in the connections on the overall deflection behaviour of an actual structure, the behaviour of a symmetrical parallel chord truss, as pictured in Figure 8, was determined for various joint stiffnesses using the Software RStab by Dlubal [16]. This study focuses exclusively on the analysis of the influence of inaccuracies within the joint between the connected truss members. Other parameters that additionally influence the deflection behaviour, such as deviations in strut length or joints position, were not considered.

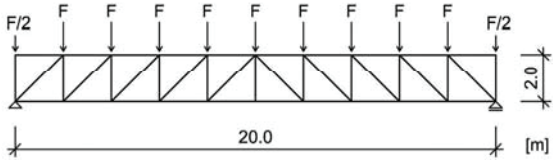

Figure 8: *Illustration of the investigated parallel chord truss.*

The truss was designed with a span of 20 m and an overall height of 2.0 m with a declared strength class of GL24h for all chord and strut elements. As would be the case within the actual construction, the top and bottom chords were modelled as continuous beams with a cross section of 120/200 mm. The vertical truss members were modelled as two 60/120 mm cross sections placed at the outer sides of the chords, while the diagonal struts, subjected to compression, were chosen as in the experimental investigations with a cross section of 120/120 mm.

The considered load cases were the dead weight, a load from a possible superstructure (permanent) and snow (variable). The loads of 7.0 kN and 4.8 kN, respectively, were applied to each node of the top chord and resulted in the maximum utilisation (0.99) of the structure (in particular the diagonal strut near the support) within the ultimate limit state (ULS) according to [5]. The normal forces under the serviceability limit state (SLS) characteristic load combination are presented in Figure 9.

https://doi.org/10.52202/069179-0192

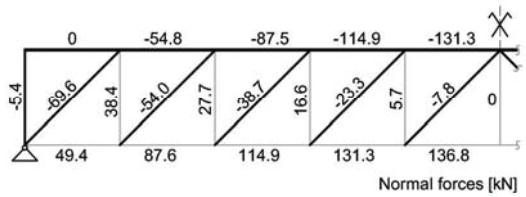

Figure 9: *Normal forces [kN] in the individual truss members (characteristic serviceability limit state SLS load combination).*

In order to make a statement in regard to the influence of inaccuracies of the step joints on the deflection of the entire truss system, the determined load-bearing behaviour from the experimental investigations was implemented within the RStab model. The stiffest and the most ductile connections of each configuration were chosen for a direct comparison, with the reference geometries always being the former and the latter being the configuration underlined in Table 1, resulting in a comparison of Configurations A6 and A4, B2 and B1, C3 and C1 as well as D3 and D2. In addition, the deformations of a truss structure with pin-joints (rigid joints with frictionless nodes) was calculated. The mechanical joint-properties of the compression struts based on the experiments were approximated within the model based on the determined load-bearing behaviour using a multi-linear modelling approach as presented in Figure 10. The kinks within the approximation were set at the end of the non-linear range, at the end of the linear-elastic range and at the point of the maximum force with their corresponding deformation followed by a constant plateau. The calculation was rounded off with the evaluation of a system with a compression joint stiffness C of 20 kN/mm, as defined by Seim [6], and a tensile joint stiffness C of 25 kN/mm using ring connectors for two shear planes with a diameter of 65 mm according to [17].

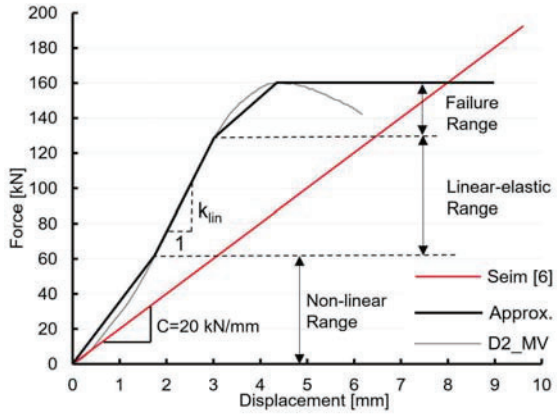

Figure 10: *Illustration of the multi-linear approximation of the load-bearing behaviour in the modelling process of Configuration D2_MV and the linear-elastic behaviour according to Seim [6].*

The results of the numerical investigations are presented in Table 2. It must be mentioned, that within the calculations only the instantaneous deformations w_{inst} were considered and the additional deflections caused by creep where neglected.

Table 2: *Maximum deflection in mid span for the serviceability limit state SLS with the reference geometries highlighted in bold.*

Configuration of compression strut	Maximum deflection in mid span [mm]
Pin-joints	32.9
With C=20 kN/mm according to Seim [6] (compression) and C=25 kN/mm (tension)	66.8
A4_MV	52.5
A6_MV	**48.3**
B1_MV	46.7
B2_MV	**47.3**
C1_MV	55.5
C3_MV	**49.2**
D2_MV	55.3
D3_MV	**46.5**

The results show that the stiffness C of the joints has a significant influence on the deformations when cumulating them over an entire truss structure. As expected, the system with pin-joints and the system with the stiffness defined by Seim [6] represent the upper and lower limits of the assessed systems, with the rigid system showing less than half of the deflection of the other. When considering the deflection w_{inst} without consideration of creep, a limit of l/300 according to [5] is set at 66.7 mm, which is slightly exceeded by the conservative assumptions of Seim [6].

It must be noted that the present study did not use variable cross sections for the compression struts, as this is also often not the case in practice (higher effort in design and execution). The chosen design, however, leads to various load levels within the struts, with the highest being - 69.6 kN at the supports, with a maximal utilisation, and the lowest being in the middle with -7.8 kN and low utilisation. By prestressing the connection, by for example a superelevation of the truss [18], the load level in the minimally utilised struts can be raised resulting in a load-bearing behaviour with a maximum stiffness. The prestressing would also eradicate the effects of the undesirable inaccuracies by counteracting the initial non-linear range, before any external load is even applied.

The present numerical investigation further shows that the most unfavourable positioning of inaccuracies (Configuration A4) within the double-step joint entails a 9% increase of the total deflections of the structure compared to the reference geometry (Configuration A6) and a 60% increase compared to the truss model implementing pin-joints. The investigated load level was not sufficient to use the potential in terms of the linear-

elastic range of the more efficient reference geometry B2. The required load within the joint should lie between 75 (end of linear-elastic range B1) and 100 kN (end of linear-elastic range B2) to exploit the potential of B2 compared to B1 in terms of minimising the deflections. It has to be mentioned, however, that this load level cannot be reached for the given cross section within the static proof in the ULS according to [5] for the given cross section and thus represents a theoretical approach. A noticeable increase in deflection is noticed for both Configurations C3 and D3 compared to their reference geometries with 13% and 16%, respectively.

4 CONCLUSION

With the deflection of timber constructions, especially trusses, essentially depending on the stiffness of the joints, the presented investigations are of high scientific value. Within this paper the influence of intentionally placed inaccuracies on the load-bearing behaviour of step joints is presented. The initial goal of this study was to investigate if specific placements of gaps within joint could influence the failure mechanisms or harbour benefits in regard to the load-bearing behaviour. Four different configurations of multi-step joints were produced and tested in experimental investigations with various inaccuracies and compared to perfect fit reference geometries. The results show that the load-bearing behaviour is negatively affected by inaccuracies with stiffness and load-bearing capacity decreases of up to 16% and 19%, respectively. Furthermore, the individual ranges of the load-bearing behaviour depend on the position of the gaps and show a predominantly negative influence, with a perfect fit critical for the highest possible stiffness in the connection and smallest possible deflection of an entire truss structure. If pin-joints are considered within dimensioning for example by using a FE software the deflection is significantly underestimated, while stiffness estimations from literature, e.g. Seim [6], show rather conservative results with higher deflections than can be expected in reality (without a consideration of creep).

As an endnote it should be mentioned that the use of multi-step joints does not provide any significant advantages considering the deflection of entire systems when compared to the traditional double-step joint.

PREFABRICATED FOUNDATION SYSTEMS FOR TIMBER BUILDINGS

Davide Canetti[1], Francesca Paoloni[2], Riccardo Fanti[3], Alessandro Setti[4], Andrea Polastri[5], Fabrizio Tamburini[6]

ABSTRACT: Wall-to-foundation constructive detail represent a critical issue for timber constructions due to the risk of decay of wooden components, for this reason the designer has to propose solutions aimed to enhance the durability; furthermore, has to consider several aspects such as mechanical connection, thermal insulation, electrical and plumbing systems. This paper presents an innovative concrete prefabricated beam-foundation element, aimed to solve the issues related to durability avoiding unexpected capillary rise of water creating a physical barrier between the ground and the wooden elements. Experimental tests were conducted to characterized the mechanical properties of the analyzed system: results of the experimental campaign are presented and discussed.

KEYWORDS: timber structures, experimental test, CLT-foundation connection, prefabricated beam foundations

1 INTRODUCTION

In the last decades one of the main issue of timber construction is represented by the timber wall-to-foundation details. The design of this construction detail has to deal with mechanical connection, thermal insulation, electrical and plumbing systems and finally durability. The foundation systems have the fundamental task of transfer loads from the structure to the ground: proper connections to anchor the upper structure to the foundations have to be designed. The shape and type of foundations determined the distributions of loads and deformations, conditioning the bearing capacity of the ground and the behaviour of upper structure. For timber buildings, traditional foundation system consists in a slab at the base of entire structure or foundation beams located below the structural wall, in both cases obtained with reinforced concrete casted in situ. These foundation systems, in case of low-mid rising timber buildings, often results be overdesigned and the high stiffness of traditional reinforced concrete foundations compared to the stiffness of timber structures allows to neglect differential vertical settlements and their effects on upper structure. This characteristic simplifies the design of timber elements and connections. Non-structural requirements have an important role in design phase of foundation system. Practitioners have to pay particular attention in the design of details, in particular for wall-to-foundation node [1]. They have to adopt some expedients reported in the state of the art to avoid any kind of issue related to durability that can be occurred during the service-life of a timber structure [2,3,4,5,6,7]. In order to avoid unexpected capillary rise of water from the ground, the foundations system has to be design as a waterproof barrier between the ground and the wooden wall. Usually, concrete beams were casted in situ above the foundation slab along perimeter wall panels. Levelling and alignment of the beam elements are the most critical issue due to imprecision of casted concrete slab and to the presence of the steel rebars protruding from the slab. Recently, several companies proposed different timber-to-foundation systems made with aluminium [8], or reinforced concrete [9,10], aimed to solve those critical aspects. This paper present results of an experimental campaign conducted on an innovative "beam type" foundation system (Figure 1) proposed by Canetti et al. [10]. Tests were performed in order to characterize the mechanical behaviour of the foundation system for different configurations of loads. Different widely used typology of timber walls, like Light Frame Timber (LFT) and Cross Laminated Timber (CLT) are suitable for this foundation system. The wide range of width of concrete beams make eligible the use of bio-based material walls that exhibit a large thickness compared to traditional systems or wall with diagonal boards that combined traditional technology and circular economy.

2 PREFABRICATED CONRETE BEAM FOUNDATION SYSTEM

The system here illustrated is composed by reinforced SCC concrete (Self Compacting Concrete) linear elements with rectangular section. The prefabricated beam is intended to be used as a base for structural/non-structural timber walls; in particular, the foundation was optimized for LFT and CLT structures.

The foundation elements are made in a prefabrication plant following specific production controls, proper formworks were designed in order to obtain the required rectangular sections, with a width from 120mm to 200mm and a depth up to 380mm; the maximum length is equal to 4000mm. Thanks to the special adjustable metal formwork and the use of self-compacting concrete, it is possible to create linear elements almost totally free of geometric defects (the expected production tolerances are +/- 6 mm on nominal dimensions) so to guarantee an excellent result during the assembly at the construction site.

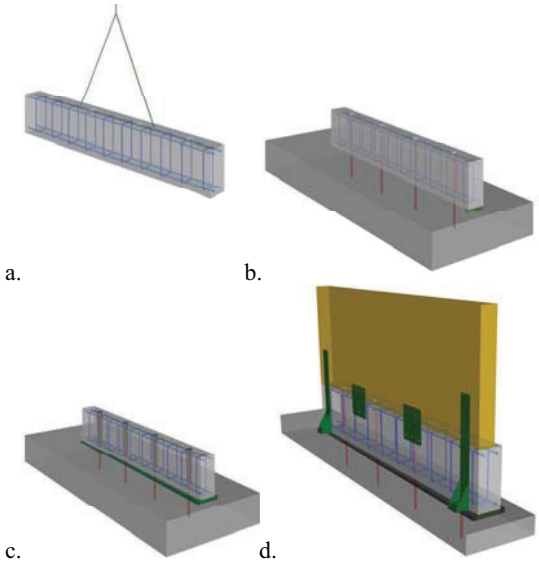

Figure 2: *on site construction phases: a) lifting; b) levelling and anchoring; c) filling vertical cones and horizontal gap with repair mortar; d) connecting timber wall to the prefabricated system*

The design, production and on site operations takes place according to the following procedures: typically, the design phase starts with the executive structural design plant; in particular, it is necessary to properly define the ground floor walls of the timber building and the associated maximum vertical forces per unit length and the maximum horizontal shear forces per unit length along the shear-wall. The designer develops a detailed executive plan of the foundation, standard prefabricated beam modules with a length equal to 2000mm are adopted; where is not possible sub-modules and non-standard elements are designed.

Afterwards, designers perform a structural verification of the anchor bar that connect the prefabricated modules to the foundation slab, a minimum longitudinal reinforcement have to be provided.

Last step is the development of production drawings and a clear assembly diagram to be use on construction site. All the indications needed for handling and storage on site are given through installation tables.

The production of the elements at the concrete prefabrication plant has to consider the installation of the bushings for lifting them. Concrete cubes for product quality control have to be stored and tested.

Once the prefabricated concrete beam modules are on the construction site have to be positioned through the appropriate lifting points, which are already set up in each element (Figure 2a).

Foundation beams are then levelled using proper metal plates and anchored (glued with proper epoxy resin) to the foundation slab with B450C (16mm diameter) reinforcing bar (Figure 2b).

The final operation consists in casting special repair mortar in order to fill all the gap between the prefabricated elements and the foundation, followed by the filling of the upper cones (Figure 2c) using high compressive strength and anti-shrinkage pourable mortar. When the prefabricated elements are properly fixed to foundation timber walls can be installed above the concrete beams and anchored with steel plates to the beam against shear loads and directly to the foundation slab with hold-downs to prevent the rigid rotation (Figure 2d). Steel plates and hold-downs are nailed or screwed to the timber walls and connected to beams and slab by means of threaded rods.

The structural elements are made according to EN13225:2013 [11]. The concrete beam presents several holes with conical shape along its length centred at the middle of the element's width for insertion of vertical anchor bars: lower diameter of 25mm and a flaring with an inclination of 1° towards the outside of the hole. The number of holes has to be designed by the practitioner: equally spaced holes at 500mm are typically adopted.

The concrete cover to be used is 30mm for an ordinary carbonation class XC2, with concrete cover factory control and a nominal life of 50 years. The main geometrical and mechanical properties of prefabricated concrete beam are reported in Table 1.

Table 1: *Geometrical/mechanical properties of concrete beam*

Prefabricated concrete beam	
Concrete	C30/37
Consistency class	SCC
Exposure class	XC2
w/c ratio	0,40
Calcareous filler [kg/m^3]	148
Sand 0-4 [kg/m^3]	245

3 EXPERIMENTAL CAMPAIGN

An experimental campaign with three series of monotonic tests for a total number of 10 test typologies were carried out in order to completely characterized the mechanical behaviour of the prefabricated concrete foundation system. The prefabricated concrete beam tested specimens are characterized by a depth equal to 350mm, width from 120 to 160mm and length from 560 to 1300mm. The concrete elements are reinforced either with steel bars and hoops or with steel fibers.
Different configurations were studied by means of specific tests. The experimental tests were designed and performed on: anchor system of the beam element in tensile configuration (Figure 4a), beam-to-slab connection in shear configuration (Figure 4b) and panel-to-beam (CLT-to-concrete) connection (Figure 4c).

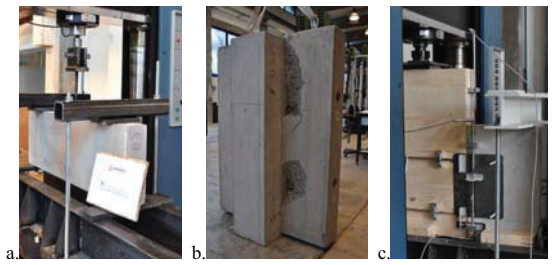

Figure 4: *Prefabricated beam foundation element: a) tensile test; b) specimen after the shear test; c) wall panel-to-beam connection test.*

The tensile tests on anchor system of beam element were carried out according to setup in Figure 4a. Beam elements are characterized by a depth equal to 350mm, width equal to 120mm and a length equal to 1000mm. The single rebar that protrude from the upper surface of the concrete element is fixed to the testing machine in order to transfer the tensile load (Figure 5a).

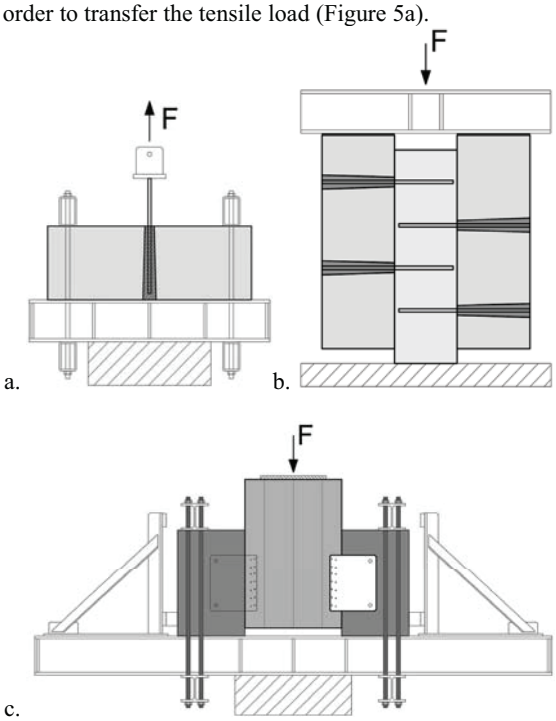

Figure 5: *Test setup: a) anchor system of beam element tensile test; b) beam-to-slab connection shear test; c) panel-to-beam connection shear test*

The element is held down through two rectangular steel profiles. Two different typologies of specimens were tested: beam element reinforced either with steel bars or with steel fibers, according to Table 2. Two tests for each configuration were carried out.

Table 2: *Configurations of anchor system specimens*

ID	test	width [mm]	anchor	d [mm]	reinforcement	n° [-]
1	tensile	120	rebar	16	rebars/hoops	2
2	tensile	120	rebar	16	fibers	2

The beam-to-slab connection specimens were tested according to setup in Figure 4b: two beam elements are fixed (one at each side) of the central concrete element

https://doi.org/10.52202/069179-0193

(slab) through two rebars with a spacing equal to 500mm. Beam elements are characterized by a depth equal to 350mm, width from 120 to 160mm and a length equal to 1300mm. The compression load is applied to the two beam elements by a hydraulic jack through a rigid steel beam, as shown in Figure 5b. The tested configurations are reported in Table 3.

Table 3: *Configurations of beam-to-slab connection specimens*

ID	test	width [mm]	anchor	d [mm]	reinforcement	n° [-]
3	shear	120	rebar	16	rebars/hoops	2
4	shear	120	rebar	16	fibers	2
5	shear	160	rebar	16	rebars/hoops	2
6	shear	160	rebar	16	fibers	2

The panel-to-beam (CLT-to-concrete) connection specimens were tested according to setup in Figure 4c. A compression load is applied by the testing machine to a 5-layer 120mm thick CLT panel (Figure 5c). Two steel plates connect the CLT panel to the two concrete beam elements: the connection plates are placed at the opposite face of the central element. Steel plates are nailed to the panel through fourteen 4x60mm Anker nails and anchored with two 8.8 threaded bars in concrete beam (in this case study the concrete elements are reinforced with fibers). The bars are fixed to the concrete beam with epoxy resin or screwed in special threaded bushing placed during the casting phase (at the production site). The tested configurations details are reported in Table 4. One test for each configuration is carried out.

Table 4: *Configurations of wall panel-to-beam connection specimens*

ID	test	width [mm]	reinforcement	threaded bar fixed system	n° [-]
7	shear	120	fibers	steel bushing	1
8	shear	120	fibers	epoxy resin	1
9	shear	160	fibers	epoxy resin	1
10	shear	160	fibers	steel bushing	1

Tests were performed according to EN26891:1991 [12]. The load rate was not greater than 0,2 mm/s and the maximum load was reached in 300 ± 120 s in all tests.

Results of the three series of monotonic test are reported in Table 5 in terms of mode of failure, stiffness k, maximum force F_{max} and corresponding displacement v_{max}.

Table 5: *Mechanical parameters and mode of failure of the tested specimens*

ID	test	k [kN/mm]	F_{max} [kN]	v_{max} [mm]	mode of failure
1	tensile	-*	59,6	-*	concrete cone combined to pull-out failure
2	tensile	-*	96,9	-*	concrete cone combined to pull-out failure
3	shear	32,7	127,4	29,2	large deformations**
4	shear	52,6	177,5	22,1	limit load***
5	shear	49,9	162,9	28,7	large deformations**
6	shear	43,4	172,1	15,4	limit load***
7	shear	9,6	50,9	14,6	steel-to-timber connection
8	shear	6,9	46,2	13,5	steel-to-timber connection
9	shear	9,7	54,2	14,3	steel-to-timber connection
10	shear	6,5	57,2	15,7	steel-to-timber connection

*displacements were not measured in this test configuration
**test was interrupted due to large deformations (>30mm)
***test was interrupted due to limit load of the hydraulic jack (>400kN)

For the shear tests the mechanical parameters are referred to a single shear plane (i.e. for single concrete beam in beam-to-slab tests and for a single steel plate in panel-to-beam tests). In the cases where two tests are carried out in the same configuration, the average values are reported.

The tensile tests show the same failure mode: the pull-out of rebar combined with the formation of a concrete cone is observed (Figure 6a). In tensile tests the displacement is measured through the testing machine.

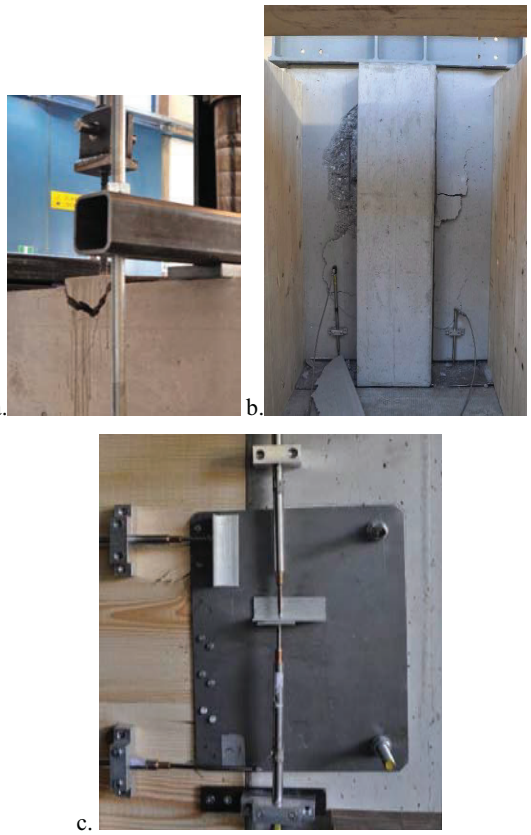

Figure 6: *Failure modes: a) tensile test; b) beam-to-slab connection shear test; c) panel-to-beam connection shear test*

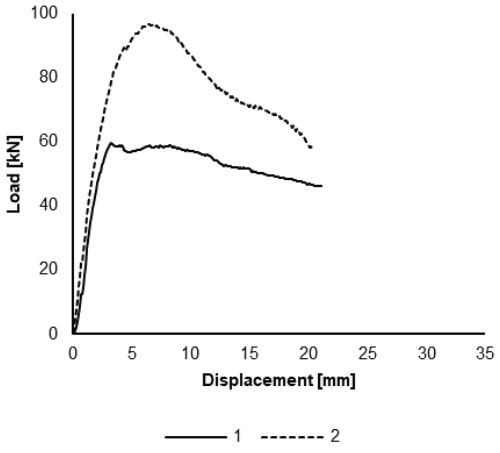

Figure 7: *Tensile tests results*

https://doi.org/10.52202/069179-0193

The fiber-reinforcement beam specimens showed a higher strength and similar value of stiffness compared to rebar reinforcement. The load-displacement curves for both configurations are reported in Figure 7: as mentioned above, the mean values were obtained from two specimens of the same typology.

The shear tests on beam-to-slab connection are interrupted for two different reasons: in case of concrete beam reinforced with rebars tests are interrupted at 30mm of displacement (consistent with the provisions reported in EN12512:2005 [13]), whereas, in case of fiber-reinforcement tests are interrupted due to the reaching of load limit of the hydraulic jack (applied load shouldn't exceed 400 kN). At the end of the tests, in both cases, cracks and spalling of concrete near connections are observed, as shown in Figure 4b. A comparison in terms of load-displacement curves is reported in Figure 8 (mean displacements were obtained from the four LVDTs measurements). After reaching the yielding point (approximately at 5mm of displacement for all specimens) the load in fiber-reinforced specimens rapidly increase until the load limit of the hydraulic jack while slowly increase in other specimens (reinforced with steel bars) until 30 mm of displacement.

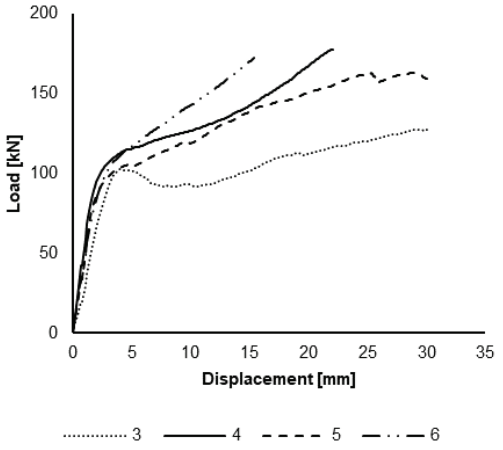

Figure 8: *Shear tests results: beam-to-slab connection*

The shear test on panel-to-beam (CLT-to-concrete) connection failed due to reaching the steel-to-timber connection (nails) strength, as shown in Figure 6c. Rotation of the steel plate and cracks in CLT panels in the nailed areas are observed. The experimental values of maximum strength F_{max} and corresponding displacement v_{max} are approximately the same for each specimen, due to the same failure mode registered in the tests. The values of stiffness of steel-to-timber connection are similar to the values obtained in other experimental campaigns. The width of the beam element (120mm or 160mm) and the different fixing systems, used to anchor the steel threaded bars, seems have no influence on the mechanical behaviour of the tested specimens. No failures are observed in the beam elements. A comparison between the load-displacement curves of the four tested specimens is reported in Figure 9.

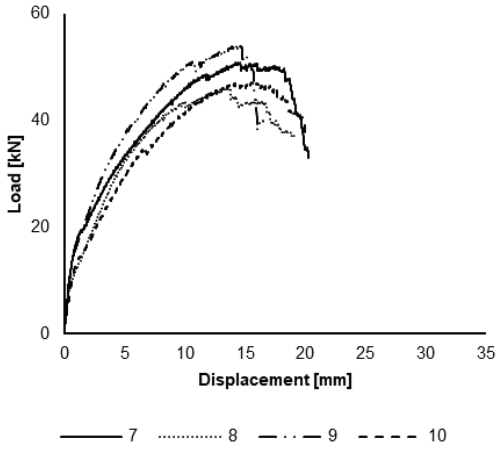

Figure 9: *Shear tests results: wall panel-to-beam connection*

4 CONCLUSION

The paper presents an innovative concrete prefabricated beam foundation system aimed to mitigate the risk of durability issues in timber elements and to ease the on-site building procedure. In particular, results obtained from an experimental campaign are presented and discussed. Tensile tests on anchor system, shear test on beam-to-slab (concrete-to-concrete) and on panel-to-beam (CLT-to-concrete) connection are reported in this paper. The tensile tests on anchor system showed a mode of failure due to the pull-out of rebar combined with the formation of a concrete cone. Beams reinforced with fibers exhibited higher strength than beams reinforced with rebars. The shear tests on beam-to-slab connection show significant strength and stiffness; no failures were observed in case of beams reinforced with steel fibers (the limit load of hydraulic jack is 400kN). Beams reinforced with rebars also exhibited high level of strength and stiffness but less than beams with steel fibers, due to the local cracks and large zone of spalling of concrete cover; after the yielding point, the load slowly increase until the limit displacement, equal to 30mm, where tests were interrupted. The panel-to-beam connection specimens were characterized by a steel-to-timber nail failure mode. Yielding of nails allowed to reach a ductile failure mode. No cracks near the threated bars were observed. Regardless of the width of concrete element no failures were observed in beams. The prefabricated concrete beam presented in this paper can be considered a valuable foundation system developed to guarantee the durability of timber structures. A simple and fast assembling system for timber walls on the construction site, at the foundation level, is ensured through these elements.

UPPER AND LOWER RESISTANCE OF SMALL STEEL-TO-TIMBER CONNECTIONS AND COMPARISON WITH REVISED EYM

Jørgen Munch-Andersen[1]

ABSTRACT: The European Yield Model for lateral resistance of connections is revised in the draft for a new Eurocode 5, EN 1995-1-1, for timber structures. In the future there will be only one formula, applying to both timber-to-timber and steel-to-timber connections as well as one or more shear planes. Results from testing of small steel-to-timber connections is compared to estimates using the revised EYM with strength parameters taken from the code as well as the actual values. There is a significant reserve that complicates the estimate of the upper value of the resistance, which is of interest for designing for robustness (against progressive collapse) and against brittle failure during earthquake. The ratio between the upper and lower characteristic resistances is investigated, and methods to reduce the ratio are discussed.

KEYWORDS: EYM, steel to timber, lateral resistance, upper characteristic resistance, lower characteristic resistance

1 INTRODUCTION

The revised version of the European Yield Model (EYM) - to appear in the coming revision of Eurocode 5 part 1-1 for timber structures [1] - is applied to laterally loaded connections with steel plates connected to structural timber using strength parameters determined for the actual timber and fasteners used.

The results are compared to the lateral resistance determined by testing according to in EN 1380 [5]. Investigations at mean value level are carried out, from which the actual rope-effect [16],[17] is determined for the various combinations of fasteners and steel plates used.

The coefficient of variation (CoV) for the different combinations is estimated, which enables to determine the 'true' lower and upper characteristic resistances. The lower value is further compared to lower value obtained using the EYM [1], [2].

The upper value is used to estimate an 'overstrength' factors as the ratio between the 'true' upper and the lower characteristic resistance obtained using the EYM in Eurocode 5.

The overstrength factor is of interest when designing for robustness using the principle of segmentation, where fuse-elements with a known upper value of resistance are needed to halt progressive collapse [1],[4]. It is also needed when designing for seismic loads to ensure the formation of hinges in the fasteners before the timber around the connection fails in a brittle manner.

2 REVISED EYM

The revised EYM is basically the traditional formula for timber-to-timber connections with one shear plane [2], having an equation for each of the six possible failure modes (a)-(f), see Figure 1.

$$F_{D,k}(\mathrm{i}) = \begin{cases} f_{h,k1}\, t_{h1}\, d & \text{(a)} \\ f_{h,k2}\, t_{h2}\, d & \text{(b)} \\ \dfrac{f_{h,k1}\, t_{h1}\, d}{1+\beta}\left(\sqrt{\beta + 2\beta^2\left(1+\dfrac{t_{h2}}{t_{h1}}+\left(\dfrac{t_{h2}}{t_{h1}}\right)^2\right)+\beta^3\left(\dfrac{t_{h2}}{t_{h1}}\right)^2}-\beta\left(1+\dfrac{t_{h2}}{t_{h1}}\right)\right) & \text{(c)} \\ 1{,}05\,\dfrac{f_{h,k1}\, t_{h1}\, d}{2+\beta}\left(\sqrt{2\beta(1+\beta)+\dfrac{4\beta(2+\beta)M_{y,k}}{f_{h,k1}\, d\, t_{h1}^{\,2}}}-\beta\right) & \text{(d)} \\ 1{,}05\,\dfrac{f_{h,k1}\, t_{h2}\, d}{1+2\beta}\left(\sqrt{2\beta^2(1+\beta)+\dfrac{4\beta(1+2\beta)M_{y,k}}{f_{hk,1}\, d\, t_{h2}^{\,2}}}-\beta\right) & \text{(e)} \\ 1{,}15\cdot 2\sqrt{\dfrac{\beta}{1+\beta}}\sqrt{M_{y,k}\, f_{h,k1}\, d} & \text{(f)} \end{cases}$$

where $\beta = f_{h,k2} / f_{h,k1}$

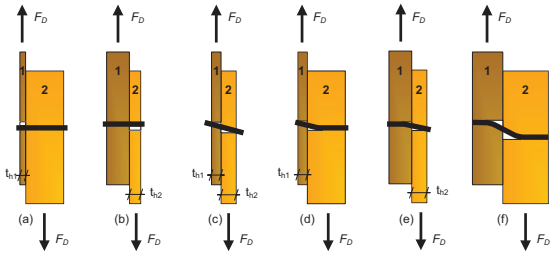

Figure 1: *The dowel contribution F_D to the lateral resistance F_v in EYM. d is the fastener diameter, M_y is the yield moment, t_{h1} and t_{h2} are the embedment depths and f_{h1} and f_{h2} the embedment strengths of member 1 and 2.*

[1] Jørgen Munch-Andersen, BUILD, Aalborg University - Copenhagen, jcma@build.aau.dk

https://doi.org/10.52202/069179-0194

The EYM estimates the lateral resistance as

$$F_{v,k} = \text{Min}\,[F_{D,k}(i) + F_{T,k}(i)]$$

where $F_{D,k}(i)$ is the dowel (or Johansen) contribution and $F_{T,k}(i)$ is the rope-effect contribution, which normally is taken as a fraction of the axial tension resistance, $F_{ax,k}$, but for failure modes (a) and (b) there is no rotation of the fastener so there is no rope-effect).

Multiple shear planes are dealt with by specifying which of the six failure modes that cannot exist and therefore shall be disregarded in the general EYM-formula. For two shear-planes that is mode (c) and (e), when member 1 is the outer members.

Metal-to-timber connections are dealt with by using the actual embedment strength for the metal – which for e.g. steel is called the bearing strength and can be determined according to EN 1993-1-7. It is at least 600 MPa for steel plates. For e.g. aluminium, the actual value should be used, which is considerably smaller.

A further advantage of using the actual embedment strength and thickness of the metal plate is that there is no need for the definition of thick and thin steel plates in [2], the revised EYM-formula will identify the relevant failure mode just like it does for timber-to-timber connections.

It should be noted that the present formulas for steel-to-timber [2] are based on the timber-to-timber formula, just assuming infinite embedment strength and zero thickness of the steel plates. Failure modes (b), (e) and (f) are then associated with 'thick' steel plates which are defined as $d \geq t_1$ and ´thin' as $d \leq 0{,}5\ t_1$. For intermediate values the above-mentioned interpolation is used.

The definition of 'thick' is about the plate thickness needed to clamp a fastener that fits into the holes in a normal steel plate, if the fasteners yield stress is about 600 N/mm^2, so it was a fair approach at the time it was developed. Nowadays, it can be much higher, so the old approach is unsafe. Likewise, it is unsafe if the formula is used for aluminium plates.

'Thin' steel plates were defined as $d \leq 0{,}5\ t_1$, most likely as an 'engineering judgement'.

It is often forgotten that the strength of the metal plate around the fasteners should be checked according to the relevant rules (steel, aluminium, ...). In [2] the failure mode that equals (a) in Figure 1 is left out in the formulas for steel plates, so for e.g. two shear planes with a metal plate as the inner member, to the present Eurocode 5 gives no requirement to the steel plate thickness.

The corrections factors 1,15 and 1,05 in failure modes (d)-(f) partly accounts for the smaller uncertainty of the properties of steel parts than for timber, partly that $k_{\text{mod}} = 1$ for the metal parts. The higher factor applies to mode (f) with two hinges in the fastener and the smaller one hinges. The factors are kept in the draft [1] because the disadvantages of introducing a physically more correct methods by far outweighs the advantages, including that applying results from testing according to EN 1380 [5] is possible without special rules. (There are some mistakes in [2] regarding the use of the correction factors and where the rope-effect exists).

3 TEST PROGRAM

The test program is summarized in Table 1. Test according to EN 1380 to determine the lateral resistance F_v are carried out with four makes of ring shank nails (ID 1 to 4), one makes of smooth nail (ID 5) and two makes of screws (ID 6 and 7). The fasteners are all designed to fit into steel plates with 5 mm holes. Nominal lengths are ranging from 25 to 60 mm. Examples are shown in Figure 3. The resulting $F_{v,obs}$ for each test is taken as the smaller of the maximum load and the load at 15 mm displacement.

Table 1: *Test program, geometry, and mean values of strength parameters. The total number of tests is n = 160.*

a. Per length. b. Normalized to the mean value for length 50 mm. c. All lengths considered as one population.

Figure 3: *Examples of fasteners used.*

Tests are carried out in three series named 10, 20 and 40. Test results for Series 10 and 20 originates from[10], for Series 40 from [11]. The timber batches are different for each series. Tests to determine the withdrawal strength f_{ax} for each fastener and batch are also carried out, the results are shown in Table 1.

For Series 10 is used timber with densities fulfilling the requirements to both methods given in EN ISO 8970:2010 [8], where the focus was on limiting the density variation, see [19].

For Series 20 and 40 is used timber with 'low' and 'high' density centred around 350 kg/m^3 and 500 kg/m^3 respectively, representing the extreme values for structural soft wood timber of European strength class C24 with characteristic density 350 kg/m^3 and mean density 420 kg/m^3. The mean density in all series is close to 420 kg/m^3.

The latest edition, EN ISO 8970:2020 [9], focuses on a natural variation of the density of the test specimens and includes methods to correct available data to the natural density variation. Where relevant, all test results are normalized to represent the density 420 kg/m^3 using these methods.

Actual values of yield moments and withdrawal strengths are determined according to EN 409 [6] and 1382 [7] Steel plates with four different thicknesses ranging from 0,9 mm to 4,0 mm has been used. For some thicknesses also test with 6,5 mm holes was carried out as a supplement to the normal 5,0 mm.

4 ACTUAL DISTRIBUTION

In this section only the influence of the nominal length and the density is considered, the rest is considered as residuals. Apart from the yield moment there is little difference between the four makes of ring shank nails (ID 1 to 4). A study of the observed values of F_v does not reveal any dependency on the hole diameter and only a very limited dependency on the yield moment and the steel plate thickness. This is further discussed in section 5.

Since the density distribution is not fulfilling the requirement to a natural variation in the new EN/ISO 8970 [9], i.e. a normal distribution with a coefficient of variation, CoV ~ 10 %, it is necessary to normalize the observations to a reference density, here taken as 420 kg/m^3. The contribution from the density variation to the total CoV is then added as defined in [9].

The observed values are normalized to $F_{v,420}$ by multiplying by $(420/\rho)^c$, where ρ is the actual density. It is found that $c = 1{,}3$ ensures a good fit to the expected LogN-distribution. This value of c is within the expected range, but estimation of c according to Annex B in [9] is not possible since the densities does not follow the normal distribution.

In the following is used ln($F_{v,420}$) as the dependent variable since it is expected to be normally distributed, as al resistances are. Table 2 shows the statistical characteristics of ln($F_{v,420}$) for each nail length and Figure 2a the corresponding distribution functions. Note that e.g. $F = 2000$ N => ln(F) = 7,6 and $F = 4000$ N => ln(F) = 8,3.

https://doi.org/10.52202/069179-0194

Table 2: *Statistical characteristics of ln($F_{v,420}$) for nails, which is assumed to be normally distributed.*

Nail length	35 mm	40 mm	50 mm	60 mm	All
Mean ln(F_v)	7,77	7,89	8,08	8,15	8,08
Std.dev.	0,16	0,10	0,12	0,16	0,13

When adjusting so the mean value for each length becomes equal to the mean value for 50 mm length, the curves shift as shown in Figure 2b, where normal distributions with std.dev. 10% and 17% are seen to include most of the observations. When all date after the shifting are considered as one population the distribution becomes the one shown in Figure 2c, closely following a standard distribution with std.dev. 14 % (meaning that $F_{v,420}$ has CoV_{420} = 14%, see e.g. Annex D.7 in Eurocode 0, [3]). According to e.g. [9] the contribution from the natural density variation, which for strength class C24 is CoV_ρ = 10%, increases the total variation to

$$CoV_{tot} = \sqrt{CoV_{420}^2 + CoV_\rho^2} = \sqrt{0{,}14^2 + 0{,}10^2} = 17\%$$

The lower characteristic value then becomes

$$F_{v,0,05} = \exp(\text{mean } \ln(F_{v,420}) - 1{,}65 \cdot 0{,}17) = \exp(7{,}80) = 2440 \text{ N}$$

and the upper

$$F_{v,0,95} = \exp(\text{mean } \ln(F_{v,420}) + 1{,}65 \cdot 0{,}17) = \exp(8{,}36) = 4280 \text{ N}$$

The ratio is then 4280/2440 = 1,75. This can be generalized to the values in Table 3.

Table 3: *Ratio between upper and lower characteristic value of a LogN-distributed variable X as function of the standard deviation of ln(X).)*

	Characteristic /mean value		
Std.dev.	Low (5%)	High (95%)	Ratio
5%	0,921	1,086	1,18
8%	0,876	1,141	1,30
11 %	0,834	1,199	1,44
14 %	0,794	1,260	1,59
17 %	0,755	1,324	1,75
20 %	0,719	1,391	1,93
23 %	0,684	1,462	2,14
26 %	0,651	1,536	2,36
29 %	0,620	1,614	2,60
32 %	0,590	1,696	2,87
35 %	0,561	1,782	3,17
38 %	0,534	1,872	3,50

For the two makes of screws the same procedure leads to the final distribution for length 50 mm shown in Figure 4, with the mean value ln($F_{v,420}$) = 8,17 and std.dev. = 11 %. According to Table 3 this gives a ratio of 1,44. The total variation for screws becomes CoV_{tot} = 15%.
There are too few observations for smooth nails to make a meaningful analysis for these on their own. Further, the influence of the conditioning is severe [15], so many more tests are required.

5 OBSERVATIONS COMPARED TO EYM USING MEAN VALUES

In this section the observed lateral resistances F_v are compared to an estimate based on EYM, replacing the characteristic values of the strength parameters with the best available estimate for their mean values.
The EYM is used for estimating the mean lateral resistance in the form

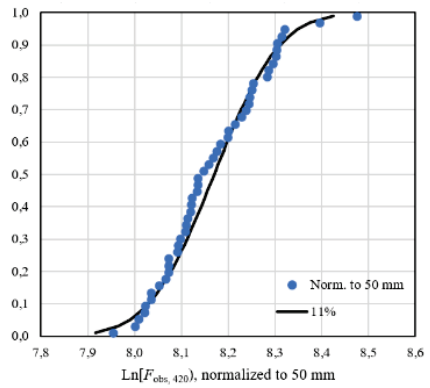

Figure 4: *The distribution function for ln(F_v) for the two makes of screws when normalized to the mean value for length 50 mm and all lengths then considered as one population.*

$$F_v = F_D + F_T \text{ with } F_T = \alpha F_{ax} \quad (1)$$

For F_D is used the formula in Figure 1 setting the correction factors 1,05 and 1,15 equal to 1 because there are no partial factors and k_{mod} adjustment involved.
The measured mean values for the yield moments M_y are given in Table 1. The CoV is about 5%.
For the embedment strength the formula in Eurocode 5 (without predrilling) is used, just replacing the characteristic density by the actual density, thus using

$$f_h = 0{,}082\, \rho\, d^{-0{,}3} \quad (2)$$

The embedment depth t_{h2} is taken as L_g, Table 1. This length includes the point length because the range of lengths used for the tests clearly shows this to be the best estimate. This is demonstrated below, compare Figure 6a and Figure 7.
The withdrawal strength f_{ax} is used for estimating the rope-effect contribution F_T. The rope-effect is taken as a fraction α of the tension resistance F_{ax}. The 'best' value of α is discussed below.
$f_{ax,420}$ given in Table 1 is the withdrawal strength for density 420 kg/m^3 and is determined to apply to the profiled length excluding the point length. The value for the different makes of ring shank nails respectively screws are very similar, so the same values are assumed as seen in Table 1. The withdrawal strength used in the EYM is adjusted to the actual density as

$$f_{ax} = f_{ax,420}\, (\rho/420)^{c_ax} \quad (3)$$

where ρ is the actual density and c_{ax} is the exponent that gives the best estimate (smallest CoV) when estimating $f_{ax,420}$. The value of the exponent might be different for the

https://doi.org/10.52202/069179-0194

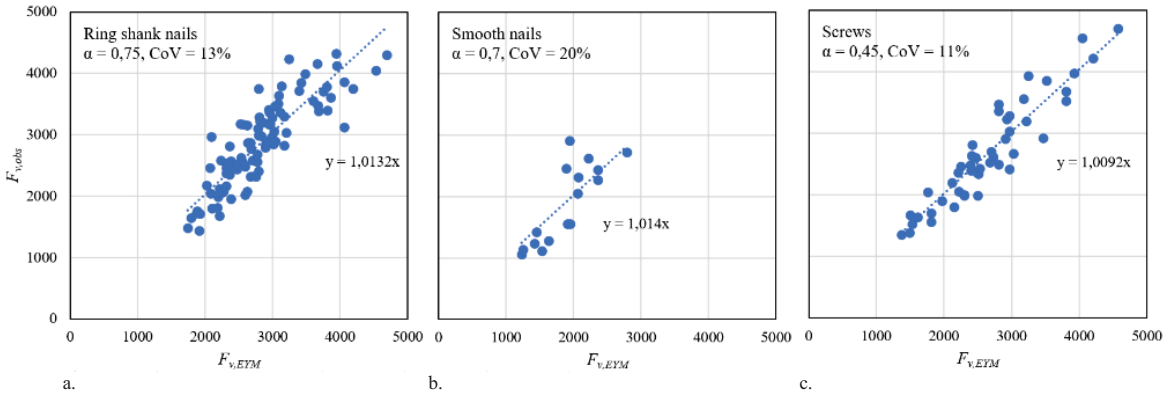

Figure 5: *Observed lateral resistance versus estimate using EYM with mean value of strength parameters. α is the rope-effect factor that ensure a slope just above 1. CoV is the variance of EYM regarded as a model of the resistance in accordance with Annex D.7 in EN 1990 [3].*

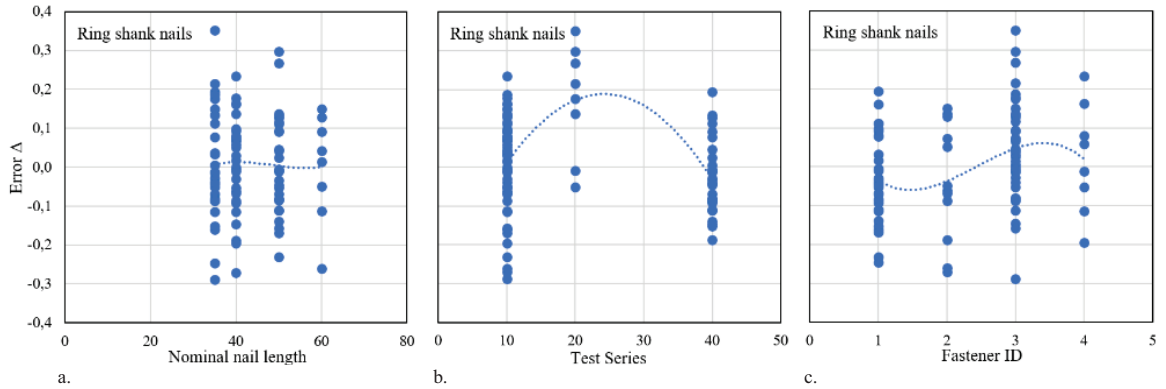

Figure 6: *The error Δ as dependent on the nail length, test series and fastener ID, see Table 1.*

different fastener types. For ring shank nails it was 1,5 and for smooth nails 2,0. For screws any value between 1,0 and 1,5 was about equally good. Henceforth, 1,5 is used for ring shank nails and screws, but the influence is small. For screws is used the effective diameter $d_{ef} = 1{,}1d_{core}$, where d_{core} is the diameter of the core of the thread, both for estimating f_{h2} and in the formula for F_D in Figure 1. For the withdrawal resistance F_{ax} is used the outer thread diameter. These definitions are in accordance with amendment A2 to EN 1995-1-1 [2].

Figure 5 shows plots for each type of fastener of the observed values of F_v against the estimated value using EYM with mean values of strength parameters. The rope-effect factor α given is the one that ensure a slope of the trend line slightly above 1. A slope above 1 means that the mean value model is conservative.

Assuming again that F_v is logN-distributed the CoV of the EYM-model can be estimated from annex D.7 i EN 1990 [3] as the standard deviation of the error Δ, where

$$\Delta = \ln(F_{v,obs}/F_{v,EYM})$$

The CoV's in Figure 5 are determined this way. If a change to the model reduces this CoV, the model is better. A tool to get ideas on how to improve a model is to plot the relation between the error Δ and one of the input parameters.

As an example, Figure 6 shows such plots for the error versus the length of ring shank nails, the test series, and the fastener ID. A polynomial trend line is shown, which has sufficient terms to pass through the weighted average for each variation, so attention should only be made to where the trend line crosses the vertical lines with the determined errors.

Figure 6a illustrates that the influence of the nail length seems to be modelled very well. Figure 6b indicates that the observations in Series 20 are higher than expected from the strength parameters, about 20 %. It is not unexpected that other properties of the timber than the density influences the resistance, see e.g. [18], so the 'error' is in part caused by the natural variation. Finally, Figure 6c indicates that faster ID 2 causes somewhat smaller resistance than average and ID 3 higher, but it is hardly significant, less than 5%. Further, it is part of the natural variation of fastener properties.

Figure 7 is similar to Figure 6a, except that the embedment depth t_{h2} is reduced by the point length. It is obvious that this introduces a systematic error in the model, even the CoV is hardly increased.

https://doi.org/10.52202/069179-0194

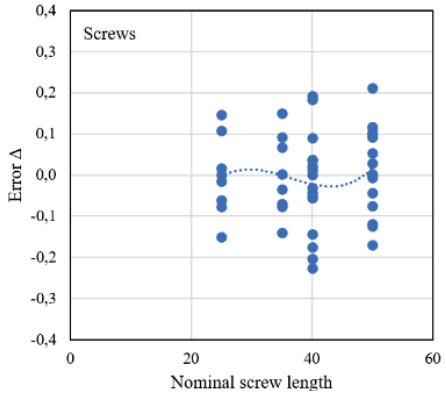

Figure 8 is equal to Figure 6a, but for screws. Again, the influence of the nail length seems to be modelled very well. The dependency on test series and fastener ID is not shown, it is at the same level as for ring shank nails.

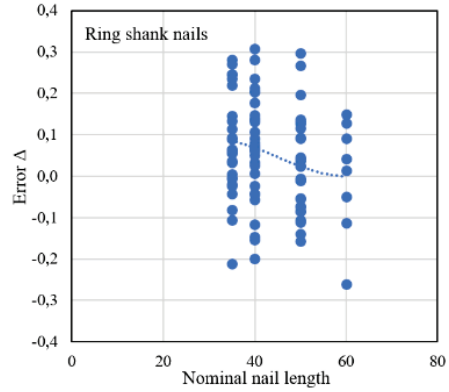

Figure 7: *The error Δ as dependent on the nail length when t_{h2} is reduced by the point length.*

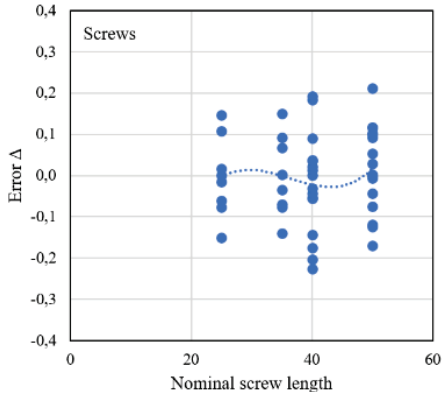

Figure 8: *The error Δ as dependent on the screw length.*

Similar plots for the steel plate thickness and the oversized holes compared to the normal 5 mm holes shows no trends that cannot be attributed to the general variation, mostly related to those combinations tested in Series 20.
As stated above, the rope-effect factor α given in Figure 5 was just chosen to make the EYM fit to the observed resistances. It could be that the dowel contribution F_D was under- or overestimated, e.g. if the formula for the embedment strength is incorrect. This can be investigated by using

$$F_v = \delta F_D + \alpha F_{ax} \quad (4)$$

and then find the combination of δ and α that minimize the CoV of the model keeping the slope just above 1, see Table 4. The values in bold are those used for Figure 5a and c. The table shows that by decreasing δ from 1 to 0,8 or 0,9 the CoV is slightly reduced, but it is a very flat minimum, so there is no evidence for not using $\delta = 1$. The flat minimum is of course related to the fact that the density is decisive for both F_D and F_{ax}.
In the next section it is shown that the sensitivity to the value of M_y is much smaller than to the density. Due to the limited amount of data, it should be regarded as a coincidence that the optimal value for δ seems to be 0,85 for both nails and screws.

Table 4: *Weighing of dowel contribution F_D by δ and axial resistance F_{ax} by α to minimise the CoV of the estimated lateral resistance F_v. The bold values are used in Figure 5 and henceforth.*

δ	0,7	0,8	0,9	**1,0**	1,1
Ring shank nails					
α	0,99	0,91	0,83	**0,75**	0,67
CoV	0,129	0,127	0,127	0,129	0,132
Screws					
α	0,56	0,52	0,48	**0,45**	0,41
CoV	0,106	0,105	0,105	0,107	0,111

It can be deducted from the estimated CoV's that the additional parameters taken into account in EYM do not really improve the accuracy because the CoV's found in Figure 2 for nails and Figure 4 for screws are almost identical to those given in Figure 5. In Figure 4 only a simple adjustment for density and the length of the fastener is applied, whereas in Figure 5 also the influence of the actual values of the yield moment and the steel plate thickness are taken into account by the EYM. So, the CoV should be smaller, but it is 11% for screws in both cases and only drops from 14 % to 13 % for nails. This means that other circumstances than those included in the EYM has a significant influence.

6 CHARACTERISTIC RESISTANCE FROM TESTS AND EYM

The mean value model for the lateral resistance F_v represented by Formula (1) appears from Figure 5 to be a reasonable model for the real resistance when using the strength parameters given in Table 1 and the rope-effect factor α given in Figure 5, i.e. 0,75 for ring shank nails and 0,45 for screws.
The CoV of the model is in section 4 estimated as 17 % for ring shank nails and 15 % for screws for connections using timber C24. According to Table 3, the lover characteristic resistance should then be 0,76 respectively 0,78 of the mean measured value for a certain set of conditions.

https://doi.org/10.52202/069179-0194

6.1 EVM ESTIMATE OF RESISTANCE

In this section mean values of $F_{v,EYM}$ has been estimated for a range of parameters representing the conditions for the tests where F_v were observed. The geometry and properties of the fasteners used is generally as in Table 1. All steel plate thicknesses 0,9, 1,5, 2,0 and 4,0 mm are used for all parameter combinations.

For nails the point length is taken as 6,0 mm in all cases and all the nominal lengths 35, 40, 50 and 60 mm are included. Two yield moments are used, 7500 Nmm and 15000 Nmm.

For screws all the nominal lengths 25, 35, 40 and 50 mm are included. Two yield moments are used, 5000 Nmm and 7500 Nmm.

These 128 estimates are compared to estimates using the same geometries, but inserting characteristic values of the strength parameters M_y, f_h, and f_{ax} in the model, as intended in Eurocode 5.

The characteristic yield moment is determined assuming a CoV of 5%, which means that the characteristic value is 92% of the mean value. For f_h, and f_{ax} is simply used the mean density ρ_m = 420 kg/m^3 for determining the mean value and ρ_k = 350 kg/m^3 for determining the characteristic value in Formula (2) and (3). The aforementioned factors 1,05 and 1,15 are also applied as they are meaningful for the characteristic values.

Hereby is determined pairs of $F_{v,EYM,mean}$ and $F_{v,EYM,charac}$, the relation for ring shank nails is shown in Figure 9 as the blue points. Not surprisingly, the ratio is fairly constant. For screws the relation is shown as the blue point in Figure 10, the slope is seen to be the same as for nails. The slope 0,83 for both nails and screws reflects mainly the ratio between the characteristic and mean value of the density which is 350/420 = 0,833, see 6.4.

6.2 LIMITS TO ROPE-EFFECT

Eurocode 5 has some limitations on the rope-effect, which reduce the characteristic resistance significantly. In the present issue [2] the rope-effect factor, here called α, is limited to 0,25, in the draft it is increased to 0,4 for nails. In both versions, the rope effect contribution F_T is limited

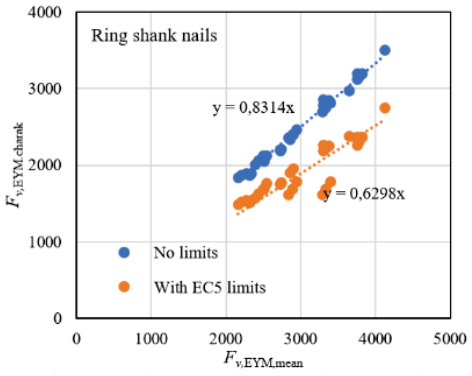

Figure 9: *The characteristic lateral load resistance for nails versus the mean resistance, without and with limits given in Eurocode 5 [2].*

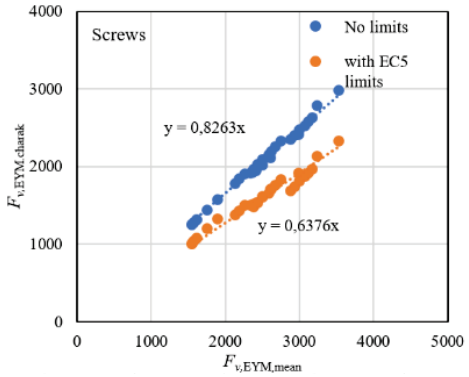

Figure 10: *The characteristic lateral load resistance for screws versus the mean resistance, without and with limits given in Eurocode 5 [2].*

to 0,5 F_D for nails and 1,0 F_D for screws, where F_D is the dowel contribution given in Figure 1. The latter limit is thought to prevent the need for large displacements to reach the estimated resistance but appears rather conservative here since the observed values of F_v used are already limited to 15 mm displacement.

Applying the limitations given in [2]causes a drop as illustrated by the orange points in Figure 9 and Figure 10. The characteristic resistance obtained from Eurocode 5 is seen to end up around 63 % of the mean value.

6.3 OVERSTRENGTH

By overstrength is as stated above understood the factor to arrive from the lower characteristic resistance determined from Eurocode 5 to the real upper characteristic resistance.

In 6.2 is found a factor of 1/0,63 = 1,58 from the characteristic resistance determined form Eurocode 5 to the real mean value and from Table 3 is found that the upper characteristic value is 1,39 times the mean value for a connection if the resistance has a real CoV of up to 20 %. An basic overstrength factor of about 1,58 · 1,39 = 2,2 should therefore be assumed in design.

It is obvious that if the EYM in Eurocode 5 estimate a more accurate (higher) characteristic resistance, the overstrength factor will be smaller.

6.4 SENSITIVITY TO PARAMETERS

The significance of an accurate value of the strength parameters is investigated, assuming the EYM is 'correct'.

For the yield moment the significance is limited. Comparing the EYM results for the two values used for nails, 7500 Nmm and 15000 Nmm, shows that this halving of the yield moment only reduced $F_{v,EYM}$ by 10%.

The steel plate thicknesses ranges from 0,9 mm to 4 mm. The thicker one increases $F_{v,EYM}$ by 7 % compared to the thinner, so again a limited significance.

But if the density is changed by 10%, $F_{v,EYM}$ also change by about 10 %. This is mainly because f_h, is assumed proportional to the density in (2) and f_{ax} is increasing a little more than proportional when $c_{ax} > 1$, see (3).

https://doi.org/10.52202/069179-0194

The low sensitivity to the yield moment and the plate thickness contributes to explains why the CoV in Section 5 does not decrease when using the EYM rather than just correcting for density and length as in Section 4.

6.5 IMPROVEMENT OF THE EYM

Any good model should give a close estimate of the mean value and have a low CoV. The EYM is giving a too low estimate for the mean value and there might be physical phenomenon not taken into account, resulting in a high CoV.

It is obvious that an increase of the rope-effect factor α, will improve the estimate of the mean value, but at the same time a likely source to variability not accounted for by the EYM, is the rope-effect factor α, which might depend on other properties in a more complicated way than assumed now. This is important to understand before the full rope-effect contribution should be used for design. There might also be time dependent issues, even these are more prone to significant impact for larger fasteners.

It is likely that the rope-effect factor will depend on the yield moment and the thickness of the steel plate and the ratios between fastener og plate properties. The rope-effect could, e.g., be higher for thin steel plates than for thick, so the small gain from a thick plate in the dowel contribution is lost again in the rope-effect contribution.

Sørensen [11] noted that the rope-effect consists of two contributions, the component of the axial load in the fastener in the direction of the external load and the friction between the members as they are pressed together by the axial load. The photos in Figure 11 illustrates that the withdrawal resistance might not be the correct measure for the axial load in the fastener when approaching the ultimate load since there are gaps between the fastener and the timber. Sørensen suggested that the axial load could depend on friction between the fastener and the timber rather than the withdrawal resistance. These phenomena were dealt with already by Johansen [12] and Meyer [13], and further by Svensson & Munch-Andersen [16], [17].

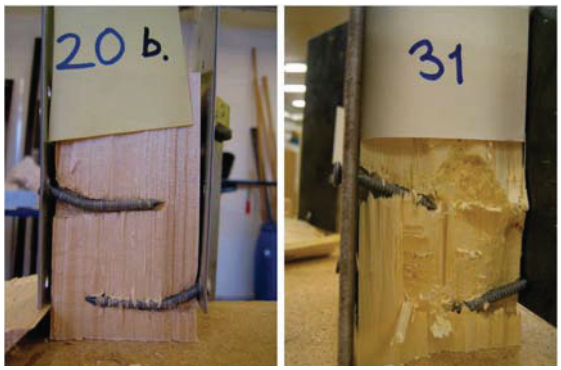

Figure 11: *Observed failure modes. Left, a normal nail, where a hinge is formed in the timber. Right, a hardened nail, where no hinges are formed, even the steel plate is 4 mm thick. [11].*

7 CONCLUSIONS AND FUTURE WORK

The EYM (Euorpean Yield Model) as intended in Eurocode 5 [1] seems to give a good estimate for the dowel-effect contribution F_D to the lateral resistance F_v, but there is a significant reserve when estimating the characteristic lateral load resistance $F_{v,k}$ using the EYM (European Yield Model) as intended in Eurocode 5 [1], [2]. The main reason is that the rope-effect contribution revealed by tests is significantly higher than considered in the code, also in the draft for a new Eurocode 5 [1].

This reserve is to some extent needed to account for e.g. shrinkage and to limit displacements, but it seems larger than necessary. Besides the unnecessary costs and uses of resources it complicates the design when the upper value of the resistance is needed for design, typically when designing for earthquake, where failure need to occur as hinges in the fasteners, and for robustness when the segmentation principle is used and the connection should act as a fuse, halting the collapse.

The overstrength factor – the gap from the lower characteristic resistance estimated from Eurocode and up to the real upper characteristic resistance determined from tests – is estimated to be about 2,2 for the investigated steel to timber connections with small diameter fasteners. This provides that the timber used is not stronger than anticipated. If, e.g., the densities are as for C30 and not as for C24 as assumed in the design, the overstrength factor will increase about 8 % to 2,4. A general factor probably needs to take such a possibility into account.

The rope-effect contribution is limited by fractions of both axial tension resistance and the dowel resistance, see 6.2. Both limits need to be increased if a higher utility of the real resistance of should be allowed. As mentioned, a purpose of the limit seems to be to limit the deformations, which might be reasonable, but the observed resistances used for this study is already limited to 15 mm in accordance with EN 1380 [5], so further limitations should not be necessary to ensure an acceptable deformation at the characteristic resistance.

It should also be noted that when using tests according to EN 1380, e.g. via an EAD and ETA, the 15 mm limit is the only one applying, thus making it quite unattractive to uses the EYM compared to testing.

In further studies focus should be on correct estimate for the rope-effect. One tool would be to examine the displacements during loading more closely – data are available for the tests this study is based on, but not yet used. For Series 40 [11] the actual failure mode is also registered, which should be compared to the prediction from the EYM. Figure 11 might indicate that a fastener with a high yield moment (so it does not form hinges) might need larger displacement to reach its maximum resistance than if the yield moment is lower.

STRENGTH CHARACTERIZATION OF OVERLAPPED TIMBER SCREWS

Luca Marchi[1], Davide Trutalli[1], Luca Pozza[2], Roberto Scotta[1]

ABSTRACT: The possibility of transmission of axial forces between self-tapping screws fastened in the opposite faces of a timber element and loaded contrariwise is analysed. The screws are intended to be placed sufficiently close one to another and the threaded shanks overlapped by a suitable length. Experimental tests are conducted, varying type, penetration depth and overlapping length of the screws, to evaluate the actual strength and the type of failure of this fastening technique.

KEYWORDS: Self-tapping screws, Withdrawal capacity, Overlapping length, Withdrawal tests

1 INTRODUCTION

The choice of type and arrangement of steel connections to realize timber joints plays a key-role in the capacity of timber structures.

Full-threaded Self-Tapping Screws (STS) are generally used to strengthen a timber element or to connect two or more timber components of a structure, taking advantage of their high axial strength [1]. The increasing interest in such technique is due to its effectiveness since these screws are fast to be installed and do not always require pre-drilling of the timber element. Examples are available in [2–5].

Recent works confirmed that particular attention must be paid to the design of spacing and edge distance to avoid anticipated brittle failures in the timber element, either for solid wood or laminated timber products (e.g., block shear failure, tension orthogonal to the grain) [6].

The ongoing revision of Eurocode 5 [7], based on detailed works recently published in the literature, aims to provide a design toolbox for the practitioners, which helps them in dealing with the design of modern fasteners with different anchoring materials [8].

To this aim, this work analyses the transmission of axial forces across a glued laminated timber element by means of pairs of STS fastened on the opposite faces, placed sufficiently close one to another and with a suitable overlapping length. The screws are installed with a spacing lower than the one required by current European Code [7]. The aim is to analyse, by means of experimental tests, the increased/decreased capability of transmitting axial forces between the screws through the timber member with such particular arrangement.

2 MATERIALS AND METHODS

Experimental tests were performed at the laboratory of Material testing of the University of Padova exploiting a universal testing machine.

2.1 TEST SETUP

Two couples of the same type of screws (four screws in total per single test) were simultaneously pulled contrarywise by means of a proper symmetric pulling configuration, designed, and realized to avoid possible eccentricities of loads (Figure 1). Two steel C-beams reinforced on both webs and flanges with 100-mm steel plates accommodated specifically designed millings that were able to provide a sufficiently rigid pulling force on the screw's head. Specific washers were designed to fit with the screw's countersunk heads avoiding local damages during the pulling tests. Tests were performed according to the load protocol of EN 26891:1991 [9]. Displacements were measured by placing one potentiometer place in proximity to each of the four screws.

Insertion of the screws close to verticality was assured by predrilling the wooden sample with a 5-mm drill bit up to a depth of 60 mm. Then, STS were pre-installed on the glulam samples, leaving a gap between the head and the surface to allow the positioning of the sample between the supporting U-shape beams. Once in place, a torque wrench was used to tighten the screws and provide direct contact between each of the four screws heads with the tensioning steel frame. Pretension on the STS was avoided through real-time reading of the load cell installed on the testing machine.

In addition, withdrawal tests of single STS according to EN 1382:2016 [10] were taken as reference for comparative purposes (Figure 2).

https://doi.org/10.52202/069179-0195

A total of 35 tests were performed, 30 of which for testing the overlapping conditions and 5 as reference for the withdrawal capacity. Average and characteristic values of all the main mechanical parameters were calculated according to EN 14358:2016 [11].

Figure 1: *Test setup: load transfer*

Figure 2: *Test setup: withdrawal capacity*

2.2 SPECIMEN CHARACTERISTICS AND MATERIALS

Specimen design aimed to obtained a balanced solution between observing a failure governed by the screws withdrawal and failure due to excessive tension orthogonal to the grain. By varying the overlapping length failure should occur between the two possibilities.
Tests involved the use of carbon steel fully-threaded STS fastened to glulam timber samples. Three key parameters were considered in the definition of the test campaign, namely:

- dependency on the overlapping length of the STSs l_o: reference values were 60, 100 and 140 mm or *6d*, *10d* and *14d*;
- dependency on the total penetration length of the STSs l_{eff}: reference values were 130, 150 and 170 mm;
- Alignment between each couple of STS: parallel or perpendicular to the grain direction.

Although the screw's nominal diameter *d* should was potentially an essential variable to be analysed, it was not included in the parametric test: a fixed nominal diameter equal to 10 mm was considered as a good compromise to investigate the load transmission phenomenon while keeping the dimensions of the timber specimens sufficiently small to be manipulated in the testing machine while respecting the provisions on minimum edge distances reported in Eurocode 5 [7]. In detail, dimensions equal to 32x10x20 cm and 28x20x20 cm were chosen for the test in the parallel and perpendicular to grain screws layout (Figure 3). Spacing between the two opposite facing screws was set at a constant value of $2d = 20$ mm. All glulam specimens were cut from two beams having a cross-section of 20 x 28 cm and a certified strength class equal to GL24h [12]. At the age of the tests, all specimens were correctly dried, and each wood sample was assessed with a pin-type digital hygrometer; an average moisture content of 13.97% was measured, thus slightly above the reference value of 12.00%. Wood density was also extrapolated by weighting and measuring each sample, resulting in an average value equal to 431.59 Kg/m³.
Details on specimen nomenclature and relative characteristics are reported in Table 1.

2.3 ANALYTHICAL CALCULATION

Values of the experimental resistance were compared with the analytical load bearing capacity. For the comparison, both the equation reported in the homologation document of the producer [13]:

$$F_{ax,\alpha,Rk} = n_{ef} \cdot k_{ax} \cdot f_{ax,k} \cdot d \cdot l_{ef} \cdot (\frac{\rho_k}{350})^{0,8} \qquad (1)$$

and the one included in Eurocode 5 [7] were used:

$$F_{ax,\alpha,Rk} = \frac{n_{ef} \cdot f_{ax,k} \cdot d \cdot l_{ef}}{1,2cos^2\alpha + sin^2\alpha} \cdot (\frac{\rho_k}{\rho_s})^{0,8} \qquad (2)$$

In the computation, the characteristic withdrawal parameter $f_{ax,k}$ and the factor k_{ax} were respectively set equal to 10.5 N/mm² and 1.0 according to [13]. The characteristic tensile load bearing capacity of the steel $f_{tens,k}$ was equal to 25kN [13].
Finally, the characteristic strength orthogonal to the grain $f_{i90,k}$ for the timber necessary to compute the load capacity $F_{t,90,k}$ of the specimen was set equal to 0.5N/mm².

3 RESULTS AND DISCUSSION

Table 2 reports in summary the maximum pulling load F_{max} obtained from each test as well as average and characteristic values $F_{test,m}$ and $F_{test,k}$.
Three failure modes were evidenced during the experimental tests: screw withdrawal, wood failure for tension orthogonal to the grain or rolling shear. Results shows that for both l_{ov} equal to 100 and 140 mm, when STS were arranged parallel to the grain, force transmission could be mostly ensured thus avoiding the premature splitting of wood. In both configurations, in eight out of ten trials failure was governed by the withdrawal of the STS. The only difference observed was was that for the higher l_{ov}, failure was due to rolling shear rather than tension orthogonal to the grain.
For the lowest l_{ov} of 60 mm, failure on the timber side was mostly happening. This explains why tests on configuration 60-90, namely the ones with the smallest transfer capability, were interrupted before the completion of the series (Table 2).

3.1 LOAD VS. DISPLACEMENT CURVES

Figure 4 reports the curves obtained from the withdrawal tests of the STS according to EN 1382:2016 [10].
Figure 5, Figure 6 and Figure 7 show the load vs. displacement curves obtained from the tests of specimens with l_{ov} equal to 60, 100 and 140 mm respectively. Load refers to a couple of STS, i.e., the total load measured from the load cell divided by two. Displacement is the average displacement calculated from the four potentiometers.

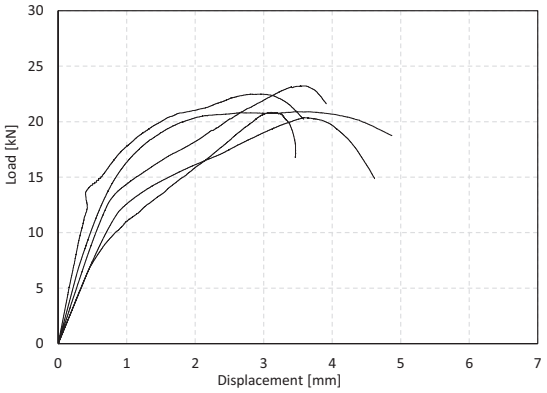

Figure 4: *Load vs. displacement curves of the withdrawal tests according to EN 1382:2016 [10]*

The seldom presence of a red cross at the end of a curve indicates that failure ended with premature failure of the

https://doi.org/10.52202/069179-0195

wood. As a reference, theoretical limits computed for the withdrawal capacity $F_{ax,Rk}$ of the STS and the resistance of timber orthogonal to the grain $F_{t,90,k}$ are also plotted. Additionally, By observing the curves, it emerges the sudden brittle behaviour of wood failure which clearly anticipates the withdrawal of the STS, and that opposes to the typical smooth curve that characterizes failure due to withdrawal.

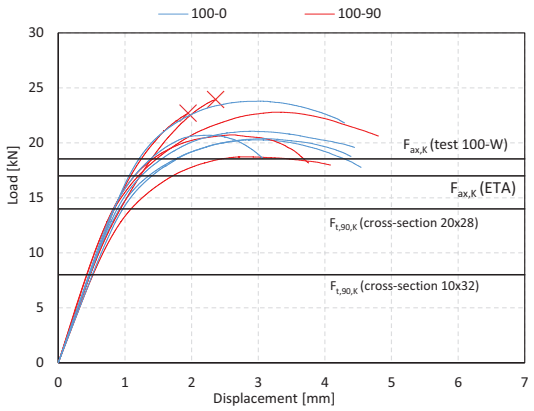

Figure 5: *Load vs. displacement curves with l_{ov} = 60mm*

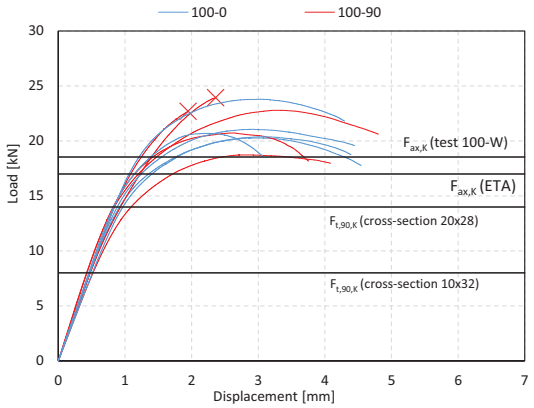

Figure 6: *Load vs. displacement curves with l_{ov} = 100mm*

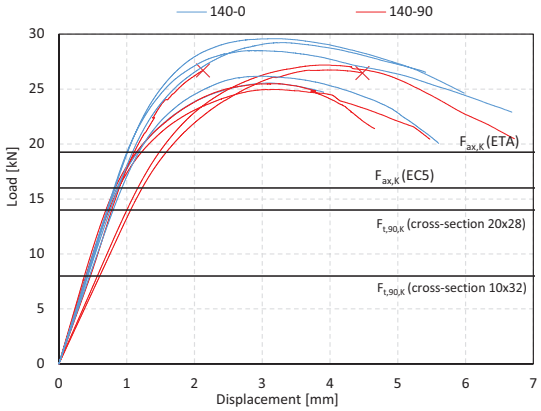

Figure 7: *Load vs. displacement curves with l_{ov} = 140mm*

3.2 FORCE COMPARISON

Figure 8 summarizes the results in terms of characteristic load bearing capacity between analytical and experimental values extrapolated for the three different values of l_{ov}.

The intermediate overlapping length (l_{ov} = 100 mm) can be retained the reference point from where to start comparing the data as the comparison includes also the reference values of $F_{ax,Rk}$ *(test W)* obtained from the withdrawal tests. In this configuration, the joint was almost able to completely exploit the capacity of the STS without incurring into premature brittle failure of the wooden medium. Comparable values of $F_{test,k}$, $F_{ax,Rk}$ (ETA) and $F_{ax,Rk}$ (Test) demonstrates it.

This phenomenon gains more evidence for the configuration analysing the maximum overlapping length (l_{ov} = 140 mm) were $F_{test,k}$ was consistently higher the $F_{ax,Rk}$ calculated from the homologation document (+22.1%). On the opposite, the lowest overlapping length (l_{ov} = 60 mm), did not allow a sufficient load transmission between the couple of STSs, as can be seen by comparing the $F_{test,k}$ with the $F_{ax,Rk}$ calculated from the homologation document (-14.7%).

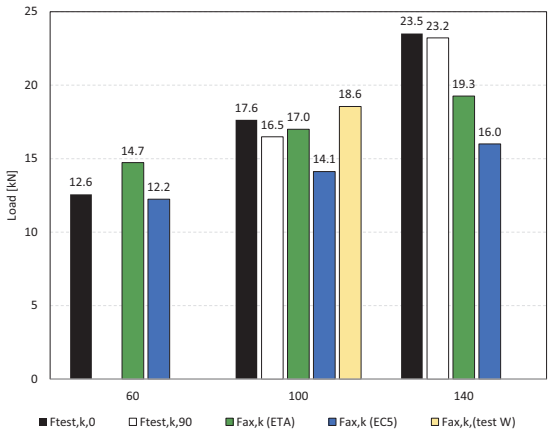

Figure 8: *Comparison of the analytical and experimental load bearing capacity for different l_{ov}*

3.3 FORCE TRANSMISSION IN WOOD

Specimens involving a withdrawal failure were cut along the vertical plane containing the couple of STSs for a detailed visual inspection. Figure 9 and Figure 10 shows the different behaviour of the wood grain in case of STS arrangement parallel and perpendicular to the grain respectively. In the first case, it can be observed how the couple of screws involve the wood fibres between them which, given the short distance, worked in predominant shear. Observing the wood fibres near the screws but on the opposite direction it is also clear the length of the fibres involved in the resisting model during the screws withdrawal.

In the second case, it is clear how no transfer between the overlapping length is visible. The orthogonal alignment of the wood fibres does not allow any interaction between the screws and force transmission is given only by the wooden medium, leading to frequent premature of the

https://doi.org/10.52202/069179-0195

timber element when splitting resistance is lower than the screws withdrawal capacity.

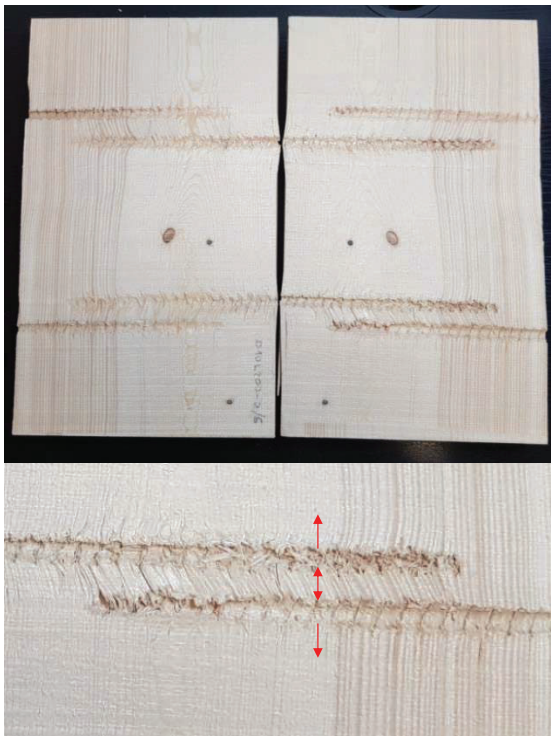

Figure 9: *Inspection of wood grain deformation on specimen 140-0/5 after withdrawal failure*

Figure 10: *Inspection of wood grain deformation on specimen 100-90/5 after withdrawal failure*

4 CONCLUSIONS

In this work, the possibility of transmitting axial forces between screws through the timber element, by partially overlapping the threaded parts was analysed.
Results from experimental tests, varying both the penetration and the overlapping length, showed that only a balanced configuration between effective penetration length (i.e., withdrawal capacity) and overlapping length allowed to transmit high axial forces without incurring into brittle failures of the wooden medium.
Future works may extend the studied configurations to different screws nominal diameters, different spacing between the opposed screws and possibly different screws as well.

ACKNOWLEDGEMENT

The authors would like to thank Eng. Alessandro Rubini for the help in performing the experimental tests during the development of his master thesis.

MEASUREMENT OF AXIAL FORCE OF SCREWS FOR SPLIT REINFORCEMENT AT TIMBER-STEEL-TIMBER DOWEL JOINT

Kenji Kobayashi[1], Keita Ogawa[2]

ABSTRACT: In this study, joint shear test of timber-steel-timber dowel joint was performed by changing the cross-sectional dimensions of the member, the position and the number of the self-tapping screws for reinforcement. The axial force of the screw was measured using a strain gauge which is placed in the centre of the screw, and the influence of the position and the number of the screws in lateral tensile force was confirmed.

Ultimate displacement became higher by using screws for reinforcement. In Pre-Divided (PD) test specimens, the ultimate displacement was equivalent to that of SR specimen by using two screws per shear plane. It was confirmed that the measured axial force in PD test specimen corresponds to the load axial force after the split occurs. When using two screws, closer screw to the dowel mainly resist to lateral tensile force. The ratio of lateral tensile force changes as the displacement progresses. Total lateral tensile load exceeded 30% of joint shear load in PD specimens.

KEYWORDS: Split reinforcement, Dowel joint, Axial force

1 INTRODUCTION

Timber-steel-timber dowel joint is generally used in large scale timber structures. Ductile behaviour can be ensured by bending deformation of a dowel and embedment at timber member under lateral loading. On the other hand, depending on the conditions of the joint, timber member easily splits due to the lateral tensile stress caused by the dowel, and sufficient ductility cannot be obtained. To prevent splitting failure, it is effective method to insert full-threaded self-tapping screws near the dowel.

Schmid [1] and Bejtka [2] proposed the theoretical models to calculate the force generated in the reinforcing screw. It is proposed that reinforcement elements should be designed to resist 30% of the load transferred by each dowel-type fastener and shear plane [3]. But it is still uncertain how much axial force occurs to reinforcement screws.

Wolfthaler et al. [4] tried to measure the axial force generated in the screw for splitting reinforcement by implementing a strain gauge in the screw. As a result, depending on the conditions, an axial force larger than 30% is generated, and it is pointed out that the load on the screw located at the end of the multiple dowel joint was particularly large. However, the measured axial force is not the same as the transverse tensile force generated at the joint because it is considered that not only the screw but also the wood transfers the lateral tensile force. Furthermore, the effects of the cross-sectional dimensions of the member and the driving position of the screw are also unknown.

In this study, joint shear test of timber-steel-timber dowel joint was performed by changing the cross-sectional dimensions of the member, the position and the number of the self-tapping screws for reinforcement. The axial force of the screw was measured using a strain gauge which is placed in the centre of the screw, and the influence of the position and the number of the screws in lateral tensile force was confirmed.

2 MATERIALS AND METHODS

2.1 Materials

Sugi glulam of strength grade E65-F255 [5] was used for side member. The dimensions of the specimen were 582 mm in length and 105 mm in width, and the thickness t was 45, 75, and 105 mm on each side. A steel plate with thickness of 9mm was used for central member. A steel dowel was used to connect timber and steel plates and the diameter was 16mm. Full-thread screws (pane-lead X, Synegic co. ltd.) were used for split reinforcement. A picture of the screw is shown in Figure 1. A strain gauge (BTM-6C, Tokyo Measuring Instruments Lab.) was implemented in the centre of the screw to obtain the axial force during the joint shear test. The relationship between strain and axial force in each screw was obtained in advance.

2.2 Test setup

The list of test conditions is shown in Table 1. The first number in each type name indicates the thickness of one side of the specimen. Three thicknesses of 45mm, 75mm, and 105mm were selected. The following symbols represent the reinforcement conditions. Test setup of each reinforcement condition is shown in Figure 2. There were three types of test specimens. Non-reinforced test specimens (hereinafter referred to as NR) has no reinforcement screws and only timber resists to lateral tensile forces. Screw reinforcement test specimens (hereinafter referred to as SR) has one or two reinforcement screws around dowel joint part. At pre-divided test specimens (hereinafter referred to as PD), the glulam was divided into two in the width direction at the center of the dowel, and they were connected by screws so that the lateral tensile stress generated by the dowel during the test is transferred only by the screw. One or two screws were inserted on each side, which is the same as that of SR specimens. The position of the screw is shown in Figure 3. The screws were placed symmetrically on each member. At the test specimen with one screw, self-tapping screw was driven into the position A in the figure. Distances between dowel centre and the position A was 3*d* (*d*: diameter of the dowel). This value was determined to avoid touching the dowel to the screw during the test. Distances between shear plane and the position A was 1.5*d*. At the test specimens with two screws, self-tapping screws were driven into the positions of AB, AC, and AD, respectively. Distances between dowel centre and the position B was 5*d* and two screws are located parallel to the grain. Distances between shear plane and the position B was 3*d* and two screws are located perpendicular to the grain. Position D was located on the unloaded side and the distance was 1*d* to get as close as possible to the dowel.

The upper part of the specimen was fixed to a steel plate with a thickness of 12 mm using a bolt with a diameter of 24 mm A steel plate with a thickness of 9 mm was connected to the lower part of the specimen by a dowel with a diameter of 16 mm. Therefore, there is a total gap of about 3 mm in the lower part of the specimen. Arrangement of the dowel was determined based on the standard of Architectural Institute of Japan [6].

The relative displacement between the main material and the side material was measured with a displacement transducer SDP-

100C (Tokyo Measuring Instruments Lab.). The axial force was obtained from the strain measured during the joint shear test. In the test, a monotonous load was applied in the tensile direction, and the test was stopped when the load dropped to 80% or less of the maximum load after the maximum load was applied, or when the displacement reached 30 mm.

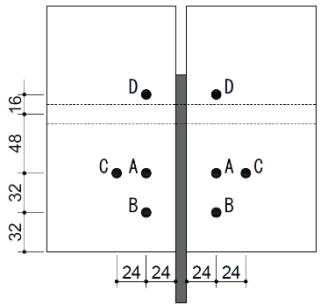

Figure 3: *Position of reinforcement screws*

3 RESULTS AND DISCUSSION

3.1 Failure pattern

Figures 4-5 show examples of failure patterns of NR and SR specimen after the test. In the NR specimen, failure due to row shear and splitting was observed. In the SR specimens reinforced with a single screw, the rate of failure due to splitting and row shear decreased, and the shear displacement of the joints until failure increased. In the SR specimen using two screws, no shear failure or splitting failure occurred in the wood even when the displacement exceeded 30 mm.

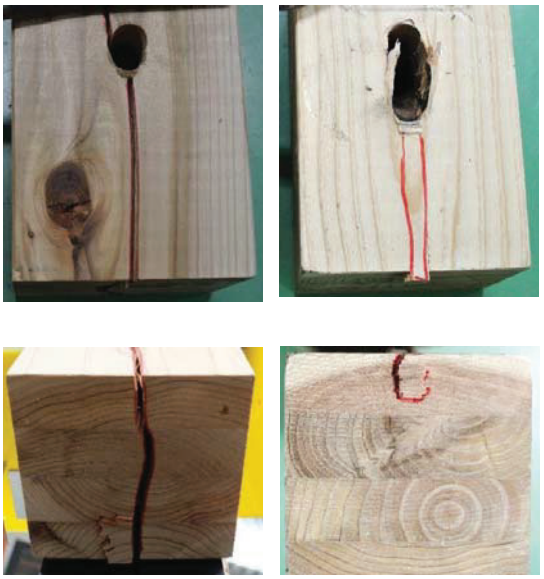
Figure 5: *Failure of specimens with the thickness of 75mm*



105-NR *105-SR-A*

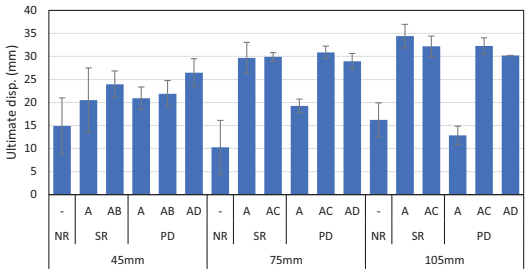
Figure 6: *Failure of specimens with the thickness of 105mm*

3.2 Ultimate displacement

Figure 7 shows a comparison of the ultimate displacements under each condition. By screw reinforcement, the average value of ultimate displacement increased by 37 to 60% in the SR test specimen with a thickness of 45 mm, 188 to 190% in the test with a

https://doi.org/10.52202/069179-0196

thickness of 75 mm, and 98 to 112% in the test with a thickness of 105 mm compared to NR test specimens. At thicknesses of 75 mm and 105 mm, the ultimate displacement was 30 mm or more. Most of the specimens were not failed and the loading was stopped.
In PD test specimens, the ultimate displacement was not improved by one screw in the test specimens with thickness of 75 mm and 105 mm. The deformation performance equivalent to that of SR specimen was obtained by using two screws.



c

Figure 7: *Comparison of ultimate displacement*

3.3 Axial forces measured by screws

As an example of the measurement result of the axial force acting on the screw, the result of the matching test specimen of 45-SR-A and 45-PD-A is shown in Figure 8. PD specimens showed slightly lower load-bearing capacity than SR specimens. At the moment of cracking, the shear load decreased slightly, while the axial force on the screw increased immediately. Similar behaviour was also reported by Wolfthaler et al [3]. In 45-SR-A test specimen, it was confirmed that the axial force increased with the occurrence of splitting.
On the other hand, in 45-PD-A test specimen, the axial force increased immediately after the load was applied. Since the axial force is almost the same after the split occurs in the main materials on both sides, it can be said that the measured axial force in PD test specimen corresponds to the load axial force after the split occurs.

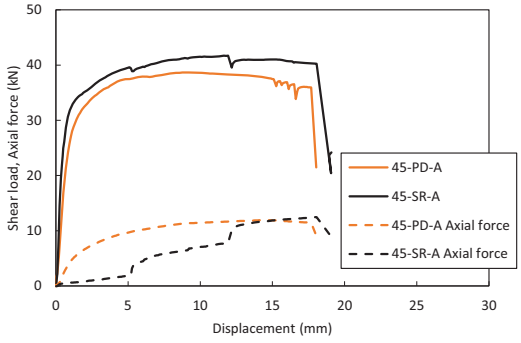


Figure 8: *Load-displacement relationship of 45-SR-A and 45-PD-A*

Ratio of average total axial force of screw on each type to shear force is shown in Figure 9. Axial loads decrease at 45-SR-A and PD-A specimens with all thickness. In these specimens, the number of screws was not enough and withdrawal of screw was observed. At PD specimens with two screws, total axial force finally reached around 30~40% of joint shear load in PD specimens. On the other hand, final axial load was about 10% at SR specimens with two reinforcement screws. This tendency was similar between specimens with different thickness.

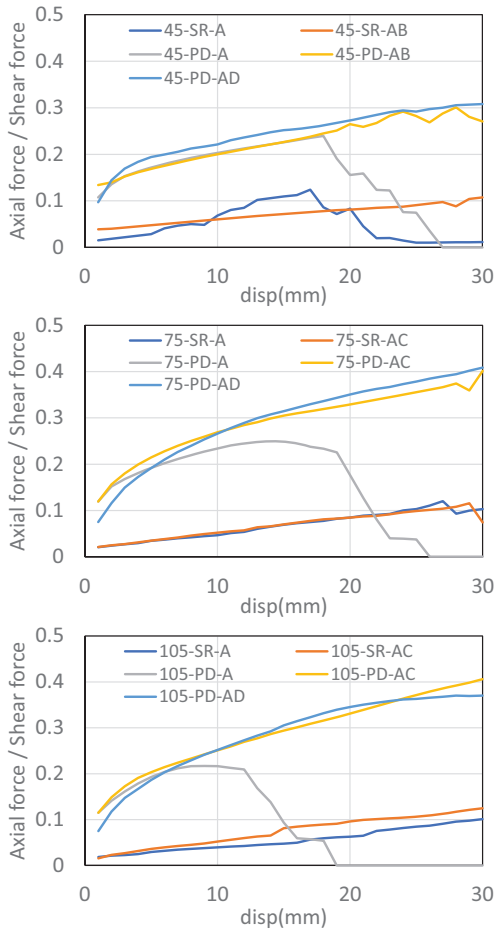

Figure 9: *Ratio of average total axial force of screw on each type to shear force*

Ratio of axial force of screw at each position to shear force is shown in Figure 10. In the reinforced type with one screw, both the shear load and the axial force decreased in the 75mm and 105mm thickness series. This is because the strength of the reinforcing screw was insufficient, and the screw was pulled out, leading to destruction. In the reinforcement type with two screws, no fracture accompanied by a decrease in axial force was observed. In the test type with a thickness of 45 mm, when the driving position was AB, the axial force of B was slightly higher at the initial stage of deformation, but as the

https://doi.org/10.52202/069179-0196

deformation progressed, the screw of A showed higher axial force. Ultimately, the A screw bears a lateral tensile force that is 1.5 times greater than that of the B screw. On the other hand, when the driving position is AD, most of the lateral tensile force was borne by screw A at the initial stage of deformation, but in the end, screw D also borne nearly half of the lateral tensile force.

In the test type with a thickness of 105 mm, when the driving position is AC, although the axial force of screw A, which is closer to the sheared surface, showed a slightly higher axial force, there is a difference from screw C and the axial force tends to increase as deformation progresses. It was mostly the same.

A common point in all measurement results is that the load ratio and distribution of the axial force are nonlinear, and it is difficult to determine a single value with a simple dynamic model. It suggests the need for a model that considers the nonlinear behaviour of wood due to Dowel's local bearing pressure and changes in stress distribution.

Fig. 5 shows the ratio of axial force of screw at each position to shear force in PD test specimens. It was confirmed that the screw position A mainly bears the axial force. The axial force at position C was slightly smaller than the axial force at position A, and a screw at position D initially showed a negative axial force in 105-PD-AD specimen.

Total axial force finally reached about 30-40% of the shear force in PD specimens. Axial force of 30% of shear force was sufficient to ensure the deformation performance of the joint even if the contribution of tensile stress perpendicular to the grain was ignored.

4 CONCLUSION

- Ultimate displacement became higher by using screws for reinforcement. In Pre-Divided (PD) test specimens, the ultimate displacement was equivalent to that of SR specimen by using two screws per shear plane.
- It was confirmed that the measured axial force in PD test specimen corresponds to the load axial force after the split occurs.
- When using two screws, the closer screw to dowel mainly resist to lateral tensile force. The ratio of lateral tensile force burden changes as the displacement progresses.
- Total lateral tensile load exceeded 30% of joint shear load in PD specimens.

RIGID GLULAM JOINTS TO CONCRETE ABUTMENTS WITH GLUED-IN STEEL RODS

Kai Simon[1], Simon Aicher[2]

ABSTRACT: It is reported on rigid moment and shear force resistant connections of glulam to concrete or steel abutments based on glued-in steel rods. The connections are especially meant for clamped columns and integral bridge decks and wide-span end-clamped floors. In order to prevent premature splitting failure of the joint and to enforce a rather even shear force distribution on spaced rods the issue of lateral joint reinforcement by self-tapping screws or/and glued-on plywood panels is emphasized. The proposed design equations are calibrated by results of an extensive experimental campaign, revealing that the new Eurocode EC5-1-1 is overly conservative regarding lateral forces and respective normal force interaction. It is revealed case study-wise that the investigated rigid joint configurations present superior rotational stiffness and load capacities vs. today´s primarily employed mechanical fastener solutions with slotted-in steel plates or grout embedment of the GLT column in bucket foundations. The study demonstrates a technically competitive and environmentally advantageous timber solution vs. precast concrete columns. It offers new options for hybrid timber-concrete applications for timber bridge decks and clamped wide-span floors.

KEYWORDS: rigid glulam connections, moment and shear force resistant joints vs. concrete abutments, lateral joint reinforcement, self-tapping screws, glued-on plywood panels, clamped columns, bridge decks and floors, hybrid timber-concrete joints

1 INTRODUCTION

Today moment and shear force resistant connections of glulam (GLT) beams to concrete abutments, mainly occurring with columns, are realized by slotted-in steel plates fixed by dowel type fasteners. In order to achieve a high rotational stiffness, the steel "swords" have to be rather long altogether with a high number of dowels (Fig. 1a). Alternatively, the GLT column foot can be directly grouted in bucket foundations (Figure 1b). Both alternatives do not represent a practical construction method in case of rigidly jointing horizontally oriented beams for a timber bridge deck or a wide-span timber floor slab (Figure 1d). Rigid joints based on glued-in steel rods cast-in or screwed to RC abutments present a powerful tool to solve this connection task. Assets beyond high load capacity and stiffness consist in high fire resistance due to the hidden steel bars, minimized corrosion potential and less/no timber durability hazard of the joint due to protection from free or condensation water. A further asset of rigidly clamped column bearings consists in the creation of frame-type construction solutions, leading to reduced efforts in bracing especially at irregular spacings of columns in open space wide-span timber floor systems.

2 TECHNICAL CHALLENGE

The potential of rigid joints in glulam and LVL by glued-in rods is evident from numerous research work, increasing numbers of use in timber construction works and hence its consideration in the presently drafted new Eurocode 5-1-1 [1]. Today such joints are mostly used for timber to timber connections. Hybrid timber to steel joints based on glued-in rods exist (e.g. Figure 2) however are rare (e.g. [4; 5]). The assets of axially loaded steel rods glued-in parallel or inclined to wood fiber direction is widely acknowledged and sufficiently covered by commonly agreed-on design rules. However, in moment-rigid joints, e.g. at a clamped column basis lateral rod

https://doi.org/10.52202/069179-0197

forces resulting from shear force and torsional moment and their interaction with axial forces has to be considered, too. Lateral rod forces induce tensile stresses perpendicular to grain in the end grain area, which can lead to crack formation parallel to the rod axis at low load levels in case the rod distance to the loaded edge $a_{4,t}$ is small. The lateral force resistance of glued-in rods, as addressed now in [1], clearly represents a rather worst-case scenario of a rod positioned very close to the loaded edge. A previous more plausible and economically advantageous design approach has been dropped ([2] and [3]).

In order to prevent premature crack formation by lateral forces the joint has to be adequately reinforced perpendicular to grain. At present it is unknown which type of reinforcement is the best option and to what extent it increases the load capacity and stiffness of the joint. These questions set the frame for the reported research work which aims to provide ready to use joint construction and design solutions.

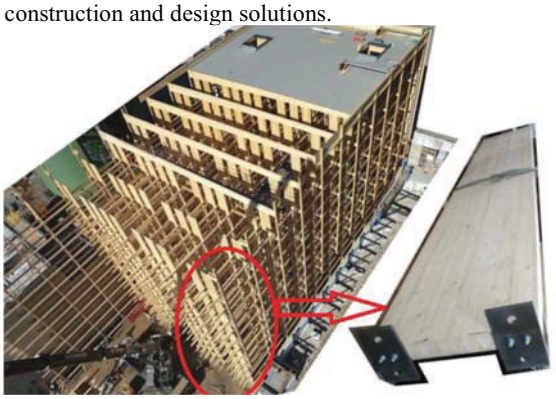

Figure 2: *Example of a timber high bay racking built by Kaufmann Bausysteme GmbH, Reuthe, Austria, in 2007 consisting of clamped columns connected by glued-in steel rods [4]; the joint behaviour and capacity were verified at MPA Stuttgart.*

3 GLUED-IN RODS: STATE OF THE ART

3.1 GENERAL

Research on glued-in steel rods dates back to the 1970ies [5; 6]. The investigations focussed on load capacity of the joints subjected to different loading modes and apt adhesives to enable strong and durable joints. Compilations of previous research, although not exhaustive can be found in [7]. Execution and design of glued-in rods was firstly standardized in DIN 1052:2004 [8] and DIN EN 1995-1-1/NA [9] in conjunction with nationally approved adhesives [10-13]. Based on increased knowledge and built heritage glued-in rod connections have now been incorporated in the draft of Eurocode 5-1-1 [1] referencing EN 17334 [14] with regard to testing and qualification of 2-component adhesives for glued-in rod applications.

3.2 AXIAL LOADING

The literature on axially loaded rods glued in glulam parallel to fiber is vast, e.g. [2; 6; 7; 15-17]. The latest European design proposal for axially loaded rods stated in prEN 1995-1-1 [1] is closely related to specifications given in DIN EN 1995-1-1/NA [9]. The European design equation for the characteristic axial capacity $F_{ax,Rk}$ of a single glued-in steel rod parallel to fiber with bonded-in length l_w reads

$$F_{ax,Rk} = min\begin{Bmatrix}\pi \cdot d \cdot l_{w,ef} \cdot f_{w,k} \\ E_s \cdot A_s \cdot \varepsilon_{u,timber}\end{Bmatrix} \leq F_{t,k} \qquad (1)$$

where

d	nominal diameter of the rod
$l_{w,ef}$	effective withdrawal length as minimum of: l_w; 40·d; 1000 mm
$f_{w,k}$	characteristic withdrawal (shear) strength of the bond line acc. to [1; 9] or e.g. Z-9.1-705 [10]
E_s	modulus of elasticity of the steel rod
A_s	nominal stress area acc. to EN ISO 898-1 for threaded rods and acc. to EN 10080 for ribbed steel bars
$\varepsilon_{u,timber}$	failure strain of timber parallel to grain (= 2,4 ‰ for softwood)
$F_{t,k}$	characteristic tensile resistance of the steel rod (see [1])

Figure 3 depicts the relationship of $f_{w,k}$ with bond / withdrawal length l_w for configurations of rods bonded parallel to fiber as specified in [1; 9]. Further, test results with various slenderness rod ratios and different adhesives presented in [7] are shown.

Spacings and edge distances of axially glued-in rods are specified in [1] as $a_2 = 5 \cdot d$ and $a_{4,c} = 2.5 \cdot d$, see Figure 4.

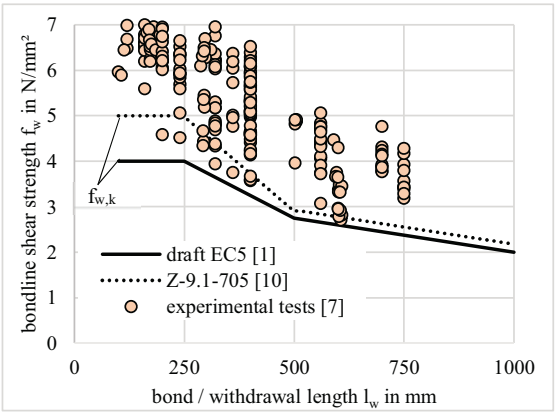

Figure 3*: Bond line withdrawal / shear strength of axially loaded steel rods glued-in parallel to fiber in softwood GLT depending on withdrawal i.e. bond length l_w from test results [7] and design rules acc. to draft EC5 [1] and Technical approval [10]*

https://doi.org/10.52202/069179-0197

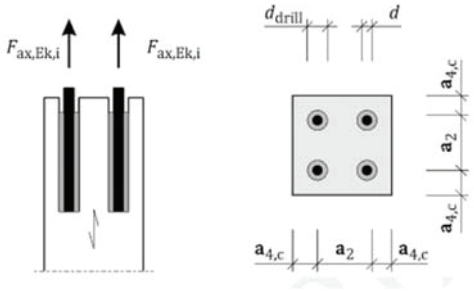

Figure 4: *Notations of spacings and edge distances of axially loaded steel rods glued-in parallel to GLT fiber*

3.3 LATERAL LOADING

Figure 5 shows the basic lateral force resistance behaviour as dependent on the distance to the loaded edge $a_{4,t}$ (see Figure 6) as obtained in former tests by Riberholt in 1977 [15], Möhler and Hemmer in 1981 [16] and then by Blaß and Laskewitz in 2001 [2]. The depicted results represent a test configuration of GLT with metrically threaded glued-in steel rods with a diameter d and bond length l_w of 16 mm and 320 mm (= 20 · d), respectively. A design model by Blaß and Laskewitz [2] based on a calculation model for splitting perpendicular to grain by Ehlbeck et al. [3] which describes the increasing load carrying capacity for larger distances $a_{4,t}$ quite well (see dotted line in Figure 5), was not considered in a standard. Instead the design model presented by Riberholt in 1988 [17] was established in DIN 1052:2004 [8] and later in the German Annex of Eurocode 5 [9]. The design model is based on the Johansen yield model [18] for dowel-type steel fasteners. With regard to splitting perpendicular to grain the model stipulates a minimum distance $a_{4,t} = 4 \cdot d$ to the loaded edge but doesn´t consider any capacity increase for larger edge distances. The most recent European design equations for the lateral load carrying capacity of rods glued-in GLT parallel to grain acc. to prEN 1995-1-1 are

$$F_{lat,Rk} = min \begin{cases} d \cdot f_{h,k} \left(\sqrt{(l_h + 2e)^2 + {l_h}^2} - l_h - 2e \right) & \text{(2a)} \\ d \cdot f_{h,k} \cdot \left(\sqrt{e^2 + \frac{2M_{y,k}}{d \cdot f_{h,k}}} - e \right) & \text{(2b)} \end{cases}$$

where

d	nominal diameter of the glued-in rod
l_h	embedment depth ($l_h = l_w$)
e	distance between load and bond line ($e = l_{can}$)
$M_{y,k}$	the characteristic yield moment of the rod specified as

$$M_{y,k} = 0{,}3 \cdot f_{u,k} \cdot {d_e}^{2,6} \quad (3)$$

where

d_e	the equivalent tensile stress diameter for rods with metric thread
$f_{u,k}$	characteristic tensile strength of steel rod

and the characteristic embedment strength

$$f_{h,k} = 0{,}1 \cdot \frac{0{,}082 \cdot (1 - 0{,}01 \cdot d_{drill}) \cdot \rho_k}{k_{mat}} \quad (4)$$

where

d_{drill}	the drill diameter of the hole in the timber part
k_{mat}	$= k_{90} \cdot \sin^2\alpha + \cos^2\alpha$
k_{90}	$= 1{,}35 + 0{,}015 \cdot d$
ρ_k	characteristic density of the timber

Acc. to [1] the embedment strength for a laterally loaded bonded-in rod inserted parallel to grain should be taken as 10% of the embedment strength of a laterally loaded bonded-in rod inserted perpendicular to grain. Hence as angle α between load and fiber direction is 0° in the here considered configuration, $k_{mat} = 1$ in Eq. (4). It should be mentioned that the embedment strength $f_{h,k}$ for dowels inserted parallel to grain given in [1] is specified extremely conservative and has been significantly lowered as compared to the previous EC5 draft [19] and German Annex of EC5 [9], see below (chapter 6.1).

Spacing a_2 and edge distance $a_{4,c}$ in [1] conform to the provisions of axially loaded steel rods; $a_{4,t}$ is prescribed as 4·d as previously in [8], see Figure 6.

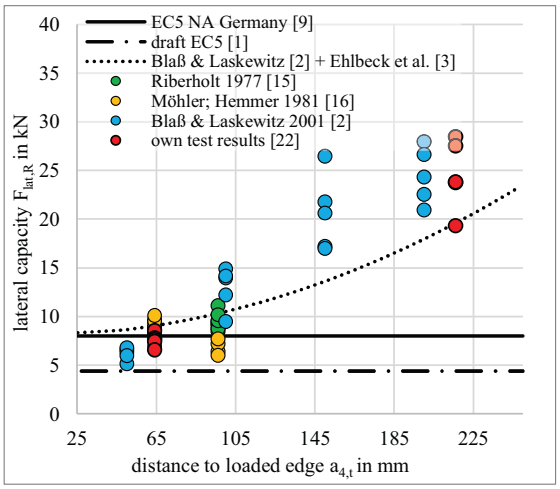

Figure 5: *Lateral resistance capacity of a single rod configuration (d_{rod} = 16 mm, metrically threaded) glued-in parallel to grain acc. to literature [2 - 3; 15 - 16], codes [1; 9] and own experimental tests*

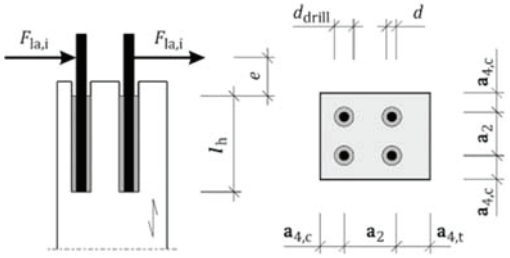

Figure 6: *Spacings and distances of laterally loaded steel rods glued-in parallel to GLT fiber*

https://doi.org/10.52202/069179-0197

4 COMBINED AXIAL AND LATERAL LOADING

For combined lateral and axial loadings acting on glued-in rods prEN1995-1-1 [1] specifies the interaction relationship:

$$\left(\frac{F_{ax,Ek}}{F_{ax,Rk}}\right)^n + \left(\frac{F_{lat,Ek}}{F_{lat,Rk}}\right)^n \leq 1{,}0 \qquad (5)$$

where n = 2. It should be mentioned that the exponent n in Eq. (5) has been changed from formerly n = 1 in [19] to n = 2, as firstly proposed by Riberholt [15] and specified previously in the German Annex of EC5 [9]. The exponent of n = 2 was also substantiated by tests of the authors.

5 RESEARCH PROGRAM AND TEST SET-UPS

Extensive research on rigid joints of GLT to concrete foundations or steel beams / sockets by means of glued-in steel rods started at MPA in 2014 in conjunction with the development of the Stuttgart timber model bridge (STMB) (see e.g. [20; 21]).

Figure 7: *Test specimen of Stuttgart Timber Model Bridge with rigid GLT to concrete connection with glued-in rebars [24]*

Based on the very successful use of the rigid concrete - glulam joint in the STMB project a comprehensive research program was initiated to clarify remaining open questions of this jointing technology. Hereby especially effects of different reinforcement alternatives intended to prevent premature splitting parallel to fiber in the joint area and respective design methods were of prime interest. It is obvious that a transparent validation of the reinforcement gains necessitates as basis knowledge about the load carrying capacity of unreinforced joints inevitably, too. In the same sense it is further important to understand the reinforcement mechanisms and gains firstly at pure axial and lateral rod loading before addressing a combined loading situation as existent in any rigidly clamped reinforced connection.
The load capacities of different actions were identified via: axial tests, predominant shear force tests realized as bending tests and cantilever tests with combined axial and lateral force action. The loading principles of the shear and cantilever tests are shown in Figure 8. It can be seen that the cantilever tests were performed with two different moment – shear force ratios of M/V = 0,55 and 1,15, respectively. All mentioned loading configurations were tested unreinforced and with three different reinforcement alternatives, shown in Figure 9.

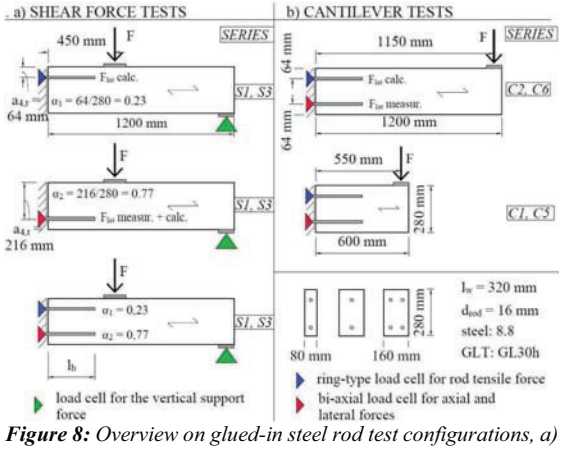

Figure 8: *Overview on glued-in steel rod test configurations, a) quasi pure lateral loading; b) combined axial and lateral loading in cantilever tests*

The investigated reinforcements were i) self-tapping screws (d_{screw} = 8 mm), ii) laterally and iii) end-grain bonded beech plywood panels with a thickness of 20 mm. Tables 1 and 2 give a condensed overview on the test program (see also [22] and [23]). In all cases the glulam (GLT) specimens were of strength class GL30h. The cross-sectional height was throughout 280 mm and widths were 80 mm and 160 mm being 5 or 10 times the steel rod diameter of d = 16 mm, respectively. The spacings of the steel rods were set as the minimally possible acc. to [1] and [9], being $a_{4,t}$ = 4·16 mm = 64 mm. The withdrawal length and the diameter of the drill hole in the GLT were throughout l_w = 320 mm (20·d) and d_{drill} = 20 mm, respectively, representing a practically relevant configuration. The distances of the screws from the end-grain face, from the width edge and from the rod were chosen (closest possible) as $a_{3,CG}$ = 28 mm, $a_{4,CG}$ = 20 mm and a_5 = 20 mm.

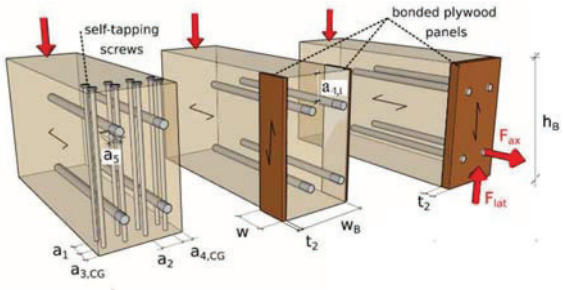

Figure 9: *View of investigated reinforcement alternatives for rigid glued-in rod joints being self-tapping screws, laterally and end-grain bonded beech plywood plates*

https://doi.org/10.52202/069179-0197

In order to grasp the load sharing between the rods with regard to both, lateral and axial forces, specifically designed test set-ups were used to measure both rod loadings with uni- and bi-axial load cells. The axial forces were measured at all rods: Bound to the size of the load cells the lateral force was however measured exclusively at the rod(s) located further from the loaded edge. The lateral force at the rod(s) placed at $a_{4,t}$ (Figure 6) was then derived from the difference of the applied and measured forces. For details see also [23]. To realize a clamped connection of the steel rods to a steel frame, comparable to a concrete connection with in-between positioned load cells, the glued-in rods were either screwed directly to the frame or connected via fitting parts. Figure 10 shows the realized test-set up for the cantilever configuration with M/V = 1,15. The tests were performed either in monotonic or multiple reversed loading, the latter not discussed here. The horizontal and vertical displacements at the clamped and free end of the specimens were measured, too.

Additional to the full-scale beam and cantilever tests small scale tests were performed with regard to determination of the embedment strength of steel dowels of 16 mm and 20 mm diameter oriented parallel to grain in order to verify Eq. (4). These tests were aligned with EN 383 [25]. Further, the bond strength of the bond line between end-grain face of the glulam and the wide plywood panel face, so far unknown, was investigated with block shear specimens. These specimens were tested either in dry condition or after treatment in boiling water acc. to EN 14374, Annex B [26], followed by re-drying at 60°C. The tests were aligned with EN 14080 [27] but shear length had to be reduced due to excessive indentation in the GLT subjected to compression perpendicular to grain when applying the shear force.

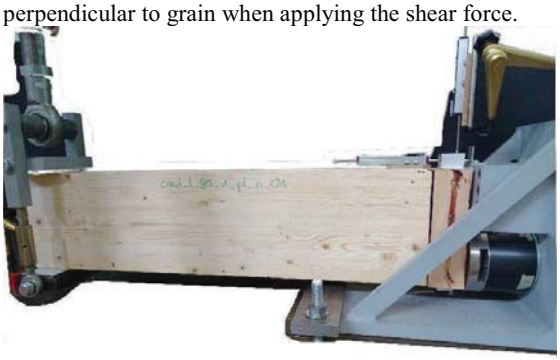

Figure 10: *Test set-up of a cantilever type GLT specimen (b = 80 mm) with two glued-in rods and lateral reinforcement at the clamped end by bonded beech plywood strips*

6 TEST RESULTS

6.1 EMBEDMENT STRENGTH

The results of the embedment strength tests are shown in Figure 11. Despite the rather low number of specimens it is evident that the strength-density relationship given in the EC5-1-1 draft [1] is too conservative especially in the usual density range of softwood glulam. At a density of about 350 kg/m³ the minimum experimentally obtained f_h values are about 5,5 N/mm² as compared to a characteristic value of about 2,5 - 3 N/mm² derived standard-wise from Eq. (4).

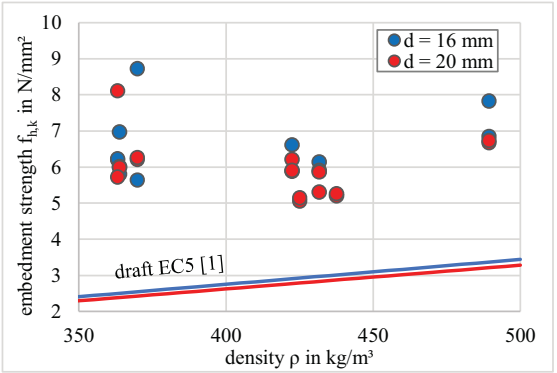

Figure 11: *Test results of GLT embedment strength tests of dowels oriented parallel to grain*

https://doi.org/10.52202/069179-0197

6.2 STRENGTH OF GLT-PLYWOOD END-GRAIN BOND LINES

Up to today end-grain bonding is considered being ineffective and of very low strength and bond line integrity. The only known approach to end-grain bonding then however of two CLT end-grain faces is pursued in the Swiss TS3 technology [28]. For bond lines between end-grain faces of GLT and plywood surfaces no shear strength values can be found in literature. Figure 12 shows the test results and further the requirement acc. to EN 14080 for fiber-parallel face bonded spruce laminations is shown. It can be seen that most of the results fulfil the requirement acc. to [27]. The obtained shear strengths varied from 3,5 - 6 N/mm² with a very high wood failure percentage of almost 100%. The difference between the higher strengths of the untreated specimens vs. the treated ones was about 20% on the mean level. So, the effect of the boiling water treatment revealed to be unexpectedly very low.

For a design of an end-grain reinforced joint (see chapt. 7) mean and minimum values of the shear strength $f_{v,b,end\text{-}grain}$ of 4,6 N/mm² and 3,5 N/mm², respectively, can be proposed tentatively.

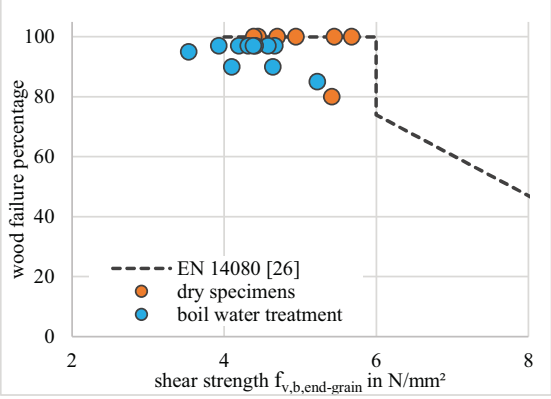

Figure 12: *Bond line shear strength test results of bond lines between GLT end-grain and beech plywood panels*

6.3 SHEAR FORCE TESTS

Figure 13 shows in condensed manner the results of the shear force tests for the unreinforced case (see also Figure 5) and the two reinforcement alternatives being screws and end-grain bonded plywood panels. Firstly, it can be seen that the new tests on the unreinforced joints fully confirm the former findings in literature [2; 15] that the shear force capacity increases significantly with larger distances from the loaded edge. However, most important is the finding that the reinforcement leads to extreme capacity increases vs. corresponding unreinforced configurations. Further, a significant difference between reinforcement with screws and end-grain bonded plates can be seen, whereby the latter method results throughout in higher values. It is sensible that the highest reinforcement increase is obtained for the most inconvenient rod placement with a small $a_{4,t}$ value. Here screws and end-grain plates deliver capacity increases at the mean level by factors of 3,0 and 5,2. These capacity increases, then still large, are reduced to factors of 1,7 and 2,1 in case of a favourable high distance $a_{4,t}$. For the general joint situation with two opposite rods reinforced by screws and end-grain plates mean capacity increases by factors of 1,8 and 2,6 were observed.

Both reinforcement alternatives produce extremely differing stiffnesses and damage evolutions as shown in Figure 14. At very low loads the unreinforced and both reinforced joint configurations reveal comparable stiffnesses in lateral direction. In case of screw reinforcement the stiffness gets highly nonlinear at very low loads. Contrary, the stiffness of the end-grain reinforced joint remains strictly linear up to about 50% of ultimate load and beyond this threshold a progressive nonlinear stiffness evolution starts. The failure mechanisms differ as follows. In case of screw reinforcement similar as with unreinforced joints splitting parallel to fiber occurs starting at the end-grain face at the rod positions closer to the loaded edge. However, the crack propagation is strongly delayed by the screw forces normal to the crack faces. At ultimate load and very large deformations in the rod embedment area a sudden load drop due to cracking of the GLT parallel to grain at the screw reinforcement occurs. Contrary in case of end-grain plate reinforced joints the nonlinearity without any crack formation is induced by deformations of the rod embedment area in the plywood. At ultimate load finally also splitting in combination with either a tensile failure in the net cross-section of the panel (see Figure 17) or a failure of the bond line between the GLT end-grain and reinforcement panel occurs. Details of reinforcements with laterally bonded plywood stripes which delivered comparable capacity gains as the screw reinforcements are not discussed here, as their range of application is limited to rather slender beams because of an expressed decline of the reinforcement effect with increasing width of the GLT.

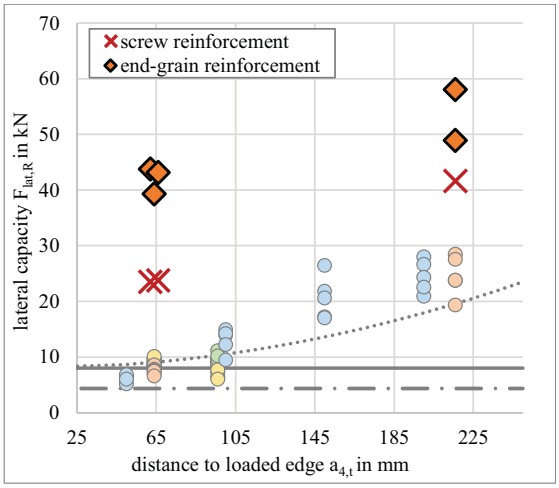

Figure 13: *Test results of quasi pure laterally loaded steel rods glued in GLT parallel to fiber without and with reinforcements by i) self-tapping screws or ii) end-grain bonded plywood*

https://doi.org/10.52202/069179-0197

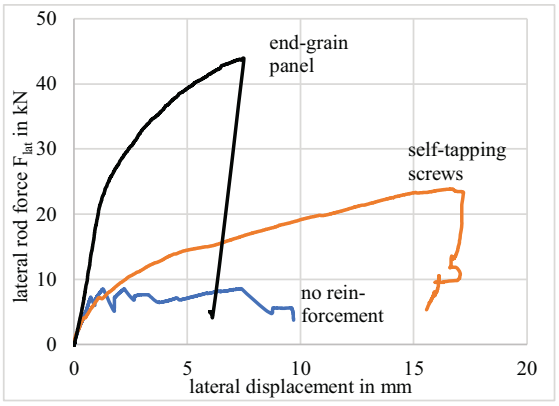

Figure 14: *Stiffness evolution of quasi pure laterally loaded steel rods glued in GLT parallel to grain without and with reinforcement of self-tapping screws or an end-grain bonded plywood panel*

6.4 CANTILEVER TESTS

A brief compilation of the empiric ultimate axial ($F_{ax,u}$) and lateral ($F_{lat,u}$) forces on the mean level is shown in Figure 15. On the left side the results of the shorter (M/V = 0,55) and on the right side the results of the longer (M/V = 1,15) cantilever beams are given. It can be seen, that the capacity gain of reinforced vs. unreinforced joints is decreasing with higher moment to shear force ratios. For a quantification in rough manner the capacities of the different reinforcement alternatives are lumped. At the short cantilevers the capacity gains at $F_{ax,u}$ and $F_{lat,u}$ closely resembling are denoted by factors of 1,7 – 1,8. At the long cantilevers the reinforcement gain of $F_{ax,u}$ and $F_{lat,u}$ decreases to an equal factor of about 1,3. This fact results from the already very high axial force capacity of the unreinforced joints at the higher M/V-ratio resulting in a mean withdrawal strength of f_w = 5,2 N/mm². This narrows the potential for a capacity increase as i) f_w is limited to maximally about 7 N/mm² in pure axial loading and ii) the yield capacity of the steel rod itself is 100,4 kN for the given configuration.

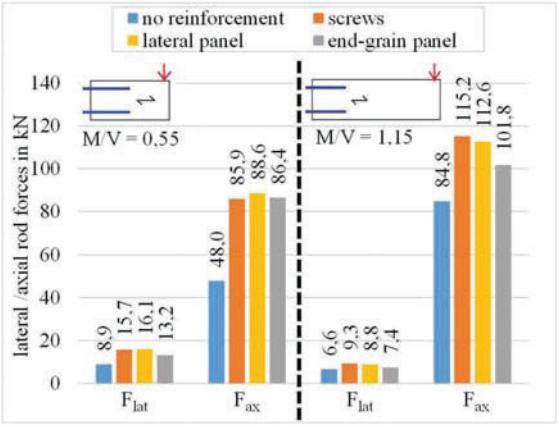

Figure 15: *Test results of cantilever type specimens with clamped glued-in steel rod connections without or with reinforcement*

Figure 16 shows the ultimate capacities of all tests with pure axial, pure lateral and combined moment and shear loading. For comparison the interaction line for the characteristic forces of unreinforced joints acc. to draft EC5-1-1 [1] as derived from Eqs. (1) to (5) is given, too. Similarly, as in case of lateral loading (see Figure 13) the enormous capacity gains throughout all possible $F_{ax} - F_{lat}$ force combinations enabled by the investigated joint reinforcements are evident.

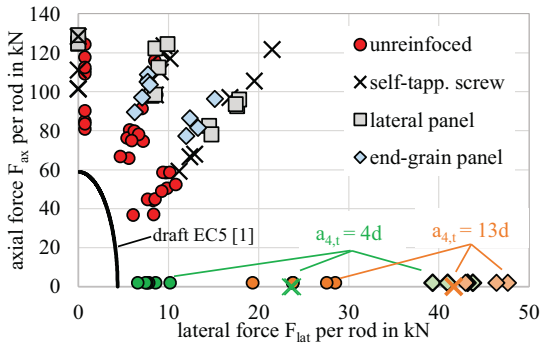

Figure 16: *Compilation of test results from pure axial, pure lateral and combined loaded glued-in rod joint configurations without and with reinforcements*

7 DESIGN PROPOSAL FOR END GRAIN REINFORCED RIGID JOINTS

Riberholt [15], [17] holds the merit for firstly presenting experimental tests with rods glued-in parallel to grain and loaded laterally as well as by combined moment and shear force action. He observed splitting as a weakness of the joints when either the beams were very slim or the rod was close to the loaded beam edge. Based on the test results the lateral rod capacity of unreinforced joints and for an eccentricity of e = 0 mm was then proposed as

$$F_{lat,unreinf,Rk} = f_{h1,k} \cdot d \cdot \sqrt{\frac{2 \cdot M_{y,Rk}}{f_{h1,k} \cdot d}} = \sqrt{2} \cdot \sqrt{f_{h1,k} \cdot d \cdot M_{y,Rk}} \,. \quad (6)$$

Eq. (6) conforms to draft EC5-1-1 [1], here Eq. (2b), and mirrors the case of a single plastic hinge in the timber dowel-jointed to a thin steel plate (Note: Eq. (6) differes from Eq. 8.9 in EC5-1-1 [29] by the prefactor of 1,15 and the missing rope effect consideration.

To overcome the joint splitting deficiency, Riberholt investigated a reinforcement by a 9 mm birch plywood panel glued-on the GLT end-grain. Based hereon Eq. (6) was then extended [17] to the case of an end-grain reinforcement as (see [23])

https://doi.org/10.52202/069179-0197

$$F_{lat,reinf,Rk} = \left[\left(\sqrt{\left(\frac{2 \cdot M_{y,Rk}}{f_{h1,k} \cdot d}\right) - {t_p}^2 \cdot \left(\frac{f_{h2,k}}{f_{h1,k}} - 1\right)} - t_p\right) \cdot f_{h1,k} + t_p \cdot f_{h2,k}\right] \cdot d \quad (7)$$

where

$f_{h1,k}$ embedment strength of spruce (rod parallel to grain and loaded laterally) similar to Eq. (4)

$f_{h2,k}$ embedment strength of the plywood panel as $f_{h2,k} = 0{,}11 \cdot (1 - 0{,}01 \cdot d_{drill}) \cdot \rho_{k,ply}$ [1]

$M_{y,Rk}$ yield moment of the steel rod similar to Eq. (3)

t_p thickness of the plywood panel

d steel rod diameter

d_{drill} the drill diameter of the hole in the timber part

Equation (7) describes a failure mode of a single plastic hinge in the GLT or of two yield hinges in case the glued-on end-grain panel is thick. If the embedment strength of the GLT parallel to grain is neglected ($f_{h1,k} = 0$) in a conservative design approach as being roughly 20 times smaller as compared to $f_{h2,k}$, the lateral capacity acc. to Eq. (7) results in

$$F_{lat,emb,reinf,Rk} = f_{h2,k} \cdot d \cdot t_p \quad (8)$$

and mirrors a pure dependency of the joint capacity with the panels embedment strength.

For the investigated specimen configuration, the lateral force resistances acc. to Eqs. (6) to (8) result in

$F_{lat,Rk,unreinf} = 4{,}4$ kN,

$F_{lat,reinf,Rk} = 19{,}9$ kN and

$F_{lat,emb,reinf,Rk} = 19{,}2$ kN

where $f_{h1,k} = 2{,}8$ N/mm², $\rho_{k,GLT} = 430$ kg/m³, $d_{drill} = 20$ mm, $f_{h2,k} = 60$ N/mm² ($\rho_{k,panel} = 680$ kg/m³); $M_{y,Rk} = 210$ kNmm (with $f_{u,k} = 800$ N/mm², $d_e = 13{,}54$ mm); $d = 16$ mm; $t_p = 20$ mm, e is assumed to be 0.

In addition to the embedment / plastic hinge resistance capacity of the end-grain panel the shear force transfer of the plate bonded to the GLT end-grain face has to be verified for the bond line interface (Figure 17a). Although the panel is bonded over the entire end-grain face area an uneven shear stress distribution has to be considered. In a first approach a roughly triangular distribution can be assumed or as proposed here in conservative manner an effective shearing length of

$h_{b,eff} = 2 \cdot a_{4,t}$

is chosen. The width of the effective bond area is assumed to be

$w_{b,eff} = 5 \cdot d_{rod}$,

which is the minimum spacing between rods acc. to [1].

The characteristic lateral capacity of the bonded GLT-panel interface is then given by

$$F_{lat,bond,Rk} = h_{b,eff} \cdot w_{b,eff} \cdot f_{v,b,end-grain,k} \quad (9)$$

where

$f_{v,b,end-grai\ ,k}$ characteristic bond line shear strength of GLT vs. plywood panel

According to the test results given above for the shear strength with $f_{v,b,end-grain,k} = 3{,}5$ N/mm², the joint bond capacity for a single rod in the given case is

$F_{lat,bond,Rk} = 2 \cdot 64$ mm $\cdot 5 \cdot 16$ mm$\cdot 3{,}5$ N/mm² $= 35{,}8$ kN.

Further the tension capacity of the panel net cross-section in direction of the shear force, being in general parallel to beam height, has to be verified as (see Figure 17b)

$$F_{lat,panel,t,Rk} = t_p \cdot (w_{b,eff} - d_{drill}) \cdot f_{t,plate,k} \quad (10)$$

where

$f_{t,plate}$ characteristic tensile capacity of the plywood panel, assumed as $f_{t,plate,k} = 30$ N/mm² acc. to [8].

Eq. (10) then results for the plywood plate used in the tests in a tensile capacity of

$F_{lat,panel,t,Rk} = 20$ mm$\cdot (80$mm$ - 20$ mm$) \cdot 30$N/mm² $= 36{,}0$ kN

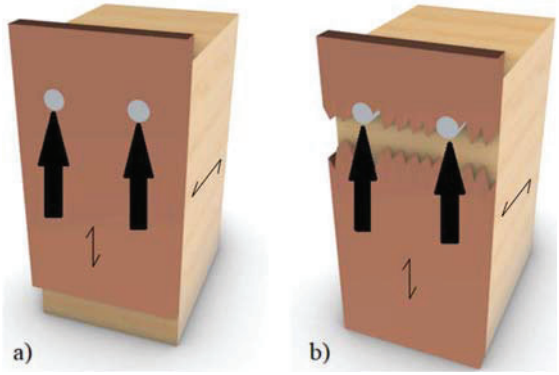

Figure 17: *Failure mechanisms of the end-grain bonded plywood reinforcement a) bond line shear failure b) tensile failure*

Summarizing: for the design of a glued-in rod joint with an end-grain reinforcement the following conditions of the lateral force resistance have to be satisfied:

$$F_{lat,Ek} \leq F_{lat,Rk} = min \begin{cases} F_{lat,emb,reinf,Rk} & Eq.\,(8) \\ F_{lat,bond,Rk} & Eq.\,(9) \\ F_{lat,panel,t,Rk} & Eq.\,(10) \end{cases} \quad (11)$$

Eq. (11) results as outlined in capacities of 19,2 kN, 35,8 kN and 360 kN, respectively. The minimum resistance of 192 kN results from the embedment failure (Eq.(8)) of the glued-on plywood panel. It is apparent that the above derived characteristic design resistance of the joint is significantly lower as compared to the test results. The minimum test result of a laterally loaded end-grain reinforced joint with $a_{4,t} = 4 \cdot 16$ mm $= 64$ mm is by a factor of 2 higher than the result of the embedment design equation. The reason therefore can be explained from the load displacement curve (see Figure 14), which shows that the stiffness develops increasingly non-linear beyond a shear force of about 20 kN which conforms roughly to the characteristic embedment capacity of the bonded plywood panel. A more profound discussion of this altogether with an improved design equation for the

lateral joint capacity resulting from plate embedment and rod yielding is given separately.

8 CONCLUSIONS

In rigidly clamped unreinforced glulam joints made with glued-in rods the connection capacity is widely determined by the lateral loads resulting from the shear force. The lateral rod force leads to tensile stresses perpendicular to grain and hence to premature splitting which undermines the activation of the axial rod capacity potential. Reinforcements of glued-in rod joints are not considered in the draft of the new Eurocode 5 [1]. The presented research on glued-in rods subjected to pure lateral and combined moment-shear-force loading proved that reinforcements by self-tapping screws as well as by laterally and end-grain bonded plywood panel(s) enable the full utilization of the axial rod withdrawal capacity.

End-grain reinforcements of the GLT beam by bonding a plywood panel with a resorcinol adhesive so far not used in timber engineering at all seems to be superior as compared to self-tapping screws because of a lower result scatter. It further provides the potential to reduce the edge distances of the glued-in rods. On the other hand, self-tapping screws which enable high capacity gains, too, are very easy to install and highly apt for reinforcements of existing unreinforced joints.

Laterally bonded plywood strips are comparably efficient as self-tapping screws and end-grain bonded plates but are confined to rather narrow GLT cross-sections due to the limited reinforcement spread.

Auxiliary investigations related to derivation of design equations revealed that the embedment strength of dowel-type-fasteners, here rods, oriented parallel to grain is specified much too conservative in the new draft of Eurocode 5 [1]. Similarly, the missing consideration of the distance to the loaded edge in the draft EC5 design equations for the lateral rod capacity lead in most cases to overly conservative resistances of unreinforced joints. Regarding end-grain reinforcements by plywood made from hardwoods the test results exceed a formerly literature proposed design equation by a factor of two. A new design approach in order to represent the true potential of this promising jointing technology is presently being developed.

ACKNOWLEDGEMENT

The partial support of this work by Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) to project RP3 of IntCDC (Integrative Computational Design and Construction for Architecture) and Germany´s Excellence Strategy is gratefully acknowledged.
